Abstract: The ability of gonadal steroids to impact on the developing brain and organize permanent sex differences during a perinatal sensitive period has been established for over 50 years. What has been lacking is an understanding of the mechanistic basis of this process, termed sexual differentiation of the brain. Recent advances have identified target-derived growth factors to direct neuronal circuits and an unexpected role for prostaglandins in synaptic patterning. The advent of transgenic mice with null mutations for estrogen receptor isoforms, aromatase and the androgen receptor have confirmed and extended our understanding of steroid action in the developing brain. Differential cell death regulated by steroids in males versus females is a major determinant of volumetric sex differences in particular regions. Sex differences in reproductively relevant brain areas, predominantly in the diencephalon, are far greater in magnitude and more readily generalize across species than those related to cognition or emotionality. Nonetheless, the potential heuristic value of studying sex differences, and its potential importance to the etiology of gender-biased neurological disorders and diseases of mental health, have not been fully realized.

List of Abbreviations: AVPv, anteroventral periventricular nucleus; BNST, bed nucleus of the stria terminalis; CAH, congental adrenal hyperplasia; COX-1,2, cyxlooxegenase 1,2; FSH, follicle stimulating hormone; GABA, gamma-amino butyric acid; GAD 65,67, glutamic acid decarboxlase 65,67; GAP-43, growth associated protein 43; INAH, interstitial nucleus of the anterior hypothalamus; LH, lutenizing hormone; LHRH, lutenizing hormone releasing hormone; LTD, long term depression; LTP, long term potentiation; MRI, magnetic resonance imaging; PGE2, prostaglandin E2; PN, postnatal; POA, preoptic area; PVN, paraventricular nucleus; SDN, sexually dimorphic nucleus; SNB, spinal nucleus of the bulbocavernosus

1 Introduction

The study of sex differences in the brain is a topic of general interest, but opinion on *why* it is of interest varies considerably. Some think it is interesting to study sex differences in the brain because of the importance to fundamental reproductive physiology, which begins with the LHRH neuron, continues with sexual behavior, and ends with parental care and in mammals' lactation. Others find it fascinating because all the known sex differences in behavior and physiology are not directly related to the need to procreate but impact on fitness, survival, or just the desire to have fun. These would be the gender differences observed in aggression, learning strategies, food preferences, stress responsiveness, and novelty seeking. There are also profound sex differences in the relative risk of developing specific neurological disorders or diseases related to mental health, something that touches almost everyone's life directly or indirectly at some time. Still others think studying the mechanistic basis for sex differences in the brain is an advantageous window to normal developmental processes caused by a readily available and controllable variable, namely, gonadal steroids, which can be used to trigger differentiation of the brain in a particular direction. And finally, many are fascinated by all these aspects of sex differences in the brain and are enamored of meeting the challenge of integrating levels of analysis that range between biopsychology to physiology, endocrinology, and neuroscience.

2 Historical Overview

The modern concept of sexual differentiation of brain and behavior is generally tied to a single seminal paper by Phoenix, Goy, Gerall, and Young (Phoenix et al., 1959), which postulated the organizational/activational hypothesis of steroid effects on the brain. All four authors went on to pursue highly distinguished careers in behavioral neuroendocrinology, and their work continues to stand as the framework on which most hypotheses are hung for analyses, even if for purposes of refuting their original hypothesis. It is important, however, to acknowledge the tremendously rich history on which Phoenix et al. were hanging their own hypothesis. Even a cursory reading of the book, *Hormones and Behavior* published by Frank A. Beach in 1948 reveals a strikingly sophisticated view of an already mature field. Subject matter ranges from hormonal effects in males and females on fish, amphibia, reptiles, birds, and mammals, bisexuality of mating behavior,

emotion, conditioning, and other types of learning, morphology, metabolism, metamorphosis, and molting to difficulties of experimentation and interpretation. References dating back to the 1920s and 1930s are common, including one titled "The female sex cycle as a factor in learning in the rat" published in 1926 (Ball, 1926), which sounds like it could have been published in yesterday's issue of *Brain Research*.

Returning to the work of Phoenix et al.—female guinea pigs were treated with testosterone during pregnancy, and the female offspring born to these mothers did not act like females as adults, meaning there was no evidence of an estrous cycle (the rodent equivalent of a menstrual cycle), and the females did not display sexual receptivity when in the presence of a male suitor. Even more striking, if provided with testosterone as adults, these genetic females behaved exactly as genetic males. Similar studies were conducted on the rat by Charles Barraclough and colleagues, with the distinction that in these experiments the females were not treated with testosterone until they were born, and the focus was the impact on reproductive physiology rather than behavior (Gorski and Barraclough, 1963). Two important things emerged. One was that the rat was a better model than the guinea pig, which is a highly precocial species, unlike humans. The second was that a graduate student involved in these early findings named Roger Gorski decided to pursue the neuroanatomical correlates of this early hormone action and was the first to report a major sexual dimorphism in the mammalian brain in 1978 (Gorski et al., 1978). In the interest of historical fairness, however, he was not the first person to think of looking for sex differences in the mammalian brain. Studies conducted 10 to 15 years earlier by Don Pfaff (Pfaff, 1966) and the team of Raisman and Field (Raisman and Field, 1971) had reported small but significant differences in the microneuroarchitecture of the rat brain, differences that required an electron microscope to be detected. In retrospect, these researchers can appreciate that they might have missed the forest for the trees in their search for sex differences in the brain.

No one expected there to be major neuroanatomical differences—it had been assumed if there were sex differences in the brain at all, they would be subtle and exacting. The discarding of this dogma came from an unlikely source, the canary. The complex and delightful song of male canaries is familiar to many. Reasoning that such a highly refined behavior must have a neuroanatomical underpinning, Fernando Nottebohm and his student at the time, Arthur Arnold, set about discovering the song control nuclei in the canary brain and reported in 1976 that these nuclei were either wholly absent or greatly diminished in female canaries (Nottebohm and Arnold, 1976), which are subdued both in plumage and in song. By analogy, Roger Gorski decided it would be a good idea to step back and take a more distant look at the rat brain, particularly in those regions controlling sexual behavior, and thus was discovered the sexually dimorphic nucleus (SDN) of the preoptic area. Many other brain regions have since been documented to be larger in one sex than in the other, although how this occurs mechanistically remains a mystery and what it means functionally is equally unclear. Within about a decade of the discovery of volumetric sex differences in the brain were a series of studies describing remarkable differences in synaptic patterning in discrete regions of the male versus female brain (Matsumoto and Arai, 1980). Although much harder to study, these synaptic patterning differences are much easier to relate to function.

The 1990s was an era of intense interest in sex differences in the human brain and how these might relate to sexual preference (LeVay, 1991; Breedlove, 1994). Emphasis on the complicated question of human sexual preference distracted attention away from the basic question of sex differences and in many ways undermined the field by infusing it with political agendas. What this might ultimately have cost will never be known. This brings us to the present day and the advent of transgenic mice, gene arrays, explant cultures, and other modern tools for exploring the multitude of ways in which a male and female can differ. These tools are reenergizing the field and paradigm shifts, such as the notion of a genetic contribution to brain sex differences (Arnold et al., 2004) and differential de novo steroidogenesis in select brain regions (Prange-Kiel et al., 2003; Amateau et al., 2004) promise to shed light on this fascinating topic.

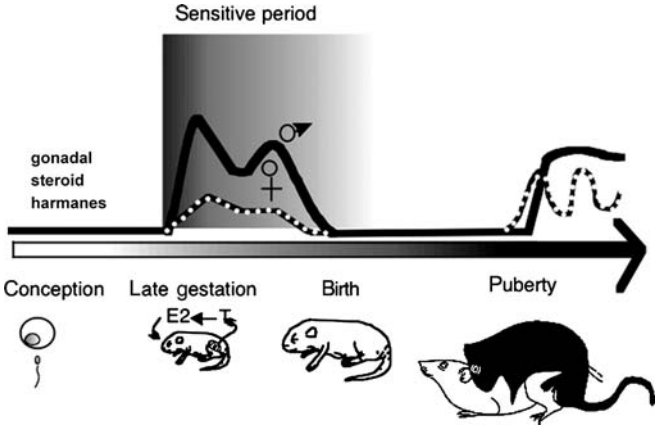
2.1 Organizational/Activational Hypothesis

Returning to the organizational/activational hypothesis of hormone action, it can be said that it is in essence a framework for the concept that early hormone action exerts permanent (organizational) effects on the

neural architecture that are then acted upon in the adult. In most species the early exposure occurs perinatally, meaning around birth. In rats and mice gestation lasts 20–22 days with litter size being on the order of 6–12. During late gestation there is copious production of testicular androgens leading to a hormonal surge selectively in males. A second surge occurs at birth, such that males experience two- to threefold more androgen exposure than females. In rodents these hormonal surges are the result of a complex interplay between active steroidogenesis, probably from the adrenals and gonads, and changes in metabolism that lead to a buildup of steroids (Baum et al., 1988). In primates, there is an activation of the hypothalamic–pituitary–gonadal axis during fetal development in males that must then be actively suppressed postnatally until puberty (Plant, 2001). Regardless of differences in etiology, in both species the outcome is the same—a sexually dimorphic exposure to gonadal steroids during a restricted developmental period. The principles of the organizational/activational hormone effects are illustrated in *Figure 11-1*.

Figure 11-1

The organizational/activational construct for sexual differentiation is based on the principle of an early sensitive period that is operationally defined as beginning with the onset of gonadal secretion of steroid hormones in the male, and as the termination being that point at which the female becomes unresponsive to the impact of exogenously administered steroid hormone. The actions of gonadal steroids during this sensitive period are considered organizational, and generally permanent, and this differentiated neural substrate is then acted upon (activational) by the appropriate gonadal steroids in adulthood to produce stereotypic sexual behavior or physiology. Different physiological and behavioral endpoints vary in the precise timing of the sensitive period although most differentiation is complete by the end of the first postnatal week of life



2.2 The Sensitive Period

Sensitive periods are a general phenomenon in developmental neurobiology, referring to an opportunistic window during which events must occur or forever be precluded. An illustration of this, familiar to many, is the lazy eye. If the good eye is patched when an individual is still a child so that the lazy eye has to work harder, the condition is corrected. If, however, the good eye is not patched until adulthood, the lazy eye cannot be coaxed into compensating. This example actually involves the musculature controlling eye movement but the same is true for the brain's detection of visual stimuli. If kittens are raised in an environment that consists only of horizontal bars they will be forever incapable of "seeing" vertical bars and vice versa (Hubel, 1967). There are many other examples of sensitive periods that occur at different times during development and involve both intrinsic and extrinsic stimuli (Kameyama, 1991; Morreale de Escobar, 2001; Lewis, 2004). In the case of sex differences in the brain, the stimulus is intrinsic, being

hormones. The sensitive period is operationally defined by the onset when hormonal secretion begins and the termination being that point beyond which extrinsic hormone is ineffective at exerting an organizational effect. Exogenous administration of testosterone to females has revealed different timing for the termination of the sensitive period for distinct endpoints. The two major endpoints are physiology and behavior, the latter being the control of gonadotropin secretion from the anterior pituitary and the former being largely reproductive behavior. The sensitive period for determining whether lutenizing hormone (LH) secretion from the anterior pituitary is responsive to both positive and negative feedback (females) or only negative feedback (males) is generally postnatal, whereas the control of sexual behavior has two overlapping time periods, one for masculinization of behavior and another for elimination of female behavior, also known as defeminization. Sensitive periods have also been explored for morphometric endpoints. The ability of exogenous steroid to increase the volume of the SDN ends precipitously at postnatal day 6 (PN6) (Rhees et al., 1990). The corpus callosum, the major fiber track between the two cerebral hemispheres, also exhibits sexually dimorphic characteristics, and these appear to be established much later than most other endpoints, occurring around PN 10–14 (Fitch et al., 1990), a time at which gonadal steroids are not generally considered sexually dimorphic, although truth be told, this has not been carefully investigated.

2.2.1 Is There a Sensitive Period in Humans?

In humans, the sensitive period for sex determination (i.e., development of the gonads and accessory duct systems) occurs relatively early, within the first trimester. This is followed by a period of gonadal activation during the second trimester, leading to elevated androgen in males. At birth, there is a second surge in androgen secretion in males in response to a release of LH from the newborn pituitary (Corbier et al., 1990, 1992). As a result, newborn males have two- to threefold higher levels of testosterone than females for the first day or two of life. Androgen levels then drop and remain relatively low in both sexes until they begin to diverge again at about 12 years of age, at which point males again have two- to threefold higher levels, as opposed to the fivefold higher levels that characterize the adult (Granger et al., 1999). This is in part due to a drop in androgen production or increased aromatization by the female adrenal postpuberty. Because of the elevated androgens in males shortly after sex determination in the first trimester, this period is often sited as the time when sexual differentiation of the brain occurs but is based on no definitive evidence other than that this is when androgens are elevated. In the rodent, we have been able to clearly define the end of the sensitive period as refractoriness to the effects of exogenous hormone administered to females. In humans, we have no parallel data, leaving the end of the sensitive period for determination of sex differences in human brain an open question.

2.3 Organizational Hypothesis—Revised

Whereas the organizational/activational hypothesis remains a viable and useful framework for empirical investigation of the etiology of sex differences, it also is not an absolute, there being many and varied exceptions. This includes the venerable SDN. The initial determination of the sensitive period was based on the ability of exogenous steroid administration to females to increase SDN volume and this was found to drop rather precipitously at PN6. Further work, however, established that removal of the gonads in males as late as PN29 reduced SDN volume, indicating a need for prolonged exposure to some gonadal factor for final crystallization of SDN size (Davis et al., 1995). This finding illustrates a more general point, that all organization does not occur within the first few days of life. In fact there appears to be a second organizational period associated with puberty in which many of the neural circuits regulating adult behaviors are "finished" or fully organized. This principle is illustrated by the simple observation that administration of gonadal hormones to animals prior to puberty does not induce the normal complement of adult behavior, and conversely, depriving an animal of steroids during puberty permanently changes sensitivity to subsequent steroid exposure (see for review, Sisk and Foster, 2004). Lastly, other brain regions remain sensitive to gonadal steroids throughout life. The posterodorsal subdivision of the medial

amygdala receives olfactory input and is related to male arousal. It is larger in males than females, and if adult males are deprived of testosterone, it shrinks to female size and reduces the response of males to female olfactory cues (Cooke et al., 1999). The cellular mechanisms regulating organization events associated with puberty and morphological endpoints that remain sensitive to steroids in adulthood remain relatively unexplored.

2.4 Sex Differences Versus Hormonally Modulated Endpoints

Related to a revised organizational hypothesis is the need for clarification of what constitutes a sex difference. Many behavioral and physiological endpoints are modulated by circulating steroid hormones in the adult animal. This includes the obvious, such as reproductive behavior, but also includes responses such as anxiety, learning and memory, or aggression. In the case of reproductive behavior, there is both a sex difference and a hormonal modulation. Only masculinized brains will respond to testosterone to increase male sexual behavior, and the more testosterone the more robust the behavior (within limits). For learning and memory, there is a mean level of responding in males when quantified by latency in a maze or threshold for induction of long-term potentiation (LTP), and the response in females is different from males but the mean is higher than males under one hormonal condition and lower than males under another hormonal condition (Warren et al., 1995; Cordoba Montoya and Carrer, 1997; Ito et al., 1999). This is not a sex difference, it is a hormonally modulated response. The distinction is more than just semantics. Understanding whether something is a genuine sex difference or a hormonally modulated response speaks to mechanism (Becker et al., 2005).

2.5 The Aromatization Hypothesis

When exploring the specificity of hormonal effects on the developing brain, researchers were quick to notice that compared to testosterone, estradiol was as effective, and often even more effective, at inducing masculinization. This seemed counterintuitive given that estradiol is equated with femininity, and in fact estradiol must be suppressed for proper development of the testis, whereas testosterone is the quintessential male hormone. The conundrum was clarified when several additional pieces were added to the puzzle with the use of the rodent model. First is that fetal and newborn rodents have high circulating levels of a steroid-binding globulin called α-fetoprotein, which has a strong affinity for estradiol. This helps to sequester the estradiol of maternal origin in the bloodstream of the fetus, effectively preventing its entry into neurons and other cells. Testosterone, however, is not bound by α-fetoprotein and moves freely into neurons. The second piece of the puzzle is that aromatase, the p450scc enzyme that converts testosterone to estradiol, is found at very high levels in some regions of the developing brain. Neurons of the hypothalamus, preoptic area, and hippocampus exhibit more aromatase activity during the perinatal sensitive period than at any other time in life (Maclusky et al., 1994). About one week after birth, levels will drop precipitously and for the rest of life the majority of estradiol synthesis will be in the periphery, mostly the ovary, although neurons continue to locally produce estradiol from testosterone throughout life. A third piece of the puzzle is the distribution of estrogen receptors, which is broader and for the most part denser than that of androgen receptors. The ability to locally synthesize estradiol within neurons allows for fine-tuning of steroid hormone differentiation within discrete subregions of the brain. Again, a lesson should be taken from research on songbirds in which the brain has been found capable of synthesizing estradiol de novo; this possibility has now been confirmed in mammalian brains. The adult male hippocampus makes small but detectable quantities of estradiol de novo from estradiol and the rate of synthesis is regulated by neuronal activity as transduced by NMDA receptor activation and calcium influx (Hojo et al., 2003). The female hippocampus also appears capable of making its own estradiol particularly early in development (Amateau et al., 2004), which may provide this telencephalic brain structure with necessary trophic effects provided by this powerful steroid.

The role of aromatization in primates appears to be much less than that for rodents. Instead, it is the direct action of androgens on neurons that differentiates the brain into a masculine phenotype (Wallen and

Baum, 2002). There also appears to be far less of a role for early postnatal hormone exposure in primate models than in rodents, but both this and the potential for an important involvement of estradiol in primate brain differentiation remain to be definitively established. Regardless of the specifics of the hormone and the timing of its action, it is clear that gonadal steroids exert profound and permanent effects on the primate brain that are analogous to those seen in rodents.

3 Morphometric Sex Differences in the Brain

Sex differences in morphometry can be divided into two broad categorizations based on level of analysis: (1) differences in the size of a brain region or structure and (2) differences in the shape and connectivity of individual neurons and glia. The majority of attention has been focused on differences in size of readily identifiable structures such as fiber tracks or particular nuclei. This is in part because of ease of measure. Volumetric measures can be made on fixed tissue sections, including that from postmortem human brain, and overall size can be extrapolated from a few sections. Other advantages of size analysis include the ability to measure the size of a nucleus based on neurochemical identity, such as staining for calbindin or vasopressin, or it can be done just based on a Nissl stain. Lastly, the use of MRI to measure the size of structures in the living human brain has provided considerable insight into the dynamics of size changes in relation to growth. The latter illustrates an important principle in any studies of brain morphometry, that it is often very dynamic. Size of a particular structure may be dimorphic between the sexes at one point in life but not another, which raises the interesting question of what the functional significance of size is, and how such dimorphisms are regulated.

By synaptic patterning we mean the frequency and density of synaptic contacts within a particular brain region. Not all synapses are made equal and they come in three basic flavors. One is the axosomatic synapse, referring to an axon terminating on the soma (cell body) of another neuron. Second is the axodendritic synapse, when an axon terminates on the dendrite of a target neuron, and the last is a specialization of this known as the axodendritic spine synapse. Spines are small protuberances on dendrites that are the site of predominantly excitatory synapses and changes in spine density are a hallmark of synaptic plasticity. We used to think of the brain as a relatively hard wired structure; once connections were made they were permanent. This is still true to some degree, as discussed in the previous section on sensitive periods. However, it is now apparent that the brain is also constantly revising some proportion of its synaptic connections, strengthening some and dismantling others. These changes can underlie learning and memory, sensitization or changes associated with stress and disease. Hormones too can exert profound effects on synaptic patterning in the adult brain, a topic covered in other chapters in this text. These effects are transient, and portions of the female brain may remodel with each successive estrous cycle (in rodents, and perhaps with each menstrual cycle in women, although currently unknown). It is now apparent that hormones sculpt the neuroarchitecture of the developing brain and establish permanent sex differences in synaptic patterning. For instance, the density of axodendritic spine synapses is twice as great in one hypothalamic region (the arcuate nucleus) in females as males whereas the opposite is true in another hypothalamic area (the preoptic area), with males having double the number of dendritic synapses as females. Surprisingly, it appears that a specialized type of glia, known as astrocytes, are playing a central role in the establishment of sexually dimorphic synaptic patterning (McCarthy et al., 2002). What makes it surprising is that this cell type is not generally thought of as a primary target for steroid action, in part because there is little evidence that it possesses receptors for estradiol.

3.1 Morphometric Sex Differences Correlate with Sex Differences in Physiology and Behavior

As noted earlier, we have made substantial progress at cataloging the many morphometric changes induced in the developing brain in response to gonadal steroid exposure during the perinatal sensitive period. These studies are frequently conducted by anatomists using techniques ranging from histochemistry to electron

microscopy. Another cadre of researchers focuses on sex differences in behavior and how they are modulated by steroids developmentally and in adulthood. A particularly powerful approach is a combined morphometric and physiological/behavioral assay analysis but the restriction to only correlative statements remains. Nonetheless, there has been sufficient advance to allow strong inference regarding how changes in brain morphology might determine physiological and behavioral outcomes in some instances. Therefore, rather than separately reviewing the current state of the art on each, a synthesis of the neuroanatomy, physiology, and behavior may provide an integrated view of sexual differentiation of the brain, the cause and the consequences.

4 Sexual Differentiation of Sex Behavior

Studies attempting to elucidate the mechanistic basis of sex differences in the brain benefit from a robust and reliable endpoint, namely, sexual behavior in the albino laboratory rat. Whether an adult rat responds to sexual advances from another adult rat with a male response (mounting, intromitting, and ejaculating) or a female response (lordosis) is entirely dependent on two variables: (1) the hormonal milieu during a perinatal sensitive window that must match (2) the hormonal milieu of the adult. Male sexual behavior is opportunistic and readily expressed whenever a receptive female is present. Female sexual behavior is physiologically constrained to be expressed only in proximity to ovulation. A fascinating but mechanistically unexplained distinction in male and female sexual behavior is the impact of experience. Males improve with practice and if testosterone is removed (via castration), will continue to exhibit high levels of copulatory behavior that only gradually extinguishes over a period of months. Females, by contrast, get it right the first time and every time, but, they will only exhibit lordosis under the proper hormonal umbrella. If steroids are eliminated, so is the behavior. In terms of ultimate causation, the adaptive basis for the distinction is obvious; there is no benefit and possible cost to females mating outside the window of opportunity for conception, whereas males maximize fitness by never missing an opportunity to share the wealth. Proximately, meaning at the mechanistic level, this dichotomy in the nature of the plasticity attendant to both behaviors suggests distinct and separate neuronal circuitries, be they physically or merely functionally so.

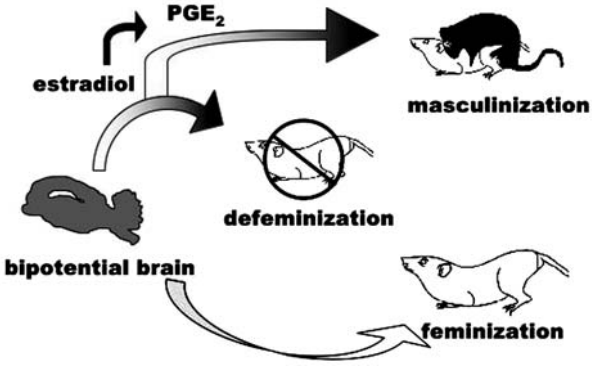
4.1 Masculinization, Defeminization, and Feminization

A useful framework for investigating mechanistic questions of sexual differentiation is the operationally defined and distinct processes of masculinization, feminization, and defeminization. **Masculinization** refers to an active developmental process initiated by gonadal steroids during the perinatal sensitive period followed by expression of normal male copulatory behavior in adulthood. **Feminization** is essentially what happens in the absence of masculinization, meaning it is the default pathway leading to expression of lordosis under the proper hormonal conditions in adulthood. **Defeminization** is distinct from but normally occurs in tandem with masculinization and refers to the process whereby the ability to express female sexual behavior is lost (see *Figure 11-2*). Defeminization appears to be exclusively regulated by estradiol, whereas masculinization involves both estrogens and androgens (Whalen and Edwards, 1967; Vreeburg et al., 1977; Auger et al., 2002).

The neural circuitry controlling male sexual behavior has been mapped by lesion studies and expression of the immediate early gene, c-fos. Olfactory input via the main and accessory olfactory bulbs is transmitted to the subnuclei of the amygdala and converges on the preoptic area (POA). From there the information is sent down to the midbrain and critical spinal cord nuclei for the control of the penis and suppression of micturation (Wood, 1997; Coolen et al., 1997; Murphy and Hoffman, 1998). The POA serves as a critical nodal point for the integration of sensory cues and is a principal site for steroid hormone action. Developmentally, the POA is exquisitely sensitive to estradiol, which is locally aromatized from testicular testosterone. Males have two- to threefold more estradiol in the POA than females over the first few days of life (Rhoda et al., 1984; Amateau et al., 2004), and the actions of this steroid masculinize the neuronal

Figure 11-2

The tripartite nature of sexual differentiation of reproductive behavior has been defined as Masculinization, the active induction of neural substrates that mediate male sexual behavior that is triggered by the gonadal steroid testosterone and its metabolite, estradiol; Feminization, the default pathway that leads to a neural substrate conducive to female reproductive behavior; and Defeminization, which is the active removal of the default pathway and is also triggered by gonadal steroids during the sensitive period for sexual differentiation



substrate. As a result, the POA is a prominently sexually dimorphic brain region at both the volumetric and cellular levels. The SDN of the POA is 5–7 times larger in males, and there is a greater density of dendritic spine synapses on POA neurons in males (Raisman and Field, 1973; Amateau and McCarthy, 2002a). A growth associated protein (GAP-43) selectively concentrated in axonal growth cones during development is significantly higher in newborn male POA than female (Shughrue and Dorsa, 1994), and astrocytes of the male POA have more and longer processes that branch more frequently than those of females (Amateau and McCarthy, 2002b). All of these morphometric sex differences are dependent upon perinatal estradiol. Exogenous administration of estradiol increases the number of dendritic spines on the POA neurons of females to a level equal to that of males, and differentiates astrocytes and increases the expression of GAP-43. Together it can be assumed that these differences in morphometry converge in a coherent manner that then provides the neural substrate mediating the expression of sex-typic reproductive behavior. However, this still does not tell us how the morphometric differences were established, and what the precise action of estradiol is. Surprisingly, the effects of estradiol on dendritic spines are mimicked by exogenous administration of the prostaglandin (PGE2) and prevented by indomethacin, an inhibitor of prostaglandin synthesis (Amateau and McCarthy, 2002a, 2004), raising the interesting possibility that a prostaglandin is a major determinant of sex differences in synaptic patterning in the POA.

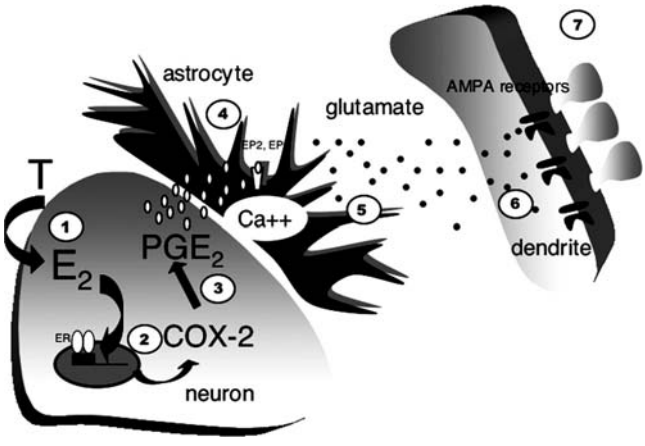
4.2 Prostaglandin E2 Mediates Behavioral Masculinization of Sex Behavior

Prostaglandins are synthesized from the precursor, arachidonic acid, by the rate limiting enzyme cyclooxegenase (COX), which comes in three forms. COX-1 is constitutively active whereas COX-2 and -3 are inducible forms. COX-3 is particularly enriched in brain (Shaftel et al., 2003). Arachidonic acid is converted to the prostanoid prostaglandin H2 (PGH2), and then prostaglandin G2 (PGG2), before diverging into multiple endpoints as a function of specific synthetic enzymes leading to the synthesis of eight distinct prostanoids. The synthesis of PGE2 requires PGE synthase, which also has a constitutively active and an inducible form. The inducible form, mPGE2, is yoked to COX-2 such that stimuli that induce an increase in COX-2 inevitably lead to an increase in PGE2. In the developing POA, estradiol acts to increase both the mRNA and protein for COX-2, having no effect on PGE synthase, nonetheless, estradiol treatment results in a sevenfold increase in POA PGE2 levels, without altering the other prostanoids (Amateau and McCarthy, 2002a).

This still leaves the question of how a prostaglandin could increase the density of dendritic spines on POA neurons unanswered. The importance of astrocytes to neuronal functioning is continuing to emerge. Recent evidence from other brain regions reveals that glutamate is released by astrocytes in a calcium-dependent manner, and that this glutamate impacts on neuronal function. A prominent trigger of astrocytic glutamate release is PGE2 (Sanzgiri et al., 1999). A major regulator of dendritic spines is glutamate, and in the developing POA the effects of either estradiol or PGE2 on dendritic spines can be blocked with the specific glutamate receptor antagonist, NBQX, which is specific to the AMPA form of the glutamate receptor. Antagonists to the NMDA form were without effect. Thus, in an attempt to connect the dots, we have developed a working model in which testosterone enters POA neurons where it is locally converted to estradiol. Estradiol binds to its receptor and induces transcription of the COX-2 gene. Induction of COX-2 leads to increased PGE2 production within the neuron, from which it is released to act on the adjacent astrocyte. The effects of PGE2 on the astrocytes are twofold. One is to contribute to the morphometric differentiation of the astrocytes; the other we speculate is to induce the release of glutamate, which in turn acts back on the neuron to evoke the formation of dendritic spines, thereby establishing a sexually dimorphic synaptic pattern (see *Figure 11-3*). This is a working model and not all components

Figure 11-3

A working model proposes that within the preoptic area, estradiol is derived by local aromatization from its precursor, testosterone, (1) and induces synthesis of COX-2 through conventional genomic means (2). COX-2 is the inducible form of cyclooxygenase and is the rate-limiting enzyme in all prostaglandin production but is preferentially yoked with the production of PGE2 (3). There is no definitive evidence that both COX-2 and PGE2-synthase are exclusively in neurons but we speculate such. We further speculate that PGE2 is released by neurons to act on the EP2 and EP3 receptors that are localized to astrocytes (4), inducing the release of glutamate (5), which in turn acts in part via AMPA-receptors (6) to induce the formation of dendritic spines on nearby neurons (7). The increased dendritic spines are presumed to represent a parallel increase in the density of excitatory synapses that will ultimately determine the expression of male sexual behavior in the adult



are equally firm, but that there is an interaction between neurons and glia in the establishment of synaptic sex differences seems clear. This principle is generalizable to other sexually dimorphic brain regions (see later).

But again, critical questions remain. What do changes in dendritic spines on POA neurons have to do with behavior? One way to find out is to treat newborn females with a dose of PGE2 known to induce dendritic spines to the same level as seen in males, raise them to adulthood, remove the ovaries, and provide them with testosterone before testing them for male sexual behavior. Alternatively, males deprived of their

PGE2 by neonatal treatment with a COX-2 inhibitor could also be tested for ability to display male sexual behavior. We conducted these experiments and the results were conclusive—females neonatally treated with PGE2 exhibited adult levels of male sexual behavior identical to that seen in control males, whereas males developmentally deprived of PGE2 were duds, exhibiting no sexual interest in the stimulus females across three 30-min trials. At first pass, it is hard to imagine that a brief disruption in PGE2 synthesis developmentally could have such profound and apparently permanent effects. Equally implausible is the observation that two injections of PGE2, one on the day of birth and one the day after, are sufficient to fully masculinize the female brain in regard to sexual behavior. However, when we examined the brain for prostaglandin mediated changes in dendritic spines, we found that the effects that are manifested within the first two days of life are still apparent at 21 days and, even more impressively, at 90 days of age (Amateau and McCarthy, 2004). This provides us with a striking correlation between changes in dendritic spine synapses and adult behavior, but it is nonetheless, a correlation. Many neonatal manipulations will impair adult male sexual performing, but to our knowledge there are no previous reports in which a female brain is masculinized without steroid exposure. This is not just an interesting anomaly; the ability to masculinize the brain without steroids allows for investigation of questions not previously possible. For instance, can an animal be masculinized but not defeminized? Also, is a male-sized SDN a requisite for male sexual behavior? Furthermore we can ask, are the effects of PGE2 specific to male sexual behavior, or do they also effect maternal behavior, anxiety, olfaction, or any of a host of other relevant behaviors?

4.3 Other Factors Contribute to Masculinization and Defeminization

Given that steroid receptors are primarily transcription factors, an obvious and fundamental question is what genes are being activated as a result of hormone action during development? Based on the changes in both the mRNA and protein levels of COX-2 and the importance of prostaglanin production, we can say with some confidence that COX-2 is likely to be a direct product of gene induction by estradiol. However, it is certainly not the only gene product likely to be regulated by direct transcriptional regulation via estrogen receptors during the perinatal sensitive period. Progesterone receptors are induced by estradiol and are higher in males (Quadros et al., 2002) but this is not unexpected given that induction of progesterone receptors is a well-established response to estradiol in the adult brain. Sex differences in synaptic patterning and size of specific projections might be explained in part by GAP-43, a growth-associated protein abundant in axons but not dendrites and elevated in the developing brain during the period of neurite outgrowth, extension, and synaptogenesis. During the sensitive period for sexual differentiation, males have markedly higher levels of GAP-43 in the POA (Shughrue and Dorsa, 1994). Growth factors have also been implicated in the establishment of sex differences in the brain, but not strongly so. Infusion of antibodies against NGF blocked the defeminization of female sexual behavior but did not alter control of gonadotropin release (Kornack et al., 1991; Ricceri et al., 1997), further supporting the notion that these are physiological processes undergoing distinct differentiation. Dopamine and serotonin are both prominently involved in male sexual performance in the adult animal, in both the appetitive and consummatory components. The possibility that dopamine is a causal agent establishing sex differences has been proposed, as it can either enhance or inhibit neurite outgrowth depending on the receptor composition of a particular neuron (Hull et al., 1998, 1999). There is empirical evidence for both also contributing to normal male brain development, but there is little known mechanistically as to precisely how either of these neurotransmitters mediates masculinization.

The use of subtractive hybridization of cDNA isolated from newborn male and female rat hypothalamus identified granulin (epithelin) as a gene expressed at higher levels in males. A curious and interesting aspect of this finding is that just prior to and at birth, males and females have equally high levels of granulin, which then drop in females, resulting in a marked sex difference by postnatal day 10. Functional significance of this difference was demonstrated with the use of antisense oligonucleotides to reduce granulin protein during the sensitive period, resulting in compromised adult male sexual behavior (Suzuki et al., 2000; Suzuki and Nishiahara, 2002). The opposite, inducing granulin production in females to masculinize the brain, has not yet been achieved leaving the precise role of this protein unknown.

Now that we have some insight into the cellular mechanism of masculinization, and we know that it is not involved in defeminization or feminization, the next step will be to identify the mechanisms mediating these other developmental phenomena. In the case of defeminization we are aided in part by knowing the hormonal trigger, estradiol, leaving feminization as perhaps the most intractable of the three processes. To our knowledge, there have been no clear examples of disruption of feminization with the exception of studies suggesting a role for estradiol in normal feminization (McCarthy et al., 1993; Bakker et al., 2002). Thus, one of the greatest challenges ahead is determining how the neural circuitries controlling female sexual behavior are meant to develop unless coopted by male gonadal steroids and defeminized.

4.4 The Sexually Dimorphic Nucleus of the Preoptic Area Does Not Correlate with Masculinization of Behavior

In the rat, the SDN of the POA is a major brain region regulating expression of male sexual behavior, but there is no unique role elucidated for the SDN. The SDN-POA is an area that is several fold larger in males than females (Gorski et al., 1980) and is entirely a product of differential estradiol exposure. Morphologically, it is a collection of large dense and darkly staining cells embedded within the medial preoptic nucleus. Other than their size and propensity for taking up Nissl stain, there is little to distinguish these cells from the surrounding ones. A notable exception is high levels of the calcium-binding protein, calbindin (Sickel and McCarthy, 2000). Neurons of the surrounding POA seem entirely devoid of this particular cellular marker. Neurons of the SDN contain estrogen receptors, express aromatase, and are largely GABAergic (Sagrillo and Selmanoff, 1997). Projections to and from the SDN are profuse, and given its location in the heart of the POA, it seems as natural as a major nodal site for the regulation of male sexual behavior. Analogous nuclei have been identified in a variety of species including guinea pigs, gerbils, sheep, nonhuman primates, and humans (Bleier et al., 1982; Swaab and Fliers, 1985), but with the exception of the gerbil in which the SDN regulates scent marking (Heeb and Yahr, 1996), there remains a lack of understanding of precisely why this collection of cells exists. Conflicting reports indicated the SDN of male rats was not critical for control of sex behavior (Anderson et al., 1986; Houtsmuller et al., 1994). Masculinization induced by exogenous administration of PGE2 to females allowed for the expression of male sex behavior in females that were not concurrently defeminized (because there was no steroid provided) and these masculinized females had a female-sized SDN (Amateau and McCarthy, 2004), supporting speculation that the SDN may relate more to defeminization than masculinization. Recent data suggest a different role for the SDN, specifically, the preference for an estrous female over a male (Houtsmuller et al., 1994; Woodson and Gorski, 2000; Roselli et al., 2002). Although an interesting idea, this too remains in the realm of correlation, as there is no clear way to manipulate the volume of the SDN without also manipulating gonadal steroids during the perinatal sensitive period. Understanding how the SDN becomes dimorphic may provide the needed insight into definitively establishing its function(s).

4.4.1 The SDN-POA Illustrates General Principles of Morphometric Sex Differences

So what do we know about how the dimorphism of the SDN is established? Actually, a fair amount. We know that it is not due to sex differences in the number of neurons born or their migration into a particular location, although these two variables may play minor roles (Jacobson and Gorski, 1981). We also know that the sexual dimorphism is not evident until as late as postnatal day 5, long after the neonatal surge in testosterone in males, and is not fully established until at least a week after birth (Sickel and McCarthy, 2000). It appears a single variable will ultimately determine the volume of the SDN, that is, how many neurons succumb to naturally occurring cell death or apoptosis (Arai et al., 1996; Davis et al., 1996). The single variable determining whether the cells live or die is estradiol. If there is enough, the neurons survive, if there is not, they die. Once outside the sensitive period, no amount of estradiol will restore SDN volume, but as to what estradiol is doing, dead neurons tell no tales.

Thus, it appears we have a nucleus of unknown function and unknown origin, yet the SDN remains a topic of considerable intrigue and serves as a valuable example of many principles of neuroanatomical sex differences. First, variance in size does not necessarily correspond to variance in function. Second, sex differences in the size of a region or particular nucleus appear to occur via the common route of differential apoptosis, either induced by or protected from the actions of gonadal steroids. Put quite simply, males and females start out with the same number of neurons in a particular area (meaning there is no sex difference in neurogenesis or migration) and then neurons begin to die in one sex either as a result of insufficient hormone exposure or in response to hormone exposure. This scenario has been established for the SDN, a motor nucleus in the spinal cord controlling the penis called the SNB, a subdivision of the bed nucleus of the stria terminalis (BNSTc) and the hippocampus, all of which are larger in males, and for a nucleus in the hypothalamus that controls the LH-surge, the anteroventral periventricular nuclues (AVPv), and the visual cortex, both of which are larger in females. Exactly how steroids are dictating whether neurons will live or die is unknown and complicated by the fact that the peak of cell death (or survival) appears to be several days after differential hormone exposure. Intriguingly, for the BNST and AVPv, brain regions in which estradiol has opposite effects on cell death, the mechanism appears to involve the cell death gene BAX in both cases (Forger et al., 2004). That these two interconnected cell groups showing opposite patterns of sexual differentiation in response to estradiol are determined by the same gene highlights how much we have to learn about the cellular and molecular mechanisms of sexual differentiation. And if it were not already confusing and confounding enough, in the same brain, BAX does not regulate the sex difference in the number of dopaminergic neurons found in the AVPv, suggesting further heterogeneity of mechanism (Forger et al., 2004).

A third general principle is that no one sexually dimorphic structure stands alone. Just as the SDN is embedded in the medial POA, the mPOA is also intricately and reciprocally connected with other brain structures that are either themselves dimorphic or constitute part of a neural network controlling sexually dimorphic physiology and behavior. Virtually all components of this network have a high concentration of neurons expressing receptors for estrogen and/or androgens. This principle critically relates to a fourth, identifying the mechanism by which steroids modulate neuroanatomical sex differences is complicated by the potential of steroid effects that act directly on the cells of interest as well as indirectly via hormonal modulation of afferent input. It is further complicated by the fact that parameters affecting cell death appear to be intermingled with factors determining neurochemical phenotype, making for a complex mosaic of effects that remains poorly understood.

5 Sexual Differentiation of Gonadotropin Secretion

The gonadotrophs of the anterior pituitary are the site of synthesis of the gonadotropins, LH and FSH (follicle stimulating hormone), two essential ingredients of the hypothalamic–pituitary–gonadal axis. Both are released from the gonadotrophs directly into the bloodstream and travel to their target organs, the gonads, where they promote steroidogenesis and gamete production and/or maturation, respectively. In males of nonseasonally breeding species, such as man and his commensal rodents, there is a constant and pressing need for both steroidogenesis and gamete production and both are maintained by regular pulses (hourly or less) of LH and FSH into the blood stream. The pulses of LH and FSH are in turn maintained at constant levels via negative feedback exerted by the gonadal steroids they are designed to produce, creating a closed loop system that maintains homeostasis. In females, by contrast, the gametes are sequestered in the ovary and only a select few are allowed to mature with each reproductive cycle. The maturation process is regulated by an intricate balance between LH and FSH and steroid production, and this culminates in the process of ovulation whereby the ova are released into the body to be made available for fertilization. The primary event responsible for ovulation is a massive surge in release of LH, which will act on the mature follicles to soften the stigma and promote expulsion of the ova along with its attendant radiating crown of granulosa cells. The surge of LH release from the gonadotrophs is the direct result of a surge in release of LHRH from the neurosecreteory neurons of the preoptic area and mediobasal hypothalamus that project to the median eminence and thereby gain access to the primary portal plexus leading to the anterior pituitary.

Achieving sufficient release of LHRH requires synchronized bursting of the neurons and this is achieved via mechanisms that remain poorly understood but clearly involve rising estradiol on a background of previously low levels of estradiol. The combination of synchronized LHRH neuronal firing, increased LH synthesis, and greater sensitivity of the gonadotrophs to LHRH is referred to as "positive feedback" effects of estradiol and is required for ovulation to occur. A masculinized brain does not respond to rising estradiol with positive feedback and the loss of this ability is determined by gonadal steroids during the perinatal sensitive period. Newborn females treated exogenously with testosterone, or its aromatized product, estradiol, will be forever sterile due to the inability to generate an LH surge and thereby ovulate. If females are given low doses of masculinizing hormone, or the exposure to steroid occurs late in the sensitive period, the adult female will show some fertility shortly after puberty but then will display rapid reproductive aging and enters into a period known as "persistent estrus" characterized by chronically elevated estradiol due to the absence of ovulation and therefore, there is no formation of a corpora lutea and progesterone production. Alternatively, restricted prenatal androgen exposure is sufficient to completely prevent LH surges in adulthood and this appears to be, at least in part, because of a lack of induction of progesterone receptors by estradiol in the preoptic area (Foecking et al., 2005).

Although the activity of the LHRH neuron is the central mediator of LH release, afferent input to these neurons plays an important modulatory role, particularly in controlling the precise temporal aspects of positive feedback. Local GABAergic neurons are particularly important and their escape from tonic inhibition prior to the LH surge is a prerequisite for the surge to occur. GABA neurons in the vicinity of LHRH neurons possess estrogen receptors of both subtypes and increasing estradiol is associated with decreased levels of the GABA synthetic enzymes, GAD-65 and GAD-67 (Grattan et al., 1996). A potential target for differentiation of the effects of estradiol on gonadotropin neurons is these local inhibitory interneurons. Use of microdialysis to accurately characterize the dynamic nature of GABA release in relation to the timing of the LH surge indicates that the profile of release is markedly sexually dimorphic in the presence of equivalent hormonal milieus as adults (Tin-Tin-Win-Shwe et al., 2004). This could reflect changes in the morphometry of the GABA neurons, changes in the synthesis of GABA, or changes in the mechanics of release. Regardless of this, the findings highlight the potential for a particular neurochemical cellular phenotype to be permanently differentiated in development to mediate adult reproductive responses.

In addition to the local control, important regulatory components of the LHRH cell bodies originate from projections outside the preoptic area. Some afferent inputs are derived from nearby neighborhoods, such as those originating in the AVPv, which is within the hypothalamus/preoptic continuum, whereas others are as distant as the brain stem (see Simerly, 2002 for review). There is also evidence of an additional modulatory role for the arcuate nucleus, through which the LHRH axons course on their way to the median eminence.

5.1 A Neuroanatomical Circuit for Sex Differences in Positive Feedback

Given that investigation of the cellular mechanisms mediating positive feedback effects of estradiol on LHRH release remains an enigmatic and highly controversial area, it is not surprising that relatively few inroads have been made into understanding how this sexually dimorphic response is established. The greatest traction has been achieved in the elegant work of Simerly and others on two related fronts. One is that the AVPv (also called the PePOA) exhibits an unusual sexual dimorphism in that it is larger in females than males (Simerly, 1998). Interestingly, this sex difference is entirely due to estradiol, just like the SDN-POA, and it is also entirely because of differential, naturally occurring cell death or apoptosis, just like the SDN-POA. Only in the AVPv the effect is in the opposite direction; estradiol actually increases cell death (Murakami and Arai, 1989). The remarkable opposing actions of estradiol on cell death in two diencephalic nuclei that are in close proximity to each other have never been explained. It is also unclear how the volume of the AVPv relates to its role in control of the LH surge. Neurons of this region project directly to LHRH neurons and a strong correlation has been found between levels of c-fos expression in neurons of the AVPv and LHRH neurons at the time of the LH surge (Le et al., 1999), suggesting that excitation in the AVPv is

directly related to excitation of LHRH neurons. This raises the question of what regulates excitation of AVPv neurons and relates to the second major avenue through which insight is being gained into the sexual differentiation of gonadotropin secretion. Considerable focus has been on either the volume of a brain region (usually a function of the number of neurons) or the morphometry of individual neurons. Equally important, however, is how many neurons project to a particular region, in other words, the size of an afferent input. One of the most, if not the most, sexually dimorphic projection in the brain is that from the principal nucleus of the bed nucleus of the stria terminalis (pBNST) to the AVPv (Hutton et al., 1998), being almost ten times larger in males than females.

An essential first step in determining how the sex dimorphism in the projection from the pBNST to the AVPv is established was achieved with the use of a combined explant culture system. This provided the critical advantage of being able to ask whether a pBNST from a male neonate would innervate an AVPv derived from a female and vice versa. Surprisingly, the AVPv of males (which is smaller) releases a target derived factor that promotes innervation by pBNST neurons, regardless of whether they are from males or females. Treating the AVPv in culture with estradiol achieves the same end (Ibanez et al., 2001). To date, this is the only known example of steroid induction of a target-derived diffusible factor that regulates innervation. The neurochemical nature of the innervation provides additional critical information as it appears to be largely GABAergic (Polston et al., 2004). Thus, a working model can be constructed in which a tenfold greater inhibitory GABAergic projection for the pBNST to the twofold to threefold smaller AVPv of males results in tonic inhibition of the AVPv and provides a physiological explanation for the failure of males to exhibit an LH surge in response to estradiol treatment in adulthood (Simerly, 2002). This is a beautiful example of a functional circuit directly related to sexually dimorphic reproductive function. This simplistic view, however, requires reexamining and refinement in light of recent evidence that AVPv neurons responsive to estradiol are actually of a dual phenotype, both GABAergic and glutamatergic, with the relative impact of each varying as a result of differing estradiol levels and photoperiodic timing of the LH surge (Ottem et al., 2004).

5.2 Are Sex Differences in Astrocyte Morphology Relevant to Positive Feedback?

As mentioned earlier, there is additional modulation of the LH surge by regulation of the LHRH neurons at the level of the arcuate/median eminence. Astrocytes are a subtype of glia, and can be further divided into reactive and protoplasmic astrocytes, as well as tanycytes, a specialized astrocyte found only in the arcuate/median eminence. Protoplasmic astrocytes can be identified by their expression of glial fibrillary acidic protein (GFAP), which when visualized by immunocyochemistry, reveals long sinuous and multiple branching processes. These nonneuronal cells have long been implicated in the process of synaptic plasticity in neuroendocrine brain regions that integrate physiologic stimuli from the body. Garcia-Segura, Naftolin, and colleagues (Garcia-Segura et al., 1996; Garcia-Segura et al., 2000) have shown a similar involvement of astrocytes in synaptic plasticity in the arcuate nucleus with the exception that the dominant stimulus is estradiol, which drives changes in astrocyte morphology over the course of the estrous cycle. The surface area covered by astrocytic processes is dramatically increased on the afternoon of proestrus and correlates with a reduction in GABAergic synapses, leading to the postulate that disinhibition in the arcuate plays a positive role in the induction of the LH surge (Olmos et al., 1989; Parducz et al., 1993; Horvath et al., 1997). There is also a role for tanycytes, the end-feet of which appear to surround the terminals of LHRH neurons as they enter into the median eminence in proximity to the primary portal plexus. Steroid hormone treatments that induce an LH surge result in a retraction of this glial ensheathment of the LHRH nerve terminals, thereby increasing availability of the releasing hormone to the vasculature (King and Rubin, 1994). Whether developmentally established sex difference in the responsiveness of either protoplasmic astrocytes or tanycytes to gonadal steroids in adulthood contributes to sexual differentiation of gonadotropin secretion, remains unknown.

Noting the marked remodeling of arcuate astrocytes that occurs in the adult female brain in response to estradiol exposure observed by Garcia-Segura and colleagues, the potential for a similar effect was

investigated in the developing brain. A sexually dimorphic morphology of arcuate astrocytes is established as early as the day of birth and maintained throughout life. Males have longer and more frequently branching astrocytes with an overall stellate appearance than the predominantly bipolar and simple morphology of astrocytes in the arcuate nucleus of immature females. This sex difference appears to be entirely a function of testicularly derived testosterone being aromatized to estradiol in the neonatal male brain, as astrocytes of the female can be induced to differentiate to a point that is indistinguishable from that of males by exogenous testosterone or estradiol, but not dihydrotestoterone (Mong et al., 1996). A plausible scenario for estradiol regulation of astrocytes would be via direct binding to ER in the astrocytes and regulation of a target structural gene, such as GFAP. However, as with most things, when it comes to steroids and reproduction, the cellular mechanisms were anything but obvious. Efforts to find ER in astrocytes of the arcuate nucleus produced only negative results (Mong and McCarthy, 1999), but this can only be taken as absence of evidence rather than evidence of absence. However, it was further demonstrated that the amino acid transmitter, GABA, is a critical mediator of estradiol-induced astrocyte differentiation. Blocking GABA synthesis for the first two days of life with antisense oligonucleotides to the rate limiting enzymes GAD-65 and GAD-67 prevented the differentiation of astrocytes, which occurs in males or androgenized females. More important, administration of the GABA-A receptor agonist, muscimol, early in life, induced differentiation of astrocytes in females that was of the same magnitude as that normally occurring in males (Mong et al., 2002). Astrocytes in vitro have been shown to possess GABA-A receptors (Fraser et al., 1994) and to change morphology in response to receptor activation (Matsutani and Yamamoto, 1997). Given that GAD is synthesized exclusively in neurons, this suggests that GABA is released by neurons to act on nearby astrocytes to alter their morphology. Thus, it seems that astrocytes are not the primary site of hormone action, but instead they are responsive to hormonally induced signals originating in the neurons.

Interest in glial–neuronal interactions has increased dramatically in the last half decade. That glia would have a sexually dimorphic morphology permanently established during the neonatal sensitive period seemed surprising at first, but when considered in the context of how intimate the relationship between neurons and glia is, and how neurons exhibit lifelong differences in morphology, it becomes apparent that what would be truly surprising is if astrocytes were NOT sexually dimorphic. An important question is the relationship between astrocytic and neuronal morphology. In the arcuate nucleus, increased astrocyte complexity is inversely correlated with the density of dendritic spine synapses on the nearby neurons (Mong et al., 1999). The mechanistic basis for this inverse relationship is not known but has been speculated to be a result of physical inhibition of spine formation. In other words, the astrocytes act like a blanket over the neurons, suppressing the sprouting of spines. There is no evidence either in support of or against this theory, but it seemed plausible enough until other brain regions were investigated.

The discovery of a sex difference in astrocyte morphology in the arcuate nucleus prompted a similar analysis in the preoptic area. Here too, astrocytes of males have more, longer, and increasingly bifurcated processes than females and as with the arcuate, this is a function of estradiol action (Amateau and McCarthy, 2002b). Parallel analysis of neuronal morphology, however, demonstrated that the relationship between glia and neurons was exactly the opposite to that seen in the arcuate; more complex astrocytes were positively correlated with increased density of dendritic spine synapses (Amateau and McCarthy, 2002a). Another notable difference was the mechanism regulating astrocyte morphology. Instead of GABA, morphology appears to be determined at least in part by PGE2, the same prostaglandin shown to increase dendritic spines and masculinize the POA in regard to male sex behavior (McCarthy et al., 2002). Once again, the same steroid hormone estradiol regulates markedly different pathways to achieve the same end, more complex astrocytes. Whether or not estradiol acts directly on astrocytes and if astrocytes in the POA possess estrogen receptors, is currently unknown.

6 Sexual Differentiation of Cognition

Cognition, also referred to as learning and memory, is a value-laden metric even when assessed with apparently objective criteria. Rats and mice have been frequently used to demonstrate sex differences in cognition, and underlying morphometric differences in the hippocampus or cortex are often cited as

further evidence for differential learning between the sexes. It is presumed that this is based in early organizational events similar to that observed for reproductive endpoints. But is this assumption warranted? The hippocampus is vitally important to learning and memory, and there is no argument that despite having little or no role in the control of reproductive function, it is a sensitive target for gonadal steroids. Considerable attention has been paid to estradiol modulation of synaptic plasticity in the adult (Desmond and William, 1998; Woolley, 1999) and the effects of hormonal treatment on cognitive functioning (Kampen and Sherwin, 1994; Sherwin, 1997; Daniel et al., 1999; Daniel and Dohanich, 2001; Sandstrom and Williams, 2001; Williams, 2002; Luine et al., 2003; Li et al., 2004). Interest in estradiol action on the mature and aging hippocampus has been further increased by controversy surrounding the use of hormone replacement therapy in women. There is irrefutable evidence that estradiol potently enhances synaptic efficacy in the hippocampus by increasing the density and functionality of dendritic spine synapses in the female rat (Woolley et al., 1997; Rudick and Woolley, 2003). Behavioral tests designed to temporally correlate physiological changes with spatial learning have provided equally strong evidence of enhanced cognitive ability in response to estradiol action in the hippocampus (Sandstrom and Williams, 2001). The considerable body of work on estradiol and the hippocampus leads toward the logical assumption that there are substantial sex differences in the hippocampus as well. Indeed, the effects of estradiol on spatial learning tasks in rats and verbal recall tasks in humans are often interpreted as the basis for sex differences in cognitive abilities. However, when questions are specifically framed to ask are there *sex differences* in the hippocampus and hippocampally regulated functions, the evidence is often in favor of either no sex difference, very subtle sex differences, or differences in which hormonal modulation in the female results in a mean response that varies but stays within the range of the male response.

6.1 What is the Evidence of Sex Differences in the Hippocampus?

Volumetrically, males have a larger hippocampus than females (Madeira and Lieberman, 1995; Nunez et al., 2000), with the CA1 region being 16% larger in males in one study (Isgor and Sengelaub, 1998). A sex difference is evident within the first week of life, although it is observed inconsistently and is small in magnitude (~10%) (Hilton et al., 2003; Nunez et al., 2003). In mice, males have more granule cells in the dentate gyrus than females, but this was observed only in three of six strains examined (Wimer and Wimer, 1985). It is important to compare these small and unreliable sex differences with the robust volumetric sex differences observed in subnuclei of the reproductively important POA where differences are in the range of 300–700% (Gorski et al., 1980; Simerly, 2000, 2002).

When examined at the level of physiology, estradiol enhances LTP in ovariectomized females (Cordoba Montoya and Carrer, 1997) and in naturally cycling females (Warren et al., 1995), and this is proposed as the physiological basis for increased learning efficacy following estradiol exposure. Unfortunately, few studies have compared LTP induction across the sexes and in the one that has, the magnitude of LTP induced in females on the afternoon of proestrus (high estradiol) was the same as that seen in males during the morning (Warren et al., 1995). There was also no sex difference in the input–output curves generated by evoked excitatory field potentials. Hippocampal-dependent fear conditioning, another form of learning, was similarly examined for sex differences using cycling females and intact males. In this instance, males and estrous females performed similarly, whereas females in proestrus showed less spatial–contextual conditioning than both males and estrous females (Markus and Zecevic, 1997). In contrast to the well-established ability of estradiol to enhance LTP in CA1 induced by Schaffer collateral stimulation, it reduces LTP at perforant path synapses, an effect believed to be functionally related to the impaired contextual (hippocampal-dependent) fear conditioning also observed in estrogen-replaced ovariectomized rats (Gupta et al., 2001). This was again one of the few studies that compared sexes and interestingly a different pattern appears in that intact males and ovariectomized females show identical fear conditioning but now both differ significantly from estradiol-treated females. Induction of LTD at CA3-CA1 synapses is also enhanced by estradiol treatment of females. A low-frequency (2Hz), asynchronous conditioning stimulation protocol does not produce LTD in slices prepared from ovariectomized females but does so readily in slices from estradiol replaced females (Zamani et al., 2000). Unfortunately, there was no sex comparison in this study,

so it is unknown if the threshold for LTD induction varies between males and females. Changes in the density of dendritic spines on CA1 pyramidal neurons are correlated with LTP and again, there is a sex difference but the direction of the sex difference varies with the phase of the female estrous cycle, being higher in males than in the proestrous females, but lower than males in diestrous females (Shors et al., 2001). Thus, in regard to the cognitively relevant endpoints of LTP, dendritic spine density, and fear conditioning, it appears there is a hormone-dependent modulation of the response in females, but this response varies around the mean in males and therefore does not constitute a sex difference per se.

At the behavioral level, males learn spatial tasks like the radial arm maze or Morris water maze faster than females, but with practice they both perform the task equally well and empirical evidence indicates no difference in memory capacity between males and females. Thus, sex differences are limited to acquisition of the task, not steady-state performance. In fact, when the cues used for acquisition are altered, females outperform males. Systematic control of environmental variables reveals that males use the geometrical cues, such as the shape of the room or location of large objects as guides, whereas females attend to local small-scale details (Williams, 2002). Thus, both sexes learn: they just use different strategies to do it. Even more important, if males and females are familiarized with the spatial task in advance, resulting in a reduction in the natural tendency of females to show greater thigmotaxis than males, females actually outperform males on finding the hidden platform in the water maze. Moreover, there is no sex difference during the probe trial in which the platform is removed (Perrot-Sinal, 1996). These studies illustrate the potential for nonlearning-related parameters, such as response to novelty, to skew results to appear as if there are sex differences in spatial ability when in fact there are not.

Learning can also be assessed with conditioning paradigms such as contextual fear and passive avoidance. Males reach criteria for acquisition in both of these tasks faster than females. The phosphorylation, and thereby activation of the transcription factor CREB, is often used as a marker for neuronal activation and as an indicator of the active gene transcription required for consolidation of long-term memory. The number of neurons expressing pCREB increased in the CA1 of male rats after fear conditioning, but did not change in females (Kudo et al., 2004). Removal of gonadal steroids in males did not alter their performance, hinting at the possibility that this sex difference is determined organizationally, but by no means establishing it.

Sex differences in spatial navigation tasks have been examined within the framework of organizational versus organizational hormone actions. All the traditional strictures apply in that removal of the male testis early in life feminizes learning in adulthood, and treating newborn females with testosterone or estradiol masculinizes their responses as adults (Williams et al., 1990; Williams and Meck, 1991; Roof, 1993). Thus, as with the majority of other sex differences in the brain, estradiol has been implicated as the masculinizing factor. Females treated with estradiol for the first 10 days of life show masculine learning patterns as adults, and males castrated neonatally are predictably female-like in their responses (Williams et al., 1990). However, note that females were not treated with an aromatase inhibitor and removing the testis in males would remove both androgens and estrogens. In a separate study, the effects of hormonal manipulation during late gestation included treatment with the nonaromatizable androgen, dihydrotestosterone, and the antiandrogen flutamide. Animals were tested on a water maze as adults and at the behavioral level the findings are unambiguously interpretable as an *androgen*-mediated effect on spatial learning, with there being no effect of exogenously administered estradiol (Isgor and Sengelaub, 1998). This study is not without its caveats, but raises the interesting possibility that androgens, not estrogens, mediate sex differences in spatial ability. Interestingly, these same authors performed a morphometric analysis of adult brains from neonatally treated animals and found androgen effects on neuron number in CA3 that were consistent with enhanced spatial performance, but in CA1 cell number was increased by estradiol. We have also noted an effect of increased cell number by postnatal estradiol administration to females that is selective to the CA1 field (Hilton et al., 2003), suggesting there may be considerable regional heterogeneity of steroid action and/or availability within the developing hippocampus. Estradiol effects restricted to the CA1 field may be the functional basis for the simplifying of associational–perceptual processes that improve acquisition of spatial tasks as proposed by Williams and Meck (1991).

An additional approach for assessing the role of estradiol on hippocampal function is to knock it out. This has been achieved with transgenic technology in the form of the aromatase deficient mouse (ArKO). Male ArKO mice have severely disrupted male sexual behavior (Honda et al., 1998), consistent with the

effects of perinatal aromatase inhibition in the rat. However, both males and females are equally impaired in a spatial reference test, the Y-maze (Martin et al., 2003). Adult female mice lacking functional ERα (ERαKO) show retention deficits on a hippocampal dependent inhibitory avoidance task, a form of trace conditioning (Fugger, 2000).

So are there sex differences in the hippocampus? Yes, there clearly are, but they are of a much smaller magnitude than generally assumed and perhaps more important, they may have little if anything to do with dichotomous developmental exposure to estradiol.

7 Sexual Differentiation of Stress and Anxiety

As central as the hippocampus is to learning and memory, it is equally important to the negative feedback control of the hypothalamic–pituitary–adrenal axis or stress response system. Pyramidal neurons express high levels of glucocorticoid receptors, Type I and Type II, and projections via the subiculum regulate the output of the paraventricular nucleus (PVN), which projects directly to the anterior pituitary to regulate ACTH release into circulation. Increased circulating levels of glucocorticoids act on the hippocampus in a negative feedback loop to decrease the output of the PVN and return the system to homeostasis (see for review Van de Kar and Blair, 1999). Dysfunction of this feedback loop is observed in a significant portion of patients suffering debilitating depression (Wong and al., 2000) and reduced hippocampal volume is associated with a number of neuropsychiatric disorders including post-traumatic stress syndrome and schizophrenia (Nopoulos et al., 1997).

There are sex differences in stress response in adults, with females exhibiting a more robust and longer-lasting increase in glucocorticoids and behavioral impairment following exposure to a stressor (Shors et al., 2001; Bale et al., 2002), and this sex difference appears to be organizationally determined (McCormick et al., 1998). Sex differences in the hippocampus have been speculated to underlie the variance observed in adult stress response, but this connection has not been definitively established. The stress axis is highly complex with multiple components and involves several extra-hippocampal sites of negative feedback including the highly sexually dimorphic POA (Viau and Meaney, 1996). Experimental designs previously employed would preclude definitively concluding that any sex differences observed in stress responding are the result of organizational steroid influences on the hippocampus.

Learning and memory and stress intersect in the form of the Yerkes–Dodson Law, which states that learning is enhanced by stress at one level, but impaired if that stress is increased or unaffected if the stress is decreased (see for review de Kloet et al., 1999; Williams, 2002). This centuries old tenet has been recast recently in light of sex differences. Exposure to acute stress in male rats enhances learning, but has the opposite effect in females, impairing their performance in an eye-blink conditioned reflex experiment. Treatment of neonatal females with testosterone results in a male-like performance as adults, whereas castration of newborn males leads to a female-like response. Antagonizing the androgen receptor during late gestation blocks the enhanced learning induced by stress in adult males (Shors and Miesegaes, 2002), suggesting these effects are mediated by androgens, not estrogens.

These brief reviews of sex differences in cognition and stress response are not meant to provide a comprehensive overview of these highly complex and multivariable systems. Instead, the intent is to highlight that when considering sex differences in these systems, there is a need for caution in evoking similar terminology or in use of assumptions regarding sex differences in brain regions of physiological mechanisms that are directly relevant to reproduction. A complete understanding of the ways in which the sexes do NOT differ is just as important as the ways in which they do.

8 Evidence for Sexual Differentiation of the Human Brain

Interest in sex differences of the human brain predates all of the animal literature and can reasonably be assumed to have emerged shortly after the realization that the brain is in fact the site of control of thought, movement, emotion, and much physiology. As with rodents, male human brains are larger than females,

and as with rodents, there are many subregions that are larger in males than females. However, unlike the research on animal models, studies in humans are fraught with numerous technical as well as political pitfalls. Technically, the greatest challenge had been the predominant source of the tissue, cadavers. Differences in time from death to collection and fixation combined with variance in sex, age, ethnicity, and life history combine to make for a heterogeneous sample under the best of circumstances. However, the recent extensive use of magnetic resonance imaging (MRI) highlights an unexpected advantage of studies on humans, namely, the ability to precisely quantify large regions in regard to gray versus white matter and to prospectively study the same individual over time (Giedd, 2004). The use of functional MRI has also allowed for assessing the relative activity of a particular brain region in men versus women and revealed sex differences in uniquely human aspects of speech (Shaywitz et al., 1995).

The use of MRI has also confirmed and extended a fundamental principle in the study of human brain sex differences, the importance of developmental age. The size of particular brain regions is amazingly dynamic and comparisons between the sexes must incorporate a longitudinal view to be truly interpretable. Early studies of a human analog of the SDN found a hypothalamic nucleus that is larger in males than females. A more detailed analysis across the lifespan revealed that the degree of difference varies with age, not manifesting until after about 10 years of age, becoming maximal in young adulthood and gradually declining in both sex difference and in size in older adults (Swaab and Fliers, 1985). In some ways, this even more neatly parallels the rat in that the sex difference in SDN volume is not apparent until 5 days of age and is maximal just postpuberty. However, enthusiasm must be tempered by the fact that the sexual activity and life experiences of humans are also going to be dramatically different between 10 years of age and young adulthood and it is plausible that experience, rather than sex (meaning gender in this case) has a major impact on the size of a particular brain region. Other investigators have examined the human hypothalamus and seen a more complex picture. Rather than a single SDN, they have characterized a series of hypothalamic nuclei referred to as the interstitial nuclei of the anterior hypothalamus (INAH) and numbered 1 through 4 (INAH-1,-2,-3,-4) with INAH-1 being the original SDN. Working with Roger Gorski, Laura Allen found no sex difference in INAH-1 but instead reported that both INAH-2 and -3 were larger in males (Allen et al., 1989).

The technical limitations inherent in use of tissue from cadavers may have been a major contributing factor to inconsistencies in reports of sex differences on cortical volume, size of the cerebellum, and in particular, the size and shape of the corpus callosum, the major fiber tract between the two cerebral hemispheres. Like the hypothalamus, all these studies suffered the same limitations of being conducted on postmortem tissue. The increasing use of MRI to quantify the volume of brain regions in living subjects has helped to clarify some of these discrepancies in that the approach offers the great advantage of allowing for a precise matching of the age, socioeconomic status, and ethnicity of the male and female subjects through the use of recruitment. But like all advances, it also has shortcomings. Although the resolution of MRI scanning has increased tremendously in the last decade, the precision of the images is still far from that which is obtained on fixed tissue, and questions such as cell density or cell type cannot be answered with this approach. Smaller brain structures, such as the INAHs, cannot yet be visualized by MRI.

One of the great advantages of MRI is the ability to distinguish white from gray matter and thereby gain insight into the rate of myelination of particular regions and fiber tracts. Human brain development proceeds in the same way as other mammals in that myelination is a relatively late process that occurs in tandem with the pruning of excessive synapses. Relative changes in white versus gray matter can be taken as an index of the processes of myelination and synaptic pruning, respectively. In a cross-sectional study, changes in white versus gray matter were examined in boys and girls ranging in age from 7 to 17. Both sexes exhibit an increase in white matter and decrease in gray matter with age, but the relative changes in males were significantly greater, having over a threefold loss in gray matter volume and more than twofold increase in white matter than females (De Bellis et al., 2001). Females also showed a significant age-related change in gray and white matter, but the change appeared to be occurring at a different rate compared to males. This echoes the general principle of brain development in males and females elucidated earlier; the same things happen, they just happen in different degrees and/or at different times.

Establishing cellular mechanisms that determine sex differences in human neuroanatomy or behavior can be considered challenging at best. The use of strong inference based on studies done on primates and

so-called natural experiments on humans is currently the most promising approach. Studies on primates indicate that the overall process of sexual differentiation in regard to reproductive physiology and behavior is a hormonally driven process analogous to that in rodents, but differs in some important details. One is that it appears that the sensitive period for sexual differentiation of nonhuman primates is entirely prenatal, with little or no impact of exogenous hormone administration once birth has occurred. The second is that in contrast to rodents in which estradiol is the masculinizing hormone, in nonhuman primates it appears that androgens are the causative agent (see for review Wallen and Baum, 2002). Interestingly, in primates α-fetoprotein binds both androgens and estrogens, as opposed to only estrogens in rodents. Presumably, the male primate fetal testis makes sufficiently high quantities of androgens to overwhelm the absorptive barrier of α-fetoprotein, although a role for adrenal androgens cannot be ruled out. A potential role for estrogens in primate brain sexual differentiation, of either males or females, also cannot be ruled out, but precisely what that role might be is unclear at this time.

The most commonly explored naturally occurring experiment for human brain sexual differentiation is girls exposed to high levels of androgens early in gestation because of a genetic defect of steroidogenisis in the adrenal that results in excessive androgen production. This is referred to as congenital adrenal hyperplasia (CAH) and is most frequently due to defective 11-β-dehydroxylase in the glucocorticoid synthetic pathway. Affected girls are born with ambiguous genitalia that are partially masculinized. The hormonal imbalance is corrected at birth and the physical abnormalities are sometimes, but not always, corrected surgically within the first few years of life. These girls have been the subject of intense study in a number of different cultures and this topic has been extensively reviewed (Berenbaum, 1999; Hines, 2002, 2004). A sweeping generalization that can be made about almost every endpoint that has been assessed is that CAH girls fall somewhere between unaffected male and female siblings on measures of masculinization. This is true whether the endpoint is rough-and-tumble play, sexual attraction to girls, spatial learning, or expression through spontaneous drawing (Iijima et al., 2001). The caveat that these girls might be raised differently than unaffected girls can never be fully dismissed, but on balance the evidence suggests that prenatal androgens influence brain development in a manner that is analogous to, but perhaps not equivalent in magnitude to, the permanent organizational effects exerted by estradiol in the perinatal rodent brain.

9 Why is It Important to Study Sexual Differentiation of the Brain?

Across the spectra of neurological and mental health disorders and diseases, an individual's gender is a major predictive factor of relative risk. Interestingly, the risk clusters according to the developmental timing of onset. Males are at considerably higher risk for disorders with very early onset, such as autism, dyslexia, stuttering, attention deficit, hyperactivity disorder, early onset of schizophrenia, and Tourette's syndrome. By contrast, females are at higher risk of postpubertal adult onset of illnesses such as major depressive disorder, general anxiety disorder, obsessive/compulsive disorder, and anorexia/bulimia. Many factors are likely to contribute to this difference, including cultural and environmental variables, but endemic differences in the brain are a critically important yet poorly understood contributor to the etiology of sex differences in mental health and disease (Crick and Zahn-Waxler, 2003). That architectural and neurochemical sex differences in the brain are permanently established early in development by the steroid hormone milieu, has been known for close to 50 years. The cellular mechanisms of how neuronal sex differences are established has been woefully underinvestigated, despite its clear utility for understanding basic brain development and potential as an entry point into the origins of mental illness and neurological disease.

10 Conclusions and Future Directions

Sex differences in brain and behavior will no doubt continue to fascinate the researcher and lay person alike. It is a question that impacts on medicine, education, the criminal justice system, and even religion. From the point of view of biologists, it is a lucrative entry point into a multitude of systems endpoints ranging from signal transduction to complex social behaviors. Given all this interest, do we know as much as we

should? The phenomenon has been described for close to 50 years, and we do know a great deal about where and when sex differences in the brain arise, but as to how, we know very little. When phenomena are poorly understood at the mechanistic level, it is often because the subject is either exceedingly complex, or not of much interest. In the case of sexual differentiation, the endpoints are robust, the effects of hormones are reliable, and the outcomes are highly relevant, but in terms of complexity it probably trumps all others due to the convergence of biological (genetic and hormonal), social, environmental, and cultural influences in both the quantifiable outcomes and the interpretation of those outcomes. The National Institute of Mental Health, National Institute of Neurological Disorders and Diseases, and the National Institute of Drug Abuse have all identified sex differences in the brain as an underinvestigated topic and one targeted for increased research emphasis (http://www.nimh.nih.gov/strategic/strategicplanmenu.cfm). Gender is a major predictor of relative risk of a range of neurological disorders and diseases of mental health, response to injury, and predilection to drug addiction. Moreover, only by understanding how the brain differs between men and women can we also understand how it does not. The similarities are as important as the differences.

7 Sex Differences in Human Brains 503

1 Introduction

Current research on sex differences in the brain stems from two relatively independent lines of research. One focused on sex differences in gonadotropic hormone release, the other on hormonal control of sexual behavior. The first line traces back to Harris and Jacobsohn's demonstration that pituitary transplants placed directly under the hypothalamus are able to drive ovarian cycles in female rats irrespective of whether they came from male or female donors. This dispelled an earlier claim that the pituitary was responsible for sex differences in gonadotropic hormone release and pointed at the brain instead (Harris and Jacobsohn, 1952). Barraclough and his collaborators subsequently showed that injecting testosterone propionate shortly after birth renders female rats permanently infertile (Barraclough and Leathem, 1954; Barraclough, 1961). After showing that the anterior preoptic area was responsible for cyclicity in gonadotropic hormone release, Barraclough and Gorski (1961) suggested that in the presence of androgens the anterior preoptic loses its ability to sustain this cyclicity. Around the same time, Phoenix and colleagues (1959) showed that testosterone propionate injections into pregnant guinea pigs increased the display of male sexual behavior in female offspring while it had the opposite effects on female sexual behavior. This work led to the realization that gonadal hormones influence sexually dimorphic behaviors in two fundamentally different ways. Early in life, they direct the development of neural circuitry that generates male- or female-typical functions and behaviors in adulthood. These developmental effects are permanent and called organizational. For example, testosterone exposure during development increases the likelihood that animals will show male sexual behavior as adults. However, to show male sexual behavior, animals have to be exposed to testosterone in adulthood as well. This adult effect is transient and therefore called activational (Becker et al., 2005).

Phoenix and colleagues did not expect that the developmental effects would cause as dramatic changes in morphology as those observed in reproductive organs. They suggested that early androgen exposure causes "a more subtle change reflected in function rather than in visible structure." The first reports of sex differences hinted that differences were indeed subtle. For example, in 1960, Kato detected higher serotonin levels in female than in male rat brains. A little while later, Pfaff (1966) showed that neonatal castration of rats permanently changed the size of nucleoli in hypothalamic neurons. In 1970, McEwen and his colleagues showed that neonatal steroid treatment changed testosterone and estradiol uptake in rat brains (McEwen and Pfaff, 1970; McEwen et al., 1970). And one year after that, Raisman and Field (1971) reported the first sex difference in neural connectivity: male rats showed more synapses from non-strial origin on dendritic shafts and fewer on dendritic spines than did females. Although the functional significance of this finding is still completely unclear, it was a milestone because it showed that neonatal manipulations of gonadal hormone levels could reverse morphological sex differences levels (Raisman and Field, 1971, 1973). This mapped very well onto the ideas of Phoenix et al. (1959) on the organizational effects of gonadal hormones.

After these admittedly subtle findings, Nottebohm and Arnold (1976) reported some very conspicuous differences in the size of song control nuclei in the brain of zebra finches and canaries. These differences reinforced the notion that studying sex differences in brain structure could narrow the gap between structure and function, because the correlation between structure and function was very striking in birds. Males, which sing, had much larger song control nuclei than did females, which do not sing. Soon thereafter, equally impressive differences were found in gross anatomy of mammalian brains. Arguably, the most famous of these was found in the sexually dimorphic nucleus of the medial preoptic area (SDN) in the rat, which was discovered by Gorski and his colleagues (1978). This nucleus is five times larger in males than in females, which is remarkable considering that many researchers must have overlooked this difference, which is visible to the naked eye in Nissl-stained sections.

Currently, hundreds if not thousands of sex differences in neural structure have been found almost anywhere in the brain (see for example, Juraska, 1991; Segovia and Guillamon, 1993; Kawata, 1995; Madeira and Lieberman, 1995; Tobet and Hanna, 1997; Cooke et al., 1998; Breedlove et al., 1999; Segovia et al., 1999; Morris et al., 2004). There are also a number of excellent reviews on development and function of sex differences in other neurotransmitter systems (see for example, Fink, 1998; McCarthy et al., 2002, 2005).

This review describes how focusing on the neurotransmitter components of sexually dimorphic structures helps in studying the development and function of sex differences in the brain.

2 Function of Sex Differences in the Brain

Studying sex differences in the brain holds a number of promises. First, studying sex differences in hormonally manipulated animals offers a unique perspective for studying how neural systems develop to generate sex-specific behaviors. Second, sex differences allow one to study how differences in brain structure translate into differences in function. There are sound clinical reasons for pursuing these questions as solving them may explain why so many behavioral and neurological disorders show marked sex differences in incidence and severity (Swaab et al., 2003). Nature, however, has been reluctant to deliver on these promises. Although for many sex differences, we know which hormones control sexual differentiation and when they do that, we barely know how. Only a smattering of molecular and cellular processes that mediate hormonal effects on sexual differentiation has been identified (see e.g., Auger et al., 2000; Amateau and McCarthy, 2004; Forger et al., 2004; Forger, 2006). In addition, except for a handful of sexually dimorphic cell groups, most of which control specific sexually dimorphic muscle systems (Kelley, 1988; Breedlove, 1992), the functional significance of practically all sex differences in the central nervous system is unknown (De Vries and Boyle, 1998). The complexity of the connections of the areas where these differences are found and the technical difficulties of manipulating specifically the sexually dimorphic elements in these areas form significant roadblocks.

One way around these roadblocks may be to focus on the neurotransmitter systems that make up these areas. That approach may reveal whether sexual differentiation selectively affects particular cell systems, which will help in revealing the cellular processes underlying differentiation. Focusing on neurotransmitter systems also helps in tracing the anatomical connections of sexually dimorphic areas, and therefore in assessing the impact of a particular dimorphism on other brain areas. Finally, knowing which neurotransmitter systems are involved will allow manipulations such as injecting receptor agonists and antagonists to test the function of specific sexually dimorphic components (De Vries, 1990). This chapter illustrates how focusing on neurotransmitter systems throws light on the function of sex differences in the brain by focusing on the sexually dimorphic vasopressin projections of the bed nucleus of the stria terminalis (BST) and the medial amygdaloid nucleus (MeA). This is one of the most consistently found sex differences among vertebrates and probably one of the best understood (De Vries and Panzica, 2006).

3 Sex Differences in Vasopressin Projections in the Brain

3.1 Bed Nucleus of the Stria Terminalis and Amygdala

The BST and MEA are telencephalic structures that show a high degree of sexual dimorphism and that have been implicated in the regulation of autonomic as well as reproductive functions, for example, gonadotropin release and male sexual behavior (Harris and Sachs, 1975; Emery and Sachs, 1976; Beltramino and Taleisnik, 1978, 1980, 1985; Valcourt and Sachs, 1979). In rats as well as mice, subregions of the BST, such as its principal nucleus, are bigger and contain more neurons in males than in females (Del Abril et al., 1987; Guillamon et al., 1988; Hines et al., 1992; Forger et al., 2004). The MeA shows similar differences (Mizukami et al., 1983; Hines et al., 1992; Cooke et al., 1999). There are also differences in the number of synapses in the MeA (Nishizuka and Arai, 1983) and in specific neurotransmitters other than vasopressin. For example, the posterodorsal area of the MeA and the principal nucleus of the BST contain more cholecystokinin-immunoreactive cells and receive denser substance P-immunoreactive innervation in males than in females (Malsbury and McKay, 1987, 1989, 1994; Micevych et al., 1988a, b).

In rats, the MeA and BST share similar patterns of projections to the hypothalamus (Simerly, 1990; Canteras et al., 1995; Gu et al., 2001). The principal nucleus of the BST, which shows the most striking sex differences in volume of all subregions of the BST (Hines et al., 1992; Forger et al., 2004), sends dense projections to nuclei in the periventricular zone of the hypothalamus, especially the anteroventral periventricular nucleus, preoptic periventricular nucleus, and the arcuate nucleus of the hypothalamus, each of which regulates hormonal secretion from the anterior pituitary (Simerly, 1995). However, the MeA and BST also innervate the medial preoptic and ventromedial nuclei of the hypothalamus, which are more commonly associated with behavior. Because the MeA and BST relay multimodal sensory information to the hypothalamus (Alheid et al., 1995), Simerly has proposed that the larger size of subnuclei of MeA and BST in males suggest that the degree of convergence of sensory information from these limbic regions onto neurons in the hypothalamus may differ as well (Simerly, 2002). The vasopressin projections from the MeA and BST, which are the focus of this chapter, project primarily to areas outside the hypothalamus that are much less intimately linked to reproductive functions (De Vries et al., 1985).

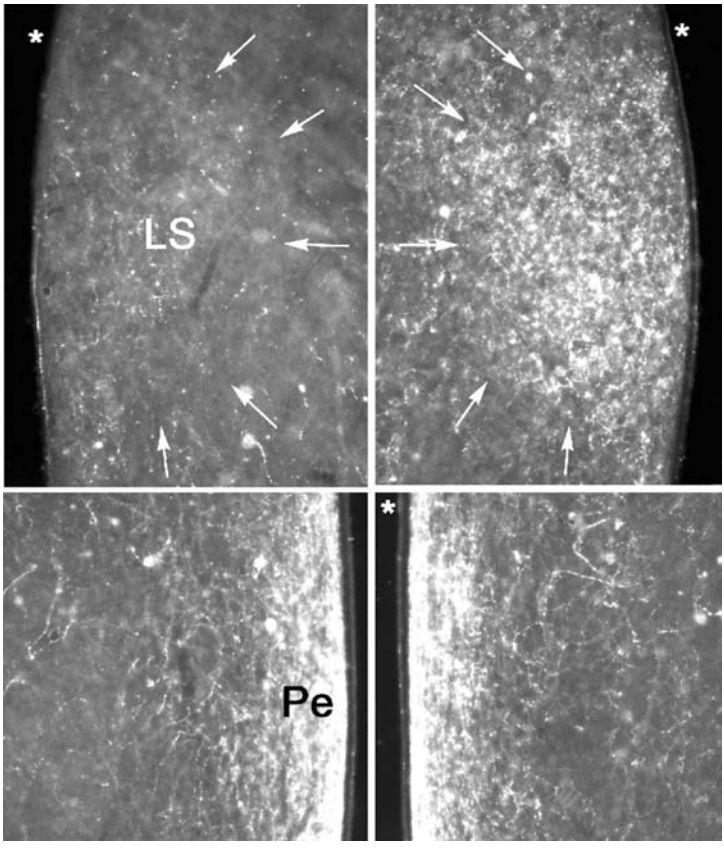
3.2 Nature of Sex Difference

We found the sex differences in these vasopressin projections by chance, before any other sex difference had been detected in a specific neurotransmitter system by anatomical means, and before we knew that these projections came from the BST and MeA. We noted an enormous variability in the density of vasopressin innervation of the lateral septum and lateral habenular nucleus in rats of twelve days and older while we were studying the development of what we thought were the projections of the suprachiasmatic nucleus. Separating subjects by sex revealed that vasopressin-immunoreactive (-ir) projections are much denser in males than in females from the twelfth postnatal day onwards (De Vries et al., 1981). At the time we found this sex difference, the suprachiasmatic and paraventricular nuclei were seen as the most important sources of vasopressin innervation of the brain (De Vries and Buijs, 1983). There are, however, several other areas outside the hypothalamus that contain vasopressin-expressing cells that do not stain as readily for vasopressin as do cells in the suprachiasmatic and paraventricular nucleus. The biggest cohorts of these cells were discovered in the BST and the MeA after pretreating animals with the axonal transport blocker colchicine (Caffe and Van Leeuwen, 1983; Van Leeuwen and Caffe, 1983). By mapping how lesions of the different possible sources of vasopressin innervation affected vasopressin fiber staining throughout the brain and by retrograde tracing studies that focused on the lateral septum, we showed that the BST and MeA provide a large share of the central vasopressin projections, especially to limbic structures such as the lateral septum, the lateral habenular nucleus, and several midbrain structures such as midbrain central gray, dorsal raphe nucleus, pontine peripeduncular nucleus and the locus coeruleus (De Vries and Buijs, 1983; Caffe et al., 1987). The sex differences in, and steroid responsiveness of, vasopressin fiber staining matched our anatomical studies remarkably well and therefore strengthened our conclusions: vasopressin cells and projections from the paraventricular and suprachiasmatic nucleus did not show obvious sex differences and steroid effects whereas those derived from the BST and MeA did (De Vries et al., 1985; De Vries and Al-Shamma, 1990) (*Figure 12-1*).

Corresponding to the sex difference in the density of vasopressin innervation, the BST of male rats has about two to three times more vasopressin-ir cells (Van Leeuwen et al., 1985; De Vries and Al-Shamma, 1990; Wang et al., 1993) and cells that can be labeled for vasopressin mRNA than does the female BST (Miller et al., 1989b; De Vries et al., 1994). Although a similar trend was found in the number of vasopressin-ir cells in the MeA in two studies (De Vries and Al Shamma, 1990; Wang et al., 1993), these differences were not significant, presumably because vasopressin staining of MeA cells was more variable than that of BST cells. A birth-date labeling study that used large numbers of male and female rats did find significantly more vasopressin-ir cells in the MeA, however (Al Shamma and De Vries, 1996). In addition, in situ hybridization studies consistently labeled two times more MeA cells for vasopressin mRNA in males than in females (Szot and Dorsa, 1993; Wang and De Vries, 1995). Although vasopressin-ir cells are present in the posterodorsal area of the MeA and the principal nucleus of the BST, the subregions with the most

Figure 12-1

Sex differences in vasopressin innervation. Dark-field microphotographs of vasopressin-immunoreactive fibers in a male- (*right panels*) and female rat (*left panels*) in the lateral septum (*LS; top panels*), which receives its innervation from the BST and MeA, and the periventricular nucleus of the hypothalamus (*Pe; bottom panels*), which receives suprachiasmatic nucleus innervation. Note that fiber density is sexually dimorphic in the LS (*arrows*) but not in the Pe; * lateral ventricle in *top panels* and third ventricle in *bottom panel*



conspicuous size differences (Hines et al., 1992; Cooke et al., 1999; Forger et al., 2004), in the rat BST, most vasopressin cells are found lateral and ventral to these areas (Caffé and Van Leeuwen, 1983; Van Leeuwen and Caffé, 1983).

Although global sex differences in cell number and density of the projections have not been found in other vasopressin-ir projections, some of them are partly sexually dimorphic. For example, male gerbils have much denser vasopressin-ir projections to the sexually dimorphic area of the preoptic/anterior hypothalamic area (SDA) than do females, but projections to the periventricular nucleus of the hypothalamus do not differ (Crenshaw et al., 1992); both projections most likely come from the same source, the suprachiasmatic nucleus (Crenshaw and De Vries, 1991). The global differences in BST and MeA projections may be related to differences in the number of vasopressin-ir cells in the BST and MeA, whereas the partial sex differences in suprachiasmatic projections may be related to sex differences in the targets they innervate; in this case, to a presence of a sex difference in the SDA, an area homologous to the medial preoptic nucleus in rats (De Vries et al., 1988), and the absence of a similar difference in the periventricular nucleus (Commins and Yahr, 1984).

3.3 Causes of Sex Difference

Sex differences in vasopressin innervation of the brain depend on organizational and activational effects of gonadal hormones and possibly also on the compositions of the sex chromosomes, independently of gonadal hormones.

3.3.1 Activational Effects

3.3.1.1 Effects of Gonadectomy In rats, the vasopressin projections of the BST and MeA are exquisitely responsive to gonadal steroids. Gonadectomy eliminates vasopressin mRNA and peptide expression in BST and MeA cells, but treatment with gonadal steroids reverses these changes (De Vries et al., 1984, 1985; Van Leeuwen et al., 1985; Miller et al., 1989a). These changes are relatively slow. In males, vasopressin immunoreactivity disappears gradually from BST and MeA projections in about two to three months (De Vries et al., 1984); in mice, an equally slow decline was found (Mayes et al., 1988). Biosynthesis of vasopressin probably declines much faster because already one day after castration, vasopressin mRNA levels are significantly lowered, while 1 week later only one tenth of labeled cells remains (Miller et al., 1992). Vasopressin peptide apparently hangs around in terminals for several weeks after vasopressin biosynthesis has been shut down. This discrepancy in the rate of decline of vasopressin peptide and message suggests that castration acutely reduces vasopressin release. The lingering peptide levels suggest that BST projections maintain the capacity to influence brain functions and behavior by releasing vasopressin.

Although no studies have addressed directly whether gonadectomy reduces vasopressin release in BST and MeA projection, indirect evidence suggests that it does. If rats are primed with an intracerebroventricular (icv) vasopressin injection, a second vasopressin injection given two days later will cause motor disturbances (Poulin and Pittman, 1991). Injections of hypertonic saline will likewise sensitize rats to the motor effects of icv vasopressin injections, presumably because hypertonic saline boosts septal vasopressin release (Demotes-Mainard et al., 1986; Landgraf et al., 1988). Once rats have been castrated, icv vasopressin injections still sensitize rats to the motor effects of subsequent vasopressin injections, but hypertonic saline does not, suggesting that castration has blocked septal vasopressin release (Poulin and Pittman, 1991).

Although the sex differences in, and hormonal effects upon, vasopressin-ir projections likely influence vasopressin release in rats, they do not change receptor density or sensitivity. Long-term castration does not affect vasopressin binding in rats (Tribollet et al., 1988), nor does it affect number and affinity of vasopressin receptors, vasopressin-stimulated phospho-inositol hydrolysis in septal tissue, or the ability of vasopressin to sensitize septal tissue to the motor effects of a subsequent vasopressin injection (Poulin and Pittman, 1991). This is unexpected, because changes in other peptide systems typically change receptor function (Catt et al., 1979). In BST and MeA projections, however, steroids appear to influence vasopressin function at the level of production and release rather than at the receptive site.

3.3.1.2 Estrogen Versus Androgen Effects Testosterone influences vasopressin production by androgen as well as by estrogen receptor-mediated mechanisms. In castrated male rats, estradiol—an estrogenic metabolite of testosterone (Naftolin et al., 1975)–partially restores vasopressin immunostaining in castrated male rats, while dihydrotestosterone--a non-aromatizable, androgenic metabolite of testosterone (Lieberburg and McEwen, 1975)–cannot by itself restore vasopressin immunostaining. However, in combination with estradiol, dihydrotestosterone enhances vasopressin immunostaining (De Vries et al., 1986). These same steroids influence vasopressin mRNA production in much the same way (De Vries et al., 1994; Wang and De Vries, 1995). Estrogen receptors are also more important for vasopressin expression in mice, as deletions of the aromatase and estrogen receptor alpha in knockout strains of mice dramatically reduce vasopressin expression in this system (Plumari et al., 2002; Scordalakes and Rissman, 2004). Since virtually all vasopressin cells in the BST and MeA in rats are immunoreactive for estrogen as well as androgen receptors (Axelson and Van Leeuwen, 1990; Zhou et al., 1994), androgen and estrogen may influence vasopressin production by directly acting on vasopressin-ir cells.

Because there are no apparent androgen- and estrogen-responsive elements in the promoter region of the vasopressin gene (Young, 1992; Adan and Burbach, 1992), it is not clear whether androgens and estrogens influence the transcription of vasopressin messenger RNA by acting directly on the promoter. Experiments with luciferase reporter cell systems suggest that there is an estrogen response element about 4 kb upstream from the vasopressin gene, which may confer estrogen sensitivity to vasopressin gene expression in vivo (Shapiro et al., 2000). There is some doubt, however, whether steroids influence vasopressin mRNA transcription at all, since a nuclear run-on assay of BST tissue did not show any effect of castration on vasopressin gene transcription. Since the same study showed that castration decreased, while testosterone increased the length of the poly (A) tail of vasopressin mRNA–which may enhance its stability–, gonadal hormones may influence vasopressin mRNA levels at a posttranscriptional level (Carter and Murphy, 1993).

Androgens and estrogens may influence the vasopressin production indirectly, by influencing each other's effectiveness. Estrogens might, for example, increase the responsiveness of individual BST and MeA cells to dihydrotestosterone treatment by preventing the metabolic inactivation of dihydrotestosterone in the brain (cf. Södersten, 1980). Estrogens might also increase the effectiveness of androgen receptors of vasopressin-producing cells by altering the duration of androgen receptor occupation, as has been observed in the preoptic area of male rats (Roselli and Fasasi, 1992).

3.3.1.3 Role of Circulating Hormones Given the hormone responsiveness of BST and MeA projections, sex differences in circulating gonadal hormones can certainly contribute to differences in vasopressin expression. Although females have relatively high levels of estradiol, the level at which they activate androgen receptors is probably lower. In addition, their higher progesterone levels may further depress vasopressin expression because, in male rats, progesterone inhibits vasopressin expression (Auger and Vanzo, 2006). This may be a direct effect, because practically all vasopressin neurons in the BST and MeA express progesterone receptor (Auger and De Vries, 2002). It is not known, however, whether progesterone has the same effects in females as it does in males.

Sex differences in gonadal hormone levels cannot explain all sex differences in vasopressin cells and projections that are observed in intact animals (De Vries et al., 1981; Miller et al., 1989b). Gonadectomized male and female rats that are treated with similar levels of testosterone still show differences in cell number and density of the projections (De Vries and Al-Shamma, 1990; Wang et al., 1993; De Vries et al., 1994). Circulating hormones may, however, be the main factor in species such as prairie voles, where differences in vasopressin-ir fiber density (Bamshad et al., 1993) or vasopressin mRNA expression (Wang et al., 1994a) are extreme. These differences are still impressive, but much smaller if adult male and female voles are treated with similar levels of testosterone (Lonstein et al., 2005).

Differences in testosterone metabolism can contribute to such residual sex differences in testosterone-treated rats because the male BST has higher levels of aromatase, the enzyme that catalyzes the aromatization of testosterone into estradiol, than does the female BST (Roselli, 1991). Testosterone may, therefore, stimulate BST cells more effectively in male than in female rats. However, a sex difference in aromatase levels cannot be the only factor, because there are still sex differences in vasopressin mRNA levels if rats are treated with a combination of estradiol and dihydrotestosterone (De Vries et al., 1994). In males, more BST cells produce vasopressin mRNA in response to estrogen stimulation. In addition, these cells show more labeling per cell, suggesting that in addition to a difference in the number of cells that express vasopressin, there are also sex differences in estrogen responsiveness of individual cells.

Even more so than differences in estrogen responsiveness, however, sex differences in androgen responsiveness contribute to sex differences in vasopressin-producing cells in the BST. Dihydrotestosterone, when given in combination with estradiol, significantly increased the number of vasopressin mRNA labeled cells in males but not in females (De Vries et al., 1994).

Since it is not known at which level androgens and estrogens act on vasopressin synthesis, it is not yet clear which factor contributes to sex differences in androgen and estrogen responsiveness of vasopressin cells. One factor may be steroid receptors levels of individual cells. Although no sex differences have been found in estrogen receptors (Brown et al., 1992), the number of androgen receptors associated with the cell nuclear fraction is higher in the BST of males than of females (Roselli, 1991). Such a sex difference might

explain why dihydrotestosterone increases the number of vasopressin mRNA labeled cells in males but not in females.

3.3.2 Organizational Effects

Research on sexual differentiation of these projections in mammals has been done predominantly in rats and mice. When we first tested whether gonadal hormones influence sexual differentiation of vasopressin-ir projections (De Vries et al., 1983), we did not know yet that gonadal hormones influenced vasopressin expression in adulthood. We manipulated rats hormonally in the first three weeks after birth and measured vasopressin innervation at postnatal day 28, at which age the sex difference in vasopressin innervation was extreme, with females showing virtually no vasopressin innervation and males dense fiber networks in the lateral septum (De Vries et al., 1981). We found that gonadal hormones influenced these projections in the first as well as in the third postnatal week (De Vries et al., 1983), much later than what could be expected based on the critical periods within which gonadal hormones influence the development of other sexually dimorphic systems (Gorski 1984; Yahr, 1988; Forger, 2001). In retrospect, that study did not answer whether perinatal levels of gonadal hormones influence sexual differentiation of vasopressin-ir projections, because subjects were put to death within four weeks after hormonal manipulation, which is considerably sooner than what is needed for vasopressin to disappear from the fibers after gonadectomy (De Vries et al., 1984). We readdressed the same question by comparing the effects of neonatal manipulations on vasopressin expression in three-month-old rats all of which had been treated with testosterone for four weeks before they were put to death. We first showed that male rats that were castrated as adults had more vasopressin-ir cells in the BST and a higher density of vasopressin-ir fibers in the lateral septum than did neonatally castrated male rats. The latter had cell numbers and fiber densities equivalent to those of female rats, whether ovariectomized at birth or as adults. This suggested that testicular secretions after birth masculinize vasopressin-ir projections of the BST. A second experiment showed that males castrated at birth or at postnatal day 7 had fewer vasopressin-ir cells in the BST and MeA and a lower vasopressin-ir fiber density in the lateral septum than did male rats castrated at postnatal day 21 or as adults, suggesting that testicular secretions masculinize vasopressin-ir projections around day 7. Treatment of neonatally gonadectomized male and female rats with testosterone propionate at postnatal day 7 confirmed this, because it increased vasopressin-ir fiber density in the lateral septum. It also fully restored the number of vasopressin-ir cells in the BST of neonatally castrated males but not of females (Wang et al., 1993). This discrepancy may be due to prenatal differences in gonadal hormones. Another possibility is that sex chromosomal complement (XX vs XY) makes a difference independently of gonadal hormone levels (see section 12.6.3).

3.4 Development of Cellular Phenotype

3.4.1 Ontogeny

To understand the mechanisms by which steroids influence the development of vasopressin expression, one would like to study the early development of these cells. This is made difficult by the late onset of vasopressin expression in the BST and MeA. In males, vasopressin mRNA becomes first detectable at postnatal days three and five, and in females at postnatal days 21 and 35, respectively (Szot and Dorsa, 1993). This makes it nearly impossible to recognize future vasopressin cells during the period that gonadal steroids influence their sexual differentiation. There may be indirect ways to distinguish vasopressin cells from surrounding cells in the BST. Using the thymidine analog bromo-2-deoxy-5-uridine (BrdU) as a birth marker, we determined that most vasopressin-ir cells are born on embryonic day 12 and 13 (counting the day that sperm plugs were found as embryonic day 1), which places them in the earliest cohort of cells that survive to form the adult forebrain (Al-Shamma and De Vries, 1996). This was a surprise, because most cells in the BST and MeA are born on embryonic days 14–16 (Bayer, 1980; Bayer, 1987). This difference in cell birth may be exploited to study the sexual differentiation of the vasopressin-ir cells by following the

development of cells labeled by BrdU injections on embryonic days 12 and 13. Alternatively, future vasopressin cells may be labeled by staining them for peptides that are co-expressed such as galanin (see below).

3.4.2 Differentiation of Cellular Phenotype

Although differences in the level of vasopressin mRNA expression per cell may contribute to the differences in the density of vasopressin projections, differences in number of vasopressin cells are probably the main factor. In theory, two fundamentally different types of processes could cause a difference in vasopressin cell number: first, processes that determine absolute cell number, such as cell birth, cell death, or cell migration, and second, processes that influence the phenotype of existing cells. The early birth of vasopressin cells eliminates differential cell birth and migration as likely factors, because the cells are born at least a week before hormones trigger their sexual differentiation (Wang et al., 1993; Al-Shamma and De Vries, 1996). Differential cell death can probably also be ruled out. Recently, we compared wild-type mice and mice with a null mutation in the gene coding for the cell death factor, Bax. This mutation blocks most neuronal cell death and eliminates sex differences in cell number of several brain areas (Forger et al., 2004). This mutation increased the number of vasopressin cells in males as well as females, but kept the sex difference intact (De Vries et al., unpublished). This suggests that developmentally programmed cell death determines the final number of potential vasopressin cells in males and females but not the differences between them.

All evidence points at testosterone stimulating an already existing group of cells to express vasopressin. After discovering that practically all vasopressin cells in the BST co-express galanin, but not all galanin cells vasopressin, and that males have more vasopressin cells than do females but similar numbers of galanin cells, Planas et al. (1995) proposed that differences in vasopressin expression depend on the percentage of galanin cells that co-express vasopressin. During development, higher levels of testosterone may stimulate more galanin neurons to co-express vasopressin. In support of this idea, vasopressin and galanin neurons in the BST and MeA show the same unusual birth profile with both days of birth earlier than most surrounding cells (Han and De Vries, 1999). As in mice, BST cells produce galanin well before birth (Tobet et al., 1999), galanin may be a good marker for the cells in which sexual differentiation of vasopressin production takes place.

It is currently unknown whether gonadal steroids target BST and MeA cells directly or act via other cells to differentiate vasopressin expression. Androgen- and estrogen receptors appear to be involved, as estradiol and dihydrotestosterone can masculinize vasopressin expression (Han and De Vries, 2003). Although vasopressin cells in the areas express estrogen receptor alpha, androgen, and progesterone receptors in adult rats (Axelson and Van Leeuwen, 1992; Zhou et al., 1994; Auger and De Vries, 2002), it is unknown whether the same cells do this during sexual differentiation. It is unknown, however, whether vasopressin cells also express gonadal steroid receptors during sexual differentiation.

4 Comparative Aspects

The sex difference in, and hormone responsiveness of, vasopressin innervation are conserved features. These features have been found in various rodent species, i.e., European (Buijs et al., 1986) and Djungarian hamsters (Bittman et al., 1991), Mongolian gerbils (Crenshaw et al., 1992), prairie and meadow voles (Bamshad et al., 1993), mice (Mayes et al., 1988), and in other mammalian species, e.g., ferrets (De Vries and Baum, unpublished). Similar dimorphism and hormonal responsiveness are present in homologous vasotocin-immunoreactive projections in nonmammalian vertebrates, i.e., in amphibians: rough-skinned newts (Moore, 1992) and bullfrogs (Boyd et al., 1992); in reptiles: the lizards *Gekko gecko* (Stoll and Voorn, 1985) and *anolis carolinensis* (Propper et al., 1992), the turtle *Pseudemys scripta elegans* and the snake *Python regius* (Smeets et al., 1990); and in birds: Japanese quails (Viglietti-Panzica et al., 1992), and canaries (Voorhuis et al., 1988). More complete listings can be found in Goodson and Bass (2001) and De Vries and Panzica (2006). Not all species with homologous vasotocin-immunoreactive or vasopressin-immunoreactive

projections show conspicuous sex differences, for example, rainbow trouts (Van den Dungen et al., 1982), the amphibians *Rana ridibunda, Xenopus-laevis, and Pleurodeles waltii* (Gonzales and Smeets, 1992a, b), and guinea pigs (Dubois-Dauphin et al., 1989). Since differences were not quantified, it is not known whether sex differences are non-existent or just subtle in these species. The BST of humans and the BST and MeA of macaques have vasopressin-ir cells, and although neither species have shown significant innervation of the lateral septum, other areas that receive hormone-responsive vasopressin innervation in rats (i.e., the ventral tegmental area and midbrain central gray of macaques, and the locus coeruleus of humans and macaques) did show such projections, although without notable sex differences (Fliers et al., 1986; Caffe et al., 1989). It is not known whether vasopressin projections in these species are steroid responsiveness either. However, the marmoset, another primate, has more vasopressin-ir cells in the BST of males than of females (Wang et al., 1997). Finally, Syrian hamsters stand apart in that no trace of vasopressin projections of the BST and MeA can be found (Dubois-Dauphin et al., 1990; Albers et al., 1991; Ferris et al., 1995; Miller et al., 1999). Curiously, the lateral septum of Syrian hamster has vasopressin binding sites (Ferris et al., 1993) and is sensitive to the behavioral effects of vasopressin (Irvin et al., 1990). These variations in vasopressin/vasotocin projections may be exploited to reveal the processes underlying their sexual differentiation and identify their function (see e.g., Goodson and Bass, 2001).

5 Function of Sex Differences in Vasopressin Expression

5.1 Function of Vasopressin Innervation in the Brain

The widespread occurrence of sex differences in vasopressin and vasotocin projections suggests that these differences serve a function important enough to conserve it through evolution. Identifying this function is intimately connected to determining the role of vasopressin and vasotocin in the brain. This review will focus mainly on vasopressin. For excellent reviews on vasotocin, see, for example, Goodson and Bass, 2001; Panzica et al., 2001; Rose and Moore, 2002.

Revealing what functions the sexually dimorphic vasopressin projections of the BST and MeA may serve, is helped by vasopressin being one of the first peptides found to influence behavior and, in fact, among the first to be called a neuropeptide (De Wied, 1969). A great many studies address vasopressin effects on centrally regulated functions and behaviors, such as learning and memory (De Wied, 1969), cardiovascular functions (Versteeg et al., 1983), thermoregulation (Kasting, 1989), and motor behaviors (Kasting et al., 1980). Many of these studies involved injecting vasopressin or its analogs into the ventricles or into areas that do not necessarily receive vasopressin-ir input. Since there are several different vasopressin systems (De Vries and Miller, 1998), the results of such studies cannot always be related to any specific vasopressin system. More recent studies, done with the anatomy of the central vasopressin pathways in mind, have indicated a number of functions in which specifically BST and MA projections may be involved. For example, the vasopressin innervation of the septal area has been implicated in thermoregulation, osmoregulation, social recognition memory, motor disturbances, and aggressive behavior (see below). Competition studies using nonradioactive vasopressin analogs (Dorsa et al., 1988), electrophysiological studies (Raggenbass et al., 1987), in situ hybridization studies (Ostrowski et al., 1992), and functional studies (see below) indicate that vasopressin receptors in this area resemble vasopressor receptors (V_{1A} receptors), and not the antidiuretic receptor (the V_2 receptor) or the vasopressin-oxytocin receptor which is found in the hippocampus (Audigier and Barberis, 1985). Given the sexually dimorphic nature and extreme hormone responsiveness of vasopressin projections, one is tempted to conclude that this system is involved in sexually dimorphic functions or at least in functions that are influenced by gonadal steroids, such as reproductive behaviors and the regulation of gonadal hormone release. Lesion studies have indeed implicated the BST and MeA in male sexual behavior, the regulation of gonadal hormone release, and the control of parental behavior (Harris and Sachs, 1975; Emery and Sachs, 1976; Beltramino and Taleisnik, 1978, 1980, 1985; Valcourt and Sachs, 1979; Fleming et al., 1980; Numan and Numan, 1996), but it is unknown specifically which BST and MeA projections contribute to these functions. In fact, research of the past fifteen years suggests that the sex differences and hormone responsiveness of vasopressin projections

are somewhat of a red herring. Some of these reproductive functions are discussed first, followed by functions that have been directly related to vasopressin projections of the BST. This is done against the backdrop of sex differences in vasopressin projections.

5.1.1 Sexually Dimorphic Behaviors

5.1.1.1 Female sexual behavior Vasopressin projections of the BST and MeA may control female sexual behavior. Lesion and stimulation studies suggest that areas innervated by these projections influence female sexual behavior. The lateral septum, for example, has an inhibitory influence on the lordosis response (Nance et al., 1974; Zasorin et al., 1975). Its vasopressin innervation may play a role in this, because intraventricular injections of vasopressin stimulate female sexual behavior whereas similar injections of vasopressin antagonist inhibit it (Södersten et al., 1985). Similar effects have recently been obtained by Pedersen and Boccia (2006). Intraventricular injections, however, may interact with any vasopressin system in the brain. In fact, circadian fluctuations in the effects of these injections and of vasopressin levels in the brain made us suggest that suprachiasmatic, and not BST and MeA, projections formed the substrate for vasopressin's effects on female sexual behavior (Södersten et al., 1985). A direct link between the vasopressin innervation of the lateral septum and female sexual behavior has never been tested. Nevertheless, if septal vasopressin inhibits female sexual behavior, then the higher levels of vasopressin in males versus females correlate well with males being far less likely to show female sexual behavior than are females.

5.1.1.2 Male sexual behavior Remarkable similarities in hormone effects on vasopressin expression and behavior in rats make it particularly tempting to associate the vasopressin projections of the BST and MeA with male sexual behavior. Castration causes an equally gradual decline in male sexual behavior as it does in vasopressin content of the BST and MeA projections (Davidson, 1966; De Vries et al., 1984). Similarly, testosterone metabolites stimulate male sexual behavior the same way as vasopressin expression, with estradiol being much more effective than 5α-dihydrotestosterone (Baum and Vreeburg, 1973; Larsson et al., 1973; De Vries et al., 1986; De Vries et al., 1994; Wang and De Vries, 1995). Although injections of vasopressin directly into the lateral septum do not affect male sexual behavior (Koolhaas et al., 1991), the effects of vasopressin or its antagonists on male sexual behavior in other areas that receive input from the BST and MeA have not been studied. However, treating rats with a centrally acting vasopressin analogue reversed the decline of male sexual behavior following castration (Bohus, 1977), which supports the idea that central vasopressin pathways stimulate male sexual behavior. Comparative research suggests, however, that vasopressin's role may be more complicated because intracerebroventricular injections of vasotocin into Japanese quail, which show similar sex differences in vasotocin innervation as do rats in vasopressin innervation, inhibit certain aspects of male sexual behavior (Castagna et al., 1998; Panzica et al., 2002). One could argue that if vasopressin projections are an integral part of the circuitry that controls male sexual behavior, whether in an activating or inhibitory role, it still makes sense that males have a denser innervation than do females. This idea, however, seems less compelling than the one proposed earlier for a role of the sex difference in vasopressin innervation in female sexual behavior. However, at the very least, it suggests that correlations should be treated with caution if one wants to link sex differences in brain structure with sex differences in brain function.

5.1.1.3 Aggressive Behavior Septal vasopressin has also been implicated in other sexually dimorphic behaviors that are influenced by gonadal steroids, for example, intermale aggression. Just as the vasopressin content of the BST and MeA projections, intermale aggression declines gradually after castration (DeBold and Miczek, 1984). Furthermore, injections of vasopressin into the lateral septum or the MeA reverse this decline (Koolhaas et al., 1990, 1991). In fact, in all vertebrate classes, vasopressin and its non-mammalian homologue, vasotocin, have been linked to aggressive behavior and related behaviors, such as social dominance (Ferris et al., 1986; Ferris and Potegal, 1988; Winslow et al., 1993; Marler et al., 1995; Delville et al., 1996; Chu et al., 1998; Goodson, 1998a, b; Semsar et al., 1998, 2001; Goodson and Adkins-Regan, 1999; Bester-Meredith and Marler, 2001; Tito et al., 1999; Lema and Nevitt, 2004; Thompson

et al., 2004; Goodson et al., 2004b; Maney et al., 2005), including in humans (Coccaro et al., 1998; Thompson et al., 2004). As with female sexual behavior, the higher levels of vasopressin/vasotocin in males correlate well with the higher levels of resident-intruder aggression displayed by males versus females. Interestingly, in hyenas, in which females are more aggressive and dominant over males (Matthews, 1939; Hamilton, 1986), males have either the same or a lower vasopressin fiber density in the septum and other BST and MeA projection sites (Rosen et al., 2001). And perhaps it is no coincidence either that in Syrian hamsters, which as mentioned earlier lack the vasopressin projections of the BST and MeA entirely; females are as aggressive as males and tend to dominate males of similar body weight (Payne and Swanson, 1970; Marques and Valenstein 1977; Huhman et al., 2003; Taravosh-Lahn and Delville, 2004).

5.1.2 Nondimorphic Functions

5.1.2.1 Social Behaviors Unlike sexual and aggressive behavior, several other functions are influenced by septal vasopressin for which there is no clear relationship with the sex differences in vasopressin innervation (De Vries, 1988). For example, in male rats, social recognition memory can be boosted or inhibited by injections of vasopressin or a V_{1A} antagonist, respectively, into the lateral septum (Dantzer et al., 1988). In females, which do not differ from males in social recognition memory, injections of a V_{1A} antagonist do not inhibit social recognition memory (Bluthe and Dantzer, 1990). In this case, one cannot correlate the sex difference in vasopressin innervation with a functional sex difference. Rather, these data suggest that the neurochemical underpinnings of social recognition memory differ between the sexes.

5.1.2.2 Homeostatic Functions When we first discovered the sex difference in vasopressin projections, septal vasopressin had only been linked to functions that did not differ dramatically between sexes, for example, fever control (Cooper et al., 1979). In fact, this is a very well established function for vasopressin because the fever-reducing effects of vasopressin and fever-enhancing effects of $V1_a$ receptor antagonists injected specifically into the ventral septal area have been demonstrated repeatedly for a variety of mammals (Kasting, 1989). Although the source of vasopressin innervation in the ventral septal area has not been traced directly, it almost certainly comes from the BST. This innervation disappears after lesioning the BST but not after lesioning other sites that produce vasopressin (De Vries and Buijs, 1983). It is also denser in males than in females (De Vries and Al-Shamma, 1990) and loses its vasopressin content after castration (De Vries et al., 1985). In addition, electrical stimulation of the BST influences electrical activity of ventral septal neurons similarly as does exogenous application of vasopressin (Disturnal et al., 1985a, b). Finally, electrical stimulation of the BST reduces pyrogen-induced fever, presumably by enhancing vasopressin release because V_{1A} receptor antagonist injected into the ventral septal area can block this effect (Naylor et al., 1988).

The steroid-responsiveness of the vasopressin innervation of the ventral septal area has been exploited to demonstrate that endogenous vasopressin release reduces fever. Castration, which presumably reduces vasopressin release in the lateral septum, lengthens pyrogen-induced fever (Pittman et al., 1988). Another study considered how castration affected the ability of interleukin-1 to induce not only fever but also "sickness behavior" (increased sleepiness, lethargy, reduced social activities, reduced food intake), and showed that vasopressin treatment can reverse this castration effect. Taking social investigation of juvenile conspecifics as an index of sickness behavior, these studies showed that castrated rats were more sensitive to the fever-inducing and behavioral effects of interleukin-1. In addition, vasopressin more effectively attenuated the effects of interleukin 1 in castrated- than in intact rats and, conversely, the V_{1A} receptor antagonist potentiated the effects of interleukin 1 in intact- but not in castrated rats (Dantzer et al., 1991; Bluthe and Dantzer, 1992).

In European hamsters, which unlike Syrian hamsters show vasopressin projections from the BST (Buijs et al., 1986), vasopressin release in the lateral septum may prevent hypothermia. In this species, the density of the vasopressin-ir fiber plexus in the lateral septum is high during the summer, when testosterone levels are high, and low during fall and winter, when testosterone levels are low and the animals hibernate (Buijs et al., 1986). Chronic infusions of vasopressin into the lateral septum prevented the bouts of hypothermia

that are associated with hibernation (Hermes et al., 1989). In addition, silastic implants with testosterone given at the beginning of the hibernation season kept the density of vasopressin-ir innervation of the lateral septum high and prevented hibernation, possibly by sustaining the release of vasopressin in the lateral septum. Together, these studies show a good correlation between levels of vasopressin expression and temperature regulation that may be related to levels of circulating gonadal hormones. Sex differences in vasopressin expression and temperature regulation do not show such a correlation.

6 Sex Differences in the Neurochemical Underpinnings of Functions

When we realized after finding the sex difference in vasopressin innervation that vasopressin had only been implicated in functions that do not differ clearly by sex, we suggested that there may be compensatory mechanisms, such as sex differences in other transmitter systems, that may keep such functions similar (De Vries et al., 1981). I soon forgot our own suggestion and, when reviewing sex differences in neurotransmitter systems, I mainly linked differences in neurotransmitter systems to differences in overt functions and behaviors (see for example, De Vries, 1984, 1990). Our work on voles forced me to revisit the idea that sex differences in neurotransmitter systems may just as well be linked to behaviors that do not differ ostensibly by sex.

Such differences may be adaptive if sex differences in circulating gonadal hormones would otherwise cause undesirable sex differences in overt physiology or behavior. For example, the wide-spread distribution of gonadal steroid receptors in multimodal areas such as the lateral septum and the CA1 region of the hippocampus, which are involved in many functions that are not, or only marginally, sexually dimorphic, may require compensatory sex differences to keep such functions similar. Because these areas are constantly exposed to circulating gonadal steroids levels that differ by sex, their level of activation may differ as well. Although differences in activation may be expected for sexually dimorphic functions controlled by such areas, they are more difficult to explain for functions that do not show clear sex differences. For example, practically every neuron in the lateral septum expresses androgen receptors (Sar and Stumpf, 1975; Simerly et al., 1990; Zhou and De Vries, 1994). The higher levels of circulating androgen in males versus females may therefore cause chronic differences in androgen receptor activation in practically every lateral septal neuron. Such a difference might make sense for the inhibitory actions of the septum on female sexual behavior (Nance et al., 1974; Zasorin et al., 1975; De Vries, 1990), but is more difficult to understand for functions that are not or only marginally sexually dimorphic, such as thermoregulation. Perhaps additional sex differences such as the denser innervation of vasopressin in males compensate for differential androgenic effects, thereby preventing undesirable sex differences in some functions, while generating them in others.

6.1 Parental Behavior

Sex differences in neurochemistry may also compensate for changes in gonadal hormones that occur in one sex, but not in the other. Parental behavior in species where males and females provide parental care, such as prairie voles (Lonstein and De Vries, 1999a), may serve as an example. In rodents, hormonal changes associated with pregnancy increase parental responsiveness so that once pups are born females are fully maternal (Rosenblatt et al., 1988; Bridges, 1990). In voles, the stakes are even higher as females also have to undergo parturition before they are fully parental. Females whose pups were delivered by Caesarian section do not show increased parental responsiveness (Hayes et al., 2005). In males, paternal behavior must clearly be induced through different mechanisms. This may imply that neural circuits involved in parental behavior must differ to guarantee a similar behavioral output between males and females.

The sexually dimorphic vasopressin innervation may play such a role in prairie voles. In this species, sexually naive males are commonly spontaneously parental, whereas sexually naive females are not (Lonstein and De Vries, 1999b). In males, mating activated vasopressin mRNA production in BST and MeA cells (Wang et al., 1994a), while decreasing vasopressin content of BST and MeA projections to the lateral septum

(Bamshad et al., 1994). These changes suggest that mating increases vasopressin release in the lateral septum. Recently, Lim and Young (2004) provided additional evidence for mating-induced increase of vasopressin from BST projections in males, by showing that boosting V_{1A} receptor expression increases mating-induced Fos expression in the ventral pallidum, another target of BST projections. The changes in vasopressin neurotransmission in males may very well explain the increase in paternal responsiveness seen in males after mating (Bamshad et al., 1994), because vasopressin injections into the lateral septum stimulated paternal responsiveness in virgin voles, whereas injections of a V_{1A} receptor antagonist inhibited it (Wang et al., 1994b). Vasopressin does not appear to play a role of significance in females, because vasopressin expression is nearly absent in the BST and does not change after mating (Bamshad et al., 1993; Wang et al., 1994a). In this case, the sex difference in vasopressin innervation may allow fathers to show similar responses to pups as do mothers.

Interestingly, this does not necessarily mean that vasopressin is essential for paternal behavior under all hormonal conditions. Castration, which eliminates vasopressin expression in BST and MeA projections in voles as it does in rats (Wang and De Vries, 1993), does not eliminate parental behavior in males (Lonstein and De Vries, 1999b). The same is true for social recognition memory, which does not change dramatically after long-term castration but can no longer be blocked by vasopressin antagonists (Bluthe et al., 1990). This suggests that the neurochemical underpinnings of some behaviors may vary between different hormonal states the same way as they do between males and females.

6.2 Pairbonding

Mating-induced changes in vasopressin release may affect other social behaviors in voles as well (Young and Wang, 2004). Following mating, prairie voles form stable pairbonds and display increased aggression towards unfamiliar conspecifics and increased paternal responsiveness (Getz et al., 1981). In males, these changes could be blocked by intracerebroventricular injections of a V_{1A} antagonist (Winslow et al., 1993) suggesting that endogenous vasopressin release drives these changes. Interestingly, pairbonding may also be regulated differently in males and females. Whereas intracerebroventricular injections of vasopressin stimulate pairbonding, oxytocin injections do not. In female prairie voles, however, the reverse is true (Insel and Hulihan, 1995). In addition, adrenalectomy prevents pairbonding in males, but facilitates it in females; in both cases corticosteroid injections counter the effects of adrenalectomy (DeVries et al., 1996). These sex-dependent neuropeptide and corticosteroid effects may very well reflect differences in the neurochemical underpinnings of pairbonding in voles.

Between the extreme possibilities of functions that do not differ by sex, but the underlying neurochemistry does (such as parental behavior in voles), or functions that are sexually dimorphic thanks to sex differences in underlying neurochemistry (such as aggressive behavior), there are probably many intermediate situations. For example, fear and anxiety-related behaviors, which vary by sex, but not extremely so (Palanza, 2002; Toufexis et al., 2006), show dramatic differences in the extent to which they are controlled by vasopressin. For example, male vasopressin V_{1A} receptor knockout mice show a reduction in anxiety-like behavior (Bielsky et al., 2004), but their female counterparts are unaffected (Bielsky et al., 2005), presumably because a loss of V_{1A} receptors has less of an impact in animals that had little vasopressin to begin with, but perhaps also because the neural circuitry underlying anxiety-like behaviors differs in males and females.

6.3 Sex Differences as Compensation for Sex Chromosomal Effects

A relatively new idea is that sex chromosomal complement (XX versus XY) directly affects sex differences in the brain (Arnold, 1996, 2004). Such direct effects of sex chromosomal complement can be detected with a model system that can distinguish between differences caused by sex chromosomal complement (XX vs. XY) or different gonads (testes vs. ovaries) (De Vries et al., 2002). In this model, female mice with an XX genotype were crossed with males with an XY^- Sry genotype. These XY^- *Sry* mice lack the Sry gene on the

Y chromosome, which normally directs the growth of the testis (Koopman et al., 1991). Nevertheless, they develop a male phenotype, because they have an *Sry* transgene inserted on an autosomal chromosome. This cross generates XX and XY^- mice of either sex depending on whether they inherited the *Sry* transgene. Comparing XX and XY^- mice within sex (defined on basis of type gonad) revealed a number of differences that may be caused directly by differences in sex chromosomal complement, including differences in vasopressin innervation of the lateral septum, which was denser in XY^- than in XX animals irrespective of gonadal sex (De Vries et al., 2002; Gatewood et al., 2006). As these mice still showed respectable differences between gonadal males and females irrespective of sex chromosomal complement, hormones as well as sex chromosomal complement appear to control sexual differentiation of vasopressin expression in mice. Interestingly, females, but not males, showed an effect of sex chromosomes on parental and aggressive behavior (Gatewood et al., 2006), both of which are modulated by vasopressin (see Sections 12.5.1.1.3 and 12.6.1).

If sex chromosomal complement, like sex steroids, can induce sex differences in neural structure, there is no reason why such differences may also cause as well as prevent sex differences in behavior. Although the idea that sex differences at the molecular and cellular level, whether caused by sex chromosomal complement or hormones, may generate as well as prevent sex differences in behavior may sound unorthodox, similar ideas are well accepted in other fields of biology. In fact, sex differences in mechanisms underlying any physiological or behavioral endpoint may be the norm, not the exception. This is definitely the case at the chromosomal level. In mammals, every cell treats X chromosomes differently, depending on whether it is found in a male or female body. In females, cells show random X inactivation, the silencing of most genes on one of the two X chromosomes; in males, cells do not (Lyon, 1999). This X inactivation is generally seen as a compensatory mechanism, meant to ensure that X chromosomal genes, many of which serve basic household functions, are expressed at roughly the same rate in males and females (Lyon, 1999). The energy spent on inactivating one of the two X chromosomes is, presumably, a cost of the evolution of two sexes (Charlesworth, 1996). Clearly, differential expression of sex chromosomal genes is essential for generating a male and female genotype. But for all we know, much of this expression is restricted to only a few tissues at rather restricted periods of our life. In mice, for example, expression of the Sry gene is needed for only half a day (embryonic day 11–11.5), in only one cell-type (cells that will become Sertoli cells), to set in motion a cascade of events that generates the male phenotype (Burgoyne et al., 1988; Lovell-Badge et al., 1995). X inactivation, however, has to take place in practically all cells of the female body, throughout life, in any tissue, sexually dimorphic or not (Lyon, 1999). Similar compensatory processes, meant to counter undesired side effects of sexual differentiation, may take place repeatedly, in developing as well as in adult animals, from the molecular to the macroscopic level.

6.4 Sex Difference in Other Neurotransmitter Systems

6.4.1 Cholecystokinin

Brains may be exactly the place to look for such compensatory processes, in particular because like sex chromosomes, neural circuits often serve more than one function, some dimorphic, others not. Generating a sex difference in any such circuit, for example, to generate reproductive behavior is therefore likely to cause sex differences in other functions served by the same circuits. If such sex differences are maladaptive, evolution will favor the development of compensatory mechanisms. It is, therefore, unlikely that the sexually dimorphic vasopressin innervation of the brain would be the only system that may cause sex differences in some functions but prevent them in others. Cholecystokinin neurotransmission may provide another example. Cholecystokinin binding in the ventromedial hypothalamic nucleus is higher in males than in females (Micevych and Ulibarri, 1992), which fits with a potential role of cholecystokinin in female sexual behavior (Micevych and Sinchak, this volume). However, cholecystokinin has also been implicated in food intake, which does not show nearly as dramatic a sex difference as does female sexual behavior (Willis et al., 1986; Schick et al., 1994). The challenge is to understand how sexually dimorphic systems such

as the cholecystokinin system can be involved in diverse functions–some sexually dimorphic, others not, and how such sexually dimorphic systems can prevent sex differences in some functions, whereas causing them in others. Solving this problem will require a much better understanding of the various components that contribute to the control of specific functions. How daunting such a task is, is illustrated in the chapter, in this volume, by Micevych and Sinchak, who review the various transmitter systems that have been implicated in female sexual behavior.

6.4.2 Sry and Dopamine

Dopamine cells in the substantia nigra offer another interesting example. Male mice have about 10% to 20% more dopamine cells in their substantia nigra than do females (Dewing et al., 2006). Although sex differences in dopamine neurotransmission in the striatum have been linked to sex differences in certain motor behaviors (Becker, 1999), it is not clear whether this particular sex difference contributes to those differences. Behind this relatively moderate sex difference, however, hides a rather impressive sex difference in how sex chromosomal genes affect these cells. In males, mesencephalic dopamine cells express the *Sry* gene (Dewing et al., 2006). Treating males with *Sry* antisense oligonucleotides blocks the production of *Sry* protein as well as lowers tyrosine hydroxylase levels, the rate-limiting enzyme in the production of dopamine, and causes motor defects. In females, the same treatment has no effect. This suggests that *Sry* is necessary to normalize the motor function. Therefore, this may be an example where a difference in sex chromosomal gene expression compensates for a sex difference in this system, possibly caused by differential exposure to gonadal hormones (Dewing et al., 2006).

6.4.3 Sex Chromosomal Factors Other than Sry and Dopamine

Sry may not be the only sex chromosomal gene that acts on dopamine cells. Cultures of mesencephalic cells harvested on embryonic day 14 differ in the number of cells that will express tyrosine hydroxylase (TH) depending on the sex of origin (Reisert and Pilgrim, 1991; Sibug et al., 1996). As these cells were harvested after the onset of gonadal differentiation including the development of the testosterone-producing fetal Leydig cells (Haider, 2004), one cannot exclude hormones as a factor. However, by using the same cross of XX with XY^- *Sry* mice described earlier, Carruth et al. (2002) showed that sex chromosomal complement rather than previous exposure to gonadal hormones determines the level of TH expression in vitro. Cultures from XY^- mice developed more TH neurons than did XX cultures regardless of the sex of origin. As *Sry* gene expression was similar between XX and XY^- mice (either absent in gonadal females or present in gonadal males), these differences must be caused by other factors, for example, expression of Y chromosomal genes other than *Sry,* dosage differences of X chromosomal genes, or differential imprinting of maternal and paternal X chromosomes (Arnold, 2004).

Interestingly, mesencephalic cells do not show a sex difference during development in vivo (Lieb et al., 1996). One possible explanation is that, in vivo, the internal milieu prevents XX and XY specific gene expression from inducing sex differences in mesencephalic cells in vivo. A much more provocative idea is that XX and XY specific gene expression occurs in vivo, perhaps to compensate for effects of factors derived from other brain regions that would have caused undesirable sexual differentiation if left unchecked. Ideas like these are perfectly testable. For example, one could identify the elements on X and Y chromosomes that cause the differences in TH expression in vitro. Equating the influence of these elements in XX and XY animals should eliminate the difference in vitro and induce a difference in vivo. In fact, such experiments have been done, not necessarily with testing this idea in mind. For example, Bluthe and Dantzer's (1990) demonstration that vasopressin V1a receptor antagonists blocked social recognition memory in males, but not in females, could be regarded as a test of the idea that the sexually dimorphic vasopressin innervation keeps social recognition memory similar. This manipulation caused a sex difference, where there was not

one before. In fact, sexually dimorphic involvement of neurotransmitter systems in functions that are similar between sexes may be suspected in all cases where drug manipulations causes sex differences that were not present in untreated animals (Villalba et al., 1997).

7 Sex Differences in Human Brains

Like animal brains, the human brain is sexually dimorphic. There are, for example, volume differences in several brain structures, including the anterior commissure, the left planum temporale, and several nuclei in the hypothalamus and BST (Swaab and Fliers, 1985; Allen et al., 1989, 1991; Allen and Gorski, 1990, 1991; Hofman and Swaab, 1991; Zhou et al., 1995; Wisniewski, 1998). In addition, several neurotransmitters differ in levels, metabolism, or distribution; for example, serotonin (Arato et al., 1991; Biver et al., 1996; Nishizawa et al., 1997), dopamine (Pohjalainen et al., 1998; Kaasinen et al., 2001), vasoactive intestinal polypeptide, and somatostatin (Zhou et al., 1995; Kruiver et al., 2000; Chung et al., 2002). Although sex differences in human brains are often associated with differences in behavior (for example, cortical difference with differences in cognitive abilities and hypothalamic differences with differences in sexual behavior and sexual orientation), these sex differences may also normalize behavior in men and women.

In fact, the human literature provides ample evidence that male and female brains may use different strategies and, therefore, different neural systems to perform the same tasks. For example, strokes can have different outcomes in men and women, even if they occur in the same regions (Inglis et al., 1982; Kimura et al., 1985; Hier et al., 1994; Roof and Hall, 2000), and functional imaging studies suggest that men and women use telencephalic regions differently even for functions that do not differ by sex (Shaywitz et al., 1995; Jaeger et al., 1998; Derbyshire et al., 2002; Grabowski et al., 2003; Cahill et al., 2004; Piefke et al., 2005). Ironically, the prediction that the neurochemical underpinnings of nondimorphic behaviors may also differ in humans is tested each time, when medical practitioners prescribe psychoactive drugs in similar dosages to men and women to treat their behavioral disorders (Hrdina, 2000). Even though these disorders may present similar symptoms, many of the drugs used to treat them act on neurotransmitter systems that are sexually dimorphic, such as the central serotonin innervation (Arato et al., 1991; Biver et al., 1996; Nishizawa et al., 1997). For that reason alone, the effectiveness of these treatments may vary by sex. Unfortunately, few researchers take note of the results of these unintended experiments (Hrdina, 2000). Experiments designed to test the activity of psychotropic drugs on physiological parameters such as the activity of the hypothalamo-pituitary adrenal axis, however, show that drugs can have different effects in men and women (Rhodes and Rubin, 1999). This will be an even bigger issue in developing drug interventions geared to interact with systems, such as the central vasopressin innervation, that show in their central fuctions.

Abstract: Control of glucocorticoid secretion is essential for the health and survival of all vertebrate organisms. Hyper- and hypo-secretion of glucocorticoids are associated with disease processes, underlying the importance of maintaining normal daily glucocorticoid rhythms and generating appropriate glucocorticoid responses to stress. This chapter reviews the principle neurochemical mechanisms that operate in the CNS to regulate excitation and inhibition of the hypothalam-pituitary-adrenocortical (HPA) axis. Daily glucocorticoid secretion is controlled by monoamine and GABAergic circuitry, likely relayed through the suprachiasmatic nucleus. Glucocorticoids appear to play a role in circadian inhibition, exerted via the mineralocorticoid receptor. Neurochemical activation of the HPA axis is highly dependent on modality and intensity. Notably, brainstem norepinephrine/epinephrine neurons are selectively involved in HPA axis activation by systemic stressors. Activation of the HPA axis by psychogenic stressors is intensity-dependent, with peptidergic (vasopressin, Orphanin FQ) and glutamatergic systems playing a role in responses to mild, but not intense stressors. Responses to intense psychogenic stressors appear to involve serotonergic and peptidergic systems (e.g., brainstem glucagon-like peptide 1). Inhibition of the HPA axis is accomplished by GABAergic signals and glucocorticoid feedback, the latter of which is controlled by combined actions at glucocorticoid and mineralocorticoid receptors. The neurochemical systems underlying chronic stress-induced changes in HPA function remain to be elucidated. Overall, the data to date identify numerous candidate neurochemical systems capable of modulating HPA axis activity. Selective targeting of these systems may prove useful for treatment of HPA axis-related disease states.

1 Introduction

1.1 Hypothalamo–Pituitary–Adrenocortical Axis

The hypothalamo–pituitary–adrenocortical (HPA) axis is a key regulator of systemic homeostasis. Stimulation of this axis culminates in the secretion of glucocorticoid hormones, which act on multiple peripheral effectors as well as the brain to promote adaptation to adversity. In most contexts, the primary function of glucocorticoids is to redistribute energy resources. Contemporary theory holds that this redistribution process is involved in restoration or defense of homeostasis following challenge. For example, glycogenolytic effects of glucocorticoids promote mobilization of glucose in the wake of energy expenditure, whereas antiinflammatory actions of glucocorticoids are thought to "brake" ongoing immune responses (Munck et al., 1984).

However, it is important to emphasize that release of glucocorticoids also occurs in anticipation of adverse events. There are numerous environmental factors that will trigger glucocorticoid release in the absence of a frank physical stimulus. For example, rodents exhibit marked hormonal responses to open,

illuminated spaces (Emmert and Herman, 1999), presumably to reduce risk of predation, as well as to predator odors (Morrow et al., 2000), or the physical presence of predators (Figueiredo et al., 2003). Furthermore, there is ample evidence that secretion of glucocorticoids can be paired to previously innocuous stimuli, i.e., the organism can "learn" to produce a glucocorticoid response. The relevance of the anticipatory response is likely to be hinged on the predicted occurrence of energy expenditure; the process is in motion before the survival challenge (prolonged flight, fight, and injury) is encountered.

The characteristics of stimulus-induced glucocorticoid release are tightly linked to the concept of "stress." The definition of "stress" has been through numerous revisions since the original coining of the term by Selye (1956); within the context of our work, stress can be viewed as "a real or perceived threat to homeostasis." The response to stress takes many forms, of which glucocorticoid secretion is one. Notably, "stressors" typically engender a very rapid and short-lived sympathetic response and a rise in plasma norepinephrine (sympathetic nerves) and epinephrine (adrenal medulla), comprising the so-called 'sympathoadrenomedullary' response. In addition, stressors may invoke behavioral responses that may or may not occur in concert with physiological changes. Unlike the physiological responses, these behavioral responses are quite dependent on internally or externally perceived cues. Thus, the glucocorticoid response is one component of the integrated set of events responsible for adapting to "stress" – and should not be confused with being synonymous with the stress response.

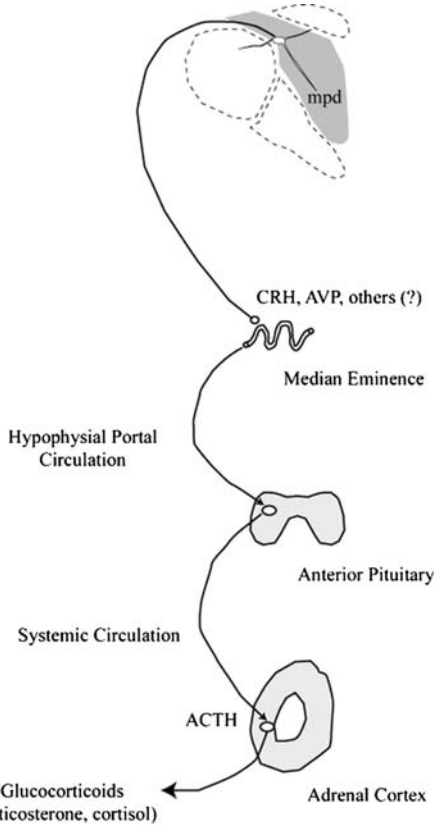
The multifaceted array of stimuli that provoke stress responses can be coalesced into generalized categories that have some construct validity. Stress responses initiated by the types of stimuli relying on physical perturbations (e.g., hypoglycemia, inflammation, blood loss, and pain) are direct "reactions" to these stimuli. These types of stimuli are currently categorized as "systemic," "interoceptive," or "physiological" stressors. Stress reactions initiated by innate or learned cues occur before a physical perturbation is present; i.e., they "anticipate" the physical stimulus. In these cases, the "stimuli" for the stress response are generated within the brain as a result of the interpretation of physically innocuous sensory information. This subtype of stressor has been categorized as "psychogenic," "neurogenic," "processive," "exteroceptive," or "emotional" stressors. The latter category of stressor triggers "innate" response patterns, programmed into the brain over the course of evolution, and/or "learned" responses, i.e., association of sensory stimuli with danger or adversity. This hypothetical classification of stimuli – which we will refer to as "systemic" or "psychogenic" stress (Herman et al., 2003) – has heuristic value in understanding the neurochemistry of stress (at least as concerns the HPA axis) and will be a recurring theme of this chapter.

The hypothalamic paraventricular nucleus (PVN) is the initiation point of neuronally-mediated stress responses (Antoni, 1986; Whitnall, 1993) (*Figure 13-1*). Activation of the HPA axis is mediated by a discrete set of neurosecretory neurons localized in the medial parvocellular zone of this nucleus. These neurons project to blood vessels in the external lamina of the median eminence, where they release numerous ACTH "secretagogues," the most important of which are corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP) (Antoni, 1986; Whitnall, 1993). Importantly, these neurons also express glucocorticoid receptors (GR) (Uht et al., 1988) and may serve as a site of "negative feedback" regulation of the HPA axis by glucocorticoids.

Generally, dendrites of medial parvocellular PVN neurons do not extend beyond the PVN proper (van den Pol, 1982; Rho and Swanson, 1989). Thus, processing of afferent information largely occurs within the nucleus, either by direct synaptic innervation or interactions among neighboring cell populations (e.g., magnocellular neurons or glial cells). This point is important, as numerous regions, including limbic structures such as the hippocampus, medial amygdala, and lateral septum (Oldfield and Silverman, 1985; Oldfield et al., 1985; Canteras and Swanson, 1992; Cullinan et al., 1993; Canteras et al., 1995), send projections to the neuropil immediately outside the PVN. The absence of dendritic extensions from PVN neurons into this "peri-PVN zone" makes it unlikely that these limbic regions directly influence the PVN.

The PVN is one of the most highly vascularized regions in the brain (McGinty et al., 1983). Thus, the PVN, including its parvocellular component, has direct access to signaling molecules that can traverse the blood–brain barrier. In addition, there is some evidence suggesting that the PVN vessels themselves can produce signaling molecules, such as prostaglandins, nitric oxide (NO), or carbon monoxide (CO)

Figure 13-1
Organization of the HPA axis. Corticotropin releasing hormone (CRH) neurons located within the medial parvocellular region (mp) of the hypothalamic paraventricular nucleus (PVN) drive pituitary corticotrophs via the portal vasculature, stimulating ACTH. ACTH, in turn, mediates the synthesis and release of corticosteroids from the adrenal glands



(Vincent et al., 1994; Rivest, 2001; Rivier, 2002), following appropriate stimulation (e.g., cytokine binding). The vascularity also assures parvocellular PVN neurons access to glucocorticoids, which distribute freely across the blood–brain barrier.

1.2 Normal Domains of HPA Axis Function

1.2.1 Basal Corticosteroid Secretion

It is well known that the HPA axis is driven by cues related to "stressors"; however, it is important to note that there is a powerful circadian rhythm of glucocorticoid secretion. In most organisms, glucocorticoids peak immediately before the onset of waking (Dallman et al., 1987, for review). The levels attained during the diurnal peak are not trivial; typically, in rats, circadian peak levels of corticosterone are roughly half the secreted product generated during a robust stress response. This contrasts markedly with extremely low levels seen during the nadir, which can approach the lower limits of detection in some assays. The net impact of the rhythm is a roughly 40- to 50-fold fluctuation in corticosterone levels every day. Daily corticosterone variations have a potentially profound impact on brain (and body) glucocorticoid signaling

across the day; low levels seen during the nadir are only sufficient to bind the high-affinity mineralocorticoid receptor (MR), whereas peak levels can occupy the majority of GRs in addition to MRs (see De Kloet et al., 1998, for review). Emerging evidence ascribes different functions to MR, GR, and possibly, MR–GR heterodimers (e.g., Trapp et al., 1994), indicating that the level of glucocorticoids may indeed dictate how glucocorticoid signals are interpreted in the brain and periphery.

1.2.2 Acute Stress Responses

Glucocorticoid secretion is generally part of the acute response of the organism to stress. It is often erroneously referred to as part of the "fight or flight" response; in fact, the actions of glucocorticoids, being mostly genomic in nature, are generally delayed, and are thus more relevant to survival well after an initial, sympathetically-mediated "fight or flight" reaction has occurred. Indeed, it is thought by some that the glucocorticoid response is primarily geared to restoration of homeostasis (Munck et al., 1984). The net result of glucocorticoid release is best thought of as a redistribution of resources, e.g., mobilizing energy reserves, modulating immune function, and/or inhibiting energy-intensive systems not required for survival.

1.2.3 Glucocorticoid Negative Feedback

Glucocorticoids released following stress have negative feedback actions on the HPA axis. Feedback effects of glucocorticoids happen in three different time frames: rapid effects occur within minutes, intermediate feedback over hours, and delayed feedback over days (Keller-Wood and Dallman, 1984). Rapid or "fast," feedback is rate-sensitive (occurs when corticosteroid levels are rising) and is exerted at the level of ACTH secretion, perhaps via the PVN; these rapid effects are almost certainly nongenomic and thus unlikely to act through the "traditional" GR. Intermediate feedback effects operate on the time frame of genomic responses, but typically do not involve changes in pituitary proopiomelanocortin (ACTH precursor) synthesis or storage; rather, the history of glucocorticoid release is able to modify later secretory patterns, perhaps via neuronal mechanisms. The last realm of feedback is mediated by direct changes in transcription and protein synthesis so as to downregulate the capacity of the pituitary to make and secrete ACTH (Keller-Wood and Dallman, 1984).

Neuronal pathways mediating glucocorticoid negative feedback are yet to be defined. The GR is abundantly expressed in the pituitary, PVN, and numerous brain regions implicated in HPA axis regulation (Aronsson et al., 1988; Arriza et al., 1988; Ahima and Harlan, 1990; Herman, 1993), and studies have implicated some or all of these loci in feedback processes (Herman et al., 2003). Given that glucocorticoids are capable of rapid inhibition of PVN activity and presynaptic glutamate release (Saphier, 1987; Di et al., 2003), it is likely that fast feedback is mediated to some degree at the PVN. The proopiomelanocortin gene has a known negative glucocorticoid response element that affords direct transcriptional repression by glucocorticoids (Drouin et al., 1989), which may well account for delayed feedback effects. The intermediate realm of feedback is currently under some debate; it appears to occur at the level of the brain (Levin et al., 1988), but the exact location is poorly understood. Strong cases can be made for the PVN itself, the hippocampus, and the medial prefrontal cortex as potential feedback loci; however, in most cases the data in the literature are mixed (see Herman et al., 2003, for review) and it is likely that feedback is mediated by distributed rather than dedicated circuits.

1.2.4 Chronic Stress

Chronic drive of the HPA axis with prolonged stress precipitates long-term changes in both central and peripheral effector systems. These include adrenal hypertrophy, associated with prolonged exposure of the adrenal cortex to ACTH, and thymic atrophy, a probable result of chronic glucocorticoid elevation (Prewitt and Herman, 1997). Chronic glucocorticoid release consequent to stress may also have an impact on other endocrine systems [e.g., inhibition of testosterone release (Tamashiro et al., 2005)]. Glucocortioids are

directly linked to chronic stress-related hippocampal damage and cognitive deficits (McEwen and Sapolsky, 1995; Sapolsky, 2000) and may also be related to the decreased food intake (Dallman et al., 2003), behavioral anhedonia (Willner et al., 1992), and altered cardiovascular tone (Grippo et al., 2002) characteristic of prolonged stress exposure.

The overall impact of a given chronic stress regimen on HPA axis function is highly dependent on design. Most chronic stress designs create long-term increases in basal corticosterone release (Ottenweller et al., 1992; Gomez et al., 1996; Prewitt and Herman, 1997). This enhanced release can be observed 16–24 h after the last stress exposure, indicating that the HPA system has undergone long-term upregulation. Enhanced basal release of ACTH may or may not accompany the corticosterone changes, suggesting that in some cases sensitivity of the adrenal may be affected by chronic stress. At the level of the pituitary, chronic stress generally enhances proopiomelanocortin mRNA and pituitary ACTH stores (Shiomi et al., 1986); in contrast, CRH-R1 binding is decreased (Anderson et al., 1993; Fuchs and Flugge, 1995), suggesting a downregulatory response to enhanced CRH secretion. In the hypothalamus, chronic stress generally increases PVN CRH and AVP mRNA expression (DeGoeij et al., 1991, 1992b; Imaki et al., 1991; Herman et al., 1995; Prewitt and Herman, 1997), PVN and median eminence CRH peptide levels (Chappell et al., 1986), and the extent of CRH/AVP colocalization in the median eminence (Whitnall, 1989), all of which are consistent with enhanced PVN activity and secretagogue release. Enhanced PVN CRH expression is negatively correlated with PVN glucocorticioid receptor levels (Herman et al., 1995; Makino et al., 1995; Prewitt and Herman, 1997), implying reduced hypothalamic glucocorticoid feedback efficacy following chronic stress. Chronic stress also causes changes in upstream stress regulatory circuits; for example, chronic regimens can reduce hippocampal expression of glucocorticoid and/or MRs (Sapolsky et al., 1984; Herman et al., 1995; Gomez et al., 1996; Prewitt and Herman, 1997), and increase expression of tyrosine hydroxylase in the locus coeruleus (LC) (Mamalaki et al., 1993). The overall connection between these mRNA changes in stress regulatory regions and the stress-induced drive of the HPA axis remains to be determined.

Repeated exposure to some stressors (restraint, cold) can cause habituation of HPA axis responses (Akana et al., 1992; Cole et al., 2000). For example, the corticosterone response to a fifth daily session of restraint is roughly half the magnitude of the first (Cole et al., 2000). It is important to note that the animal still responds to an individual stressor and is therefore still subject to the cumulative impact of multiple stress exposures. The habituation response is stressor-specific; for example, HPA axis responses to immobilization do not show decrements with repeated exposure (Dobrakovova et al., 1982). Failure to habituate is likely associated with stressor intensity (e.g., movement of the limbs is completely prohibited in immobilization, whereas limited movement is allowed in restraint).

Finally, chronic stress can also result in HPA axis facilitation or sensitization, whereby responses to novel stressors are enhanced following repeated homotypic stress exposure (Akana et al., 1992; Bhatnagar and Dallman, 1998). In facilitation paradigms, responses are either the same as naïve controls (i.e., blockade of habituation) or substantially higher. Facilitation appears to be mediated within the CNS (see later).

Chronic stress results in numerous physiological and behavioral changes that are similar to human disease or aging pathology. For example, chronic stress-induced adrenal hypertrophy, weight loss, anhedonia, and dexamethasone feedback resistance are highly reminiscent of melancholic depression (Willner et al., 1992), a disease with clear links to glucocorticoid hypersecretion and stress. In addition, chronic stress can cause memory impairment and cellular atrophy in the hippocampus, both of which are seen in rodent (and human) aging models (McEwen and Sapolsky, 1995). Thus, chronic drive of the HPA axis represents a significant health risk factor for the organism.

2 Neurochemistry of HPA Axis Regulation: Overview

The neurochemistry of HPA axis regulation has been studied extensively and has yielded a voluminous (if not confusing) literature. In this chapter, we focus on understanding how various neurotransmitter, neuropeptide, and steroid systems affect the central activation of the HPA axis, with a particular focus on the PVN. This limits the interpretation of our review in two important ways, and this should be kept in mind as one proceeds. First, this chapter focuses on central actions of neurochemical systems on the HPA

axis, centered on the PVN CRH neuron. Thus, we will not discuss results of systemic injections of neuromodulatory agonists/antagonists to any substantial extent, unless these injections are made in conjunction with some central treatment or measure. The reader should note that multiple systems have the capacity to act at the pituitary and/or adrenal to directly modulate ACTH and corticosteroid release, respectively. While these actions are not discussed here, it is important to consider that direct pituitary or adrenal regulation of HPA axis output offers major modulatory mechanisms that should not be underestimated. Second, the roles of particular neurochemical species are discussed in the context of the domains of HPA axis function: basal (circadian), acute stress, and chronic stress, under the assumption that the given neurochemical systems may affect different aspects of HPA axis integration. Importantly, a large number of neuropeptides activate the HPA axis after central injection; however, few of these species have been tested for necessity (usually due to lack of specific receptor antagonists) and most have not been placed in the context of diurnal regulation. Thus, we discuss these as possible candidate regulators, but do not incorporate them into our general neurochemical scheme for HPA integration. Finally, the "other" stress responses noted above (autonomic, behavioral) will have input into HPA axis activity. For example, autonomic activity during stress can have an impact on PVN activation by multiple central and peripheral mechanisms, and indeed, it is fair to say that a substantial portion of the HPA axis stress response may be a reaction to sympathoadrenomedullary activation (Ulrich-Lai and Engeland, 2002). In addition, an organism's behavior may also affect HPA outcome. For example, avoiding an anxiety-provoking situation (e.g., open arms of an elevated plus-maze in rodents) may effectively decrease the magnitude of the HPA response by minimizing exposure to the "danger" of falling. Thus, by showing greater "anxiety," the organism can conceivably diminish homeostatic threat and the attendant glucocorticoid response. Thus, while we do not address sympathoadrenal and behavioral stress systems directly, it is important to acknowledge their possible roles in "tuning" the HPA axis.

3 Glucocorticoids and Feedback

Glucocorticoids have powerful inhibitory actions on the HPA axis. Genomic actions of glucocorticoids are mediated by two types of GRs: type I, or MRs and type II, or GRs. Differential ligand affinities [the K_D for MR is 0.5–1.0 nM, GR is 2.5–5 nM (Reul and de Kloet, 1985)], brain region specificity (McEwen et al., 1968), and receptor binding mechanisms (Rogerson et al., 2004) likely dictate the role of the two receptors in basal HPA axis regulation, circadian drive, and the HPA axis response to stress. Under conditions of low glucocorticoid secretion (e.g., circadian secretory nadir), both MR and GR are in the cytosol (van Eekelen et al., 1987), encased in chaperone complexes [consisting of heat shock proteins 90, 70, 30, heat shock cognate 70, p23, and an immunophilin moiety FKBP51 or 52 (Fuller et al., 2000)]. These stabilize tertiary structure by encouraging proper protein folding and conformation, maintaining the receptor in a high affinity state for glucocorticoid binding. Upon ligand binding, a nuclear localization signal is exposed and receptors translocate to the nuclear compartment, where they enhance or repress transcription by (1) binding as homodimers (or perhaps heterodimers) on DNA response elements (Trapp et al., 1994) or (2) altering transcriptional effects of other nuclear factors by way of protein–protein interactions (Gottlicher et al., 1998).

The two adrenocorticosteroid receptors are differentially distributed in the brain; MR is primarily located in limbic system brain regions (i.e., hippocampus and septum), whereas GR is widely distributed in the CNS, with high levels of expression in the hippocampus, the cortex, the amygdala, and in CRH neurons of the PVN (Herman, 1993). Thus, both receptor species are expressed in regions implicated in inhibition of the HPA axis. Expression patterns are both autonomous (e.g., MR in lateral septum, GR in PVN) and overlapping (e.g., hippocampus), affording the ability of the two receptors to work individually or in concert. Colocalization of MR and GR is evident in neurons of the hippocampus, allowing for possible interaction between the two receptors via heterodimerization, a process that has been demonstrated in vitro (Herman et al., 1989; Van Eekelen and De Kloet, 1992; van Steensel et al., 1996; Han et al., 2005). As would be predicted by the differential affinities of these receptors for ligand, approximately 70% of MR is available to bind glucocorticoid at the circadian nadir; little unbound MR is available during the circadian rise in

corticosterone secretion. Availability of the GR varies substantially across the diurnal cycle; binding capacity is much greater at the circadian low (85–100% unbound), decreasing to 60–75% around the circadian corticosteroid peak (Spencer et al., 1993).

Administration of spironolactone, a potent MR antagonist, increases morning ACTH release in non-adrenalectomized (Spencer et al., 1998) and corticosterone replaced (20% and 50%, respectively) adrenalectomized rats. Higher levels of corticosterone replacement (50%) are necessary for PM inhibition of ACTH, suggesting a role for GR in this process; however, inhibition of MR prohibits inhibitory actions of corticosterone on the PM rise (Bradbury et al., 1994). In intact rats, combined treatment with GR and MR antagonists increases circadian peak corticosterone secretion, consistent with the notion that the two receptors work together to control peak daily secretory rhythms (Spencer et al., 1998). Together, these data suggest that both receptors are involved in basal HPA axis inhibition. However, central injection studies indicate that i.c.v. MR antagonist treatment increases resting morning corticosterone levels in the rat, whereas GR antagonist is without effect, suggesting that binding to the MR is important in the control of basal HPA activity (Ratka et al., 1989; van Haarst et al., 1997), at least at the level of the CNS. Experiments in humans indicate that blockade of the MR increases basal cortisol and ACTH levels (Deuschle et al., 1998).

Glucocorticoid inhibition of acute HPA axis stress responses may also be mediated by the combined actions of GR and MR. Systemic injection of either a GR (RU45055) or MR (RU28318) antagonist does not affect corticosterone secretion driven by acute restraint; however, blockade of both receptors increases the corticosteroid responses to novelty, consistent with a role for both receptors in acute stress feedback (Spencer et al., 1998). Notably, blockade of GR but not MR produces long-term elevation of corticosterone observed following an acute stress, suggesting a role for GR in terminating corticosteroid secretory responses (Moldow et al., 2005). Results following central injections of adrenocorticosteroid receptor antagonists generally support the combined-action model. Central administration of the GR antagonist RU486 enhances the magnitude of the corticosteroid response to novelty, whereas both MR and GR antagonists prolong the magnitude of the HPA response to this stimulus, consistent with a role for both receptors in stress control (Ratka et al., 1989). However, it is important to note that central administration of corticosterone itself can enhance HPA axis activity in adrenalectomized rats, increasing ACTH responses to stress and PVN CRH mRNA levels (Laugero et al., 2002).

The primary brain regions responsible for GR and/or MR control of the HPA axis are currently being established. Previous studies suggest that limbic structures, such as the hippocampus and prefrontal cortex, are involved in corticosteroid-dependent termination of stress responses; however, there is considerable conflicting data on this topic (Jacobson and Sapolsky, 1991; Herman et al., 2003). Recent studies employing a conditional forebrain GR knockout mouse model, which has a selective deletion of GR in the hippocampus and cortex, reveal elevated corticosterone and ACTH at both the trough and nadir of the circadian rhythm. Basal PM glucocorticoid secretion is resistant to dexamethasone suppression (Boyle et al., 2005). Together, these data implicate forebrain GRs in inhibition of basal HPA tone. This work is supported by data from transgenic mouse models that overexpress GR (reduced basal secretion) or an antisense GR construct (increased basal secretion) in neurons (Kellendonk et al., 2002).

Chronic exposure to homotypic stressors often promotes habituation of corticosterone (Keim and Sigg, 1976) and ACTH (Campmany et al., 1996; Gadek-Michalska and Bugajski, 2003) responses to stress. Acute treatment with MR or combined MR–GR antagonists prevents habituation, whereas GR antagonist alone is ineffective (Cole et al., 2000). These data indicate that the MR may be selectively involved in HPA axis habituation.

Finally, it is important to consider the role of glucocorticoids in fast feedback inhibition of the HPA axis. Glucocorticoids inhibit PVN neurons within seconds to minutes of exposure (Saphier, 1989) and it is well established that systemic administration of glucocorticoids immediately prior to stress can effectively block ACTH release (Keller-Wood and Dallman, 1984). Genomic actions of corticosteroids are unlikely to account for such rapid inhibition of the HPA axis. Thus, numerous investigators propose the existence of a membrane GR that can bind corticosteroids and effect immediate physiological changes (Orchinik et al., 1991; Evans et al., 2000; Di et al., 2003). A receptor with appropriate characteristics has been detected in amphibian (Orchinik et al., 1991), but is yet to be definitively identified and cloned. Recent studies suggest that the fast feedback effects of corticosteroids on PVN neurons are mediated through inhibition of

presynaptic glutamate release, by way of a G-protein coupled receptor activating synthesis of endocannabinoids (acting as retrograde messengers) (Di et al., 2003).

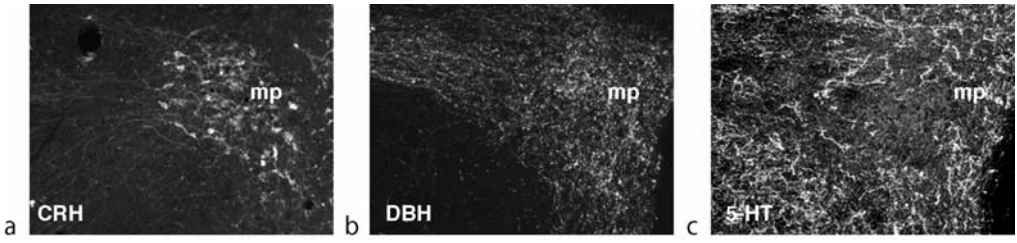
4 Monoamine Neurotransmission

4.1 Norepinephrine/Epinephrine

Brainstem norepinephrine (NE)/epinephrine (E) systems provide direct innervation to the medial parvocellular PVN and play a major role in HPA axis regulation. The A2/C2 (nucleus of the solitary tract) and A1/C1 (ventrolateral medulla) cell groups provide the primary NE/E innervation to the PVN, with the former comprising the major input to the hypophysiotropic, CRH-containing medial parvocellular region (see *Figure 13-2*). Axons of these cell groups ascend in the ventral noradrenergic-ascending bundle

Figure 13-2

Innervation of the PVN by norepinephrine/epinephrine and serotonin terminals. Corticotropin releasing hormone (CRH) neurons densely populate the medial parvocellular (mp) subdivision of the paraventricular nucleus (a). The mp PVN region is richly invested by fibers positive for dopamine beta-hydroxylase, an enzyme, specific for norepinephrine and epinephrine neurons (b). In contrast, the mp PVN contains a relatively small number of serotonin (5-HT) positive fibers, with most terminal localized outside the PVN proper (c)



(VNAB) (Fuxe, 1965; Swanson et al., 1981; Cunningham and Sawchenko, 1988) to form synaptic connections with CRH containing neurons in the PVN (Liposits et al., 1986). The LC also contributes to HPA axis regulation; however, this region does not directly innervate the medial parvocellular PVN (Cunningham and Sawchenko, 1988). Thus, the effects of the LC on PVN neurons are likely transsynaptic in nature, acting through other brain regions known to be involved in the regulation of the HPA axis (e.g., prefrontal cortex, amygdala, and hippocampus) (Herman and Cullinan, 1997). Consistent with the importance of NE/E signaling in PVN integration, parvocellular PVN neurons express α_{1A}, α_{1B}, α_{1D}, and α_2-adrenoceptors, with clear evidence for colocalization of α_{1B} (and to a lesser extent α_{1D}) in CRH neurons (Cummings and Seybold, 1988; Williams and Morilak, 1997; Day et al., 1997; Sands and Morilak, 1999).

In the PVN, extracellular NE levels and α2-NE receptor binding show diurnal patterns that parallel plasma corticosterone levels (Jhanwar-Uniyal et al., 1986; Stanley et al., 1989). Deprivation of NE following destruction of the VNAB with 6-hydroxydopamine (6-OHDA) reduced the amplitude of diurnal patterns of ACTH and corticosterone secretion (Szafarczyk et al., 1985), consistent with α1 and/or α2 regulation of basal secretory patterns. Firing rates of LC neurons also show a diurnal pattern (Aston-Jones and Bloom, 1981a) that regulates state-dependent gene expressions in many brain regions (Cirelli and Tononi, 2004). As the LC does not have direct projections to the PVN, it may affect circadian activities of the HPA axis indirectly through the suprachiasmatic nucleus, the main regulatory site of the biological clock in the brain (Cagampang et al., 1994; Sage et al., 2001). Taken together, the brainstem NE system plays a significant role in regulating the circadian rhythm of HPA axis activity.

Norepinephrine appears to play a major stimulatory role in HPA axis activation. Stimulation of the A1, A2, LC, or VNAB increases the firing rate of PVN neurons (Day et al., 1985; Saphier, 1989; Saphier and Feldman, 1989). Electrical stimulation of the VNAB activates the HPA axis, indicated by an increase of CRH release into the hypophysial-portal system (Plotsky, 1987). In addition, local administration of NE rapidly activates CRH and AVP gene transcription (Itoi et al., 1999) and c-Fos expression in PVN neurons (Cole and Sawchenko, 2002), consistent with direct action at the level of CRH neurons. The effects of central NE–E administration or VNAB stimulation on portal CRH release or ACTH/corticosterone secretion can be blocked by either α1 (Plotsky, 1987; Szafarczyk et al., 1987) or α2 (Daniels et al., 1993) adrenoreceptor antagonists.

A variety of systemic as well as psychogenic stressors activate NE cells in the brainstem (A1/C1 and A2/C2 regions) (Li et al., 1996; Dayas et al., 2001b). Release of NE in the hypothalamus or PVN can be observed following exposure to different stressors, including inescapable shock (Anisman and Sklar, 1979), immobilization (Yokoo et al., 1990a; Pacak et al., 1993), conditioned fear (Yokoo et al., 1990b; Cullinan et al., 1993), ether inhalation (Szafarczyk et al., 1985), and formalin injection (Palkovits et al., 1999). Lesion studies further corroborate NE involvement in acute stress responses; for example, HPA axis responses elicited by various stressors are attenuated by brainstem hemisections (Pacak et al., 1996) and 6-OHDA lesions of PVN terminals (Gibson et al., 1986) or the VNAB (Gaillet et al., 1993).

Despite the ability of a variety of stressors to elicit PVN NE secretion, accumulating evidence indicates that ascending NE/E systems may be preferentially involved in responses to systemic stress (Herman and Cullinan, 1997). 6-OHDA lesions of the VNAB or the PVN markedly attenuate ACTH and/or corticosterone responses to systemic stressors such as ether (Szafarczyk et al., 1985; Gaillet et al., 1991; Herman et al., 2002), interleukin-1 (Chuluyan et al., 1992), or hypoglycemia (Ritter et al., 2003). In contrast, corticosterone responses to psychogenic stressors such as restraint stress (Gaillet et al., 1991; Chuluyan et al., 1992; Herman et al., 2002), immobilization (Pacak et al., 1993), and forced swim (Ritter et al., 2003) are not attenuated, suggesting that effects of NE/E are modality-specific. Notably, brainstem hemisections that markedly decrease PVN NE release, NE turnover, and CRH mRNA expression do not affect corticosterone responses to immobilization (Pacak et al., 1993, 1996), suggesting that the HPA axis response to this stimulus is independent of PVN NE, and is possibly driven by forebrain or midbrain circuitry. Some studies also suggest that NE/E lesions may dissociate ACTH and corticosterone responses to stress; although VNAB lesions did not attenuate corticosterone responses to restraint stress, ACTH responses were significantly blunted (Gaillet et al., 1991). VNAB lesions seem to have more marked effects on stress-activated ACTH release than corticosterone release following systemic stressors such as ether (Szafarczyk et al., 1985). Thus, it is plausible that NE/E lesions may also be affecting the HPA axis at the level of the adrenal.

Noradrenergic neurons originating in the LC appear to have indirect effects on HPA axis activity. Various stressors activate NE cells at the LC (Aston-Jones and Bloom, 1981b; Abercrombie and Jacobs, 1987; Grant et al., 1988). Despite the lack of a direct connection between the LC and medial parvocellular PVN, lesions of the LC attenuate ACTH and corticosterone responses to restraint stress (Ziegler et al., 1999), implying that the LC transsynaptically activates the HPA axis. Indeed, following stress, an increase in NE level is observed in many regions of the brain receiving projections from LC, including the amygdala, the hippocampus, and the medial frontal cortex (Abercrombie et al., 1988; Tanaka et al., 1991; Cenci et al., 1992), all of which are implicated in stress regulation (Herman et al., 2003).

Chronic stress appears to sensitize electrophysiological responses of LC NE neurons (Jedema and Grace, 2003). The LC NE system also exhibits chronic stress facilitation, whereby both LC c-Fos induction and forebrain NE release to a novel, heterotypic stressor are markedly potentiated (Nisenbaum et al., 1991; Gresch et al., 1994; Jedema et al., 1999). In general, NE turnover is increased in chronically stressed animals (Thierry et al., 1968; Irwin et al., 1986; Nisenbaum et al., 1991), implying an ongoing increase in NE release with repeated stimulation. These data strongly suggest that the LC participates in adaptations to chronic stress; however, the role of the LC in chronic drive of the HPA axis is less clear. Lesions of the LC do not alter elevated PVN CRH mRNA, adrenal hypertrophy, thymic atrophy, or corticosterone hypersecretion seen following exposure to a chronic variable stress regimen (Ziegler et al., 1999), suggesting that the influence of the LC on long-term stress integration is not pronounced.

4.2 Serotonin

The HPA axis is regulated by ascending input from the 5-hydroxytryptamine (5-HT; serotonin) containing neurons in the raphe nuclei (see Fuller, 1992; Van de Kar, 1997, for review). Dorsal raphe neurons provide a limited direct innervation of CRH neurons in the PVN (*Figure 13-2*) (Sawchenko and Swanson, 1985; Assenmacher et al., 1987; Kitazawa et al., 1987; Liposits et al., 1987) that may underlie 5-HT actions. However, it should be noted that serotonin richly innervates numerous CNS structures involved in stress regulation, as well as the immediate surround of the PVN (Sawchenko et al., 1983). Thus, 5-HT effects on the HPA axis may be either direct or transsynaptic.

Serotonin seems to be particularly important in the regulation of HPA axis rhythmicity. Lesions of the raphe nuclei (Vermes et al., 1974; Lissak et al., 1975) or pharmacological depletion of brain 5-HT by the 5-HT synthesis inhibitor, p-chlorophenylalanine, disrupt the circadian corticosterone rhythm (Krieger and Rizzo, 1969; Scapagnini et al., 1971; Vernikos-Danellis et al., 1973). Injection of the serotonin neurotoxin 5,7-dihydroxytryptamine (5,7-DHT) into the suprachiasmatic nucleus led to flattening of circadian corticosterone fluctuations 2–7 weeks later (Williams et al., 1983; Banky et al., 1986). Studies in genetically modified mice also support a role for 5-HT in basal HPA integration; for example, 5-HT transporter knockout mice show decreased basal plasma corticosterone levels (Lanfumey et al., 2000), and basal AVP (but not CRH) mRNA is reduced in the PVN of 5-HT_{3A} receptor knockout mice (Bhatnagar et al., 2004).

There is also substantial evidence for a role of 5-HT in HPA activation. 5-HT stimulates CRH secretion from isolated rat hypothalamic explants (Calogero et al., 1989a) and there is strong evidence that in vivo administration of 5-HT precursors (5-HTP, L5-HTP), releasers (p-chloroamphetamine, fenfluramine), and reuptake inhibitors (fluoxetine, citalopram) activate the HPA axis (Fuller and Snoddy, 1990; Spinedi and Gaillard, 1991; Fuller, 1992; Fuller et al., 1996; Moncek et al., 2003) and increase PVN CRH mRNA (Jorgensen et al., 2002) in the rat. However, it is important to note that other studies suggest that the role of 5-HT may be more complex. For example, administration of the 5 HT-1A agonists 8-OH DPAT or ipsapirone in conjunction with stress augments stress-induced HPA activation (Korte et al., 1992; Cassano and D'Mello A, 2001). In addition, blockade of 5-HT reuptake by fluoxetine does not potentiate forced swim or hypoglycemia-induced increases in plasma corticosterone secretion (Fuller and Snoddy, 1977).

Specific 5-HT receptor subtypes appear to be involved in the stimulatory effects of 5-HT on the HPA axis. Systemic administration of 5-HT_{1A}, 5-$HT_{1A/7}$, or 5-HT_{2C} receptor-selective agonists induce the release of ACTH and corticosterone in vivo (Koenig et al., 1987; Lorens and Van de Kar, 1987; Gilbert et al., 1988; Przegalinski et al., 1989; Van de Kar et al., 1989; Alper, 1990; Owens et al., 1991; Li et al., 1992, 1994b; Matheson et al., 1997a, b; Mikkelsen et al., 2004). In addition, systemic administration of 5-$HT_{1A/7}$ or 5-HT_{2C} receptor-selective agonists cause c-Fos and CRH mRNA induction in the PVN (Jorgensen et al., 2002; Mikkelsen et al., 2004). Furthermore, direct application of 5-HT_{1A}, 5-$HT_{1A/7}$, or 5-$HT_{2A/2C}$ receptor agonists into the hypothalamus leads to the release of CRH and plasma ACTH (Haleem et al., 1989; Di Sciullo et al., 1990; Pan and Gilbert, 1992; Rittenhouse et al., 1994; Bluet Pajot et al., 1995). These data indicate that 5-HT_{1A} and 5-HT_2 receptors appear to be important mediators for 5-HT control of the HPA axis at the level of the hypothalamus.

Subtraction experiments aimed at reducing 5-HT levels have led to more mixed results. Pharmacological studies indicate that blockade of 5-HT_{1A} receptors reduces HPA axis responses to both restraint and immune challenge (Jorgensen et al., 1998); however, blockade does not prohibit HPA axis responses triggered by ultrasonic vocalizations (Groenink et al., 1996), suggesting that serotonergic actions may be associated with stressor modality or intensity. Posterior hypothalamic deafferentation or injections of the serotonergic neurotoxin 5,7-DHT into the raphe or PVN inhibit the effect of several stressors on plasma corticosterone secretion (Feldman et al., 1984, 1987, 1990; Feldman and Weidenfeld, 1995), again consistent with the removal of excitatory input. However, electrolytic lesions of the midbrain raphe nuclei cause facilitation of stress-induced plasma corticosterone secretion (Cassano and D'Mello A, 2001). Other studies indicate that destruction of 5-HT terminals by i.c.v. injection of 5,6-dihydroxytryptamine decreases plasma corticosterone secretion after immobilization stress (Richardson, 1984). Notably, stress-induced secretion of plasma ACTH and corticosterone is decreased following injections of 5,7-DHT or ketanserin into the

amygdala (Feldman and Weidenfeld, 1998; Feldman et al., 1998), suggesting that the inhibitory effects of 5-HT may be transsynaptic in nature.

Serotonin receptor or 5-HT transporter knockout mice display altered HPA axis responses to acute stress. Serotonin transporter knockout mice have elevated plasma ACTH secretion in response to saline injection (Li et al., 2004), but do not hypersecrete ACTH in response to injection of a 5-HT_2 receptor agonist (Li et al., 2003a) or following immobilization stress (Tjurmina et al., 2002). Plasma corticosterone concentrations are elevated by the 5-HT_{1A} receptor agonist flesinoxan in wild-type mice but not in 5-HT_{1A} receptor knockout mice (Pattij et al., 2001). Additionally, 5-HT_{1A} receptor knockout mice show decreased corticosterone secretion after open field exposure (Gross et al., 2000), whereas 5-HT_{3A} receptor knockout mice show reduced plasma ACTH secretion following restraint or lipopolysaccharide administration (Bhatnagar et al., 2004), suggesting both receptors may be involved in HPA stimulation. However, aged 5-HT_{2C} receptor knockout mice show increased ACTH and corticosterone secretion after restraint stress (Chou-Green et al., 2003), arguing for functional differences among the 5-HT receptors in HPA regulation. Thus, it is likely that the effects of 5-HT on the HPA system are determined by the actions of distinct receptor subunit expression patterns in stress-integrative brain regions.

Serotonin is also involved in the control of HPA axis responses to chronic stress. For example, systemic injection of 8-OH-DPAT decreased chronic mild stress-induced ACTH secretion (Grippo et al., 2004). Increasing serotonin availability through inhibition of reuptake appears to attenuate HPA axis responses to chronic stress; for example, long-term pretreatment with imipramine blocks repeated immobilization-induced increases in PVN CRH mRNA levels and glutamic acid decarboxylase 65/67 (GABA synthesizing enzyme) mRNA in the BST (Butterweck et al., 2001). CRH mRNA upregulation in the PVN during exposure to chronic variable stress is attenuated by concurrent administration of venlafaxine (a 5-HT/NE reuptake inhibitor) (Stout et al., 2002). Central serotonin reduction by an i.c.v. injection of 5,7-DHT had no effect on the progressive reduction in corticosterone secretion with increasing number of tests (Chung et al., 1999), indicating that serotonin depletion is not able to disrupt HPA axis habituation to this stressor.

4.3 Dopamine

The neurotransmitter dopamine appears to play an excitatory role in the regulation of both basal and acute responses of the HPA axis. Dopamine depletion of the medial prefrontal cortex, dorsal striatum, and ventral striatum by 6-OHDA lesion of the ventral tegmental area attenuates basal as well as stress-induced plasma corticosterone secretion (Casolini et al., 1993). Systemic or i.c.v. administration of D1 and D2 dopamine receptor agonist elevates serum ACTH (Borowsky and Kuhn, 1992), and infusion of the selective dopamine uptake inhibitor GBR12909 into the third ventricle or PVN increases serum ACTH levels (Borowsky and Kuhn, 1993). Dopamine may modulate HPA axis activity at extrahypothalamic sites, as infusions of a mixture of D1 and D2 dopamine receptor agonists (SKF 38393 and quinpirole) into the medial prefrontal cortex, dorsal striatum, and ventral striatum elevate plasma corticosterone (Ikemoto and Goeders, 1998). Dopamine may also regulate HPA axis responses to stressors differently depending on stressor type; D1 and D2 dopamine receptor antagonists attenuate plasma ACTH responses to systemic stressor (IL1-β), but not mild psychogenic stressors (air puff) (Spencer et al., 2004).

4.4 Histamine

Histamine (HA) is a monoamine transmitter that is synthesized in a limited population of neurons in the tuberomammillary nucleus of the hypothalamus, thought to be important in neuronal control of sleep–wakefulness and arousal (Siegel, 2004). A role for HA in the circadian rhythm of the HPA axis is supported by evidence that central depletion of HA attenuates the diurnal variation of corticosterone and ACTH secretion

without affecting the mean basal levels of these hormones (Itowi et al., 1989). However, treatment with the H_1 antagonist mepyramine did not affect the basal rates of CRH, AVP, or OT mRNA expression, while H_2-receptor blockade using cimetidine had only a mild inhibitory effect (Kjaer et al., 1998). Moreover, inhibition of HA synthesis and release using either α-fluromethylhistamine (FHA) or treatment with an H_3-receptor agonist did not affect basal secretion of ACTH (Soe-Jensen et al., 1993). Thus, HA may play a role in rhythmic activity of the HPA, but may not be directly responsible for inhibition or activation of CRH neurons.

Neuronal HA may play a more important role in regulating the HPA axis response to stress (Kjaer, 1996). Central injections of HA elevate plasma levels of ACTH and beta-endorphin in a dose-dependent manner (Kjaer et al., 1992a). This effect appears to be mediated by the HA type 1 and type 2 (H_1 and H_2) receptors, as central injections of H_1 and H_2-receptor agonists produce similar effects on pituitary stress hormones (Kjaer et al., 1992b). Evidence suggests that the HA-induced activation of the HPA axis is in part due to increased CRH secretion from the PVN. Specifically, intracerebroventricular (i.c.v.) administration of HA, HA_1-, and HA_2-receptor agonists has been shown to increase CRH mRNA (Kjaer et al., 1998) and c-Fos expression (Kjaer et al., 1994) in CRH containing neurons in the PVN. Moreover, these agents have been shown to increase CRH release into the portal venous blood with an associated three to fourfold increase in plasma ACTH levels (Kjaer et al.,1992a). This effect on ACTH secretion was diminished by pretreatment with anti-CRH antibodies (Kjaer et al., 1992a). A role for vasopressin in the stress- and HA-induced activation of the HPA axis has also been described (Kjaer et al., 1993), possibly via a mediating action produced by binding to V_{1a} receptors located on CRH neurons (Kjaer, 1996), as well as a permissive effect on CRH-induced ACTH secretion by the anterior pituitary of stress hormones (Kjaer et al., 1993).

Evidence also supports a role for HA in the stress-induced activation of the HPA axis, as pretreatment with H_1- and H_2-receptor antagonists (Knigge et al., 1989), as well as bilateral posterior hypothalamic lesion and treatment with agonists of the HA type 3 (H_3) presynaptic autoreceptor (Knigge et al., 1999), attenuate secretion of pituitary hormones in response to stress.

Although differences in brain HA turnover in the diencephalon (Ito et al., 1999) and brain H3 receptor density (Endou et al., 2001) have been reported in rats exposed to chronic versus acute stress, the role of HA in the regulation of the HPA response to chronic stress is not yet defined.

5 Acetylcholine and Amino Acid Neurotransmission

5.1 Acetylcholine

The HPA axis is also regulated by acetylcholine. Acetylcholine is a potent activator of CRH release in vitro, effects that appear to be mediated by either muscarinic or nicotinic receptors (c.f., Hillhouse et al., 1975; Jones et al., 1976; Tsagarakis et al., 1988; Calogero et al., 1989b). In vivo stimulatory effects of acetylcholine have been verified by central injection studies, e.g., central application of nicotine activates the HPA axis (Matta et al., 1987). Direct injections of a nicotinic antagonist into the PVN were not sufficient to block effects of nicotine on HPA activation, suggesting that CRH neurons are not directly activated by nicotinic receptors (Matta et al., 1987). In contrast, injections of acetylcholine directly into the region of the PVN increase ACTH release in a dose-dependent manner; these effects appear to be mediated by muscarinic receptors (Ohmori et al., 1995). Subsequent work indicates that nicotinic effects are likely mediated through ascending catecholaminergic inputs from the brainstem (Fu et al., 1997). Thus, central acetylcholine activation of the HPA axis appears to have a PVN component, mediated by muscarinic receptors, and a brainstem component, mediated by nicotinic receptors. Interestingly, the magnitude of responses to peripheral muscarinic and nicotinic stimulation differs in males and females, suggesting the possibility for sex differences in central responsiveness to acetylcholine or cholinergic agents (Rhodes et al., 2001). This regulatory scheme predicts a multifaceted role for acetylcholine in HPA axis regulation.

Studies using nicotinic receptor antibodies report decreased ACTH and corticosterone release following ether stress (Weidenfeld et al., 1983) or acoustic (but not photic or sciatic) stimulation (Weidenfeld et al.,

1983, 1988), suggesting a role for the nicotinic cholinergic receptor system in HPA activation following acute systemic or psychogenic stress. Notably, chronic homecage crowding reduces ACTH and corticosterone responses to central muscarnic stimulation (Bugajski, 1999) and peripheral nicotine (Bugajski et al., 2002), suggesting a possible role for cholinergic receptor downregulation in chronic stress-induced changes in HPA axis function.

5.2 Gamma-Aminobutyric Acid

GABA is a major inhibitory modulator of HPA axis activity. Electron microscopic studies have documented that half of all synapses in the PVN are GABAergic (Decavel and Van Den Pol, 1990), suggesting that GABA plays a major regulatory role in HPA axis activation. In support of this hypothesis, microinjection of the GABA-A receptor antagonist bicuculline methiodide (BMI) into the PVN is sufficient to cause corticosterone secretion and induction of c-Fos expression in parvocellular PVN neurons (Cole and Sawchenko, 2002; Bartanusz et al., 2004). These results indicate that GABA provides tonic inhibition under basal HPA axis conditions. In addition, BMI injections increase AVP heteronuclear RNA in the medial parvocellular PVN (Kovacs et al., 2004), suggesting that the expression of this HPA "amplification factor" is also under tonic inhibition by GABA. In addition, BMI induce transcription of CRH and AVP in hypothalamic slices (Bali and Kovacs, 2003), confirming GABAergic inhibition of secretagogue biosynthesis. Ibotenate lesions of PVN-projecting cell populations in the posterior bed nucleus of the stria terminalis increase CRH mRNA in the medial parvocellular PVN under resting conditions (Herman et al., 1994). Given that this region sends a predominantly GABAergic projection to the PVN (Cullinan et al., 1993), these data suggest that GABA innervation may be necessary for maintenance of basal HPA tone.

Pharmacological analyses confirm that GABA is a major inhibitor of stress responses. Corticosterone and ACTH secretion are attenuated by i.c.v. injection of a GABA-A agonist (muscimol) (Makara and Stark, 1974) as well as by local injection of benzodiazepines (Imaki et al., 1995). Microinjection of the GABA-A agonist muscimol directly into the PVN inhibits stress-induced corticosterone release and medial parvocellular PVN c-Fos induction, whereas infusion of muscimol into the PVN by microdialysis decreased PVN c-Fos activation in response to ether stress (Kovacs et al., 2004). These data support the hypothesis that GABA directly inhibits stress-induced activation of CRH neurons. Cell culture and electrophysiological studies confirm direct GABAergic effects; for example, direct application of muscimol to parvocellular PVN neurons inhibits miniature excitatory postsynaptic currents (Boudaba et al., 1996).

Sources of GABAergic innervation to the PVN are fairly well characterized. GABA input emanates from several major sources, including the peri-PVN region, dorsomedial hypothalamic nucleus, medial preoptic nucleus/area, and bed nucleus of the stria terminalis, among others. Thus, it is not possible to identify a single source of GABA innervation to the PVN, indicating that inhibition of the PVN may reflect the net activity of several GABA circuits. However, it is important to note that many of these GABA systems are activated by stressful stimuli; for example, swim stress activates glutamic acid decarboxylase mRNA-expressing (i.e., GABAergic) neurons in the peri-PVN region, dorsomedial hypothalamus, preoptic area, and bed nucleus of the stria terminalis (Cullinan et al., 1995, 1996; Campeau and Watson, 1997), and glutamic acid decarboxylase mRNA expression is elevated in these same PVN-projecting regions following restraint (Bowers et al., 1998).

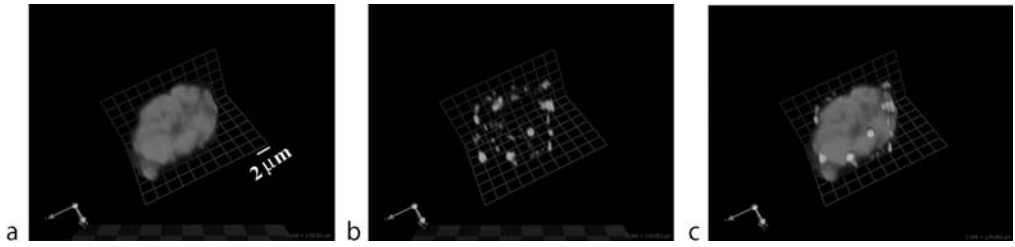
GABA systems may also play a role in chronic stress-induced HPA axis hyperactivity. Elevated glutamic acid decarboxylase 65 mRNA expression is observed in numerous PVN-projecting GABA cell populations following chronic variable stress (Bowers et al., 1998), consistent with chronic drive of these cell populations. Importantly, chronic stress decreases expression of key GABA-A receptor subunits in the parvocellular PVN (Cullinan and Wolfe, 2000), suggesting a reduced net impact of GABA on CRH neurons following prolonged activity. Consistent with this hypothesis, electrophysiological analyses indicate that GABAergic inhibitory postsynaptic currents are reduced following chronic stress (Joels et al., 2003; Verkuyl et al., 2004), likely due to a reduced number of GABAergic synaptic contacts (Verkuyl et al., 2004) resulting in a disinhibition of HPA axis activity.

5.3 Glutamate

Glutamatergic terminals directly innervate CRH neurons (see *Figure 13-3*) and are sufficient to induce activation of the HPA axis. Infusion of glutamate into the third ventricle increases the secretion of corticosterone in anesthetized rats (Makara and Stark, 1975). Similarly, injection of glutamate directly

Figure 13-3

Confocal micrographs demonstrating appositions between glutamatergic boutons (green) and CRH neurons (red). This is a three-dimensional rendering of a glutamate (vesicular glutamate transporter 2(VGLUT2)-positive)-innervated CRH neuron, showing the shape of the CRH immunoreactive soma (a), and the patterning of boutons around the cell (b). The overlay (c) demonstrates close apposition of VGLUT2 boutons to the CRH neuron, including overlap of immunoreactivity (yellow regions), and occupancy of apparent depression in the cell soma. The results strongly suggest innervation of CRH neurons by VGLUT2-expressing cell populations. Reprinted with permission from Ziegler, Cullinan and Herman, J. Comp. Neurol. 484 (2005)



into the PVN increases the secretion of ACTH, depletes the median eminence of CRH, and elevates basal corticosterone in anesthetized rats (Darlington et al., 1989). These acute effects of glutamate may be mediated by NMDA receptors (Feldman and Weidenfeld, 1997). Interestingly, peripheral administration of MK-801, an NMDA receptor antagonist, induces ACTH (Jezova et al., 1995) and corticosterone secretion (Pechnick et al., 1989) in unstressed animals, but blunts the ACTH response to stress (Jezova et al., 1995). These effects were probably due to central action of the drug, because peripheral administration of an NMDA antagonist that does not cross the blood–brain barrier does not affect basal ACTH levels. NonNMDA receptors may also play a role in acute effects of glutamate on the HPA axis, as administration of DNQX, a nonNMDA antagonist, into the lateral ventricles stimulates corticosterone and ACTH secretion (Tokarev and Jezova, 1997).

Peripheral administration of NMDA and kainate, like their antagonists, stimulates ACTH and corticosterone responses in rats (Zelena et al., 2005). Surgical lesions of the PVN prevent the ACTH and corticosterone responses to NMDA and kainate, suggesting that they may be due to actions on the PVN or higher centers (Zelena et al., 2005). In support of this idea, the ACTH response induced by NMDA and kainate receptor agonists is blocked by passive immunization with anti-CRH antibodies (Chautard et al., 1993). It is curious to note that both antagonists and agonists of these ionotropic glutamate receptors seem to have qualitatively the same effect on acute HPA output. A possible explanation of this phenomenon may be that the drugs are working on different brain regions. For example, kynurenic acid, an ionotropic glutamate receptor antagonist, decreases the corticosterone response to acute restraint stress when injected into the PVN, but increases the corticosterone response when injected dorsal to the PVN (Ziegler and Herman, 2000). The latter data indicate that whereas glutamate can directly activate PVN neurons, neighboring GABA neurons are also receptive to glutamate and may confer inhibition of CRH neurons. This supposition is confirmed by recent studies indicating that application of glutamate to an area dorsal and lateral to the PVN proper selectively activates glutamic acid decarboxylase-expressing neurons in the peri-PVN zone (Cole and Sawchenko, 2002). Thus, the common effects of peripheral injections of agonists/antagonists may be related to differential activation of circuits relevant to HPA excitation and inhibition. Alternatively, an optimal "glutamate tone" may be required for control of the HPA axis, whereby too little or too much glutamate signaling results in HPA activation.

In addition to ionotropic glutamate receptors, metabotropic glutamate receptors may also be involved in regulating the HPA response to stress. Acute systemic administration of an mGluR2/3 antagonist induces corticosterone secretion in mice (Scaccianoce et al., 2003). The effect of mGluR2/3 antagonist on corticosterone release is presumably mediated at the hypothalamus, as this drug is sufficient to induce CRH release from isolated hypothalami in vitro. However, neither mGluR2/3 agonists nor antagonists significantly alter corticosterone levels in vivo in the rat (Johnson et al., 2001). Acute dosing with group III agonists (mGluR4, 6, 7, and 8) stimulate a corticosterone response (Johnson et al., 2001). Interestingly, both agonists and antagonists to group I receptors (mGluR1 and mGluR5) increase serum corticosterone (Johnson et al., 2001), similar to results discussed already for ionotropic glutamate receptors. Thus, it is apparent that the different classes of metabotropic glutamate receptors have quite different profiles of HPA axis regulation.

Chronic administration of the NMDA antagonist felbamate increases basal blood levels of corticosterone in mice, but attenuates the corticosterone response to chronic social defeat stress (Pistovcakova et al., 2005). In contrast, chronic blockade of both NMDA and AMPA receptors attenuates the response to acute immobilization stress, but not to footshock or ether stress (Zelena et al., 1999). Chronic blockade of NMDA or AMPA receptors does not affect the HPA response to any of these stressors. The data suggest a possible role for glutamate in long-term regulation of the HPA axis. In support of this hypothesis, chronic mild stress alters the expression of both ionotropic and metabotropic glutamate receptors; for example chronic mild stress increases expression of mGluR5 in the CA1 region of the hippocampus, whereas expression is decreased in the CA3 region (Wieronska et al., 2001). Recent data from our group indicate that a 2-week chronic variable stress regimen increases GluR5 mRNA expression in the medial parvocellular PVN, consistent with enhanced glutamate signaling through nonNMDA channels. Interestingly, chronic stress reduces NMDA-R2B mRNA expression, while NMDA-R1 and NMDA-R2A subunit mRNAs are not affected (Ziegler et al., 2005). Receptor complexes containing the NMDA-R2B subunit show less calcium permeability than those containing NMDA-R2A (Loftis and Janowsky, 2003); thus, reduction in expression of this subunit at the expense of others also predicts enhanced glutamate excitability.

6 Neuropeptide Systems

6.1 Opioid Peptides

Opioid peptides are known to be important in pain processing in the CNS (Akil et al., 1984). These peptides are richly expressed in numerous PVN-projecting regions and the known inhibitory effects of opioids on synaptic transmission predict an inhibitory role in HPA regulation. In humans, this appears to be the case, as systemic administration of opiate agonists inhibits the HPA axis (Grossman et al., 1982), whereas opiate antagonists are stimulatory (Volavka et al., 1979; Morley et al., 1980; Judd et al., 1981; Grossman et al., 1982; Cohen et al., 1985). However, this does not appear to be the case in rodents, as administration of either opiate receptor agonists (Pfeiffer et al., 1985; Pechnick et al., 1985a, b; Iyengar et al., 1986, 1987; Nikolarakis et al., 1987; Gunion et al., 1991; Eisenberg, 1993) or antagonists (Eisenberg, 1984; Pechnick et al., 1985a, b; Nikolarakis et al., 1987) stimulates the HPA axis. As was the case with glutamate, it is possible that an optimal "opioid tone" needs to be present to permit normal HPA axis function.

6.1.1 β-Endorphin

β-endorphin has an excitatory role in HPA axis regulation. While there is little information regarding the role of opioid peptides on basal/circadian regulation of the HPA axis, several studies indicate that i.c.v. administration of β-Endorphin potently stimulates ACTH (Yamauchi et al., 1997) and corticosterone (Haracz et al., 1981; Iyengar et al., 1987; Gunion et al., 1991) release in a dose-dependent manner that is reversible by systemic naloxone (Haracz et al., 1981; Iyengar et al., 1987; Yamauchi et al., 1997), suggesting that centrally located opioid receptors are responsible for modulation of HPA axis activity. Systemic administration of CRH antiserum blocks β-Endorphin-mediated increases in plasma ACTH and restraint

stress-induced ACTH is inhibited by immunoneutralization of β-endorphin (Yamauchi et al., 1997). While some have argued that β-endorphin stimulates the HPA axis through an action at the μ opioid receptor (Gunion et al., 1991), other studies indicate that β-endorphin activates the HPA axis in a μ and κ opioid receptor-independent manner (Iyengar et al., 1986), and thus the mechanism is currently unclear.

In vitro analyses suggest that β-endorphin may also have inhibitory effects on the HPA axis. β-endorphin has been reported to inhibit release of CRH into the hypophysial-portal circulation in vivo (Plotsky, 1986) and from the hypothalamus in vitro (Buckingham, 1986; Plotsky, 1986; Yajima et al., 1986). Central administration of β-endorphin also attenuates CRH release in the hypophysial-portal circulation during nitroprusside-induced hypertension (Plotsky, 1986), suggesting an inhibitory role of this peptide in stimulating CRH secretion.

6.1.2 Enkephalin

As with the other opioid peptides, little is known about basal/circadian influences of enkephalin peptides on HPA axis function and regulation. Administration of i.c.v. met- or leu-enkephalin increases corticosterone secretion in rats, an effect that is attenuated by pretreatment with naloxone (Gadek-Michalska and Bugajski, 1996). In addition, administration of met-enkephalin i.c.v. potentiates restraint stress-induced plasma corticosterone secretion in rats (Gadek-Michalska et al., 1997) and ether stress-induced plasma corticosterone secretion in mice (Gibson et al., 1979, 1980). However, leu-enkephalin attenuates ether stress-induced plasma corticosterone in mice (Gibson et al., 1980), suggesting the possibility of peptide-specific actions. Met- and leu-enkephalin are reported to increase (Buckingham, 1982) or decrease (Yajima et al., 1986) in vitro CRH release from rat hypothalamic explants in a naloxone-reversible manner. Thus, the majority of studies suggest that enkephalins (particularly met-enkephalin, the major product of the proenkephalin precursor) appear to have an excitatory influence on the HPA axis; however, there are conflicting data in the literature and thus the overall contribution of these peptides remains to be definitively determined.

6.1.3 Dynorphin

Similar to other opioid peptides, dynorphin also appears to mediate an excitatory influence on the HPA axis in vivo, as i.c.v. injections potently stimulate corticosterone secretion (Iyengar et al., 1987; Gunion et al., 1991). It is unclear whether the dynorphin effects on the HPA axis are mediated through opioid receptors, as some groups have reported reversibility with naloxone (Iyengar et al., 1987) while others have not (Gunion et al., 1991). However, like β-endorphin, dynorphin inhibits basal secretion of CRH into the hypophysial-portal circulation (Plotsky, 1986) and basal in vitro release from the hypothalamus (Buckingham, 1986; Plotsky, 1986; Yajima et al., 1986). Furthermore, nitroprusside-hypotension-induced CRH release is decreased by prior i.c.v. administration of dynorphin (Plotsky, 1986). Thus, the impact of dynorphin appears to depend on the experimental preparation employed.

6.1.4 Nociceptin/Orphanin FQ

The role of nociceptin (N)/orphanin FQ (OFQ) in the regulation of the HPA axis is equivocal. Disruption of the N/OFQ gene in mice produces elevated morning plasma corticosterone levels (Koster et al., 1999), while i.c.v. administration of antisense oligonucleotides directed against the N/OFQ receptor decreases AM and PM plasma corticosterone levels in rats (Blakley et al., 2004). Administration of i.c.v. N/OFQ elevates circulating plasma ACTH and corticosterone in a dose-dependent manner, and enhances hormonal responses to mild psychogenic stressors (elevated plus-maze or open field exposure) (Devine et al., 2001; Fernandez et al., 2004), but not to more intense stressors (Devine et al., 2001). However, N/OFQ-deficient mice exhibit elevated plasma corticosterone levels following exposure to elevated plus-maze relative to wild-type littermates (Koster et al., 1999).

6.1.5 Endomorphins

Endomorphins are endogenous opioid peptides with high affinity and selectivity for the μ opioid receptors. I.c.v. administration of endomorphin-1 or endomorphin-2 does not affect plasma corticosterone, CRH, and AVP mRNA expression in the PVN or proopiomelanocortin mRNA expression in the anterior pituitary (Coventry et al., 2001), suggesting that these endogenous opioids do not play an important role in the regulation of the HPA axis.

6.2 CRH and Related Peptides

A considerable body of evidence ascribes a role for CRH in neurotransmission. In particular, central CRH systems are involved in CNS regulation of fear, anxiety, and anorexia (Heinrichs and Richard, 1999; Takahashi, 2001). In addition, several additional CRH-like compounds (urocortins I-III) have been discovered, all of which have actions on the known CRH receptors (CRH-R1 and CRH-R2).

6.2.1 Corticotropin-Releasing Hormone

Notably, the principal receptor for CRH itself is CRH-R1, which is the primary transducer of CRH action at the pituitary. The presence of CRH-R1 receptors in the pituitary largely negates the value of peripheral antagonist treatments in understanding central CRH action and as a consequence, there are relatively few studies that address central CRH actions on the HPA axis.

The role of CRH in promoting ACTH release is well established. However, it is clear that central CRH systems project to PVN neurons (Champagne et al., 1998) and CRH-synapses can be observed in apposition to CRH neurons (Silverman et al., 1989). In addition, CRH-R1 receptors are expressed in the medial parvocellular PVN following stressful stimuli (Imaki et al., 1996), whereas intermediate levels of CRH-R2 are expressed in the magnocellular PVN (Chalmers et al., 1995); these receptors provide a possible substrate for direct or local actions of CRH and related peptides on HPA axis activity.

Studies assessing the role of central CRH in HPA function point toward an important role of synaptic CRH in stress responses. Central injection of CRH elicits the release of ACTH and corticosterone (as well as NE) (Brown et al., 1982; Donald et al., 1983; Kalin et al., 1983) and induces c-Fos and CRH mRNA expression in parvocellular PVN neurons, proving that CRH itself is sufficient to activate the HPA axis, and may exert positive feedback on its own synthesis. Central (i.c.v.) injection of alpha-helical CRH attenuates ACTH responses to a conditioned fear stimulus (Nijsen et al., 2000) and reduces corticosterone (but not ACTH) responses to immune stimulation (Kaneta and Kusnecov, 2005). Central alpha-helical CRH also inhibits PVN induction of c-Fos following restraint stress (Imaki et al., 2001). However, alpha-helical CRH was not sufficient to block ACTH or corticosterone release in a different conditioned fear test (defensive prod burying task) (Korte et al., 1994), suggesting that the role of central CRH in HPA axis function may be related to stressor intensity.

As noted above, the locus of central CRH action on the HPA axis is yet to be determined. While CRH synapses can be localized to the PVN, very few CRH-R1 or R2 receptors are localized to PVN neurons under unstimulated conditions (Potter et al., 1994). Recent evidence suggests that CRH has pronounced physiological and behavioral effects at the level of the LC (Valentino and Van Bockstaele, 2001) and raphe nuclei (Roche et al., 2003). Thus, it is possible that the impact of CRH on the HPA may be transsynaptic.

Central CRH systems may also play a role in development and/or maintenance of chronic stress-induced HPA axis activation. Chronic delivery of CRH into the ventricular system results in marked anorexia, decreased thymus weight, and increased adrenal weight, similar to that seen following chronic stress. Importantly, these effects are not due to leakage of CRH into the portal circulation. The central drive of the HPA by CRH may be drived from any of several sources, including the bed nucleus of the stria terminalis or central amygdaloid nucleus. Importantly, CRH mRNA is upregulated in the former structures following pharmacological doses of glucocorticoids or severe stress, suggesting a possible role for these CRH systems in chronic stress pathologies (Makino et al., 1994a, b; Makino et al., 1999).

6.2.2 Urocortin (I)

Urocortins are homologous to CRH and show a particularly high specificity for CRH-R2. In rats, intravenous (i.v.) administration of urocortin I increases ACTH, corticosterone secretion, and pituitary proopiomelanocortin mRNA, while decreasing CRH-R1 mRNA in the pituitary. However, urocortin effects are almost entirely attributable to the affinity of urocortin for CRH-R1 (Asaba et al., 1998) and it is unlikely that urocortin is a major endogenous regulator of pituitary ACTH secretion (Masuzawa et al., 1999; Turnbull et al., 1999). This conclusion is supported by data from urocortin knockout mice indicating normal basal and stress-stimulated plasma corticosterone levels (Vetter et al., 2002; Wang et al., 2002).

6.2.3 Urocortin II and III

Urocortin II (Reyes et al., 2001) and III (Hsu and Hsueh, 2001) are more recent additions to the CRH-urocortin peptide family. They appear to be exclusive CRH-R2 ligands (Dautzenberg and Hauger, 2002, review; Venihaki et al., 2004).

While Urocortin II and III are localized to regions of brain believed to be involved in stress regulation, available evidence does not indicate an important role for these peptides in HPA axis regulation. Administration of mouse urocortin II and human urocortin III had no effect on ACTH release in mice (Pelleymounter et al., 2004). Mouse urocortin III does not exert any effect on the HPA axis stress response, but stimulates behaviors associated with reduced anxiety (Venihaki et al., 2004). In combination with the selective specificity for CRH-R2, it is possible that these peptides play a role in behavioral but not endocrine aspects of stress responsiveness (Pelleymounter et al., 2004).

6.3 Neurohypophysial Peptides

The neurohypophysial peptides vasopressin and oxytocin are both localized in magnocellular neurons of the PVN, from whence they influence water balance, blood pressure, parturition, and lactation (Hayward, 1975). Both peptides can directly influence ACTH release; in the case of vasopressin, this is largely accomplished via colocalization and corelease with CRH (Whitnall, 1993). A stimulatory influence of oxytocin on ACTH release has been repeatedly documented (Plotsky et al., 1985; Sapolsky et al., 1989; Dohanics et al., 1991); however, oxytocin is not colocalized with CRH in parvocellular neurons, suggesting a contribution of the magnocellular system in HPA axis regulation. The exact nature of magnocellular regulation of ACTH release remains somewhat vague; there is limited evidence for release of neurohypophysial peptides from axons of passage in the internal zone of the median eminence (Holmes et al., 1986), and some suggest that peptides can be diverted into the anterior pituitary portal system by retrograde blood flow. Whatever the mechanism, it is clear that there is an opportunity for the magnocellular system to contribute to HPA axis integration.

6.3.1 Arginine Vasopressin

As noted, the actions of vasopressin on CRH-induced ACTH release are well documented. However, vasopressin also modulates HPA function within the hypothalamus itself. Most notably, microinjections of vasopressin into suprachiasmatic terminal fields in the subPVN region or dorsomedial hypothalamus attenuate elevated corticosteroid levels seen following suprachiasmatic lesions, whereas injections of a vasopressin type 1 receptor antagonist increase HPA axis activity in intact animals (Kalsbeek et al., 1992). Circadian studies indicate that vasopressin release and gene transcription are negatively correlated with circulating corticosterone (Kalsbeek et al., 1996a; Yambe et al., 2002). Together, the data strongly implicate vasopressin in inhibition of basal corticosterone release during the nadir of the circadian cycle. Lesions of the suprachiasmatic nucleus are known to increase corticosterone release following mild stress (Buijs et al., 1993); thus, vasopressin may also play a role in the inhibition of stress responses.

6.3.2 Oxytocin

Oxytocin also modulates ACTH release within the CNS. Intracerebroventricular injections of an oxytocin antagonist attenuate both basal and stress-induced ACTH release (elevated platform or swim) (Neumann et al., 2000a, b). Microdialysis studies indicate that stressful stimuli release oxytocin into the PVN (Nishioka et al., 1998; Neumann et al., 2000b) and retrodialysis of an oxytocin antagonist decreases basal and stress-induced ACTH release (Neumann et al., 2000b), implying an action of local oxytocin on CRH neurons. The local influence of oxytocin may emanate from either axon collaterals of neurohypophysial/preautonomic oxytocin neurons or from local dendritic release of peptide (Ludwig, 1998).

6.4 HPA-Excitatory Neuropeptides

6.4.1 Angiotensin II

Central angiotensin II pathways are implicated in fluid balance and blood pressure regulation (Fitzsimons, 1998). Angiotensin II is richly expressed in the subfornical organ, which has direct projections to the parvocellular PVN (Lind et al., 1984). Central administration of angiotensin II results in a dose-dependent increase in CRH in the portal plasma that is reversed by the angiotensin II receptor antagonist, saralasin (Plotsky et al., 1988). Stimulation of the subfornical organ results in saralasin-reversible activation of CRH release, verifying the physiological relevance of this pathway (Plotsky et al., 1988). However, the nature of angiotensin II modulation of HPA axis function in intact animals is currently unclear; blockade of type I angiotensin receptors attenuates HPA axis responses to isolation stress, but does not affect responses to immobilization.

6.4.2 Cholecystokinin

Cholecystokinin (CCK) is a gut–brain peptide that plays a role in satiety (Smith and Gibbs, 1994). Systemic administration of CCK-A and CCK-B receptor antagonists at the peak of the circadian rhythm does not affect plasma ACTH or corticosterone levels and does not activate c-Fos expression in neurons of the parvocellular PVN (Ruiz-Gayo et al., 2000; Cano et al., 2003). These data suggest that CCK signaling is not involved in regulating the basal activity of the HPA axis.

CCK does not regulate HPA axis activity in response to most types of acute stress. For example, systemic pretreatment with a CCK-A receptor antagonist does not affect the plasma ACTH or corticosterone response to acute forced swim stress in rats (Hernando et al., 1996). Systemic pretreatment with CCK-A or CCK-B receptor antagonists does not affect the plasma ACTH and corticosterone response to systemic IL-1β (Day and Akil, 1999). Similarly, intraparaventricular thalamic nucleus infusions of CCK-B receptor antagonist do not affect the HPA axis response to restraint stress (Bhatnagar et al., 2000). However, CCK signaling does appear to activate the HPA axis in response to acute metabolic stress. Systemic pretreatment with CCK-A but not CCK-B receptor antagonist prevents increases in plasma ACTH and corticosterone in response to acute fasting during the dark period of the circadian rhythm (Ruiz-Gayo et al., 2000). Both CCK-A and CCK-B receptor antagonists attenuate c-Fos expression induced in parvocellular PVN neurons in response to acute fasting (Cano et al., 2003). Moreover, administration of a CCK-A receptor antagonist blocks increases in c-Fos expression in parvocellular PVN in response to 2-deoxyglucose treatment (Cano et al., 2003). Collectively, these data demonstrate that CCK signaling activates the HPA axis during acute metabolic stress.

Central CCK systems may also play a role in modulating HPA axis responses to repeated or prolonged stress. Infusion of CCK-B receptor antagonist into the paraventricular thalamic nucleus increases the plasma ACTH response to novel restraint stress in chronic cold stressed rats, but not euthermic controls, suggesting that during chronic stress CCK-ergic inputs to the paraventricular thalamus are activated and act downstream on the PVN to limit chronic stress-induced facilitation of the HPA axis response to novel stress (Bhatnagar et al., 2000).

6.4.3 Glucagon-Like Peptide-1

Glucagon-like peptide-1 (GLP-1) is an insulinotropic gastrointestinal peptide that is expressed in the central nervous system, where it exerts anorectic actions (Kinzig et al., 2002). GLP-1 is expressed exclusively in the nucleus of the solitary tract (NTS) and ventrolateral medulla (Drucker, 1990; Larsen et al., 1997; Merchenthaler et al., 1999). Notably, despite the rich presence of NE/E neurons in this region, colocalization of catecholaminergic markers and GLP-1 is minimal, indicating that these are mutually exclusive neuronal populations. Nonetheless, like the NE/E systems, GLP-1 containing neuronal fibers heavily innervate the parvocellular PVN (Drucker, 1990; Shughrue et al., 1996; Merchenthaler et al., 1999) and form direct synaptic contacts with CRH-immunoreactive cell bodies (Sarkar et al., 2003).

Several studies implicate GLP-1 in HPA axis regulation. I.c.v. infusions of GLP-1 increase plasma ACTH and/or corticosterone (Larsen et al., 1997; Kinzig et al., 2003), whereas pretreatment with a GLP-1 antagonist attenuates ACTH/corticosterone responses to lithium chloride and elevated platform exposure (Kinzig et al., 2003). Lithium chloride induces c-Fos expression in GLP-1 cells in the NTS (Rinaman, 1999), further supporting a role for endogenous GLP-1 in stress integration. These data suggest that GLP-1 is involved in responses to both psychogenic and systemic stressors. However, GLP-1 receptor knockout mice show an inconsistent phenotype; for example, adrenal weights are reduced, hypothalamic CRH mRNA expression is not altered, and responses to a mild stressor are slightly increased (MacLusky et al., 2000). In chicks, central administration of GLP-1 does not trigger plasma corticosterone secretion (Furuse et al., 1997). Thus, while the results suggest a role for GLP-1 in stress integration in rats, the receptor mechanism and species specificity are yet to be established.

6.4.4 Neuropeptide Y

Central neuropeptide Y (NPY) neurons are implicated in the regulation of energy balance (Woods et al., 1998). Immunoneutralization with NPY antiserum (i.c.v.) does not affect nonstress plasma ACTH and cortisol levels in dogs (Inui et al., 1990), suggesting that NPY signaling does not regulate basal HPA axis activity.

Central administration of NPY (i.c.v. and intraPVN) to rats increases circulating ACTH and corticosterone levels (Harfstrand et al., 1987; Wahlestedt et al., 1987; Leibowitz et al., 1988; Hanson and Dallman, 1995; Sainsbury et al., 1996) and activates c-Fos expression in parvocellular PVN neurons (Li et al., 1994a; Lambert et al., 1995; Xu et al., 1995). Similarly, i.c.v. infusion of NPY activates the HPA axis neuroendocrine response in dogs (Inoue et al., 1989) and sheep (Brooks et al., 1994; Liu et al., 1994). Treatment of hypothalamic explants with NPY in vitro evokes the release of CRH (Tsagarakis et al., 1989; Blasquez et al., 1995). These results demonstrate that NPY has the ability to activate the HPA axis centrally.

Administration of NPY during acute stress facilitates the HPA axis response. For example, central administration (intraPVN or intracisternal) of NPY to rats during anesthesia/surgical stress amplifies plasma ACTH and corticosterone levels and increases CRH protein and mRNA in the hypothalamus (Haas and George, 1987; Wahlestedt et al., 1987; Suda et al., 1993). Furthermore, immunoneutralization with NPY antiserum (i.c.v.) decreases the plasma ACTH and cortisol response to acute hypoglycemia stress in dogs (Inui et al., 1990). Collectively, these data suggest that NPY acts during acute stress to enhance the HPA axis response.

Chronic continuous i.c.v. infusion of NPY produces an initial increase in plasma ACTH and corticosterone that largely normalizes by day 4 of treatment, and results in thymic atrophy (Akana et al., 1996; Sainsbury et al., 1997; Baran et al., 2002). The normalization of basal HPA axis activity during chronic NPY infusion is likely due to glucocorticoid negative feedback as subsequent challenge with acute restraint or cold stress is unable to activate the HPA axis (Akana et al., 1996). Moreover, chronic i.c.v. NPY infusion in rats with limited negative feedback due to clamped levels of corticosterone results in increased morning plasma ACTH before stress, and a facilitated plasma ACTH response to restraint (Akana et al., 1996). These studies demonstrate the ability of NPY to provide prolonged activation of the HPA axis in the absence of negative feedback. Moreover, the data suggest that NPY treatment is not sufficient to mimic chronic stress-induced facilitation of the HPA axis response to novel acute stress.

6.4.5 Neurotensin

Neurotensin appears to activate the HPA axis under both basal and stimulated conditions. While central administration of the neurotensin receptor antagonist SR48692 to rats had no effect on morning ACTH and corticosterone, it was able to attenuate the evening rise in ACTH (but not corticosterone) (Rowe et al., 1997), suggesting the involvement of neurotensin in the evening rise in HPA activity. Importantly, chronic local injection of SR48692 into the PVN region attenuates corticosterone and ACTH response to novelty and restraint (Nicot et al., 1997; Rowe et al., 1997), consistent with a role for neurotensin in mediating HPA responses to psychogenic stressors. Neurotensin antagonist injections also reduce PVN CRH mRNA, which may contribute to the blockade of HPA responsiveness (Nicot et al., 1997). Central administration of neurotensin 1–13 or 8–13 is sufficient to induce the release of ACTH and corticosterone in a CRH-dependent manner (Gudelsky et al., 1989; Rowe et al., 1995), further consistent with a role in HPA excitation.

6.4.6 Vasoactive Intestinal Polypeptide

Vasoactive intestinal polypeptide (VIP) is expressed in the SCN and displays a circadian biosynthetic rhythm that is opposite that of SCN AVP [increased at the end of the light phase (Yang et al., 1993)]. Unlike vasopressin, microinjection into the PVN region stimulates ACTH and corticosterone secretion (Alexander and Sander, 1994). In combination, these data have led some to suggest that SCN VIP may play a role in the circadian rise in HPA axis secretory activity (Kalsbeek et al., 1996b).

6.5 HPA-Inhibitory Neuropeptides

6.5.1 Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) is involved in the regulation of plasma sodium levels and cardiac function (McGrath et al., 2005). There are three known members of the natriuretic peptide family; of these, ANP and C-type natriuretic peptide (CNP) are expressed in the brain (ironically, the third, "brain natriuretic peptide" is not) (Langub et al., 1995; Ryan and Gundlach, 1995). These peptides are somewhat unique, in that they signal through natriuretic peptide A and B receptors that function as guanylate cyclases (NPR-A and NPR-B). ANP appears to play an inhibitory role in central HPA integration. ANP blocks CRH release in vitro (Ibanez-Santos et al., 1990), while i.c.v. application of ANP antiserum attenuates ether-stimulated corticosteroid secretion in rats (Fink et al., 1991). In humans, intranasal application of ANP inhibits ACTH and cortisol responses to insulin-induced hypoglycemia (Perras et al., 2004).

6.5.2 Galanin

The role of galanin in basal HPA axis regulation is unclear. Transgenic mice with either an upregulation of brain galanin or a knockout of galanin have normal serum corticosterone levels (Hohmann et al., 2003). However, in rats, i.c.v. immunoneutralization with galanin antiserum in the morning increases plasma ACTH levels, indicating that galanin normally acts centrally to suppress HPA axis activity at the diurnal nadir (Hooi et al., 1990). Infusion of M40, a galanin antagonist, into the bed nucleus of the stria terminalis does not affect morning nonstress levels of ACTH, suggesting that the suppressive action of galanin at the diurnal nadir occurs at brain sites other than the bed nucleus of the stria terminalis (Khoshbouei et al., 2002). Infusion of galanin into the PVN of rats in the predark period (near the peak of the circadian rhythm) decreases plasma corticosterone, whereas galanin infusions in the prelight period (near the nadir of the circadian rhythm) have no effect on plasma corticosterone, indicating that the exogenous galanin inhibits HPA axis activity and that this activity is linked to the circadian cycle (Tempel and Leibowitz, 1990).

Similarly, acute or chronic i.c.v. infusions of galanin in rats and mice do not affect corticosterone levels near the nadir of the diurnal rhythm (Melander et al., 1987; Smith et al., 1994; Hohmann et al., 2003). The lack of effect of central galanin infusion on plasma corticosterone at the nadir of the rhythm may indicate that galanin suppression of the HPA axis is already maximal, so the addition of exogenous galanin is ineffective.

The ability of acute central infusion of galanin to decrease nonstress plasma corticosterone depends on the time of administration (see above). In contrast, acute central infusion of galanin decreases the HPA axis neuroendocrine response after stress regardless of the time of day. Galanin administration (i.c.v.) to anesthetized rats attenuates surgery-induced increases in plasma corticosterone (Balment and al Barazanji, 1992). IntraPVN infusion of galanin prevents the small increases in plasma ACTH that are observed in saline-infused controls and decreases the plasma ACTH response to ether stress (Hooi et al., 1990). These data suggest that galanin can act in the PVN to suppress HPA axis activation during acute stress. In contrast, infusion of M40, a galanin receptor antagonist, into the bed nucleus of the stria terminalis immediately before immobilization stress decreases the stress-evoked plasma ACTH response, demonstrating that galanin signaling in this region normally acts to facilitate the HPA axis response to acute stress (Khoshbouei et al., 2002). These data suggest that galanin acts differentially at multiple brain sites to modulate HPA axis responses to acute stress.

Galanin-like peptide (GALP), a neuropeptide with sequence homology to galanin, has recently been characterized. Amino acids 9–21 of GALP are identical to the biologically active N-terminal (amino acids 1–13) of galanin. Central administration (i.c.v.) of GALP increases plasma ACTH in a dose-dependent manner, in contrast to the observation of reduced plasma ACTH following galanin infusion (Onaka et al., 2005). GALP has a higher affinity for galanin receptor 1 (GALR1) than for galanin receptor 2 (GALR2), whereas galanin has an equal affinity for the two receptors, suggesting that the opposing effects of these neuropeptides may be due to differential activation of galanin receptor subtypes.

6.5.3 Melanin-Concentrating Hormone

Central administration of melanin-concentrating hormone (MCH) in nonstressed rats produces contradictory results. Some investigators report that i.c.v. and intraPVN MCH infusion in male rats near the nadir of the circadian rhythm activates the HPA axis, increasing both plasma ACTH and corticosterone (Jezova et al., 1992; Kennedy et al., 2003) and augments the number of c-Fos positive neurons in the PVN (Hervieu, 2003). In support of these findings, MCH increases CRH release from hypothalamic explants in vitro (Kennedy et al., 2003). However, others report no effect of MCH administered near the nadir of the diurnal rhythm and suppression of plasma ACTH is observed when MCH is administered near the peak of the circadian rhythm (Nahon, 1994; Bluet-Pajot et al., 1995). Similarly, i.c.v. MCH does not affect plasma corticosterone levels at the nadir of the diurnal rhythm in female rats (Tsukamura et al., 2000). Hypothalamic MCH mRNA displays a diurnal variation that peaks near the end of the lights-on period (Nahon, 1994), suggesting that the ability of exogenous MCH to regulate nonstress HPA axis activity may depend in part on the amount of endogenous MCH present at a particular point in the diurnal cycle.

During acute stress, infusion (i.c.v.) of MCH attenuates HPA axis activation in rats. For example, MCH prevents increases in plasma ACTH and corticosterone after mild handling stress (Ludwig et al., 1998) and blocks the ACTH response to ether stress (Nahon, 1994; Bluet-Pajot et al., 1995). Collectively these results suggest that MCH has a stimulatory effect on the HPA axis during times of low HPA axis activity and an inhibitory effect on the HPA axis during times of high HPA axis activity.

6.5.4 Somatostatin

Central immunoneutralization of somatostatin via i.c.v. or intrahippocampal (CA3 and DG) infusion of antiserum in rats does not affect plasma corticosterone levels near the peak of the circadian rhythm, but prevents dexamethasone-induced suppression of plasma corticosterone (Ferrara et al., 1991). These data

suggest that somatostatin does not modulate the circadian rise of plasma corticosterone, but may mediate glucocorticoid negative feedback, thereby affecting basal HPA axis tone.

Acute central administration (i.c.v.) of somatostatin analogs does not affect plasma ACTH in sheep (Wang et al., 1987) or cortisol in dogs (Miles et al., 1994), whereas chronic intermittent infusion (i.c.v.) of somatostatin analogs decreases plasma ACTH in rats (Starcevic et al., 2000). Moreover, acute central (i.c.v.) infusion of somatostatin analogs attenuates the HPA axis response to acute stress, including (1) inhibition of ether and tail-suspension stress-induced increases in plasma ACTH in rats (Brown et al., 1984); (2) prevention of carbachol-induced increases in plasma cortisol in dogs (Miles et al., 1994); and (3) abolishment of hemorrhage-induced increases in plasma ACTH in sheep (Wang et al., 1987). Lastly, immunoneutralization (i.v.) of somatostatin during anesthesia or handling stress augments the stress-induced increase in plasma corticosterone in cockerels (Cheung et al., 1988). Collectively, these data demonstrate that the somatostatin analogs act to attenuate HPA axis responses during acute stress.

6.5.5 Substance P

Central administration (i.c.v.) of nonspecific neurokinin receptor (NK-R) and specific neurokinin-1 receptor (NK-1R) antagonists to nonstressed rats increases plasma ACTH, plasma corticosterone, and CRH mRNA expression in the medial parvocellular PVN (Larsen et al., 1993; Jessop et al., 2000), suggesting that substance P (SP) exerts tonic inhibitory control over basal HPA axis activity.

Substance P decreases potassium-stimulated release of CRH from in vitro preparations of rat hypothalamus (Faria et al., 1991). I.c.v. or intraPVN infusions decrease plasma ACTH and corticosterone in nonstressed rats (Unger et al., 1988; Saphier et al., 1994; Culman et al., 1995). Central infusion (i.c.v.) of SP also decreases plasma ACTH in rats during stress, including surgical anesthesia (Chowdrey et al., 1990). These data show that SP can act centrally to inhibit HPA axis activity. Intracerebroventricular infusion of an NK-1R specific antagonist prolongs the plasma ACTH and corticosterone response to restraint stress and increases CRH mRNA expression in parvocellular PVN neurons of stressed rats (Jessop et al., 2000). Moreover, systemic treatment with NK-R antagonist increases the plasma ACTH and corticosterone responses to acute ether and cold stress (Malendowicz et al., 1996). These studies demonstrate that SP normally acts to limit HPA axis activation during acute stress.

Substance P signaling may also attenuate HPA axis responses during chronic stress. Systemic treatment with an NK-1R antagonist augments increases in plasma ACTH, plasma corticosterone, and CRH mRNA expression in the PVN during adjuvant-induced arthritis (Chowdrey et al., 1995). Intracerebroventricular infusion of NK-R antagonist similarly enhances plasma ACTH, plasma corticosterone, and CRH mRNA expression in the medial parvocellular PVN of rats given chronic saline treatment (Larsen et al., 1993). These data suggest that SP also acts to reduce HPA axis activation during chronic inflammatory and osmotic stressors.

6.6 Putative Excitatory Neuropeptides

In addition to the neuropeptide systems noted above, there are several neuropeptides that are sufficient to activate the HPA axis upon central injections under unstimulated conditions. As it is not yet clear whether these peptides are necessary for induction of HPA axis responses to stress/circadian drive, it is too early to determine whether they are physiological activators of the HPA axis. These neuropeptidergic systems are noted in *Table 13-1*.

6.6.1 Calcitonin Gene-Related Peptide/Adrenomedullin

Central application (i.c.v.) of calcitonin gene-related peptide (CGRP) to rats increases plasma corticosterone and this effect is blocked by pretreatment with CRH antiserum (Kovacs et al., 1995). IntraPVN

Table 13-1
Neuropeptides Sufficient to Elicit HPA Axis Activation Under Unstimulated Conditions

Neuropeptide	Corticosteroid	ACTH	CRH release	PVN c-FOS	Other
Adrenomedullin		*	*		
AGRP		*	*		
CGRP	*	*	*		
CART	*	*	*	*	*a
CNP		*	*		
Ghrelin	*	*	*	*	
α-MSH†	*	*	*	*	*a,b
Neuropeptide B	*	*	*		
Neuropeptide W	*		*		*c
Orexins (A and B)	*(A>B)	*(A>B)	*(A)	*(A)	*c,d

a, induces CREB phosphorylation in medial parvocellular PVN neurons; b, increases CRH hnRNA expression in PVN; c, depolarizes PVN neurons; d, increases CRH and/or AVP mRNA in PVN. Abbreviations: AGRP, agouti-related peptide; CGRP, calcitonin gene-related peptide; CART, cocaine-amphetamine regulated transcript; CNP, C-type natriuretic peptide; α-MSH, alpha melanocyte stimulating hormone

†α-MSH may also inhibit HPA axis responses to stress: see text

infusion of CGRP increases plasma ACTH and corticosterone (Dhillo et al., 2003). In addition, CGRP treatment of hypothalamic explants in vitro stimulates the release of CRH and AVP (Dhillo et al., 2003). Adrenomedullin (ADM), another member of the calcitonin peptide family, has homology to CGRP and has similar biological activity (Wimalawansa, 1996). Like CGRP, central administration (i.c.v.) of ADM activates the HPA axis, including increases in plasma ACTH and induction of c-Fos in CRH neurons in the medial parvocellular PVN (Shan and Krukoff, 2001; Ji et al., 2004). Collectively, these data demonstrate that central CGRP and ADM can activate the HPA axis, and suggest that CGRP and ADM may be similarly involved in HPA axis activation in response to stress.

6.6.2 Cocaine- and Amphetamine-Regulated Transcript

CRH-positive neurons in the PVN are densely innervated by cocaine- and amphetamine-regulated transcript (CART)-positive nerve fibers (Vrang et al., 2000; Sarkar et al., 2004). Central administration of CART (i.c.v.) induces c-Fos expression and the phosphorylation of CREB in CRH-positive neurons in the medial parvocellular portion of the PVN in rats (Vrang et al., 1999, 2000; Sarkar et al., 2004). CART stimulates the release of CRH from medial basal hypothalamic explants that include the PVN (Stanley et al., 2001). Moreover, i.c.v. administration of CART evokes increases in plasma ACTH and corticosterone (Vrang et al., 2000; Stanley et al., 2001; Baranowska et al., 2004), and intraPVN injection of CART increases plasma ACTH in rats (Stanley et al., 2001). Together, these data demonstrate the ability of central CART to activate the HPA axis and suggest that CART may be similarly involved in mediating the stress response of the HPA axis stress response.

6.6.3 C-type Natriuretic Peptide

Unlike ANP, i.c.v. injection of CNP stimulates ACTH release in sheep (Charles et al., 1992) and decreases hypothalamic CRH levels in the rat (Gardi et al., 1997), suggesting a stimulatory role for this peptide in HPA axis regulation.

6.6.4 Ghrelin

Ghrelin is a recently discovered gut peptide that is expressed in the brain and has a role in energy balance (Horvath et al., 2001). Central application (i.c.v.) of ghrelin to rodents increases plasma ACTH and corticosterone (Wren et al., 2002; Bjursell et al., 2005). Moreover, intraPVN infusion of ghrelin increases the number of c-Fos-positive neurons in the PVN (Olszewski et al., 2003), and application of ghrelin to rat hypothalamic explants evokes the release of CRH and AVP (Wren et al., 2002; Mozid et al., 2003). These data suggest that ghrelin may act centrally to activate the HPA axis and modulate its response to stress.

6.6.5 Melanocortins

Melanocortins are thought to play a major role in central regulation of food intake and body weight (Schwartz et al., 2000). Transgenic mice with disruptions of the melanocortin signaling system, including melanocortin receptor 4 (MC4R) knockout mice (Huszar et al., 1997), and agouti and AGRP overexpressing mice (Graham et al., 1997; Harris et al., 2001) have normal nonstress plasma corticosterone levels. Moreover, acute and chronic central administration (i.c.v.) of MCR nonselective or of MC4R selective antagonists in rats does not affect plasma corticosterone levels (Von Frijtag et al., 1998; Baran et al., 2002; Lu et al., 2003; Cragnolini et al., 2004). Similarly, i.c.v. infusion of [Nle^4,D-Phe^7]-α-MSH (NDP-MSH; a long-acting α-MSH analog) in the morning in rhesus monkeys does not affect plasma cortisol levels (Xiao et al., 2003). These data suggest that the melanocortin system is not involved in regulating the nonstress activity of the HPA axis. However, humans with a heterozygous missense mutation in MC4R (a G to A substitution at codon 103) have higher nonstress salivary cortisol levels in the morning (near the peak of the circadian rhythm) that decrease to normal in the evening, relative to G/G homozygotes, suggesting that alterations in MC4R can affect the basal circadian rhythm of HPA axis activity in humans (Rosmond et al., 2001).

Acute central administration (i.c.v.) of nonselective melanocortin agonists, including α-MSH, $ACTH_{1–24}$, and MTII, increases plasma ACTH and corticosterone in rats (Wiegant et al., 1979; Ludwig et al., 1998; Von Frijtag et al., 1998; Lu et al., 2003; Cragnolini et al., 2004), whereas administration of a selective MC3R agonist does not (Von Frijtag et al., 1998). Activation of the HPA axis by nonselective melanocortin agonists is blocked by cotreatment with MC4R selective antagonists or with MCR nonselective antagonists, suggesting that central activation occurs via actions at MC4R (Von Frijtag et al., 1998; Lu et al., 2003). Central administration (i.c.v.) of α-MSH also modulates PVN activity, increasing phosphorylation of CREB (Sarkar et al., 2002), and induction CRH gene transcription (Lu et al., 2003) in the medial parvocellular PVN. Infusion of NDP-MSH into the PVN increases plasma ACTH and corticosterone, and treatment of PVN-containing hypothalamic explants with α-MSH increases the release of CRH and AVP (Dhillo et al., 2002). Thus, central treatment with melanocortin agonists activates the HPA axis, probably via actions at MC4R.

Conversely, melanocortin signaling appears to attenuate HPA axis responses during acute stress. Transgenic mice overexpressing ectopic agouti protein (an endogenous antagonist of MCR) show increased plasma corticosterone responses to restraint stress (Harris et al., 2001; Karkaeva et al., 2005). In addition, Cragnolini et al. (2004) demonstrated that while i.c.v. infusion of α-MSH evokes increases in plasma corticosterone in rats, infusion of either γ-MSH (a selective MC3R agonist) or lower doses of α-MSH inhibits IL-1β-induced corticosterone release; this inhibition by α-MSH was prevented by cotreatment with MC4R selective or MCR nonselective receptor antagonists (Cragnolini et al., 2004). Similarly, central infusion (i.c.v.) of AGRP, a melanocortin receptor antagonist, in rhesus monkeys increased the plasma ACTH response to IL-1β (Xiao et al., 2003), suggesting that endogenous melanocortin agonists normally act to suppress the HPA axis response to this stressor. Moreover, i.c.v. infusion of AGRP in rhesus monkeys (Xiao et al., 2003) and intraPVN infusion of AGRP in rats (Dhillo et al., 2002) increases plasma ACTH, and treatment of PVN-containing rat hypothalamic explants with AGRP increases the release of CRH and AVP (Dhillo et al., 2002). These data suggest that administration of an exogenous melanocortin receptor

antagonist may act to block endogenous melanocortin receptor signaling, thereby activating the HPA axis. This indicates that endogenous melanocortin signaling normally acts to inhibit the HPA axis or alternatively AGRP may be acting via a currently unidentified melanocortin receptor and/or brain site to activate the HPA axis.

6.6.6 Neuropeptide B

Central treatment (i.c.v.) with Neuropeptide B (NPB) increases plasma ACTH and corticosterone and this hormonal release is attenuated by pretreatment with anti-CRH antiserum (Samson et al., 2004). These data demonstrate that central NPB is capable of activating the HPA axis and suggest that NPB may be similarly involved in HPA axis activation in response to stress.

6.6.7 Neuropeptide W (NPW)

Central administration (i.c.v.) of NPW increases plasma corticosterone (Baker et al., 2003; Taylor et al., 2005). Systemic pretreatment with CRH receptor antagonist attenuates the plasma corticosterone response to centrally applied NPW (Taylor et al., 2005). Moreover, application of NPW to hypothalamic slice preparations depolarizes parvocellular PVN neurons (Taylor et al., 2005). These data demonstrate that NPW can act centrally to activate the HPA axis, possibly via direct actions on hypophysiotropic CRH neurons.

6.6.8 Orexins/Hypocretins

The orexins (hypocretins) are hypothalamic peptides believed to be involved in the regulation of sleep and wakefulness (Siegel, 2004). Central administration (i.c.v.) of orexin A and orexin B increases plasma ACTH and corticosterone in rats; however, the response to orexin A is more robust than the response to orexin B (Hagan et al., 1999; Ida et al., 2000; Jaszberenyi et al., 2000; Kuru et al., 2000; Al-Barazanji et al., 2001; Jones et al., 2001; Russell et al., 2001; Samson et al., 2002; Brunton and Russell, 2003). Moreover, i.c.v. orexin A activates c-Fos mRNA and protein expression (Date et al., 1999; Edwards et al., 1999; Kuru et al., 2000; Sakamoto et al., 2004), and increases CRH and AVP mRNA expression (Al-Barazanji et al., 2001; Brunton and Russell, 2003) in parvocellular cells of the PVN. In vitro application of orexin A depolarizes PVN parvocellular neurons in hypothalamic slice preparations (Samson et al., 2002) and stimulates the release of CRH from hypothalamic explants (Russell et al., 2001). Collectively, these data suggest that orexins may act directly or indirectly on PVN hypophysiotropic neurons to activate the HPA axis.

7 Local Transmission

7.1 Nitric Oxide

Neurons of the PVN express high levels of neuronal nitric oxide synthase and thus have the capacity to signal through generation of NO. A role for this gaseous transmitter in HPA axis integration has been documented (Rivier, 2001). Central administration of the nitric oxide synthesis inhibitor L-NAME attenuates ACTH release following footshock stress (Kim and Rivier, 2000), whereas i.c.v. administration of the NO donor SIN-1 elicits ACTH release in unstressed rats (Seo et al., 2002). Interestingly, the effects of i.c.v SIN-1 can be blocked by immunoneutralization of CRH and AVP (Seo et al., 2002), further suggesting that the central excitatory effects of NO are mediated through release of one or both secretagogues. The fact that SIN-1 induces transcription of the immediate early gene NGFI-B in the medial parvocellular region of the PVN is consistent with this hypothesis (Seo et al., 2002).

7.2 Carbon Monoxide

CO is generated in the CNS by the action of hemoxygenases, which can be localized to neurons of the PVN (Vincent et al., 1994). Intracerebroventricular injections of the hemoxygenase inhibitor protoporhyrin decrease ACTH release, PVN NGFI-B induction, and PVN CRH heteronuclear RNA levels following stress (Turnbull et al., 1998; Kim and Rivier, 2000), all suggestive of an excitatory role for endogenous CO in HPA axis excitation. It should be noted that CO inhibition also caused a small increase in blood pressure, which may or may not be of relevance to the observed diminution of the HPA axis response.

7.3 Endocannabinoids

Endocannabinoids function as retrograde messengers in the brain. Recent data indicate that endocannabinoids act within the PVN to inhibit presynaptic glutamate release and thereby inhibit parvocellular neurons (Di et al., 2003). Endocannabinoid inhibition is triggered by glucocorticoids, suggesting an involvement in fast feedback inhibition of the HPA axis (Di et al., 2003). However, more global manipulations have contrasting effects; systemic administration of the cannabinoid receptor-1 (CB1) antagonist SR141716 inhibits corticosterone release and PVN c-Fos activation following restraint. Central or peripheral injections of the endogenous endocannabinoid anandamide increase PVN c-Fos expression, and elicit ACTH and corticosterone release (Weidenfeld et al., 1994; Wenger et al., 1997). It should be noted that CB1 receptors are widespread in the CNS; thus, it is possible that global cannabinoid manipulations affect upstream circuitry that results in HPA axis activation.

8 Gonadal Steroids

Effects of estrogens, progestins, and androgens on the HPA axis are evident in multiple steroid manipulation models and mediate, at least in part, marked sex differences in HPA axis regulation. In rodents, it is well known that females display higher basal and stress-related HPA activity than males (Kitay, 1961; Critchlow et al., 1963; Le Mevel et al., 1979; Viau and Meaney, 1991; Carey et al., 1995; Figueiredo et al., 2002). Importantly, the enhanced glucocorticoid or pituitary responses to acute stress observed in female rats are particularly pronounced during the proestrous phase of the estrous cycle (Ogle and Kitay, 1977; Viau and Meaney, 1991) and are abolished by ovariectomy (Critchlow et al., 1963; Seale et al., 2004a), highlighting the influence of ovarian steroids on the HPA axis. Females are known to secrete higher levels of corticosteroid-binding globulin (CBG), which can reduce free corticosterone levels. However, it is apparent that CBG differences are not sufficient to negate stress-induced corticosterone surges (McCormick et al., 1995), indicating that females remain hyperesponsive to stress.

8.1 Estrogens/Progestins

The finding that ovariectomy attenuates corticosterone hypersecretion in female rats suggests a stimulatory influence of ovarian steroids on the HPA axis. Indeed, estradiol administration to ovariectomized females enhances basal ACTH secretion (Carey et al., 1995; Viau and Meaney, 1991) and reestablishes the ultradian pattern of corticosterone secretion (Seale et al., 2004b). However, the role of estrogens on stress responsiveness appears to be more complex than previously thought. While early investigations using supraphysiological doses or prolonged (21 days) estradiol regimens demonstrated stimulation of ACTH and corticosterone responses to a variety of stressors (e.g., restraint, footshock, and novelty) (Viau and Meaney, 1991; Burgess and Handa, 1992; Carey et al., 1995), emerging studies using physiological doses or shorter (7 days) estradiol treatments indicate that this steroid inhibits ACTH response (Redei et al., 1994; Young, 1995; Dayas et al., 2000) and decreases or has no effect on corticosterone responses to acute stressors, including restraint or footshock (Redei et al., 1994; Young, 1995).

The mechanisms responsible for estradiol effects on the HPA axis remain poorly understood. While it is clear that estrogens can act at multiple levels of the HPA axis, there is considerable controversy among these studies. For example, while some studies indicate that estradiol stimulates CRH mRNA expression in the PVN (Patchev and Almeida, 1996; Li et al., 2003b), similar to its role in vitro (Vamvakopoulos and Chrousos, 1993), others show that estradiol either decreases PVN CRH peptide/mRNA (Haas and George, 1988; Paulmyer-Lacroix et al., 1996) or has no effect on its transcription (Redei et al., 1994). Here, it is important to note that estrogen receptor ERα expression is lacking in the PVN (Shughrue et al., 1997; Laflamme et al., 1998) and while ERβ is richly expressed in the magnocellular oxytocin and AVP neurons of the PVN, its colocalization with CRH PVN neurons, if any, is very limited (Alves et al., 1998; Hrabovszky et al., 1998; Isgor et al., 2003). These findings suggest that estrogenic effects on CRH-secreting parvocellular neurons occur most likely via nongenomic mechanisms or via transsynaptic inputs, or both.

The role of progesterone in HPA axis activity has not been sufficiently addressed. Although the study by Viau and Meaney (1991) indicated that progesterone inhibits the facilitatory effects of estradiol on ACTH responses to stress, other studies do not find a role for this progestin on the basal or stress-related HPA axis activity (Carey et al., 1995; Young, 1995).

Although relevant to human health, the role of ovarian steroids on chronic stress responses has received little attention. High doses of estrogens potentiated plasma corticosterone secretion and AVP mRNA expression in the PVN of ovariectomized female rats submitted to repeated-restraint stress (Lunga and Herbert, 2004). Interestingly, while estradiol decreased basal CRH mRNA in the PVN of ovariectomized rats compared vehicle-treated animals, it had no effect on that of acute or repeated stressed rats (Lunga and Herbert, 2004), suggesting the presence of additional mechanisms in the stress response of females. Future studies probing the precise involvement of estrogens on chronic stress will be valuable for the understanding and treatment of stress-related pathologies (e.g., major depression and anxiety) that affect women at a higher rate than men.

Overall, a consensus has not yet emerged regarding the impact of estrogens or progestins on CRH neurons. The dissociation between central, estradiol-induced downregulation of CRH, reduced ACTH release under physiological replacement regimens, and possible stimulatory effects at the adrenal suggest that female gonadal steroids influence all aspects of the HPA system.

8.2 Androgens

Several lines of evidence demonstrate that testosterone inhibits basal and stress-induced HPA axis activity in male rats (for review, see Viau, 2002). Under basal conditions, gonadectomized male rats have higher plasma ACTH and plasma corticosterone levels than intact controls, as well as increases in corticosterone pulsatility (Seale et al., 2004a). Similarly, gonadectomized males show higher corticosterone and ACTH responses to numerous stressors, including footshock, novel open field, restraint, noise, or lipopolysaccharide administration than gonad-intact males (Handa et al., 1994; Viau and Meaney, 1996; Seale et al., 2004b). The facilitatory effect of gonadectomizing on HPA axis responses to acute stress is reversed with testosterone or with the nonaromatizable androgen dihydrotestosterone proprionate (DHT) (Handa et al., 1994; Viau and Meaney, 1996; Seale et al., 2004b), indicating that the inhibitory effect of androgens on the HPA axis most likely occurs via an androgen receptor-mediated mechanism.

Gonadectomy enhances AVP, CRH, and GR mRNA expression at the level of the PVN under resting conditions in male rats. Importantly, Viau et al. (1999) demonstrated that, under basal conditions, the activity of the HPA axis is regulated by corticosterone-dependent effects on CRH and testosterone-dependent effects on ACTH in the PVN. For example, gonadectomy blocked the enhanced AVP mRNA, but not CRH mRNA expression in the PVN following adrenalectomy in male rats (Viau et al., 1999). On the other hand, stress-induced PVN activity is regulated by corticosterone and testosterone interactions (Viau, 2002).

Although androgen receptor immunoreactivity is present in the oxytocin- and vasopressin-containing neurons of the medial parvocellular PVN, it is absent in other parts of the PVN including the CRH-containing parvocellular neurons (Zhou et al., 1994; Martini et al., 1996). In addition, very little, if any,

ACTH-secreting cells of the anterior pituitary gland express androgen receptors (Thieulant and Duval, 1985), suggesting that testosterone acts at or above the level of the PVN. Additionally, it is important to bear in mind that testosterone can be metabolized in the brain to DHT and estradiol (Martini et al., 1996; Celotti et al., 1997) and thus may act through estrogen receptors as well.

There is strong evidence to support the idea that testosterone can act at extraPVN sites to modulate HPA axis activity. For example, crystalline testosterone or corticosterone implants in the medial preoptic area, a brain region rich in GR and androgen receptor, reduce plasma ACTH and corticosterone responses to restraint, and decrease AVP but not CRH in the median eminence (Viau and Meaney, 1996). In addition, lesions of the medial preoptic area abolished the inhibitory effects of testosterone on ACTH and corticosterone responses to restraint stress (Viau and Meaney, 1996). Furthermore, systemic testosterone stimulated CRH and AVP mRNA expression in the anterior fusiform and posterior bed nucleus of the stria terminalis, respectively, and enhanced AVP message in the medial amygdala in a glucocorticoid-independent manner (Viau et al., 2001).

It is well established that increased plasma testosterone correlates with dominant behavior and consequently, reduced testosterone levels are related to subordinate behavior. For example, in the visible burrow system, a model of rodent social stress (Blanchard et al., 1995), subordinate male rats are characterized by severe weight loss, decreased plasma testosterone levels, and increased basal levels of corticosterone compared with dominant males (Monder et al., 1994). However, the neural mechanisms relating plasma testosterone levels with social stress remain poorly understood. In one study, a subgroup of subordinate males had impaired corticosterone response to restraint stress and display a lower number of CRH-containing neurons in the PVN compared with dominant males or responsive subordinates (Albeck et al., 1997). Interestingly, AVP mRNA levels did not change with behavioral rank of these animals. In another study (DeGoeij et al., 1992a), subordinate male rats displayed lower testosterone levels and increased AVP-ir but not CRH-ir in the median eminence. As in the case of estrogens and progestins, more studies are needed to unravel the role of testosterone in chronically stressed males.

9 Discussion

The reports summarized above highlight the multiplicity of neurochemical systems involved in HPA axis integration. General features that emerge from this dataset suggest that, while complex, several candidate neurochemical systems can be implicated in various aspects of HPA integration. In addition, it is clear that the involvement of a given neurochemical species in HPA axis regulation is multifaceted; involvement in one aspect of HPA axis regulation does not necessarily imply a role in other functional domains. Regulation of particular aspects of HPA axis function by the various neurochemical systems can be summarized briefly as follows:

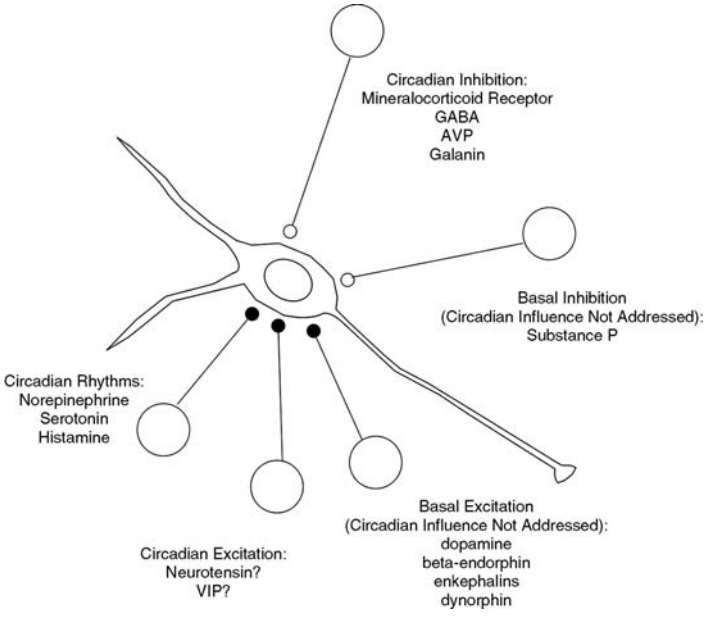
9.1 Basal Regulation of the HPA Axis

Studies involving neurochemical regulation of basal HPA axis (*Figure 13-4*) tone address three major features: circadian secretion across the diurnal cycle, activation of corticosteroid secretion prior to the circadian peak, and inhibition of corticosterone secretion at the trough of the rhythm. Lesion studies provide solid evidence that monoamines are involved in the maintenance of diurnal rhythms. In particular, serotonin has been implicated as a major factor in this process, likely working indirectly through the suprachiasmatic nucleus. The effects of NE on rhythmicity appear to be mediated by the ventral noradrenergic bundle, suggesting that effects can be direct (via PVN) or indirect (via other hypothalamic structures).

Circumstantial evidence implicates vasoactive intestinal peptide circadian drive of the HPA axis. Effects of VIP would likely be mediated by neurons in the suprachiasmatic nucleus. Neurotensin may also play a role in this process, as antagonism of neurotensin receptors blocks the evening rise in ACTH in the rat; however, no effects on evening corticosterone secretion were seen, making the interpretation of these data somewhat unclear.

Figure 13-4

Neurochemical systems mediating basal tone of the HPA axis. Basal function of the HPA axis is characterized by a marked circadian rhythm in glucocorticoid and to a lesser extent, ACTH release. Circadian secretory rhythms appear to be mediated by noradrenergic and serotonergic systems. Orphanin FQ has also been implicated in this process. GABAergic, galaninergic and vasopressinergic (AVP) systems are associated with generation of the circadian trough in glucocorticoid secretion; one or more of these systems may be communicating corticosteroid feedback information driven by the mineralocorticoid receptor. In addition, dopamine and opioid peptides are implicated in basal HPA axis excitation, whereas substance P may be inhibitory; the role of these systems in circadian rhythms has not been definitively established



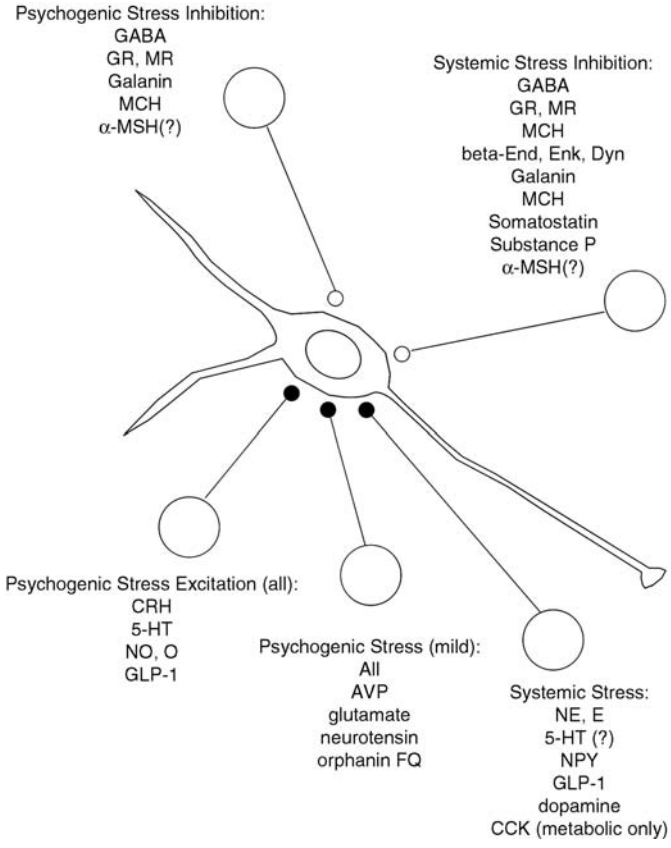
Several factors are implicated in basal HPA inhibition, determined from studies indicating that damage or receptor blockade can result in elevated basal corticosterone at the circadian nadir. Not surprisingly, GABA, a primary inhibitor of the HPA axis, is prominent among these. A series of studies by Buijs' group indicate that AVP is an inhibitor of circadian secretion in the morning (Kalsbeek et al., 1992, 1996a, b); interestingly, AVP actions appear to involve the subPVN region and dorsomedial hypothalamus, both GABA-rich regions. Thus, it is plausible that AVP actually exerts its effect by way of PVN-projecting GABAergic neurons. Substance P also plays a major role in basal inhibition of parvocellular CRH neurons, likely through projections from regions such as the bed nucleus of the stria terminalis, dorsomedial nucleus, and lateral hypothalamus (Bittencourt et al., 1991); again, these are known to be major sources of GABAergic innervation to the PVN. Finally, a number of studies implicate the MR as a steroidal mediator of basal inhibition; the site at which glucocorticoid binding to MR regulates basal tone is yet to be established.

9.2 Acute Stress Excitation

The above reports indicate that two major issues need be considered in defining factors important in HPA axis activation: modality and intensity (*Figure 13-5*). The former concept fits into current notions dividing stressors into "psychogenic" and "systemic" categories (Herman and Cullinan, 1997; Sawchenko et al., 2000; Dayas et al., 2001a; Herman et al., 2003), while the latter indicates that the "psychogenic" category should be subdivided according to intensity.

Figure 13-5

Neurochemical systems mediating excitation and inhibition of the acute stress response. Different neurochemical systems appear to be responsible for stressor modality-specific excitation and inhibition of the HPA axis. Norepinphrine (NE) and perhaps epinephrine (E) appear to be selectively involved in HPA axis responses to systemic stressors. There is also some evidence to suggest a role for serotonin (5-HT) in this process. Neuropeptide Y (NPY), glucagon-like peptide 1 (GLP-1), nitric oxide (NO), carbon monoxide (CO), and dopamine also mediate systemic stress responses, while the influence of CCK seems to be limited to metabolic stimuli. Serotonin, NO, CO, and GLP-1 are also involved in communicating responses to psychogenic stressors of various intensity and may be ubiquitous initiators of HPA to all stress modalities. Glutamate, AVP, orphanin FQ, and angiotensin II appear to be selectively involved in activation of the HPA axis by ''mild'' stressors. Stress inhibition is mediated by glucocorticoid information from MR and GR-sensing cells and by GABAergic, galaninergic, and melanin concentrating hormone systems. The latter systems inhibit both systemic and psychogenic stress responses. Systemic stress responses are also mediated by opioid peptides [beta-endorphin (beta-End), enkephalins (Enk) and dynorphin (Dyn)] and substance P



9.2.1 Psychogenic Stress (Mild)

Several reports have emerged that indicate that some neurochemical systems appear important in activating responses to mild stress (e.g., novelty), but have no influence on more "severe" stressors (e.g., restraint, footshock). Systems falling into this category include glutamate, AVP, OFQ, and angiotensin II. These systems may thus be involved in setting the threshold of psychogenic stress responses.

Interpretation of the case for glutamate requires some caveats. The data supporting selective involvement of glutamate in mild stress employ i.c.v. administration of antagonists. Glutamate is a fairly ubiquitous transmitter and is present in both excitatory and inhibitory stress circuits in the brain. In addition, data from our group have shown that corticosterone responses to restraint are blocked by intraPVN injection of the pan-ionotropic glutamate receptor antagonist kynurenic acid, whereas injections immediately outside the PVN exacerbate stress responses (Ziegler and Herman, 2000). Thus, the ability of global delivery of antagonist to modify the activity of both positive and negative inputs indicates that high-resolution methods are required to fully define the role of glutamate in stress integration.

9.2.2 Psychogenic Stress (General)

Several different systems are implicated in psychogenic stress activation: serotonin, NO, CO, prostaglandins, GLP-1, and perhaps, NE originating in the LC. In the case of GLP-1, excitation is likely derived from direct PVN projections from the NTS. Serotonin is a bit harder to pin down, as both the PVN and the GABA-rich PVN surroundings are in receipt of serotonin afferents; wherever the locus of action, it is clear that local serotonin release is involved in HPA axis activation. Interestingly, the gaseous transmitters are likely generated in the PVN region itself, emanating either from the parvocellular neurons themselves, from neighboring magnocellular neurons or even from blood vessels. These data suggest a "feed-forward" mechanism whereby these factors can reinforce an initiated response. Finally, there are some data implicating the LC in activation of the HPA axis; this is likely mediated through extraPVN NE actions on other forebrain stress circuits.

9.2.3 Systemic Stress

The most notable difference between systemic and the aforementioned psychogenic class of stressor is the prominent involvement of NTS or ventral medullary NE and/or E in the former. Indeed, there is convincing evidence that lesions that severely compromise PVN NE levels have little effect on psychogenic stress responses (Pacak et al., 1993). Thus, it is likely that the ascending NE systems from the NTS and perhaps the ventrolateral medulla, are differentially sensitive to stimuli that signal internally driven homeostatic disruption (e.g., blood loss, respiratory distress, infection). This contrasts with the neighboring, yet distinct GLP-1 system, which is involved in both psychogenic and systemic stress integration.

NPY also plays a role in HPA axis responses to systemic stress. The source of PVN NPY appears to be divided between the arcuate nucleus and NTS. Given that NPY is colocalized with NE in the NTS (Hokfelt et al., 1987), it is tempting to speculate that the excitatory effects of NPY are mediated through this circuit.

As was the case with psychogenic stress, the gaseous transmitters NO and CO are stress-excitatory. Given the sensitivity of these systems to cytokines, these systems may be important in activation of the HPA by inflammatory stimuli.

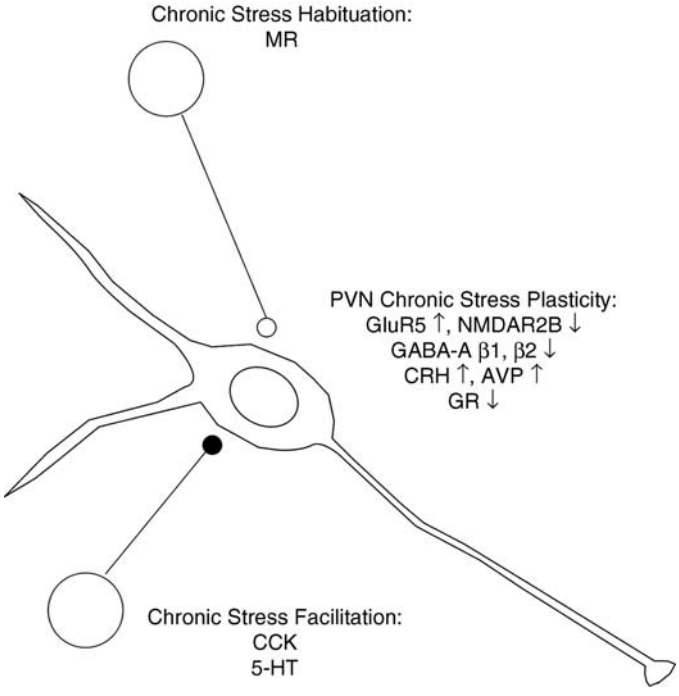
9.3 Acute Stress Inhibition

In contrast with activational circuitry, differential inhibition of psychogenic versus systemic responses has not been extensively assessed. Thus, the designation in *Figure 13-3* indicates the contexts in which the agents have been studied, rather than reflecting direct comparison among stressors (*Figure 13-6*).

In cases where both classes of stressors have been studied, it is apparent that, not surprisingly, GABA inhibits HPA axis responses to both modalities. These data are in keeping with the preponderance of GABA innervation to the PVN (Decavel and Van Den Pol, 1990), the presence of ample GABA-A receptors in CRH neurons (Cullinan, 2000), and the documented direct influence of GABA on the PVN (Cullinan, 1998; Cole and Sawchenko, 2002). The rich network of systems supplying GABAergic terminals to the PVN affords inhibition at multiple levels through multiple pathways.

Figure 13-6

Neurochemical systems mediating chronic stress responses. Systems responsible for drive of the HPA axis by chronic stress are currently unknown; ascending NE from the locus coeruleus system and central CRH neurons may play a role in this process. The process of chronic stress facilitation appears to involve serotonergic and CCK-ergic systems, whereas habituation is subject to control by MR. The neurochemical phenotype responsible for MR inhibition has yet to be determined. Chronic stress-induced hyperfunction of CRH neurons may be mediated by alterations in the PVN itself; both CRH and AVP are increased in CRH neurons, and GR mRNA is decreased, suggesting possible reduction in feedback. In addition, expression of GABA-A receptor subunit expression is reduced in the medial parvocellular PVN, consistent with reduced GABA signaling, whereas glutamate receptor subunit mRNA expression is altered in such a manner as to predict enhanced excitability (GluR5 is increased, NMDAR2B is decreased relative to NMDAR2A)



Like GABA, the neuropeptides galanin, MCH, and SP inhibit responses to both psychogenic and systemic stressors. Galanin is present in numerous circuits innervating the PVN, notably including the dorsomedial hypothalamus and the PVN itself, whereas MCH is present in nearby dorsal hypothalamic regions. Both areas project directly to the PVN and are rich in GABA neurons. In addition, PVN-projecting SP neurons are localized in the bed nucleus of the stria terminalis, dorsomedial hypothalamus, and lateral hypothalamus, all of which are rich in GABAergic neurons. Together, these data raise the possibility that these peptides may be released in conjunction with GABA.

There is some evidence to support an inhibitory effect of testosterone on HPA axis stress responses, elaborated through the medial preoptic area (Viau and Meaney, 1996). Once again, these effects may be mediated by PVN-projecting GABAergic systems in this region.

Finally, it is clear that glucocorticoids play multiple inhibitory roles in HPA integration. First, fast feedback effects are apparent at the level of the PVN, mediated by an as yet to be determined receptor. This receptor has been demonstrated in vitro; this hypothesized mechanism is yet to be tested in vivo. Second, central injections of the GR and MR antagonists prolong HPA axis responses to novelty and GR blockade

enhances peak responsiveness, indicating that both nuclear receptors act to inhibit HPA responses, probably through transcriptional mechanisms. Finally, a wealth of systemic injection studies using agonists and antagonists indicate glucocorticoid inhibition of the HPA axis; however, it is important to consider that peripheral injections do not readily distinguish central from pituitary actions of glucocorticoids. In this regard, it is important to note that recent studies suggest that central corticosterone injections can actually increase ACTH release (Tanimura and Watts, 1998; Laugero et al., 2002), suggesting that glucocorticoids can have central facilitatory actions on the axis.

9.4 Chronic Stress Regulation

Despite a wealth of data indicating that chronic stress elevates biosynthetic and probably secretory activity of hypophysiotrophic PVN neurons, the precise neurochemical systems mediating this action remain to be determined. Circumstantial evidence implicates GABAergic and glutamatergic signaling in this process, as PVN GABA-A and nonNMDA receptor subunit expression are altered in a way that predicts enhanced excitability of CRH neurons (Cullinan, 1998; Ziegler et al., 2005). Downregulation of PVN or upstream limbic GRs may also be involved in enhanced HPA activation, through the release of glucocorticoid negative feedback.

Repeated exposure to a given stressor can result in marked habituation of the HPA axis response. This habituation appears to be heavily influenced by glucocorticoids acting through the MR. Notably, chronic stress exposure also produces HPA axis facilitation, whereby the HPA axis response to a novel stressor is enhanced. Facilitation occurs regardless of whether the chronic stress protocol involves repeated exposure to a single stress (c.f., Akana et al., 1992) or random exposure to a variety of different stressors (chronic variable stress) (Herman et al, unpublished observations). The process of facilitation appears to be under the control of CCK circuits at the level of the paraventricular thalamus (Bhatnagar and Dallman, 1998).

9.5 Other HPA Modulators

There are considerable data implicating various neurochemical systems in HPA regulation by virtue of the ability of i.c.v. injection to activate corticosterone or ACTH release and/or CRH neurons. Many of these have not been examined extensively with respect to effects on basal drive, acute stress, or chronic stress, and thus the overall relevance remains to be determined. It is important to realize that all these are important candidates that may be worthy of future attention.

In addition, it is also clear that several neuropeptide systems have mixed effects on HPA axis function. For example, α-MSH has opposite effects on basal (excitatory) versus stress-induced (inhibitory) HPA activity. Similarly, opioid peptides activate the HPA axis under basal conditions, but can have both stimulatory and inhibitory effects on stress-induced secretion. Thus, the impact of these two neuropeptidergic systems on HPA axis function appears to be context-dependent.

10 Summary

Overall, it is apparent that multiple neurochemical systems combine to regulate basal HPA axis tone, activation and inhibition. The neurochemical regulatory data add weight to connectional data linking the suprachiasmatic nucleus to the control of circadian corticosteroid rhythms; the brainstem to the control of systemic stress processing; and the limbic system to the control of psychogenic responses. Riding atop these generalized pathways are modality and intensity characteristics that are likely communicated differentially by various sensory and associational circuits, and summated at the PVN from the array of input from multiple neurochemical sources. Neurochemical control of chronic stress remains unresolved; it is likely that glucocorticoid-related information is a determining factor in the seemingly counterintuitive ability to maintain or even facilitate HPA axis function in a high-stress environment, but the pathways to this end are

far from clear. Given that chronic stress likely lies at the center of human stress-related dysfunction, an understanding of the mechanism of maladaptive HPA axis responses in chronic stress will be important in the development of new treatments and strategies for intervention in affective disease states, psychosis, and drug addiction.

5 Conclusion 588

Abstract: The response to stress involves the active release of hormones and other mediators that produce adaptation in the aftermath of acute stress (allostasis) and yet can lead to pathophysiology when the same mediators are not shut off or are dysregulated over weeks and months (allostatic load). The brain is the key organ of stress since it interprets what is potentially threatening and therefore stressful and it determines the behavioral and physiological responses of the individual. Behavioral responses include fighting or fleeing, eating too much of the wrong things, smoking, drinking and losing sleep at night. Behavioral responses may also include health promoting behaviors such as regular moderate exercise. Hence lifestyle and behavior are key contributors or "being stressed out" and hence to allostatic load. The brain also is a target of stress and remodeling of dendrites and formation or down-regulation of synapses is a key aspect. In hippocampus and prefrontal cortex, repeated stress causes dendrites to shrink and spine synapses to decrease in number whereas in basolateral amygdala stress causes increased dendritic branching and synapse density. Mediators of structural remodeling include not only adrenal steroids but endogenous neurotransmitters, neurotrophins, the extracellular protease, tissue plasminogen activator, and cell surface adhesion molecules. Remodeling of neural circuitry under repeated stress leads to impaired memory, increased anxiety and aggression and impaired attention. Changes of this type may occur in depression and anxiety disorders.

List of Abbreviations: ADX, adrenalectomy; EAA, excitatory amino acids; LTP, long term potentiation; LTD, long term depression; PBP, primed burst potentiation; GRE, glucocorticoid response element; NMDA, N-methyl-D-aspartate; HPA, hypothalamo-pituitary-adrenal; CRF, corticotrophin releasing factor; AVP, arginine vasopressin; Acg, anterior cingulated; PL, prelimbic; IL, infralimbic; CE, central amygdala; B, basal amygdala; AB, anterior basal amygdala

1 Introduction

We all think we know what stress is, but it is still difficult to define it. For the purposes of this chapter, we define stress as a "threat, real or implied, to homeostasis," and we define stress response as involving both behavioral (e.g., "fight or flight") and physiological (i.e., neuroendocrine, autonomic, and immune) responses. In reality, stress is a word we give to the challenges to an organism of many kinds, whether physical (temperature, physical exertion, trauma) or psychological (surprise of the unexpected, threat of danger, defeat). But in fact, the physiological systems that respond to physical and psychological stressors are called into play during virtually every moment of the day, and are closely linked to biological rhythms of sleep and waking, and to the day—night cycle and patterns of feeding, and physical activity. As a result, we introduce two terms, allostasis and allostatic load, which focus attention on the physiological systems that respond to stressors with two, somewhat paradoxical, outcomes, namely, they help an organism to adapt in the immediate aftermath of a challenge but are also involved in damage and pathophysiology when they are overused or dysregulated.

Besides physiology of adaptation, the word stress often implies psychological factors such as frustration, exhaustion, fear, anger, and hostility (as in being "stressed out"), which are products of the activity of the nervous system. Consequently, we discuss brain areas such as the amygdala, hippocampus, and prefrontal cortex, which are involved in processing emotions and emotional memories, and which also regulate output of the physiological systems of allostasis and allostatic load. We discuss how these brain regions are altered by acute and chronic stress and how these changes, in turn, contribute to physiological and behavioral responses to stressful events, culminating in successful adaption, on the one hand, and mood and anxiety disorders, on the other hand, that have consequences for physical as well as mental well-being. The purpose of this chapter is, therefore, to integrate the behavioral and physiological aspects of allostasis and allostatic load into a seamless interaction between the nervous system and the neuroendocrine, autonomic and immune mediators that operate throughout the whole body.

2 The Response to Stress: Neuroendocrinology and Neurochemistry

2.1 Allostasis and Allostatic Load

When a stressful event occurs, the initial response of the brain, body, and behavior is a protective one, and hormones, cytokines, and other mediators, such as the neurotransmitters, are used to survive and to adapt to the challenge. Many functions are enhanced by acute stress, including aspects of memory, immune function, and metabolism. However, repeated stressful experiences can have deleterious effects, in part because the very same mechanisms that help protect in the short run are now either mismanaged and/or overused (McEwen, 1998). And, over weeks, months, and years, the dysregulation and overactivity of these systems can promote changes that appear to be deleterious. The following examples illustrate the paradox of protection versus damage.

For the *immune system*, acute stress promotes immune function by enhancing movement of immune cells to places in the body where they are needed to defend against a pathogen; yet, chronic stress suppresses immune function and uses the same hormonal mediators to suppress immune function (Dhabhar and McEwen, 1999). Thus, animals that evade a predator but are injured have the acute enhancement of immune function to help heal wounds and fight infections.

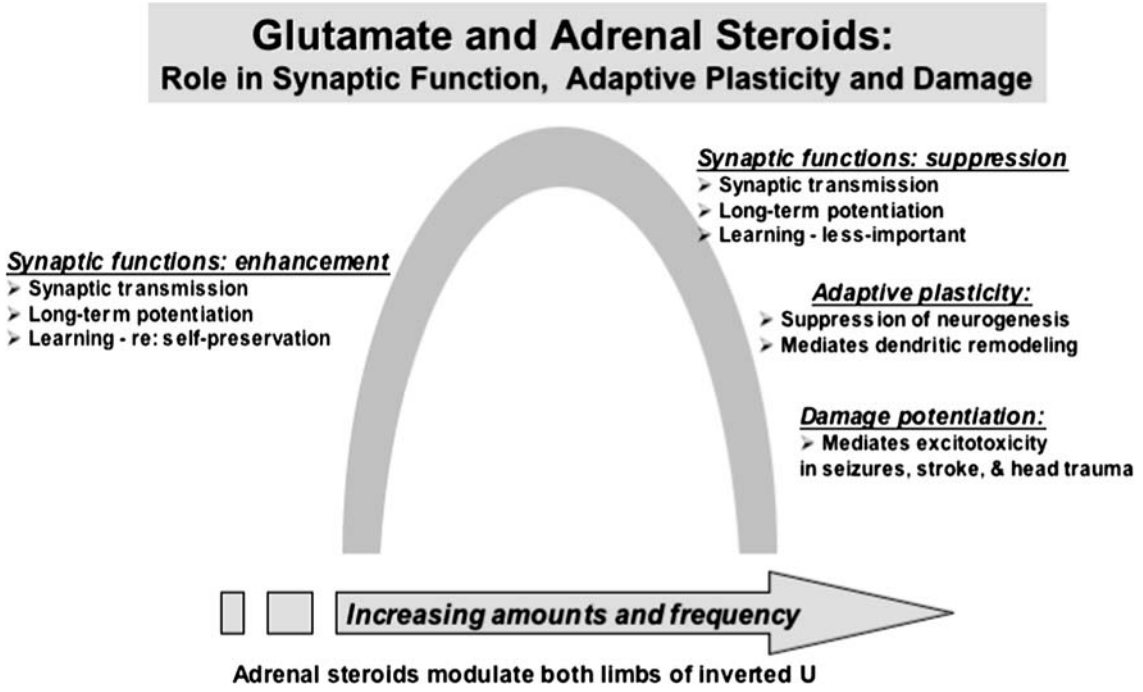
For the *cardiovascular system*, we see a similar paradox. Getting out of bed in the morning requires an increase in blood pressure and a reapportioning of blood flow to the head so we can stand up and not faint (Sterling and Eyer, 1988). Blood pressure rises and falls during the day as physical and emotional demands change, providing adequate blood flow as needed. Yet, repeatedly elevated blood pressure promotes generation of atherosclerotic plaques, particularly when combined with a supply of cholesterol, lipids, and oxygen-free radicals that damage the coronary artery walls (Manuck et al., 1995). Beta adrenergic receptor blockers are known to inhibit this cascade of events and to slow down the atherosclerosis that is accelerated in dominant male cynomologus monkeys exposed to an unstable dominance hierarchy (Manuck et al., 1991).

For *metabolism*, the paradox is also evident. Glucocorticoids, so named because of their ability to promote conversion of protein and lipids to usable carbohydrates, serve the body well in the short run, by replenishing energy reserves after a period of activity, like running away from a predator. Glucocorticoids also act on the brain to increase appetite for food, and to increase locomotor activity and food seeking behavior (Leibowitz and Hoebel, 1997), thus regulating behaviors that control energy input and expenditure. This is very useful in manual labor or in playing active sports, but it is not beneficial when we grab a pizza and a beer while watching television or writing a paper, particularly when these activities may also be generating psychological stress—e.g., watching distressing news or worrying about getting the paper done in time. Comfort foods appear to reduce anxiety by reducing activity of the hypothalamic-pituitary-adrenal (HPA) axis and subsequently reducing activity of the anxiogenic corticotropin-releasing hormone (CRH) system of the amygdala (Dallman, 2003). Inactivity and lack of energy expenditure creates a situation in which chronically elevated glucocorticoids that may result from either poor sleep, ongoing stress, or as side effects of excessive intake of "comfort food" impedes the action of insulin to promote glucose uptake. One of the results of this interaction is that insulin levels increase and, together, insulin and glucocorticoid elevations promote the deposition of body fat, and this combination of hormones also promotes the formation of atherosclerotic plaques in the coronary arteries (Brindley and Rolland, 1989). Thus, whether psychological stress, sleep deprivation, or a rich diet is increasing the levels of glucocorticoids, the consequences in terms of allostatic load are the same—insulin resistance and increased risk for cardiovascular disease. Thus, catecholamines and a combination of glucocorticoids and insulin can have dangerous effects on the body, besides their important short-term adaptive roles (Brindley and Rolland, 1989).

Finally, *in brain*, the normal activity of stress hormones and excitatory amino acid (EAA) neurotransmitters promotes memory and synaptic plasticity; yet somewhat higher, acute levels of glucocorticoids can inhibit synaptic plasticity and promote long-term depression (LTD), as is described later in this article. See *Figure 14-1*, which depicts this relationship as an inverted U. Moreover, as also depicted in *Figure 14-1*,

Figure 14-1

Adrenal steroids and the excitatory amino acid (EAA) neurotransmitter, glutamate, play a synergistic role in synaptic functions, adaptive plasticity, and damage in the hippocampus and possibly in other brain regions. The intensity and duration of the activation of the HPA axis and the EAA system determines which of the outcomes will occur. The downward limb of the inverted U includes 3 levels of effect, beginning with acute and transient effects on synaptic function and then leading to chronic effects that produce adaptive plasticity. Finally, overstimulation of the HPA axis and EAA system in head trauma, seizures, and ischemia leads to permanent damage in which EAA and glucocorticoids also participate



prolonged overactivity of stress hormones in the blood and EAA in the brain suppresses neurogenesis in dentate gyrus (DG) and causes debranching of dendrites in hippocampus and medial prefrontal cortex, whereas chronic stress causes neurons in amygdala to show dendritic growth (McEwen, 1999), as we summarize later in this chapter (Sousa et al., 2000; Wellman, 2001; Vyas et al., 2002). Furthermore, the inverted U depicted in *Figure 14-1* has a more sinister aspect, in that extreme overactivity of stress hormones and EAA in head trauma, seizures, and stroke causes permanent damage and cell loss in the hippocampus (Sapolsky, 1992).

The hippocampus contains receptors for adrenal steroids, which regulate excitability and morphological changes. Along with many other brain regions, the amygdala and the prefrontal cortex also contain adrenal steroid receptors, which influence function in this structure as well, along with other tissue mediators such as extracellular proteases, neurotrophins, and neurotransmitters, as are summarized in Section 3. However, because adrenal steroids have led the way in the understanding of stress effects on the brain and body, we emphasize their role in both allostasis and allostatic load, recognizing that they are but one of a system of interacting mediators.

2.2 Adrenal Steroids and Their Receptors and Effects

2.2.1 Adrenal Steroid Receptors and Effects on Excitability and Neurochemistry

Adrenal steroids modulate the excitability of hippocampal neurons, as illustrated by the phenomenon of long-term potentiation (LTP) (Bliss and Lomo, 1973). A single burst of high-frequency stimulation to hippocampal afferents immediately alters the responsiveness of neurons to subsequent acute stimulation, an effect lasting from over many hours to days. A number of recent studies on the hippocampal CA1 field and the dentate gyrus have demonstrated that acute stress and acute glucocorticoid elevation produce an impairment in LTP or its close relative, primed-burst potentiation, PBP (Diamond et al., 1992, 1994; Pavlides et al. 1993). There is a U-shaped dose response curve, with low levels of corticosterone facilitating PBP and high levels inhibiting PBP in the CA1 region (Diamond et al., 1992). See *Figure 14-1*. In both the dentate gyrus and CA1 and CA3 fields, LTP can be modulated rapidly (within 1 h) and biphasically by adrenal steroids acting, respectively, via Type I and Type II receptors (Pavlides et al., 1995a, b, 1996). Moreover, in awake, freely moving adrenalectomized (ADX) rats, the enhancement of LTP by the Type I receptor agonist, aldosterone, lasts for at least 24 h, at which time it is still markedly higher than that found in ADX rats given only vehicle treatment before LTP induction (Pavlides et al., 1994).

Regarding how these biphasic effects come about, it is very likely that principal neurons in dentate gyrus and Ammon's horn contain both types of receptors, considering the distribution of mRNA, immunocytochemical reactivity, and binding for Type I and Type II adrenal steroid receptor subtypes (Herman et al. 1989; van Steensel, 1995). In studies on pyramidal neurons of the CA1 region, adrenal steroids have been shown to act via Type I and Type II adrenal steroid receptors to maintain and modulate excitability of hippocampal neurons (Beck et al., 1994; Joels and De Kloet, 1994; Birnstiel and Beck, 1995). Type I receptor activation in hippocampus from ADX rats is associated with reduced calcium currents through voltage-gated channels, reduced responses to serotonin via 5HT-1A receptors and to carbachol via muscarinic receptors and stable responses to synaptic inputs involving excitatory and inhibitory amino acids (Hesen and Joels, 1996a, b). Additional activation of Type II receptors causes increased calcium currents and enhanced responses to EAA, serotonin and carbachol (Joels and De Kloet, 1994; Joels, 1997), and very high levels of Type II receptor activation markedly increases calcium currents (Kerr and Campbell, 1992), and also leads to increased NMDA receptor expression on hippocampal neurons (Weiland et al., 1995). Acute stress also increases NMDA R1 mRNA but decreases AMPA receptor subunit A mRNA levels without affecting mRNA levels of subunits B and C (Bartanusz et al., 1995). Kainate receptor mRNA levels were also affected by acute corticosterone treatment, with low dose occupancy of Type I receptors increasing mRNA levels for kainate receptor 1 and 2 and also for the GluR7 subunit of the AMPA receptor and high dose occupancy of Type II as well as Type I receptors reversing this effect (Joels et al., 1996). Besides these effects,

specific Type I and Type II agonists given to bilaterally ADX rats produce a variety of other effects on various aspects of gene expression in hippocampus associated with neurotransmission (Lupien and McEwen, 1997).

What is surprising about these nonoverlapping actions of Type I and Type II receptors on gene products in hippocampus is that they defy the classical model of adrenal steroid receptor action via a common glucocorticoid response element (GRE) (Evans and Arriza, 1989) and point to a different and possibly more complex mode of mineralocorticoid and glucocorticoid regulation of gene expression (Miner and Yamamoto, 1991; Reichardt and Schutz, 1998). It should be noted that the regulation of preprotachykinin A gene mRNA levels in rat forebrain regions does follow the predictions of the classic GRE in that both Type I and Type II agonist treatments of ADX rats elevate mRNA levels for this neuropeptide (Pompei et al., 1995).

The fact that Type I and Type II adrenal steroid receptor activation has been characterized separately in ADX rats using selective agonists raises the question of what happens when both receptors are activated simultaneously over the physiological range of corticosterone. Under such conditions it is necessary to consider Type I/Type II receptor heterodimers (Trapp et al., 1994), and those of other comodulators of steroid-regulated gene expression such as immediate early genes (see later). This is important, because we have noted that hippocampal neurons in Ammon's horn and dentate gyrus express both types of receptors, and it remains to be seen how different the consequences of combined receptor activation are from the information summarized using selective Type I and Type II receptor agonists and antagonists.

Another issue to be resolved is the extent to which pyramidal neurons and granule neurons show similar molecular responses to adrenal steroids in affecting their excitability. There is also the unanswered question whether neurons in other brain regions, such as amygdala and prefrontal cortex (discussed later) also respond in the same ways to adrenal steroids. From the standpoint of LTP, the biphasic actions of adrenal steroids in dentate gyrus and Ammon's horn occur in pathways using NMDA receptors and not in the mossy fiber non-NMDA pathway (Pavlides and McEwen, 1999). The question whether there is commonality of adrenal steroid effects on NMDA receptor expression, on calcium channel activity, and on the sensitivity to carbachol and to serotonin via 5HT1A receptors (discussed earlier) is therefore an important issue when looking at different brain regions.

2.2.2 Adrenal Steroid Metabolism as a Control Point for Glucocorticoid Actions

Glucocorticoids such as cortisol and corticosterone are converted to the 11-dehydro form by 11-hydroxysteroid dehydrogenase-2 and the products, cortisone and 11-dehydrocorticosterone, are converted back to the parent glucocorticoids by 11-hydroxysteroid dehydrogenase-1 (Funder et al., 1988; Seckl and Walker, 2001). Each enzyme has differential expression in various tissues. 11-HSD-1 is very prominent in the liver and overexpression of this enzyme in liver leads to obesity (Masuzaki et al., 2001). 11-HSD-2 is expressed in kidney collecting tubules and inactivates cortisol and corticosterone to prevent continual sodium reabsorbtion and hypertension, which occurs after blocking 11-HSD-2 by glycyrrhetinic acid, a constituent of licorice (Funder et al., 1988). 11-HSD-2 expression is low in brain whereas 11-HSD-1 expression is measurable in the brain (Sandeep et al., 2004). Knockout of 11-HSD-1 in mice results in a slower rate of brain aging with respect to memory tasks that are dependent on the hippocampus (Yau et al., 2001). Blockade of 11-HSD-1 activity for months in elderly human subjects improves cognitive function and the effect is particularly evident in individuals with Type 2 diabetes. It is interesting to note that poor glucose tolerance is associated with impaired declarative memory and hippocampal volume reduction associated with "mild cognitive impairment" (Convit et al., 2003). Moreover, Type 2 diabetes is associated with increased risk for Alzheimer's disease (Arvanitakis et al., 2004). In this regard, the hippocampus is sensitive to the effects of Type 1 diabetes and expresses two insulin sensitive glucose transporters, Glut 4 and Glut 8, for which the translocation to membranes is regulated by circulating insulin and glucose (McEwen and Reagan, 2004). Insulin is reported to enhance cognitive function in cognitively impaired elderly subjects (Craft et al., 1995), and IGF-1 is able to increase neurogenesis in the dentate gyrus and mediates exercise-induced increases of cell proliferation in this brain region (Aberg et al., 2000; Carro et al., 2000). Thus, the hippocampus is influenced by insulin related molecules and by glucocorticoids.

2.3 Allostasis and Mechanisms for Neuroendocrine Adaptation of HPA Axis

The HPA axis is controlled via releasing factors secreted into the portal blood supply in the median eminence of the hypothalamus. Corticotrophin releasing hormone (CRH) is the principal factor and is produced by neurons in the paraventricular nucleus of the hypothalamus. Vasopressin also plays a regulatory role and is more important for some stressors than others as a stimulus of ACTH release. Glucocorticoid negative feedback takes two forms, rate sensitive control that is related to rising and falling levels of glucocorticoids and level sensitive feedback that is more tonic and sustained. Whereas rate sensitive feedback may involve rapid nongenomic actions of glucocorticoids, level sensitive feedback is classically viewed as a direct action of glucocorticoids on glucocorticoid receptors in the PVN. Yet, recent evidence challenges this mechanism in that, after adrenalectomy, increased ACTH levels are reduced not only by glucocorticoids but also by metabolizable sugars.

The hypothalamic regulation of CRH and ACTH release is influenced by pathways from many forebrain structures (*Figure 14-2*). The hippocampus and amygdala are key limbic brain structures that process experiences by interfacing with lower vegetative brain areas, such as hypothalamus, and higher cortical centers. They also help to interpret, on the basis of current and past experiences, whether an event is threatening or otherwise stressful and help to determine the behavioral, neuroendocrine, and autonomic responses. See *Figure 14-3*. The amygdala is an essential neural component in the memory of fearful and emotionally laden events, whereas the hippocampus is concerned with determining the context in which

Figure 14-2

The HPA axis is regulated by excitatory and inhibitory neural inputs to the bed nucleus of the stria terminalis (BNST). The BNST relays information to the paraventricular nucleus of the hypothalamus (PVN), which, in turn, regulates ACTH secretion from the anterior pituitary via corticotropin releasing factor (CRF) and arginine vasopressin (AVP). The hippocampus, through the ventral subiculum, and the medial prefrontal cortex (mPFC) are involved in shutting off the HPA stress response via the BNST and the preoptic region of the hypothalamus (POA) (Herman and Cullinan, 1997). The brainstem catecholaminergic system has a direct stimulatory role in the PVN. Glucocorticoid negative feedback operates at multiple levels and via both rapid and delayed actions (Keller-Wood and Dallman, 1984); in the amygdala, there is positive feedback, whereas in the PVN and anterior pituitary there is negative feedback. Metabolic hormones also play a role in negative feedback processes (Pecoraro et al., 2004)

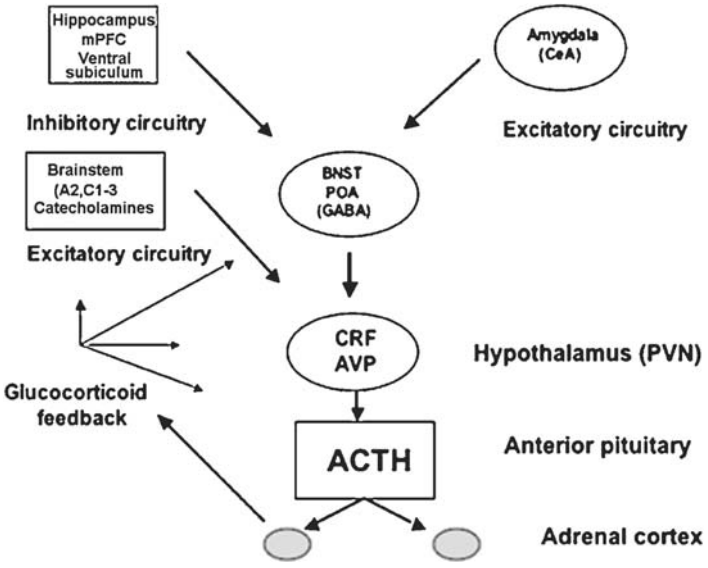


Figure 14-3

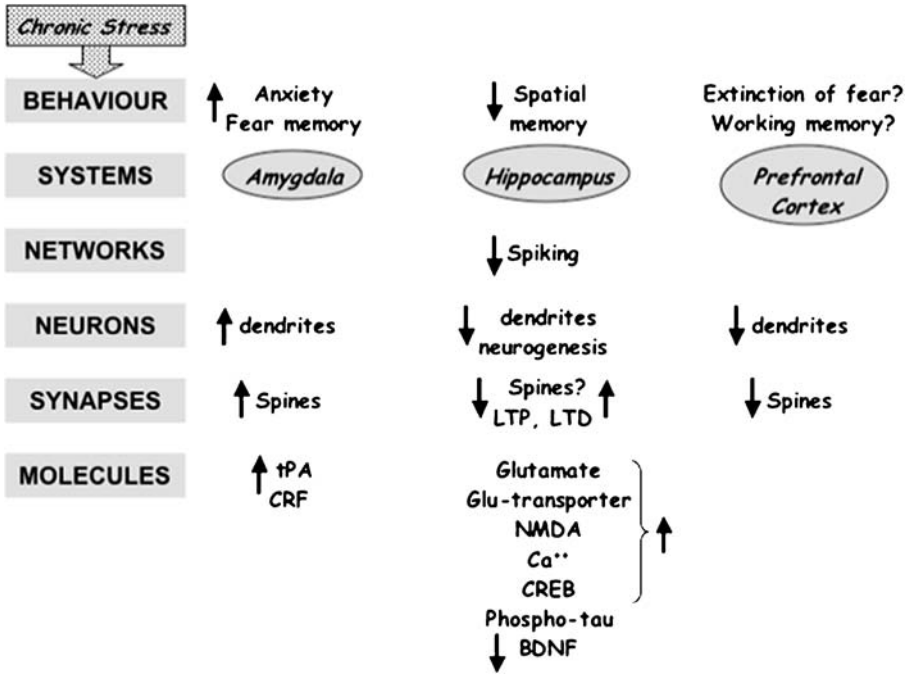
Chronic stress increases fear and anxiety while impairing spatial memory. The amgydala, which plays a pivotal role in fear and anxiety, shows growth of dendrites and spine synapses with chronic stress that is mediated, in part, by CRF and tissue plasminogen activator (tPA). After chronic stress, the hippocampus, which is important for spatial memory, shows decreased neural activity and suppression of dentate gyrus neurogenesis and dendritic remodeling; there may also be alterations in spine synapse number and distribution. Mediators of these changes include glutamate and glucocorticoids along with neurotrophins such as BDNF, NMDA receptors, and calcium fluxes, CREB and tau phosphorylation. After chronic stress, the medial prefrontal cortex, which is involved in extinction of fear memory, as well as working memory and executive function, shows dendritic remodeling and loss of spine synapses. Although not yet tested, it is possible that this results in impairment of fear extinction and working memory and executive function



such events take place as well as other aspects of episodic and declarative memory (Squire and Zola-Morgan, 1991; Eichenbaum and Otto, 1992; Phillips and LeDoux, 1992). Whereas lesions of the central or lateral amygdala will abolish conditioning of the freezing response of an animal to a tone paired with a shock, a hippocampal lesion has no such effect; on the other hand, the hippocampal lesion will abolish conditioning of the freezing response to the "context", i.e., to the environment of a particular conditioning chamber (Phillips and LeDoux, 1992).

The amygdala and hippocampus are also linked to each other anatomically and functionally (Knigge, 1961; Pitkanen et al., 2000; Petrovich et al., 2001). For example, lesions of the basolateral amygdaloid nucleus reduce long-term potentiation in the dentate gyrus and stimulation of this nucleus facilitates dentate gyrus long-term potentiation (Ikegaya et al., 1994, 1995). Moreover, amygdala lesions block the inhibitory effects of stressors on hippocampal-dependent memory tasks (Kim et al., 2001). The hippocampus and amygdala also have a regulatory role in the HPA axis activity, with the hippocampus in general being inhibitory and the amygdala acting as a facilitator of the HPA stress response (Knigge, 1961; McEwen, 1977; Jacobson and Sapolsky, 1991; Herman et al. 1996).

However, this statement oversimplifies a great deal of complexity. For example, within the hippocampus, certain sites respond to electrical stimulation by increasing HPA activity (Dunn and Orr, 1984),

even though, as noted earlier, the overall role of the hippocampus appears to be to shut off HPA activity. Moreover, other brain areas are involved, e.g., a brain lesion and steroid implant study indicate that parts of the medial prefrontal cortex (mPFC; see *Figure 14-3*) are a site of glucocorticoid negative feedback and play a role in containing the HPA response to psychological (e.g., restraint) stress, but not to ether stress (Diorio et al., 1993). Yet, the mPFC role is not simple either, since another report indicates that other parts of the mPFC participate in the stimulation of HPA activity (Sullivan and Gratton, 1999).

As noted, glucocorticoid implants into the mPFC reduce the magnitude of the HPA response to stress (Diorio et al., 1993) pointing to the important topic of steroid feedback in the control of HPA activity. It is important to note that the HPA axis is dynamically regulated, and steroid feedback operates at several levels in relation to neural control of the turning on and shutting off of the stress response (Akana et al., 1988; Jacobson et al., 1988). Besides rate sensitive and level sensitive feedback, delayed feedback may be viewed as both a thermostat (steroid elevation turning down ACTH release) and a modulation of neural activity impinging upon the CRF and AVP neurons PVN. The glucocorticoid-modulated input can be inhibitory (perhaps via the GABA system) as well as excitatory (Herman et al., 1996).

The demonstration that constant steroid feedback via corticosterone pellets implanted into ADX rats normalizes ACTH levels but allows for sustained ACTH secretion after stress highlights the importance of neural control in the shutoff of the HPA stress response (Akana et al., 1988; Jacobson et al., 1988). In the same study, diurnal exposure to CORT in the drinking water also normalized ACTH levels in ADX rats but allowed for a more rapid termination of the HPA stress response, even when no steroid was present. This further highlights the importance of understanding the role of adrenal steroids in priming neural mechanisms that subserve shutoff of the HPA axis (Akana et al., 1988; Jacobson et al., 1988).

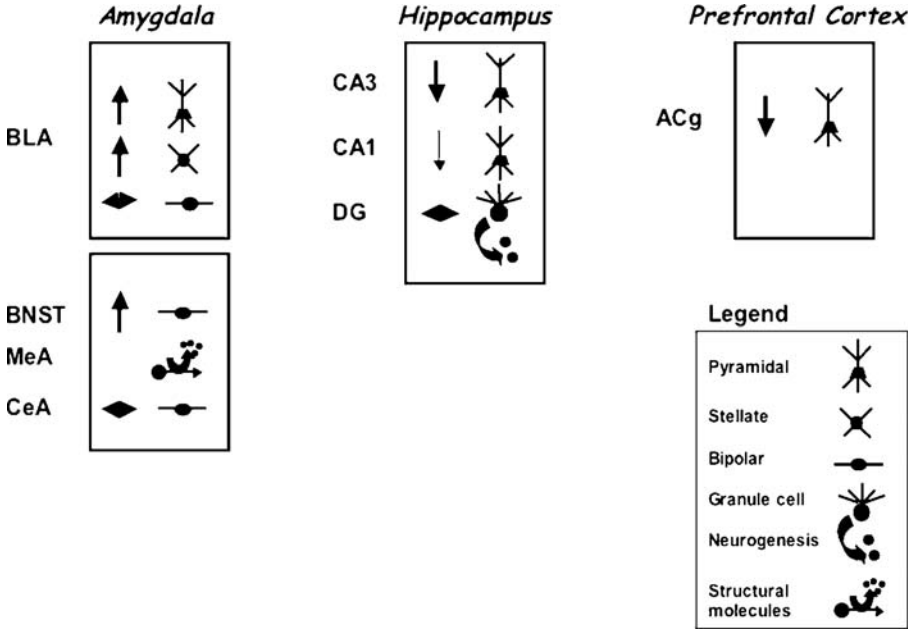
Because of these two interrelated roles of the hippocampus, that is, a role in aspects of memory (*Figure 14-3*) and regulation of HPA activity (*Figure 14-2*), impairment of hippocampal function through changes in either excitability, reversible plasticity, or permanent damage may be expected to have two effects. The first is to impair hippocampal involvement in episodic, declarative, contextual, and spatial memory; impairments of these functions are likely to debilitate an individual's ability to process information in new situations and to make decisions about how to deal with new challenges. The second effect is to impair the hippocampal role in regulating HPA activity, particularly the shutoff of the stress response, leading to elevated HPA activity and further exacerbating the actions of adrenal steroids in the long-term effects of repeated stress. This concept, first called the "glucocorticoid cascade hypothesis" of hippocampal aging (Sapolsky et al., 1986), stands at the center of the notion of "allostasis" and "allostatic load," described earlier in this chapter. Yet, in looking into the roles of adrenal steroids and other modulators in the effects of stress on the hippocampus, it is important not only to recognize the roles of other brain regions such as the amygdala and prefrontal cortex, but also to consider the adaptive role played by the acute secretion of adrenal steroids in the response to acute stressors.

3 The Effects of Stress: Behavior, Cells, Synapses, and Molecules

Over the past decade, there is growing appreciation of the fact that, in addition to affecting endocrinologic and physiologic aspects of body and brain function, stress also has a profound impact on neural plasticity at multiple levels of neural organization. These effects on plasticity mechanisms are manifested as behavioral effects at one end of the spectrum and down to the level of cells, synapses, and molecules at the other (*Figure 14-3*). Moreover, the rich database of hippocampal synaptic plasticity has provided a very useful foundation to gain mechanistic insights into the cellular and molecular effects of stress in excitatory neurons. Although much of the early evidence on stress-induced plasticity emerged from studies of the hippocampus, more recent work has taken into account the important role played by other areas, such as the amygdala and prefrontal cortex (*Figure 14-3* and *14-4*). Findings from these studies have given rise to an intellectual framework that enables us to investigate molecular and biochemical underpinnings of neuronal plasticity mechanisms, and how these mechanisms are adversely affected by stress and emotional disorders. A combination of behavioral, morphological, electrophysiological, pharmacological,

Figure 14-4

Remodeling of neurons occurs in amygdala, hippocampus, and medial prefrontal cortex of rats after chronic stress. Repeated restraint or immobilization stress causes reduction in dendritic length and branch points of CA3 pyramidal neurons in the hippocampus; CA1 pyramidal cells do not exhibit the same degree of atrophy. Repeated stress also impairs neurogenesis in the dentate gyrus (DG). In striking contrast to the hippocampal effects, chronic stress increases dendritic arborization in spiny pyramidal and stellate neurons, but not in bipolar neurons. Chronic stress also causes dendritic hypertrophy in bipolar neurons of the bed nucleus of stria terminalis (BNST), but not central nucleus (CeA). Further, molecular markers related to structural remodeling, such as tPA and GAP-43, are up-regulated in the medial (MeA) and central (CeA) nuclei by repeated stress. Repeated restraint stress also leads to dendritic atrophy in pyramidal neurons of the anterior cingulated region (ACg) of the medial prefrontal cortex



and molecular techniques have been used to explain how stress elicits *global* changes in a brain's output, on the basis of *local* changes in individual neurons and their networks.

3.1 Behavioral Adaptations to Stressors

We begin with the facilitative effects of adrenal steroids on adaptive behaviors, i.e., how they enhance allostasis that leads to behavioral adaptation. The amygdala and hippocampus are both involved in contextual fear conditioning and in passive avoidance learning. In fear conditioning, glucocorticoids enhance learned fear (Corodimas et al., 1994). Moreover, they play an important role in forming the memory of context in contextual fear conditioning (*Figure 14-3*) but not of the actual effect of footshock in rats that are already familiar with the context where the shock is administered (Pugh et al., 1997a, b). This suggests that the hippocampal role in contextual fear conditioning is enhanced by moderate levels of glucocorticoids, but the fear conditioning is either not so dependent on glucocorticoids or is so strong that glucocorticoid influences are hard to demonstrate. Yet, there is evidence for an influence of glucocorticoids on the flow of information within the amygdala.

Glucocorticoids potentiate serotonin inhibition of the processing of excitatory input to the lateral amygdala from the thalamus, suggesting that there is a mechanism for containing or limiting the sensory input that is important for fear conditioning (Stutzmann et al., 1998). Thus, adrenal steroids may regulate the nature of the signals that reach the amygdala and allow for greater discrimination of the most salient cues for learning.

Moreover, in passive avoidance, both catecholamines and glucocorticoids play a role in facilitating the learning (Cahill et al., 1994; Roozendaal, 2000). Catecholamines work outside of the blood–brain barrier and their effects can be blocked by beta adrenergic blocking agents that do not cross the blood–brain barrier (Cahill et al., 1994). Glucocorticoids enter the brain, and local implants of exogenous corticosterone into hippocampus, amygdala, and nucleus tractus solitarii (NTS) are all able to enhance passive avoidance learning (Roozendaal, 2000).

Adrenal steroids also play a supporting role in the learning of a spatial navigation task in mice (Oitzl et al., 2001). Adrenalectomy impairs the acquisition of the memory of hidden platform location in the Morris water maze, and glucocorticoid administration restores the normal learning curve; however, in mice in which the glucocorticoid receptor was deleted and replaced with a GR that lacks the DNA binding domain, glucocorticoids have no effect to improve task acquisition (Oitzl et al., 2001). This finding illustrates a role for glucocorticoid receptors acting upon the genome in a task that is known to depend on the hippocampus. Interestingly, other actions of glucocorticoids via glucocorticoid receptors are known to involve the protein–protein interactions that are not prevented in mice carrying the GR defective in the DNA binding domain (Reichardt and Schutz, 1998).

Other evidence for glucocorticoid actions supports an inverted U-shaped dose-response curve in which low to moderate levels of adrenal steroids enhance acquisition of tasks that involve the hippocampus, whereas high levels of glucocorticoids disrupt task acquisition (Diamond et al., 1992; Pugh et al., 1997b; Diamond et al., 1999; Conrad et al., 1999a). And, indeed, elevated levels of glucocorticoids, along with overactivity of EAA suppress neurogenesis, promote dendritic remodeling, and even higher activity of glucocorticoids and excitatory amino acids promote damage in strokes, seizures, and head trauma (*Figure 14-1*). Adrenal steroids have biphasic effects upon excitability of hippocampal neurons that may underlie their biphasic actions on memory and recall (Diamond et al., 1992; Pavlides et al., 1994, 1995a, b; Pavlides and McEwen, 1999).

Whereas some studies have reported spatial memory deficits following stress (Luine et al., 1994) or chronic corticosterone treatment (Bodnoff et al., 1995), other studies (Conrad et al., 1999b) suggest that stress might also impair memory through nonhippocampal mechanisms, such as enhanced emotionality. Furthermore, stress facilitates classical eye-blink conditioning (Shors et al., 1992) and this facilitation requires activation of NMDA receptors in the basolateral amygdala (BLA) (Shors and Mathew, 1998). Corticosterone injections have also been shown to potentiate fear conditioning (Corodimas et al., 1994).

3.2 Stress and Dendritic Remodeling: Hippocampus and Beyond

Prolonged and severe stress leads to behavioral abnormalities manifested as cognitive impairments as well as affective disorders. Investigations into cellular mechanisms underlying stress-induced cognitive deficits have focused primarily on the hippocampus, a structure involved in forming declarative/episodic/spatial memories (O'Keefe and Nadel, 1978; Squire and Zola-Morgan, 1991; McEwen, 1999; Martin et al., 2000), not only because of its susceptibility to stress-related damage but also because of its negative feedback regulation (*Figure 14-2*) of the stress response via the HPA axis (Herman et al., 1989; Jacobson and Sapolsky, 1991; Sapolsky et al., 1991; Herman and Cullinan, 1997). Earlier studies on how stress and stress hormones affect the rat hippocampus revealed that 21 days (6 h per day) of repeated restraint stress produces significant dendritic remodeling in CA3 pyramidal neurons (*Figure 14-3* and *Figure 14-4*) (Watanabe et al., 1992; Magarinos and McEwen, 1995a, b; Sousa et al., 2000). This dendritic remodeling is characterized by a reversible shortening and debranching of apical dendrites (Conrad et al., 1999b) and is mediated by mechanisms involving high levels of glucocorticoid secretion, glutamate, and serotonin (Magarinos and McEwen, 1995a, b). These findings, in turn, have contributed to rodent models of

stress-induced neuronal atrophy that may provide one potential explanation for the hippocampal shrinkage associated with post-traumatic stress disorder, recurrent depressive illness, and Cushing's disease (Starkman et al., 1992; Bremner et al., 1995; Sheline et al., 1996; Bremner et al., 1997; Starkman et al., 1999, 2003).

Although hippocampal plasticity may mediate cognitive aspects of behavioral impairments caused by severe stress, changes in the amygdala are more likely to contribute to the affective aspects of stress disorders. In addition to a critical role for the amygdala in fear and anxiety (Davis, 1992; LeDoux, 1994; Davis et al., 1994), there is growing evidence for striking differences between the hippocampus and amygdala with respect to stress. This contrast between the hippocampus and amygdala is manifested in two ways—how these two structures affect the stress response and how they, in turn, are affected by stress. First, anatomical studies indicate that limbic inputs impinging on the paraventricular nucleus (PVN) of the hypothalamus and hypothalamic GABA-ergic neurons can be either excitatory from the hippocampus and thereby enhancing GABA-ergic tone, or inhibitory from the amygdala and thereby reducing GABA-ergic tone (Herman et al., 1989; Jacobson and Sapolsky, 1991; Sapolsky et al., 1991; Pitkanen and Amaral, 1994; Herman and Cullinan, 1997). This in turn implies that whereas enhanced hippocampal input would suppress the HPA axis, enhanced amygdaloid input could have the opposite effect on HPA activity. Thus, one potential difference between the hippocampus and amygdala with respect to the neural circuitry underlying stress comes from their disparate roles in the regulation of the HPA axis (*Figure 14-2*).

Evidence for a second important difference comes from behavioral studies demonstrating how chronic stress affects hippocampal- or amygdala-dependent learning and memory (*Figure 14-3*). In rodents, severe stress facilitates fear and anxiety-like behavior (Conrad et al., 1999b; McGaugh and Roozendaal, 2002; Korte and De Boer, 2003; Vyas et al., 2003a, b), but impairs spatial learning (Luine et al., 1994). Whereas repeated stress that produces dendritic remodeling in the CA3 region impairs hippocampal-dependent learning (Conrad et al., 1996), the basolateral amygdala has been shown to be essential for stress-induced facilitation of aversive learning (Liang et al., 1994; Shors and Mathew, 1998). Further, there are reports indicating that the debilitating effects of chronic stress on anxiety and fear can be long-lasting and persist well beyond the actual period of exposure to stress (Adamec et al., 1999; Conrad et al., 1999b). These observations are particularly striking in comparison to the mixed results from studies on the effects of stress on hippocampus-dependent behavior. Some of these reports indicate that hippocampal spatial memory deficits are reversible and temporally limited (Luine et al., 1994; McEwen, 1997). Some findings also suggest that the capacity for stress to impair memory is influenced by the brain memory system (hippocampal versus nonhippocampal) involved in solving the task (Kim et al., 2001). Therefore, the same behavioral perturbation, in the form of chronic stress, elicits contrasting functional outputs from the hippocampus and amygdala that appear to have divergent properties in terms of their temporal persistence after the termination of stress.

One possible explanation for these conflicting results involving hippocampal spatial learning comes from a study reporting that stress-induced dendritic atrophy of CA3 neurons is reversible within 7–10 days after the termination of the 21 days of restraint stress paradigm (Luine et al., 1994; Conrad et al., 1999b). The divergent nature of the behavioral outputs of the hippocampus and amygdala in response to stress is further highlighted in an interesting pharmacological study by Conrad et al. (Conrad et al., 1999b). This study reports that although tianeptine, an atypical antidepressant, prevented CA3 atrophy, it failed to prevent enhanced fear and anxiety after repeated restraint stress. The particularly relevant finding of this study was that repeated restraint stress facilitated fear conditioning to both context and tone independently of causing hippocampal CA3 dendritic atrophy. This led the authors to conclude that chronic stress may have a powerful effect on the amygdala, which could override any influence of the hippocampus. Taken together, these findings raise the possibility that cellular substrates for stress-induced changes in emotional behavior may reside in the amygdala and recent reports, reviewed in the next section, have provided new evidence in this direction.

3.3 Stress and Structural Plasticity in the Amygdala: Implications for Anxiety-Like Behavior

Unlike the hippocampus, relatively little is known about how stress affects the amygdala and the nature of its role in the stress response. One recent study (Vyas et al., 2002) used the same experimental strategy that

previously elucidated properties of stress-induced dendritic remodeling in hippocampal CA3 neurons. In this study, the effects of two different models of chronic stress on hippocampal and amygdaloid neuronal morphology in rats were examined. In agreement with previous reports, chronic immobilization stress (2 h per day for 10 days) induced dendritic atrophy and debranching in CA3 pyramidal neurons of the hippocampus. In striking contrast, principal neurons in the basolateral complex of the amygdala (BLA) exhibited *enhanced* dendritic arborization in response to the same chronic stress. This stress-induced enhancement in dendritic arborization was restricted only to BLA pyramidal and stellate neurons, which are presumably excitatory projection neurons (McDonald, 1982, 1992) (*Figure 14-4*). Moreover, these patterns varied depending on the type of chronic stress used. Thus, chronic unpredictable stress, which was relatively less effective in remodeling CA3 pyramidal neurons, caused atrophy in bipolar/bitufted neurons without affecting spiny pyramidal and stellate cells of the BLA. The efficacy of chronic immobilization, and not unpredictable stress, in eliciting dendritic hypertrophy in BLA was also shown to be relevant in terms of its anxiogenic properties. Thus, only chronic immobilization stress caused a significant increase in anxiety-like behavior as manifested by a reduction in open-arm exploration and risk-assessment behavior in the elevated plus maze (Vyas and Chatterji, 2004). Interestingly, even after 21 days of stress-free recovery, animals exposed to immobilization stress continued to exhibit enhanced anxiety (Vyas and Chatterji, 2004; Vyas et al., 2004). At the cellular level, chronic immobilization stress (CIS)-induced dendritic remodeling of spiny BLA pyramidal neurons is also as persistent as enhanced anxiety after 21 days of recovery. Moreover, BLA hypertrophy, elicited by chronic immobilization stress, is distinct from hippocampal CA3 atrophy, which is reversible within the same period of stress-free recovery (Vyas and Chatterji, 2004). These findings on persistent dendritic remodeling in the amygdala, in addition to highlighting important differences with hippocampal structural plasticity, raise the possibility that certain forms of chronic stress, by affecting specific neuronal elements in the amygdala, may lead to the long-lasting behavioral manifestations of enhanced emotionality.

Although plasticity mechanisms in the BLA, which play a key role in the acquisition and consolidation of fear memories, have received considerable attention, recent reports also point to the importance of noncortical amygdalar nuclei that influence its output. For example, work by Davis and colleagues (Davis and Shi, 1999; Davis, 2000), using the startle reflex, indicates that the bed nucleus of stria terminalis (BNST) in the so-called extended amygdala, may be involved in processing signals more akin to cue-nonspecific fear or anxiety, whereas the central nucleus of the amygdala (CeA) is more involved in cue-specific fear. Interestingly, chronic stress also enhances dendritic arborization in BNST neurons (Vyas et al., 2003a, b). Further evidence for stress-induced plasticity in amygdalar nuclei, which receive information from the BLA, comes from a recent study using a knockout mouse model (Pawlak et al., 2003). This study identified the serine protease tissue–plasminogen activator (tPA) in the amygdala, but not the hippocampus, as a critical component in the sequence of molecular events linking repeated restraint stress-induced amygdalar plasticity with the development of anxiety-like behavior.

These findings also point to novel aspects of stress-induced plasticity, in the temporal and spatial domain, which will require further investigation. First, unlike stress-induced dendritic hypertrophy in the BLA, stress-induced up-regulation of tPA was restricted to the medial (MeA) and central (CeA) nuclei of the amygdala. This highlights the need to examine subtle region-specific, possibly even cell-specific, effects within the amygdalar network. Second, the temporal features of these effects are equally important. For example, an acute episode of restraint stress triggered a cascade of molecular signals related to tPA within the first few hours following exposure to stress, and all of these preceded the eventual development of anxiety in the animal. In other words, there may be considerable differences between the spatio-temporal dynamics of stress-induced changes in molecular signals, neuronal plasticity, and ultimately, behavioral output. Further, an acute episode of stress may elicit plasticity that is considerably different in terms of its spatio-temporal features from that induced by repeated episodes of the same stressor over time.

In summary, recent evidence on stress-induced plasticity in various nuclei of the amygdala expand the scope for studying effects of stress on emotional behavior. In particular, a growing body of findings indicates that plasticity mechanisms triggered as a result of stress-induced amygdala activity can strengthen the excitatory drive within the BLA and thereby influence subsequent information processing by its downstream targets, such as the MeA, CeA, and BNST. This, in turn, suggests that chronic stress could lead to an imbalance in HPA axis function through a gradual loss of hippocampal inhibitory control as well as gain in

excitatory control exerted by the amygdala. Taken together, these studies on stress-induced plasticity in the various nuclei of the amygdala may provide putative cellular substrates for exploring psychiatric disorders that are characterized by diminished cognitive capabilities and abnormally high fear response.

3.4 Stress and Structural Plasticity in the Prefrontal Cortex

The medial prefrontal cortex (mPFC) and prelimbic cortex show structural remodeling after repeated stress and repeated corticosterone treatment, which is similar to that found in the hippocampus, namely a shortening of dendritic length and a simplification of dendritic branching in layer II/III neurons (*Figure 14-4*) (Wellman, 2001; Wellman, 2004; Radley et al., 2004) There is also a reduction after 21days of chronic restraint stress in spine density on the apical dendrites of layer II/III neurons (Radley et al., 2004). The net result of these changes is estimated to be a reduction of 40% in synaptic input to the mPFC. Neurons in this region receive input from the amygdala and may be responding to increased output from the amygdala during stress (Kim et al., 2001; Diamond et al., 2004). It is not yet known if the infralimbic cortex of the mPFC also shows remodeling after 21 days of chronic restraint stress. This would be important because of the involvement of this region in extinction of fear conditioning (Santini et al., 2004). A prediction of these structural changes is that prefrontal cortical functions in working memory, executive function, and memory extinction would be impaired by chronic stress.

3.5 Cellular and Synaptic Correlates for Stress-Induced Plasticity in the Hippocampus

Investigations into cellular mechanisms underlying stress-induced impairments have focused largely on two common metrics of hippocampal plasticity—one structural, and the other electrophysiological. The morphological changes triggered by stress have been described earlier. In this section, we describe some data obtained from the second approach that has been guided by the hypothesis that stress, possibly by disrupting synaptic transmission and plasticity mechanisms, leads to deficits in hippocampal memory.

A variety of rodent models of stress have been shown to impair hippocampal LTP (McEwen, 1999; Kim and Diamond, 2002). Evidence for the involvement of excitatory amino acids and NMDA receptors, in hippocampal dendritic remodeling (Magarinos and McEwen, 1995b; McEwen, 1999), provided early insights into the underlying synaptic signaling mechanisms. A series of recent studies using whole-cell recordings in CA3 pyramidal cells indicate that repeated restraint stress increased the amplitude and deactivation time-constant of the NMDA current, without affecting the AMPA/kainate receptor mediated currents at commissural–associational inputs (Kole et al., 2002). This stress-induced enhancement in NMDA-receptor signaling, however, is a condition that is likely to facilitate, and not impair LTP induction. Moreover, intracellular calcium, a key determinant of hippocampal LTP, is also enhanced by glucocorticoids (Kerr and Campbell, 1992; Joels and Vreugdenhil, 1998). These findings, therefore, are difficult to reconcile with the significant body of evidence for stress-induced impairment of LTP.

But there is also evidence that not all forms of LTP are equally susceptible to suppression following exposure to stress or corticosterone (Alfarez et al., 2002). It should also be noted that a majority of reports on stress-induced impairment of LTP are not based on studies in area CA3 of the hippocampus, which undergoes the most significant atrophy among all hippocampal regions. The same group that earlier reported stress-induced increases in NMDA currents at CA3 commissural–associational synapses (Kole et al., 2002), has recently demonstrated that brief social stress prevented induction of LTP by low-frequency tetanic stimuli, even after a 21-day time delay (Kole et al., 2004a). Interestingly, repetition of the same stress did not result in a greater suppression of LTP, but a reversal of synaptic potentials resembling LTD, at commissural–associational synapses (Kole et al., 2004b).

The apparent contradiction between stress-induced impairment of LTP and increase in NMDA-receptor signaling may be explained by the possibility that enhanced NMDA currents give rise to a form of metaplasticity that favors a saturation of LTP (Kim and Yoon, 1998). This saturation of LTP, in turn, raises

the threshold for subsequent LTP induction, which is manifested either as a reduction in the magnitude of LTP elicited, or a complete prevention of further LTP, or, in extreme cases, a depression of synaptic strength in the form of LTD. Such a scenario is based on the Bienenstock–Cooper–Munro (BCM) theory of synaptic plasticity, which proposes that the threshold for triggering LTP or LTD, itself, is modifiable and depends on the previous history of activity of the synaptic inputs (Bienenstock et al., 1982; Abraham and Bear, 1996).

In other words, the same tetanic stimuli that elicit robust LTP in an "unstressed" or "naïve" synapse, can fail to do so in a "stressed" synapse that has already strengthened or saturated due to stress-induced increase in NMDA currents or calcium influx, thereby reaching a state in which further LTP is not favored. This framework, rooted in the concepts of BCM theory and stress-induced metaplasticity (Bienenstock et al., 1982; Abraham and Bear, 1996; Kim and Yoon, 1998), provides a useful basis for future studies that will require careful examination of the various forms of hippocampal synaptic plasticity, that depend on both NMDA-receptor dependent and independent mechanisms (Johnston et al., 1992).

The traditional approach to examining the functional consequences of stress-induced dendritic remodeling has been driven by the logic that a reduction in postsynaptic dendritic surface will adversely affect the availability of synaptic inputs, and thereby synaptic plasticity. This framework, which focuses primarily on synaptic transmission and plasticity, overlooks the important point that changes in dendritic architecture can also affect intrinsic excitability properties of neurons in ways that do not necessarily have to be mediated directly through modulation of synaptic transmission. Theoretical studies point to a significant role for dendritic morphology in modulating various facets of neuronal excitability including patterns of action potential firing (Mainen and Sejnowski, 1996; Krichmar et al. 2002; van Ooyen et al., 2002; Narayanan et al., 2004), and propagation of action potentials (Vetter, 2001).

Such modulation of intrinsic excitability gains particular significance in light of the strong excitatory recurrent connections through associational inputs to the *stratum radiatum* region of CA3, which also exhibits the most robust stress-induced dendritic remodeling among all subregions of the hippocampus. Interestingly, in vivo recordings in area CA3 indicate that, in addition to suppressing LTP, repeated stress also leads to epileptic afterdischarges and shifts in current sources and sinks along apical dendrites (Pavlides et al., 2002). Thus, the cumulative effects of altered synaptic and neuronal excitability, propagated through recurrent loops, may affect the balance of excitation and inhibition in the hippocampal CA3 network. Such a shift in the overall balance of excitation and inhibition, due to repeated and severe stress, could contribute to excitotoxicity and eventual neurodegeneration in the hippocampus (Orchinik et al., 2001).

This view raises another fundamental question that is at the core of the large body of experimental evidence for stress-induced dendritic remodeling: Is this simply a reflection of damage caused by repeated stress or a manifestation of adaptive plasticity that attempts to counter stress-induced damage? Although a comprehensive answer to this complex question still eludes us, there are several interesting findings that may provide an explanation. First, stress-induced CA3 atrophy is reversible, which is indicative of homeostatic mechanisms that enable the neuron to adapt to the levels and duration of stressful conditions. For example, in hibernation, there is rapid remodeling of dendrites and synaptic connections in the hippocampus that appears to reduce the vulnerability of the DG-CA3 region to permanent damage when energy supplies are low (Popov and Bocharova, 1992; Popov et al., 1992; Arendt et al., 2003).

Second, modulation of synaptic transmission and plasticity caused by stress could represent a second category of plasticity, some of which could contribute to functional impairment in learning and memory. Such deficits in synaptic plasticity and behavioral output, however, could still lie within a range that is reversible depending on the severity and duration of the stressor. Third, mechanisms of intrinsic plasticity, as described earlier, could also provide an important means of homeostasis that is yet to be studied in detail. One recent report (Kole et al., 2004b), using the tree shrew, suggests that chronic stress can indeed trigger homeostatic maintenance in excitability of CA3 pyramidal neurons. In principle, a reduction in dendritic arbors would predict an increase in input resistance, and consequently enhanced rates of action potential firing in CA3 neurons (Narayanan et al., 2004). Surprisingly, results from whole-cell recordings used in this study indicate that chronic stress actually reduced the input resistance by 20–25% (Kole et al., 2004b). Moreover, all active membrane properties, including depolarization-induced action potential kinetics and complex spiking patterns, did not change after chronic stress. Taken together, these data show that despite dendritic remodeling and enhanced cortisol release, the efficacy of somatic excitability of CA3 pyramidal

neurons is largely preserved after long-term stress. This is a striking example of how intrinsic mechanisms of homeostatic plasticity can coexist with and counter structural remodeling caused by repeated stress.

In summary, a growing body of experimental evidence indicates that chronic exposure to stress can activate a complex repertoire of plasticity mechanisms in the hippocampus. Based on the considerable evidence pointing to factors that are common to both stress-induced damage and synaptic plasticity mechanisms subserving normal hippocampal function, the challenge now is to gain a mechanistic understanding of how these factors may contribute to degeneration, as well as adaptive changes, caused by stress.

3.6 Cellular and Synaptic Correlates for Stress-Induced Plasticity in the Amygdala

Findings on the cellular and molecular underpinnings of plasticity mechanisms elicited by stress in the hippocampus, as outlined earlier, will also provide a useful framework for future investigations of such mechanisms in the amygdala. Although at present little is known about such plasticity mechanisms in the amygdala, some recent evidence provides interesting insights into putative mechanisms that may play a critical role in the amygdala. In one study (Stutzmann et al., 1998), aimed at investigating the in vivo modulation of sensory transmission in the lateral amygdala (LA) by corticosterone, iontophoretically applied serotonin (5-HT) inhibited both synaptically and glutamate-evoked action potentials in a majority of neurons examined. However, after adrenalectomy (ADX), which eliminates endogenous corticosterone, 5-HT no longer inhibited evoked activity in the LA. High, but not low, doses of corticosterone administrated to ADX animals reinstated the inhibition of excitatory transmission of 5-HT. Furthermore, immunocytochemical labeling of the glucocorticoid receptor in the intact rat demonstrated nuclear staining throughout several amygdala regions, including the LA. In contrast, no nuclear labeling was visible after ADX. These data suggest that the ability of 5-HT to modulate glutamatergic activity in thalamic inputs to the LA depends on the levels of corticosterone present. However, they do not necessarily mean that genomic actions of glucocorticoids are involved, as the effects described by Stutzman et al. (1998) are rapid and as nongenomic actions of glucocorticoids are known in brain (Makara and Haller, 2001).

Moreover, these findings also point to the potential importance of both serotonergic and inhibitory modulation of amygdalar activity during a stressful experience. Interestingly, the importance of the serotonergic system in the amygdala is also evident from recent studies on the modulation of fear (Burghardt et al., 2004) and stress-related amygdalar plasticity with tianeptine, an atypical antidepressant that is believed to act on the 5-HT reuptake mechanism (reviewed in McEwen and Chattarji, 2004).

A key role for inhibition comes from another recent report that examined how synaptic plasticity in the amygdala, induced by corticotrophin releasing factor (CRF), may translate stress into anxiety-like behavior (Rainnie et al., 2004). In this study, non-anxiety-inducing doses of a potent CRF type 1 and 2 receptor agonist, urocortin, was infused locally into the BLA of rats. After five daily injections of urocortin, the animals developed anxiety-like behavior that persisted for more than 30 days. Importantly, whole-cell patch-clamp recordings from BLA neurons of these anxious animals revealed a pronounced reduction in both spontaneous and stimulation-evoked inhibitory postsynaptic potentials (IPSPs), leading to a hyper-excitability of the BLA network. Moreover, this form of urocortin-induced plasticity appears to be dependent on NMDA receptors and subsequent calcium–calmodulin-dependent protein kinase II (CaMKII) activation.

Preliminary studies (Bennur and Chattarji, 2004) also show, using whole-cell recordings in amygdala slices, that chronic immobilization stress leads to a reduction in inhibition along with enhanced NMDA receptor currents in principal neurons of the LA. Thus, future studies will have to focus on the causal links between stress-induced plasticity mechanisms that involve modulation of glutamatergic, serotonergic, and inhibitory transmission in the amygdala and how these collectively give rise to stress disorders at the behavioral level in which CRF may play an important role. In this connection, recent evidence from the mouse indicates that the ability of acute stress to increase anxiety and promote plasticity within the medial and central regions of the amygdala via a tissue plasminogen activator-dependent mechanism

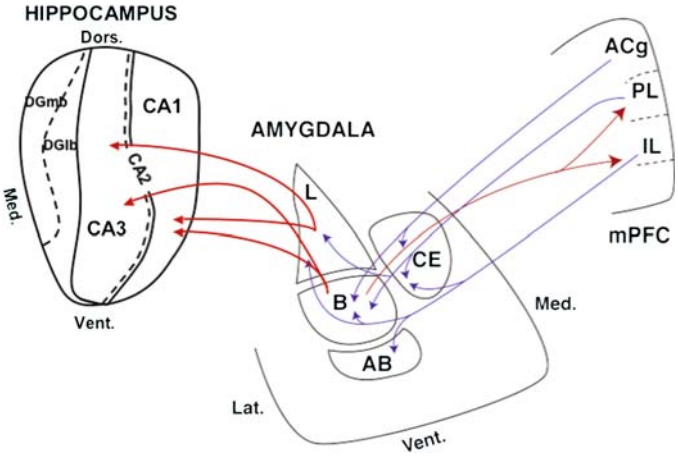
(Pawlak et al., 2003), as discussed earlier, is dependent on CRF-induced activation of tPA activity (Matys et al., 2004).

4 Future Directions

Finally, although much of the earlier discussion treats stress-induced plasticity in the hippocampus, amygdala, and prefrontal cortex as separate or independent processes, there is considerable physiological and anatomical evidence (e.g., Petrovich et al., 2001) pointing to interactions among these brain areas that could have implications for how stress responses are integrated across structures at the systems level. We have already referred to the extensive connectivity among these three brain regions (*Figure 14-5*). A key

Figure 14-5

The amygdala is reciprocally connected to the medial prefrontal cortex and sends projections to Ammon's horn of the hippocampus [depicted as an unfolded flat map, (Petrovich et al., 2001)] but not to the dentate gyrus (Petrovich et al., 2001). It is possible that stress-induced adaptive plasticity in both hippocampus and medial prefrontal cortex depends on activity in amygdala



question is whether activity in the amygdala may play a key role in driving changes in hippocampus and prefrontal cortex. This possibility is suggested by two observations already described in this article. First, as reviewed earlier, there is the finding that acute stress causes rapid changes in amygdala structural plasticity in both rats and mice that occur before the cumulative effects of repeated stress can be found in the prefrontal cortex and hippocampus. Second, in human depressive illness, hyperactivity in the amygdala is reported in the first episode of depression (Drevets, 2000), and there are several reports on increased amygdala volume (Frodl et al., 2002, 2003), whereas hippocampal shrinkage is reported as a function of the duration of symptoms of depression (Sheline et al., 1999; MacQueen et al., 2003) and also in post-traumatic stress disorder (Bremner et al., 1995).

Furthermore, there is accumulating evidence for a pivotal role for the amygdala in modulating synaptic plasticity in the hippocampus (Diamond et al., 1994; Kim and Diamond, 2002). For example, pharmacological inactivation of NMDA receptors in the BLA impairs LTP in the dentate gyrus (Abe, 2001). High-frequency stimulation of the BLA has also been shown to facilitate LTP in dentate gyrus (Abe, 2001). Activation of the amygdala, as well as exposure to stress, elicits a biphasic modulation of hippocampal LTP, which is manifested first as an immediate excitatory effect, followed by an inhibitory effect that is more long-lasting (Akirav and Richter-Levin, 1999). Since hippocampal responses are altered following lesions or pharmacological inactivation of the amygdala, one experimental approach to studying interactions among

these three brain areas is to lesion or reversibly inactivate key efferent pathways from the amygdala while applying stressors that normally cause structural plasticity. The use of viruses to introduce genes that alter responses in amygdala neurons should also be considered.

5 Conclusion

Future studies will have to focus on integrating current and new findings in two broad directions. First, within each of the three brain areas that constitute the key components of the neural circuitry of stress (hippocampus, amygdala, prefrontal cortex), an integration across multiple levels of neural organization has to be achieved—from genetic and molecular mechanisms at one end of the spectrum, to systems and behavioral level analyses at the other. Second, integration across the three structures will also be critically important in elucidating their roles in the emotional and cognitive aspects of stress disorders.

Abstract: Increased levels of pup licking/grooming and arched-back nursing by rat mothers over the first week of life alter the epigenome at a glucocorticoid receptor gene promoter in the hippocampus of the offspring. Differences in the DNA methylation pattern between the offspring of high- and low-licking/grooming—arched-back mothers emerge over the first week of life. They are reversed with cross-fostering, persist into adulthood, and are associated with altered histone acetylation and transcription factor (NGFI-A) binding to the glucocorticoid receptor promoter. Central infusion of the adult offspring with the histone deacetylase (HDAC) inhibitor trichostatin A removes the previously defined epigenomic group differences in histone acetylation, DNA methylation, NGFI-A binding, glucocorticoid receptor expression, and hypothalamic–pituitary–adrenal responses to stress. This suggests a causal relation between the epigenomic state, glucocorticoid receptor expression, and the effects of maternal care on stress responses in the offspring. These findings demonstrate that an epigenomic state of a gene can be established through a behavioral mode of programming, and that in spite of the inherent stability of this epigenomic mark, it is dynamic and potentially reversible.

1 Introduction

Epidemiological studies reveal the importance of family function and early life events as predictors of health in adulthood (Repetti et al., 2002). Such studies show that the quality of family life influences the development of individual differences in vulnerability to illness throughout life. As adults, victims of childhood physical or sexual abuse are at considerably greater risk for mental illness, as well as for obesity, diabetes, and heart disease (e.g., Bifulco et al., 1991; Brown and Anderson, 1991; McCauley et al., 1991; Felitti et al., 1998; Heim et al., 2002; Newport et al., 2002). Persistent emotional neglect, family conflict, and conditions of harsh, inconsistent discipline all serve to compromise growth (e.g., Montgomery et al., 1997), intellectual development (Ammerman et al., 1986; Trickett and McBride-Chang, 1995), and to increase the risk for adult obesity (Lissau and Sorensen, 1994), depression, and anxiety disorders (Holmes and Robins, 1987, 1988; Gottman, 1998). Cold, distant parent–child relationships are associated with a significantly increased risk of chronic illness in later life (e.g., Parker, 1981; Canetti et al., 1997; Russak and Schwartz, 1997).

"Stress diathesis" models have emerged as explanations for the relationship between the quality of early life and health in adulthood. These models suggest that adversity in early life alters the development of neural and endocrine systems in a manner that predisposes individuals to disease in adulthood. The relation between the quality of the early environment and health in adulthood appears to be mediated by parental influences on the development of neural systems that underlie the expression of behavioral and endocrine responses to stress (Seckl and Meaney, 1993; Nemeroff, 1996; Sroufe, 1997; Francis and Meaney, 1999; Heim et al., 2000; Repetti et al., 2002). Adversity or decreased quality of parental investment increases the magnitude of emotional, autonomic, and hypothalamic–pituitary–adrenal (HPA) responses to stress in adulthood. These models are constructed on two principal assumptions. First, that prolonged activation of neural and hormonal responses to stress can promote illness, and second that early environmental events influence the development of these responses. There is strong evidence in favor of both ideas. In humans, forms of parenting that enhance the risk of chronic illness in the offspring increase endocrine and autonomic responses to stress in adulthood (De Bellis et al., 1994; Heim et al., 2000). There is considerable evidence for comparable effects in primates (Higley et al., 1991; Suomi, 1997; Bennett et al., 2002) and rodents (Meaney, 2001). Moreover, prolonged exposure to elevated levels of stress hormones, including corticotropin-releasing factor (CRF), catecholamines, most notably norepinepherine, and glucocorticoids promote the development of a diverse range of high-risk conditions, such as visceral obesity, hypertension, and insulin intolerance, or overt pathology, including diabetes, depression, drug addiction, and multiple forms of coronary heart disease. The clinical risks associated with prolonged activation of the HPA and autonomic systems are a logical consequence of the otherwise adaptive stress response. In response to neural signals associated with the stressor, there is an increased release of glucocorticoids from the adrenal gland and catecholamines, particularly norepinephrine from the sympathetic system. The combined actions of these hormones increase the availability of energy substrates, such as those derived

from lipids and glucose metabolism, to maintain the normal cellular output and organ efficiency. These actions protect against catastrophes such as hypotensive shock. These hormones, along with the central CRF and catecholamines, act on multiple brain regions to increase vigilance and fear, and enhance avoidance learning and fear conditioning, which reduces the chances of further encounters with the offending conditions.

Support for the basic elements stress diathesis models appears compelling. Adversity during perinatal life alters development in a manner that seems likely to promote vulnerability, especially for stress-related diseases. Diathesis describes the interaction between development, including the potential influence of genetic factors, and the prevailing level of stress in predicting health outcomes. Such models have considerable appeal, and could potentially identify both the origins and the nature of vulnerability derived from either epigenetic influences, such as early family life, or genomic variations (e.g., Bennet et al., 2002; Caspi et al., 2003).

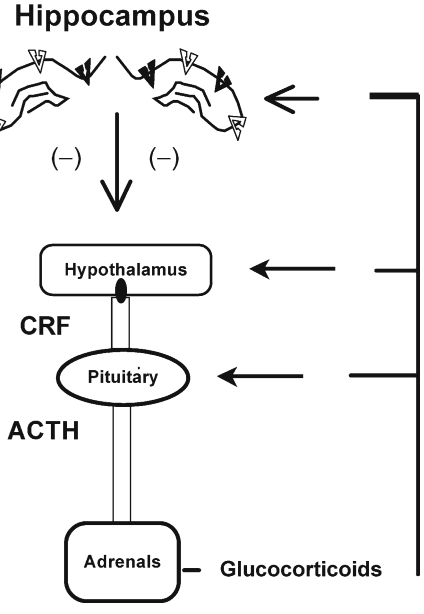
2 The Development of Individual Differences in Stress Responses

2.1 Handling Studies

In the late 1950s and early 1960s, the pages of *Science* and *Nature* were frequently dedicated to articles reporting the effects of postnatal handling (also known as infantile stimulation) on the development of responses to adverse stimuli, or stressors (Levine, 1957, 1962). The handling paradigm involves a brief (i.e., ~15 min) separation of the pups from the dam. This period falls well within the range of normal mother–pup separations that fall between nursing bouts, and does not constitute any major deprivation of

Figure 15-1

The nexus of the hypothalamic–pituitary–adrenal axis are the corticotropin-releasing factor (CRF) neurons of the paraventricular nucleus of the hypothalamus. CRF is released into the portal system of the anterior pituitary stimulating the synthesis and release of adrenocorticotropin (ACTH), which then stimulates adrenal glucocorticoid release. Glucocorticoids act on mineralocorticoid and glucocorticoid receptors in multiple brain regions, including the hippocampus, to inhibit the synthesis and release of CRF (i.e., glucocroticoid negative feedback)



parental care. In infant rats and mice, handling during infancy decreases the magnitude of both behavioral and HPA responses to stress in adulthood. These findings demonstrate that the early environment influences the development of even rudimentary defensive responses to threat.

Levine and others suggested that the effects of handling are actually mediated by changes in maternal care. Indeed, handling increases the licking/grooming of pups by the mother (Lee and Williams, 1975; Liu et al., 1997). Subsequent studies support the maternal-mediation hypothesis. One approach was to examine the consequences of naturally occurring variations in maternal licking/grooming. These studies indicate that the adult offspring of high-licking/grooming (LG) mothers resembled postnatally handled animals on measures of behavioral and endocrine responses to stress, while those of low-LG mothers were comparable to nonhandled animals. Cross-fostering studies, where pups born to high-LG mothers were fostered at birth to low-LG mothers (and vice versa), suggest a direct relationship between maternal care and the postnatal development of individual differences in behavioral and HPA responses to stress (Francis et al., 1999; Caldji et al., 2003). Finally, these studies suggest that variations within a normal range of parental care can dramatically alter development. As in humans, parental care need not include forms of overt abuse or extreme neglect to influence the development of the offspring. In large measure, this is likely because natural selection has shaped offspring to respond to subtle variations in parental behaviors as a forecast of the environmental conditions they will ultimately face following independence from the parent (Hinde, 1986).

2.2 Maternal Care in the Rat: Behavioral and HPA Responses to Stress

Central CRF systems furnish the critical signal for the activation of behavioral, emotional, autonomic, and endocrine responses to stressors. There are two major CRF pathways regulating the expression of these stress responses. First, a CRF pathway from the parvocellular regions of the paraventricular nucleus of the hypothalamus to the hypophysial-portal system of the anterior pituitary, which serves as the principal mechanism for the transduction of a neural signal into a pituitary–adrenal response (Rivier and Plotsky, 1986; Plotsky, 1991; Antoni, 1993; Whitnall, 1993). In responses to stressors, CRF, as well as cosecretagogues, such as arginine and vasopressin, are released from hypothalamic neurons into the portal blood supply of the anterior pituitary where they stimulate the synthesis and release of adrenocorticotropin hormone (ACTH). Pituitary ACTH, in turn, causes the release of glucocorticoids from the adrenal gland. CRF synthesis and release are subsequently inhibited through a glucocorticoid negative-feedback system mediated by both mineralocorticoid and glucocorticoid receptors in a number of brain regions including and perhaps especially in the hippocampus (De Kloet et al., 1998).

CRF neurons in the central nucleus of the amygdala project directly to the locus coeruleus and increase the firing rate of locus coeruleus neurons, resulting in increased noradrenaline release in the vast terminal fields of this ascending noradrenergic system. Thus, i.c.v infusion of CRF increases extracellular noradrenaline levels (Emoto et al., 1993; Lavicky and Dunn, 1993; Page and Valentino, 1994; Valentino et al., 1998). The amygdaloid CRF projection to the locus coeruleus (Moga and Gray, 1989; Koegler-Muly et al., 1993; Gray and Bingaman, 1996; Van Bockstaele et al., 1996; Valentino et al., 1998) is also critical for the expression of behavioral responses to stress (Butler et al., 1990; Liang et al., 1992; Swiergiel et al., 1993; Koob et al., 1994; Schulkin et al., 1994; Stenzel-Poore et al., 1994; Bakshi et al., 2000; Davis and Whalen, 2001). Hence, the CRF neurons in the hypothalamus and the central nucleus of the amygdala serve as important mediators of both behavioral and endocrine responses to stress.

We examine the relation between maternal care and the development of behavioral and endocrine responses to stress using a rather simple model of naturally occurring variations in maternal behavior over the first 8 days after birth (Champagne et al., 2003). We characterize individual differences in maternal behavior through direct observation of mother–pup interactions in normally reared animals. These observations reveal considerable variation in two forms of maternal behavior—LG of pups and arched-back nursing (ABN). Licking/grooming includes both body as well as anogenital licking. ABN, also referred to as "crouching," is characterized by a dam nursing her pups with her back conspicuously arched and legs splayed outward (Stern, 1997). Although common, it is not the only posture from which dams nurse. A blanket posture represents a more relaxed version of the arched-back position where the mother

is almost lying on the suckling pups. As can be imagined, it provides substantially less opportunity for movement by the pups such as nipple switching. Dams also nurse from their sides and often move from one posture to another over the course of a nursing bout. Interestingly, the frequency of LG and ABN is correlated across animals and thus we are able to define mothers according to both behaviors; high- or low-LG-ABN mothers. For the sake of most of the studies described here, high- and low-LG-ABN mothers are females whose scores on both measures were ± 1 SD above (high) or below (low) the mean for their cohort. Importantly, high- and low-LG-ABN mothers do not differ in the amount of contact time with pups. Differences in the frequency of LG or ABN do not occur simply as a function of time in contact with pups. High and low-LG-ABN mothers raise a comparable number of pups to weaning, and there are no differences in the weaning weights of the pups, which suggest an adequate level of maternal care across the groups. These findings also suggest that we are examining the consequences of variations in maternal care that occur within a normal range. Indeed, the frequency of both pup LG and ABN is normally distributed across large populations of lactating female rats (Champagne et al., 2003).

The critical question concerns the potential consequences of these differences in maternal behavior for the development of behavioral and neuroendocrine responses to stress. By comparison with the adult offspring of low-LG-ABN mothers, as adults, the offspring of high-LG-ABN mothers show reduced plasma ACTH and corticosterone responses to acute stress (Liu et al., 1997; Weaver et al., 2004). Circulating glucocorticoids act at glucocorticoid and mineralocorticoid receptor sites in corticolimbic structures, such as the hippocampus, to regulate HPA activity. Such feedback effects commonly target CRF synthesis and release at the level of the hypothalamus. The high-LG-ABN offspring showed significantly increased hippocampal glucocorticoid receptor mRNA expression, enhanced glucocorticoid negative feedback sensitivity, and decreased hypothalamic CRF mRNA levels. Moreover, (Liu et al., 1997) found that the magnitude of the corticosterone response to acute stress was significantly correlated with the frequency of both maternal LG ($r = 61$) and ABN ($r = 0.64$) during the first week of life, as was the level of hippocampal glucocorticoid receptor mRNA and hypothalamic CRF mRNA expression (all $r > 0.70$).

The offspring of the high- and low-LG-ABN mothers also differ in behavioral responses to stress (Caldji et al., 1998a,b; Francis et al., 1999; Menard et al., 2004). As adults, the offspring of the high LG-ABN show decreased startle responses, increased open-field exploration, and shorter latencies to eat food provided in a novel environment. The offspring of low-LG-ABN mothers also show greater burying in the defensive burying paradigm (Menard et al., 2004), which involves an *active* response to a threat. The offspring of the high-LG-ABN mothers exhibit decreased CRF receptor levels in the locus coeruleus, and increased GABAA/benzodiazepine receptor levels in the basolateral and central nucleus of the amygdala, as well as in the locus coeruleus (Caldji et al., 1998a,b, 2003) and decreased CRF mRNA expression in the CnAmy. Benzodiazepine agonists suppress CRF expression in the amygdala (Owens et al., 1991). Predictably, stress-induced increases in hypothalamic levels of noradrenaline that are normally stimulated by CRF were significantly higher in the offspring of the low-LG-ABN offspring.

Maternal care during the first week of life is associated with stable individual differences in GABAA receptor subunit expression in the brain regions that regulate stress reactivity. The adult offspring of high-LG-ABN mothers show significantly higher levels of GABAA/benzodiazepine receptor binding in the basolateral and central nuclei of the amygdala as well as the locus coeruleus. These findings provide a mechanism for increased GABAergic inhibition of amygdala–locus coeruleus activity. Importantly, maternal care also affects the behavioral sensitivity to acute benzodiazepine administration (Fries et al., in press). A series of in situ hybridization studies (Caldji et al., 2003) illustrate the molecular mechanism for these differences in receptor binding and suggest that variations in maternal care might actually permanently alter the subunit composition of the GABAA receptor complex in the offspring. The offspring of the high-LG-ABN mothers show increased levels of the mRNAs for the $\gamma 1$ and $\gamma 2$ subunits, and contribute to the formation of a functional benzodiazepine binding site. Such differences are not unique to the γ subunits. Levels of mRNA for the $\alpha 1$ subunit of the GABAA/benzodiazepine receptor complex are significantly higher in the amygdala and locus coeruleus of high compared with Low-LG-ABN offspring. The $\alpha 1$ subunit appears to confer higher affinity for GABA, providing the most efficient form of the GABAA receptor complex through increased receptor affinity for GABA. The adult offspring of the low-LG-ABN mothers actually show increased expression of the mRNAs for the $\alpha 3$ and $\alpha 4$ subunits in the amygdala and the locus

coeruleus. Interestingly, GABAA/CBZ receptors composed of the α3 and α4 subunits show a reduced affinity for GABA compared with the α1 subunit. Moreover, the α4 subunit does not contribute to the formation of a benzodiazepine receptor site. These differences in subunit expression are tissue specific; no such differences are apparent in the hippocampus, hypothalamus, or cortex. Thus, differences in GABAA/benzodiazepine receptor binding are not simply due to a deficit in subunit expression in the offspring of the low-LG-ABN mothers, but of an apparently "active" attempt to maintain a specific GABAA/benzodiazepine receptor profile in selected brain regions.

Together with the findings from earlier handling studies, the results of these studies suggest that the behavior of the mother toward her offspring can "program" behavioral and neuroendocrine responses to stress in adulthood. These effects are associated with sustained changes in the expression of genes in brain regions that mediate responses to stress and form the basis for stable individual differences in stress reactivity. These findings provide a potential mechanism for the influence of parental care on vulnerability/resistance to stress-induced illness over the lifespan.

2.3 Cross-fostering Studies: Evidence for Direct Maternal Effects

Individual differences in behavioral and neuroendocrine responses to stress in the rat are associated with naturally occurring variations in maternal care. Such effects might serve as a possible mechanism by which selected traits might be transmitted from one generation to another. Indeed, low-LG-ABN mothers are more fearful in response to stress than are high-LG-ABN dams (Francis et al., 2000). Individual differences in stress reactivity are apparently transmitted across generations: Fearful mothers beget more stress reactive offspring. The obvious question is whether the transmission of these traits occurs only as a function of genomic-based inheritance. If this is the case, then the differences in maternal behavior may simply be an epiphenomenon, and not causally related to the development of individual differences in stress responses. The issue is not one of inheritance, but of the mode of inheritance.

The results of recent studies provide evidence for a nongenomic transmission of individual differences in stress reactivity and maternal behavior (Francis et al., 1999). One study involved a reciprocal cross-fostering of the offspring of low- and high-LG-ABN mothers. The primary concern here was that the wholesale fostering of litters between mothers is known to affect maternal behavior (Maccari et al., 1995). To avert this problem and maintain the original character of the host litter, no more than 2 of 12 pups were fostered into or from any one litter (McCarty and Lee, 1996). The critical groups of interest are the biological offspring of low-LG-ABN mothers fostered onto high-LG-ABN dams, and vice versa. The limited cross-fostering design did not result in any effect on group differences in maternal behavior. Hence, the frequency of pup licking/grooming and ABN across all groups of high-LG-ABN mothers was significantly higher than that for any of the low-LG-ABN dams regardless of litter composition.

The results of the behavioral studies are consistent with the idea that variations in maternal care are causally related to individual differences in the behavior of the offspring. The biological offspring of low-LG-ABN dams reared by high-LG-ABN mothers were significantly less fearful under conditions of novelty than were the offspring reared by low LG-ABN mothers, including the biological offspring of high-LG-ABN mothers (Francis et al., 1999). Subsequent studies reveal similar findings for hippocampal glucocorticoid receptor expression and for the differences in both the α1 and γ2 GABAA receptor subunit expression in the amygdala (Caldji et al., 2003). These findings suggest that individual differences in patterns of gene expression and behavior can be directly linked to maternal care over the first week of life.

3 Environmental Programming of Glucocorticoid Receptor Expression

3.1 Molecular Basis for the Effect of Maternal Care on HPA Responses to Stress

Postnatal handling, which increases maternal licking/grooming, and increased levels of licking/grooming increase 5-HT turnover in the hippocampus in day 6 rat pups. Interestingly, postnatal handling results in

specific increases in 5-HT in the hippocampus and prefrontal cortex, where glucocorticoid receptor expression is increased. Serotonin levels in the hypothalamus, septum, and amygdala are unaffected and glucocorticoid receptor levels in these regions are not altered by handling.

In vitro, the treatment of primary hippocampal cell cultures with 5-HT increases glucocorticoid receptor expression and this effect is mediated by 5-HT_7 receptor activation (Mitchell et al., 1990a,b, 1992; Laplante et al., 2002). The 5-HT_7 receptor, positively coupled to cAMP and glucocorticoid receptor expression in cultured hippocampal neurons, is significantly increased after treatment with 8-bromo cAMP or with various doses of the specific 5-HT_7 receptor agonist, 3-(2-Aminoethyl)-1H-indole-5-carboxamide maleate (5-carboxamidotryptamine; 5-CT) for 4 days. The effect of 5-CT on glucocorticoid receptor expression is blocked by methiothepin. Likewise, 5-CT produces a significant increase in cAMP levels and the effect is blocked by methiothepin. Pindolol, which binds to the 5-HT_{1A} but not the 5-HT_7 receptor, has little effect [also see Mitchell et al. (1992)]. These results further implicate the 5-HT_7 receptor. The increase in glucocorticoid receptor expression is also mimicked with 5-methoxytryptamine (5-MeOT), an effect blocked with methiothepin as well as H8, an inhibitor of PKA (cyclic nucleotide-dependent protein kinase). Over the course of these studies, we found that other serotonergic agonists could partially mimic the 5-HT effect on GR levels; however, this was the first evidence that a more selective serotonergic agonist, 5-CT, could fully mimic the 5-HT effect. Moreover, across all studies, the magnitude of the serotonergic effect on cAMP concentrations is highly correlated ($r = 0.97$) with that on glucocorticoid receptor expression. This observation is consistent with the idea that the effect of 5-HT of glucocorticoid receptor expression in hippocampal neurons is mediated by a 5-HT_7 receptor via the activation of cAMP.

Significantly, the increase in glucocorticoid receptor binding capacity following 5-HT treatment persists following 5-HT removal from the medium; for as long as the cultures can be maintained, there is a sustained increase in glucocorticoid receptor levels as long as 50 days beyond the removal of 5-HT from the medium. Thus, 5-HT can act directly on hippocampal neurons to increase glucocorticoid receptor expression, and the effect of 5-HT on glucocorticoid receptor density observed in hippocampal culture cells mimics the long-term effects of early environmental events.

Activation of cAMP pathways can regulate gene transcription through effects on a number of transcription factors, including of course, the cAMP-response element binding protein (CREB) via an enhanced phosphorylation of CREB. pCREB regulates gene transcription through pathways that involve the transcriptional cofactor, CREB-binding protein (CBP). Primary hippocampal cell cultures treated with 8-bromo cAMP, 5-CT, or 5-HT show a significant increase in CBP expression.

The 5-HT_7 receptor is positively coupled to adenylyl cyclase. In vivo, both handling and increased maternal licking/grooming result in an increased level of hippocampal cAMP concentrations and the activation of PKA over the first week of postnatal life (Mitchell et al., 1992). Activation of PKA results in the tissue-specific induction of a number of transcription factors. The day 6 offspring of high-LG mothers or pups of the same age exposed to handling show increased hippocampal expression of NGFI-A (also known as, zif-268, krox-24, egr-1, zenk, etc). In vitro, 5-HT increases NGFI-A expression in cultured hippocampal neurons and the effect of 5-HT on glucocorticoid receptor expression in hippocampal cultures is completely blocked by concurrent treatment with an oligonucleotide antisense directed at the NGFI-A mRNA.

These studies suggest that maternal licking/grooming results in an increased expression of NGFI-A, which in turn might then regulate glucocorticoid receptor expression. Other rodent models examining environmental regulation of hippocampal glucocorticoid receptor expression also suggest a correspondence between NGFI-A levels and glucocorticoid receptor expression (Mohammed et al., 1993; Andrews et al., 2004). In each case, increased levels of NGFI-A are associated with enhanced glucocorticoid receptor expression. However, the critical site for glucocorticoid receptor regulation remains to be defined.

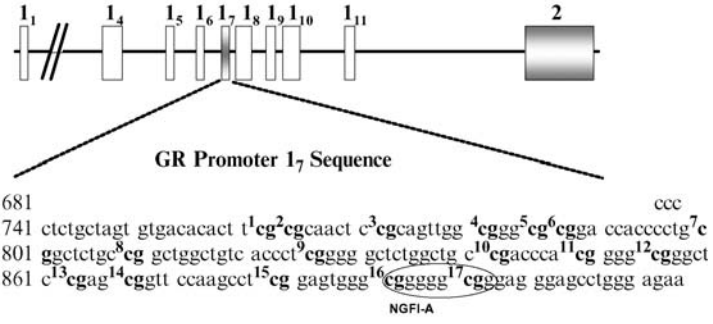
3.2 Glucocorticoid Receptor Gene Regulation

We assumed that a potential target for regulation is the promoter region of the glucocorticoid receptor gene. We (McCormick et al., 2000) identified and characterized several new glucocorticoid receptor

mRNAs cloned from rat hippocampus. They encode a common protein, but differ in their 5′-leader sequences presumably because of alternative splicing of potentially several different sequences from the 5′ noncoding exon 1 region of the glucocorticoid receptor gene. The alternate exon 1 sequences are unlikely to alter the amino acid sequence of the glucocorticoid receptor protein; an in-frame stop codon is present immediately 5′ to the translation initiation site in exon 2, common to all the mRNA variants. Of the ten alternate exon 1 sequences identified by 5′-RACE, four correspond to alternative exon 1 sequences previously identified in mouse, exons 1_1, 1_5, 1_9, and 1_{10} (Strähle et al., 1992; Chen et al., 1999). There is a consensus 5′ splice site immediately downstream of each of these exon 1 sequences. Thus, each alternative exon 1 is spliced onto the first coding exon to create diverse glucocorticoid receptor mRNAs. Most alternative exons are located in a 3-kb CpG island upstream of exon 2 that exhibits substantial promoter activity in transfected cells. Ribonuclease protection assays demonstrate significant levels of six alternative exon 1 sequences in vivo in the rat, with differential expression in the liver, hippocampus, and thymus presumably reflecting tissue-specific differences in promoter activity. Hippocampal RNA contains significant levels of the exon 1_7-containing glucocorticoid receptor mRNA variants expressed at undetectable levels in the liver and thymus.

Figure 15-2

The 5′ noncoding variable exon 1 region of the hippocampal glucocorticoid receptor gene contains multiple alternate exon 1 sequences (McCormick et al., 2000), four of which correspond to alternative exon 1 sequences previously identified in mouse, exons 1_1, 1_5, 1_9 and 1_{10}. Transfection studies show that the activity of individual constructs fused to a luciferase reporter in different cell types is similar with one notable exception; the exon 1_7 promoter sequence has the highest activity of any single promoter construct (McCormick et al., 2000)



In transient transfection experiments, a construct encoding the whole CpG island of the glucocorticoid receptor gene, including eight of the alternate exon 1 sequences and the splice acceptor site within the intron 5′ of exon 2, fused to a luciferase reporter gene within exon 2, exhibited substantial promoter activity in all cell lines tested. This activity results from transcripts originating at any point within the CpG island that are spliced from an appropriate donor site onto the splice acceptor site 5′ to exon 2 and, we presume, represents the sum of the activity of individual promoters on the genomic DNA fragment. Promoter activity is also associated with particular regions of the CpG island, where the fusion to luciferase was made within specific exon 1 sequences. In these cases, no splice acceptor site is available within the luciferase gene, and a transcriptional fusion was generated between the specific exon 1 and the luciferase reporter; luciferase activity therefore reflects transcription through the specific exon 1. Relative activity of these constructs in different cell types is similar with one notable exception, the exon 1_7 promoter sequence. The exon 1_7, fused to luciferase within exon 1_7, has the highest activity of any single promoter construct in B103 and C6 cells, both of which are CNS derived. The activity of this construct is lower in hepatic cells. In vivo, glucocorticoid receptor mRNA transcripts containing exon 1_7 are present at significant levels in the hippocampus, but absent in the liver, suggesting that factors present in

the cells of CNS origin are responsible for transcription initiation at the promoter upstream of exon 1_7 in rat hippocampus.

Interestingly, exon 1_7 usage is altered by postnatal handling, which increases glucocorticoid receptor expression in the hippocampus. Handling selectively elevated glucocorticoid receptor mRNA containing exon 1_7; there is, for example, no effect on exon 1_{10} (McCormick et al., 2000). Predictably, maternal care also affected the expression of glucocorticoid receptor splice variants: Variants containing the exon 1_7 sequence were significantly increased in the adult offspring of high-LG-ABN mothers.

3.3 NGFI-A Regulation of Glucocorticoid Receptor Gene Expression

The CpG island of the glucocorticoid receptor gene contains GC boxes (GCGGGGGCG), which form the core consensus site for NGFI-A. There is indeed a sequence exactly matching the consensus-binding site for the family of zinc finger proteins that includes NGFI-A (Crosby et al., 1991) within exon 1_7. Thus, increases in NGFI-A induced by maternal licking/grooming could increase transcription from a promoter adjacent to exon 1_7, leading to increased glucocorticoid receptor mRNA. In previous studies, we found that handling increased the binding of both NGFI-A to a promoter sequence for the human glucocorticoid receptor containing consensus sequences for both transcription factors. Since neonatal handling increases maternal licking/grooming, these finding suggest that naturally occurring variations in maternal behavior might regulate glucocorticoid receptor expression in neonatal offspring through a 5-HT-induced increase in NGFI-A expression, and the subsequent binding of NGFI-A to the exon 1_7 promoter. Recent findings support this idea, including studies using the chromatin immunoprecipitation (ChIP) assay in which the in vivo formation of protein–DNA complexes is examined using cross-linking with paraformaldehyde perfusion and subsequently precipitated from soluble hippocampal samples using specific antibodies. Protein binding, defined by the specificity of the antibody, to specific DNA sequences is then quantified following PCR amplification with targeted primers and Southern blotting. ChIP analysis of hippocampal samples from postnatal day 6 pups reveals dramatically increased NGFI-A binding to the exon 1_7 promoter in the offspring of high- compared with low-LG-ABN mothers. These findings confirm that maternal care regulates the binding of NGFI-A to the exon 1_7 promoter sequence in pups.

More recent studies confirm the transactivational effect of NGFI-A at the exon 1_7 sequence. We used a cotransfection model with HEK cells (intentionally aiming as far from the neural target as possible) with an NGFI-A expression vector and an exon 1_7-luciferase construct. Cotransfection of the NGFI-A vector and the exon1_7-luciferase construct resulted in a robust increase in luciferase activity, reflecting NGFI-A-induced activation of transcription through the exon 1_7 promoter. Recall that an NGFI-A antisense completely blocks the effects of 5-HT on glucocorticoid receptor expression in hippocampal cell cultures.

These findings suggest that NGFI-A might increase glucocorticoid receptor expression in hippocampal neurons, and provide a mechanism for the effect of maternal care over the first week of life. However, while there are striking differences in NGFI-A expression in the offspring of high- and low-LG mothers at day 6 of postnatal life, hippocampal NGFI-A expression in adulthood is unaffected by maternal care. There is no difference in hippocampal NGFI-A expression in the adult offspring of high- and low-LG-ABN dams. We are thus left with the defining question of early experience studies: How are the effects of early life events sustained into adulthood?

4 The Epigenome and Epigenetic Programming of Stress Responses

4.1 DNA Methylation and Chromatin Structure

While we are all familiar with linear models of DNA and protein–DNA interactions, such models ignore the fact that most of the DNA is tightly packed into nucleosomes that involve a close relationship between DNA wrapped around a core of histone proteins. The conformation or structure of the histone–DNA configuration regulates gene expression. The relation between DNA and histone is maintained, in part, by

electrostatic bonds occurring between the positively charged histones and the negatively charged DNA. This chromatin structure commonly precludes transcription factor binding to DNA and underscores the importance of enzymes that modify histone–DNA interactions. One class of such proteins, histone acetyltransferase (HAT; Roth et al., 2001), catalyzes the acetylation of selected amino acids on the protruding histone tails, most commonly histone 3 (H3) or H4. Positively charged amino acids such as lysine and arginine are common targets for acetylation. Histone acetylation modifies the histone–DNA relation. For example, acetylation of the lysine (K) residue on H3 serves to neutralize the positively charged histone, opening the histone–DNA relationship, and facilitating transcription factor binding to DNA. Thus, H3-K9 acetylation serves as a marker of active gene transcription. Many known transcriptional cofactors, such as CBP, are HATs. Histone acetylation is dynamic and is regulated by HDACs, which serve to block histone acetylation and suppress gene expression. Thus, chromatin structure can be viewed as dynamic and clearly subject to modification through intracellular signals that trigger either HATs or HDACs downstream (Bird and Wolffe, 1999; Bird, 2001; Li, 2003). Indeed, in addition to CBP, several known transcriptional cofactors act as histone acetylases. The study of histone acetylation provides a remarkable advance in our understanding of the dynamic and complex regulation of gene expression. Likewise, histone modifications involving methylation, phosphorylation, ribosylation, and ubiquitination can all modify chromatin structure and thus gene expression.

4.2 The Chemistry of DNA Methylation

In addition to chromatin, which is associated with DNA, the DNA molecule is itself chemically modified by methyl residues at the 5′ position of the cytosine rings in the sequence CG in vertebrates (Razin and Riggs, 1980; Wolffe et al., 1999). What distinguishes DNA methylation in vertebrate genomes is the fact that not all CGs are methylated in any given cell type (Razin and Szyf, 1984). Different CGs are methylated in different cell types, generating cell-type-specific patterns of methylation. Thus, the DNA methylation pattern confers upon a genome itself its cell type identity. Since DNA methylation is part of the chemical structure of the DNA, it remains long after all other proteins and epigenomic marks are degraded, and thus it has extremely important diagnostic potential (Shi et al., 2003). It was originally believed that the DNA methylation pattern is established during development, and is then maintained faithfully throughout life by the maintenance DNA methyltransferase (Razin and Szyf, 1984; Reik et al., 2000). The DNA methylation reaction was believed to be irreversible; thus the only way methyl residues could be lost was believed to be through replication in the absence of DNA methyltransferase by passive demethylation (Razin and Riggs, 1980; Wolffe et al., 1999). This mechanism is not applicable to postmitotic tissue such as neurons in the brain. However, our recent data and the data reviewed here support an alternative model that the DNA methylation pattern is dynamic and is an equilibrium of methylation and demethylation reaction (Szyf, 2001). We propose that DNA methylation is a reversible signal like any other biological signal and could therefore potentially change in response to environmental and physiological signals. The notion that DNA methylation is reversible in postmitotic cells has immense implications on our understanding of the potential role of DNA methylation in marking gene expression in the brain.

The hallmark of DNA methylation patterns is the correlation between chromatin and the DNA methylation pattern. Active chromatin is usually associated with unmethylated DNA while inactive chromatin is associated with methylated DNA (Razin and Cedar, 1977; Kadonaga, 1998; Bird and Wolffe, 1999). This tight linkage between DNA methylation and chromatin structure has important implications on our understanding of the function of DNA methylation as well as the processes responsible for generating, maintaining, and altering DNA methylation patterns under physiological and pathological conditions. It was originally believed that DNA methylation precedes and is dominant over chromatin structure changes (e.g., Hashimshony et al., 2003). Methylation was believed to be generated independently of chromatin structure. Methylated DNA attracts methylated DNA binding proteins that recruit repressor complexes containing HDACs, which results in an inactive chromatin (Jones et al., 1998; Nan et al., 1998). The model positioning DNA methylation as driving chromatin inactivation is widespread and profoundly influences our understanding of how altered DNA methylation is involved in cancer. Nevertheless, at

present there are data suggesting that the state of chromatin structure can also determine DNA methylation and that chromatin can affect DNA methylation in both directions triggering either de novo DNA methylation or demethylation (Cervoni and Szyf, 2001). These data revise the classic model of a DNA methylation pattern, which is predetermined during development and is then maintained through life, and gives a more dynamic view of the DNA methylation pattern as an interface between the dynamic environment and the static genome. Thus, although DNA methylation is an extremely stable signal, it can be altered later in life when there is a sufficiently stable and consistent signal to activate the chromatin. Transient changes in chromatin structure are not accompanied by changes in DNA methylation. The DNA methylation pattern is proposed to guard the epigenome from random noise and protect it from drifting (Szyf, 2001). This relation between the chromatin state and DNA methylation forms a molecular link through which environmental signals might alter DNA methylation in specific genes in postmitotic neurons. Behavioral signals trigger cellular signaling pathways whose downstream consequence is activation of *trans*-acting factors. These trans-acting factors recruit HAT to the target gene resulting in increased histone acetylation, chromatin opening, and increased accessibility to DNA demethylases. Since methylation of cytosine is an extremely stable chemical bond on DNA, this modification will remain stable for years. For methylation signals to serve as stable marks, they should not be responsive to chromatin noise or short-term signals. The mechanism proposed here also allows for a reversal of the methylation mark by a similar intense change in chromatin structure later in life (Szyf, 2001). This model has important implications on our understanding of how behavioral signals can stably alter glucocorticoid gene expression and how these stable marks in the genome are potentially reversible later in life by specific interventions in spite of their remarkable stability.

DNA methylation marks genes for silencing by a number of mechanisms. The first mechanism is indirect and links DNA methylation to inactive chromatin structure. A region of methylated DNA juxtaposed to regulatory regions of genes attracts different members of a family of methylated DNA binding proteins. The better-studied member of this class is MeCP2, which recruits HDACs (Jones et al., 1998; Nan et al., 1998) and histone methyltransferases (Fuks et al., 2003) to methylated genes (Razin, 1998; Bird and Wolffe, 1999). This results in a modification of chromatin around the gene precipitating an inactive chromatin structure. A different mechanism, which is relevant to our discussion here, involves direct interference of a specific methylated CG residing within a *cis*-recognition sequence for a transcription factor with the interaction of transcription factors, such as the inhibition of binding of cMyc to its recognition element when it is methylated. Essentially, the methylated C serves as a mutation of the recognition element. A third mechanism involves a combination of binding a methylated DNA binding protein and inhibition of activity of a transcription factor (Kudo, 1998). While the first mechanism is dependent on the general density of methyl cytosines within the region associated with a gene rather than methylation of a specific CG, the second mechanism requires a discrete methylation event and is relevant to the mechanism proposed here.

4.3 Maternal Care and DNA Methylation

The important consideration is the stability of cytosine methylation, which is preserved by covalent carbon–carbon bonds and could therefore as a long-term memory of early life behavioral signaling lead to chromatin activation of the glucocorticoid receptor promoter in the offspring of high LG-ABN and lack of chromatin activation in low LG-ABN. DNA methylation changes might provide a mechanism for environmental programming effects occurring in early development. Glucocorticoid receptor gene expression is increased throughout the hippocampus in the adult offspring of high- compared with low-LG-ABN mothers (Liu et al., 1997). The exon 1_7 glucocorticoid receptor promoter sequence appears to be significantly more active in the adult offspring of high compared with low-LG-ABN mothers and was therefore the focus of initial studies of possible maternal effects on DNA methylation. To test the hypothesis that maternal care alters the DNA methylation mark of the glucocorticoid receptor promoter, Weaver et al. (2004) examined the level of methylation across the entire exon 1_7 glucocorticoid receptor promoter sequence in the hippocampus using the sodium bisulfite mapping technique in the adult offspring of

high- and low-LG-ABN mothers. Sodium bisulfite treatment of DNA samples converts nonmethylated cytosines to uracils, which are then detected as thymidine on subsequent sequencing gels (Frommer et al., 1992). Methylated cytosines are unaffected by sodium bisulfite and the differences in methylation status are thus apparent and easily quantifiable on sequencing gels. We found significantly greater methylation of the exon 1_7 glucocorticoid receptor promoter sequence in the offspring of the low-LG-ABN mothers. These findings are consistent with the hypothesis that maternal effects alter DNA methylation patterns in the offspring.

To determine whether DNA methylation of specific target sites on the glucocorticoid receptor promoter changes in response to maternal care, we mapped the differences in methylation using the NaBis mapping technique, focusing on a region around the NGFI-A consensus sequence within the exon 1_7 promoter. The results reveal significant differences in the methylation of specific regions of the exon 1_7 glucocorticoid receptor promoter sequence. Notably, the cytosine within the 5′ CpG dinucleotide of the NGFI-A consensus sequence is always methylated in the offspring of low-LG-ABN mothers, and rarely methylated in the offspring of high-LG-ABN dams. This is consistent with site-specific DNA methylation silencing of the glucocorticoid receptor promoter.

To directly examine a causal relation between maternal behavior and DNA methylation changes within the exon 1_7 glucocorticoid receptor promoter, Weaver and colleagues (2004) performed an adoption study. As per this study, the biological offspring of high- or low-LG-ABN mothers were cross-fostered to either high or low dams within 12 h of birth (as described earlier; see Francis et al., 1999; Caldji et al., 2003). These studies could rule out either a purely genetic or a prenatal basis for the variation in DNA methylation in the offspring of high-LG-ABN versus low-LG-ABN. Cross-fostering the biological offspring of high- or low-LG-ABN mothers produced a pattern of exon 1_7 glucocorticoid receptor promoter methylation associated with the rearing mother. The cross-fostering procedure reverses the difference in methylation at specific cytosines. The cytosine within the 5′ CpG dinucleotide of the NGFI-A consensus sequence is hypomethylated following cross-fostering of the offspring of low-LG-ABN to high-LG-ABN dams, with no effect at the cytosine within the 3′ CpG dinucleotide. Thus, the pattern of methylation of the cytosine within the 5′ CpG dinucleotide of the NGFI-A consensus sequence within the exon 1_7 glucocorticoid receptor promoter of the biological offspring of low-LG-ABN mothers cross-fostered to high-LG-ABN dams is indistinguishable from that of the biological offspring of high-LG-ABN mothers. The reverse is true for the offspring of high-LG-ABN mothers fostered to low-LG-ABN dams. Interestingly, cross-fostering does not have the same effect on the CpG methylation status on each individual dinucleotide in the exon 1_7 sequence. For example, the CpG dinucleotide of the AP-1 consensus sequence within the exon 1_7 glucocorticoid receptor promoter of the biological offspring of high-LG-ABN mothers cross-fostered to low-LG-ABN dams remains hypomethylated. However, the CpG dinucleotide of the AP-1 consensus sequence within the exon 1_7 glucocorticoid receptor promoter of the biological offspring of low-LG-ABN mothers cross-fostered to high-LG-ABN dams remains hypermethylated. The molecular basis for such selectivity is unknown. These findings suggest that variations in maternal care alter the methylation status within specific sites of the exon 1_7 promoter of the glucocorticoid receptor gene and represent the first demonstration of a DNA methylation pattern established through a behavioral mode of programming. Parental imprinting (Sapienza, 1990), a well-established paradigm of inheritance of an epigenomic mark, requires germ-line transmission (Li, 2003).

4.4 Site-Specific Methylation of the 5′ CpG Dinucleotide of the NGFI-A Response Element Blocks Transcription Factor Binding

The obvious question concerns the functional importance of such differences in methylation. DNA methylation affects gene expression either by attracting methylated DNA binding proteins to a densely methylated region of a gene or by site-specific interference with the binding of a transcription factor to its recognition element (Razin, 1998; Bird and Wolffe, 1999). Data showing site-specific demethylation of the cytosine within the 5′ CpG dinucleotide of the NGFI-A response element is consistent with the hypothesis that methylation at this site interferes with the binding of NGFI-A protein to its binding site. To address this question, we determined the in vitro binding of increasing concentrations of purified recombinant NGFI-A

protein (Milbrandt et al., 1987) to its response element under different states of methylation using the electrophilic mobility shift assay (EMSA) technique with four ^{32}P-labeled synthetic oligonucleotide sequences bearing the NGFI-A binding site. This binding site was either (a) nonmethylated, (b) methylated in the 3′ CpG site, (c) methylated in the 5′ CpG site, (d) methylated in both sites, or (e) mutated at the two CpGs with an adenosine replacing the cytosines. NGFI-A formed a protein–DNA complex with the nonmethylated oligonucleotide, while the protein was unable to form a complex with either a fully methylated sequence or a sequence methylated at the 5′ CpG site. NGFI-A binding to its response element was only slightly reduced with the sequence methylated at the 3′ CpG site. The effect of selective cytosine methylation on NGFI-A binding was further confirmed by competition experiments. NGFI-A recombinant protein was incubated with a labeled, nonmethylated oligonucleotide in the presence of increasing concentrations of nonlabeled oligonucleotides containing the NGFI-A consensus sequence that were either 3′ CpG methylated, 5′ CpG methylated, methylated at both sites, or mutated at the two CpGs with an adenosine replacing the cytosines. The nonmethylated oligonucleotide completely eliminates the formation labeled oligonucleotide protein–DNA complex, while the mutated oligonucleotide is unable to compete away the labeled oligonucleotide protein–DNA complex. Neither the oligonucleotide methylated in both the 3′ and 5′ CpGs nor the 5′ CpG methylated oligonucleotide were able to compete. Importantly, the 3′ CpG methylated oligonucleotide, which mimics the sequence observed in the offspring of high-LG-ABN mothers, exhibited substantial competition, suggesting that binding activity is retained despite the methylation at this site. The results indicate that while methylation of the cytosine within the 5′ CpG dinucleotide reduces NGFI-A protein binding to the same extent as methylation in both CpG sites, methylation of the cytosine within the 3′ CpG dinucleotide only partially reduces NGFI-A protein binding. These data support the hypothesis that methylation of the cytosine within the 5′ CpG dinucleotide in the NGFI-A response element of the exon 1_7 glucocorticoid receptor promoter region in the offspring of low LG-ABN mothers inhibits NGFI-A protein binding.

This is an important finding for our understanding of the processes by which maternal care programs hippocampal glucocorticoid receptor expression and thus HPA responses to stress. Although there are substantial differences in NGFI-A expression between the offspring of high- and low-LG-ABN mothers in early postnatal life, no such differences are apparent in adulthood. Our hypothesis is that the cytosine methylation in the binding site for NGFI-A interferes with NGFI-A binding to the glucocorticoid receptor exon 1_7 promoter. Therefore, it was predicted that the lower cytosine methylation in the adult offspring of high- compared with low-LG-ABN mothers would result in greater NGFI-A binding to the exon 1_7 promoter. This prediction was confirmed using a chromatin-immunoprecipitation (ChIP) assay examining in vivo formation of protein–DNA complexes in hippocampal tissue from adult animals (Weaver et al., 2004). Animals were perfused with paraformaldehyde to fix protein–DNA complexes at the time of sacrifice. NGFI-A-bound DNA complexes were then immunoprecipitated using a selective antibody. The protein–DNA complexes were uncross-linked, and the precipitated genomic DNA was subjected to PCR amplification with primers specific for the exon 1_7 glucocorticoid receptor promoter sequence. The results indicated a threefold greater binding of NGFI-A protein to the hippocampal exon 1_7 glucocorticoid receptor promoter in the adult offspring of high- than in low-LG-ABN mothers. Using the same tissue samples and an antibody against the acetylated form of H3, we also found dramatically increased acetylated H3 association with the exon 1_7 glucocorticoid receptor promoter in the offspring of the high-LG-ABN mothers. As described earlier, histone acetylation is associated with active states of gene expression. These findings are therefore consistent with the idea of increased NGFI-A binding to the exon 1_7 promoter and increased transcriptional activation.

We confirmed that DNA methylation inhibits the ability of NGFI-A to activate the exon 1_7 promoter in isolation from other potential differences between adult offspring of high- and low-LG-ABN dams using a transient cotransfection assay in human HEK 293 cells. These cells are not of hippocampal origin and thus allow us to measure the transcriptional consequences of the interaction of NGFIA with either a methylated or nonmethylated version of the glucocorticoid receptor exon 1_7 promoter per se. Although transfection of HEK cells containing an exon 1_7-luciferase reporter construct with an NGFI-A expression vector significantly increases luciferase activity, this effect is dramatically reduced if the CpG dinucleotides within the exon 1_7 sequence are methylated. Moreover, the effect of NGFI-A on transcription through an exon

1_7-luciferase reporter construct was almost completely abolished with a point mutation at the 5′ cytosine (a cytosine to adenosine mutation). Taken together, these findings suggest that an "epimutation" at a single cytosine within the NGFI-A consensus sequence alters the binding of NGFI-A and might therefore explain the sustained effect of maternal care on hippocampal glucocorticoid receptor expression and HPA responses to stress.

4.5 How Does Maternal Care Alter Cytosine Methylation?

Maternal behavior could either inhibit de novo methylation or stimulate demethylation. To address this question, we performed a developmental study of the methylation pattern of glucocorticoid receptor exon 1_7 promoter from embryonic day 20 to day 90. High- and low-LG-ABN mothers differ in the frequency of pup licking/grooming and ABN only during the first week of life. More important, this period corresponds to the appearance of the difference in DNA methylation in the offspring in studies using sodium bisulfite mapping to precisely map the methylation status of the cytosines within the exon 1_7 glucocorticoid receptor promoter over multiple developmental time points. This analysis demonstrates that just before birth, on embryonic day 20, the entire exon 1_7 region is unmethylated in both groups. Strikingly, 1 day following birth (postnatal day 1) the exon 1_7 glucocorticoid receptor promoter is de novo methylated in both groups. The 5′ and 3′ CpG sites of the exon 1_7 glucocorticoid receptor NGFI-A response element in the offspring of both high- and low-LG-ABN mothers, which exhibit differential methylation later in life, are de novo methylated to the same extent. These data show that both the basal state of methylation and the first wave of de novo methylation after birth occur similarly in both groups. Whereas it is generally accepted that DNA methylation patterns are formed prenatally and that de novo methylation occurs early in development, there is at least one documented example of postnatal de novo methylation of the HoxA5 and HoxB5 genes (Hershko et al., 2003). Since similar analyses are not documented for other genes, it is unknown yet whether changes in methylation are common around birth or whether they are unique to this glucocorticoid receptor promoter. One aspect of these findings that is important is that of the complete absence of cytosine methylation on embryonic day 20. As the majority of the pyramidal cells of Ammon's Horn are born between embryonic days 16 and 20, it seems unlikely that methylation patterns, at least on the exon 1_7 promoter of the glucocorticoid receptor, are generated at the time of DNA replication and cell division, as would normally be the case with imprinted genes.

The differences in the status of methylation of the exon 1_7 glucocorticoid receptor developed between the two groups emerge between postnatal days 1 and 6, which is precisely the period when differences in the maternal behavior of high- and low-LG-ABN dams are apparent. There are no differences in maternal licking/grooming between high- and low-LG-ABN mothers beyond day 8 (Caldji et al., 1998a,b; Champagne et al., 2003). By postnatal day 6, the 5′ CpG dinucleotide of the NGFI-A response element is demethylated in the high, but not in the low-LG-ABN group. These findings are consistent with data from the cross-fostering experiment, which illustrates that the differences between the two groups developed following birth in response to maternal behavior. The group difference in CpG dinucleotide methylation then remains consistent through to adulthood. Our findings suggest that the group difference in DNA methylation occurs as a function of maternal behavior over the first week of life. The results of earlier studies indicated that the first week of postnatal life is indeed a "critical period" for the effects of early experience on hippocampal glucocorticoid receptor expression.

4.6 Reversal of the Maternal Effect on Glucocorticoid Receptor Expression and HPA Responses to Stress

These findings suggest that maternal behavior produces an active demethylation process at selected and presumably targeted sites. The resulting demethylation of the 5′ CpG dinucleotide within the NGFI-A

response element of the exon 1_7 promoter enhances NGFI-A binding, increasing glucocorticoid receptor gene transcription and HPA responses to stress.

These findings raise the question of how maternal high LG-ABN might activate a demethylation of the glucocorticoid receptor exon 1_7 promoter. As discussed earlier, a testable working hypothesis is that high LG-ABN leads to activation of NGFI-A as a downstream effector of activation of a 5-HT signaling through increased cAMP and PKA. Increased NGFI-A increases the frequency of occupancy of the GR exon 1_7 promoter. NGFI-A interaction with the GR exon 1_7 promoter leads to increased acetylation and increased accessibility of the GR exon 1_7 promoter to demethylase resulting in DNA demethylation. This hypothesis predicts that pharmacological activation of chromatin using HDAC inhibitors should result in the activation of GR exon 1_7 promoter demethylation. However, the question is whether this reversibility will be limited to early life exclusively or whether it is possible to reverse these marks later in life as well, if the appropriate signals to activate the chromatin structure are applied or by a pharmacological activation of chromatin structure.

Our hypothesis is that the DNA methylation is a steady state of DNA methylation and demethylation whose direction is determined by the state of chromatin structure (Szyf, 2001). This hypothesis predicts that both DNMTs and demethylases are present in adult neurons and that if the chromatin state is altered by either persistent physiological or pharmacological signals one should be able to change the state of methylation of a gene in postmitotic tissue such as adult hippocampal neurons. We previously established that pharmacological activation of chromatin structure by HDAC inhibitors could trigger replication-independent active demethylation of DNA (Cervoni and Szyf, 2001). The hypothesis was tested and showed that the demethylation of the GR exon 1_7 promoter is driven by histone acetylation and could be activated in adult neurons as well. This understanding leads to an obvious prediction: HDAC inhibition should reverse the effects of cytosine methylation on NGFI-A binding to the exon 1_7 promoter, GR expression, and HPA responses to stress. We tested this idea with central infusion of adult offspring of high- or low-LG-ABN mothers with the HDAC inhibitor, trichostatin A (TSA), for four consecutive days. As expected, ChIP assays revealed that TSA infusion significantly increased the level of acetylated H3 at the exon 1_7 site (i.e., HDAC inhibition resulted in increased histone acetylation) in the offspring of low-LG-ABN mothers to levels comparable with those observed in the offspring of high LG-ABN mothers. The increased histone acetylation is associated and enhanced with NGFI-A binding to the exon 1_7 promoter sequence and completely eliminates the effect of maternal care. As expected, enhanced NGFI-A binding to the exon 1_7 promoter increased hippocampal glucocorticoid receptor expression. Hippocampal glucocorticoid receptor expression in the TSA-treated adult offspring of low-LG-ABN mothers is indistinguishable from that of the high LG-ABN groups. Most important, TSA infusion also eliminates the effect of maternal care on HPA responses to stress. During and following exposure to acute stress, plasma corticosterone levels in TSA-treated offspring of low-LG-ABN mothers are indistinguishable from those of TSA- or vehicle-treated high-LG-ABN mothers. There was no effect of TSA on any measure in the offspring of high-LG-ABN animals. This is understandable because under normal circumstances there is considerable H3 acetylation and NGFI-A binding at the exon 1_7 sequence in these animals.

These findings have important implications on our understanding of the mechanisms linking early maternal behavior and stable changes in behavior later in adulthood, as well as on our understanding of the mechanisms responsible for maintaining the DNA methylation pattern in adult postmitotic tissues. First, our data support the idea that demethylation is driven by activation of chromatin and that HDAC inhibitors produce demethylation even in nondividing cells (i.e., in a replication-independent manner). Second, our data are consistent with the hypothesis that the demethylation of GR exon 1_7 in offspring of high-LG-ABN rats early after birth is driven by increased histone acetylation as discussed earlier. Third, these data provide the first evidence that molecular mechanisms that underlie the effects of early life-experience neural function are potentially reversible in adulthood. This consideration is of obvious social and therapeutic implications. Fourth, these data provide the first in vivo evidence for our hypothesis that the DNA methylation pattern is dynamic even in postmitotic tissues and that its steady state is maintained by the state of chromatin acetylation (Szyf, 2001). Fifth, our data provide a general mechanism for how external signals could change the DNA methylation pattern and thus the chemistry of the genome itself even during adulthood.

4.7 Dissection of the Molecular Mechanisms Linking Maternal Behavior and Active Demethylation of GR exon 1_7 Promoter in the Hippocampus

The data discussed above support the hypothesis that histone acetylation could produce active demethylation of the GR exon 1_7 promoter, yet several questions remain unanswered. How, for example, is histone acetylation targeted to the exon 1_7 promoter as a consequence of maternal behavior? We propose that maternal behavior stimulates 5-HT, which stimulates NGFI-A and that NGFI-A then targets HATS and eventually demethylases to the glucocorticoid receptor exon 1_7 promoter. To dissect the different molecular components of this hypothesis, we took advantage of both hippocampal primary neuronal cell cultures as well as nonneuronal cell lines. The two systems have different strengths and could be used to test different components of the model. First, we tested the hypothesis that 5-HT acts through cAMP to produce hypomethylation. Hippocampal cell cultures treated with either 5-HT or 8-bromo-cAMP, a stable cAMP analog, show increased glucocorticoid receptor expression following 4 days of treatment. Treatment of hippocampal cells in culture with 5-HT also results in the hypomethylation of the 5′ CpG dinucleotide of the NGFI-A consensus sequence within the exon 1_7 promoter of the glucocorticoid receptor gene, with no effect at the 3′ site. Treatment with 8-bromo-cAMP produces an even more pronounced effect on cytosine methylation at the 5′ CpG site. In both studies, cultures maintained under control conditions show complete methylation of both the 5′ and 3′ CpG sites of the NGFI-A consensus sequence. Bromodeoxyuridine labeling, which marks newly generated cells, reveals little or no cell replication in the cultures at the time of 5-HT treatment. These findings reinforce the idea that the alterations in cytosine methylation occur independently of cell replication and in response to intracellular signals associated with variations in maternal care. These cells establish that 5-HT signaling induced by maternal care triggers replication-independent changes in methylation of GR exon 1_7 promoter through an increase in cAMP. Since increased cAMP activates NGFI-A, it seems that ectopic expression of NGFI-A can target the demethylation process to the GR exon 1_7 promoter. However, this would not explain the selective effect at the 5′ cytosine.

To test the hypothesis that NGFI-A targets demethylation to GR exon 1_7 promoter, nonneuronal cell line HEK 293 is resorted to. Here, we can isolate the direct effect of NGFI-A from other neuron-specific events that might confound the interpretation of data from the hippocampal cultures. By comparing the fate of a transiently transfected methylated GR exon 1_7 promoter–luciferase vector in the presence and absence of NGFI-A, we could better determine the specific effects of NGFI-A on demethylation. Since the nonintegrated plasmid does not bear an origin of replication and does not replicate in HEK 293 cells, the assay measures the effects of NGFI-A on active replication-independent demethylation. Whereas in vitro methylated glucocorticoid receptor exon 1_7 promoter–luciferase vector remains methylated in HEK 293 cells, coexpression of NGFI-A results in active demethylation of a significant fraction of the transfected plasmids. To demonstrate that this DNA demethylation requires direct contact between NGFI-A and its recognition element, site-directed mutagenesis of the two CpGs included in the NGFI-A recognition element was performed. Our preliminary results suggest that these manipulations abolished the ability of NGFI-A to activate and demethylate the glucocorticoid receptor exon 1_7 promoter (Weaver et al., unpublished data, 2005). These experiments provide a molecular mechanism on how demethylation is triggered to specific sequences. The outstanding question is to determine how NGFI-A triggers demethylation on binding to specific sequences. One possibility is that NGFI-A directly recruits a demethylase to the gene or that as proposed before it recruits a HAT that increases acetylation, thus increasing the accessibility to demethylase as proposed earlier (Cervoni and Szyf, 2001).

4.8 The Putative Demethylase

The results of the studies with hippocampal cell cultures, the HEK 293 cells, and the developmental timecourse study suggest a process of active demethylation. In the developmental studies, the 5′ CpG site is initially methylated to the same extent in the offspring of high- and low-LG-ABN mothers. Over the course of the first week following birth, the methylation mark is functionally removed from the 5′ site in

the offspring of high-LG-ABN mothers. Prevailing models of DNA methylation propose that the methylation pattern of newly synthesized DNA is exclusively determined by the methylation pattern of the parental strand, and thus thought to be preserved in somatic cells. This model cannot explain the data described here nor recent data clearly demonstrating demethylation in response to changes in chromatin structure, such as those induced by TSA (Cervoni and Szyf, 2001). In response to such findings, Szyf and colleagues (Bhattacharya et al., 1999) proposed that DNA methylation is enzymatically reversible and that DNA methylation is dynamic in fully differentiated cells. This idea remains controversial. Active demethylation was nevertheless clearly demonstrated early in embryogenesis and the parental genome undergoes replication-independent, active demethylation hours after fertilization, well before the initiation of replication. Demethylation at very early stages in development has been relatively accepted, but the possibility of postnatal demethylation, and especially in fully differentiated somatic cells, has been hotly disputed. However, active replication demethylation was demonstrated in EBV-infected B cells and more recently, it was repeatedly demonstrated in HEK 293 cells. The HEK 293 transient transfection provided direct evidence that active replication-independent demethylation takes place in somatic cells and that it is dependent on the chromatin state. Fully in vitro methylated plasmid is transiently transfected into the cells. The plasmid, which does not bear an origin of replication, does not replicate in these cells and this has been validated using a DpnI restriction analysis (Cervoni and Szyf, 2001). Upon treatment of the cells with TSA, the plasmid undergoes complete demethylation that could only be accomplished by a processive demethylase. A recent paper on altered expression of IL-2 expression T lymphocytes following activation clearly implicates an active process of demethylation in a normal nontransformed somatic cell. Our results (Weaver et al., 2004) are the first demonstration of active demethylation in postmitotic neurons in vivo.

Earlier studies from Szyf's laboratory extracted active DNA demethylase activity from a human lung cancer cell line and identified a protein with demethylase activity (Bhattacharya et al., 1999), which was cloned concurrently by Bird's group and named MBD2 (Hendrich and Bird, 1998). Interestingly, the protein, MBD2, was found by Bird's group and others to also associate with a chromatin-remodeling complex containing HDAC, which is involved in silencing of gene expression through the recruitment of a repressor complex. The assignment of a demethylase (dMTase) function to a protein that was independently discovered as a recruiter of repressor complexes triggered the expected controversy in the field and there are reports that MBD2 failed to produce demethylase activity. However, the observation that MBD2/dMTase expression produces the demethylation of some but not all promoters in a dose- and time-dependent manner has been confirmed (e.g., Cervoni et al., 2001; Detich et al., 2002). Clearly, the contextual factors that determine MBD2 demethylase activity remain to be fully explained. Interestingly, MBD2 increased gene expression in those instances where promoter demethylation occurred, suggesting that not all promoters respond in the same orderly manner. Indeed, the same is true for DNA methylation, which impedes the DNA binding of most, but not all transcription factors; SP1 binds to methylated DNA. Antisense knock down of MBD2 resulted in inhibition of active demethylation induced by valproate and caused hypermethylation and silencing of the prometastatic gene uPA in metastatic breast cancer cells. Another group reported that ectopic expression of MBD2/dMTase in a hepatocyte cell line caused demethylation and activation of the hexokinase type 2 gene (Goel et al., 2003). Additional support for the demethylase activity of MBD2/dMTase emerges from the finding that expression of MBD2/dMTase is correlated with demethylation within the promoters of *C-ERBB-2* and *SURVIVIN* genes in ovarian cancers (Hattori et al., 2001a,b) and hypomethylated *cMyc* in gastric cancer (Fang et al., 2004). In addition, the Drosophila homolog of MBD2, dMBD2/3, formed foci that associated with DNA at the cellular blastoderm stage, concurrent with the activation of the embryonic genome, and also associated with the active Y chromosome (Marhold et al., 2002).

To test the hypothesis that MBD2 is associated with maternally induced demethylation, we performed an in situ hybridization assay with probes for the mRNAs for a number of methylated binding proteins at day 6 postpartum. Our analysis revealed that MBD2/dMTase expression is elevated in the hippocampus at this point in time in offspring of high- versus low-LG-ABN mothers. A ChIP analysis with an antiMBD2/dMTase antibody demonstrates significantly increased binding of MBD2/dMTase to the exon 1_7 GR promoter in day 6 offspring of high- versus low-LG-ABN mothers. We also found increased NGFI-A

binding to the same sequence in day 6 offspring of high-LG-ABN offspring. We then performed a bisulfite mapping of the state of methylation of the exon 1_7 glucocorticoid receptor promoter bound to MBD2 and precipitated in the ChIP assay with antiMBD2 antibody. If MBD2 is the demethylase involved in this process or if it is part of the demethylase complex, then MBD2-bound exon 1_7 sequences at day 6 should be found in the process of demethylation. Indeed, most of the MBD2-bound DNA was unmethylated or partially unmethylated.

In summary, our findings suggest that shortly after birth there is a wave of de novo methylation that results in the methylation of both CpG sites within the NGFI-A consensus sequence. Such events would impede the binding of NGFI-A to the exon 1_7 promoter. However, in the offspring of the high-LG-ABN mothers, NGFI-A expression is increased to the point where binding occurs despite the "low-affinity" status of the binding site. The binding of NGFI-A is associated with histone acetylation and the subsequent availability of the site to demethylase. In support of this idea, the treatment of the adult offspring of the low-LG-ABN mothers with TSA increases H3 acetylation and NGFI-A binding (see earlier) and results in the demethylation of the 5′CpG site of the NGFI-A consensus sequence (Weaver et al., 2004). Although this model remains speculative (and controversial) at this time, these findings do suggest that modifications to the DNA methylation status in fully differentiated cells are clearly possible and pharmacologically reversible, an idea that holds considerable potential therapeutic implications.

5 Experience-Dependent Chromatin Plasticity? Environmental Variability Meets Epigenomic Predictability

The defining question of early experience studies concerns the mechanism by which environmental effects occurring in early development are "biologically embedded" and thus sustained into adulthood (i.e., so-called "environmental programming" effects). The offspring of high-LG-ABN mothers exhibit increased hippocampal glucocorticoid receptor expression from the exon 1_7 promoter and dampened HPA responses to stress that persist into adulthood. We propose that the differential epigenomic status of the exon 1_7 glucocorticoid receptor promoter in the offspring of high-LG-ABN mothers serves as a mechanism for this maternal effect. It is important to note that these findings are restricted to the study of a single promoter of but one gene in one region of the brain. The degree to which such results might generalize to other instances of environmental programming remains to be determined. Moreover, further studies are required to determine how maternal behavior alters the epigenomic status of the exon 1_7 glucocorticoid receptor promoter. The developmental timecourse study is critical. Recall that the 5′ CpG dinucleotide of the NGFI-A consensus sequence of the exon 1_7 promoter is methylated to the same elevated level in the newborn offspring of high- and low-LG-ABN mothers. It is only over the first week of life that the difference emerges, with the decline in the methylation of the 5′ CpG site in the offspring of high but not low-LG-ABN mothers. Note that no such demethylation occurs at the neighboring 3′ CpG site. The impressive selectivity suggests a demethylation process that is targeted in some manner. It is critical to define the processes by which such apparently active demethylation might occur. Regardless of these yet unanswered questions, these findings provide the first evidence that maternal behavior stably alters the epigenome of the offspring, providing a mechanism for the long-term effects of early experience on gene expression in the adult. These studies offer an opportunity to clearly define the nature of gene–environment interactions during development and how such effects result in the sustained "environmental programming" of gene expression and function over the life span. Finally, it is important to note that maternal effects on the expression of defensive responses, such as increased HPA activity, are a common theme in biology such that the magnitude of the maternal influence on the development of HPA and behavioral responses to stress in the rat should not be surprising. Maternal effects on defensive responses to threat are apparent in plants, insects, and reptiles. Such effects commonly follow from the exposure of the mother to the same or similar forms of threat and may represent examples where the environmental experience of the mother is translated through an epigenetic mechanism of inheritance into phenotypic variation in the offspring. Indeed, maternal effects could result in the transmission of adaptive responses across generations (Meaney, 2001). Epigenomic modifications of targeted regulatory sequences in response to even reasonably subtle variations in

environmental conditions might serve as a major source of epigenetic variation in gene expression and function and ultimately as a process mediating such maternal effects. We propose that epigenomic changes serve as an intermediate process that imprints dynamic environmental experiences on the fixed genome resulting in stable alterations in phenotype. Such variations may then serve as a source of individual differences in vulnerability/resistance to chronic illness over the life span depending on the conditions of the prevailing environment. It is a question of fit.

1 Introduction

1.1 Body Weight Is a Regulated Variable

Body weight (or more accurately body adiposity) is a regulated variable. To maintain body adiposity over time, caloric intake must equal caloric expenditure. Such an intricate process relies on the interactions of a number of physiological systems. As an example, there is a negative feedback regulator system that is composed of signals derived from adipose tissue, which inform the central nervous system (CNS) about the status of peripheral energy balance. Signals from adipose tissue or peripheral fat stores comprise one side of the hypothesized feedback loop. On the receiving side of this regulatory system are one or more central effector systems that translate adipose-store information into appropriate subsequent behavior. When the system detects low adipose stores, food intake is increased whereas energy expenditure is decreased in an attempt to maintain body adiposity and body weight. This negative feedback loop also functions in the presence of high adipose stores, such that intake is reduced while energy expenditure is increased, again in an attempt to maintain body weight.

1.1.1 Leptin

There are at least two peripherally derived hormones that provide key afferent information to the CNS for body weight regulation. Leptin, a peptide hormone secreted from adipocytes in proportion to fat mass, has received tremendous attention during the last several years. Considerable evidence has been derived that implicates leptin as one of the body's adiposity signals (Elmquist et al., 1999; Ahima et al., 2000; Schwartz et al., 2000; Cone et al., 2001). Leptin levels in the blood correlate directly with body fat, and peripheral or central administration of leptin reduces food intake and increases energy expenditure.

More important, leptin levels are better correlated with subcutaneous fat than with visceral fat in humans, such that the reliability of leptin as an adiposity signal varies with the distribution of body fat. As is described later, there is a sexual dimorphism with respect to how body fat is distributed. Males tend to have more body fat located in the visceral adipose depot, whereas females tend to have more fat in the subcutaneous depot. Because females tend to have more subcutaneous fat than males, on the average, leptin is therefore a better correlate of total adiposity in females than in males (Havel et al., 1996b). Further, when energy balance is suddenly changed (for example, if an individual has fasted for a day), plasma leptin levels decrease far more than body adiposity in the short term (Ahren et al., 1997; Buchanan et al., 1998; Havel, 1999). Hence, although much has been written about leptin as an adiposity signal, it is not ideal in and of itself, suggesting that other signals may exist. One candidate is the pancreatic hormone, insulin.

1.1.2 Insulin

Insulin is well known for its role in regulating glucose homeostasis, however, an oft underrepresented role for insulin is as an adiposity signal. Plasma insulin levels also directly correlate with adiposity, and whereas

leptin is a better correlate of subcutaneous adiposity, insulin correlates better with visceral adiposity (Bjorntorp, 1991, 1992, 1997a; Woods et al., 1998). Moreover, when energy balance changes, there are changes in plasma insulin that closely follow changes in homeostasis (Schwartz et al., 1992a). Therefore, both leptin and insulin can be considered as adiposity signals, each indicating something different to the brain; insulin is a correlate of visceral adiposity and leptin is a correlate of subcutaneous adiposity and together or separately, they are markers of changes of metabolic status.

2 Peripheral Signals of Energy Balance

2.1 Leptin

Leptin is a 146-amino acid peptide that is expressed primarily in adipose tissue. Obesity is associated with increased leptin synthesis and secretion, whereas fasting and weight loss are associated with decreased leptin synthesis and secretion (Zhang et al., 1994; Maffei et al., 1995; Ahima et al., 1996; Campfield et al., 1996; Considine et al., 1996; Dagogo-Jack et al., 1996; Dua et al., 1996; Havel et al., 1996b; Kolaczynski et al., 1996; Matson et al., 1996; White and Tartaglia, 1996; Woods et al., 1997; Brunner and Levens, 1998; Buchanan et al., 1998; Clement et al., 1998; Keim et al., 1998; Banks et al., 1999; Baskin et al., 1999a, b; Seeley et al., 1999a, b; Trayhurn et al., 1999; van Dijk et al., 1999; Ahima et al., 2000; Jeanrenaud and Rohner-Jeanrenaud, 2000). Leptin influences many physiological processes, including lipid and glucose metabolism, thermogenesis, reproduction, and many endocrine functions (Zhang et al., 1994; Halaas et al., 1995; Maffei et al., 1995; Friedman, 1997; Kamohara et al., 1997; Friedman, 1998; van Dijk et al., 1999). Compelling evidence suggests that a primary site of leptin action is in the CNS. As body fat increases, more leptin is secreted and enters the brain (Caro et al., 1996; Schwartz et al., 1996a). Leptin acts upon its receptors in the brain to cause a net catabolic response including reduced caloric intake and loss of body weight.

2.1.1 Leptin Receptor Activation: STAT3

Leptin receptors belong to the class I cytokine receptor family (Nakashima et al., 1997), which acts through Janus Kinases (JAK) and signal transducers and activators of transcription (STAT) (Baumann et al., 1996; Ghilardi et al., 1996; White et al., 1997). Several isoforms of the leptin receptor can be produced by alternative splicing, resulting in receptors with the same extracellular domain but different intracellular domains (Tartaglia et al., 1995; Chua et al., 1996; Cioffi et al., 1996; Lee et al., 1996; White and Tartaglia, 1996; White et al., 1997). Isoforms with longer intracellular domains (i.e., with more amino acids) interact with more varied intracellular signaling systems. When the longest and most reactive isoform, called Ob-Rb, binds with a ligand, JAKs become autophosphorylated and catalyze the tyrosine phosphorylation of several STAT proteins. The activated STATs in turn dimerize and translocate to the nucleus, where specific gene responses are elicited (Vaisse et al., 1996; McCowen et al., 1998). Only STAT3 has been found to be activated by leptin in vivo (Vaisse et al., 1996), and this occurs in several hypothalamic areas including the paraventricular (PVN), arcuate (ARC), periventricular, and lateral hypothalamic (LH) nuclei (Bjorbaek et al., 1998; Elmquist et al., 1998a, b; McCowen et al., 1998). A ratio of phosphorylated to nonphosphorylated STAT3 is used as a marker of Ob-Rb activation.

2.1.2 Leptin Activation of SOCS-3

Within the hypothalamus, leptin is thought to stimulate some cell types and to inhibit others. c-Fos is a widely used marker of neuronal activation, and leptin administration elicits c-fos expression in certain hypothalamic neuronal populations (van Dijk et al., 1996). On the inhibitory side, Bjorbaek et al. (1998, 1999a, b) demonstrated that leptin administration rapidly induces the expression of a member of the family

of suppressors of cytokine signaling proteins (SOCS)-3 (Hirano et al., 1997; Starr et al., 1997). SOCS-3 is an intracellular protein induced by activation of cytokine receptors such as the long form of the leptin receptor (Tartaglia et al., 1995; Bjorbaek et al., 1998, 1999a, b). SOCS-3 attenuates leptin signaling by blocking phosphorylation of the receptor and downstream STAT proteins involved in signal transduction (Starr et al., 1997; Nicholson and Hilton, 1998). In Chinese hamster ovary (CHO) cells transfected with Ob-Rb, expression of SOCS-3 inhibits leptin-induced tyrosine phosphorylation of JAK2 proteins, suggesting that SOCS-3 is a leptin-regulated inhibitor of proximal leptin signaling in vivo (Bjorbaek et al., 1999a, b). The point is that when leptin interacts with its receptor, it initiates several intracellular processes (e.g., JAK–STAT pathways) that contribute to decreased food intake and related responses; and it simultaneously activates other processes (e.g., SOCS-3) that turn off the JAK–STAT activation, thus limiting its time of action. Very little SOCS-3 mRNA is present in the unstimulated rat brain, but systemic leptin administration rapidly induces expression of the SOCS-3 gene in regions of the rat brain that express Ob-Rb mRNA (Elmquist et al., 1998a, b; Elias et al., 1999). Thus, excessive SOCS-3 activity in leptin responsive neurons is a potential mechanism for leptin resistance (Bjorbaek et al., 1999a, b).

2.1.3 Leptin/Insulin Convergence

Leptin functionally enhances or "sensitizes" some actions of insulin. The underlying molecular mechanisms for the insulin-sensitizing effects of leptin are unclear, and results obtained from studies are conflicting regarding the effect of leptin on insulin-stimulated signal transduction. Whereas the long form of the leptin receptor has the capacity to activate the JAK/STAT3 (Vaisse et al., 1996; Tartaglia, 1997) and mitogen activated protein kinase (MAPK) pathways, leptin is also able to stimulate tyrosine phosphorylation of insulin receptor substrate (IRS-1) (Vaisse et al., 1996), and to increase transcription of fos, jun (Cohen et al., 1996). Some early data suggested that leptin can impair the early steps of insulin signaling including autophosphorylation of the insulin receptor and tyrosine phosphorylation of IRS-1 in certain cell types such as rat-1 fibroblasts and hepatocytes (Cohen et al., 1996). Other studies demonstrated that leptin can mimic effects of insulin such as stimulation of tyrosine phosphorylation of IRS-1 in 293 cells and stimulation of glucose transport and glycogen synthesis in C2C12 myotubes (Berti et al., 1997). The latter may be mediated by stimulation of PI 3-kinase, although unlike insulin, this does not involve IRS-1 (Kellerer et al., 1997). Even under conditions in which leptin decreased tyrosine phosphorylation of IRS-1 in hepatocytes, IRS-1-associated-PI3 kinase activity increased (Cohen et al., 1996) indicating possible crosstalk of the insulin and leptin signaling pathways, but not a complete convergence.

2.2 Insulin

Considerable evidence implicates insulin as an adiposity signal and a key regulator of food intake. Kennedy (1953) hypothesized that adipose tissue produced a hormone that acts as a negative feedback signal for the control of adiposity, and one early suggestion was that this signal is insulin (Woods and Porte, 1976, Baskin et al., 1987; Woods et al., 1996). Data supporting insulin's role as an adiposity signal have been collected over the past two decades and include studies using several species and techniques (Woods et al., 1985, 1990; Schwartz et al., 1994). To summarize that literature, plasma insulin levels correlate directly with body weight and in particular with body adiposity (Bagdade et al., 1967; Polonsky et al., 1988); like leptin, insulin is secreted in direct proportion to fat mass; obese animals and humans have higher basal insulin levels, and they secrete more insulin in response to a meal than lean individuals (Bagdade et al., 1967; Woods et al., 1974). During positive energy balance, insulin increases, whereas insulin decreases during negative energy balance. Insulin resistance in obese animals and humans is characterized by the requirement of greater insulin secretion to maintain euglycemia. Type 2 diabetes mellitus is characterized by insulin resistance, and this is often associated with elevated levels of plasma glucose and obesity, and specifically with visceral adiposity (Bjorntorp, 1997a).

2.2.1 Peripheral Effects

The second line of evidence consistent with insulin being a prime candidate as an adiposity signal is that insulin maps onto acute changes of energy metabolism and adiposity more accurately and more rapidly than its adipocyte cousin, leptin. Insulin secretion tracks changes of energy balance on the order of minutes to hours, as opposed to days as is the case for leptin, and these changes are always in direct proportion to the size of the adipose mass (Polonsky et al., 1988). Additionally, insulin directly regulates glucose and lipid utilization and storage. In the absence of insulin, or during times of insulin resistance and therefore insufficiency of insulin action, insulin sensitive tissues cannot take up glucose, and therefore glucose accumulates in the blood. During these times, adipocytes cannot take up glucose and store fat. When more insulin is secreted to regulate glucose during insulin resistance, the excess insulin causes increased accumulation of fat in adipocytes and leads to obesity. Reductions of insulin sensitivity are associated with both obesity and hyperglycemia, leading ultimately to diabetes.

2.2.2 Central Effects

In the brain, insulin receptors (IRs) and insulin receptor mRNA are found in regions involved in the regulation of food intake and body weight, especially in the hypothalamic ARC nucleus (Corp et al., 1986; Baskin et al., 1990; Schwartz et al., 1992a, b). Direct injections of insulin into the third ventricle (i3vt), which has direct access to the ARC, decrease expression of the anabolic orexigenic effector peptide, neuropeptide Y (NPY) in the ARC (Sipols et al., 1995). ARC NPY fibers project to the paraventricular hypothalamic nucleus (PVN), and intra-third-cerebroventricle (i3vt) insulin causes increased expression of corticotrophin-releasing hormone mRNA in the PVN (Sipols et al., 1995; Schwartz et al., 1996b). These results demonstrate that the insulin signal is tied to the changes in food intake associated with hypothalamic neuropeptides (e.g., Benoit et al., 2002).

Insulin enters the brain via a saturable transport process that moves insulin from the plasma into brain interstitial fluid (Hachiya et al., 1988; Schwartz et al., 1990; Baura et al., 1993; Banks et al., 1997; Woods et al., 2003). Fluctuations of plasma insulin directly affect the rate of entry of insulin to CNS, although higher levels of insulin exceed the saturation point (Baura et al., 1992, 1993). Once saturation has occurred, the entry of insulin to brain remains relatively constant (Schwartz et al., 1992a, 1994). Disruptions in insulin transport have been associated with dysregulation of body weight and obesity.

2.2.3 Central Insulin and Food Intake

Administration of exogenous insulin either as a single injection or over repeated injections into the brain reduces food intake, consistent with its being an adiposity signal (Woods et al., 1979; Brief and Davis, 1984; Plata-Salaman et al., 1986; Chavez et al., 1995a; Woods et al., 1996; Air et al., 2002). Insulin reduces food intake in part by modulating the body's response to short-term signals that terminate meals. Central administration of insulin potentiates the anorexic effects of peripherally administered cholecystokinin (CCK) (Riedy et al., 1995) and centrally administered CRF (Richardson et al., 2000). Additionally, peripherally administered insulin, in amounts that do not cause hypoglycemia, also decreases food intake (Brief and Davis, 1984; McGowan et al., 1990; Chavez et al., 1995b). Consistent with these data, administration of antibodies to insulin directly into the brain increases food intake and body weight (Strubbe and Mein, 1977; McGowan et al., 1992), as does selective absence of neuronal insulin receptors (Bruning et al., 2000) or compromise of the ability to synthesize insulin receptors locally in the hypothalamus (Obici et al., 2002). It is important to note that there is no evidence that alterations in food intake after administration of insulin, either systemic or central, produce aversive consequences (Chavez et al., 1995b). That is, administration of exogenous insulin does not appear to make animals ill. Collectively, these data suggest that insulin is an adiposity signal that provides information to the CNS on the state of energy balance.

2.3 Ghrelin

Recently, the 28-amino acid gastric hormone, ghrelin, has been linked with meal initiation. Ghrelin is also expressed in pancreas, duodenum, and hypothalamus (Kojima et al., 1999), and ghrelin and its receptors are also located in the hypothalamus. Ghrelin administration stimulates food intake and increases body fat mass (Tschöp et al., 2000). The ghrelin receptor, also known as the growth hormone secretagogue receptor (GHS-R1a) (Smith et al., 1999), is localized in specific neurons of the arcuate nucleus that coexpress the orexigenic neuropeptides NPY and AGRP (e.g., Cowley et al., 2003). Endogenous ghrelin is increased during fasting and prior to meal initiation and decreased immediately following nutrient intake in rodents and humans (Tschöp et al., 2000, 2001). Based on these findings, ghrelin has been proposed to be an endogenous meal initiation factor (Cummings et al., 2001). Whereas numerous reports have focused on the orexigenic effects of ghrelin (Horvath et al., 2001; Inui, 2001; Cummings and Shannon, 2003), some have also investigated its effects on activity or energy expenditure (Tschöp et al., 2000; Asakawa et al., 2001; Muccioli et al., 2002), demonstrating that ghrelin can significantly attenuate energy expenditure.

2.4 Dysregulation by Dietary-Induced Obesity

When leptin or insulin is administered into the brain of experimental animals, there is a selective reduction of body fat, with lean body mass being spared (Chen et al., 1996). Consistent with this, when insulin is administered into the brain, there is a reduction of the respiratory quotient (RQ) suggesting that the body is oxidizing relatively more fat (Park et al., 1992). These observations suggest that one action of these adipose signals within the brain is to reduce body fat, and a corollary of this is that fat intake would be expected to be reduced as well. Consistent with this, when insulin is administered i3vt, fat intake is selectively reduced (Chavez et al., 1996). Hence, it is reasonable to hypothesize that leptin and insulin, acting in the brain, reduce body fat by increasing lipid mobilization and oxidation and simultaneously by reducing the consumption of dietary fat.

The epidemiological data that increasing dietary fat accelerates the development of obesity are quite compelling and have been summarized in several reviews (Gibney, 1995; Bray and Popkin, 1998; Samaras et al., 1998). Additionally, studies on animals provide strong corroborative evidence; i.e., across numerous experiments, diets, and species, the conclusion that increased consumption of high-fat (HF) diets leads to increased body fat is inescapable (Bray et al., 1990; Hill et al., 1992; Warwick and Schiffman, 1992; Warwick, 1996; Golay and Bobbioni, 1997; West and York, 1998). More important, there are strong genetic influences that dictate whether or not a given individual will be prone or resistant to becoming obese when exposed to an HF diet (Levin and Routh, 1996; West, 1996; Leibel et al., 1997; Levin et al., 1997; Reed et al., 1997; Bray and Popkin, 1998; West and York, 1998). As Bray and Popkin point out, an HF diet can be viewed as the environmental agent that acts on a susceptible host animal to produce the noninfectious disease, obesity.

Experiments in which animals were rendered obese and then placed on a low(er) fat (LF) diet have been somewhat equivocal, with some reporting loss of body weight (Bernstein et al., 1975; Hill et al., 1992) and others no weight reduction (Faust et al., 1978; Rolls et al., 1980; Harris et al., 1986; Uhley and Jen, 1989; Hill et al., 1992). One important parameter is evidently the age at which the obesity is initially induced. Younger rats (as well as older rats made obese by maintenance on an HF diet for longer intervals) may increase their number of adipocytes (Lemonnier, 1972; Faust et al., 1978; Hill et al., 1992). When subsequently placed on an LF diet, such animals tend not to lose weight (or body fat). However, if the number of adipocytes does not increase, obese animals placed on an LF diet lose weight to the level of rats never made obese at all (Hill et al., 1992). Without assessing fat cell number, we have observed that adult rats given an HF diet and held at an obese weight for a prolonged interval lose weight to control levels when returned to an LF diet (Bernstein et al., 1975). One conclusion that has been reached from this literature is that it is easier to induce obesity in a lean individual with an HF diet than it is to induce leanness in an obese individual with an LF diet (Hill et al., 1992; Bray and Popkin, 1998).

3 Central Effectors

Within the CNS, in order to regulate food intake and body weight effectively, diverse signals need to interact in meaningful ways and to engage neurochemical systems that influence energy intake and energy expenditure. The best known of these CNS systems are in the ventral hypothalamus, and they can be roughly partitioned into those whose activity reduces body fat (catabolic effector systems) and those whose activity increases body fat (anabolic effector systems). Anabolic effectors elicit increased food intake, decreased energy expenditure, and consequently increased stored energy in the form of adipose tissue. They are hypothesized to become more active when energy stores are low as indicated by reduced levels of insulin and leptin (i.e., when the body is in negative energy balance). Catabolic effectors do just the opposite. Activated by positive energy balance, they decrease food intake, increase energy expenditure, and result in decreased adipose tissue mass. A critical aspect of this negative feedback model is that hormones responsive to the level of adiposity inhibit anabolic pathways while activating catabolic pathways, and it is the balance between these two pathways that ultimately determines the animal's ingestive behavior and defended level of adiposity.

The catabolic and anabolic effector systems are in actuality a series of discrete neurotransmitter systems and axonal pathways in the brain, and many of the key details of this overall schema have emerged in the last few years. Although receptors for leptin and insulin are located throughout the CNS, both are concentrated in the ARC in the ventral hypothalamus. Hence, ARC neurons are sensitive to these hormones and consequently to the amount of adipose tissue in the body.

3.1 Neuropeptide-Y

The best-described anabolic effector peptide in the brain is NPY. Although NPY mRNA and peptide are distributed widely throughout the CNS, NPY-containing cell bodies in the ARC are especially important in the control of energy homeostasis (Schwartz et al., 1992b). Although these ARC NPYergic neurons directly influence several areas of the brain, major projections are to the nearby PVN and the lateral hypothalamic area (LHA). ARC NPYergic neurons respond to negative energy balance (e.g., to food deprivation) by synthesizing more NPY mRNA, and they consequently release more NPY in the PVN (Kalra et al., 1991; Schwartz et al., 1992b) and presumably the LHA as well. More important, animals in negative energy balance have low levels of adiposity hormones, resulting in elevated NPY mRNA in the ARC. Local replacement of either insulin or leptin in the vicinity of the ARC normalizes the elevated NPY mRNA in the ARC in fasted animals (Schwartz et al., 1992b; Sipols et al., 1992). Hence, the activity of these ARC NPY neurons is under the direct influence of at least two adiposity signals.

3.2 Melanocortins

The hypothalamic melanocortin (MC) system is the best-known central effector system controlling food intake and energy balance. The evidence for this is multifold: First is the phenotype of the agouti mouse. This yellow mouse has an autosomally transmitted trait resulting from deletion of DNA 3' of the coding region of the agouti gene, which results in ectopic expression of the agouti protein (Bultman et al., 1992). In melanocytes, this inappropriate expression results in antagonism of alpha-melanocyte-stimulating-hormone (a-MSH) signaling. The resulting phenotype is a yellow coat. However, the agouti mouse is obese as well as yellow. This observation led to the hypothesis that ectopic agouti protein antagonizes central MC receptors involved in food intake. Indeed, though melanocortins have been known to influence food intake since the 1980s, it was only during the last decade that their receptors were cloned and localized to the hypothalamus (Mountjoy et al., 1992). As predicted, agouti is an antagonist of these receptors (Lu et al., 1994). More important, an endogenous agouti-related peptide (AgRP) was subsequently found to be expressed in the ARC and to project to the sites of the hypothalamic MC receptors (Fan et al., 1997).

Consistent with the hypothesis that the MC system mediates the effects of adipose hormones is the finding that expression of the MC gene products is regulated by energy balance. During periods of negative energy balance (and consequently low adipose hormones), expression of AgRP mRNA is increased whereas expression of the melanocortin precursor molecule, pro-opiomelanocortin (POMC), is decreased (Mizuno et al., 1999). During positive energy balance (and high levels of adipose hormones) on the other hand, expression of POMC mRNA is increased and AgRP is decreased. Further, POMC-containing neurons also have receptors for the adipocyte hormone, leptin (Cheung et al., 1997; Mountjoy and Wong, 1997; Seeley et al., 1997). These findings suggest that the hypothalamic MC system is a likely central target of adipose signals and a mediator of their effects on food intake.

The brain expresses two types of MC receptors, MC3R and MC4R (Mountjoy et al., 1994). Distribution of MC3R is limited to areas of the hypothalamus, whereas MC4R are located throughout the brain. Most data suggest that MC4R are critical for the MC involvement in food intake. Indeed, an important piece of evidence linking MCs to food intake also supports the hypothesis that MC4R is the critical receptor. Mice with targeted deletion of the MC4R gene are phenotypically similar to the yellow (agouti) mouse (Huszar et al., 1997). Although not yellow, they exhibit profound obesity as well as hyperinsulinemia. As predicted, nonselective MC3/4R agonists (e.g., MTII) do not reduce food intake in MC4R-/- mice (Marsh et al., 1999). Although the issue is complicated by findings that MC3R-/- also have increased body fat but not increased food intake (Chen et al., 2000), such findings support the hypothesis that the MC system plays an important role in the control of energy balance.

Additional evidence suggesting a role of MCs in the control of food intake comes from experimental administration of both naturally occurring and synthetic peptides. Ii3vt administration of a-MSH decreases food intake (Tsujii and Bray, 1989; McMinn et al., 2000), as does i3vt administration of synthetic agonists, including MTII and Ro27-3225 (Fan et al., 1997; Thiele et al., 1998; Benoit et al., 2000). Conversely, administration of MC receptor antagonists, such as AgRP or the synthetic agonist, SHU-9119, elicits long-lasting increase in food intake (Fan et al., 1997; Ollmann et al., 1997; Rossi et al., 1998; Hagan et al., 1999; 2000). These data are consistent with the hypothesized role of the MC system in the control of food intake. Further, the presence of both an endogenous agonist and antagonist of the same receptor make this system a prime candidate for the translation of negative feedback signals from adipose tissue.

4 Sex Difference in Body Weight Regulation

4.1 Estrogens

Although estrogens are mainly produced in the ovaries and testes, a significant proportion is synthesized in adipose tissue, from the precursor steroids, dehydroepiandrosterone and androstenedione (Horton and Tait, 1966; Grodin et al., 1973; Corbould et al., 1998). The local concentration of estrogen within adipose tissue is largely determined by the expression of the enzyme, p450 aromatase, which is responsible for the conversion of androstenedione to estrone and T to estrogen (Horton and Tait, 1966; Corbould et al., 1998). Sex hormone- and fat depot-specific differences in the activity of aromatase, and therefore local estrogen biosynthesis, may underpin depot- and sex-specific patterns of fat distribution. The aromatase P450 gene contains a glucocorticoid (GC) response element, indicating the potential for GC regulation of P450 aromatase (Zhao et al., 1995). Furthermore, cortisol (the human GC) in women, but not men, increases aromatase activity in subcutaneous fat (McTernan et al., 2002). The observation that individuals of both sexes with natural mutations of the gene encoding aromatase develop visceral obesity associated with insulin resistance, hypercholesterolemia, and increased triglyceride levels (Conte et al., 1994; Morishima et al., 1995; Carani et al., 1997) suggests an important role of estrogens in limiting visceral fat and thus determining fat distribution. Estrogen, therefore, may have hormonal and/or paracrine actions in fat depots as adipocytes also express estrogen receptors.

The two isoforms of the estrogen receptor, ERα and ERβ, are the products of separate genes, and both are expressed in the brain and adipose tissue (Lieberburg and McEwen, 1975; McEwen 1975; McEwen et al., 1975a, b; Maclusky et al., 1976; Gray and Wade, 1981; Korach et al., 1996; Heine et al., 2000).

Comparison of the ligand-binding specificity and tissue distribution of ER α and β suggests that there are specific actions of estradiol that can be attributed to one receptor but not the other (Krege et al., 1998; Schomberg et al., 1999; Vidal et al., 2000). The role of each in mediating the attenuating effects of estrogens on food intake, body weight, and body fat distribution has not been conclusively determined. When estrogen acts on its receptors, it increases PI3K activation (Simoncini and Genazzani, 2003; Simoncini et al., 2003) and stimulates its downstream signaling cascade analogously to what occurs following insulin administration and binding to the insulin receptor (Niswender et al., 2003). Mice with targeted deletion of the ERα (but not the ER β) have increased total white adipose tissue (WAT), increased insulin resistance, and impaired glucose tolerance in both sexes (Heine et al., 2000; Ohlsson et al., 2000; Vidal et al., 2000; Geary et al., 2001). Humans lacking either ERα or aromatase also have increased insulin resistance (Morishima et al., 1995; Simpson et al., 2002). Novel compounds are now available that have various estrogenic and antiestrogenic activities on specific estrogen receptors that could be used to test the specific roles of ERα and/or ERβ.

In sum, higher estrogen levels are associated with a pattern of relatively more subcutaneous and less visceral fat, and these in turn are inversely correlated with the risk of metabolic complications (elevated visceral fat is highly correlated with disease). Estrogen receptors in adipose tissue itself and/or in brain are likely to mediate these effects, potentially through activation of PI3K.

4.2 Androgens

In obese men, there is a reciprocal relation between adipose mass and androgens. Specifically, total and free testosterone are both decreased in proportion to the degree of obesity (Zumoff et al., 1990; Isidori et al., 1999) and aging (Hartman et al., 2001). Testosterone levels within the normal physiologic range promote insulin sensitivity (Phillips, 1977; Marin et al., 1992b) and fat deposition in the visceral depot (Marin, 1995; Bhasin et al., 1996; Bjorntorp, 1997); however, decreased testosterone results in insulin insensitivity (Laughlin and Barrett-Connor, 2000; Tsai et al., 2000), and an even greater increase of visceral adiposity (Marin and Arver, 1998). Visceral fat as well as the brain contains androgen receptors, implying that androgen action in either or both locations could contribute to fat distribution.

4.3 Gonadal Regulation of Leptin

Leptin levels are higher in females, even before puberty, compared with males, and this is independent of differences in body composition (Frederich et al., 1995; Ostlund et al., 1996; Rosenbaum et al., 1996; Kennedy et al., 1997; Saad et al., 1997; Demerath et al., 1999; Clegg et al., 2003). After puberty, estrogen and testosterone modulate leptin synthesis and secretion directly, apparently via sex steroid receptor-dependent transcriptional mechanisms (Machinal et al., 1999). In rats, ovariectomy increases leptin levels acutely, and this is reversed by administration of estradiol (Shimizu et al., 1997; Machinal et al., 1999). Leptin secretion rate and leptin mRNA expression are two to three times higher in subcutaneous than visceral fat (Montague et al., 1997; Casabiell et al., 1998).

Leptin levels are inversely correlated with testosterone (Vettor et al., 1997; Wabitsch et al., 1997; Luukkaa et al., 1998; Isidori et al., 1999; Kristensen et al., 1999) and exposure of human fat cells to testosterone or dihydrotestosterone inhibits leptin expression (Wabitsch et al., 1997). In aging and obese men, there is increased aromatase activity and conversion of androgens to estrogen, resulting in increased plasma leptin (Zumoff et al., 1990; Jockenhovel et al., 1997; Morley and Perry, 2000). Testosterone replacement normalizes elevated serum leptin levels in hypogonadal men and in castrated male rats. In hyperandrogenic women, testosterone causes accumulation of visceral adipose tissue. Subcutaneous adipose tissue, on the other hand, has few androgen receptors and estrogen down-regulates the androgen receptors found there (Bjorntorp, 1997b). Estrogen may therefore be protective against androgen effects on female body fat distribution. When estrogen levels become sufficiently low, visceral fat accumulation increases in females.

4.4 Body Fat Distribution

Body fat distribution is an important correlate of metabolic disorders (Kannel, 1985; Larsson, 1991). Excess fat in the central region of the body (visceral, "android," or male-pattern obesity) (Wajchenberg, 2000) is correlated with increased risk and mortality from disorders including diabetes mellitus, hyperlipidemia, hypertension, and atherosclerosis. In contrast, subcutaneous ("gynoid," or female-pattern) fat distribution is poorly correlated with risk for these metabolic diseases (Lapidus et al., 1984; Ohlson et al., 1985; Donahue and Abbott, 1987; Donahue et al., 1987; Bjorntorp, 1996).

4.4.1 Visceral Fat

Visceral fat is characterized by having relatively more capillaries and efferent sympathetic axons per unit volume than subcutaneous white fat, and it drains into the hepatic portal vein. Visceral fat has four times more GC receptors than subcutaneous fat and it is therefore more sensitive to the fat-accumulating effects of circulating GCs and triglycerides (Pedersen et al., 1994). Visceral fat tissue responds to circulating GCs by further increasing its size. Large central fat deposits may contribute to disease in part by releasing free fatty acids into the portal circulation, which can promote other risk factors, such as synthesis of cholesterol and insulin resistance (Bjorntorp, 1997a). Consistent with this, visceral fat is relatively insensitive to insulin (Bolinder et al., 1983a, b; Holmang and Bjorntorp, 1992; Marin et al., 1992b) and insulin action is markedly impaired in individuals with visceral obesity (O'Shaughnessy et al., 1995; Carey et al., 1996). Weight loss is characterized by an initial reduction in visceral fat (as opposed to subcutaneous fat), in part because visceral adipocytes are more metabolically active (Micheli et al., 1969; Bjorntorp, 1992b, c, d, e; Marin et al., 1993). Surgical removal of intra-abdominal fat in rodents prevents the onset of age-dependent insulin resistance and glucose intolerance (Gabriely et al., 2002). Surgical removal of subcutaneous fat tissue of equal weight has no appreciable impact on the same parameters (Gabriely et al., 2002).

Gonadal steroids have been proposed as regulators of the distribution of fat into various depots (Elbers et al., 1999a, b). Visceral fat increases with androgen levels (as well as with age and GC levels) in both genders (Enzi et al., 1986; Bjorntorp, 1992c, e; Bouchard et al., 1993). Postmenopausal women develop increased visceral adiposity, and those who receive estrogen replacement therapy do not (Haarbo et al., 1991a, b; Gambacciani et al., 1997), suggesting a role of estrogen in limiting visceral fat mass (Bjorkelund et al., 1996; Colombel and Charbonnel, 1997). Hence, both androgens and estrogens have been postulated to influence visceral fat.

4.4.2 Subcutaneous Fat

In contrast, relatively little is known of the control of subcutaneous fat. These adipocytes are scattered within and beneath a broad area of skin, are relatively poorly innervated and vascularized, and have a larger average diameter than visceral adipocytes (Wajchenberg, 2000). Because subcutaneous fat has historically been more difficult to measure precisely, its parameters have often been inferred by subtracting visceral fat from total body fat (Wajchenberg, 2000).

5 Central Integration

Leptin and insulin fill distinct niches in the endocrine system. Although leptin has been implicated in several systemic processes, such as angiogenesis (Schwartz et al., 1996a), the primary role of leptin appears to be as a negative feedback adiposity signal that acts in the brain to suppress food intake and net catabolic effector (Porte et al., 1998; Woods et al., 1998; Woods et al., 2003). Consistent with this, animals lacking leptin or functional leptin receptors are grossly obese. Insulin, in contrast, has a primary action in the periphery to regulate blood glucose and stimulate glucose uptake by most tissues. Analogous to leptin,

however, deficits in insulin signaling are also associated with hyperphagia in humans, and animals that lack normal insulin signaling in the brain are also obese (Tartaglia et al., 1995; Porte et al., 1998; Woods et al., 1998; Woods et al., 2003).

5.1 Adiposity Signals: Colocalization

The potential for redundancy between leptin and insulin has been highlighted by several recent studies in which leptin and insulin have been found to share both intracellular and neuronal signaling pathways. Although the melanocortin system has long been thought to mediate the central actions of leptin, recent studies, in which insulin significantly stimulated POMC expression in fasted rats and insulin-induced hypophagia was blocked by a nonspecific MC receptor antagonist, (Fan et al., 1997; Ollmann et al., 1997; Seeley et al., 1997; Rossi et al., 1998; Hagan et al., 1999, 2000) strongly support a role for the MC system in the regulation of energy balance by insulin as well. Furthermore, phosphatidylinositol-3-OH kinase (PI(3)K), an enzyme which is an intracellular mediator of insulin signaling (Niswender et al., 2003), appears to play a crucial role in the leptin-induced anorexia signal transduction pathway as well (Niswender et al., 2003). Although these data are consistent with the concept that leptin and insulin share such pathways, they also suggest that over time, this redundancy dissipates and their pathways diverge.

5.2 Plasticity

Recent reports have identified critical roles for mechanisms of plasticity in the control of food intake and body weight, specifically related to the function of long-term adiposity signals. Two important studies have demonstrated that exogenous administration of leptin results in increased axonal outgrowth in mouse pups lacking the leptin gene (obo) (Bouret et al., 2004), to a similar extent seen in normal, wild type mice. Additionally, leptin appears to regulate synaptic structure in hypothalamic tissue of adult rodents (Pinto et al., 2004). Previous work had already suggested a role for leptin in synaptic plasticity and neuronal outgrowth (Shanley et al., 2001; Wayner et al., 2004). For example, ob/ob mice exhibit impaired hippocampal long-term potentiation (LTP) and mice that lack leptin signaling are deficient in some memory tasks (Li et al., 2002; Ohta et al., 2003). However, the recent demonstrations of leptin action on plasticity in hypothalamic tissues suggests that the regulation of energy homeostasis systems may involve cellular mechanisms that have most often been relegated to CNS structures involved in learning. These data suggest that the energy balance regulatory system is linked to systems of structural plasticity. In fact, this may be one mechanism whereby the body resets the adipostatic set-point, as occurs in obesity. We have recently uncovered a role in energy balance for some genes normally associated with "plasticity," known as syndecans.

5.3 Plasticity in Energy Balance

Syndecans are a family of highly abundant cell-surface heparan sulfate proteoglycans (HSPGs) (proteins with covalently attached, highly acidic sugar chains), which are unique in their ability to bind extracellular peptides such as hormones and growth factors. They act as coreceptors by modulating interactions of peptide ligands with their activity-generating receptors. In mammals, the syndecans are composed of four transmembrane HSPGs and members of the glypican family of glycerophosphoinositol-linked HSPGs. Together, these account for nearly all HSPGs that are unbiquitously expressed at cell surfaces (Bernfield et al., 1999; Park et al., 2000). Syndecan family members are found on virtually every cell type (Bernfield et al., 1999) but are differentially expressed in a tissue-specific manner. Syndecan-1 is found predominately on epithelial cells whereas syndecan-3 is found primarily on neural crest-derived cells and neurons. They are induced during development and injury and in response to a wide spectrum of physiological stimuli (Lauri et al., 1998; Bernfield et al., 1999; Hsueh et al., 1999).

The discovery of an important energy balance function of syndecan-3 paralleled the discovery of AgRP's action during the course of studies into the obesity of the agouti mouse. The association of an obese phenotype with a peripheral physiological system led to the hypothesis that a related central system should exist. During the course of studies on a transgene of syndecan-1, Reizes et al. (2001) inferred and subsequently confirmed that endogenous CNS syndecan-3 plays an important role in the regulation of food intake and body weight.

In those studies, Reizes induced overexpression of syndecan-1. For reasons that are still not clear, this did not result in ubiquitous expression, but rather yielded high levels of syndecan-1 expression in specific areas of the brain where it would normally not be found, and in particular, the syndecan-1 transgene was highly expressed in hypothalamus. Syndecan-1 transgenic mice have severe maturity-onset obesity and type-II diabetes. The phenotype of this obesity closely resembles that of previously characterized mice with disruptions of the MC-signaling pathway including the agouti lethal-yellow, AgRP-overexpressers, and MC4-receptor knockout mice (Huszar et al., 1997; Ollmann et al., 1997). Additionally, syndecan-1 was found to potentiate the obesity of the lethal yellow (Ay/a) mice, and to potentiate the activity of AgRP and agouti signaling protein in cell culture preparations. Finally, it was also discovered that syndecan-1 only promoted obesity when it was localized to the cell surface. Mice that constitutively shed syndecan-1 from the cell membrane, because the membrane-binding region of the gene had been deleted, had a complete reversal of the obese phenotype (Reizes et al., 2001). These findings were consistent with the hypothesis that the syndecan-1 transgene acts as a coreceptor for AgRP on MC3 and MC4 receptor-containing neurons. This, in turn, led to the hypothesis that syndecan-3, expressed in hypothalamic tissues, is a coreceptor for endogenous AgRP antagonism.

6 Behavioral Outcomes

There is a long history of research on the behavioral mechanisms that influence food intake. We have previously described several of the possible "psychological" or "motivational" factors that can play important roles in the regulation of food intake and meal size—factors that may contribute to the development of obesity (Woods 1991; Woods and Strubbe, 1994). At the simplest level of analysis, "behavioral outcomes" can include changes in activity or energy expenditure that obviously impact on energy balance and food intake. At a more sophisticated level, these processes might also include psychological mechanisms that underlie changes in intake or food-seeking behaviors. We address these briefly here but recommend the work by Stricker and Woods (2004) for a more extensive discussion.

6.1 Activity and Energy Expenditure

Body fat reflects the difference between energy intake and energy expenditure over time (Ravussin and Gautier, 1999; Ravussin, 2005). Thus, understanding the regulation of energy balance can be partitioned into understanding the factors that regulate caloric intake and factors that regulate caloric expenditure (Schwartz et al., 2003; Seeley and Woods, 2003). Although much is being learned about the mechanisms of caloric intake, less attention has been paid to the control of energy expenditure (e.g., physical activity or exercise) (Levine, 2003) or how dietary fats might affect caloric expenditure.

A compelling case can be made that obesity is associated with lowered rates of energy expenditure (Ravussin and Bogardus, 1992). For example, previous research indicates a strong link between time spent watching television or working at a computer with obesity in children and adults (Arluk et al., 2003; Georgiades et al., 2003; Giammattei et al., 2003). Particularly relevant to human obesity is the phenomenon of nonconscious, nonexercise activity thermogenesis (NEAT), or spontaneous physical activity (SPA). NEAT is defined as the energy expended for everything we do that is not sleeping, eating, or sports-like exercise (Levine, 2002, 2003; Levine et al., 2002). Even trivial physical activities can increase metabolic rate substantially and it is the cumulative impact of a multitude of such exothermic actions that culminate in an individual's daily NEAT (Snitker et al., 2001; Ravussin, 2005).

6.2 Reward and Hedonics

One obvious mechanism by which different dietary fats might give rise to different amounts of caloric intake is the concept of "palatability" or hedonics. It is well known that certain tastes and combinations of macronutrients elicit greatly increased food intake in rats and other species. Generally, this has been described using concepts like hedonic reward, pleasure, and other psychological factors. Although there is a rich and instructive historical debate on the functions and utilities of these conceptual frameworks, one can conceptualize such issues simply: "Do humans and other animals consume more of a given food because they like it more than other food stuffs?" Although seemingly simplistic, it is perhaps one of the most important questions that we can ask with regard to body weight and obesity in humans. If increased intake and resultant changes in body weight are due solely to differences in palatability or hedonic value, then it makes little sense to ask whether HF diets first impair physiological systems (e.g., insulin signaling) to cause obesity.

The first line of evidence supporting the role of palatability in the control of intake comes from experiments that examine learning about flavors. Numerous experiments indicate that the acceptance or avoidance of flavors can be manipulated through conditioning procedures (Capaldi et al., 1983; Sclafani and Nissenbaum, 1988; Elizalde and Sclafani, 1990; Capaldi, 1991; Sclafani, 1991). For example, rats will increase their intake of a less preferred flavor solution (such as the bitter taste of quinine) if its presentation has historically been followed by another, preferred flavor solution (Breslin et al., 1990). In other kinds of experiments, delivery of a flavor that is normally preferred can support the learning of a conditioned place preference in rats (Delamater et al., 2000). In these paradigms, rats are given an equal amount of experience in two novel contexts, each of which has a drinking tube. In one context, the drinking tube delivers water or a nonpreferred solution. In the other, the tube delivers a highly preferred sucrose solution. At a later test, rats are given a choice between the two contexts but without access to the drinking tubes. The common finding is that they spend more time in the context where they had received the sucrose solution. These data indicate that flavor itself can be a powerful stimulus capable of supporting learning.

Dianne Figlewicz-Lattemann, has recently obtained evidence that leptin reduces the reinforcement potency of sweet tastes. In that experiment, food-deprived rats were given access to sucrose in a conditioned place preference paradigm after receiving leptin or saline. As occurs when rats are trained just after eating and are sated, leptin attenuated subsequent preference for the chamber that contained sucrose. More important, the amount of sucrose consumed during training was extremely small (1.5 kcal), strongly implicating taste rather than calories as the key aspect of the stimulus in the paradigm (Figlewicz et al., 2001).

7 Concluding Remarks

The overview presented here is only a small fraction of the vast literature on the complex regulation of food intake, body weight, and energy expenditure. The goal of this chapter has been to provide a concise sample of several critical variables and hypotheses regarding this important system. However, as research continues in the topics of food intake and obesity, the field will undoubtedly change and adopt new as-yet-unexpected ideas about the control of body weight.

1 Introduction

1.1 Homeostatic Reflexes and Behaviors Maintain Body Fluid Balance

The maintenance of the internal milieu requires coordinated efforts of autonomic and endocrine reflexes and behaviors. Terrestrial animals constantly lose water and sodium to the environment. Thus, the volumes and constituents of the various body fluids are always in flux. Renal losses of sodium and water are minimized by autonomic and endocrine responses [e.g., activation of the sympathetic nervous system; release of aldosterone and the antidiuretic hormone, vasopressin (VP)]. Behavioral responses include the seeking out and ingestion of water and salty substances. The consumption of water and sodium is required to replenish the body with these substances. The motivational states that drive animals to find and consume water and salty substances are *thirst* and *salt appetite* and are defined operationally by measuring their consumption under specified experimental conditions.

Homeostatic reflexes and behaviors operate with different latencies. Sympathetic reflexes begin within moments after an imbalance of body fluids is detected. Endocrine effects are felt within minutes. Behavioral responses take somewhat longer. Thus, reflex mechanisms minimize homeostatic disturbances and allow time for behaviors to be mobilized. Coordination of these reflex and behavioral responses requires the integrative action of the central nervous system (CNS) which continuously monitors body fluid status. The reflexes and behaviors that maintain body fluid homeostasis often employ common mechanisms. They are activated by similar afferent signals to the brain and use many of the same CNS structures and neurochemical systems to accomplish their complementary roles. For example, the hormone angiotensin (ANG) II stimulates sympathetic outflow, VP release, and water and sodium ingestion through overlapping neural structures and pathways. This review summarizes the major neural and humoral signaling mechanisms that apprise the CNS of body fluid status and the key brain systems (structures and neurochemicals) that generate thirst and salt appetite.

1.2 Determinants of the Volume and Distribution of Body Fluids

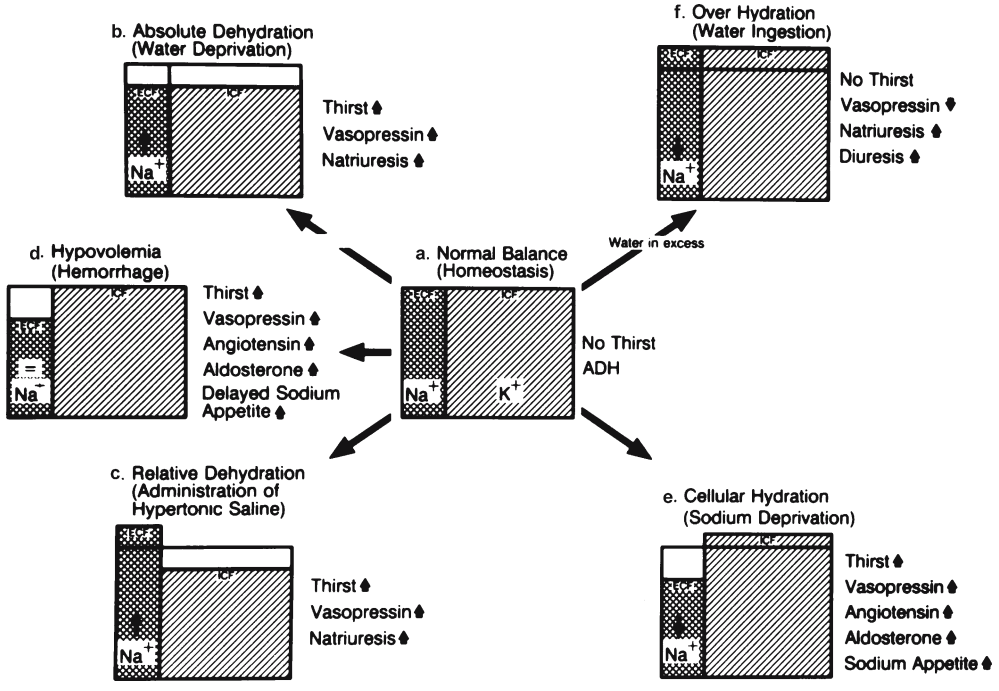
Approximately 60% of the weight of the body is water. Almost all of this water is contained in the intracellular and the extracellular fluid compartments with the amount inside the cells being approximately twice that outside. The solute composition of these fluid spaces is markedly different, and the maintenance of a 2:1 ratio of intra- to extracellular water is mostly the result of the ratio of sodium to water (sodium concentration) in the extracellular fluid. Because the cell membrane is effectively impermeable to sodium,

this monovalent ion generates an osmotic gradient, which is responsible for the movement of water between the fluid compartments.

Under normal conditions, water and sodium are gradually lost from the body (see *Figure 17-1*), and exposure to moderate physiological challenges such as periodic exercise, increases in ambient temperature, lactation and gestation will accelerate such losses. The rates of water and sodium loss to the environment can be quite different from each other. Hence, the net effect of ongoing depletion of the substances may result in a profile of loss that produces an internal state that is hypotonic, isotonic, or hypertonic. The consequence is that water will not necessarily remain distributed in a constant 2:1 proportion between the intra- and extracellular fluid compartments.

Figure 17-1

Schematic of changes in body fluid distribution and composition as a result of manipulations that produce negative and positive water and sodium balances. Above each diagram is a description of the body fluid status and an example of a manipulation used to induce it. To the right of the diagram is an indication of the control actions elicited attempting to compensate for or correct the disturbance. ECF, extracellular fluid compartment; ICF, intracellular fluid compartment; thirst = drinking water; sodium appetite = salt appetite = ingestion of salty substances, notably hypertonic NaCl solutions. Reprinted from Johnson (1990); originally adapted from Andersson (1971)



The extracellular fluid compartment is composed of two subcompartments—the cell-free fluid within the cardiovascular system (i.e., plasma) and the fluid comprising the interstitial space (i.e., that surrounding cells). The movement of water and sodium between the vasculature and interstitial spaces is virtually unimpeded so that a reduction or expansion in one of these two subcompartments is rapidly accompanied by a proportional change in volume in the other. The relative changes in amount of fluid in the extracellular space can be easily quantified by measuring changes in hematocrit or in plasma protein concentration (Stricker, 1966).

In the face of dehydration of either the cellular or the extracellular fluid compartments, physiological mechanisms are activated to minimize the rate of water loss from the body, and behaviors are mobilized to

find and drink water (i.e., thirst). In the case of extracellular depletion, additional responses are initiated to retain and to seek out and consume sodium (i.e., salt appetite). The kidneys are major targets of the physiological controls of the rates of water and sodium losses from the body. Both the sympathetic component of the autonomic nervous system and various hormones act on the kidneys to modulate the rates of sodium and water excretion (Samson, 2004). Increased sympathetic neural tone exerted on the proximal renal tubules increases the reabsorption of sodium and water to reduce the rate of loss of these substances (DiBona, 1982). Similarly, several hormonal agents each act on one or more segments of the renal tubule or collecting duct system to either increase or decrease the rates of sodium and water reabsorption. Although the kidneys represent major targets for the control of water and sodium excretion, it is worth noting that a degree of physiological control is also exerted on the sweat and salivary glands to modulate rates of loss.

Sympathetic and hormonal responses can temporarily stem the insult of severe dehydrating challenges by slowing the concomitant loss of water and sodium through the volume and composition of urine and to a lesser extent by reducing salivary secretion and sweat rates. However, it is very important to appreciate that under normal conditions the only way that the state of homeostasis can be restored in the face of water or sodium deficit is by arousal of behaviors consistent with finding and consuming sufficient amounts of water and sodium.

1.3 A Brief History of the Study of Thirst and Salt Appetite

A fair starting point for the scientific analysis of thirst is Haller's (1747) summary of what was then known about the topic, and his restatement of the age-old "dry mouth" notion, namely, that thirst arises from sensations in the mouth and throat when they become dry (Grossman, 1967; Fitzsimons, 1973). This idea was largely dispelled by the work that followed. One classic refutation was provided by the great physiologist Bernard (1856) who prepared dogs and horses with esophageal fistulas so that water imbibed by the thirsty animals passed out of a hole in the throat and did not reach the stomach and intestines for absorption. The animals drank to exhaustion apparently without relief although their mouths and throats were continuously bathed by water. By the start of the last century, thirst was largely viewed as a kind of general sensation arising from a lack of water in the blood. Mayer (1900) found increases in the osmotic pressure of blood from dogs deprived of water for several days. He thought this thickening of the blood accounted for thirst. He provided a key metric of dehydration by determining the osmotic pressure of plasma. Measuring the osmotic pressure presented a quantifiable index of a physical change that accompanies thirst. Wettendorf (1901) was impressed by how modest the change in blood osmolality is in the early stages of water deprivation. He believed that water is drawn from the tissues into the systemic circulation keeping the blood changes small, and that tissue dehydration, not increased osmotic pressure *per se*, was the stimulus for thirst.

With his influential Croonian lecture, W.B. Cannon (1918) defended the "dry mouth" theory. Cannon argued that thirst comes from local tissue desiccation, specifically of the mouth. He posited that these local conditions can be caused by the loss of water from the whole body, but that thirst does not arise from nerve endings all over the body that project to the brain. Thirst, he claimed, results from nerves innervating the mouth region that sense the local desiccation occurring there. By force of his stature in the field, Cannon's defense of the dry mouth theory unfortunately steered the course of research largely into investigations of the relationship of salivary flow and thirst.

Fundamental advances were delayed until the 1930s when seminal work was performed. Two kinds of dehydration were described—one that accompanies loss of water and the other that accompanies loss of sodium (Kerpel-Fronius, 1935). Darrow and Yannet (1935) detailed the changes in distribution of body fluids on addition and subtraction of sodium. Using dogs, they showed that sodium administered into the peritoneal cavity expanded plasma volume and contracted cell volume. They remarked that this made the dogs thirsty, but they did not measure the amount of water drunk. Upon the loss of sodium from the body, they showed contraction of plasma volume and expansion of cell volume. Their dogs were not thirsty after sodium loss, even though the mucus membranes of the mouth indicated considerable dehydration.

Gilman's (1937) work refocused interest on the cellular dehydration theory of thirst. Gilman infused dogs intravenously (iv) with equiosmolar concentrations of urea, which readily passes through the cell membrane, and of sodium, which does not. The infusions of sodium caused twice as much drinking as the infusions of urea. Gilman concluded that sodium was a more effective stimulus by virtue of being excluded from the cells and thus causing the cells to shrink as water was withdrawn from them. After Gilman, the focus of much research was on the location of the cells responsible for detecting hydrational status. In the course of studying VP release, Verney (1947) developed the concept of *osmoreceptors*—cells activated when they shrink from dehydration (see *Section 2.2.1*). Furthermore, Verney localized osmoreceptors to the base of the brain (e.g., hypothalamus) by comparing infusions of urea and sodium into the carotid arteries and other vessels on the release of VP. Infusions of sodium into the carotid arteries, which supply the hypothalamus, worked best. Wolf (1950) applied the idea of osmoreceptors to the sensing of dehydration that triggers thirst.

By mid-century, it was clear that an exclusive cellular theory of thirst did not satisfactorily explain all drinking. For example, animals deprived of water drink more than animals administered enough hypertonic saline to cause equivalent increases in osmolality. Furthermore, animals depleted of sodium eventually develop large increases in water drinking even though the cells are expanded. Wolf (1958) suggested that osmoreceptors responded not only to shrinkage but also to expansion so that any *change* in cell size is an adequate stimulus for thirst. However, Adolph and group (1954) explicitly argued the case for multiple factors in thirst. Fitzsimons (1961) effectively settled the issue in favor of Adolph and colleagues (1954) by showing that extracellular fluid depletion, specifically hypovolemia, causes thirst. Fitzsimons' strategy was to cause an effective loss of extracellular fluid by injecting animals with isotonic hyperoncotic colloid[1], which causes a localized edema by sequestering isotonic fluid into the region surrounding the injection site. This reduces plasma volume, and since the sequestered fluid is iso-osmotic, there is no effect on the volume of the intracellular compartment. This selective depletion of extracellular fluid volume causes animals to drink.

Fitzsimons' (1966, 1969b; Fitzsimons and Simons, 1969) subsequent discovery that a renal factor (i.e., renin acting through ANG II) partly mediates hypovolemic thirst was a major advance in the endocrinology of drinking (see *Section 2.2.2.1*). The notion that cellular and extracellular dehydrations are independent causes of thirst was formally stated as the *double depletion hypothesis* of thirst by both Epstein (1973) and Fitzsimons (1973). Cellular and extracellular factors are, by and large, additive in their effects on thirst (see *Section 2.4.1*).

With refinement of stereotaxic technique and its routine use in the 1950s and 1960s came rapid advances in understanding of the role of the brain (i.e., mostly the hypothalamus) in thirst and salt appetite. Electrolytic lesions of the hypothalamus profoundly alter water intake (Stevenson et al., 1950) and sodium ingestion (Wolf, 1964a). Electrical stimulation using electrodes implanted into the hypothalamus causes drinking in conscious animals (Andersson and McCann, 1955). Andersson (1952) injected concentrated saline solutions into the hypothalamus through a chronically implanted cannula and elicited water drinking in water-replete goats. Andersson's studies convinced him that the sought after osmoreceptor for thirst was really a *sodium receptor* (see *Section 2.2.1*). Grossman's (1960, 1962) ability to selectively stimulate feeding or drinking by administering adrenergic or cholinergic agents, respectively, through the same cannula implanted into the lateral hypothalamus (see *Section 4.1.2*) provided an example of chemical coding of behavior in the brain, and ushered in the neurochemistry and neuropharmacology of thirst.

Major work in salt appetite began in the 1930s. Richter (1936) showed the profound sodium chloride intake of adrenalectomized rats caused by uncontrollable urinary loss of sodium following the removal of the source of the mineralocorticoid hormone, aldosterone. Robust salt appetite is also produced by excess mineralocorticoids (Rice and Richter, 1943). By the 1960s, it was clear that salt appetite is produced under many of the same conditions as extracellular thirst, including sodium loss by glucose dialysis (Falk, 1961), hypovolemia through colloid administration (Stricker and Wolf, 1966) and procedures that generally

[1] A large molecular weight substance that remains in a depot in the intersitial subcompartment but that does not enter the systemic circulation or the cellular compartment.

increase renin secretion. This suggests that salt appetite is under many of the same controls as extracellular thirst. Spurred by the discovery of an intrinsic renin-angiotensin system (RAS) in the brain (Ganten et al., 1971a; Ganten et al., 1971b; see *Section 4.1.1*), it was shown that ANG II stimulated salt appetite upon central injection (Buggy and Fisher, 1974; Chiaraviglio, 1976). Although the doses employed in these initial studies were rather high, the dose could be lowered considerably by pretreating animals with systemic mineralocorticoids (Fluharty and Epstein, 1983). This work suggested the *synergy hypothesis* of salt appetite whereby high levels of cerebral ANG and systemic mineralocorticoids can independently stimulate salt appetite but together act synergistically (see *Section 2.4.2*).

The last 30 years or so have been notable for the diversity of work in the areas of thirst and salt appetite. The circumventricular organs (CVOs) of the brain have become regarded as key areas for sensing humoral factors because of their unique absence of a blood–brain barrier (Johnson and Gross, 1993). The CVOs are established as areas housing osmoreceptors and receptors for ANG II. The list of hormones affecting thirst and salt appetite continues to grow. There are new hormones (e.g., relaxin) and neurotransmitters under investigation as are new roles for old hormones (glucocorticoids) and neuroactive agents. The interactions among extracellular factors (i.e., pressure, volume, ANG) that produce thirst and salt appetite have become clearer. Research into the cellular basis of the *synergy hypothesis* is proceeding as are alternative accounts of the underlying mechanisms for synergy. Major advances have been made into understanding the mechanisms of satiation of thirst and salt appetite, and newer avenues of investigation include examination of the molecular bases of these states and behaviors.

1.4 Experimental Strategies and Animal Models

A variety of techniques has been used to produce deficits of body water or electrolytes in order to investigate compensatory physiological and behavioral responses. The ability to produce selective deficits in the cellular and extracellular fluid compartments has greatly facilitated the study of the underlying mechanisms of thirst and salt appetite.

Water depletion normally results from a simple lack of water to drink. It produces deficits in both the cellular and the extracellular compartments. Water is lost first from the extracellular compartment, through skin, lungs, and urine. This increases osmotic pressure of the extracellular fluid, which dehydrates cells, ultimately resulting in diminished volumes of both compartments (Marriott, 1950; Strauss, 1957). Water depletion is produced experimentally by depriving people or animals of water. Thirst is the earliest symptom, and it is usually progressive (Dill, 1938). However, a small but reliable salt appetite also occurs as a consequence of the extracellular fluid deficits (Weisinger et al., 1985a, b; Sato et al., 1996).

A relatively pure sodium depletion can occur in people who lose substantial sodium by sweating, alimentary secretions (e.g., diarrhea), or urine (Addison's disease) provided they are liberally drinking water. Sodium deficiency is produced experimentally in animals by dialysis against glucose (Gilman, 1934; Darrow and Yannet, 1935) or in humans by extensive sweating (McCance, 1936a, b; Takamata et al., 1994) or aspiration of alimentary secretions (Nadal et al., 1941) with water as the only drinking fluid. With loss of the main extracellular electrolyte—sodium—osmotic pressure falls and water shifts into the cells. This reduces extracellular fluid volume and may result in a fall in blood pressure (Gilman, 1934). Over time, the kidneys excrete water in an effort to achieve isotonicity.

Dialysis against glucose involves injections of a volume of isotonic (5%) glucose into the peritoneal space (Gilman, 1934; Darrow and Yannet, 1935, 1936). Over a few hours, there is almost complete equilibration and exchange of extracellular sodium with glucose. Subsequent removal of an equal volume of peritoneal fluid removes large amounts of sodium without a net loss of body water. The decreased concentration of extracellular sodium results in a shift of water into cells and a decrease in extracellular fluid volume. In the early use of this technique, investigators reported both diminished (Darrow and Yannet, 1935, 1936; Huang, 1955; Semple, 1952) and increased (Cizek et al., 1951; Semple, 1952; Huang, 1955) water drinking. Holmes (1960) suggested two phases to the drinking response, an acute phase with absence of thirst and a chronic phase with thirst present. Acutely, animals are described as "languid" (Darrow and Yannet, 1935). The cells are greatly expanded at this time and water drinking is almost universally found to

be diminished. Later, increased water intake is usually observed, although with considerable variability among animals. Water drinking is also observed in dogs depleted of sodium by a combination of sucrose diuresis and low-sodium diet (Holmes and Cizek, 1951) and by maintenance on sodium-deficient diets for a sufficient time (Kerpel-Fronius, 1935; Swanson et al., 1935; Radford Jr., 1959).

In human studies involving specific sodium loss, there is a reported lack of thirst (Nadal et al., 1941) or a sensation somehow distinct from thirst (McCance, 1936a, b). People may drink water, but it is not satisfying. Ingestion of sodium provides immediate relief. Sodium deficiency in human subjects produced by exercise-induced sweating followed by rehydration with water produces enhanced palatability of saline solutions (Takamata et al., 1994).

Further insight into the question of whether sodium deficiency produces thirst or salt appetite can be gained from the studies of Falk (1961, 1965, 1966). He produced sodium deficiency in rats by intraperitoneal dialysis. When water and concentrated saline were presented together so that animals have a choice of fluids to drink, the greatest increase in drinking is of the saline solution (Falk, 1965). This is appropriate as the animals have preferentially lost sodium through dialysis. This supports the idea that sodium loss does not generate true thirst even though there may be increased water intake involved.

Selective depletion of the cellular compartment is achieved by adding electrolyte to the extracellular space. This happens whenever one eats salty foods. As noted earlier, Darrow and Yannet (1935) injected sodium into the peritoneal cavity of experimental animals and observed a decrease in cell volume and increase in plasma and blood volume indicating an osmotic shift of water from the cells into the extracellular space. They reported that their animals were thirsty. Gilman (1937) later showed that the osmotic shift of water out of cells is a potent stimulus for thirst.

Selective depletion of the extracellular compartment produces hypovolemia which causes not only thirst but also salt appetite (Stricker and Wolf, 1966). After the induction of hypovolemia, animals typically ingest water for a few hours before consuming salt solutions. If only water is available for drinking, hypovolemic rats stop drinking before blood volume is restored (Stricker, 1969; Stricker and Jalowiec, 1970) because the ingested water excessively dilutes body fluids. However, by ingesting salt solutions extracellular tonicity is maintained, and animals drink sufficient amounts to fully repair blood volume deficits (Stricker and Jalowiec, 1970; Stricker et al., 1992).

Hemorrhage is a specific loss of extracellular fluid that does not affect cell volume. Although hemorrhage has been historically thought to be a potent stimulus for thirst (Starling, 1909; Cannon, 1918; Gregersen, 1941), it actually seems to be unreliable in inducing thirst. Holmes and Montgomery (1953) report that blood donors do not get thirsty. They were also unable to elicit thirst in dogs via hemorrhage (Holmes and Montgomery, 1951). Nevertheless, Fitzsimons (1961, 1969a; Fitzsimons and Oatley, 1968) found thirst after hemorrhage in rats. However it has been pointed out that the degree of hemorrhage needed to produce thirst may be debilitating because of the loss of red blood cells (i.e., acute anemia) which may account for the unreliable drinking found in earlier studies (Fitzsimons, 1972).

Procedures that interfere with the circulation can produce or mimic aspects of extracellular fluid depletion. Fitzsimons has shown that ligating the abdominal vena cava reduces venous return to the heart, and sometimes reduces blood pressure. Drinking occurs within a couple of hours (Fitzsimons, 1964, 1969b; Fitzsimons and Moore-Gillon, 1980; Fitzsimons and Elfont, 1982).

2 The Sensory Modalities that Signal the CNS about the Status of Body Water and Sodium

2.1 Overview of Chemical and Mechanical Afferent Signaling Mechanisms

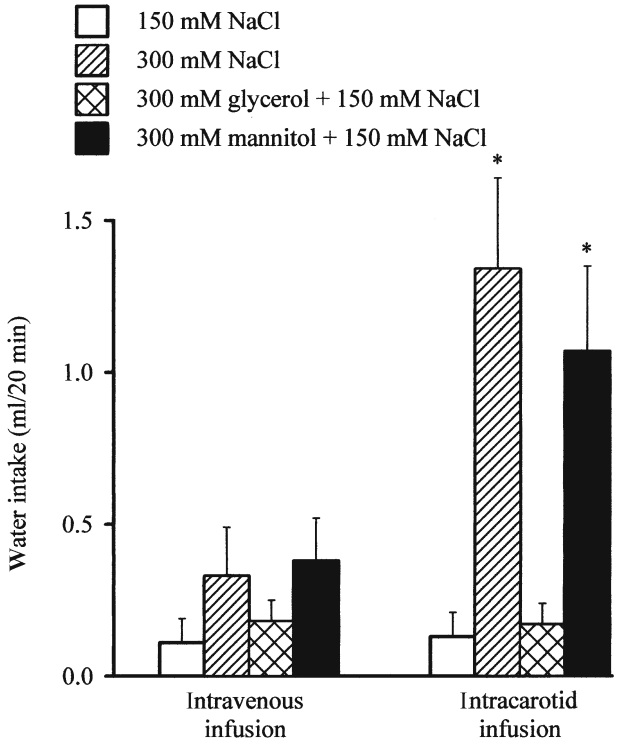
There are both chemo- and mechanoreceptors that are responsive to stimuli that are indices of body water and sodium status. These receptors are located in the systemic viscera, particularly the vasculature, kidney, and heart and in the brain. Many of the receptors and their afferents are comparable to those informational inputs critical for regulating cardiovascular functions (e.g., heart rate and blood pressure).

2.2 Humoral Mediators of Thirst and Salt Appetite

Increased osmolality of blood perfusing the brain induces thirst, releases VP, and increases sympathetic nerve activity (*Figure 17-2*). The immediate consequence of increased brain osmolalities is an acute increase in blood pressure. If the stimulus is sustained, an expansion of body fluids will occur as a result of water retention and drinking. This pattern of physiological and behavioral responses is consistent with defending a deficit and restoring body water. Decreased intracellular fluid is believed to be sensed by osmoreceptors. The term *osmoreceptor* was used to describe a hypothetical sensory cell type that transduces hyperosmolarity of extracellular fluids into neural output. The term was coined nearly 60 years ago by Verney (1947). In turn, Wolf (1958) applied the same term and concepts to account for the sensory mechanism responsible for the induction of thirst and drinking produced by administration of hypertonic solutions.

Figure 17-2

Water intake during infusion of hypertonic solutions in rats (2 ml/20 min, either split between both carotid arteries or into the vena cava). The sensors for the drinking responses are cephalic because intracarotid infusions of hyperosmotic substances worked at doses that were ineffective intravenously. The sensors are located outside the blood–brain barrier because dehydration of cells located inside the blood–brain barrier with infusions of glycerol did not work (note: glycerol passes into cells, but does not cross the blood–brain barrier). The sensors are osmosensitive rather than strictly sodium-sensitive because hypertonic mannitol as well as hypertonic saline was effective. *Indicates difference between intracarotid and intravenous infusion ($n = 8$) From Schoorlemmer et al. (2000)



A second humoral signal that evokes reflexes and behavioral responses consistent with restoration and expansion of body fluids is the peptide ANG II. Systemic administration of exogenous ANG II elevates

arterial blood pressure, releases VP and aldosterone, and increases the ingestion of water and salt. With the exception of aldosterone release, these responses can also be elicited by intracranial injections of ANG II at doses lower than those that are effective peripherally (see *Section 4.1.1*).

ANG is generated in the systemic circulation by the action of renin, which is synthesized and released from the kidney to act on a circulating substrate, angiotensinogen (AGT). The product of this enzymatic reaction is ANG I, a decapeptide which in turn is converted into ANG II by angiotensin converting enzyme (ACE) that removes two N-terminal amino acids from ANG I. ANG II is the primary effector peptide of the renin-angiotensin metabolic cascade. Although it is the most thoroughly studied, the blood-borne (also referred to as the classic or renal) RAS is not the only RAS. Beginning about 35 years ago, investigators began to find evidence for *de novo* synthesis of components of the RAS in various tissues including brain (Ganten et al., 1971a, b; see *Section 4.1.1*).

Although there are many regions in the CNS that are sensitive to osmotic changes and to ANG II, there are three specific structures lying outside the blood–brain barrier that contain receptive elements that respond to one or both of these humoral stimuli. Because of their sensitivity to blood-borne factors, these structures have been referred to collectively as *sensory circumventricular organs* (SCVOs) (Johnson and Gross, 1993; McKinley et al., 2003). Specifically the SCVOs are the subfornical organ (SFO), the organum vasculosum of the lamina terminalis (OVLT) and the area postrema (AP).

In recent years, considerable attention has been paid to mineralocorticoid receptors located in the brain and their contribution to sodium appetite (Epstein, 1982). When given in pharmacological doses (Wolf, 1964b) or in more physiological concentrations in conjunction with ANG II (Fluharty and Epstein, 1983; Fluharty and Manaker, 1983), mineralocorticoid agonists (desoxycorticosterone; aldosterone) generate the ingestion of salty solutions.

2.2.1 Osmo- and Sodium Receptors

The nature of osmoreceptors and whether there are sensory cells detecting the concentration of extracellular sodium which are distinct from osmoreceptors are the major questions in this field that have not been definitively addressed. Beginning in the 1960s Andersson and colleagues studying the goat challenged the concept of a cerebral osmoreceptor and instead proposed that the critical sensory cells are actually sodium receptors (Andersson et al., 1967; Olsson, 1969; Andersson, 1971). Their reasoning was in part based on evolving knowledge about the blood–brain barrier and the fact that Verney (1947) had based the idea of osmoreceptors on studies where hyperosmotic solutions were administered on the blood (i.e., body) side of the blood–brain barrier. Under such circumstances, it was proposed that water moved out of the brain, crossing the blood–brain barrier at a faster rate than the extracellular fluid solutes. The net effect was to increase the extracellular sodium concentration in the brain. As a test of this hypothesis, Andersson and coworkers (1967; Olsson, 1969) infused hypertonic solutions of glucose or of sucrose through the cerebral ventricular system and saw no effects on thirst or antidiuresis (i.e., VP release). Both drinking and antidiuresis were observed when an equivalent osmotic solution of hypertonic saline was delivered by the same central route. McKinley and colleagues (1974) reasoned that perhaps the sugar solutions used by the Andersson laboratory diluted CNS sodium and nonspecifically disrupted brain function. In experiments where sucrose was added to normal artificial cerebrospinal fluid (CSF), McKinley and coworkers (1974) demonstrated that such hypertonic solutions readily elicited drinking. Interesting, however, is the fact that the artificial CSF made hypertonic with sucrose is not as effective a dipsogen as infusate made equally hypertonic by adding NaCl to artificial CSF. Consequently, these investigators have speculated that there might be both osmo- and sodium receptors in the brain (McKinley et al., 1974, 1978).

There is evidence that osmo- and sodium receptors are located both in the periphery and in the CNS. One region of the body where cells are likely to be exposed to frequent and large changes in osmolality and sodium concentration is the splanchnic circulation, particularly the hepatoportal region. Assaults on fluid homeostasis are likely to occur with each meal or bout of drinking. Haberich (1968) demonstrated that water infused into the portal vein was more effective in producing diuresis than when infused systemically. Changes in vagal afferent nerve activity are produced by increasing and decreasing the osmolarity of

injections into the portal vein (Niijima, 1969; Andrews and Orbach, 1974; Adachi et al., 1976; Rogers et al., 1979). The same or similar receptor systems are also likely to contribute to the control of thirst and salt appetite. Blake and Lin (1978) found that the volume of isotonic saline consumed after water deprivation was reduced by hepatic portal vein infusions of saline and that this attenuating effect was abolished by right vagotomy. Portal vein infusions of saline have also been shown to reduce salt appetite in sodium-depleted rats (Tordoff et al., 1986, 1987). Kraly and coworkers (1995) demonstrated that thirst can be induced by intragastric delivery of hypertonic saline at a dose that it does not raise systemic osmolality, and that subdiaphragmatic vagotomy attenuated this drinking response.

Although systemic osmo- and sodium receptors may function as early sentinels and act in a feed-forward manner to initiate corrective actions, there are other osmo- and sodium receptor systems located near or within the tissues of the CNS. As previously noted, it was the work and thinking of Verney (1947), Andersson (1971; Andersson et al., 1967), and Wolf (1958) that directed attention to the importance of cerebral osmo- and sodium sensors in the control of body fluid and cardiovascular homeostasis. There are many early extracellular recording and lesion studies implicating several brain regions as being sensitive to systemically or centrally administered hypertonic solutions. For example, Silverstone and group (Clemente et al., 1957) demonstrated that systemically injected hypertonic saline increased firing of neurons in the vicinity of the AP, the most caudal of the brain's SCVOs. Similarly, Malmo and Mundl (1975) recorded osmotically activated units in the lateral preoptic area, which had previously been implicated in the control of osmotically induced thirst (Blass and Epstein, 1971; Peck and Novin, 1971) in lesion studies. Lesion and *in situ* extracellular recording studies may provide supporting evidence to implicate a region as osmo- or sodium-receptive. However, neither one of these methods is sufficient to unequivocally fulfill the criteria that a given cell type in a brain region is intrinsically responsive to extracellular osmolality or sodium concentrations. To accomplish this, it is necessary to examine responsiveness of cells when they are synaptically isolated.

From their studies on VP release, Jewell and Verney (1957) suggested that the hypothalamic cells that synthesize VP may be osmoreceptors. Mason (1980) found osmosensitive cells in the supraoptic nucleus (SON) by employing *in vitro* intracellular recording in hypothalamic slices. In more recent studies, Bourque and his colleagues found that changes in the volume of SON neurons result in modulation of mechanosensitive gadolinium-sensitive 33 pS stretch-inactivated cation channels (Bourque et al., 2002; Oliet and Bourque, 1993).

Although the VP-synthesizing cells of the SON have provided an excellent model for studying osmo- and sodium sensitivity (Oliet and Bourque, 1993; Bourque et al., 2002), it is likely that these neurons require additional input from other osmosensitive regions to effect VP release in response to physiological changes (Honda et al., 1990; Bourque and Richard, 2001). Also because the principle target of magnocellular neurons is the posterior pituitary, it is not likely that they make an important direct contribution to the neural circuitry involved in the generation of thirst or salt appetite. The periventricular region surrounding the anteroventral third ventricle (AV3V) (see Johnson and Thunhorst, 1997 for review) is another diencephalic region that has been implicated in sensing changes in osmolality or extracellular sodium concentration and providing information pertinent to thirst, release of posterior pituitary peptides and activity of the sympathetic nervous system. The importance of the AV3V region in the sensing and processing of osmotic and sodium concentration information was first appreciated in the mid 1970s from studies which found that rats with AV3V lesions had global defects in their capacity to activate many of the physiological systems that maintain body fluid and cardiovascular homeostasis (see *Section 3.1.1.1* and *Table 17-1*). One specific structure within the AV3V that is implicated in osmoreception is the OVLT. Richard and Bourque (1995) studied the relationship of OVLT with SON neurons in an explant preparation that allows selective manipulation of OVLT osmolality. Osmotic stimulation of the OVLT increased the firing rate of SON magnocellular neurons. Further evidence indicates that this excitatory drive is mediated through the release of glutamate from OVLT originating neurons that terminate on SON magnocellular neurons. (see Bourque and Richard, 2001 for review).

2.2.1.1 Transient Receptor Potential Ion Channels Recent studies employing genomic manipulations provide further insight into the molecular nature of the osmo- and sodium-sensing process. Unique

Table 17-1
Acute and Chronic Effects of AV3V* Lesions in the Rat

Acute Effects
Adipsia
Impaired secretion of vasopressin
Severe weight loss and if untreated, debilitation and death due to dehydration
Chronic Effects
Reductions in body weight
Recovery of ad libitum drinking
Impaired drinking responses to experimental challenges
• Attenuated water deprivation-induced drinking
• Abolished cellular dehydration-induced drinking
• Extracellular thirst
– Abolished angiotensin II-induced drinking
– Attenuated isoproterenol-induced drinking
– Attenuated caval ligation-induced drinking
– Attenuated polyethylene glycol treatment-induced drinking
Altered ad libitum sodium intake
Impaired sodium depletion-induced salt appetite
Impaired vasopressin secretion to hypertonic saline and ANG II
Impaired natriuresis
Impaired pressor responses to hypertonic saline and ANG II
Protection against most forms of experimentally induced hypertension
Hypernatremia
Impaired behavioral responses to defend against hyperthermia induced by heating
Impaired hemodynamic responses to defend against hyperthermia induced by heating

*AV3V is the periventricular tissue surrounding the anteroventral third cerebral ventricle

proteins associated with ion channels and transporters have attracted particular attention. Several groups recognized at about the same time that products of genes encoding members of transient receptor potential ion channels may be stretch-sensitive and activated by osmotic stimuli (Suzuki et al., 1999; Liedtke et al., 2000; Strotmann et al., 2000). Liedtke and colleagues (2000) used a candidate gene approach and found a vertebrate homolog of an osmotically gated ion channel related to the OSM-9 gene of the worm, *Caenorhabditis elegans*, and to the vanilloid receptor. They identified a novel protein in human, rat, mouse, and chicken, which has characteristics of a nonselective cation channel (initially called the vanilloid receptor related osmotically activated channel; VR-OAC) which is now called the transient receptor potential channel, vanilloid subfamily Type 4 (TRPV4). Using *in situ* hybridization, TRPV4 mRNA has been detected in neurons of the OVLT, SFO, and median preoptic nucleus (MePO) as well as in the ependymal cells of the choroid plexus in the lateral ventricles (Liedtke et al., 2000).

Employing strategies to disrupt the TRPV4 gene, two groups have studied osmotic responses in *trpv*4 null (*trpv*4-/-) mice. Mizuno and coworkers (2003) did not find effects on water intake or serum osmolality in the *trpv*4-/- mouse under conditions of ad libitum access to food and water. In contrast, Liedtke and Friedman (2003) found that *trpv*4-/- mice drink less water and become more hyperosmotic than wild-type littermates when both were given access to water but no food. In addition, under conditions of chronic infusion of a synthetic antidiuretic to induce hyponatremia, the plasma of *trpv*4-/- mice was more hypotonic, and the animals showed less suppression of drinking than wild-type controls. Currently, it appears that there may be a small role for the TRPV4-related cation channel in facilitating and inhibiting thirst under hyper and hypoosmolar conditions, respectively. However, it would appear that this may be only one molecular component of an osmosensor (Liedtke and Friedman, 2003) or that it is redundant with other osmo- and sodium receptors.

Recently, Bourque's laboratory (Naeini et al., 2006) has provided data indicating that an N-terminal variant of the transient receptor potential channel, vanilloid subfamily Type 1 (TRPV1) channel is required for osmosensory transduction in supraoptic magnocellular neurons. These cells express a form of TRPV1 that antibodies directed toward the N-terminal of the protein will bind. However, antibodies directed toward the C-terminal do not react with the same type of supraoptic cell. These researchers have also demonstrated that *trpv*1 knockout mice are hyperosmotic under basal conditions and that magnocellular neurons from these animals do not show increased membrane conductance in response to hyperosmotic stimulation.

2.2.1.2 Na_x Channel The Na_x channel is a membrane-associated protein that has come under scrutiny for the sensing of extracellular sodium status. Previously called the Na_v 2.3- (human), NaG/SCL11- (rat) and Na_v 2.3-channel (mouse), the Na_x channel is a member of a subfamily of voltage-gated sodium channels. Using Na_x knockout mice and wild-type rats, Noda and collaborators (Watanabe et al., 2000; Hiyama et al., 2002, 2004) and Mouginot and colleagues (Grob et al., 2004), respectively, have conducted both behavioral and electrophysiological studies on the Na_x channel. Na_x null mice drink excess amounts of hypertonic sodium chloride solution after dehydration by water deprivation (Watanabe et al., 2000), and populations of Na_x neurons have been identified in the SFO, OVLT, MePO, and periventricular nuclei (Watanabe et al., 2000; Grob et al., 2004).

Intracerebroventricular (icv) infusion of hypertonic saline into water deprived wild-type mice induces water intake and diminishes saline consumption, but this latter attenuated response to salt is not observed in Na_x knockout animals (Hiyama et al., 2004). However, the attenuated response to the salt solution is restored in Na_x knockout mice by transducing the SFO with Na_x cDNA (Hiyama et al., 2004). Taken together, these results indicate that structures located along the lamina terminalis house neurons that are sodium-sensitive and endowed with Na_x channels. These cells are likely to contribute to the behavioral control of hydromineral balance and cardiovascular homeostasis.

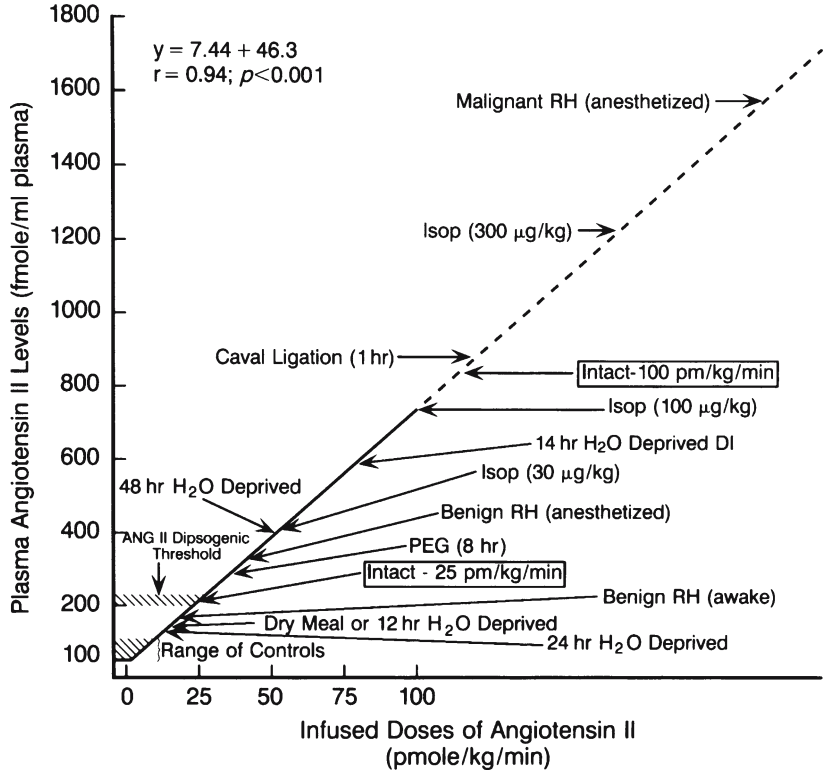
2.2.2 Systemic Peptides and Steroids

2.2.2.1 The Systemic Renin-Angiotensin System Seminal work of Fitzsimons (1969b) implicated circulating ANG II as a major stimulus for thirst. He discovered that arising from simulated hypovolemia (i.e., reduced venous return to the heart) thirst is greatly diminished by nephrectomy. He further demonstrated that renal extracts contain a thirst factor, which is identical to renin (Fitzsimons, 1969b). In general, treatments that activate the RAS (e.g., hypotension, hypovolemia, and vasodilatory drugs) induce drinking (see Fitzsimons, 1972, 1979, 1998 for reviews). Fitzsimons and Simons (1969) subsequently showed that high doses of ANG II are dipsogenic upon iv infusion. Hsiao and colleagues (1977) were able to reduce the dose that reliably induced drinking in rats by refining the drinking protocol. Mann and coworkers (1980) established that the rates of iv ANG II used by Hsiao and group (1977) produced circulating plasma levels of ANG II in the high physiological range (i.e., approximately 200 pmol/ml; *Figure 17-3*). The relatively large doses required for the dipsogenic response to ANG II has produced several challenges to accepting its physiological role in drinking (Abraham et al., 1975; Stricker, 1977, 1978; Atkinson et al., 1979; Anke et al., 1988; Pawloski and Fink, 1990). An alternative possibility has been that circulating ANG II is merely permissive of drinking during thirst-inducing procedures (e.g., hypotension, hypovolemia) by maintaining blood pressure at levels compatible with behavioral competence. Some of these concerns have been resolved by work examining the critical role of arterial pressure in the dipsogenic potency of ANG II (Evered, 1992; Johnson and Thunhorst, 1995; see *Section 2.4.3*).

It has been difficult to establish the role of the endocrine RAS in salt appetite (Fitzsimons, 1979) because of competing explanations for observed results. Surgical procedures that greatly affect sodium intake, presumably by altering the activity of the RAS (i.e., nephrectomy, adrenalectomy, renal artery constriction or ureteric ligation), do more than just produce a change in renin secretion and production of ANG II. As examples, nephrectomy may abolish salt appetite by removing the source of renin or by causing anuria (Fitzsimons and Stricker, 1971; Stricker et al., 1979). Salt appetite caused by the massive loss of sodium

Figure 17-3

Summary indicating plasma levels of angiotensin (ANG) II obtained following various challenges to activate the endogenous renin-angiotensin system. These are presented on the regression line of the relationship between infused ANG II dose (abscissa) and circulating level of octapeptide (ordinate). Intact-25 pmol/kg/min and Intact-100 pmol/kg/min indicate levels of circulating ANG II after 60-min infusions of the indicated dose into unanesthetized rats. Lower cross-hatched areas represent the range of control values of plasma ANG II. Upper cross-hatched area represents approximate ANG II plasma level at dipsogenic threshold. The threshold at which ANG II induces drinking with iv infusion was established by Hsiao et al. (1977). Abbreviations: DI, diabetes insipidus; RH, renal hypertension; PEG, polyethylene glycol; ISOP, isoproterenol. Based on the data from Johnson et al. (1981) and Mann et al. (1980); figure from Johnson and Thunhorst (1995, 1997)



following adrenalectomy may be due to increased renin secretion and formation of ANG II or to changes in salivary sodium content (Fregly and Rowland, 1985) or sodium concentration at brain sodium receptors (Weisinger et al., 1985a, b). Salt appetite caused by clipping of the renal arteries may be a pathological response to excessive renin secretion or because of sodium loss produced by a pressor natriuresis (Mohring et al., 1975). Ureteric ligation suppresses salt appetite in the face of markedly increased renin secretion due to altered renal function or to unidentified inhibitory factors (Fitzsimons and Stricker, 1971; Michell, 1995). Pharmacological interventions have their own problems. Intravenous infusions of ANG II do not consistently stimulate salt appetite in sodium-replete animals (Fitzsimons and Wirth, 1978; Findlay and Epstein, 1980; Tarjan et al., 1988; Sakai et al., 1990) other than sheep (Weisinger et al., 1986), and the effect has been attributed to pressure natriuresis and subsequent negative sodium balance (Weisinger et al., 1986; Tarjan et al., 1988; Yang and Epstein, 1991). Pharmacological blockade of the renal RAS with an ANG II receptor antagonist does not prevent salt appetite of sodium-depleted rats (Sakai et al., 1990). Studies that used systemically administered ACE inhibitor to prevent salt appetite implicated an inhibition of the brain

RAS rather than the peripheral RAS (Moe et al., 1984; Sakai et al., 1990) because of the high doses that were employed.

The brain RAS was further implicated by studies showing that centrally administered ANG II stimulates salt appetite without prior natriuresis or negative sodium balance (Buggy and Fisher, 1974; Chiaraviglio, 1976; Avrith and Fitzsimons, 1980; Bryant et al., 1980; Fluharty and Epstein, 1983; Fluharty and Manaker, 1983). Furthermore, depletion-induced salt appetite is easily inhibited by the central administration of ACE inhibitors and ANG II receptor antagonists (Buggy and Jonklaas, 1984; Moe et al., 1984; Sakai et al., 1986; Weiss et al., 1986). For these reasons, the natriorexigenic role of circulating ANG II has been minimized. According to the *synergy hypothesis* of salt appetite, ANG II derived from renal renin release serves only to stimulate the secretion of aldosterone following sodium depletion, and it is brain-derived ANG II that synergizes with aldosterone causing salt appetite through combined activity within the CNS (Epstein, 1982; Sakai et al., 1990; Yang and Epstein, 1991).

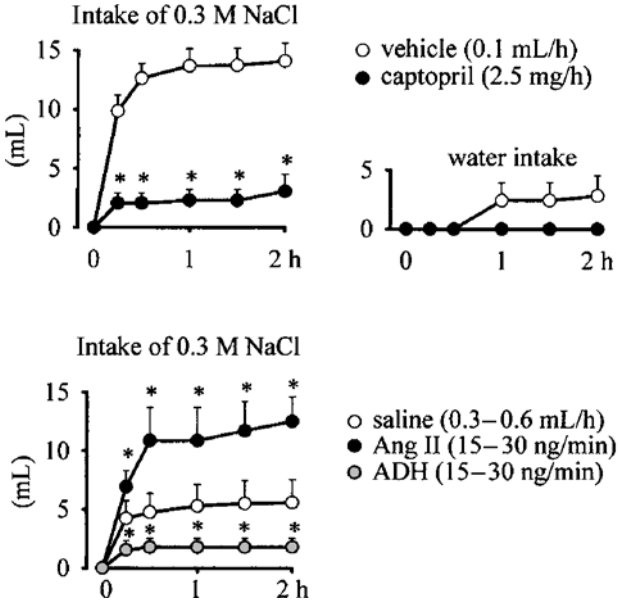
Weisinger and colleagues showed that ANG II stimulates salt appetite upon iv administration to sodium-deficient animals, including cow (Blair-West et al., 1988), sheep (Weisinger et al., 1987), rabbit (Tarjan et al., 1993), and mouse (Denton et al., 1990). The sodium-deficient animals were given enough ACE inhibitor to block the formation of endogenous ANG II peripherally and presumably in the brain. This total-body ACE blockade reduced or abolished the salt appetite response in each case. Subsequent systemic administration of ANG II stimulated salt appetite in the blocked animals, or prevented the reduction in salt appetite from occurring if administered during the ACE blockade. Since ANG II does not cross the blood–brain barrier, the results clearly show that the infused ANG II is acting on sites accessible from the blood. Others have shown that iv infusion of ANG II stimulates salt appetite in sodium-deficient rats (Thunhorst and Fitts, 1994; Fitts and Thunhorst, 1996; Schoorlemmer et al., 2001). Importantly, these later studies show that selective blockade of the systemic RAS is sufficient to prevent sodium hyphen depletion-induced salt appetite. In these studies, the rats were given doses of ACE inhibitor that prevented formation of ANG II in the circulation but not in the brain (Thunhorst and Fitts, 1994; Fitts and Thunhorst, 1996). Selective blockade of the endocrine RAS completely prevented salt appetite in response to sodium depletion despite a functioning brain RAS. Subsequent iv infusions of ANG II restored the salt appetite response within minutes. Similar results were obtained in experiments using sodium-depleted, adrenalectomized rats that completely lack endogenous mineralocorticoids (Schoorlemmer et al., 2001; *Figure 17-4*). The results point to a direct stimulatory role for the endocrine RAS in producing the salt appetite of sodium-depleted animals.

2.2.2.2 Aldosterone Aldosterone is essential for the retention of sodium by the kidney and is thus critical for normal body fluid balance. Mineralocorticoids are increased during periods of sodium deficiency, including hypovolemia (Stricker, 1983). Administration of exogenous mineralocorticoids stimulates salt appetite in both intact and adrenalectomized rats (Wolf, 1965; Fregly and Waters, 1966). The appetite depends in part on the central actions of mineralocorticoids as blockade of central aldosterone receptors (Sakai et al., 1986) or the reduction of their expression in the brain (Sakai et al., 1996, 2000) diminishes the salt appetite of sodium deficiency. However, aldosterone is not strictly essential for salt appetite because adrenalectomized rats have a pronounced salt appetite (Richter, 1936) that can be regarded as a behavioral assay of a successful adrenalectomy. Thus, the relationship between mineralocorticoid levels and magnitude of the salt appetite response is described by a U-shaped function (Fregly and Waters, 1966). Salt appetite is pronounced in the absence of mineralocorticoids, for example, after adrenalectomy when the response is driven by a severe renal loss of sodium from the body. Sodium intake is low in intact animals expressing low, basal levels of mineralocorticoids, and in adrenalectomized animals infused with low levels of exogenous mineralocorticoids that permit renal sodium retention. Salt appetite is again pronounced in either intact or adrenalectomized animals administered mineralocorticoids in excess of levels needed for sodium retention where the appetite is driven by direct actions on the brain (Fregly and Waters, 1966).

There are two types of adrenal steroid receptors, the Type 1 (mineralocorticoid) receptor and Type II (glucocorticoid) receptor (de Kloet et al., 1998). Interestingly, glucocorticoids normally occupy both subtypes in the brain (de Kloet et al., 1998). Specificity to these receptors is conferred by the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD), which converts glucocorticoids to inactive molecules thus

Figure 17-4

Top, intake of water and saline by adrenalectomized rats after sodium depletion. Either captopril or vehicle was infused intravenously ($n = 5$). Selective blockade of the systemic renin-angiotensin system nearly abolished the salt appetite response. Bottom, intake of saline by adrenalectomized rats after sodium depletion. Either isotonic saline ($n = 5$), ANG II ($n = 5$), or antidiuretic hormone (ADH; $n = 4$) was infused intravenously in a captopril (2.5 mg/h, iv) solution. ANG II restored the salt appetite response of captopril-blocked rats, but equipressor doses of ADH did not. *Indicates significant difference, $p < 0.05$. Adapted from Schoorlemmer et al. (2001)



making the Type 1 receptor available to mineralocorticoids. That is, 11β-HSD protects Type 1 receptors from occupancy by glucocorticoids. At high levels, endogenous glucocorticoids may saturate the 11β-HSD enzyme (Ferrari, 2003). The 11β-HSD is found in the brain predominantly in the anterior hypothalamus and CVOs (de Kloet et al., 1998).

Recently, Loewy and colleagues argued that aldosterone-sensitive neurons should possess three characteristics: (1) receptors for mineralocorticoids so that aldosterone can bind there, (2) 11β-HSD to convert glucocorticoids and allow aldosterone access to mineralocorticoid receptors, and (3) accessibility to aldosterone, which according to the authors does not readily cross the blood–brain barrier (Geerling et al., 2006a). In a survey of the brain (Geerling et al., 2006b), only the nucleus of the solitary tract (NTS) satisfied all criteria (i.e., cells possessing both mineralocorticoid receptors and 11β-HSD, and a location adjacent to the AP, which lacks a blood–brain barrier). Reportedly, the ventromedial hypothalamic nucleus and the medial vestibular nucleus possess 11β-HSD, but the amygdala does not (Geerling et al., 2006a). Several salt appetite inducing procedures activate NTS neurons that have 11β-HSD, and these cells are inactivated rapidly upon ingestion of sodium (Geerling et al., 2006b). It is not clear how this recent work accounts for studies implicating forebrain areas such as the amygdala in salt appetite (e.g., Sakai et al., 2000).

There are noted species differences in that mineralocorticoids are relatively ineffective in producing salt appetite in rabbit and sheep (Denton, 1982), or in dogs, gerbils and hamsters (Rowland and Fregly, 1988b). The phenomenon is controversial in mice (Rowland and Fregly, 1988a, b; Blair-West et al., 1995).

2.2.2.3 Relaxin Relaxin is a hormone secreted by the corpus luteum during pregnancy. It is dipsogenic upon iv (Sinnayah et al., 1999) and icv (Summerlee and Robertson, 1995; Thornton and Fitzsimons, 1995)

administration. Drinking in response to icv relaxin is dose-related, and is greater during the dark part of the light/dark cycle (Summerlee et al., 1998). Drinking in response to iv relaxin is also dose-related and sensitive to the presence of ANG II, as a nondipsogenic dose of ANG II triples the water drinking response to iv relaxin (Sinnayah et al., 1999). The effects of relaxin are mediated in part by a central angiotensinergic pathway as central administration of an ANG II receptor antagonist reduces drinking to systemic relaxin (Sinnayah et al., 1999). Although icv administration of relaxin causes water drinking, it does not stimulate sodium consumption (Thornton and Fitzsimons, 1995). However, antagonism of serotonin (5-HT) receptors in the lateral parabrachial nucleus (LPBN) stimulates robust sodium consumption in response to icv relaxin (Menani et al., 2004). The salt appetite response to relaxin that is observed after 5-HT receptor blockade is completely abolished by central injections of losartan, an ANG Type 1 (AT_1) receptor antagonist (Menani et al., 2004). This is further evidence that a central angiotensinergic mechanism at least partly mediates the central responses to relaxin. The icv administration of relaxin causes *c-fos* expression in brain areas associated with drinking and body fluid regulation, including the SFO, OVLT, MePO of the lamina terminalis, the SON, and the hypothalamic paraventricular nucleus (PVN; McKinley et al., 1997). Circulating relaxin activates neurons of the SFO and OVLT that directly project to the SON and PVN (Sunn et al., 2001).

2.2.2.4 Atrial Natriuretic Peptide (ANP) It has long been suspected that there should be hormonal mechanisms that cause sodium and water loss in states of volume overload (Smith, 1957). Although many substances have been proposed as primary natriuretic or diuretic agents, it was not until 1981 when de Bold and coworkers (1981) made the seminal finding that infusions of extracts of atrial tissue produced natriuresis in the rat. This led to a rapid application of biochemical techniques to identify and sequence the peptide and clone the genes of a family of natriuretic peptides that are present not only in the heart but also in other tissues including the brain (see Levin et al., 1998 for review). Both increased systemic osmolality and hypervolemia elevate circulating ANP. Systemic administration of ANP attenuates osmotically induced thirst in humans (Burrell et al., 1991). Icv injections of ANP attenuate both thirst (Antunes-Rodrigues et al., 1985) and sodium appetite (Fitts et al., 1985a).

2.3 Vascular Baroreceptors

2.3.1 Overview

The receptors identified as most important for sensing changes linked to blood volume (and hence extracellular fluid volume) and blood pressure are mechanoreceptors. These sensors are composed of free nerve endings, which are insinuated into the walls of the great veins, the heart and large arteries, and they are depolarized as these hollow structures are stretched. Depolarization generates increased nerve traffic that is proportional to the distention of the vessel or organ. The great veins and the atria are readily distensible, and the walls of these structures expand and contract as more or less blood volume fills the capacitance portion of the circulation. This yields good coupling between blood and extracellular volume and nerve traffic generated from receptors on the low-pressure side of the circulation. These sensors are referred to as low-pressure receptors (or unfortunately using a somewhat confusing and ambiguous nomenclature often as cardiopulmonary receptors).

A direct relationship between blood volume and baroreceptor activity does not exist for the pressure receptors located on the arterial side of the circulation. The arterial (or high pressure) baroreceptors are located in the aortic arch and carotid sinuses, and the afferent nerve activity from these receptors reflects changes in the arterial pressure wave throughout each cardiac cycle. Since cardiac output and arterial pressure are maintained relatively constant in the face of significant changes in blood volume, for example, under conditions of stage I shock (i.e., compensated shock), arterial baroreceptors do not always provide good information to the CNS about extracellular fluid status. However, when hypovolemia becomes sufficiently severe, cardiac output cannot be maintained and blood pressure falls. This subsequent decrease in arterial pressure can then provide information that hypovolemia is quite profound.

Input from low-pressure (i.e., blood volume) receptors and the high-pressure receptors in the aortic arch is conducted into the brain through afferents running in the vagus nerve (X cranial nerve). Arterial pressure receptors in the carotid sinuses project their information centrally by way of the glossopharyngeal (IXth cranial) nerve. The NTS is the terminal site for both of these the visceral afferent nerves (Norgren, 1981).

2.3.2 Low-Pressure Receptors

The role of vascular baroreceptors in the control of drinking is demonstrated by experimentally "loading" and "unloading" the receptors. Loading and unloading of the receptors is accomplished by procedures that produce or mimic increases or decreases in blood volume or blood pressure. For example, unloading of low-pressure receptors is produced by the constriction of a cuff placed around the vena cava (Thrasher et al., 1982a, b; Quillen Jr. et al., 1988) or by the inflation of a balloon surgically implanted inside the vena cava (Fitzsimons and Moore-Gillon, 1980). Both procedures impede blood flow through the vena cava, thereby reducing venous return to the heart, unloading of the low-pressure receptors and sometimes unloading of arterial baroreceptors as well (i.e., if the reduction in cardiac return is sufficient). These means of unloading low-pressure receptors are associated with drinking in dogs. Baroreceptors are involved in this drinking because surgical transection of the nerves supplying either the low-pressure or the sinoaortic baroreceptors (Quillen Jr. et al., 1990) reduces the drinking response. The drinking is completely abolished by simultaneous denervation of both sets of baroreceptors (Quillen Jr. et al., 1990). Drinking by hypovolemic sheep is reduced by crushing the low-pressure receptors located in the left atrial appendage (Zimmerman et al., 1981). Thus, in dog and sheep, vascular baroreceptors may provide neural afferent signals that stimulate thirst upon volume loss. In rat, a portion of hypovolemic thirst typically survives nephrectomy and the consequent loss of the source of renin (Fitzsimons, 1961). By inference, the remaining thirst is probably mediated neurally by baroreceptor input.

Loading of low-pressure baroreceptors can be mimicked by inflation of an intravascular balloon placed at the junction of the left pulmonary vein and the left atrium. Loading of low-pressure baroreceptors reduces water drinking in dogs in response to drug treatment with isoproterenol, iv infusions of hypertonic saline, and water deprivation (Moore-Gillon and Fitzsimons, 1982). Temporary vagal blockade of these baroreceptor signals increases water intake in response to reduced venous return (Fitzsimons and Moore-Gillon, 1980). These results suggest that low-pressure baroreceptors provide signals during volume expansion that inhibit further water intake.

Elegant work by Thrasher and colleagues (1999) nicely demonstrates baroreceptor control of drinking in dogs. Thrasher and group (1999) specifically increased either right or left atrial pressure during hypotension and measured drinking. Only increased left atrial pressure reduced (i.e., abolished) drinking in response to hypotension. This accords well with their work showing that increased left, but not right, atrial pressure inhibits hypotension-induced VP secretion (Andersen et al., 1994, 1995). In rats, it is the right atrium that provides inhibitory signals for thirst (Kaufman, 1984). Species differences in baroreceptor control of drinking are also underscored by Schreihofer's (1999) findings in rats that NTS lesions, which interrupt afferent input from both high- and low-pressure receptors, had no effect on water intake in response to hypovolemia. However, Quillen and coworkers (1990) found that simultaneous removal of high- and low-pressure receptor inputs by nerve transection totally abolished hypovolemic drinking in dogs. These different results may indicate that hypovolemic drinking is largely neurally mediated in dogs and hormonally mediated (i.e., ANG II) in rats. This suggestion must be tempered by the caveat that the techniques for abolishing baroreceptor input in these studies are not comparable.

The evidence for a neural contribution from baroreceptors in controlling salt appetite is less developed than for thirst. A problem with accepting a role for baroreceptors in the initiation of salt appetite is the time it takes for hypovolemia to stimulate salt appetite (Fitzsimons, 1979; Stricker, 1991). Hypovolemic treatments typically require several hours to stimulate salt intake, a delay that seems at odds with a neurally mediated response. Stricker's work suggests that the delay between the onset of hypovolemia and salt appetite is an artifact of maintaining rats on standard laboratory diet with its high sodium content (Stricker, 1981; Stricker, 1983). In effect, standard diet permits animals to acquire a reserve of body sodium

that buffers the extracellular depleting effects of hypovolemia. Rats maintained on a sodium-deficient diet for as little as 2–4 days before study develop salt appetite with the onset of hypovolemia. Rats maintained on sodium deficient diets have reduced plasma volume and sodium concentrations (Stricker, 1981; Stricker et al., 1987) and increased levels of plasma renin activity and aldosterone (Stricker et al., 1979) compared with rats maintained on standard diet. Consequently, hypovolemic treatments cause greater reductions in plasma volume, larger increases in plasma renin activity (Stricker et al., 1979) and aldosterone (Stricker et al., 1979), and blunted secretion of oxytocin (OT; Stricker et al., 1994; see *Section 4.2.1*) in rats maintained on sodium deficient diet than those maintained on standard diet. In addition, rats maintained on sodium-deficient diet have difficulty maintaining arterial pressure during hypovolemia (Stricker et al., 1979, 1987). Coupled with the greater reductions in plasma volume, the difficulty maintaining arterial pressure provides a basis by which arterial and cardiopulmonary baroreceptors may contribute important neural inputs under these conditions. The ability of atrial distension to inhibit salt appetite (Toth et al., 1987) may be circumstantial evidence that baroreceptors mediate the inhibition although it cannot be ruled out that ANP (see *Section 2.2.2.4*) released during atrial distension accounts for the effect.

2.3.3 Arterial Baroreceptors

Loading and unloading of arterial (i.e., high-pressure) baroreceptors are typically accomplished by infusions of vasoconstrictor or vasodilator drugs that raise or lower blood pressure, respectively. Increases in arterial pressure inhibit osmotic thirst (Stocker et al., 2001), hypovolemic thirst (Stocker et al., 2001), salt appetite (Thunhorst and Johnson, 1994a), and drinking in response to ANG II administered peripherally (Robinson and Evered, 1987; Evered et al., 1988; Evered, 1992) or into the brain (Thunhorst et al., 1993). Removal of arterial baroreceptor input to the brain by sinoaortic baroreceptor denervation (SAD) eliminates the inhibition of thirst to ANG II administered peripherally (Stocker et al., 2002) but not centrally (Thunhorst et al., 1993). Denervation of the arterial baroreceptors reduces salt appetite in sodium-depleted rats by half (Thunhorst et al., 1994). This may be due to the absence of baroreceptor signals, altered hormonal responses (e.g., reduced renin secretion), or both. Rats with SAD have reduced salt intake over a range of NaCl concentrations at or above isotonic levels (Rocha et al., 1997). The reduced ingestion is specific for salt because SAD does not change ingestion of water, sucrose, or dilute saline solutions (Rocha et al., 1997). When offered only 2% NaCl to drink, SAD rats consume less than controls (Rocha et al., 1993) but have exaggerated release of VP and OT (Rocha et al., 1993). This led to the idea that exaggerated OT secretion upon initial ingestion of concentrated saline might inhibit further ingestion in SAD rats (Thunhorst et al., 1994). However, OT antisense injected directly into the PVN region decreased, rather than increased, the saline consumption of SAD rats when compared with controls (Morris et al., 1995).

Lesions of the NTS remove neural input from both arterial and cardiopulmonary baroreceptors (Schreihofer et al., 1999). Rats with NTS lesions have increased thirst and salt appetite responses to hypovolemia under some conditions. Rats with NTS lesions drink exactly as much as controls during hypovolemia when water or isotonic saline are available (Schreihofer et al., 1999). However, when a choice of water and concentrated saline is provided, rats with NTS lesions drink more of both in response to hypovolemia (Schreihofer et al., 1999). Rats with NTS lesions drink greater amounts of water, with reduced latency, in response to iv infusions of ANG II (Schreihofer et al., 2000). Increased drinking in response to ANG II is also observed in dogs lacking all arterial and cardiopulmonary input after surgical denervation (Klingbeil et al., 1991) and in rats with lesions of the LPBN (Ohman and Johnson, 1986).

2.4 Interactions Between Systems

2.4.1 The Additivity of Cellular and Extracellular Thirsts

Thirst arising from simple water deprivation, probably the most common and naturally occurring situation producing thirst, involves loss of water from both fluid compartments. A thorough analysis of thirst

following water deprivation requires understanding how stimuli arising from the two major fluid compartments act simultaneously. It is possible that when multiple stimuli for thirst are present, drinking could result solely from the effects of the more intense stimulus. This is not the case, as Oatley (1964) showed in rat that the combination of hemorrhage and injection of hypertonic saline produces more drinking than either stimulus alone. Alternatively, the effects of multiple stimuli can sum, multiply, or interact in some other fashion. For example, Corbit (1968) demonstrated that cellular dehydration (i.e., i.p. hypertonic saline) and hypovolemia (i.e., hyperoncotic colloid) are independent and additive in their effects on thirst and do not interact in a multiplicative way. Fitzsimons and Oatley (1968) found that both cellular dehydration (i.e., iv hypertonic saline) and hypovolemia (i.e., hemorrhage) caused additional drinking in water-deprived animals. Again, the amount of water drunk after the combination of the osmotic or hypovolemic stimulus with water deprivation was simply the sum of the amounts drunk after each stimuli (i.e., it was additive). Furthermore, there was no interaction effect of combining the stimuli.

A variety of combinations of thirst stimuli involving intracellular and extracellular deficits have additive effects on drinking. These include hypertonic saline and hemorrhage (Oatley, 1964), water deprivation and hypertonic saline or hemorrhage (Fitzsimons and Oatley, 1968), hypertonic saline and hyperoncotic colloid (Corbit, 1968; Stricker, 1969; Blass and Fitzsimons, 1970), caval ligation and water deprivation or hypertonic saline or hypertonic sucrose (Fitzsimons, 1969a), and ANG and caval ligation (Fitzsimons and Simons, 1969) or hypertonic saline (Fitzsimons and Simons, 1969; Hsiao and Epstein, 1973). Severs and coworkers (1974) found that the amount of water drunk after icv administration of ANG II was additive with both cellular (i.e., s.c. hypertonic saline) and extracellular (i.e., polyethylene glycol) dehydration-induced drinking. In this case, a central stimulus (icv ANG) summed with both types of systemic stimuli (osmotic or volumetric). In all cases, drinking produced by one stimulus simply sums with the drinking produced by another stimulus. Additivity of thirst stimuli has been shown in gerbil (Vanderweele, 1974; Wright et al., 1987), degu and hamster (Wright et al., 1987) using hypertonic saline and hyperoncotic colloid.

In an interesting study on sham drinking in rats with gastric fistulas, Salisbury and Rowland (1990) found the usual additivity of drinking to combined cellular (i.e., hypertonic saline) and extracellular (i.e., s.c. colloid) dehydration with the fistula closed. They also found typical sham drinking responses to the individual stimuli with the fistula open (i.e., doubling of the drinking response). However, sham drinking in response to the combination of cellular and extracellular dehydration was no greater than the amount drunk with the fistula closed. That is, there was no additional drinking under sham conditions when the stimuli were combined. This contrasted with sham drinking in response to simple water deprivation, which was three times greater than with the fistula closed. It is not clear why two conditions involving combined cellular and extracellular deficits (i.e., water deprivation vs. combined colloid and hypertonic saline) should produce disparate sham drinking responses.

2.4.2 The Synergy Hypothesis

The capacity of ANG II and adrenal steroids to stimulate salt appetite led to the suggestion that they may act cooperatively or synergistically to promote salt appetite when levels of both are elevated during hypovolemia or sodium depletion (Epstein, 1982, 1984; Fluharty and Epstein, 1983; Sakai et al., 1986). As originally formulated, the *synergy hypothesis* holds that mineralocorticoids of peripheral origin (i.e., the adrenal glands) act together with ANG of central origin (i.e., the brain) to promote salt appetite. The combined effect is described as synergistic because the resulting sodium ingestion is greater than the sum of the intakes produced by the hormones separately across a range of doses. Experiments showed that subthreshold doses of systemically administered deoxycorticosterone (DOCA) or aldosterone, and centrally administered ANG II readily caused saline intake when administered together (Fluharty and Epstein, 1983; Sakai, 1986). Converging evidence showed that blockade of either ANG II or aldosterone receptors alone only partially prevented salt appetite in response to sodium depletion, but simultaneous blockade abolished it (Sakai et al., 1986). The inability to prevent depletion-induced salt appetite by peripheral infusion of ANG II antagonists (Sakai et al., 1990) led to the conclusion that ANG II of central origin, not renal origin, is responsible for the synergistic response. However, this conclusion leaves no stated mechanism to increase

brain ANG II levels following sodium depletion. A possible solution to this need is the finding that circulating ANG II is a potent stimulus of salt appetite in sodium-depleted animals (see *Section 2.2.2.1*), and if connected in series with the brain RAS, could serve as the stimulus for increased levels of brain ANG II that are vital for the synergistic response.

Since its formulation, much work on the *synergy hypothesis* has concerned cellular mechanisms by which mineralocorticoids and ANG II interact in the brain. For example, elevated mineralocorticoid levels increase ANG II receptor binding in brain tissue, specific brain nuclei, and neuronal cultures (Wilson et al., 1986; King et al., 1988; Sumners and Fregly, 1989; De Nicola et al., 1993), probably through both genomic (Fluharty and Sakai, 1995; Daniels and Fluharty, 2004) and nongenomic (Sakai et al., 2000) mechanisms. An intriguing aspect of the work regarding the proposed cellular basis of the ANG II/aldosterone synergy is the prominent role given to CVOs as the anatomical locus for the interactions (Daniels and Fluharty, 2004).

An alternative account for the synergistic behavioral response upon dual administration of mineralocorticoids and ANG II relies on the ability of mineralocorticoids to suppress secretion of OT, an inhibitor of sodium consumption (Stricker et al., 1987, 1994). In this scenario, circulating mineralocorticoids create the conditions suitable for initiating a salt appetite response by suppressing OT activity in the brain. This removes a brake on sodium consumption hence permitting greater responding to ANG II.

A synergy of ANG II and aldosterone has been found in pigeon (Massi and Epstein, 1990) but does not appear to hold for sheep and cow (Weisinger et al., 1996).

2.4.3 Interactions Between Arterial Blood Pressure and Angiotensin

Considerable work has clarified the interactions between hormonal and baroreceptor signals in the control of body fluid regulation (Stricker, 1991; Evered, 1992; Thunhorst and Johnson, 1993, 1994b; Johnson and Thunhorst, 1995). Fitzsimons and Simons (1969) first established that ANG II is dipsogenic upon iv administration in rats. The dipsogenic nature of ANG II has subsequently been confirmed in several species (Cooling and Day, 1975; Fitzsimons, 1975; Trippodo et al., 1976; Schwob and Johnson, 1977; Simpson et al., 1978), but the often weak nature of the dipsogenic response argues against an important role for ANG II in drinking behavior (Stricker, 1977, 1978; Anke et al., 1988). A resolution of the problem comes with the understanding of the confounding effects of acute hypertension on drinking behavior (Robinson and Evered, 1987; Evered et al., 1988; Evered, 1992). ANG II causes striking increases of arterial pressure in fluid-replete animals (Evered, 1992). Under natural conditions of dehydration involving hypovolemia, endogenous ANG II serves to maintain arterial pressure only at approximately normotensive levels, not at hypertensive levels. Animals drink more in response to iv infusion of ANG II if the arterial pressure response is blunted (Robinson and Evered, 1987; Evered et al., 1988).

Low-pressure receptors and arterial baroreceptors mediate the pressor-induced inhibition of water drinking in response to ANG II. In dogs, surgical removal of both sets of these baroreceptors permits greater drinking during iv ANG II (Klingbeil et al., 1991). Initial studies in rats did not find that removal of the arterial baroreceptors by themselves affected drinking in response to systemically administered ANG (Rettig and Johnson, 1986; Kadekaro et al., 1989). However, recent work by Stocker and coworkers (2002) clearly shows that removal of arterial baroreceptor input (i.e., SAD) permits greater drinking in response to high doses of iv infused ANG II. The different results may be due to the degree of completeness of the surgical denervations or the routes and doses of ANG II. Therefore, it seems that sensing increased arterial pressure inhibits drinking caused by ANG II.

Increased arterial pressure inhibits drinking when ANG II is administered centrally (Johnson et al., 1977; Harland et al., 1988; Kucharczyk, 1988). Modest reductions in arterial pressure are associated with a doubling of the dipsogenic response to centrally administered ANG II (Thunhorst and Johnson, 1993). However, the ability of arterial pressure to affect the dipsogenic response of centrally administered ANG II is not influenced by surgical denervation of the arterial baroreceptors (Thunhorst et al., 1993). The possibility remains that other systemic baroreceptors (e.g., renal baroreceptors; Stella and Zanchetti, 1991; Thunhorst et al., 1996) mediate the influences of arterial pressure on drinking in response to centrally administered ANG II.

Less thoroughly studied are the interactions between hormonal and baroreceptor signals controlling salt appetite. Although aldosterone and ANG II stimulate salt appetite, neither is essential (Stricker, 1981; Fregly and Rowland, 1985), so other mechanisms may be involved including cerebral sodium sensors (Weisinger et al., 1985a, b) and baroreceptors. The relatively small salt appetite response following prolonged iv infusions of ANG II into fluid-replete animals may be due to pressure-mediated inhibition of the response. For example, iv infusions of ANG II that elevate arterial pressure above baseline slightly reduce salt appetite of sodium-deficient sheep (Bott et al., 1967) and rats (Fitts and Thunhorst, 1996). Hypotension accelerates the appearance of salt appetite in hypovolemic rats following diuretic treatment (Thunhorst et al., 1999). The onset of salt appetite is also hastened by administering a low dose of ACE inhibitor to animals made hypovolemic by polyethylene glycol (Stricker, 1983) or diuretic treatment (Fitts and Masson, 1989; Masson and Fitts, 1989; Thunhorst and Johnson, 1994a). In these hypovolemic situations, peripheral ACE blockade abruptly reduces arterial pressure (Gardiner and Bennett, 1986; Thunhorst and Johnson, 1994a) which aids the salt appetite response (Thunhorst and Johnson, 1994a). When arterial pressure is prevented from falling under these conditions, for example by iv infusion of the pressure agent, phenylephrine, the salt appetite response is blunted whereas the water drinking response is not (Thunhorst and Johnson, 1994a). It is not known if hypotension aids salt appetite by providing neural input to the CNS or by increasing renin secretion. Increased arterial pressure may inhibit salt appetite under some circumstances. The few experiments examining salt intake in animals lacking baroreceptors suggest that the salt appetite response is severely diminished (Thunhorst et al., 1994; Morris et al., 1995; Rocha et al., 1997).

2.4.4 Interactions Between Vascular Volume and Angiotensin

Prevailing levels of extracellular fluid volume, as with arterial pressure, modify the dipsogenic and natriorexigenic responses to ANG II. Experiments in which endogenous ANG II levels are increased by various means in volume- and sodium-replete animals fail to show convincing salt appetite responses (e.g., Bott et al., 1967; Fitzsimons and Wirth, 1978). It is only when ANG II is administered in sufficiently high doses to cause pressure-induced natriuresis and hypovolemia that salt appetite is observed, and usually only after considerable delay (Fitzsimons, 1980; Findlay and Epstein, 1980). On the other hand, systemic infusions of ANG II readily elicit water drinking and sodium ingestion from animals that are water and/or sodium-deplete (Weisinger et al., 1996). This has been explicitly demonstrated in experiments using rats that were sodium- and volume-deplete following diuretic treatment (Fitts and Thunhorst, 1996) or adrenalectomy (Schoorlemmer et al., 2001). In both experiments, the typical salt appetite responses following hypovolemia were prevented by interrupting the endogenous formation of ANG II in the peripheral circulation with doses of ACE inhibitor. In both experiments, the hypovolemic animals began ingesting sodium within minutes when supplied with exogenous ANG II through iv infusion. Therefore, the ability of circulating ANG II to stimulate water and sodium ingestion is modified by extracellular volume.

Other work suggests that volume and pressure status modifies salt appetite and thirst, in response to central administration of ANG II (Thunhorst and Johnson, 2001). In a series of tests, icv infusions of ANG II were given to rats that were either normotensive or hypotensive, and to rats there were either fluid-replete or fluid-deplete. Similar to a previous report (Thunhorst and Johnson, 1993), water-drinking responses to icv infusions of ANG II were greater under hypotensive conditions than normotensive conditions, even though the intakes were accompanied by substantial urinary retention of water and sodium. Saline drinking in response to the infusion was not affected by hypotension. Likewise, saline drinking in response to icv infusions of ANG II was not affected by hypovolemia following diuresis. However, conditions that simultaneously produced hypotension and hypovolemia increased both water and saline drinking. Therefore, while reductions in arterial pressure are sufficient to increase water-drinking responses to centrally administered ANG II (Harland et al., 1988; Thunhorst et al., 1993; Thunhorst and Johnson, 1994b), reductions in both arterial blood pressure and volume are required to increase saline-drinking responses to centrally administered ANG II (Thunhorst and Johnson, 2001).

Some factors that change with the levels of extracellular fluid volume and could interact with ANG II include levels of circulating aldosterone and ANP and also neural signals from baroreceptors (Kaufman, 1984; Toth et al., 1987). Systemic mineralocorticoids potentiate the salt appetite response to centrally administered ANG II (Fluharty and Epstein, 1983), either by acting synergistically with ANG II in the brain (Fluharty and Epstein, 1983) or by suppressing secretion of OT (Stricker and Verbalis, 1990). Reductions in volume and pressure could remove residual inhibitory signals arising from baroreceptors (Toth et al., 1987) or circulating ANP that may arise when icv ANG II is infused in fluid-replete, normotensive animals.

2.4.5 The Effects of Glucocorticoids on Mineralocorticoid-Induced Salt Appetite

The hormones of stress, including glucocorticoids, participate in water and sodium homeostasis. Many situations involving stress or disease (e.g., hemorrhage, heat stress, diarrhea) are accompanied by loss of sodium from the body and increased secretion of hormones from the hypothalamus–pituitary–adrenal axis, including adrenocorticotropic hormone (ACTH). ACTH stimulates salt appetite in rabbits (Tarjan and Denton, 1991), rats (Weisinger et al., 1978), mice (Denton et al., 1999), and sheep (Weisinger et al., 1980), and water intake in mice (Blair-West et al., 1996). The hypothalamic releasing hormone for ACTH, corticotrophin releasing factor, stimulates salt appetite in rabbits (Tarjan and Denton, 1991; Tarjan et al., 1991) and mice (Denton et al., 1999) upon central, but not systemic administration (Denton et al., 1999) and thus probably acts by releasing ACTH. ACTH stimulates salt appetite when given systemically (Weisinger et al., 1978, 1980; Tarjan and Denton, 1991; Denton et al., 1999), but not centrally (Tarjan and Denton, 1991; Denton et al., 1999). A "cocktail" of adrenal hormones, including aldosterone, cortisol, and corticosterone, elicits robust salt appetite (Blaine et al., 1975; Weisinger et al., 1980). Collectively, these works suggest that the stress hormones stimulate salt appetite, and adrenal steroids, likely a combination of glucocorticoids and mineralocorticoids, ultimately mediate the salt appetite response. Animals with access to sodium solutions during ACTH treatment ingest sodium before natriuresis, and therefore not secondarily to sodium loss (Weisinger et al., 1978, 1980). However, animals without a source of sodium in addition to their food during ACTH treatment excrete sodium in excess of what they obtain from their food (Tarjan et al., 1991). The salt appetite response to stress hormones may be beneficial in preventing electrolyte imbalances.

Hypovolemic treatments that stimulate thirst and salt appetite are associated with increased levels of the glucocorticoid, corticosterone, in addition to aldosterone and ANG (Stricker et al., 1979; Rowland and Morian, 1999). Pharmacological doses of glucocorticoids increase water-drinking and pressor responses induced by ANG II (Ganesan and Sumners, 1989; Sumners et al., 1991; Scheuer and Bechtold, 2001) and both water drinking and sodium ingestion in mineralocorticoid-treated animals (Wolf, 1965; Ma et al., 1993; Zhang et al., 1993; Fluharty and Sakai, 1995; Shelat et al., 1999a, b; Fluharty, 2002). It is postulated that the powerful influences of glucocorticoids on responses to mineralocorticoids reflects synergy between these classes of steroid hormones at the cellular level (Fluharty and Sakai, 1995; Daniels and Fluharty, 2004). Thus, new versions of the *synergy hypothesis* include prominent roles for glucocorticoids and their receptors (Fluharty and Sakai, 1995; Fluharty, 2002). In the brain, glucocorticoids increase ANG II receptor binding and amplify ANG II-related intracellular signaling processes (Sumners et al., 1991; Shelat et al., 1998, 1999a, b; Fluharty, 2002; Daniels and Fluharty, 2004) and also increase Type 1 mineralocorticoid receptor binding (Fluharty and Sakai, 1995).

Glucocorticoids have powerful effects on urinary excretion that offer another mechanism for their effects on thirst and salt appetite. Basal levels of glucocorticoids are required for normal renal function (Ganong, 2005). Glucocorticoids at physiological and pharmacological levels increase glomerular filtration rate in animals and humans (Baylis et al., 1990), and they increase urine volume (Okuno et al., 1981; Suzuki et al., 1982; Yoshida et al., 1988; Baylis et al., 1990), urinary sodium excretion (Okuno et al., 1981; Suzuki et al., 1982; Yoshida et al., 1988; Baylis et al., 1990), and potassium excretion (Baylis et al., 1990). Forty years ago, Wolf (1965) speculated that glucocorticoids, namely corticosterone, potentiate sodium ingestion during mineralocorticoid treatment by stimulating glomerular filtration rate and essentially

countering the sodium retaining effects of mineralocorticoids. By facilitating the excretion of sodium, corticosterone could allow sodium to be ingested at a higher rate (Wolf, 1965).

3 Central Nervous System (CNS) Integration of Signals for Thirst and Salt Appetite

3.1 Primary Brain Structures and Systems Implicated in Thirst and Salt Appetite

A variety of physiological and neuroanatomical mapping techniques, such as ablation, electrical stimulation, metabolic activation (e.g., 2-deoxyglucose), and expression of immediate early genes (e.g., c-*fos*) has established a collection of brain structures that form a neural network that integrates information related to body fluid balance. Some structures and pathways are particularly important. Processing of visceral information within this network or *visceral neuraxis* is broadly distributed and provides redundancy so that insult to one part may not be catastrophic. This network may exhibit plasticity. For example, the central resetting of baroreceptor reflexes is well known. Likewise, the chronically enhanced sodium preference and salt appetite that result from a single episode of sodium deficiency (Falk, 1966; Sakai et al., 1987) probably involve some form of neural plasticity. Several forebrain structures, including those of the lamina terminalis and the amygdala, have demonstrated roles in facilitating thirst and sodium appetite. A hindbrain system including the AP, the NTS, and the parabrachial nucleus (Shapiro and Miselis, 1985; Cunningham Jr. et al., 1994) appears to inhibit these behavioral responses (Johnson and Edwards, 1990; Johnson and Thunhorst, 1997).

3.1.1 Forebrain

3.1.1.1 Lamina Terminalis During embryonic development, the rostral end of the neural tube closes to form the lamina terminalis. In mature vertebrates, this tissue becomes the anterior wall of the third cerebral ventricle which is associated with and houses three midline nuclei—the SFO, the MePO, and the OVLT. The SFO and OVLT, respectively, are situated dorsally and ventrally along the lamina terminalis and the MePO resides between the two. Morphological studies led to speculation that the SFO is somehow involved in sodium and water homeostasis (Diereckx, 1963; Palkovits, 1966). Simpson and Routtenberg (1973) subsequently showed that the SFO is one site in the brain that is responsible for the dipsogenic action of ANG II. They demonstrated that very low doses of ANG II injected into the SFO of rats caused drinking. Furthermore, lesions of the SFO eliminate drinking to iv administration of ANG II in rat (Simpson et al., 1978), dog (Thrasher et al., 1982a, b), and quail (Takei, 1977) but not in the sheep (McKinley et al., 1986).

The ventral area of the lamina terminalis is also important for the dipsogenic response to ANG II. Ablation of tissue surrounding the anteroventral portion of the third (cerebral) ventricle (AV3V) abolishes drinking to both systemically and centrally administered ANG II (Buggy and Johnson, 1977, 1978; Johnson and Buggy, 1978, 1997). This ablation, termed the AV3V lesion, destroys the OVLT, the ventral part of the MePO, the periventricular preoptic nuclei, and the periventricular nuclei of the anterior hypothalamus. The AV3V lesion produces a host of deficits in responding to body fluid challenges (*Table 17-1*). The totality of these effects is not localizable to a single structure within the area but is obtained only from the destruction of the whole AV3V region. Reflex and behavioral responses to humoral factors, including ANG II and increased plasma osmolality are greatly affected by AV3V lesions. Animals with AV3V lesions will evidence some drinking to a hypovolemic challenge as long as it is sustained and there is still presumably significant input from vascular baroreceptors (Buggy and Johnson, 1977). However, the drinking to hypovolemia is impaired (Lind and Johnson, 1983), probably from failure to respond to the ANG II component (Johnson et al., 1981). Selective lesions of the OVLT attenuate drinking to infusions of ANG II and to increased osmolality (Thrasher and Keil, 1987). Several reviews of the numerous aspects of the effects of AV3V lesions on body fluid and cardiovascular regulation are available (Brody and Johnson, 1980; Johnson, 1985a, b; Johnson and Edwards, 1990; Johnson et al., 1996; Johnson and Thunhorst, 1997).

In elegant studies using systemic and icv administration of osmotic solutions, two groups of investigators, McKinley and colleagues (1978) in sheep and Thrasher and coworkers (1980) in dog, made a strong case that cephalic osmoreceptors are probably located in CVOs. Further *in vivo* studies employing tissue ablation and site-specific administration of hypertonic solutions provide evidence that the structures of the lamina terminalis contain osmo- or sodium receptors responsible for drinking, antidiuretic responses, and pressor responses to hypertonic stimuli (Buggy and Johnson, 1977; Johnson and Buggy, 1978; Johnson et al., 1978; Buggy et al., 1979; Hosutt et al., 1981; Lind et al., 1984) and *in vitro* methods have lent additional support (Bourque et al., 1994). Individual or combined lesion studies of the nuclear groups of the lamina terminalis show that all parts contribute to drinking and VP secretion in response to osmotic stimuli (McKinley et al., 1982). However, ablation of nearly the entire lamina terminalis is required to abolish these responses (McKinley et al., 1999).

The participation of the SFO and the AV3V region in salt appetite is logical based on their known roles in mediating the effects of ANG II (for a fuller account see Johnson and Thunhorst, 1997). The relative importance of the SFO for salt appetite depends on the strength of the response, and duration over which the response is produced and measured. Ablation of the SFO almost completely eliminates salt appetite that is rapidly developing and measured over a few hours after sodium depletion (Thunhorst et al., 1999) or iv infusion of ANG II (Morris et al., 2002) and reduces by half the salt appetite response produced by 24 h of sodium depletion (Thunhorst et al., 1990; Weisinger et al., 1990). On the other hand, SFO ablation or interruption of its major efferent pathway to the rest of the brain does not attenuate total saline consumption over an extended 48-h period following sodium depletion (Schulkin et al., 1983) or the robust salt appetite of adrenalectomy (Wilson et al., 2002). Longer testing periods may allow for compensatory or redundant mechanisms to contribute to the salt appetite response in animals lacking an SFO. Lesions of the SFO prevent the permanent elevation in daily saline intakes that are sometimes observed after episodes of sodium depletion (Ruhf et al., 2001).

Lesions of the AV3V region also diminish depletion-induced salt appetite (De Luca Jr. et al., 1992). Lesions that encompass the OVLT and the adjacent third of the ventral MePO reduce sodium ingestion in response to renin-dependent forms of salt appetite but increase sodium intake elicited by DOCA (Fitts et al., 1990; Fitts, 1991). Selective ablations of the OVLT reduce the salt intake by one-half after sodium depletion (Chiaraviglio and Perez Guaita, 1984) and iv infusion of ANG II (Morris et al., 2002). In heroic work, it was found that simultaneous lesions of the SFO and OVLT more effectively reduce salt appetite in response to sodium depletion than either lesion alone (Fitts et al., 2004). Taken together, the functional studies illustrate the redundancy and complex unity of function (Johnson and Wilkin, 1987; Lind, 1988; Johnson, 1990) among neural groups along the lamina terminalis.

Discrete injections or infusions of ANG II into the OVLT and adjacent MePO stimulate ingestion of both water and saline (Fitts and Masson, 1990). However, injections of ANG II into the SFO produce water drinking (Simpson and Routtenberg, 1973; Simpson et al., 1978) but do not usually support saline drinking (Fitts and Masson, 1990; Colombari et al., 1996). It is suggested that ANG II may act at the SFO to engage mechanisms that inhibit salt appetite, for example OT secretion (Ferguson and Renaud, 1986; Ferguson and Kasting, 1987; Stricker et al., 1987, 1994; Ferguson and Kasting, 1988; Stricker and Verbalis, 1990; Bartanusz and Jezova, 1994). In light of this, it is interesting that injections of ANG II into the SFO cause substantial saline drinking provided that the postulated inhibitory system of the LPBN is first blocked by the administration of 5-HT antagonist (Colombari et al., 1996; see *Section 3.1.2.2*).

3.1.1.2 Amygdala Subdivisions of the amygdala are implicated in salt appetite (Johnson et al., 1999). Ablation of the basolateral amygdala diminishes salt appetite induced by DOCA treatment (Nachman and Ashe, 1974). Ablation of the medial region of the amygdala diminishes salt appetite produced by the administration of mineralocorticoids but not by sodium depletion (Nitabach et al., 1989; Zhang et al., 1993). This selective impairment is not from disrupting pathways to the ventral forebrain through the stria terminalis (Black et al., 1992). Although lesions of the medial amygdala do not affect renin-dependent salt appetite, injections of tachykinins into the medial amygdala inhibit renin-dependent forms of salt appetite (Massi et al., 1990). Ablation of the central nucleus of the amygdala (CeA) greatly diminishes the salt appetite response to DOCA, sodium depletion, s.c. administration of yohimbine and icv ANG II, and

abolishes ad libitum sodium intake (Galaverna et al., 1992; Zardetto-Smith et al., 1994). The general lack of salt intake by rats with lesions of the CeA may not result from disordered gustatory function (Galaverna et al., 1993). Rats with CeA lesions appropriately discriminate between different tastes based on their internal states, yet do not consume sodium (Seeley et al., 1993). However, it is also reported that lesions of the CeA increase the aversive value of taste stimuli (Touzani et al., 1997).

The amygdala and bed nucleus of the stria terminalis are anatomically related structures that are likely to have similar functions (Johnston, 1923; Alheid et al., 1985; de Olmos et al., 1985; Price et al., 1987). They are reciprocally connected with several nuclei involved in cardiovascular control and fluid balance (Sofroniew, 1983; Holstege et al., 1985; Moga et al., 1989). Electrolytic ablation of either of them significantly reduces sodium intake following systemic administration of yohimbine or sodium depletion (Zardetto-Smith et al., 1993; Johnson et al., 1999). However such lesions do not affect water intake to s.c. ANG II or to s.c. hypertonic saline, indicating specificity of the lesion for salt appetite.

3.1.2 Hindbrain

The hindbrain has been studied for its role in reflex control of the circulation and fluid balance at least since Claude Bernard noted that puncturing the floor of the fourth cerebral ventricle increases urinary excretion (Cushny, 1926). The role of this region in the behavioral control of fluid balance has been studied for only about 30 years.

3.1.2.1 The Area Postrema (AP) and Nucleus of the Solitary Tract (NTS) The AP is found in the fourth ventricle at the caudal aspect of the rhomboid fossa. It was the first CVO shown to be a central target for circulating ANG II (Joy and Lowe, 1970; Ferrario et al., 1972; Ueda et al., 1972) in its capacity to reduce the gain of cardiovascular baroreceptor reflexes in response to ANG II. The AP is small and difficult to manipulate. Most functional studies of the AP involve ablation, and the lesions typically encroach on adjacent NTS tissue or otherwise cause degeneration of NTS neuropil because of the rich neural interconnectivity. Thus, AP lesions are sometimes denoted as AP/mNTS lesions. Contreras and Stetson (1981) first demonstrated effects of AP lesions on water and sodium ingestion. They described increased ad libitum consumption of NaCl solutions over a range of concentrations. These intakes can be phenomenal. AP/mNTS ablated rats in sodium balance consume the equivalent of 25% of their extracellular sodium in only 3 h after first being given access to hypertonic saline (Edwards et al., 1993). The increased sodium intake may be secondary to increased sodium excretion observed after AP ablation (Hyde and Miselis, 1984), but AP lesions sometimes have minimal effects on sodium excretion (Contreras and Stetson, 1981; Watson, 1985).

Lesions of AP/mNTS also produce a general increase in water intake in response to extracellular dehydration and isoproterenol compared with intact controls (Edwards and Ritter, 1982), but they do not increase water intake in response to intracellular dehydration (Edwards and Ritter, 1982) or to centrally administered carbachol (Ohman and Johnson, 1989). Therefore, the AP/mNTS may be a part of a neural system that inhibits water and sodium ingestion and may be more important in regulating extracellular than intracellular volume.

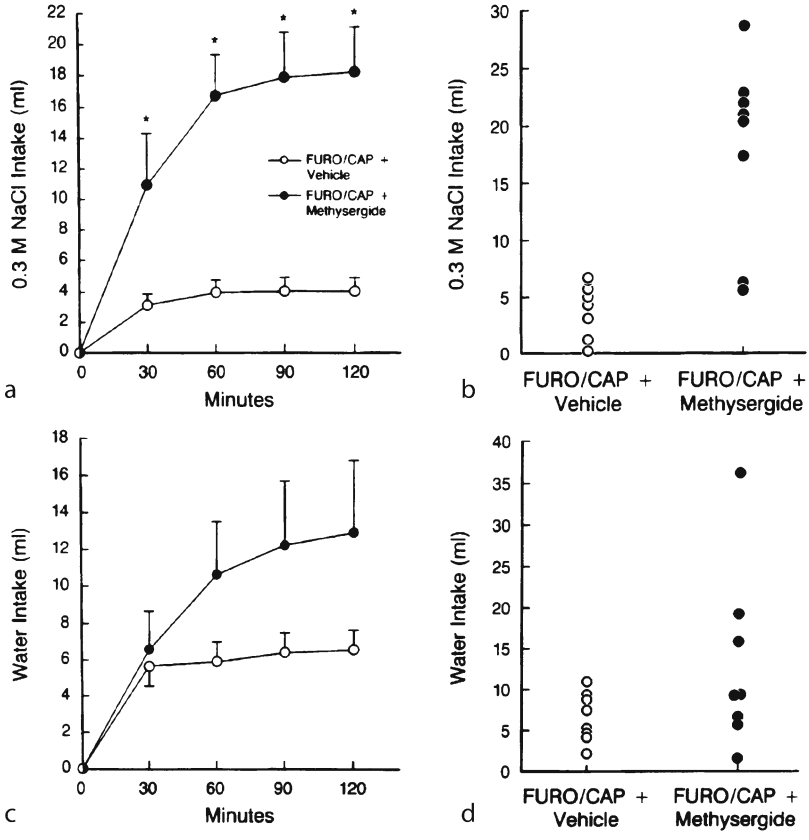
3.1.2.2 Parabrachial Nucleus The NTS and AP both send projections to the LPBN (Loewy and Burton, 1978; Norgren, 1978; Ricardo and Koh, 1978; van der Kooy and Koda, 1983; Shapiro and Miselis, 1985; Cunningham Jr. et al., 1994) including a substantial ascending serotonergic pathway from the AP (Lança and van der Kooy, 1985). In turn, the LPBN sends projections to forebrain areas involved in fluid balance such as the PVN, the CeA, and MePO (Ciriello et al., 1984; Fulwiler and Saper, 1984; Jhamandas et al., 1992; Krukoff et al., 1993; Jhamandas et al., 1996). Initially, it was thought that lesions of the LPBN would diminish thirst by interrupting ascending vascular baroreceptor information from the NTS. However, such electrolytic or chemical lesions had the opposite effect and greatly increased water drinking in response to extracellular fluid challenges (Ohman and Johnson, 1986, 1989; Edwards and Johnson, 1991; Menani et al., 1995) but not to intracellular-related fluid challenges (Ohman and Johnson, 1986, 1989; Edwards and Johnson, 1991). These results are similar to those observed after lesions of the AP and suggest that the LPBN and AP/mNTS comprise a hindbrain system that functions to limit extracellular volume expansion

(Johnson and Edwards, 1990, 1991; Johnson and Thunhorst, 1997). Support for this idea is the finding that right atrial stretch no longer inhibits some forms of extracellular thirst after lesions of the LPBN (Ohman and Johnson, 1995). In contrast to their similar effects on thirst, lesions of the LPBN and AP/mNTS have different effects on salt appetite. As noted, AP/mNTS lesions increase salt appetite under ad libitum conditions and in response to experimental challenges (Contreras and Stetson, 1981; Kosten et al., 1983; Hyde and Miselis, 1984; Watson, 1985; Edwards et al., 1993); however, LPBN lesions do not (unpublished observations).

Pharmacological manipulations of serotonergic receptors located within the LPBN have profound effects on both thirst and salt appetite. Discrete injections of 5-HT or certain selective 5-HT agonists into the LPBN suppress water intake whereas similar injections of the nonselective 5-HT receptor antagonist methysergide greatly increase water intake (Menani and Johnson, 1995). In addition, injections of 5-HT antagonist into the LPBN produce some of the largest intakes of hypertonic saline solution yet observed (Colombari et al., 1996; Menani et al., 1996, 1998b; *Figure 17-5*). This is not a nonspecific increase in behavior as NaCl intake increases preferentially to water when both are available for drinking (Menani et al., 1998a, b, 2000, 2002, 2004). In addition, ingestion of palatable sucrose solutions is not affected by similar

Figure 17-5

(a) Cumulative 0.3M NaCl intakes, (b) Individual 0.3 M NaCl intakes, (c) Cumulative water intakes, (d) Individual water intakes induced by subcutaneous furosemide (FURO; 10 mg/kg) + captopril (CAP; 5/mg/kg) after previous bilateral injections of vehicle or methysergide (4 μg/200 ml) into the lateral parabrachial nucleus (LPBN). (a, c) Values are means ± SE. *Significantly different from vehicle pretreatment tested by *t*-tests ($p < 0.05$). $n = 8$ rats. From Menani et al. (1996)



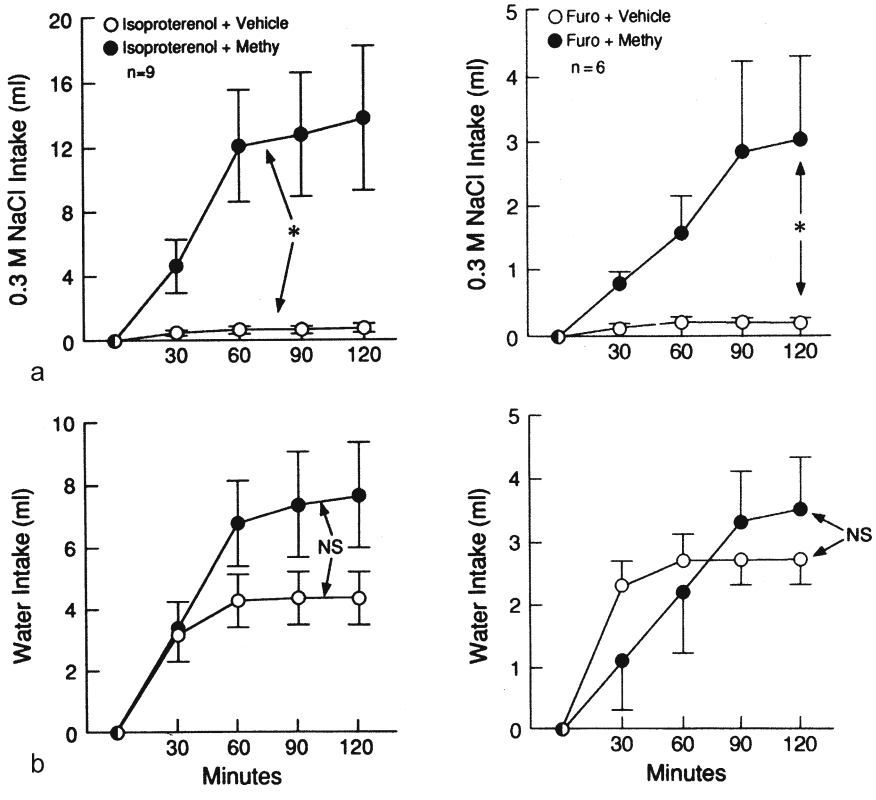
treatment (Menani et al., 1998b). The serotonergic innervation of the LPBN thus appears to limit both thirst and salt appetite responses.

Antagonism of 5-HT receptors in the LPBN increases salt intake under most conditions. It increases salt appetite in both renin-dependent and non renin-dependent models (Menani et al., 1998a, b; De Gobbi et al., 2000), and it greatly exaggerates salt appetite in response to stimuli known to produce salt intake (e.g., sodium depletion; hypovolemia; ANG II; DOCA; Menani and Johnson, 1995; Menani et al., 1998a, b; De Gobbi et al., 2000). 5-HT receptor antagonism initiates salt appetite under conditions when salt appetite is not normally found (i.e., in the first few hours after diuretic treatment; after injections of ANG II into the SFO; Colombari et al., 1996; Menani et al., 2000; *Figure 17-6*). Finally, it increases salt appetite in response to stimuli that normally inhibit salt appetite (i.e., icv carbachol and relaxin; intragastric loads of hypertonic saline; after s.c. isoproterenol treatment; Menani et al., 2000, 2002, 2004; De Luca Jr. et al., 2003). Yet, there is no effect of 5-HT blockade of the LPBN on the unstimulated animal (i.e., without some dipsogenic or natriorexigenic stimulus also present).

Injections of a 5-$HT_{2A/2C}$ receptor agonist, 2,5-dimethoxy-4-iodoamphetamine bromide (DOI), into the LPBN reduce saline and water intake after sodium depletion (Menani et al., 1996). In contrast,

Figure 17-6

The induction of salt appetite by lateral parabrachial nuclei (LPBN) injections of the nonselective 5-HT receptor antagonist, methysergide (Methy) in rats pretreated with dipsogenic stimuli (either the β-adrenoreceptor agonist, isoproterenol = left-hand panels or the diuretic, furosemide = right-hand panels) that generate virtually no hypertonic saline intake when administered by themselves. The panels show cumulative intakes of 0.3 M NaCl or water after the respective systemic dipsogenic treatments followed by either LPBN vehicle or LPBN Methy treatments. Methy treatments significantly increased the intake of 0.3 M NaCl (*$p < 0.05$), but not of water. (NS = nonsignificant; $p > 0.05$). From Menani et al. (2000)



LPBN injections of the 5-HT_{1A} receptor agonist, 8-hydroxy-2-(di-*n*-propylamine) tetralin (8-OH-DPAT) enhanced saline and water intake of sodium-deficient rats (De Gobbi et al., 2005).

Evidence from functional neuroanatomical studies combining immunocytochemistry for FOS with immunocytochemistry for 5-HT (Franchini et al., 2002) indicate that serotonergic neurons in the rostral portions of the dorsal and medial raphe groups are active when rats are in a sodium-replete state. Activity in these cells is reduced in sodium deficient rats and returns as depleted animals restore their sodium deficit. In contrast, 5-HT neurons in the AP show no response to sodium depletion but increase their activity upon ingesting sodium. Taken together, these results seem to indicate that neurons in the caudal 5-HT cell group (i.e., AP region) are phasically activated to acutely inhibit excess salt appetite, whereas cells in the anterior groups exert a tonic inhibitory influence on this ingestive behavior.

Other neurotransmitters/neuromodulators that act within the LPBN and also affect thirst and salt appetite include cholecystokinin (Menani and Johnson, 1998; De Gobbi et al., 2001), α_2-adrenergic receptor agonist (Andrade et al., 2004), GABA (Callera et al., 2005) and corticotrophin-releasing hormone (De Castro e Silva et al., 2006). Injections of cholecystokinin into the LPBN inhibit thirst and salt appetite responses to ANG II and hypovolemia (Menani and Johnson, 1998), whereas the antagonists increase these behaviors. It is interesting that the activation of α_2-adrenergic receptors in the LPBN increases water and NaCl intake after hypovolemic treatment (Andrade et al., 2004) because similar activation of α_2-adrenergic receptors in the forebrain inhibits water and sodium intake (Fregly et al., 1981; Menani et al., 1999). Stimulation of $GABA_A$ receptors in the LPBN produces a robust salt appetite response in unstimulated, euvolemic animals (i.e., in animals not otherwise hydrationally challenged; Callera et al., 2005).

Other novel findings are that the antagonism of 5-HT receptors in the LPBN causes salt appetite in response to ANG II administered into the SFO (Colombari et al., 1996), which normally produces only water intake. In addition, antagonism of AT_1 receptors in the SFO prevents the increased, or additional, salt appetite response caused by antagonism of 5-HT receptors in the LPBN during renin-dependent models of salt appetite (Menani et al., 1998a).

Taken together, results from studying the actions of several classes of neurally active agents in the LPBN indicate that many neurotransmitter systems exert an inhibitory action in this pontine structure to keep excessive sodium intake in check. Under basal conditions sodium appetite is inhibited through activity in the LPBN (probably GABAergic). When animals are predisposed to consume water or saline solutions, the amounts are modulated by actions of neurotransmitter release into the LPBN. Removal of these inhibitory actions is tantamount to fixing the switch for sodium intake to the "on" position. Understanding the mechanisms of what leads to excessive activation of sodium appetite promises to be important for gaining insight into why humans consume excess dietary sodium chloride, a predilection that has significant negative health-related consequences (MacGregor and de Wardener, 1998).

4 Major Brain Neurotransmitter/Neuromodulator Systems

Several brain neurohumoral and neurochemical systems have been implicated as major factors in the control of thirst and salt appetite. These systems often exert their actions at many sites throughout the neuraxis. As a generalization, most of these can be classified as either facilitory or inhibitory to thirst or sodium intake. In this section, several key, centrally acting agents that have been identified in the control of hydromineral intake will be categorized and discussed based on their capacity to promote or retard the intake of water or sodium solutions.

4.1 Facilitory Mechanisms

4.1.1 Brain Renin-Angiotensin System (RAS)

Shortly after Fitzsimons (1969b) implicated the renal (or systemic) RAS in thirst, he along with his coworkers (Epstein et al., 1970) demonstrated that ANG II in doses on the order of 5 to 4000 pmoles

produced avid drinking when injected into several limbic (e.g., septal area) and basal forebrain (e.g., preoptic and anterior hypothalamic nuclei) tissue sites. At the time of its publication, the Epstein and group (1970) study seemed somewhat problematic or paradoxical because the physiological source of ANG II that acted on the brain was believed to be from the systemic circulation. It was difficult to conceive that the peptide ANG II, which has a molecular weight of slightly more than 1000 Daltons, could pass the blood–brain barrier to act at central sites such as the preoptic area.

Subsequently, it was discovered that few, if any, of the initially implicated tissue sites were in fact sensitive to ANG II (Johnson and Epstein, 1975). Most of the injections in the initial studies (Epstein et al., 1970) probably leaked or diffused into the cerebral ventricles (Johnson and Epstein, 1975). Actually, the forebrain sites most responsive to ANG II are located in structures surrounding the brain ventricular system and include areas that lie both inside and outside of the blood–brain barrier. Simpson and colleagues (Simpson and Routtenberg, 1973; Simpson et al., 1978) implicated the SFO in ANG-induced drinking in the rat. In addition to the SFO, the OVLT may sense ANG II and contribute to drinking in dog and sheep (Thrasher et al., 1982a, b; McKinley et al., 1986). The MePO is ANG sensitive and located within the blood–brain barrier. It is not accessed by circulating ANG, but this structure can be readily reached by CSF-borne peptide (Johnson and Epstein, 1975).

At the time of increasing functional evidence for the central actions of ANG II (e.g., Epstein et al., 1970; Ferrario et al., 1972), two groups (Fischer-Ferraro et al., 1971; Ganten et al., 1971a, b) provided evidence that the components of the RAS were located in the brain. This gave rise to the concept of tissue RASs in which it was proposed that the agents found in this biochemical cascade were generated within specific structures, such as brain (Ganten et al., 1971a, b). Although this concept was initially received with skepticism from some investigators, the body of biochemical evidence generated over the past 35 years argues strongly for a brain RAS. Although the systemic RAS and the brain RAS may be biochemically independent, it has been proposed that the two systems are functionally coupled (Johnson, 1985a, b; Johnson and Wilkin, 1987). For example, in the case of thirst it has been hypothesized that in the state of hypovolemia circulating ANG II acts on the SFO in the mode of a hormone which in turn leads to the activation of angiotensinergic neurons that project from the SFO into areas like the MePO where synaptically released ANG II acts like a neurotransmitter (Johnson, 1985a, b; Johnson and Wilkin, 1987).

In comparison to the systemic RAS, the physiology and biochemistry of the brain RAS has proved to be a formidable scientific challenge. For the systemic RAS, the cellular and organ sources of renin, AGT, and ACE are distinct and spatially widely separated. In the brain, multiple cell types (glia vs. neurons) lie in close proximity with one another and may generate the same RAS constituent. For example, there has been a major discord regarding the cellular localization of AGT. Although there is reasonable agreement among laboratories as to the structures where AGT mRNA and protein are present, there is major disagreement as to whether it is produced only in astrocytes or also in neurons and whether different pools have different functions. These factors make the study of regulation and physiology of the brain RAS extremely complex. Recently, knockout and transgenic rodent models have provided a means to begin to dissect the complexities of the brain RAS. Such physiological genomic approaches to studying the brain RAS have often included measures of ad libitum and induced salt and water intake in their characterization of the role of this system in body fluid and cardiovascular regulation.

Early transgenic RAS models developed in mouse (Davisson et al., 1998) and rat (Mullins et al., 1990) introduced genes from other species (human AGT and human renin into mouse[2]; mouse Ren-2 into rat). Such rats and mice show increased activity of RASs at various tissue sites, including brain. The transgenic animals also have increased circulating ANG II and are hypertensive. Functional studies indicate that a central action of ANG II makes a major contribution to the elevated blood pressure of the double transgenic mice (Davisson et al., 1998). Transgenic rats with an additional Ren-2 mouse gene show increased ad libitum food and water intake, but no change in the food to water ratio (Szczepanska-Sadowska et al., 2003).

---

[2] There is a unique species specificity of renin-AGT interaction. Human renin does not cleave mouse AGT and vice versa. To enhance the formation of ANG, it is necessary to cross a mouse carrying the human renin gene with a mouse carrying the human AGT gene (i.e., produce a double transgenic model).

Recently, more informative transgenic models have been developed using techniques to affect specific brain cell types for overexpression of components of the RAS. This has been achieved by generating transgenic mice with either glia- or neuronal-targeted human renin or human AGT (Morimoto et al., 2001, 2002). The synapsin-1 promoter was used to drive human renin (Morimoto et al., 2002) and human AGT in neurons and the glial fibrillary acidic protein (Morimoto et al., 2001) drives the expression of human renin and AGT in astrocytes. In these models, expression of the human transgenes is restricted to the predicted brain cell types with minimal systemic expression. Cross-breeding various combinations of these models so that ANG was likely to be generated resulted in at best only modest increases in arterial blood pressure (Morimoto et al., 2001, 2002). However, several of the crosses resulted in increased saline intake (Morimoto et al., 2001, 2002).

Genetically manipulated mouse models are also being used to address the role of the ANG receptor subtypes in thirst and fluid homeostasis. Rodents have three ANG receptor subtypes, specifically AT_{1a}, $AT_{1b,}$ and AT_2. Knockout models implicate all three in thirst. Using AT_{1a} null mice and AT_{1b} null mice, Davisson and colleagues (2000) found the pressor response to centrally injected ANG II to be dependent on AT_{1a} receptors, but the drinking response to be mediated by AT_{1b} receptors. Li and group (2003) on the other hand found evidence for AT_2 and AT_{1b} receptors in mediating ANG-induced drinking in their mice knockout models. The AT_2 null mouse has an impaired drinking response to water deprivation (Hein et al., 1995). It is not clear why different groups reach different conclusions about the roles of the ANG receptor subtypes in thirst. Li and group (2003) have suggested that different methods for assessing drinking may contribute to the discrepancies. Another variable not considered by investigators is the effect of manipulating receptors that simultaneously affect drinking and blood pressure since blood pressure interacts with the drinking response (see *Section 2.4.3*). Careful behavioral analysis and the control of blood pressure as a variable will be needed to clarify many of these issues.

Recently developed molecular techniques for the analysis of ANG actions in the brain have also been applied to the analysis of intracellular second messenger signaling. In studies from Davisson's laboratory (Zimmerman et al., 2002), a novel ANG II signaling mechanism in brain has been demonstrated to involve reactive oxygen species. In these studies, mice were injected icv with an adenoviral-vector encoding human mitochondrial superoxide dismutase (AdMnSOD) or control vectors. Evidence of human mitochondrial superoxide dismutase was observed in periventricular tissue of the AdMnSOD animals a few days after treatment. When challenged with central injections of ANG II, the AdMnSOD-treated mice showed attenuated pressor and heart rate responses. In addition, central ANG II-induced drinking was significantly attenuated in the AdMnSOD mice.

4.1.2 Acetylcholine

Probably the first reported neurotransmitter to be injected into the brain and induce copious water intake was acetylcholine. The classic studies by Grossman (1960, 1962) demonstrated that acetylcholine or the cholinergic receptor agonist, carbachol, applied in the lateral hypothalamus produced water intake in rats. The phenomena were specific in that the cholinergic stimulation did not produce food intake, but norepinephrine (NE) delivered at the same site did induce feeding. Further characterization of this form of chemically induced drinking indicated that the intake is a result of action on muscarinic receptors (Stein and Seifter, 1962). Studies by Fisher and Coury (1962) demonstrated that crystalline carbachol applied to several sites throughout the forebrain generated drinking. These researchers (Fisher and Coury, 1962) proposed a cholinergic thirst circuit distributed throughout the limbic system. There is some evidence to suggest that cholinergic thirst in the rat mediates cellular dehydration-induced drinking as opposed to extracellular thirst (Fisher, 1973). Interestingly, central administration of carbachol strongly inhibits experimentally induced salt appetite (Fitts et al., 1985b).

In spite of the remarkable water intake induced in rats by cholinergic stimulation, and its specificity, little additional insight into the physiological significance of cholinergic thirst has been gained over the past 40 plus years. Unlike thirst in response to centrally applied ANG II which has been demonstrated in a wide number of vertebrate species (see Schwob and Johnson, 1977 for a summary of species), a reliable vigorous

drinking response induced by muscarinic agonists is limited mainly to the rat (Note: there is a small variable response in dog; Ramsay and Reid, 1975). Specification of the central site(s) of action of the cholinergic agonists that induce drinking remains problematic. The speculation that crystalline carbachol when applied to limbic tissue sites may leak into the brain ventricles and act at the SFO (Routtenberg and Simpson, 1971) has not been fully addressed. While being a sensitive site for cholinergic actions, the SFO does not appear to be necessary for the cholinergic drinking response. Ablation of the structure (Buggy and Fisher, 1976) or cutting its major efferent pathway (Masson and Fitts, 1989) has no effect on cholinergic-induced drinking.

4.1.3 Norepinephrine (NE)

Among the widely distributed neurotransmitter systems in the brain are the biogenic amines, NE, 5-HT, and dopamine. These systems consist of a relatively few cell bodies located in discrete clusters throughout the brain stem and have axons, which diverge to innervate nearly all portions of the brain. Numerous early studies with neurotoxins indicate that wholesale depletion of brain dopamine and NE renders rats adipsic and aphagic. Many of these effects on ingestive behaviors are nonspecific and are a result of the destruction of ascending nigrostriatal dopamine projections.

Using discrete methods to administer the neurotoxin 6-hydroxydopamine (McRae-Degueurce et al., 1986; Bellin et al., 1987a, b, 1988; Cunningham and Johnson, 1989), it has been possible to demonstrate that integrity of the NE innervation of the AV3V is necessary for normal dipsogenic responses to ANG II. Such a NE terminal region is not necessary for drinking induced by carbachol or by hypertonic saline. Replacing locally depleted NE with exogenous icv infusions or transplantation of neonatal NE synthesizing cell bodies into the AV3V (McRae-Degueurce et al., 1986; Cunningham and Johnson, 1989) restores drinking in impaired rats.

The AV3V region receives ascending NE innervation from the A1/C1 region of the ventrolateral medulla and the A2/C2 region of the dorsomedial medulla (Saper et al., 1983). NE pathways are activated by various stressors including hypovolemic/hypotensive challenges. Turnover of NE in the region of the MePO is increased by hypovolemic treatment that would normally induce drinking (Wilkin et al., 1987). More recently, Miyakubo and colleagues (2003) used microdialysis to show that hypovolemic rats have increased extracellular NE in the MePO before they drink. The elevated NE then decreases as drinking proceeds. Taken together, such data have been used to hypothesize that circulating ANG II acts on the SFO to activate a descending angiotensinergic pathway to the MePO, where the peptide interacts with extracellular NE released from ascending pathways carrying input from systemic baroreceptors (see Johnson and Wilkin, 1987; Johnson and Thunhorst, 1997 for review and references).

4.2 Inhibitory Mechanisms

4.2.1 Vasopressin (VP) and Oxytocin (OT)

The two long recognized and extensively studied hormones of the posterior pituitary are VP and OT. Each of these peptides is synthesized in their own unique type of magnocellular neuron in the PVN and SON and is transported to the posterior pituitary for release into the systemic circulation. Classically, VP was recognized for its antidiuretic action and as a pressor agent. OT was also noted for its effects on contractile tissues and implicated in uterine contraction and milk ejection. In addition to the hypothalamo-neurohypophyseal systems for VP and OT, there are multiple groups of VP and OT cell bodies and dispersed projections throughout the brain (Buijs, 1978).

In light of the classic functional roles of VP and OT, it seems highly plausible that VP in particular should be implicated in behaviors related to fluid balance. There is evidence in the dog that centrally administered VP induces drinking (Szczepanska-Sadowska et al., 1982). Although numerous investigators have injected VP centrally in rats in anticipation of effects on drinking, the most common behavior

observed is rotation of the body around its longitudinal axis (barrel rotations). Such a dramatic motor response greatly complicates the study of ingestive behaviors. Recent work using another approach employing central administration of OT and VP receptor antagonists suggests that VP in intrinsic brain pathways may play a facilitory role in saline intake in response to sodium depletion (Flynn et al., 2002). In light of the VP-induced motor complications, new strategies will be required to fully explore the role of VP in thirst and salt appetite.

In comparison to VP there is a much larger body of evidence implicating OT in the behavioral control of fluid balance, particularly in the central inhibition of salt appetite. Initial observations that rats maintained on a sodium deficient diet have blunted OT secretion in response to hypovolemia suggested a role of this peptide in fluid homeostasis (Stricker et al., 1987, 1994). Because systemic administration of OT has no apparent inhibitory effect on salt or water intake, (Stricker and Verbalis, 1987) attention has been directed toward central OT actions and pathways. In this light, circulating OT might serve as an index of the activity in central OT pathways. Several findings support the idea that central OT mechanisms act to limit salt intake. For example, treatments (e.g., hyperosmolality, naloxone, nausea) that stimulate OT secretion are associated with reduced salt appetite produced by hypovolemia. In addition, treatments suppressing OT release (e.g., sodium deprivation, alcohol intake) increase sodium intake (Stricker and Verbalis, 1987; Stricker et al., 1987; Blackburn et al., 1992a, b, 1994). Salt appetite induced by centrally administered ANG II is enhanced by central application of an OT receptor antagonist or after destruction of central OT neurons with a selective neurotoxin (Blackburn et al., 1992a, b, 1995). It is especially noteworthy that the concept of having an OT brake on salt intake is appealing from the standpoint of biological consistency in that OT also induces natriuresis at physiological levels in the rat (Verbalis et al., 1991).

4.2.2 Tachykinins

The neuropeptides of the tachykinin family are coded by two different genes. The preprotachykinin A gene encodes substance P, neurokinin A, neuropeptide γ, and neurokinin K; the preprotachykinin B gene codes for neurokinin B (Krause et al., 1987; MacDonald et al., 1988). Tachykinin NK1, NK2, and NK3 receptor subtypes preferentially bind substance P, NKA, and NKB, respectively (Maggi et al., 1987). Icv injections of NK3 receptor antagonists suppress both ad libitum and induced salt appetite (Massi et al., 1988a, b; Smith and Flynn, 1994). When animals are in a state of sodium deficiency, gene expression for NKB is reduced relative to the sodium-replete condition (Pompei et al., 1997). Taken together, there is a substantial body of data emerging to indicate that central NKB exerts an inhibitory effect on salt intake.

5 Summary and Conclusions

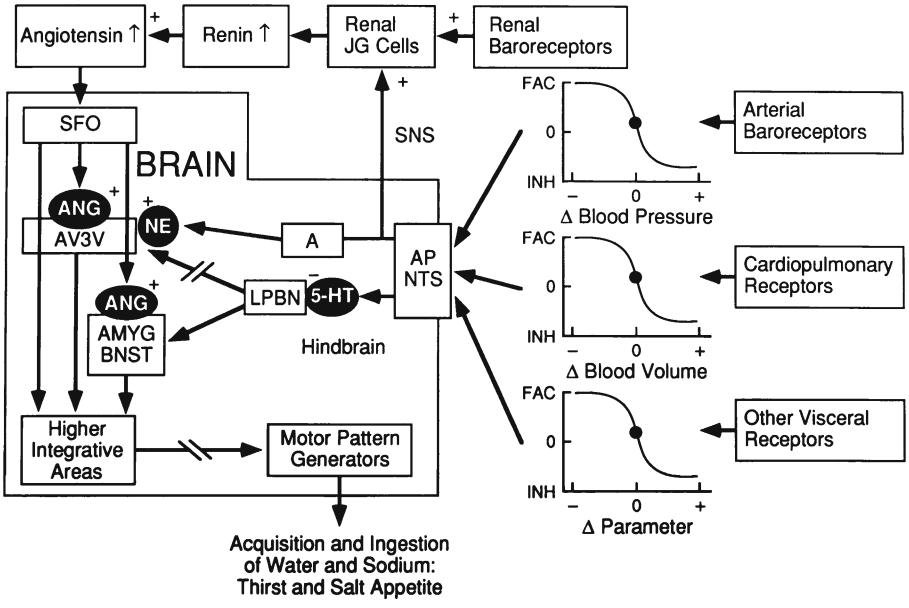
Thirst and salt appetite are appetitive states that have been viewed as generalized sensations, instinctive behaviors, drives, and negative affective conditions. They are states that give rise to behaviors that are necessary to maintain and correct homeostatic disruptions in fluid balance and distribution. Of these two appetitive conditions, thirst is the most common and easily recognized by humans. Nevertheless, salt appetite will develop in individuals as a sodium-deficient state becomes more protracted and can be defined by an increase in the palatability of concentrated salt solutions.

Significant progress has been made in the past half century by pursuing what has been in effect a sensory analysis of thirst and salt appetite. As contrasted with senses like vision or audition, there are no specific sensory organs that are devoted exclusively to sensing thirst or salt appetite. These states must be generated from available humoral and mechanical stimuli that are associated with water and sodium perturbations and cardiovascular changes (*Figure 17-7*).

Water loss from either the cellular or the extracellular compartment gives rise to thirst (i.e., the *double depletion hypothesis)* whereas, loss of isotonic fluid from the extracellular space (i.e., hypovolemia) produces a hunger for salt. Humoral and physical stimuli associated with cellular and extracellular depletions serve to

Figure 17-7

Schematic depicting the nature of neural and hormonal inputs into the brain and the central neural pathways that mediate sensory integration of signals for the generation of drinking (thirst) and sodium ingestion (salt appetite). Both inhibitory and excitatory inputs from the periphery derive from arterial and cardiopulmonary baroreceptors and probably other visceral receptors (e.g., gastric, hepatic, portal, or renal). Information carried in afferent nerves projects mainly to the nucleus of the tractus solitarius (NTS). Angiotensin (ANG) acts in the form of ANG II on angiotensin type 1 (AT_1) receptors in the subfornical organ (SFO). Information reflecting input to the SFO is carried in *descending* pathways, some of which are likely to use ANG in the mode of a neurotransmitter, to forebrain structures such as those in the anteroventral third ventricle (AV3V). *Ascending* information to the forebrain is carried in from noradrenergic cell groups (A) in the hindbrain, which are activated by arterial and cardiopulmonary receptor input under conditions of hypotension and/or hypovolemia. ANG and noradrenergic (NE) inputs act synergistically in the forebrain nuclei. A hindbrain inhibitory pathway originating in the area postrema (AP) and medial NTS ascends to the lateral parabrachial nucleus (LPBN). This projection uses serotonin (5-HT), as one of several neurotransmitters, to guard against excessive sodium and water intake thereby limiting excessive expansion of extracellular fluid volume. Inhibitory input is likely to ascend the neuraxis either directly or indirectly to interact with the forebrain structures within the visceral neuraxis devoted to regulating body fluid and cardiovascular homeostasis. From Johnson and Thunhorst (1997)



inform the brain about the status of fluid balance and distribution. Cellular dehydration is thought to be sensed by hypothesized *osmoreceptors* (and probably sodium receptors) located in the systemic viscera and in the brain. The most extensively studied osmoreceptors are in the brain. The SCVOs located along the lamina terminalis (i.e., the SFO and OVLT) are major candidate regions for containing osmosensitive cells that trigger cellular dehydration thirst. Hypovolemia, which generates extracellular thirst, is signaled by ANG II and afferent input from systemic baroreceptors located on both the high- and low-pressure sides of the circulation and possibly in the kidney. The same baroreceptors and ANG II also seem to contribute to salt appetite. Given the longer latency for the onset of the sodium seeking, salt appetite may have a higher threshold for its activation or require the addition or removal of other factors (e.g., ↑ aldosterone or ↓ OT= facilitation) for its expression.

Humoral input reaching the structures of the laminal terminalis and ascending visceral input entering the brain stem through the NTS project information about the status of body fluids into a neural network often referred to as the *visceral neuraxis*. Key structures in this circuitry include the NTS, parabrachial nucleus, PVN, SON, SFO, MePO, septal area, and components of the extended amygdala. In this system, various neuroactive agents have both excitatory (e.g., ANG II, acetylcholine, NE, glutamate) and inhibitory (e.g., tachykinins, OT, 5-HT, ANP, GABA) influences on thirst and salt appetite. To produce thirst and salt appetite, information is integrated and processed in the brain. In other words, the states of thirst and hunger for salt, as with other sensations and perceptions, are the result of sensing by receptors and then synthesis of the state or perceived condition by the brain. Finally, to understand the complex sensory biology and information processing involved in thirst and salt appetite, the field of research is constantly striving to apply the evolving concepts and methods of contemporary neuroscience.

5 A Model of Fear Memory Acquisition and Consolidation 701

6 Conclusions 702

Abstract: Over the last 20 years, research on emotion has enjoyed a resurgence in the neurosciences. Nowhere has this been more evident than in the fear system of the brain. In this chapter, we discuss the brain's "fear learning" system from a neurochemical and pharmacological perspective. We focus on the neurochemical and biochemical events that underlie fear "memory consolidation" or the processes whereby short-term fear memories are gradually transformed into stable, long-term fear memories.

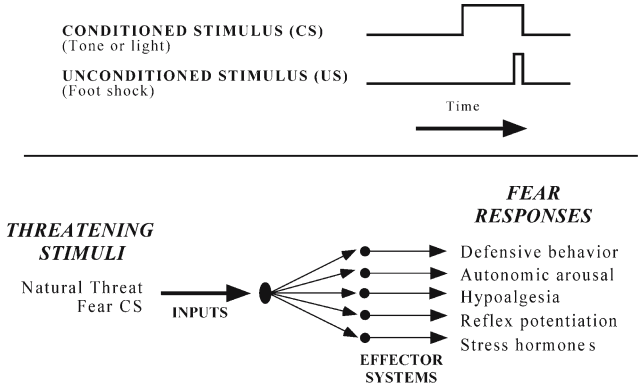
List of Abbreviations: AKAP, A-kinase anchoring protein; APV, D-2-amino-5-phosphonovaleric acid; BPAP, back-propagating action potential; CaMKII, Ca^{2+}/calmodulin-dependent protein kinase II; CR, conditioned response; CRE, cAMP-response element; CREB, cAMP-response-element binding protein; CS, conditioned stimulus; DAG, diacylglycerol; E-LTP, early-LTP; ERK, extracellular signal-regulated kinase; IP_3, inositol 1,4,5-trisphosphate; LA, lateral amygdala; L-LTP, late-LTP; LTM, long-term memory; LTP, long-term potentiation; L-VGCC, L-type voltage-gated calcium channel; MAPK, mitogen-activated protein kinase; MEK, mitogen-activated protein kinase kinase; mGluR, metabotropic glutamate receptor; MPEP, 2-methyl-6-(phenylethynyl)-pyridine; NMDAR, N-methyl-D-aspartate receptor; PKA, protein kinase A; PKC, protein kinase C; PSD, postsynaptic density; STM, short-term memory; US, unconditioned stimulus

1 Introduction

In classical or Pavlovian *fear conditioning*, an animal learns to respond defensively to an emotionally neutral stimulus (the conditioned stimulus; CS) that acquires emotional significance after being associated with a noxious stimulus (the unconditioned stimulus; US). In the laboratory, this type of associative learning has been most widely studied in rodents, where a discrete cue (such as a tone, light, or odor; CS) is paired with a brief electric shock to the feet (US). Before conditioning, the CS does not elicit fearful or defensive behavior. After as little as one CS–US pairing, however, the animal begins to exhibit a range of conditioned responses (CRs), both to the tone CS and to the context in which conditioning occurs (e.g., the conditioning chamber). In rats, these CRs include "freezing" or immobility (the rat's species-typical behavioral response to a threatening stimulus), autonomic and endocrine adjustments (such as changes in heart rate and blood pressure, defecation, and increased levels of circulating stress hormones), and other changes such as the potentiation of reflexes like the acoustic startle response (Blanchard and Blanchard, 1969; Kapp et al., 1979; LeDoux et al., 1988; Roozendaal et al., 1991; Davis, 1997) (*Figure 18-1*).

Figure 18-1

Pavlovian fear conditioning. *Top*: Fear conditioning involves the presentation of an initially innocuous stimulus, such as a tone (conditioned stimulus; CS), that is paired or associated with a noxious stimulus, such as a brief electric shock to the feet (unconditioned stimulus; US). *Bottom*: Before conditioning, the CS elicits little response from the animal. After conditioning, the CS elicits a wide range of behavioral and physiological responses that are characteristically elicited by naturally aversive or threatening stimuli



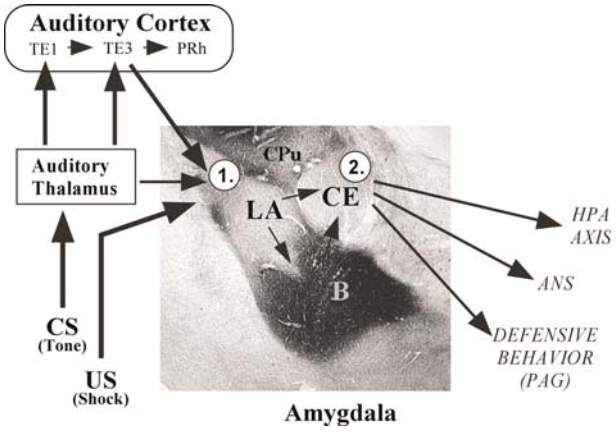
1.1 The Amygdala and Fear Conditioning

The neurobiological substrates of fear conditioning have been studied most extensively using the "auditory fear conditioning" paradigm, where an animal learns to fear a tone (CS) that is paired with footshock (US). In this review, we therefore emphasize the findings from the auditory conditioning literature, although similar mechanisms have also been proposed for conditioning to visual and contextual stimuli (Davis, 1992, 1997; Maren, 2001).

Auditory fear conditioning involves transmission of auditory CS and somatosensory US information to the lateral amygdala (LA), an area in the temporal lobe that lesion and functional inactivation studies have shown to be critical for the learning (LeDoux et al., 1990; Helmstetter and Bellgowan, 1994; Campeau and Davis, 1995; Muller et al., 1997; Wilensky et al., 2000). Anatomical tract tracing studies have shown that cells in the LA receive direct glutamatergic projections from areas of the auditory thalamus and cortex, specifically from the medial division of the *medial geniculate body* and the posterior intralaminar nucleus (MGm/PIN), and area TE3, respectively (LeDoux et al., 1985; LeDoux and Farb, 1991; Bordi and LeDoux, 1992; Romanski and LeDoux, 1993; McDonald, 1998; Doron and LeDoux, 1999). Electrophysiological evidence has indicated that inputs from each of these auditory areas converge onto single neurons in the LA (Li et al., 1996). Further, cells in the same or nearby regions of the thalamus are responsive to the footshock US (Bordi and LeDoux, 1994), as are cells in the LA (Romanski et al., 1993) (*Figure 18-2*).

Figure 18-2

Anatomy of the fear system. (a) Auditory fear conditioning involves the transmission of CS sensory information from areas of the auditory thalamus and cortex to the lateral amygdala (LA), where it can converge with incoming somatosensory information from the footshock US. It is in the LA that alterations in synaptic transmission are thought to encode key aspects of the learning. (b) During fear expression, the LA engages the central nucleus of the amygdala (CE), which projects widely to many areas of the forebrain and brainstem that control the expression of fear CRs, including freezing, HPA axis activation, and alterations in cardiovascular activity



The convergence of auditory and somatosensory information onto individual LA neurons is thought to be critical for the "plasticity" underlying fear conditioning (LeDoux, 2000; Maren, 2001; Blair et al., 2001). In support of this view, individual cells in the LA alter their electrophysiological response properties when CS and US are paired during fear conditioning. Specifically, LA neurons that are initially weakly responsive to auditory input respond vigorously to the same input after fear conditioning (Quirk et al., 1995, 1997; Maren, 2000; Repa et al., 2001; Blair et al., 2003). These changes in the responsiveness of LA cells that occur as the result of training have contributed to the view that neural plasticity in the LA encodes key aspects of fear learning and memory storage (Fanselow and LeDoux, 1999; Maren, 2001; Blair et al., 2001; Schafe et al., 2001).

In the following sections, we discuss the neurochemical and biochemical mechanisms that likely underlie plasticity and memory formation at LA synapses. We begin with a discussion of long-term potentiation (LTP), as it has been proposed that this type of synaptic plasticity is the most likely type of mechanism that underlies fear memory formation (Maren, 1999; Blair et al., 2001; Schafe et al., 2001).

2 Neurochemical Mechanisms of Fear Memory Formation: The Importance of LTP

The change in the responsiveness of LA cells during fear conditioning suggests that alterations in excitatory synaptic transmission in the LA might be critical for fear conditioning. Accordingly, many of the recent studies that have examined the neurochemical basis of fear conditioning have drawn on a larger literature that has focused on the biochemical events that underlie LTP, an activity-dependent form of synaptic plasticity that was initially discovered in the hippocampus (Bliss and Lømo, 1973). There are several good reasons behind this strategy, including the fact that LTP has also been demonstrated in thalamic and cortical auditory input pathways to the LA (Chapman et al., 1990; Clugnet and LeDoux, 1990; Rogan and LeDoux, 1995; Huang and Kandel, 1998; Weisskopf et al., 1999; Weisskopf and LeDoux, 1999). Further, auditory fear conditioning itself has been shown to lead to electrophysiological changes in the LA that resemble artificial LTP induction (McKernan and Shinnick-Gallagher, 1997; Rogan et al., 1997). Collectively, these findings provide strong support for the hypothesis that an LTP-like process in the LA may underlie fear conditioning. This, in turn, suggests that fear memory acquisition and consolidation may share a common neurochemical substrate with LTP.

There are several pharmacologically distinct forms of LTP, most of which have been identified in the hippocampus. One form critically involves the N-methyl-D-aspartate receptor (NMDAR), which is normally blocked by Mg^{2+} but which can be opened following sufficient depolarization of the postsynaptic cell during LTP induction (Malenka and Nicoll, 1993). The other, less widely studied form involves the L-type voltage-gated calcium channel (L-VGCC). Other forms require a combination of both NMDARs and L-VGCCs (Grover and Teyler, 1990; Cavus and Teyler, 1996). Importantly, both NMDAR and L-VGCC-mediated forms of LTP have been discovered in the LA (Bauer et al., 2002). The hallmark of each form of LTP is the entry of Ca^{2+} into the postsynaptic spine, which initiates a biochemical cascade of events that leads to strengthening of the synapse. Some of these biochemical cascades lead to a transient change in synaptic strength known as "early-LTP" (E-LTP) that is independent of de novo RNA and protein synthesis. Other intracellular cascades lead to a more permanent alteration in cell excitability known as "late-LTP" (L-LTP). Unlike E-LTP, L-LTP requires de novo RNA and protein synthesis (Nguyen et al., 1994; Nguyen and Kandel, 1996).

2.1 Early-LTP Versus Late-LTP

Both LTP induction and E-LTP are known to require NMDAR-mediated activation of protein kinase signaling pathways (Malenka and Nicoll, 1993; Soderling and Derkach, 2000). At least two protein kinase signaling pathways have been implicated in E-LTP: the Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) and protein kinase C (PKC). Both the alpha isoform of CaMKII (αCaMKII) and PKC are known to undergo a rapid, Ca^{2+}-induced "autophosphorylation," a state in which these enzymes can remain active in the absence of further Ca^{2+} entry for a period of time after LTP induction (Sweatt et al., 1998; Sweatt, 1999; Soderling and Derkach, 2000). In this state, both αCaMKII and PKC are thought to translocate to the postsynaptic density (PSD) where they can target and transiently influence the conductances of NMDARs and AMPARs (Lee et al., 2000, 2003; Soderling and Derkach, 2000). The transient enhancement of AMPA receptor conductance is one mechanism by which E-LTP is thought to be maintained in the absence of new protein synthesis (Sweatt, 1999; Soderling and Derkach, 2000).

While E-LTP is a short-lived phenomenon, L-LTP lasts many hours, possibly days to weeks (or longer). This persistence of L-LTP is thought to be due, in part, to structural changes at the synapse itself (Milner et al., 1998). Accordingly, L-LTP requires new RNA and protein synthesis and the activation of different classes of protein kinase signaling pathways. These include protein kinase A (PKA) and the mitogen-activated protein

kinase (MAPK) (Nguyen and Kandel, 1996; English and Sweatt, 1997; Huang et al., 2000). Once activated by stimulation that promotes L-LTP, both PKA and MAPK are thought to translocate to the cell nucleus and engage activators of transcription, including the cAMP-response-element binding protein (CREB) and cAMP-response element (CRE)-mediated gene expression (Impey et al., 1996, 1998). It is the activation of CREB and CRE-mediated genes that ultimately leads to the protein and RNA synthesis-dependent functional and/or structural changes that are thought to underlie L-LTP (Frank and Greenberg, 1994; Yin and Tully, 1996; Silva et al., 1998; Stevens, 1998; Holt and Maren, 1999).

In the subsequent sections, we will explore how the biochemical mechanisms of E-LTP and L-LTP are related to memory formation in the LA. As shown later, many of these have been implicated in short-term memory (STM) and long-term memory (LTM) of fear conditioning, respectively.

3 Neurochemical Mechanisms Underlying Acquisition and STM Formation of Fear Conditioning in the Amygdala

Like E-LTP, STM is a short-lasting form of memory that does not require new protein or RNA synthesis (Milner et al., 1998). While no consistent time frame of STM has been defined in the literature, it is generally tested shortly after training, usually within 1 h. Further, deficits in STM formation are typically assumed to reflect deficits in memory acquisition, although it should be emphasized that acquisition and STM formation are likely subserved by distinct molecular mechanisms (Rodrigues et al., 2004). In this section, we examine how glutamatergic transmission, αCaMKII, and PKC might contribute to fear memory acquisition and STM formation in the LA.

3.1 NMDA Receptors

Inspired by the hippocampal LTP literature, early pharmacological studies of Pavlovian fear conditioning examined the role of the NMDA receptor in the amygdala in fear acquisition. These initial experiments consistently showed that blockade of NMDARs in the LA impaired fear conditioning (Miserendino et al., 1990; Kim et al., 1991; Campeau et al., 1992). Later reports, however, indicated that NMDAR blockade in the amygdala also impaired the expression of previously acquired fear responses (Maren et al., 1996). These findings are consistent with electrophysiological evidence showing that NMDA receptors are involved, at least in part, in routine synaptic transmission in the LA (Weisskopf and LeDoux, 1999). As such, it has been difficult to conclude unambiguously that NMDARs are required for fear acquisition independently of a role in routine synaptic transmission.

The role of NMDARs in fear conditioning has recently been revisited by examining the effects of selective blockade of the NR2B subunit of the NMDA receptor in the LA. NMDARs are heteromeric complexes composed of several subunits, including the NR1 subunit, which is essential for channel function, as well as a range of NR2 subunits that regulate channel function (Monyer et al., 1992; Nakanishi, 1992). In vitro studies have shown that the NR1–NR2B complex exhibits longer EPSPs than the NR1–NR2A complex (Monyer et al., 1992). This characteristic of NR2B containing NMDARs is thought to provide a longer time window for coincidence detection, which is thought to be especially important during synaptic plasticity (Tsien, 2000). Indeed, recent molecular genetic studies have implicated the NR2B subunit in both synaptic plasticity and memory formation; overexpression of NR2B in the forebrain of mice results in enhanced LTP and memory formation for a variety of tasks, including fear conditioning (Tang et al., 1999).

Most previous studies that examined the role of NMDARs in the amygdala in fear conditioning have used the NMDAR antagonist D-2-amino-5-phosphonovaleric acid (APV), which blocks the entire NMDA receptor complex (Miserendino et al., 1990; Kim et al., 1991; Campeau et al., 1992). In contrast, a recent study used ifenprodil, a drug which selectively blocks the NR2B subunit of the NMDA receptor (Rodrigues et al., 2001). Pretraining intraamygdala infusions of ifenprodil dose-dependently impaired formation of both STM and LTM of fear conditioning (Rodrigues et al., 2001); that is, memory was impaired both at 1 and 24 h after infusion and training (*Figure 18-3a* and *b*). In contrast, infusions of ifenprodil before testing at either time point had no effect on fear expression. These results suggest that ifenprodil lacks the nonspecific effects on routine transmission that are characteristic of the more global NMDAR antagonist

APV. In support of this hypothesis, bath application of ifenprodil to amygdala slices also impairs LTP at thalamic inputs to LA neurons, but has no effect on routine synaptic transmission (Bauer et al., 2002; *Figure 18-3c*). These results are also consistent with those of a recent study that examined the effects of APV on acquisition of fear potentiated startle (Walker and Davis, 2000), showing that APV can, under certain circumstances, have selective effects on plasticity. Collectively, findings suggest that the NMDA receptor in the amygdala plays an essential role in both the acquisition and STM of conditioned fear.

3.2 Metabotropic Glutamate Receptors

In contrast to the ionophoric NMDAR, the metabotropic glutamate receptor (mGluR) is a G-protein linked receptor that, when bound to glutamate, can modulate synaptic transmission via linkage to a variety of intracellular cascades (Nakanishi, 1992; Pin and Duvoisin, 1995; Anwyl, 1999). The Group I mGluRs, which consist of the subtypes mGluR1 and mGluR5, appear to be particularly important for synaptic plasticity (Huber et al., 1998; Balschun et al., 1999; Kleppisch et al., 1999). Transgenic mice lacking mGluR5 display a complete loss of the NMDAR-mediated component of LTP in the CA1 region of the hippocampus (Lu et al., 1997; Jia et al., 1998, 2001) and show impairments in NMDAR-dependent hippocampal memory tasks, including spatial learning in the Morris water maze (Lu et al., 1997).

Several recent studies have examined the role of mGluRs in fear conditioning. Transgenic mice lacking mGluR5 are impaired in fear conditioning tasks (Lu et al., 1997), as rats are injected systemically with the selective mGluR5 antagonist 2-methyl-6-(phenylethynyl)-pyridine (MPEP) before fear conditioning (Fendt and Schmid, 2002). In a recent study, Rodrigues et al., showed that mGluR5 was localized in LA spines postsynaptic to auditory thalamic inputs and required for synaptic plasticity at thalamic inputs to LA neurons (Rodrigues et al., 2002). Further, in behavioral experiments, intraamygdala infusion of MPEP before fear conditioning impaired formation of both STM and LTM of fear conditioning (Rodrigues et al., 2002; *Figure 18-3d* and *e*), and also impaired LTP at thalamic inputs to the LA (*Figure 18-3f*). Similar to the results with the NR2B antagonist ifenprodil, infusion of MPEP prior to training blocked both STM and LTM, while infusion immediately before testing at either time point had no effect.

These findings suggest that mGluRs, and in particular mGluR5, are required for fear conditioning and STM formation in the amygdala. Future experiments, however, will be required to understand the exact mechanisms by which mGluRs contribute to fear conditioning. One attractive hypothesis is that activation of mGluR5 in the amygdala recruits the PKC signaling pathway. Both mGluR1 and mGluR5, for example, are positively coupled to phospholipase C, activation of which leads to the hydrolysis of phosphatidylinositol 4,5-biphosphate into inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG), two effector proteins that are directly upstream from PKC. As discussed earlier, in its active form PKC can modulate the

Figure 18-3

Neurochemical mechanisms of fear acquisition and STM Formation in the LA. Both STM (a) and LTM (b) of auditory fear conditioning is dose-dependently impaired by intra-LA infusions of ifenprodil, a selective NR2B antagonist (A–B adapted, with permission, from Rodrigues et al., 2001, Copyright by the Society for Neuroscience). (c). LTP at thalamic inputs to the LA is also impaired by ifenprodil (adapted, with permission, from Bauer et al., 2002, Copyright by the Society for Neuroscience). (d–e) Both STM and LTM of auditory fear conditioning are dose-dependently impaired by intra-LA infusions of MPEP, a selective mGluR5 antagonist. (f) LTP at thalamic inputs to the LA is also impaired by MPEP (d–f adapted, with permission, from Rodrigues et al., 2002, *Copyright Society for Neuroscience*). (g) Fear conditioning results in an increase in autophosphorylated αCaMKII in LA spines. Here, rats were conditioned and activated αCaMKII was detected in LA spines using EM and an antibody against autophosphorylated αCaMKII at Thr^{286}. The image on the left shows a labeled spine (LSp) in the LA that contains numerous αCaMKII-immunogold labeled particles. The graph on the right shows that paired, but not unpaired, training leads to significant elevations in αCaMKII-labeled particles in LA spines ($p<0.05$). (h) Both STM and LTM of auditory fear conditioning are impaired after intra-LA infusion of KN-62, a CaMKII antagonist. (i) LTP at thalamic inputs to the LA is also impaired by KN-62 (G–I adapted, with permission, from Rodrigues et al., 2004, Copyright by the Society for Neuroscience)

conductances of a number of synaptic proteins, including NMDARs and AMPA receptors, leading to short-term alterations in synaptic transmission, which could be important for memory formation. PKC, for example, is known to target two phosphorylation sites on the C-terminal domain of NR2B (Liao et al., 2001), which can modulate NMDAR conductance (Anwyl, 1999; Liao et al., 2001). In mGluR5 knockout mice, LTP of NMDAR currents in CA1 is absent, but can be rescued by activators of PKC (Jia et al., 1998). Further, an mGluR5 agonist (CHPG) has been reported to induce a slowly developing, long-lasting potentiation of NMDAR currents via PKC (Doherty et al., 1997). The role of PKC in fear acquisition and STM formation has not been explicitly tested, although mice with a specific deletion of the β isoform of PKC have impaired fear conditioning when tested 24 h after training (Weeber et al., 2000). Additional experiments will be necessary to examine the role of mGluR5-mediated PKC activation in the LA in fear conditioning.

3.3 Ca^{2+}/Calmodulin-Dependent Protein Kinase

CaMKII has been widely implicated in synaptic plasticity and memory formation (Fukunaga and Miyamoto, 1999; Fink and Meyer, 2002; Lisman et al., 2002). CaMKII consists of a family of isoforms, with the α and β isoforms being the most prominent (Bennett et al., 1983; Miller and Kennedy, 1985). αCaMKII, in particular, has been implicated as a major contributor to synaptic plasticity and memory formation. Transgenic mice with a deletion of the αCaMKII gene display deficits in hippocampal LTP and hippocampal-dependent spatial memory (Silva et al., 1992a, 1992b). Similarly, pharmacological inhibition of CaMKII blocks the induction of LTP in the hippocampal area CA1 (Ito et al., 1991; Stanton and Gage, 1996), and impairs hippocampal-dependent learning and memory (Tan and Liang, 1996).

αCaMKII has also been implicated in fear conditioning. αCaMKII is robustly expressed in LA pyramidal neurons (McDonald), where it coexists with NR2B in LA spines postsynaptic to terminals that originate in the auditory thalamus (Rodrigues et al., 2004). Fear conditioning has recently been shown to lead to increases in the autophosphorylated form of αCaMKII at Thr^{286} in spines of LA neurons (*Figure 18-3g*). Further, intraamygdala infusion or bath application of an inhibitor of CaMKII (KN-62) impairs acquisition and STM formation of fear conditioning and LTP at thalamic inputs to LA neurons, respectively (*Figure 18-3h* and *i*). This latter finding is consistent with molecular genetic experiments indicating that induced overexpression of active αCaMKII by a transgene that replaces Thr^{286} with an aspartate residue in the amygdala and striatum results in a reversible deficit in fear conditioning (Mayford et al., 1996).

3.4 AMPA Receptor Regulation

One way that αCaMKII might promote STM formation is by targeting and altering the conductance of glutamate receptors at the PSD (Shen and Meyer, 1999; Shen et al., 2000). Autophosphorylated αCaMKII, for example, is known to target and phosphorylate the GluR1 subunit of the AMPA receptor at Ser^{831} (Barria et al., 1997; Lee et al., 2000). Phosphorylation of AMPARs at Ser^{831} has been shown to enhance their conductance (Barria et al., 1997; Benke et al., 1998), and promote their mobilization and insertion into synapses (Hayashi et al., 2000; Passafaro et al., 2001). Upregulation of AMPAR conductance and/or number is in fact one mechanism believed to underlie the temporary persistence of memory (Malinow, 2003). Phosphorylation of GluR1 has recently been shown to be required for synaptic plasticity in the hippocampus and the retention of spatial memory (Lee et al., 2003). Further, fear conditioning leads to the trafficking of AMPA receptors to LA synapses (Rumpel et al., 2005). Thus, activation of αCaMKII during fear acquisition may regulate AMPARs at LA synapses and thereby contribute to the formation and maintenance of STM.

4 Neurochemical Mechanisms of LTM Formation in the Amygdala

As its name implies, LTM is a long-lasting phenomenon that can last many hours, days, weeks, or even years (Milner et al., 1998). Accordingly, LTM is typically tested at longer intervals after training, usually starting at

24 h. Further, like L-LTP, LTM requires the activation of PKA and MAPK and is critically dependent on de novo RNA and protein synthesis (Davis and Squire, 1984; Milner et al., 1998). In this section, we discuss in detail how each of these processes has been linked to LTM formation in the LA. We begin with a discussion of L-type VGCCs, as recent work has suggested that these channels play an essential role in promoting LTM formation in the LA.

4.1 L-type VGCCs

Recent experiments have shown that LTP at thalamic input synapses to the LA is, under certain conditions, L-VGCC dependent, and NMDAR independent (Weisskopf et al., 1999). These experiments used a pairing protocol in which subthreshold presynaptic stimulation of auditory afferents were paired with brief postsynaptic depolarizations (Johnston et al., 1999; Magee and Johnston, 1997; Markram et al., 1997). In this protocol, back-propagating action potentials (BPAPs) originating in the soma are thought to invade the dendrites and interact with EPSPs leading to Ca^{2+} influx through VGCCs (Magee and Johnston, 1997; Johnston et al., 1999; Stuart and Hausser, 2001). Accordingly, LTP induced by pairing in the thalamic pathway is blocked by application of the L-VGCC blockers *nifedipine* or *verapamil* (Weisskopf et al., 1999; Bauer et al., 2002).

Until recently, the contribution of L-VGCCs to fear conditioning had not been established. Bauer et al., however, examined the effect of intraamygdala infusion of the L-VGCC blocker verapamil on the acquisition and consolidation of auditory fear conditioning (Bauer et al., 2002). The findings revealed that blockade of L-VGCCs before conditioning selectively impaired LTM formation of fear conditioning at 24 h after training; acquisition and STM, assessed at 1 h, was left intact. These findings, together with those of studies that examined the role of NMDAR function in fear conditioning discussed earlier, suggest that there are two sources of Ca^{2+} in the LA that are critical for fear memory formation. One, mediated by NMDARs, appears to be selectively involved in fear acquisition and STM formation of fear conditioning (Walker and Davis, 2000; Rodrigues et al., 2001). The second, mediated by L-VGCCs, is selectively involved in LTM formation. While the effects of L-VGCC blockade are not apparent in fear conditioning for many hours after training, it is important to note that this is likely due to interference with a process that is set in motion at the time of CS–US pairing and fear acquisition. Consistent with that notion, recent reports have demonstrated that L-VGCCs play a selective role in signaling to the nucleus and initiating CRE-mediated transcription, which is known to be required for long-term synaptic plasticity and memory formation (Dolmetsch et al., 2001). Additional experiments will be necessary to determine the contribution of L-VGCCs to the activation of protein kinases and CRE-driven gene expression in the LA following fear conditioning.

4.2 Protein Kinase A and Mitogen-Activated Protein Kinase

The rise in intracellular Ca^{2+} during fear acquisition (CS–US pairing) leads, either directly or indirectly, to the activation of protein kinase second messenger pathways that are necessary for long-term synaptic plasticity and memory. The role of two of these in the LA has been studied fairly extensively in relation to fear conditioning: PKA and MAPK. There has been a great deal of recent interest in both PKA and ERK/MAPK, in part because they have been shown to be essential for the late phase of multiple forms of synaptic plasticity and memory. This has included fear conditioning, where mice that overexpress an inhibitory form of PKA, R(AB), exhibit impaired L-LTP in hippocampal area CA1 and selective deficits in LTM, but not STM, of contextual fear conditioning (Abel et al., 1997). Similarly, mice that lack *Ras*, an upstream regulator of ERK/MAP kinase, have impaired memory consolidation of auditory and contextual fear conditioning, as well as impaired amygdala LTP (Brambilla et al., 1997).

Recent pharmacological experiments have examined the role of PKA and ERK/MAPK in amygdala LTP and in fear conditioning. Huang et al., showed that bath application of inhibitors of PKA or ERK/MAPK to amygdala slices impairs L-LTP at thalamic and cortical inputs to the LA, but has no effect on E-LTP (Huang

et al., 2000; *Figure 18-4a–c*). Consistent with those findings, infusion of a PKA inhibitor or of a peptide that blocks the association of PKA with the A-kinase anchoring protein (AKAP) in the LA impairs LTM, but not STM of fear conditioning (Schafe and LeDoux, 2000; Moita et al., 2002; *Figure 18-4h*). Further, fear conditioning results in a transient activation of ERK/MAPK in the LA (*Figure 18-4d–f*), and infusion of an ERK/MAPK inhibitor into the LA before fear conditioning impairs memory consolidation; that is, rats have intact STM and impaired LTM (Schafe et al., 2000; *Figure 18-4g*). Collectively, these findings support the hypothesis that both PKA and ERK/MAPK contribute to fear memory formation by engaging cellular processes, possibly those in the nucleus, that are necessary for long-term synaptic plasticity and memory formation.

4.3 Transcriptional Regulation and Macromolecular Synthesis

Both L-LTP in the LA (Huang and Kandel, 1998; Huang et al., 2000) and LTM of fear conditioning (Bailey et al., 1999; Schafe and LeDoux, 2000) are known to require new RNA and protein synthesis in the LA (*Figure 18-4i*). The requirement for de novo RNA synthesis is particularly important, because it suggests that a nuclear event is required for both L-LTP and the transition between short- and long-term memory formation. Several transcription factors have been implicated in long-term synaptic plasticity and in memory formation, but CREB is perhaps the best studied. CREB is a family of transcription factors consisting of several functionally distinct isoforms. Some, known as activator isoforms, bind to DNA at CRE promoter regions and promote transcription. Others, known as repressor isoforms, compete with the binding of activator isoforms to DNA (Bartsch et al., 1995; Abel et al., 1998; Silva et al., 1998). CREB is an attractive candidate molecule for memory consolidation because it has direct interaction with the transcriptional machinery and also contains phosphorylation sites for the major protein kinase signaling pathways that are known to be involved in memory formation, including PKA, ERK/MAPK, and CaMKII (Silva et al., 1998).

The first evidence to suggest that CREB might be involved in memory consolidation came from a study employing a Pavlovian conditioning task in *Drosophila*. Overexpression of a dominant negative (repressor) isoform of CREB in flies impaired LTM formation in a conditioned odor aversion task (Yin et al., 1994).

Figure 18-4

Neurochemical mechanisms of LTM formation in the LA. (a–c) Long-term potentiation at thalamic inputs to the LA is impaired by inhibitors of MAPK, PKA, and protein synthesis, respectively (adapted, with permission, from Huang et al., 2000, Copyright by the Society for Neuroscience). (d) Fear conditioning leads to an increase in phosphorylated ERK1 and ERK2 at t = 60 min after training. In these experiments, rats were trained, sacrificed at different time points after conditioning, and LA homogenates were probed with antibodies that recognize phosphorylated ERK/MAPK. ERK1 (black bars) and ERK2 (gray bars) are the two isoforms of ERK/MAPK recognized by the anti-phospho-ERK antibody ($p < 0.05$). (e) The increase in activated ERK/MAPK is not accounted for by a change in the amount of total (unphosphorylated) ERK/MAPK. (f) Immuocytochemical localization of phosphorylated ERK/MAPK in the LA after fear conditioning. The image shows ERK-labeled cells in three different regions of the LA (dorsal, LAd; ventromedial, LAvm; and ventrolateral, LAvl), with most of the label concentrated in the ventral portions of the LAd, and throughout the LAvm and LAvl. Activated ERK/MAPK is also highly expressed in the nearby central nucleus (CE) and the amygdala-striatal transition zone (AST). d–f adapted from Schafe et al. (2000), copyright by the Society for Neuroscience. (g–i) LTM, but not STM, in the LA requires MAPK, PKA, and protein synthesis. In these studies, rats received intraamygdala infusions of U0126 (an MEK inhibitor, which is an upstream regulator of ERK/MAPK activation; G), Rp-cAMPS (a PKA inhibitor; H), or anisomycin (a protein synthesis inhibitor; I) at or around the time of training and were assayed for both short-term memory (1–4 h later) and long-term memory (24 h later) of auditory fear conditioning. In each figure, vehicle-treated rats are represented by the white bars, while drug-treated animals are represented by the black bars. *$p<0.05$ relative to vehicle controls. g adapted from Schafe et al. Conversely, overexpression of an activator isoform of CREB facilitated LTM; that is, behavioral training that would normally produce only STM was effective at producing LTM (Yin et al., 1995).

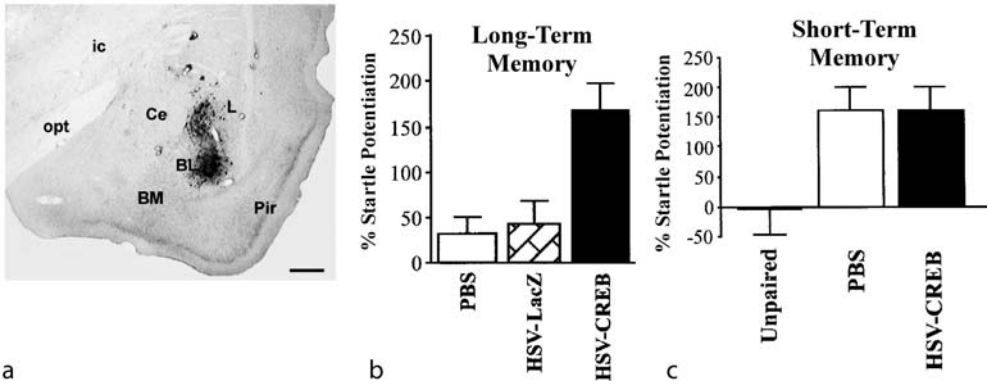
CREB has also been implicated in fear conditioning. Mice lacking two critical isoforms of CREB, the α and δ, have impaired hippocampal L-LTP and memory consolidation for auditory and contextual fear conditioning; that is, LTM is impaired, while STM is intact (Bourtchuladze et al., 1994). Further, induced overexpression of a dominant negative isoform of CREB in the forebrain impairs LTM formation of fear conditioning (Kida et al., 2002). Conversely, overexpression of the transcription factor CREB in the LA facilitates fear memory formation (Josselyn et al., 2001). In this latter study, CREB was overexpressed locally in the LA using viral transfection methods (*Figure 18-5a*). Consistent with the role of CREB in long-term synaptic plasticity and memory formation, overexpression of CREB in the LA facilitated the LTM of fear conditioning, but had no effect on STM (*Figure 18-5b* and *c*).

Figure 18-5

CREB and fear memory formation. Overexpression of CREB in the amygdala via viral transfection facilitates consolidation of fear conditioning. (a) Example of viral transfection in the LA using a control virus that overexpresses the LacZ gene, which encodes the protein β-galactosidase. (b) LTM of fear conditioning is enhanced after infusion of the virus that encodes a wild-type CREB (HSV-CREB), but not by infusion of the control virus (HSV-LacZ). (c) STM of fear conditioning is not affected by infusion of HSV-CREB into the amygdala. Adapted from Josselyn et al. (2001), copyright by the Society for Neuroscience



While CRE-mediated transcription clearly supports the development of long-term plasticity and memory, the downstream targets of CREB have remained largely unknown. However, a number of studies have shown that fear conditioning induces the expression of both immediate-early (Beck and Fibiger, 1995; Rosen et al., 1998; Malkani and Rosen, 2000; Scicli et al., 2004) and downstream genes (Stork et al., 2001; Ressler et al., 2002; Rattiner et al., 2004;) in the LA. While the specific contributions of many of these genes to fear conditioning is still unclear, it is widely believed that learning-induced gene expression ultimately contributes to changes in cell (especially synaptic) structure that stabilizes memory (Bailey and Kandel, 1993; Woolf, 1998; Rampon et al., 2000; Sweatt, 2004), presumably by altering the actin cytoskeleton underlying synaptic organization (van Rossum and Hanisch, 1999; Matus, 2000; Kasai et al., 2003). Such changes in synaptic structure have been well documented in invertebrates, where stimulation that promotes long-term synaptic plasticity has been shown to lead to an increase in new synaptic contacts (Bailey et al., 1992, 1994; Bailey and Kandel, 1993). Further, both learning and LTP result in a number of structural changes in the hippocampus and cortex, including an increase in spine head volume and widening and shortening of the spine neck (Van Harreveld and Fifkova, 1975; Fifkova and Van Harreveld, 1977; Fifkova and Anderson, 1981), spine perforation (Toni et al., 1999), and an increase in the total number of spines (Engert and Bonhoeffer, 1999; Leuner et al., 2003).

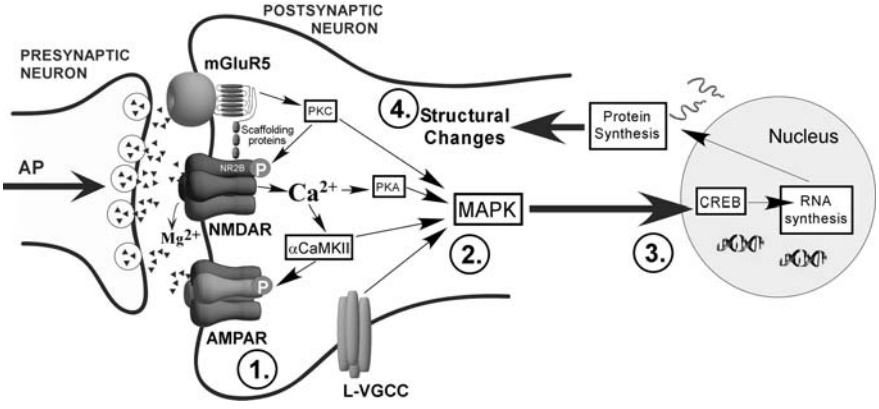
While there is little evidence that changes in synaptic structure occur in the LA following fear conditioning, recent studies have shown that fear conditioning leads to the transcription of genes involved in cytoskeletal remodeling, including the CRE-mediated gene NF-1 (Ressler et al., 2002). Further, interference with molecular pathways known to be involved in structural plasticity during early development, such as the Rho-GAP signaling pathway, disrupts memory formation (Lamprecht et al., 2002). Additional studies will be required to examine whether fear conditioning results in structural changes at LA synapses and what mechanisms might underlie these dynamic changes.

5 A Model of Fear Memory Acquisition and Consolidation

In summary, the converging evidence from a number of recent studies supports a model of fear conditioning in which CS and US inputs converge onto individual LA neurons and initiate changes in synaptic function and/or structure (Blair et al., 2001; *Figure 18-6*). The convergence of CS and US inputs onto LA

Figure 18-6

A model of fear memory consolidation in the amygdala. See text for details. (a) Acquisition and STM formation of fear conditioning requires events at the postsynaptic density, including activation of NMDARs, mGluR5, αCaMKII, and, possibly, PKC. Both αCaMKII and PKC may contribute to STM by influencing the conductance of NMDARs and AMPARs. (b) LTM formation of fear conditioning requires the activation of L-type VGCCs, PKA, and ERK/MAPK. Both PKA and MAPK are thought to translocate to the nucleus to influence gene expression. (c) CREB and CRE-mediated transcription are both required for LTM of fear conditioning. (d) The translation of CRE-mediated genes into proteins may lead to structural changes at LA spines that contribute to the permanence of LTM formation



principal cells during training leads to Ca^{2+} influx through both NMDARs (Miserendino et al., 1990; Kim et al., 1991; Campeau et al., 1992; Walker and Davis, 2000; Rodrigues et al., 2001) and also L-VGCCs (Bauer et al., 2002). Both NMDARs and L-VGCCs are likely opened by the strong depolarization induced by the footshock US by BPAPs that invade the dendrites of LA neurons (Magee and Johnston, 1997; Blair et al., 2001). The NMDAR-mediated increase in intracellular Ca^{2+}, together with mGluR5 (Rodrigues et al., 2002), leads to the activation of a variety of local protein kinases at the PSD, including αCaMKII (Rodrigues et al., 2004) and likely PKC, that promote STM formation by targeting and modulating the conductance of NMDARs and AMPARs at LA synapses (Barria et al., 1997; Benke et al., 1998). The combined entry of Ca^{2+} through both NMDARs and L-VGCCs, however, leads to the activation of PKA and ERK/MAPK (Schafe et al., 2000; Schafe and LeDoux, 2000), which appear to be exclusively involved in the formation of LTM, possibly via translocation to the cell nucleus and activation of transcription factors such as CREB (Josselyn et al., 2001). The activation of CREB by PKA and ERK/MAPK promotes CRE-mediated gene transcription

(Bailey et al., 1999; Ressler et al., 2002) and the synthesis of new proteins (Schafe and LeDoux, 2000), which likely promotes LTM formation by leading to alterations in the structure of LA synapses (Lamprecht et al., 2002; Ressler et al., 2002).

6 Conclusions

In summary, in this review we have emphasized some key synaptic events and downstream cellular cascades that are responsible for the acquisition and consolidation of fear conditioning in the LA. These findings provide a foundation for the continued study of the neural basis of emotional learning and memory at the cellular level, and also for bridging the gap between studies of memory formation and synaptic plasticity in the mammalian brain.

7 Summary 735

"Is it the blood, or air, or fire by which we think? Or is it none of these, and does the brain furnish the perceptions of hearing and sight and smell, and do memory and opinion arise from these, and does knowledge come from memory and opinion when they have attained fixity?" – Socrates (469–399 B.C.).

Abstract: The quest to understand the process of forming and storing memories has engaged scientists for hundreds of years. Recent advances in biology have led to the identification of some of the cellular and molecular mechanisms associated with these processes. Animal studies using both invertebrates and vertebrates have revealed that the mechanisms of learning and memory at the molecular level have been conserved throughout evolution, and that more complex forms of learning have been built on these evolutionarily conserved mechanisms. In this chapter, we discuss how behavioral training alters neuronal activity and neurotransmitter release leading to changes in intracellular kinase activity, protein phosphorylation, protein synthesis, and gene expression. We describe how the various phases of memory: working memory (lasting for seconds), short-term memory (lasting minutes), intermediate-term memory (lasting for hours), and long-term memory (lasting days to a lifetime) are established by the above intracellular changes. We present theories on how permanent memory storage occurs, how memories are recalled, and how they are extinguished.

List of Abbreviations: 5-HT, serotonin; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; C/EBP, CCAAT/enhancer-binding protein; CA, cornus ammonis; CaMK, calcium/calmodulin-dependent protein kinase; cAMP, cyclic adenosine monophosphate; CPEB, cytoplasmic polyadenylation element binding protein; CRE, cAMP response element; CREB, calcium/cAMP response element binding protein; CS, conditioned stimulus; DBH, dopamine β-hydroxylase; DG, dentate gyrus; EPSP, excitatory postsynaptic potential; ERK, extracellular signal-regulated protein kinase; GAP43, growth associated protein 43; GTP, Guanine triphosphate; I-1, inhibitor protein-1; IkB, Inhibitory kappa B; IL, infralimbic cortex; IP3, inositol trisphosphate; L-DOPA, 3,4-dihydroxy-L-phenylalanine; L-DOPS, L-Threo-3,4-dihydroxyphenylserine; LTD, long-term depression; LTP, long-term potentiation; MAP-2, microtubule associated protein 2; MAPK, mitogen-activated protein kinase; MRI, magnetic resonance imaging; MTT, Multiple Trace Theory; NFkB, nuclear factor kappaB; NMDA, N-methyl-D-aspartate; NMR, nictating membrane response; NO, nitric oxide; p90rsk, p90 ribosomal S6 kinase; PFC, prefrontal cortex; PKA, cAMP-dependent protein kinase A; PKC, protein kinase C; PKM, protein kinase M; PP-1, protein phosphatase I; Ser, serine; SRF, serum response factor; SRF, serum response factor; Thr, threonine; Tyr, tyrosine; US, unconditioned stimulus; VTA, ventral tegmental area

1 Introduction

Learning is the process of acquiring knowledge, while memory results from the process by which the knowledge is consolidated, stored, and later retrieved. The ability of the brain to store information about each individual's current and past experiences in a usable form – a "memory" – which can be retrieved at a later point, allows for continuity and cohesion between successive events in one's life, giving rise to a sense of self. We are who we are, because of what we learn and what we remember. As a result of acquiring and retaining knowledge, we change our behavior. When learning and memory processes are impaired, as seen in conditions such as Alzheimer's disease or following injury to the brain, a person's behavior is altered and a sense of self is often lost.

One of the major goals of learning and memory research is to understand how acquiring knowledge changes the brain and how these changes alter subsequent behavior. Over the past two decades, a great deal of progress has been made in identifying some of the molecular mechanisms underlying these processes. In this section, we discuss the cellular and molecular mechanisms that contribute to both explicit (declarative) and implicit (nondeclarative) learning and memory. Electrophysiological recordings, pharmacological and molecular biological agents, and genetic manipulation in experimental animals have been highly successful in elucidating the cellular and molecular mechanisms underlying both explicit and implicit memory formation and storage. We illustrate that the mechanisms of learning and memory at the molecular level

have been conserved throughout evolution and more complex forms of learning have been built on these evolutionarily conserved mechanisms.

2 Modulation of Neuronal Communication Underlies Memory Formation

In 1890, the American psychologist William James posed the following question in his analysis of the phenomenon of memory: "How does a man come, after having the thought of A, to have the thought of B the next moment? Or how does he come to think of A and B always together?" (James, 1890). To answer his question on how the brain forms associations between two events, James opines "When two elementary brain processes have been active together or in immediate succession, one of them on recurring, tends to propagate its excitement into the other." Although the interconnection between two memories appeared evident, the way in which this relationship developed was not clear. The synaptic mechanism for memory was proposed by Tanzi and later by Ramon y Cajal to suggest that changes in the strength of synaptic connections between neurons underlie information storage (Tanzi, 1893; Ramon y Cajal, 1911). This proposal was extended by Donald Hebb who postulated that "when an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased" (Hebb, 1949). This increase in efficiency is thought to be a neural correlate for memory storage. Hebb's postulate can be better appreciated with the following example. Pavlov's famous experiment with dogs showed that repeated pairing of the sound of a bell with the presentation of food lead to an association between the bell and food presentation (*Figure 19-1*) (Pavlov, 1927). For simplicity, assume that the sound of the bell is processed by neuron A and saliva production is caused by neuron B. Prior to the pairing, the sound of the bell (i.e., neuron A) is unable to activate neuron B and saliva production. However, the ringing bell caused neuron A to fire an action potential and presenting the food caused neuron B to fire (which results in saliva production). Repeated pairing of sound with food caused both neurons A and B to fire together. Repeated firing of the two neurons as a result of training increases the efficiency of neuron A to fire B to such an extent that activation of neuron A (as result of the bell) causes the firing of neuron B and saliva production without the presentation of food.

Several plausible mechanisms (e.g., growth of new synaptic connections, increased excitability, synaptic modification) can increase the efficiency of neuron A to cause neuron B to fire. For example, the formation of additional synapses onto neuron B would cause more transmitter release in response to the sound of the bell, and increase the efficiency of A to generate action potentials in B. As long as the synaptic strength between A and B remains high, the sound of the bell can bring back the memory of food. Thus, the cellular and molecular mechanisms that give rise to changes in synaptic strength are thought to be the mechanisms of memory storage. Within the last 15 years, neuroscience research has demonstrated that a number of biochemical activities take place within neurons (both in A and B from the above example) that allow for these changes and are required for memory storage.

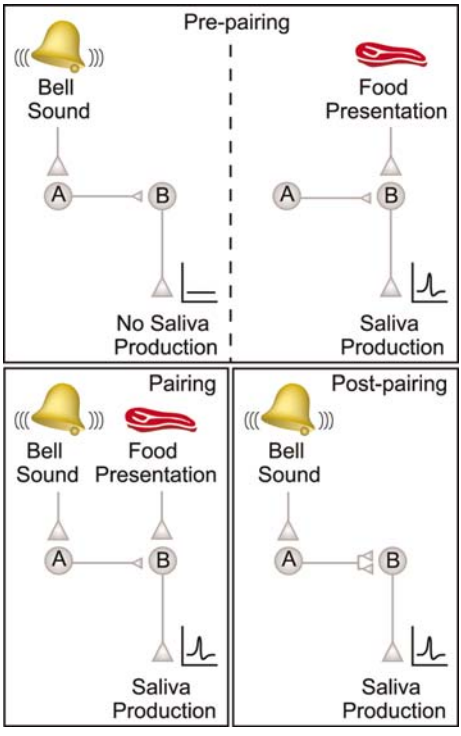
Since the original discoveries made by Bliss and Lomo (1973) in the hippocampus, potentiation of synaptic transmission has been observed in several brain regions. Several experiments have established the Hebbian nature of some forms of synaptic plasticity, although non-Hebbian forms also exist. It has been proposed that the molecular mechanisms of memory storage may share similarities with those that give rise to long-term potentiation (LTP) and long-term depression (LTD).

2.1 Glutamate Receptors

Glutamate is the most prominent neurotransmitter in the brain and has been intimately linked to LTP and LTD. Approximately half of the synapses (and nearly all excitatory neurons) use glutamate as a neurotranmitter. When this transmitter is relased in response to neuronal activity (such as during learning), it binds to specific glutamate receptors. These receptors can be divided into two classes: the ionotropic glutamate receptors and the metabotropic glutamate receptors.

Figure 19-1

Enhanced neuronal communication following associative learning. Prior to conditioning, neuron A responds to the sound of the bell but lacks the strength to cause neuron B to fire *(top left)*. Neuron B triggers saliva production in response to food presentation *(top right)*. During conditioning in which the sound of the bell and food reward are paired *(bottom left)*, neuron A and neuron B fire together. This pairing of the neuronal activities of neuron A and neuron B increases the synaptic strength (and/or excitability) between neurons A and B as result of formation of additional synaptic connections. Following the conditioning, the sound of the bell alone is now sufficient to cause neuron B to fire as a result of more transmitter release (and/or more number of action potentials) from these newly formed synaptic sites, triggering saliva production



Three subtypes of ionotropic receptors, originally classified on the basis of the action of pharamacological agonist, have been identified: AMPA, kinate and NMDA, which are abundantly expressed in the brain (Nicoll et al., 1990; Hollmann and Heinemann, 1994). AMPA and kinate receptors are sometimes referred to as non-NMDA type receptors. The binding of glutamate to these ionotropic receptors results in the opening of ion channels, which allows the movement of ions (Na^+ and Ca^{2+} in, and K^+ out) across the membrane. Functional AMPA and kinate receptors are made up of various combinations of subunits (GluR1, GluR2, GluR3, and GluR4 for AMPA; GluR5, GluR6, GLuR7, KA1, and KA2 for kianate) giving rise to a large number of receptors with varied ionic conductance. There are at least five forms of NMDA receptor subunits (NMDAR1, NMDAR2A, NMDAR2B, NMDAR2C, and NMDAR2D). NMDAR1 is essential for the formation of a functional receptor, since the subunits NMDAR2A-D do not form channels when expressed singly or in combination. Coexpression of NMDAR1 with other subunits forms channels with varying ionic conductances. These receptors have two interesting properties: (1) high permeability to Ca^{2+} and (2) opening that is dependent on the presence of glutamate and membrane voltage. At resting membrane potential, these receptors are blocked due to the binding of a Mg^{2+} ion. Mg^{2+} is expelled from the receptor when the neuron is sufficiently depolarized (as a result of the opening of AMPA receptors) allowing the flow of ions. These excitatory ionotropic receptors are essential for communication between

neurons and are consequently required for activity-dependent changes in neuronal morphology, the presumed cellular basis of storage of memories. This supposition has since been supported by numerous studies showing that blocking glutamate receptors in structures involved in memory functions results in anterograde amnesia.

There are three classes of metabotropic glutamate receptors (Class I: mGluR1, mGluR5; Class II: mGluR2, mGluR3; Class III: mGluR4, mGluR6, mGluR7, mGluR8). Activation of these receptors leads to increases in second messenger molecules (such as cAMP and calcium) and can lead to inhibition of postsynatic Na^+ and Ca^{2+} channels. Unlike ionotropic glutamate receptors, activation of metabotropic receptors can either increase or decrease excitability of postsynaptic neurons. Thus, their role in learning and memory is complex.

2.2 Hebbian LTP Requires Glutamate Receptors and Activation of Intracellular Kinases

LTP is defined as an enduring increase (greater than one hour) in synaptic efficacy that results from high-frequency stimulation of an afferent pathway. LTP exhibits three phases, (1) short: dependent on protein phosphorylation, (2) intermediate: dependent on protein synthesis, and (3) long: requiring gene expression. Molecular investigation into LTP mechanisms started with the demonstration that an antagonist for NMDA subtype of glutamate receptors blocks LTP in the hippocampal CA1 subfield (Nicoll and Malenka, 1995). At the resting potential of a neuron (approximately –70 mV), magnesium ions block the entry of calcium through the NMDA cation channel. When the neuron depolarizes and glutamate is bound, however, the magnesium ions are released from the receptor allowing the influx of calcium from the extracellular space. Rises in intracellular calcium concentrations are obligatory for all types of LTP. In addition to NMDA subtype glutamate receptors, AMPA receptors play a prominent role. These receptors are expressed throughout the brain and mediate fast excitatory synaptic transmission. Activation of AMPA receptors allows positively charged sodium ions to enter cells through its pore. This results in depolarization of the postsynaptic neuron and generation of a fast excitatory postsynaptic potential (EPSP). Several studies have shown that AMPA receptors participate in LTP in two prominent ways during induction and maintenance. First, during LTP induction, postsynaptic AMPA receptors are activated, depolarizing the neurons. This depolarization allows NMDA receptors to conduct Ca^{2+}. Following LTP induction, the number of AMPA receptors on postsynaptic neurons is gradually increased (Liao et al., 1995). This results in a larger EPSP or potentiation in response to presynaptic stimulation.

Interestingly, it was observed that in certain synapses where AMPA receptors were absent, LTP induction resulted in the insertion of these receptors into the synaptic site. This process was found to be dependent on NMDA receptor activation and calcium influx. This key observation led to the silent synapse theory in which certain synapses were silent because they lacked AMPA receptors, although they have NMDA receptors (Liao et al., 1995). During LTP induction, intracellular calcium reaches a level capable of stimulating several calcium-sensitive enzymes including calcium/calmodulin-dependent protein kinase II (CaMKII). CaMKII is one of the most abundant proteins in the brain, accounting for approximately 2% of all proteins. Once activated by the calcium-calmodulin complex, CaMKII phosphorylates the GluR1 subunit of the AMPA receptors on Ser^{831} (Barria et al., 1997). Phosphorylation of AMPA receptors by CaMKII is thought to facilitate insertion of these receptors into the silent synapse allowing the potentiated state to persist. Conversely, inhibition of CaMKII leads to rapidly decaying LTP.

In addition to CaMKII, increased intracellular calcium can activate other signaling molecules including protein kinase C (PKC), adenylyl cyclase, and mitogen-activated protein kinase/extracellular signal-regulated protein kinase (MAPK/ERK). Stimulation of adenylyl cyclase activity by calcium leads to increased synthesis of cAMP and activation of cAMP-dependent protein kinase A (PKA). Initial studies using pharmacological inhibitors and activators of the cAMP/PKA system led to the observation that this pathway is required for the long-term maintenance of the potentiated state. In neuronal cells, enhanced activity of the cAMP/PKA pathway can activate b-Raf (via GEF Rap1) resulting in the phosphorylation and activation of the ERK cascade (Weeber and Sweatt, 2002). Activated ERK translocates into the cell nucleus where it phosphorylates two important transcription factors: calcium/cAMP response element binding

protein (CREB) and serum response factor (SRF). Phosphorylation of these factors stimulates transcription of selective genes that carry the binding sites for these factors in their promoter regions. These gene products are thought to elicit growth processes in the neurons (as initially proposed by Ramon y Cajal) to maintain the potentiated state for long periods of time. As discussed below, these molecules have been shown to be required for memory formation in animals.

2.3 LTD Requires Calcium-Dependent Intracellular Signaling

In addition to potentiation of synapses, information in the brain can also be stored (or erased) by a decrease in synaptic communication between neurons, referred to as long-term depression (LTD). LTD can be induced at the Schaffer collaterals-CA1 synapses of the hippocampus by low frequency stimulation (Mulkey and Malenka, 1992; Dudek and Bear, 1993). Similar to LTP, LTD depends on AMPA and NMDA receptor functions, as well as increased intracellular calcium. However, the low frequency stimulation used to induce LTD causes only modest increases in intracellular calcium resulting in the activation of the calcium/calmodulin-dependent protein phosphatase calcineurin (also known as PP2B), but not CaMKII, which requires higher concentrations of calcium for activation. These studies show that while LTP involves protein phosphorylation, LTD is caused by dephosphorylation of specific substrate proteins. Among the proteins that are regulated by calcineurin, dephosphorylation of inhibitor protein-1 [I-1; a protein which blocks the activity of protein phosphatase I (PP-1)] has been shown to be critical. Dephosphorylated I-1 loses its ability to inhibit PP-1 allowing PP-1 to dephosphorylate substrate proteins including AMPA receptors. Dephosphorylated AMPA receptors are removed from the synaptic sites via endocytosis, thereby depressing synaptic communication.

LTD in the cerebellum has been proposed to be a mechanism for motor learning and memory. A type of associative learning called eyeblink response (or nictating membrane response, NMR) has been used to explore some of the cellular and molecular mechanisms required for motor learning and memory. In this task, a tone is used as the conditioned response (CS) and an air puff is used as the unconditioned response (US). The CS information is conveyed to the cerebellar cortex (and the deep nuclei of the cerebellum) by the mossy fibers that originate in the pontine nuclei. The mossy fibers form synapses with the granule cells of the cerebellum whose axons give rise to the parallel fibers. The US information arrives at the cerebellar cortex (and the deep nuclei) via the climbing fibers that originate in the inferior olivary nucleus. Purkinje cells send their dendrites to the molecular layer of the cerebellar cortex and form synapses with the parallel and climbing fibers. Thus, the information carried by the CS and the US converge on the dendrites of the Purkinje cells (CS and US also converge at deep nuclei). The axons of the Purkinje cells make inhibitory synapses on neurons located in the deep nuclei. Thus, stimulation of parallel fibers in the cerebellum gives rise to an EPSP in the Purkinje cell, which inhibits the activity of the deep nuclei.

When stimulation of the climbing fibers is paired with stimulation of the parallel fibers (such as when the CS and US are co-presented), the size of the EPSP in the Purkinje cell in response to parallel fiber stimulation is reduced. Thus, learning decreases the ability of Purkinje cells to inhibit neurons in the deep nuclei. This allows for the development of an eyeblink response to the CS. LTD at parallel fibers-Purkinje synapses has been shown to require increases in intracellular calcium (via ionotropic and metabotropic glutamate receptors as well as via voltage-dependent calcium channels) and subsequent activation of PKC. Although several hypotheses have been proposed as to how PKC-mediated phosphorylation causes LTD, the exact mechanism has not been established.

3 Implicit and Explicit Forms of Memory

Different types of memory can be classified into two broad categories: implicit memory and explicit memory (Squire, 1987). Implicit memory (also called nondeclarative memory or procedural memory) does not require conscious recollection and includes simple associative and nonassociative forms of memory such as classical conditioning, sensitization, and habituation. Examples of implicit memory

include riding a bicycle, driving a car, or Pavlovian conditioning. In mammals, implicit memory involves many brain structures including the cerebellum and basal ganglia. Explicit memory (also called declarative memory) involves conscious recollection of information about people, places, and things. Examples of this type of memory are remembering the words to a song, the names of streets in your neighborhood or describing the appearance of a friend. In mammals, explicit memory depends on the integrity of the temporal lobe including the hippocampus, entorhinal, perirhinal, and parahippocampal cortices.

3.1 Implicit Memory

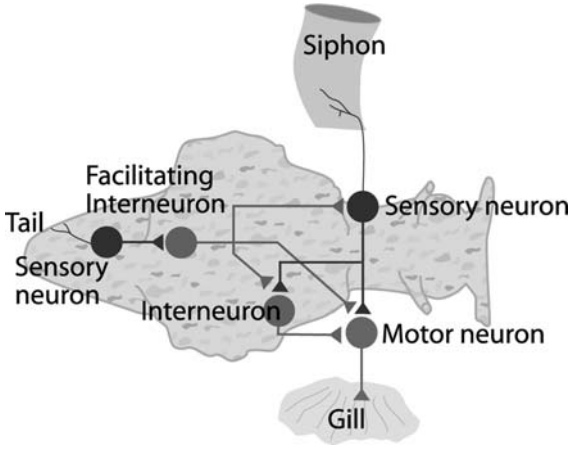
3.1.1 Habituation and Sensitization

Invertebrate model systems have contributed significantly to the understanding of cellular and molecular mechanisms of simple forms of implicit memory. Studies in *Aplysia* by Eric Kandel, James Schwartz, Vincent Castelluci, Tom Carew, John Byrne and others on habituation and sensitization have identified several molecular steps required for memory formation and storage (Kandel and Schwartz, 1982; Byrne and Kandel, 1996). Many of these mechanisms appear to be conserved all the way to humans. Implicit memories have three forms: short-, intermediate-, and long-term, all of which are associated with the facilitation of neuronal communication with distinct molecular mechanisms underlying each (Milner et al., 1998).

One behavioral response in particular, the gill withdrawal reflex in *Aplysia*, has been well characterized (Pinsker et al., 1970). A particularly well studied component of the gill withdrawal reflex is the monosynaptic connection between the sensory neurons that innervate the siphon skin and the motor neurons that innervate the gill (*Figure 19-2*). When a tactile stimulus is presented to the siphon, the siphon sensory neurons at first produce an EPSP in the motor neurons they innervate. This causes a brisk contraction of the gill (and siphon). With repeated stimulation, a progressive decrease in the amplitude of the postsynaptic

Figure 19-2

Siphon-gill component of the withdrawal reflex in *Aplysia,* which has been used to examine the cellular and molecular mechanisms underlying sensitization, habituation and classical conditioning. The siphon sensory neurons transmit the tactile information from the siphon skin to interneurons and gill motor neurons that cause gill contraction. With repeated tactile stimulation of the siphon, the gill contraction habituates due to less transmitter release from the sensory neurons. Noxious stimulation of the tail excites a different group of facilitatory neurons that release modulatory neurotransmitters onto siphon sensory neuron synaptic sites. This increases the strength between siphon sensory neurons and gill motor neurons, causing a stronger gill contraction in response to subsequent siphon stimulation. Thus, the response is sensitized



potential produced by the sensory neurons onto gill motor neurons occurs causing the reflex to habituate. This decrease in synaptic effectiveness results from a decrease in the amount of transmitter released from the terminals of sensory neurons onto the gill motor neuron.

In contrast to habituation, when a sensitizing stimulus (e.g., mild electric shock) is applied to the tail or the head region, the gill withdrawal reflex in response to a tactile stimulus is enhanced. The sensitizing stimulus activates facilitating interneurons that act on siphon sensory neurons to enhance transmitter release onto gill (and siphon) motor neurons. This causes an increase in the amplitude of the postsynaptic potential and a stronger withdrawal of the gill and siphon in response to siphon sensory neuron activity. One group of facilitating interneurons uses serotonin (5-HT) as a neurotransmitter to stimulate the sensory neurons. Other groups of facilitatory interneurons use other neurotransmitters, such as small cardioactive peptide. As discussed in *Section 4*, the action of these neurotransmitters changes synaptic communication (or synaptic strength) by stimulating distinct molecular cascades, giving rise to the different forms (short-, intermediate-, and long-term) of memory.

3.1.2 Classical Conditioning: Invertebrates

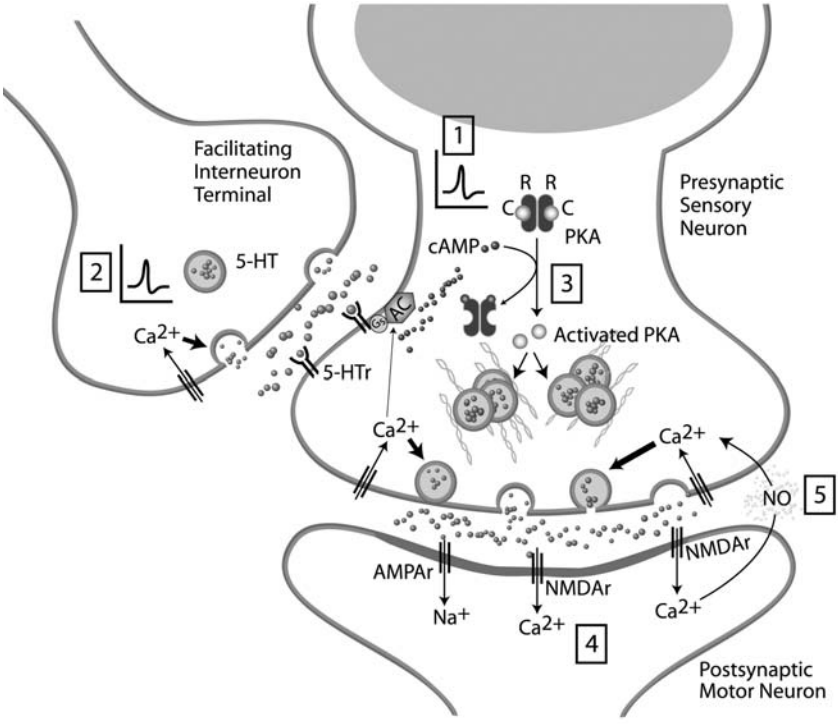
In classical conditioning (or associative learning), animals learn to associate the occurrence of two events. In other words, animals demonstrate an instinctive response (e.g., salivation) when presented with a stimulus (e.g., tone presentation) that has been paired with a second stimulus (e.g., food). As mentioned earlier, the behavioral aspects of classical conditioning were first described by Pavlov, and thus it is often referred to as Pavlovian conditioning. An understanding of the molecular events underlying classical conditioning has since emerged from studies carried out in *Aplysia, Hermissenda,* and the fruit fly *Drosophila* (Benzer, 1971; Tully, 1984; Byrne, 1987). The gill- (and siphon-) withdrawal reflex of *Aplysia* exhibits classical conditioning when a tactile stimulus [e.g., a gentle touch, the conditioned stimulus (CS)] to the siphon is paired with an electrical shock to the tail [the unconditioned stimulus (US)]. After repeated pairing of the tactile stimulus to the siphon with the tail shock (separated by about 0.5 second), the animal exhibits a robust gill contraction to the previously innocuous gill touch in anticipation of tail shock.

Both pre- and postsynaptic molecular changes contribute to classical conditioning. Presynaptically, the CS (gentle touch of the siphon) causes firing of action potentials in the siphon sensory neurons causing entry of calcium into the cell. Calcium in complex with calmodulin stimulates the activity of calcium-sensitive adenylyl cyclase, the enzyme that synthesizes cAMP. The US (tail shock) activates facilitatory interneurons resulting in release of serotonin onto the siphon sensory neuron terminals. This is thought to activate G-protein-coupled 5-HT receptors and the GTP-binding protein $G_{\alpha s}$, which also stimulates the adenylyl cyclase activity leading to cAMP production and PKA activation. Therefore, following the paired activity of the gill sensory neurons with the facilitatory interneuron, both Gαs activation and calcium influx can lead to robust PKA activation. This allows for a larger glutamate release from the siphon sensory neurons in response to a subsequent action potential. Glutamate release onto the gill motor neuron results in gill contraction. Postsynaptically, glutamate binds to AMPA receptors resulting in depolarization. Depolarization in conjunction with binding of glutamate to NMDA receptors activates them, allowing calcium entry into the motor neuron. In addition to enhancing the firing of motor neurons, which would result in robust gill contraction, postsynaptic calcium also generates a retrograde signal, possibly nitric oxide (NO), which acts upon the presynaptic terminal to stimulate transmitter release further, thereby establishing a communication pathway between the presynaptic and postsynaptic changes (*Figure 19-3*).

While *Aplysia* has provided a model system with many advantages for studying memory formation, they are not readily amenable to many of the advanced molecular and genetic manipulations as other model systems such as the fruit fly *Drosophila*. In flies and other arthropods, olfactory learning and memory involves the function of a pair of structures called mushroom bodies. Since the genetics of *Drosophila* is known in great detail, manipulation of genes within the mushroom bodies has allowed the roles of these

Figure 19-3

Molecular mechanism underlying classical conditioning in *Aplysia*. (1) The conditioned stimulus (CS, siphon touch) triggers action potentials in the presynaptic sensory neurons causing opening of voltage-sensitive calcium channels and calcium entry. (2) The unconditioned stimulus (US, tail shock) activates facilitatory interneurons that release serotonin onto the sensory neuron. (3) Both calcium- and serotonin-induced events combine to robustly stimulate calcium-sensitive adenylyl cyclase and cAMP production. The binding of cAMP to the regulatory subunit of PKA (R) releases the catalytic subunit (C) and activates the kinase. Activated PKA leads to the closure of potassium channels and increased Ca^{2+} influx allowing subsequent firing of the sensory neuron to release more glutamate. (4) Increased synaptic glutamate depolarizes the postsynaptic terminal, and together with glutamate, activates NMDA receptors allowing the influx of calcium. (5) Increased postsynaptic calcium enhances the activity of several biochemical cascades (e.g., NO production) further enhancing neuronal communication between the pre- and postsynaptic neurons



genes to be investigated. As a result of training, flies can learn to avoid an odor (CS) that has been associated with a foot shock (US). Using this paradigm, several mutant strains of flies which failed to make the required association were isolated, including *dunce*, *rutabaga*, *amnesiac*, and PKA-R1 (Dudai et al., 1976; Tully and Quinn, 1985; Han et al., 1996). Subsequent cloning of the mutant genes and measurement of enzymatic activity of the mutant proteins showed that *dunce* lacks a cyclic nucleotide phosphodiesterase, *rutabaga* is defective in calcium-sensitive adenylyl cyclase, *amnesiac* lacks peptide that stimulate adenylyl cyclase, and PKA-R1 is deficient in PKA activity. Analysis of *dunce* and *rutabaga* mutants showed that although cAMP is required for classical conditioning, either an excess (in *dunce*) or deficiency (in *rutabaga*) in cAMP could impair classical conditioning. These and other studies have shown that learning and memory, in general, are linked to the underlying neurochemical changes in an "inverted-U" manner and that a narrow range of biochemical activity is required for proper information storage.

3.1.3 Classical Conditioning in Mammals: Fear Conditioning

Memories for fearful or emotional events are robust and can be formed after only one exposure. For example, when rats are exposed to a tone (the CS) and receive a mild footshock (the US) in a training chamber, fear-related responses such as freezing (lack of movement) and increased heart rate are elicited. Following the training, if the animal is put back in the training chamber (contextual memory) or is presented the tone in an otherwise nonthreatening environment (cued memory), it will freeze and its heart rate will increase.

A great deal of evidence, from both pharmacological and lesion studies indicates that the expression of fear (both in response to contextual and salient cues) is dependent on the function of the amygdala (Cahill et al., 1995; LeDoux, 2000). Recently, studies have shown that the amygdala is not only required for the expression of fear, but that this structure also forms and stores the memory for the CS–US association. For example, intraamygdalal infusion of an acetylcholine receptor antagonist decreases fear memory, while agonists increase it (Power et al., 2003). If a tone is used as the CS, the perception of the tone is carried to the lateral amygdala via auditory afferents. When this afferent stimulation is paired with a footshock and neuronal response is tested in the amygdala, enhanced synaptic strength can be observed in these neurons in response to just the auditory stimuli. Development of this association in the lateral amygdala coincides with the formation of freezing behavior to the CS. In addition to its role in modulating memory formation, the amygdala also appears to be required for the recall of fear (or emotional) memory.

Trace conditioning, a form of classical conditioning in which a time gap separates the occurrence of the CS and the US, is thought to be a form of explicit memory, and various types of studies have implicated the hippocampus in both trace eyeblink and trace fear conditioning. For example, bilateral lesions of the hippocampus markedly impair trace learning and memory, but do not significantly impair these processes when a delay conditioning paradigm is used (McEchron et al., 1998). Recently, studies indicate that in addition to the hippocampus, the prefrontal cortex (PFC; medial prefrontal in rats) is critical for the formation of the CS–US association in trace conditioning. Furthermore, the memory for this association is also stored, at least in part, within this structure (Runyan et al., 2004). As discussed later, the neurotransmitter dopamine plays a key role in the functions of the PFC, with both excessive and insufficient levels of this neurotransmitter being linked to prefrontal dysfunction. Consistent with the key role of this neurotransmitter, blockade of dopamine D1 receptor activity within the PFC impairs long-term memory for the CS–US association following trace fear conditioning (Runyan and Dash, 2004b).

3.2 Explicit Memory

3.2.1 The Medial Temporal Lobe and Explicit Memory

The participation of the medial temporal lobe in explicit memory formation and consolidation was first demonstrated in the patient H.M. by William Scoville and Brenda Milner (Scoville and Milner, 2000). When H.M. was a young boy, he suffered a traumatic brain injury (TBI) as result of a bicycle accident. He subsequently developed posttraumatic epilepsy, which was found to be resistant to pharmacological treatment. As a final effort to lessen the seizures, the neurosurgeon, Scoville, surgically removed parts of the medial temporal lobe from both sides of H.M.'s brain. The extent of medial temporal lobe lesions in H.M. has been determined using MRI and included the hippocampus, amygdala, and overlaying parahippocampal gyrus. Although the surgery lessened the seizure episodes, it left H.M. with profound anterograde memory (new memories) deficits. His first neurological evaluation, performed nearly 2 years after the surgery, revealed that his intelligence, motivation, personality, abstract thinking, and perception were intact. However, he is unable to acquire new long-term memories, although remote memories for events in his childhood remain intact. Because of his severe impairment in forming new memories and the fact that his remote memories remain intact, H.M. has a false sense of self, thinking he is younger than he actually is, and being unable to recognize a current picture of himself. H.M. does not recognize people, including Dr. Milner with whom he has met repeatedly over a period of 40 years, requiring her to

reintroduce herself with every meeting. He displays deficits with spatial navigation, frequently becoming lost in the neighborhood he moved into following his surgery. However, H.M. is able to form new nondeclarative (implicit) memories even though his ability to form new declarative memories is severely impaired. For example, he was taught to draw by looking at his hand in a mirror, a procedural learning task that requires a great deal of practice. Although he has become quite adept at performing this task, he does not remember ever being taught to do it, nor does he remember the countless times he practiced the task. The case study of H.M., combined with subsequent studies of other patients with temporal lobe damage, has revealed that this area and the hippocampus in particular are important for the establishment of new explicit memories.

3.2.2 The Hippocampus and Spatial Memory

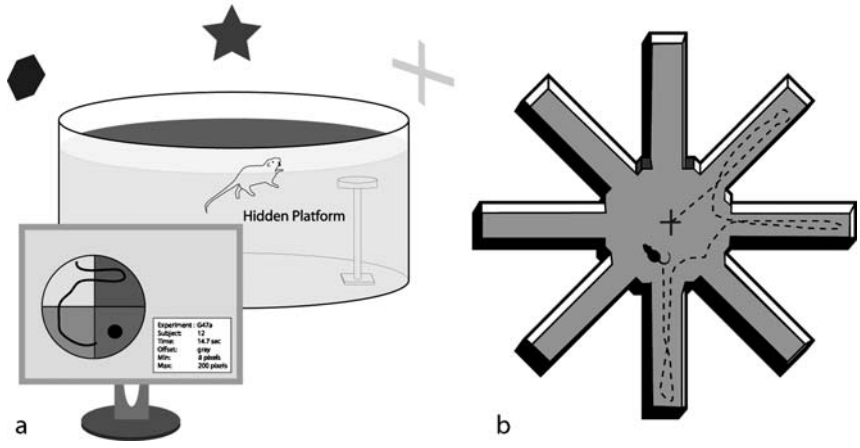
Experiments using animals, especially rats and mice, have been invaluable in exploring the neurochemical basis of explicit memory formation. One type of explicit memory in particular, spatial memory (memory of one's environment used for spatial navigation), has provided us considerable insight into the molecular mechanisms of memory storage. Using intrahippocampal recordings, John O'Keefe and John Dostrovsky demonstrated that groups of hippocampal neurons fire when a rat is in a specific location within a room (O'Keefe and Dostrovsky, 1971). For example, neuron A will fire when the animal is in the northwest corner of a room, whereas neuron B may fire when the rat is along the west wall. Interestingly, if the visual cues in the room are moved, the neurons will continue to fire in relation to the new cue positions, indicating that allocentric (outside self) visuospatial information is important for the activity of these neurons. Because of their location-specific firing, these neurons are referred to as "place" cells. Based on these findings, O'Keefe and Lynn Nadel proposed that in a new environment, stable place cell firing patterns develop which allow the animal to form a spatial map that can be used to navigate in space (O'Keefe and Nadel, 1978). Consistent with this, if a rat is allowed to freely explore a room and form stable place fields, then is blindfolded, the place cells will continue to fire based on where the animal "thinks" it is within the room. From these and other observations, behavioral tasks have been designed to specifically test the involvement of, and neuronal changes within, the hippocampus during spatial learning and memory (*Figure 19-4*).

One such task, the Morris water maze (named for its inventor, Richard Morris), was designed to test the influence of temporal lobe lesions on spatial memory (Morris et al., 1986). In this task, the goal for the animal is to locate an escape platform submerged under opaque water using only extra maze cues located throughout the room. With repeated training, the animal's latency to locate the platform decreases. This decrease in latency is used as an indicator of memory acquisition. Memory retention can be tested by removing the platform and measuring the time spent in the area in which the platform was located during training. Similar to the deficits observed in H.M., Morris and colleagues demonstrated that in the absence of the hippocampus, rats are incapable of learning or remembering the location of the hidden platform, demonstrating profound spatial deficits. Specifically, it was determined that the dorsal hippocampus in particular was important for spatial learning. In these studies, Morris demonstrated that even 25% of the hippocampus could support learning, if the residual tissue was located at the dorsal pole (Moser et al., 1995).

The radial arm maze, developed by David Olton, has also been used to provide evidence for a role of the hippocampus in spatial memory storage (Walker and Olton, 1979). In this task, eight passageways or "arms" radiate out from a central hub. Visual cues placed around the interior of the central hub or outside the maze, are used by the animals to identify the individual arms. Once placed in the maze, animals will explore the arms searching for food pellets placed at their ends. With repeated training, rats learn to use the visual cues to determine which arms have already been explored, successfully retrieving all food pellets after entering each arm only once. Hippocampally lesioned animals, by comparison, learn to search the arms as do normal animals, but fail to remember which arms have already been searched resulting in repeated entries into some arms while leaving others unexplored. These data suggest that although procedural learning and memory remains intact following hippocampal lesions (allowing the animal to perform the task), spatial memory is impaired requiring that the animal use a trial-and-error approach to finding the food pellets.

Figure 19-4

Spatial tasks can be used to examine explicit memory formation and storage in rodents. (a) The Morris water maze requires that the animal learn the position of a submerged platform using only allocentric (outside self) cues spread throughout the room. A computer-based tracking system allows for the interrogation of the search strategy and swimming path utilized by the animal to navigate to the platform from a distance. (b) The radial-arm maze tests spatial memory by allowing animals to use visual cues to identify those arms, which were baited with food during training. Correct and incorrect entries are counted and used as a measure of spatial learning and memory



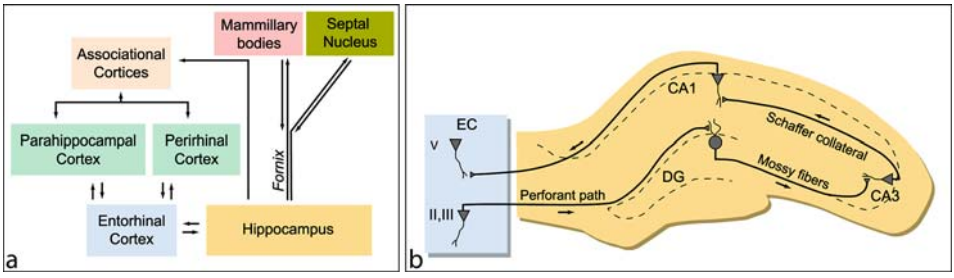
3.2.3 Neuroanatomy of the Hippocampal Formation

Explicit memory formation in the hippocampus begins with the flow of highly processed sensory information into the temporal lobe from cortical association areas such as the prefrontal and parieto-occipital cortices. Input first reaches the parahippocampal and perirhinal cortices, then the entorhinal cortex (*Figure 19-5*). The entorhinal cortex sends information to the hippocampus via a bundle of axons called the perforant path, which originate in the superficial cell layers II and III. These axons form synapses with the neurons of the dentate gyrus (DG), also called granule neurons because of their granular appearance under the microscope. As mentioned earlier, in 1966 Terje Lomo observed that following a period of conditioning stimulation, a single test stimulation of the perforant path caused a potentiated response in the DG. Later, Bliss and Lomo reported that trains of high frequency stimulation of the perforant path caused a sustained potentiation of synaptic transmission in the granule cells of DG (Bliss and Lomo, 1973). The granule neurons of the DG send their axons (called the mossy fibers) to the pyramidal neurons of the CA3 subfield, which in turn, send part of their projections to the CA1 subfield in a bundle called the Schaffer collateral. Information from the hippocampus returns to the deep layer (layer V) of entorhinal cortex, then to the parahippocampal and perirhinal cortices and finally back to the associational cortices. The hippocampus also has direct connections with neocortical areas such as the PFC. In addition, efferent and afferent connections via the fornix link the hippocampus to the mammillary bodies of the hypothalamus (postcommissural fornix) and to the septal nuclei (precommissural fornix).

The fornix, which projects to the septal and the mammillary nuclei, is a structure that is very important for hippocampal function. Substantial input from the septal nucleus and the nucleus basalis of Meynert (also called the diagonal band of Broca) supplies the hippocampus with cholinergic input via the fornix, which is essential to hippocampal function. Therefore, damage to the fornix results in memory deficits similar to those seen with hippocampal damage. Alzheimer's disease, which is characterized by a progressive memory loss, partially results from the loss of cholinergic input to the hippocampal formation as well as other brain regions.

Figure 19-5

a. Explicit or spatial information enters the hippocampus from various association cortices such as prefrontal and parieto-occipital cortices. From there, information enters the parahippocampal and perirhinal cortices, then the entorhinal cortex (EC) and finally enters the hippocampus where it is thought to be stored temporarily. The hippocampus also sends projections to and receives projections from mammillary and septal nuclei via the fornix. b. Information from the entorhinal cortex travels via the perforant path into the hippocampus. Granule cells in the dentate gyrus (DG synapse with the perforant path, while their axons (the mossy fibers) project to the pyramidal neurons of the CA3 subfield. Output from the CA3 pyramidal neurons travels to the CA1 subfield via the Schaffer collaterals. Among other areas, information leaving the hippocampus is returned to the entorhinal cortex. The EC also sends information directly to the dorsal CA1 region thereby bypassing the trisynaptic circuit (not shown)



3.2.4 The Entorhinal Cortex and Memory

As shown in *Figure 19-5*, the hippocampus receives information from and sends information to the neocortex via the entorhinal cortex. It is well accepted that the entorhinal–hippocampal circuit is obligatory for performance in spatial memory, as disruption of this structure results in an interruption in the flow of information into and out of the hippocampus. However, the role of the entorhinal cortex in memory storage has only recently been explored. Studies using noninvasive approaches that selectively impair plasticity within the entorhinal cortex indicate that this structure not only stores long-term memory, but that this information is not redundant with that stored within the hippocampus (Hebert and Dash, 2002, 2004). For example, blockade of plasticity in the hippocampus results in a loss of precise location information, whereas inhibition of information storage in the entorhinal cortex results in a loss of broad location information. These influences can be observed during memory testing of rats following Morris water maze training. In the absence of hippocampal memory storage, rats will enter the quadrant of the maze, which previously contained the platform, but will not perform a localized search. Rather, the rats will return to the tank wall to reorient themselves before reentering the target quadrant, only to once again abandon the search. In contrast, animals lacking entorhinal information storage aimlessly swim within the tank. If, by chance, the animal swims into the immediate proximity of the platform, it begins a localized search. Taken together, these results suggest that information stored in these two structures may allow for navigation from a distance (entorhinal) to a precise (hippocampus) unmarked goal.

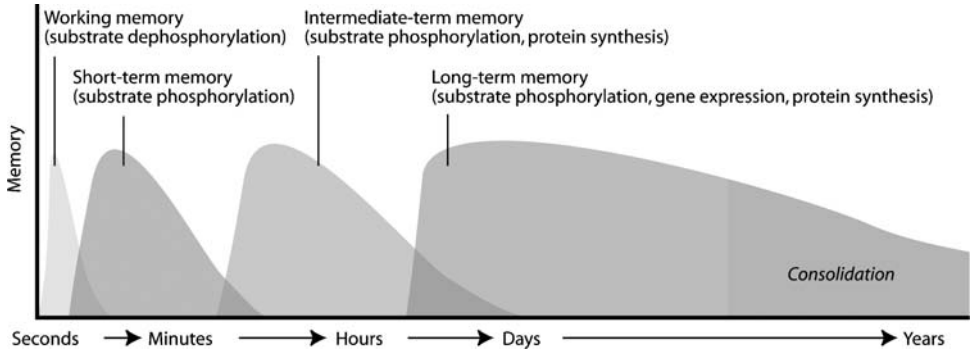
4 Each Phase of Memory Storage Requires Distinct Molecular Events

Based on the duration, memory is thought to have four phases: working (lasting seconds), short- (lasting minutes to hours), intermediate- (lasting several hours), and long-term memory (lasting days to a lifetime). Engagement of different phases of memory depends on the amount and pattern of training as well as on the learning paradigm. Recent experiments are beginning to address if the different phases of memory are interdependent or if they can develop independently of one other. For example, can long-term memory

be formed in absence of short-term memory? As we will see, distinct molecular mechanisms underlie these phases of memory (*Figure 19-6*) and in some situations, memory phases can develop independently.

Figure 19-6

Different phases of memory allow for the storage of information ranging from seconds to years. Working memory (lasting for up to 20 seconds), short-term memory (lasting for minutes), intermediate-term memory (lasting for hours) and long-term memory (lasting for hours to days) can be distinguished not only by their temporal profiles, but also by the underlying molecular mechanisms. Long-term memories can become permanent through a process called consolidation. Although it was thought that the memory phases are interdependent, giving rise to a temporal continuum of memory, recent experiments suggest that the different phases of memory may develop independently



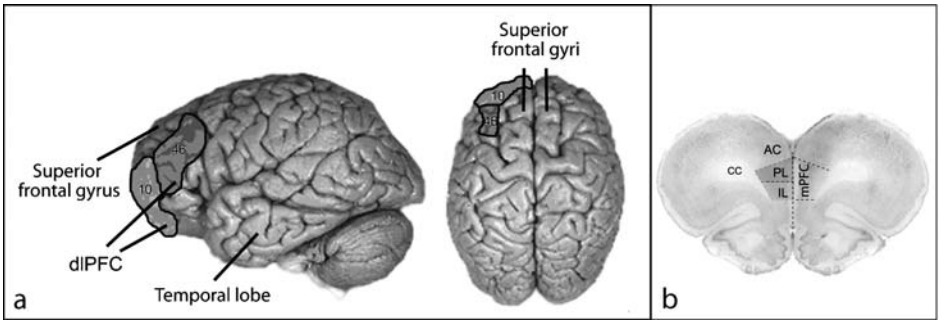
4.1 Working Memory Requires Persistent Neuronal Activity and Calcium-Sensitive Phosphatase Activity

Working memory is defined as the process of actively maintaining and integrating information for a relatively short period of time for directing goal-oriented action (Fuster, 1973). A common example is remembering a phone number long enough to dial the number. Once the number is dialed, the memory for the number is forgotten. As discussed in *Section 6*, working memory is also necessary for recreating or retrieving previously stored memory. It is thought that reverberating neuronal activity maintains working memory. Electrophysiological recordings and functional imaging studies have indicated the involvement of the dorsolateral PFC in monkeys and humans in working memory (*Figure 19-7*). In rats, the medial part of the prefrontal cortex (mPFC) is considered to be the homologue of the primate dorsolateral PFC. Several tasks, such as the delay match-to-sample and delay non-match-to-sample, have been developed to evaluate working memory function in animals. In these task, animals are required to remember a cue for a period of seconds (the delay period) in order to perform an appropriate response. For example, in a delay match-to-sample task, a monkey is shown an object (e.g. a blue ball) that is then hidden from view for a period of 5 seconds. After the delay, the subject is shown the same blue ball along with another, novel object (e.g. a red cube). The animal must correctly identify the blue ball as the familiar object in order to receive a food reward. In a delay non-match-to-sample task, the monkey must identify the novel object (e.g. the red cube in the above example) as the non-matching object. 'Delay cells' within the PFC of monkeys and rats have been shown to remain active during working memory tasks, suggesting that these neurons may transiently store information (Fuster and Alexander, 1971). Appreciation of the importance of the PFC, and delay cells in particular, has facilitated the design of experiments to test the molecular mechanisms underlying working memory.

The work of Brozoski et al. was the first to demonstrate that dopamine plays a critical role in the modulation of the working memory function of the PFC (Brozoski et al., 1979). In this experiment,

Figure 19-7

a. Color-shaded regions represent approximate anatomical location of dorsolateral prefrontal cortex (Brodmann areas 10 and 46) involved in working memory. b. Location of the rodent medial prefrontal cortex (PL+IL) in a representation of a coronal brain section. AC: anterior cingulate, cc: corpus callossum, PL: prelimbic cortex, IL: infralimbic cortex

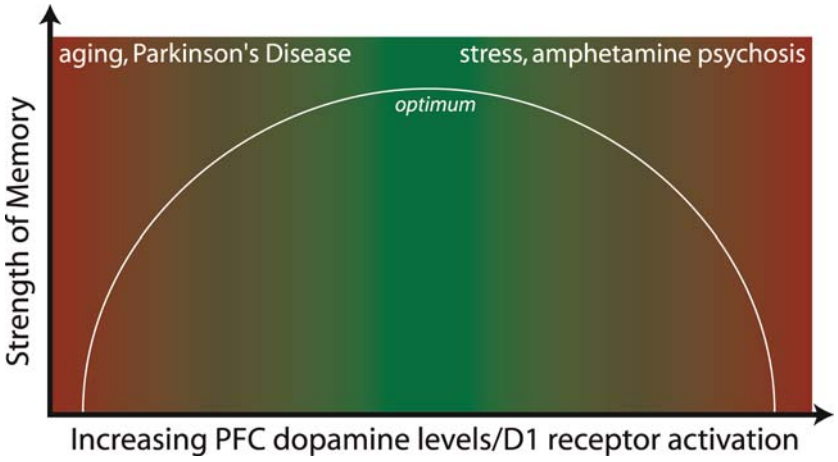


depletion of dopamine in the PFC of rhesus monkeys produced impairments in working memory performance nearly as severe as that caused by surgical ablation of the same area. Furthermore, this behavioral deficit could be pharmacologically reversed with L-DOPA or apomorphine, a mixed dopamine D1/D2 receptor agonist. The involvement of dopamine is further supported by electrophysiological recording in monkeys performing working memory tasks in which iontophoresis (a method of administering a compound using an electric current) of dopamine onto dorsolateral prefrontal neurons enhanced memory-related firing during the delay period (Williams and Goldman-Rakic, 1995). Although D1 receptor stimulation appears to be integral for proper working memory, overstimulation can impair working memory function. It has been recognized for more than 20 years that exposure to even mild stress greatly increases dopamine (as well as norepinephrine) levels in the PFC, and that these changes in neurotransmitter levels are associated with impaired working memory function. In contrast, exposure to mild stress has little effect or actually improves performance of tasks dependent on the inferior temporal cortex or cerebellum. These and other studies indicate that a limited range of dopamine levels in the PFC is optimal for working memory function. Both excessive and insufficient dopamine receptor stimulation can impair working memory performance giving rise to an inverted "U-shaped" dependency of working memory on dopamine levels (*Figure 19-8*).

Dopaminergic projections to the PFC originate predominately from the ventral tegmental area (VTA), and are often referred to as mesoprefrontal dopamine projections. Dopamine receptors are metabotropic, G-protein coupled receptors that induce their effects on neuronal activity through the stimulation or inhibition of the activity of intracellular enzymes. There are two different types or classes of dopamine-binding receptors: D1-type receptors comprised of D1- and D5- receptor isoforms (which can increase cAMP levels) and D2-type receptors comprised of D2-, D3-, and D4- receptor isoforms (which decrease cAMP levels). As indicated in *Figure 19-8*, working memory is dependent on, and is highly sensitive to, D1 receptor activity. Stimulation of D1 receptors increases cAMP formation and the activity of cAMP-dependent PKA. Although many of the actions of dopamine are thought to be mediated by the PKA cascade, it has been shown that inhibition of PKA activity in the PFC does not interfere with working memory. In contrast, stimulation of PKA activity by intraprefrontal infusion of Sp-cAMPS, a membrane permeable cAMP analogue that is resistant to breakdown by phosphodiesterases, impairs working memory in normal animals (Taylor et al., 1999). This suggests that although PKA activity is not required for the formation of working memory, excess PKA activity actually interferes with the process. Interestingly, the aging-associated decline in working memory can be blocked by the cAMP analogue Rp-cAMP, an inhibitor of PKA, suggesting that an increase in prefrontal PKA activity as a result of aging may underlie some of the working memory problems observed in this population.

Figure 19-8

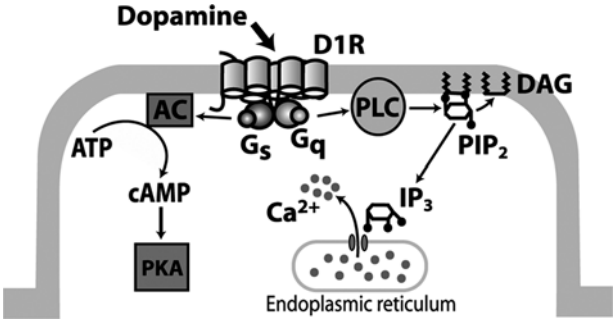
An inverted ''U''-shaped function for the role of PFC dopamine/D1 receptors in working memory. Physiological and behavioral studies indicate that normal working memory functions only within a limited range of dopamine D1 receptor activation. When prefrontal dopamine is below the optimal range (as in aging and Parkinson's disease) or above the optimal range (as occurs in stressful situations and amphetamine psychosis), working memory is impaired. Increasing D1 receptor activation (agonism) in low dopamine conditions, and decreasing D1 receptor activation (antagonism) in high dopamine conditions, improve working memory. Figure adapted from Goldman-Rakic (2000)



In addition to stimulating cAMP signaling, D1 receptors can increase phospholipase C activity via the $G_{q/11}$ proteins (*Figure 19-9*). Phospholipase C cleaves membrane phosphatidylinositol phospholipids to generate diacylglycerol and inositol trisphosphate (IP_3). IP_3 causes calcium release from intracellular stores by binding to its receptor located on endoplasmic reticulum. Increased calcium release leads to the sequential activation of calcium/calmodulin-dependent phosphatase calcineurin, calcium/

Figure 19-9

Dopamine D1 receptor activation can increase intracellular levels of cAMP and calcium. Binding of dopamine to D1 receptors activates GTP-binding proteins G_s and $G_{q/11}$ which, in turn, stimulate the activities of adenylyl cyclase (AC) and phospholipase C (PLC), respectively. Adenylyl cyclase converts ATP to cAMP, which stimulates protein kinase A (PKA). PLC cleaves the membrane lipid phosphoinositide bisphosphate (PIP_2) to generate inositol trisphosphate (IP_3) and diacylglycerol (DAG). IP3 binds to its receptor on the endoplasmic reticulum causing the release of calcium, which stimulates calcium-sensitive enzymes such as calcineurin, calcium/calmodulin-dependent protein kinase and protein kinase C



calmodulin-dependent protein kinase (CaMK) and calcium/diacylglycerol-dependent PKC as calcium accumulates. Recent biochemical studies show that while calcineurin is required for working memory, activation of PKC and CaMK (similar to that observed for PKA activation) exert a negative influence (Runyan et al., 2005). It has been proposed that following small increases in intracellular calcium, the calcium/calmodulin-activated phosphatase calcineurin is activated, leading to the dephosphorylation of specific intracellular substrates. During working memory, activation of calcineurin may lead to the dephosphorylation of ion channels in the plasma membrane of prefrontal neurons. This dephosphorylation changes the biophysical properties of the neurons leading to enhanced activity during the delay period, thereby actively maintaining working memory. As calcium levels continue to rise as a result of neuronal activity and dopamine levels, PKC and CaMK (via calmodulin) become activated. Enhanced activity of these protein kinases increases the phosphorylation of channels (possibly those previously dephosphorylated by calcineurin), thereby decreasing or blocking delay period activity and working memory. As stated above, exposure to even mild stress has been shown to increase dopamine (and norepinephrine) levels resulting in impaired working memory. Thus, mild stress may impair working memory by increasing intracellular calcium to a level sufficient to activate calcium-dependent protein kinase activity, impeding the cell's ability to dephosphorylate substrates required to maintain delay activity. Consistent with this possibility, it has been shown that stress-induced working memory impairment is due to, in part, over activation of PKC (Birnbaum et al., 2004).

4.2 Short-Term Memory Requires Kinase Activation and Phosphorylation of Preexisting Proteins but not Protein Synthesis or Gene Expression

A learning event leading to short-term memory formation (lasting minutes) causes the release of glutamate and other neurotransmitters. These neurotransmitters act upon their receptors located on postsynaptic neurons resulting in their depolarization and increase in the levels of intracellular calcium (which is approximately 100 nM in resting neurons). Increases in the levels of intracellular calcium can directly (CaMKII, PKC) and indirectly (PKA) stimulate the activity of intracellular second messenger cascades. For example, short-term sensitization of the gill-withdrawal reflex in *Aplysia* results in the release of serotonin (5-HT) from presynaptic interneurons onto the siphon sensory neurons. Binding of released 5-HT with its receptor activates the enzyme adenylyl cyclase resulting in increased cAMP levels. Among other things, this rise in cAMP leads to activation of PKA, which phosphorylates specific potassium channels (S- or serotonin-sensitive potassium channel) (Shuster et al., 1986). Phosphorylation of this channel causes prolonged channel closure, thus preventing the efflux of potassium to the extracellular space and slowing repolarization. The increase in intracellular potassium causes broadening of the action potential (since the neuron cannot quickly repolarize) allowing for more Ca^{2+} entry and enhancing transmitter release (a presynaptic mechanism for short-term memory). Moreover, the closing of the potassium channel increases the input resistance of the membrane because fewer channels are open at rest, thereby increasing neuronal excitability (i.e., more action potentials in response to the same level of depolarization) and transmitter release. As a result of these transient changes, the same stimulus can, for a short time, elicit greater transmitter release and a larger response. As long as the channels remain phosphorylated (which is on the order of minutes), short-term memory persists. Eventually, the channels are dephosphorylated by protein phosphatases, returning the neuron to a lower state of activity allowing the memory to decay. Thus, the underlying molecular mechanisms required for the formation of working memory, and those required for short-term memory, appear to be antagonistic. Recently, short-term memory mechanisms that are independent of the phosphorylation of potassium channels and the duration of action potential have also been identified (Sugita et al., 1997).

The biochemical mechanisms involved in explicit learning and memory were first demonstrated in rats performing the Morris water maze task. Richard Morris and colleagues demonstrated that rats injected with AP5, a NMDA-selective antagonist, have impaired spatial memory formation (Morris et al., 1986). Subsequently, it was shown that mice lacking the NMDAR1 subunit (also called NR1) of the NMDA receptor (resulting in impaired calcium conductance) have similar impairments (Sakimura et al., 1995).

Interestingly, overexpression of the NMDAR2B subunit (also called NR2B) of the NMDA receptor, which allows more calcium entry, enhances memory formation. As described above, calcium influx activates intracellular second messenger kinases. Studies in rats and mice have shown that inhibition of CaMKII, PKC, or PKA by pharmacological inhibitors or genetic techniques impairs short-term spatial- and fear memory, indicating that increased protein phosphorylation is required for short-term memory. For example, genetically modified mice lacking the alpha subunit of CaMKII, as well as those with a constitutively active form of the enzyme (caused by a substitution of the autophosphorylation site Thr^{286} with an Asp), have impaired spatial memory formation. In these mice, hippocampal place cells are unstable, suggesting that the animal cannot form a spatial map. Consistent with a requirement for substrate phosphorylation in short-term memory, inhibition of the calcium-sensitive protein phosphatase calcineurin leads to short-term memory enhancement (Malleret et al., 2001). These findings are consistent with those observed in *Aplysia* and other model systems, demonstrating that the molecular mechanisms underlying short-term memory have been conserved throughout evolution.

The PKC family of protein kinases is subdivided into three types according to their mechanism of activation: conventional (α, β(1), β(2), and γ), novel (δ, ε, η, θ and μ), and atypical (ζ, λ and τ). Conventional PKC isozymes are activated in response to increases in intracellular calcium and binding to diacylglycerol as a result of phospholipase C activity. Novel PKCs require diacylglycerol, but not calcium. Atypical isoforms are dependent on neither calcium nor diacylglycerol for activation. Structurally, PKC isoforms are single polypeptides consisting of two domains: (a) the N-terminal regulatory domain contains binding sites for cofactors and a pseudosubstrate (a pseudosubstrate has a consensus sequence for phosphorylation without a Serine/Threonine) that inhibits the kinase activity and (b) the C-terminal catalytic domain. The role of PKC activity in memory storage has been addressed both pharmacologically as well as with knockout mice. For example, administration of phorbol esters, which can activate novel and conventional isoforms of PKC, have been found to elicit synaptic enhancement which is indistinguishable from LTP (Malenka et al., 1986). These effects, as well as LTP itself, could be blocked by the PKC inhibitors polymyxin B and K-252b (Reymann et al., 1988a, b). Once activated, PKC translocates from the cytosol to the cell membrane where it is thought to phosphorylate several plasticity-related proteins including the presynaptic protein growth associated protein 43 (GAP43) and the postsynaptic calmodulin reservoir protein neurogranin. Although the involvement of PKC activity in neuronal plasticity has been well described, the roles of the individual isozymes have yet to be fully explored.

Although the mechanisms by which each of these kinases enhances short-term explicit memory has not been fully delineated, activation of silent synapses as result of AMPA receptor insertion (a postsynaptic mechanism for short-term memory) or inactivation of potassium channels are possibilities. Phosphorylation of AMPA receptors by protein kinases is a required step for their insertion at the postsynaptic site. Both PKC and CaMKII can phosphorylate GluR1 subunit of AMPA receptors at the same site at Ser^{831} (Barria et al., 1997). In addition, prolonged activation of PKC via the calcium-stimulated neutral protease calpain has also been implicated in certain types of short-term memory. In response to increases in intracellular calcium, calpain activity is increased resulting in the cleavage of specific substrate proteins such as PKC. Multiple PKC isozymes can be cleaved by calpain (removing the N-terminal regulatory domain) to generate constitutively active kinases (referred to as PKM) that can continue to phosphorylate substrate proteins even after calcium concentrations have returned to normal levels. In addition, PKM can diffuse away from the plasma membrane, freeing it to possibly interact with and phosphorylate targets distinct from membrane bound PKC isoforms. Although the specific substrates of PKM are still being identified, this may represent one mechanism by which protein phosphorylation is maintained, giving rise to short-term memory formation.

Although short-term memory requires protein phosphorylation, it is independent of new protein synthesis and gene expression. As discussed in the following sections, longer-lasting forms of memory result from neuronal changes, which persist beyond the temporal limitations of protein phosphorylation. While activation of protein kinases is still critical for these forms of memory, long-lasting neuronal changes require the synthesis of new proteins.

4.3 Intermediate-Term Memory Requires Protein Synthesis from Preexisting mRNA

Memory lasting for hours has been classified as intermediate-term memory. Unlike short- and long-term memory, the molecular mechanisms contributing to intermediate-term memory are only recently beginning to be examined. Studies performed in *Aplysia* indicate that a correlate of intermediate-term memory (synaptic facilitation) lasts for over 2 h, while short-term facilitation lasts less than 30 min (Sutton et al., 2004). Mechanistically, intermediate-term memory differs from short-term memory in its requirement for protein synthesis. Inhibition of protein synthesis by drugs such as anisomycin or gelonin blocks intermediate-term memory without interfering with short-term memory. Interestingly, protein synthesis at synaptic sites, but not in the soma, is required for intermediate-term memory formation suggesting a synaptic mechanism of induction (Sherff and Carew, 2004). Messenger RNAs for several molecules implicated in memory formation (e.g., CaMK II, Fragil X, nur77, PKMξ) and structural proteins [e.g., tubulin and microtubule associated protein 2 (MAP-2)] are found within the dendrites and perhaps at the synapse. How can a learning event activate synaptic protein synthesis? One model that can be envisioned is based on recent findings by Kandel and colleagues in *Aplysia*. These researchers have shown that the cytoplasmic polyadenylation element binding protein (CPEB) and its mRNA are present in the sensory-motor neuron terminals involved in the gill-withdrawal reflex (Si et al., 2003). CPEB is capable of increasing protein synthesis by elongating the poly A tails of mRNA. The release of neurotransmitters (serotonin in *Aplysia*) at specific synapses as a result of learning can activate CPEB (possibly via phosphorylation-induced conformational change, protein aggregation and/or enhanced CPEB synthesis), which would lead to enhanced synaptic protein synthesis required for intermediate term memory. An interesting aspect of CPEB is its ability to remain active via oliogomer formation and propagation of activity to newly synthesized CPEB via a prion-like mechanism. Such a self-propagating activity could be used to maintain intermediate-term memory.

The continuous activity of a specific isoform of PKC (PKMξ) has also been shown to maintain LTP in the rat hippocampus and associative memory in *Drosophila* (Drier et al., 2002). PKMξ is related to PKCξ, but it lacks the regulatory N-terminal domain making it autonomously active (Hernandez et al., 2003). The absence of the N-terminal domain was originally thought to be due to proteolytic cleavage of PKCξ, but recent evidence has demonstrated that PKMξ is translated directly from its own mRNA. PKMξ mRNA is localized at dendritic sites where it is normally repressed by BC-1, a nontranslatable mRNA that blocks the translation initiation complex. In response to learning, BC-1 repression is released allowing PKMξ mRNA to be translated into protein (*Figure 19-10*). Once translated, PKMξ phosphorylates dendritic receptors and channels which can maintain memory for hours. PKMξ activity has been shown to be not only necessary, but also sufficient for memory maintenance.

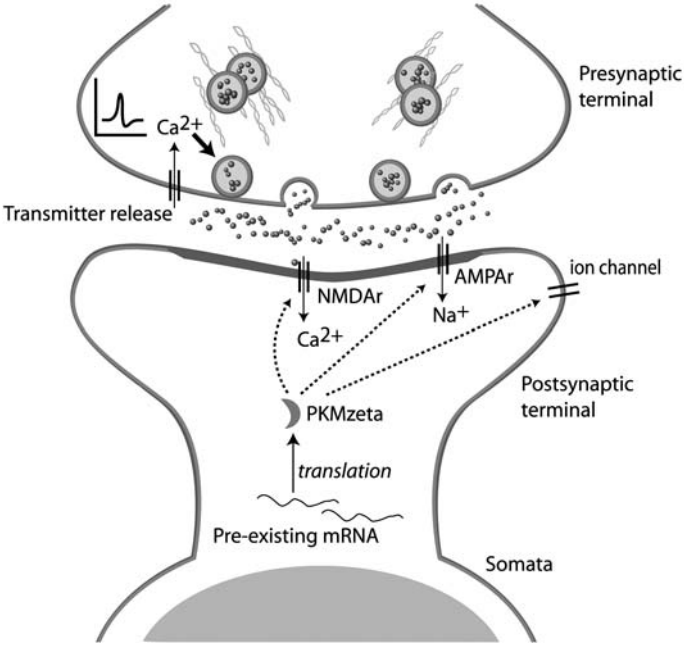
The duration of these protein synthesis-dependent persistent kinase activities determines the duration of intermediate-term memory. While intermediate-term memory requires local protein synthesis, its formation is independent of gene transcription. As seen below, the inhibition of transcription selectively impairs long-term memory without interfering with either short- or intermediate-term memory.

4.4 Long-Term Memory Requires Kinase Activation, Gene Expression, and Protein Synthesis

Similar to the shorter forms of memory, long-term memory formation begins with stimulation of neurotransmitter receptors as well as neurotrophic factor receptors during learning. Activation of NMDA receptors in conjunction with cell depolarization during learning causes a rise in calcium levels inside neurons. Elevations in intracellular calcium can activate several enzyme pathways including PKA (via adenylyl cyclase and increased cAMP), PKC, CaMK, and ERK cascades, each of which have been implicated in the formation of long-term implicit and explicit memories. Several studies demonstrated that, similar to

Figure 19-10

Translation of preexisting mRNA is required for intermediate-term memory. PKMξ mRNA is found in the dendrites of neurons where it is maintained in an untranslated state by its interaction with BC-1 (not shown). In response to learning, BC-1 repression is released, allowing PKMξ to be translated into protein. PKMξ, being constitutively active, can maintain the phosphorylation of ion channels and/or receptors for hours allowing memory to persist beyond the temporal limits of short-term memory



other forms of memory, long-term memory requires an optimal cAMP level. Consistent with this, decreased expression of G_i (a GTP-binding protein that inhibits adenylyl cyclase activity) in the rodent hippocampus results in a substantial increase in intracellular cAMP and impaired long-term spatial memory. In contrast, administration of rolipram, a cyclic nucleotide phosphodiesterase inhibitor, modestly increases cAMP levels and enhances long-term spatial memory.

As in short-term facilitation, long-term facilitation in *Aplysia* requires active PKA. As indicated before, binding of cAMP to PKA causes dissociation of the regulatory subunits from the catalytic subunit, and this catalytic subunit is responsible for phosphorylation of potassium channels. A protease (possibly proteosome or one of its subunits) that is synthesized as a result of behavioral training degrades the regulatory subunits leaving the catalytic subunit free (Chain et al., 1999). Inhibition of protein synthesis blocks this persistent kinase activity and memory. This results in persistent PKA activity that is independent of its requirement for cAMP, and thus receptor activation. The involvement of the cAMP/PKA cascade in memory formation in a wide variety of species including *Aplysia, Drosophila*, rats, and mice indicates an evolutionarily conserved mechanism for memory formation.

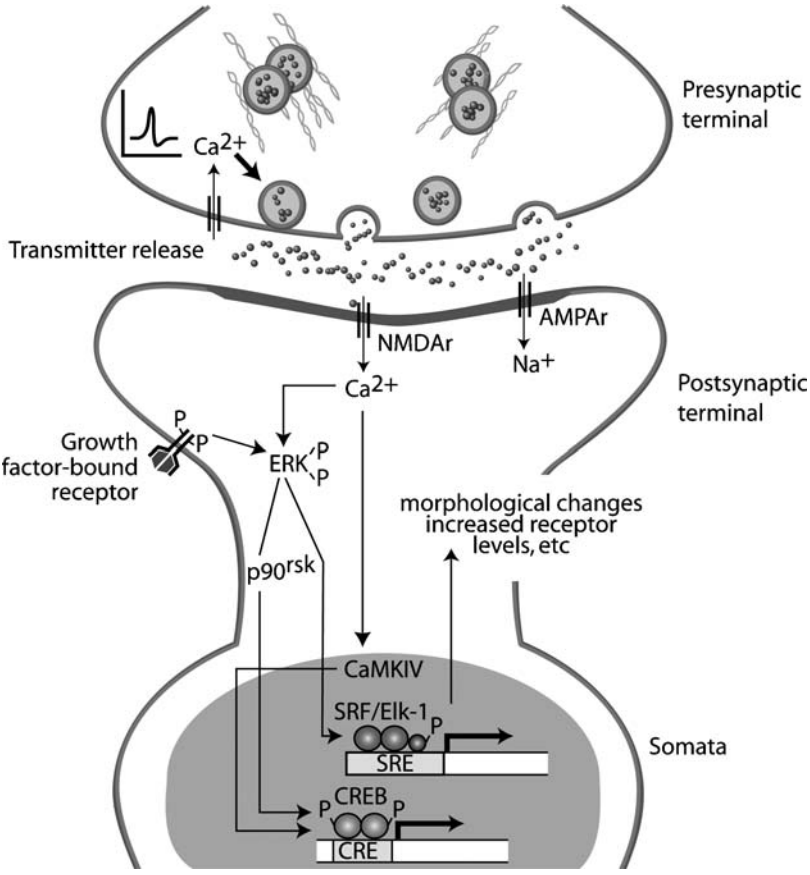
Increases in cAMP/PKA activity, as well as increases in intracellular calcium and neurotrophic factor signaling, can activate the ERK cascade. ERK is activated via dual phosphorylation on Thr and Tyr by the kinase MEK (MAP/ERK kinase). Using phosphorylation-specific antibodies for ERK, it has been demonstrated that training of rodents in the Morris water maze task increases ERK phosphorylation in hippocampal neurons. Furthermore, when ERK activation is inhibited in the hippocampus or the entorhinal cortex (the major input/output structure for the hippocampus, *Figure 19-5*) by infusion of pharmacological inhibitors of MEK, long-term memory is impaired. However, short-term memory remains

intact. Two isoforms of CaMK, CaMK II (primarily cytosolic), and CaMKIV (primarily nuclear) have also been demonstrated to be involved in memory. As discussed earlier, CaMKII activity appears to be necessary for the formation (learning) of spatial memory. In contrast, CaMKIV mutant mice show impairments in long-term spatial memory retention, and hippocampal late-LTP without having any appreciable differences in basic synaptic function or early-LTP (Kang et al., 2001). These effects of CaMKIV appear to be due to its ability to stimulate the expression of genes required for long-lasting changes in neuronal function.

Activation of the above mentioned protein kinases leads to long-term memory formation through their ability to phosphorylate and activate transcription factors, especially the cyclic AMP/calcium-response element binding protein (CREB) (*Figure 19-11*). The CREB protein was originally identified as the transcription factor that induces the expression of the *somatostatin* gene in response to increases in

Figure 19-11

A molecular model for the formation of long-term memory. Training-induced release of neurotransmitters (glutamate) and neurotrophic factors (BDNF) activates cell surface receptors and increases intracellular concentrations of second messengers (e.g., Ca^{2+} and cAMP). Second messenger-stimulated kinases phosphorylate the transcription factors CREB and SRF, as well as other transcription factors such as NFkB and C/EBP (not shown). Phosphorylated CREB protein increases the transcription of genes carrying the CRE (cAMP response element) sequence in their promotors. Some of these gene products activate late effector genes whose protein products are needed for synapse formation (or elimination) and/or enhanced excitability, transmitter release and receptor levels. These modifications result in the long-lasting changes in neuronal communication that underlie long-term memory storage



intracellular cAMP. CREB binds to a specific enhancer sequence called the CRE element (TGACGTCA) that is located in the promoter region of *somatostatin* and several other genes whose transcription is regulated by cAMP. A sustained increase in cAMP leads to the translocation of the catalytic subunit of PKA into the nucleus where it phosphorylates Ser^{133} of CREB. Phosphorylation of CREB on Ser^{133} recruits transcriptional coactivators to the promoter complex and enhances mRNA transcription (Yamamoto et al., 1988). CREB has also been shown to increase the expression of CRE-sequence containing genes in response to increased intracellular calcium levels, or activation of ERK. It is thought that CaMKIV, which is localized in the cell nucleus, phosphorylates CREB on Ser^{133} in response to sustained calcium level increases, whereas ERK can indirectly lead to CREB activation via $p90^{rsk}$. Thus, CREB can act as a convergence site for several protein kinases implicated in memory formation.

The first study demonstrating the involvement of CREB in long-term memory was carried out in *Aplysia* (Dash et al., 1990). Long-term facilitation was found to require CREB mediated gene expression because microinjection of CRE decoy oligonucleotides into the nucleus of *Aplysia* sensory neurons blocked this phenomenon. This effect was specific to long-term facilitation, as CRE oligonucleotide injection did not affect the short-term facilitation caused by brief 5-HT application. Following these discoveries in *Aplysia,* it was demonstrated that mutation of the *Drosophila* CREB gene (*dCREB2*) impairs long-term memory for classical conditioning (Yin et al., 1994). Interestingly, overexpression of CREB may enhance long-term memory in this task. In addition, genetically altered mice carrying targeted disruptions of selective CREB isoforms also show impaired spatial memory. Since these isoforms of CREB were missing throughout development of the animal, one could argue that observed deficit is due to some subtle developmental abnormalities (Bourtchuladze et al., 1994). This potential problem was eliminated by decreasing CREB protein levels in adult animals by injecting antisense oligonucleotides directly into the hippocampi. Similar to the impairments seen in CREB null mice, animals receiving antisense oligonucleotides displayed long-term spatial memory deficits.

Since these initial experiments which demonstrated a requirement for CREB in long-term memory storage, several other transcription factors have been implicated including NFkB, SRF, zif268, c-Fos, c-Jun, Jun-B, and C/EBP (*Figure 19-11*). For example, intrahippocampal infusion of double-stranded oligonucleotide decoys containing the binding sites for either nuclear factor kappaB (NFkB) or serum response factor (SRF) impair long-term spatial memory (Dash et al., 2004). NFkB, when bound to its regulatory protein IkB (inhibitor of NFkB), is normally cytosolic. Upon appropriate stimulation, IkB is phosphorylated and quickly degraded, unmasking the nuclear localization sequence in NFkB allowing it to translocate to the nucleus and initiate gene expression (Mercurio et al., 1997). As this phosphorylation of IkB can be blocked by inhibitors of the ERK cascade and ERK has been shown to phosphorylate the SRF/Elk-1 complex leading to enhanced subunit interaction and DNA binding (Gille et al., 1995), this suggests that these transcription factors may mediate some of the memory-related gene expression changes initiated by activation of the ERK cascade. Consistent with this, sequestration of SRF resulted in memory deficits, which appear to result from a loss of precise platform location information, effects consistent with those observed following inhibition of the ERK cascade in the hippocampus (Hebert and Dash, 2004).

4.4.1 Morphological Changes and Storage of Long-Term Memory

Ramon y Cajal was the first to postulate that morphological changes at the synapse may underlie lasting memories (Ramon y Cajal, 1911). Later, studies in both vertebrates and invertebrates showed that long-lasting morphological changes in the neurons involved in learning are likely to constitute the underlying cellular mechanism for long-term memory storage (Bailey and Chen, 1989). Long-term behavioral sensitization and habituation in *Aplysia* involves significant structural changes in the sensory neurons. It has been shown that the number of synaptic varicosities, the number and size of active zones, and the number of synaptic vesicles all change following long-term training (Nazif et al., 1991). When compared to untrained control animals, these morphological features increased in long-term sensitized animals, whereas they decreased in long-term habituated animals. Similar to long-term sensitization training, 5-HT or cAMP

treatment of *Aplysia* sensory neurons in culture also produce morphological changes that have been shown to be dependent on protein and RNA synthesis, possibly as a result of CREB-mediated gene expression.

Examples of morphological changes associated with memory formation have also been observed following LTP induction in the CA1 and DG subfields of the hippocampus and in intact, behaving animals. As discussed above, several aspects of synaptic structure appear to change with experience. The most consistent of these structural alterations is an alteration in the number and/or pattern of synaptic connections. The formation of additional synaptic connections as a result of training is thought to increase the synaptic efficiency between two neurons by allowing more neurotransmitter release in response to presynaptic stimulation (*Figure 19-1*). As the addition of new synaptic connections is likely to be longer lasting than increases in transmitter release caused by the phosphorylation of ion channels and receptors, changes in the morphology of neurons allow for longer lasting forms of memory.

4.4.2 Synaptic Tagging

Long-lasting forms of synaptic plasticity (or synaptic efficiency) have been shown to require gene expression and protein synthesis. Since genes are transcribed at the nucleus in the cell soma, the signals generated locally at a synaptic site must be propagated to the nucleus, and the gene products, in turn, transported from the nucleus to the synapse. As the newly synthesized proteins are transported to all synapses, this raises the question of how gene products can be targeted to the specific synapse(s) where modification is needed. Frey and Morris showed that once long-term plasticity has been induced in one pathway of a hippocampal slice, this long-term change can be "captured" by a second pathway with a stimulus that would normally produce only short-term changes (Frey and Morris, 1997). Using a single bifurcated *Aplysia* sensory neuron that forms synapses with two motor neurons, Martin and colleagues independently demonstrated the synaptic "capture" phenomenon which led to the formulation of the "synaptic tagging" hypothesis (Martin et al., 1997). This hypothesis proposes that following the induction of long-lasting plasticity at a specific synapse (called the tagged synapse), gene products are synthesized and are delivered to all the synapses of a neuron, but are incorporated into only the synapse that has been "tagged" by previous synaptic activity. In addition, since gene products are transported to all the synapses of a neuron, a weak stimulation at a previously unstimulated synapse can utilize the gene products that are already present to induce long-lasting plasticity at this second synapse. Recently, Kandel and colleagues have proposed a molecular mechanism for synaptic tagging (Si et al., 2003). In this model, CPEB (the self-propagating protein suggested to play a role in intermediate-term memory, *Section 4.3*) marks the active synapse until new gene products arrive for the cell soma.

5 The Consolidation of Memories

Long-term storage of explicit memories requires a process of consolidation, a concept and term that was first introduced by Muller and Pilzecker in 1888, when they proposed that learning does not immediately induce permanent memories but that this requires a period of time for memory to be "consolidirung" (consolidated). During this period of time, memories remain vulnerable to disruption. Memory consolidation can therefore be defined as the process by which information becomes resistant to disruption within the brain, though it is not known exactly why a consolidation period is necessary. This requirement is illustrated by the retrograde amnesia observed following traumatic brain injury. These patients demonstrated temporally-graded retrograde amnesia in that older memories were found to be spared while more recent memories were lost.

Although it is clear that the medial temporal lobe plays an integral role in memory formation, there has been considerable discussion about what function the medial temporal lobe performs that is necessary for the consolidation of explicit memory. From this debate, two conclusions can be made about the medial temporal lobe's involvement in memory consolidation: (1) it is required for the formation of usable

memory, and (2) it supports explicit memory for a period of time during which the memory is more susceptible to disruption. However, it is thought that permanent memory storage occurs outside the medial temporal lobe, within the higher association areas of the cerebral cortex. The medial temporal lobe is connected to many cortical areas, including the higher association areas, via the perirhinal and enthorhinal cortices as well as the formix and anterior commissure. It has been suggested that this connectivity would allow for a time-limited involvement of the medial temporal lobe in the storage and/or retrieval of memory representations within these cortical loci. However, it has also been proposed that certain types of memory pertaining to contextual and specific spatial representations are permanently stored within the hippocampus.

5.1 Consolidation Models

5.1.1 The Standard Model

In 1900, Muller and Pilzecker proposed that the formation of permanent memory takes time, and that during this period memory remains vulnerable to disruption. As indicated in *Section 3.2*, the patient H.M. showed profound amnesia for recent explicit memories with earlier memories remaining intact. From these observations, the Standard Model for memory consolidation was developed in order to explain the occurrence of progressively worse amnesia for more recent memories compared to remote memories (i.e., temporally graded retrograde amnesia) following hippocampal damage. This model posits that memory is initially stored in the hippocampus using sparse, nonoverlapping representations. Over time, the hippocampus induces a distributed representation of the memory in the neocortex, after which the hippocampus is no longer required (Marr, 1971). The time course for the development of this distributed neocortical representation is the key determinant for the duration of systems consolidation.

In 1985, Teyler and DiScenna proposed a variation of the Standard Model that stated that LTP in the hippocampus initially stores an index of the neocortical areas activated by the experience (Teyler and DiScenna, 1985). During memory retrieval, this hippocampal memory storage is necessary for reactivating the unique pattern of cortical areas involved in the original experiential event in the same spatio-temporal sequence. Over time, repeated hippocampal reactivation of a set of neocortical areas composing an experiential event is proposed to be involved in establishing a cortically based memory trace that is capable of hippocampus-independent memory retrieval.

5.1.2 The Multiple Trace Theory

The Multiple Trace Theory (MTT) was proposed to explain observations of flat retrograde amnesia (the loss of both recent and remote memories equally) for episodic memory (memory of a personally experienced event) following hippocampal damage (Nadel et al., 2000). The MTT incorporates a key feature of the Standard Model in the idea that the hippocampal complex (hippocampus proper, subiculum, entorhinal and perirhinal cortices, and parahippocampus) rapidly encodes all information. However, the MTT states that only nonepisodic memories (memories for facts and concepts, also called semantic memory) become hippocampus-independent over time and that episodic memory remains bound to the hippocampus. According to this theory, each reactivation of a memory results in the creation of a new hippocampally-stored memory trace. Over time, as more traces for a memory are created, the memory encompasses an increasingly larger hippocampal area. Therefore, a partial hippocampal lesion would not result in amnesia for older memories, but would give rise to a pronounced amnesia for recent memories. Complete hippocampal lesions were proposed to result in flat retrograde amnesia for hippocampal-dependent memories. However, animal studies have revealed that complete removal of the hippocampus in rats can result in a temporally graded amnesia for spatial and other hippocampal-dependent memories. Consistent with these experimental findings, it has been reported that patients with severe damage to the hippocampal

region demonstrate a temporally graded retrograde amnesia for episodic- and semantic-, as well as spatial- and non-spatial memory.

5.1.3 The "C" Theory

There is increasing evidence that long-term memory-associated molecular changes occur in both the hippocampus and the neocortex as a direct result of learning. As outlined in the previous sections, some of these early changes have been shown to be required for long-term memory. These data are not accounted for by the previous consolidation theories that maintain that initial memory storage takes place solely within the hippocampus. In addition, these previous theories do not account for the apparent longer consolidation periods in species with physically larger brains. To account for these observations, the C theory was proposed (Dash et al., 2004). This theory postulates that the initial learning event triggers changes in gene expression in neurons within both the hippocampal and neocortical areas (and possibly subcortical areas), resulting in memory storage in these structures after learning. During recall, the hippocampus serves as an initial memory coordinator for the retrieval of the components of memories stored in these neocortical and subcortical areas. This is in contrast to the Standard Model (*Section 5.1.1*) which proposed that the hippocampus itself induces memory storage in the cortical areas.

The period in which the hippocampus is required as the coordinator is the time required for consolidation. As mentioned earlier, the length of this period seems to correlate with the size of the brain. The C theory proposes that, in addition to the hippocampus, the learning event also alters gene expression in the soma of other neurons, which connect the cortical and/or subcortical areas where components of memory are stored. However, until the gene products arrive at the synapses (which are likely to be tagged) of these cells to cause the required morphological changes, the hippocampus continues to coordinate retrieval and possibly maintain the synaptic tags. As the length of time required for the transport of proteins would be dependent on the length of the projections, larger brain sizes would require more time to develop this hippocampus-independent ability for memory retrieval.

6 The Retrieval of Memories

Explicit memory retrieval involves the conscious recollection of information acquired from past learning experiences. It is thought that information is retrieved by and held in mind through working memory in response to appropriate retrieval cues. Therefore, explicit memory retrieval involves prefrontal cortical regions. During memory retrieval, working memory assembles stored representations within cortical networks. In humans, memory encoding involves the left PFC more than the right, while the retrieval of stored memory activates the right prefrontal more than the left. This observation has led to the proposal that the lateralization of frontal lobe function in memory encoding and retrieval is due to the stronger involvement of the right hemisphere in emotional- and imagery-based autobiographical episodes.

There are some data supporting the view that memory loss results from a deficit in retrieval processes, rather than a loss of memory itself. For instance, patients with memory disorders show a benefit from recognition and contextual cues, suggesting that damage to the hippocampus, rather than resulting in the loss of memory per se, results in the inability to retrieve recent memories. These findings are consistent with the C theory since memory is initially formed not only in the hippocampus but also in the neocortex. Since the hippocampus initially coordinates retrieval of memory, damage to this structure would result in impaired retrieval of information stored in neocortical sites. Although the neurochemical basis of memory retrieval is not well understood, recent studies employing gene deletion techniques have implicated norepinephrine/epinephrine in the retrieval of spatial and contextual memory. For example, deletion of the gene encoding dopamine β-hydroxylase (DBH), the enzyme responsible for norepinephrine/epinephrine synthesis, results in impaired memory recall (Murchison et al., 2004). Interestingly, if a precursor for norepinephrine (L-DOPS), which can be converted to norepinephrine in the absence of DBH activity, is

injected into the hippocampus of *dbh* null mice prior to memory testing, their memory recall is normal. Pharmacological studies corroborate the role of norepinephrine in memory recall and further extend these findings to implicate the β1-adrenergic receptor in the retrieval process.

Recent studies also indicate that memory retrieval is not a passive process. These experiments have demonstrated that when a memory is reactivated (remembered), strong or robust memories can be temporarily suppressed if protein synthesis is impaired (Nader et al., 2000; Runyan and Dash, 2004a). For example, the association of a tone with a footshock in a trace conditioning paradigm (when the CS and US are separated by a time gap) requires hippocampal function and memory storage. As expected, if protein synthesis is impaired by anisomycin infusion immediately after training, cue-elicited long-term memory is impaired. If the memory is allowed to form, anisomycin infusion no longer has any effect. However, if a reminder (e.g., tone presentation) is given, then anisomycin is infused, and the original memory is lost. This effect appears to be related to memory strength, as weaker memories are not influenced by anisomycin infusion (Eisenberg et al., 2003). Although the reason for this effect is not known, this could arise from a weakening of the ability of the hippocampus to coordinate memory retrieval.

6.1 Forgetting and Memory Extinction

Forgetting is a normal process and several psychological theories have been proposed as to its cause (Mansuy, 2005). Dominant amongst these is the idea that memories are most often forgotten when they encounter interference during the consolidation period. Thus, older memories (those that have been consolidated) are predicted to decay at a slower rate than newer memories of the same synaptic weight. This interference could be the result of experiences, which are similar to the initial learning event, sometimes referred to as cue overload. However, interference cannot explain all forms of forgetting, especially those related to forced forgetting. This type of memory loss is most often observed in persons following a traumatic event such as sexual abuse.

Pathological conditions such as stroke, trauma, vitamin B1 deficiency (Korsakoff's syndrome), and following electroconvulsive therapy to treat depression, all result in forgetting (often referred to as amnesia). For example, electroconvulsive therapy is thought to interfere with gene expression and protein synthesis, impairing the consolidation of new memories while leaving older memories intact. Similarly, mild brain trauma can cause both limited retrograde (impairment of memory recall for events prior to the condition) and anterograde (impairment of new memory formation following the pathological condition) amnesias in the absence of overt cell loss, possibly by altering neuronal function via aberrant expression of genes and proteins.

Unlike forgetting, memory extinction is new learning and not an erasure of the initial memory. For example, if a CS is repeatedly presented in the absence of the original US, the conditioned response will be lessened. This reduction in response is thought to occur as a result of competing memory representations. Imaging studies in humans, and lesion studies in animals, have implicated the PFC in memory extinction. For example, patients with posttraumatic stress disorder (an anxiety disorder in which extreme distress occurs after a person is reminded of the event by a personal "trigger") have depressed ventral PFC activity (Bremner, 1999). Regardless of new experience, these patients are incapable of learning that the "trigger" does not predict a new traumatic event. Similarly, rats with mPFC lesions can acquire fear in a delayed tone-shock training paradigm, but require many more unpaired tone presentations to extinguish the fear than control animals (Morgan et al., 1993). In a recent study, Milad and Quirk demonstrated that tone (CS) paired with brief electrical stimulation of the infralimbic cortex (IL) (part of the mPFC, *Figure 19-7*) in a delayed conditioning paradigm caused enhanced memory extinction (Milad and Quirk, 2002). These and other studies show that PFC activity is required for memory extinction and that a loss of prefrontal function results in attenuated extinction. Since extinction is thought to be new learning, the process is likely to require some of the same molecular mechanisms necessary for memory formation. Consistent with this, inhibition of either protein synthesis or the ERK cascade within the mPFC impairs extinction memory (Hugues et al., 2004; Santini et al., 2004). When animals are tested a day or two following an extinction session, no reduction in the robustness of memory is observed.

7 Summary

Memory at the cellular level is stored via altered communication between neurons as a result of synaptic modulation and/or changes in excitability. Both explicit- (also called declarative memory requiring concious recollection) and implicit (also called nondeclarative memory) memory encoding utilize similar molecular mechanisms. Working memory, defined as the online holding of information for guiding behavior, is required for higher cognitive functions and is dependent on the function of the PFC. Both reverberating circuits within the PFC and intracellular protein dephosphorylation/phosphorylation, modulated by the action of dopamine and other neurotransmitters, are required for normal working memory. Short-term memory, lasting for minutes-to-hours, requires the phosphorylation of preexisting proteins including cell surface ion channels, and may involve insertion of AMPA receptors into the synapse resulting in enhanced synaptic communication. Intermediate-term memory, lasting for minute-to-hours requires the synthesis of proteins from preexisting mRNA, which may lead to prolonged kinase activation and protein phosphorylation. Long-term memory, lasting for days to a lifetime, is dependent on gene expression and protein synthesis giving rise to long-lasting morphological changes. This form of memory is dependent on the activation of specific transcription factors, of which CREB has been the best characterized. Explicit memory storage is initally dependent on the function of the hippocampus, a structure in the medial temporal lobe. These memories are made permanent by a process called consolidation, for which numerous theories have been proposed. The "C" theory posits that the molecular events underlying long-term memory storage are initiated in the hippocampus and neocortex (and possibly in subcortical structures) with similar time courses and that the period of hippocampal dependency is determined by the time required to transport the newly synthesized proteins to the appropriate cortical synapses. Explicit memory retrieval, like memory encoding, involves the PFC and working memory. During retrieval, working memory processes activate stored representations allowing for behavioral action, and if required, further modification of the memory. Memories can be actively suppressed by a process of extinction, in which new, conflicting memories compete. The molecular mechanisms underlying extinction appear to be similar to those involved in the original learning experience.

Acknowledgments

The authors would like to thank Drs. John H. Byrne and John Redell, as well as Diasinou Fiorovante, Evangelos Antzoulatos, and the members of the Dash laboratory for their critical readings of this material. 5 General Principles and Significance 763

Abstract: The reward system consists of multiple interactive neural systems. This chapter provides an overview of the neurotransmitters and brain regions involved with reward. The neural systems important for reward include brain areas involved in learning that a stimulus is rewarding or associated with reward and separate neural systems that mediate "wanting" and "liking" for a stimulus. The ascending dopamine systems are thought to be necessary for "wanting," whereas "liking" is mediated by GABAergic and opioid neurons in the nucleus accumbens shell in association with the ventral pallidum and parabrachial nucleus. The specific systems and molecular mechanisms mediating food reward versus the rewarding aspects of drugs of abuse are discussed. Sex differences in the reward system are highlighted.

1 Introduction

Some behaviors are exhibited because they result in the consummation of a primary reinforcer such as food, drink, or sex. Other behaviors are learned through association with primary reinforcers or conditioned reinforcers. The neural system that receives and evaluates the rewarding properties of stimuli has been known for some time as the reward system. In this chapter, the reward system is described as multiple interactive neural systems. The goal of this chapter is to provide an overview of the neurotransmitters and brain regions involved with reward, and to discuss sex differences in the reward system.

Historically, the ascending dopamine projection from the midbrain to the nucleus accumbens (NAcc) has been viewed as coding some aspect(s) of reward, or being the currency of reward itself in the brain (Wise, 1978; Bassareo et al., 2002; Di Chiara, 2002; Schultz, 2002; Wise, 2004). While this dopamine projection plays a role in some aspects of reward, it has been clear for some time that many other neurotransmitter systems are involved. In addition, neural and behavioral adaptations occur as an unconditioned stimulus acquires rewarding properties, or as compulsive drug-taking behavior develops in an addicted animal. In other words, neural plasticity is an important part of the neurochemistry and molecular biology of reward. Consequently, the study of reward is described in the language and based on the principles of learning theory (e.g., Di Chiara, 1998; Berridge and Robinson, 1998b; Kelley and Berridge, 2002; Salamone and Correa, 2002; Berridge and Robinson, 2003; Cardinal and Everitt, 2004; Schultz, 2004). A thorough discussion of the many views of reward from a learning theory perspective is beyond the scope of the current review; the reader is referred to recent reviews (Salamone and Correa, 2002; Berridge and Robinson, 2003). The interpretation of the role different neurotransmitters play in reward, however, does require an understanding of how various psychological constructs are being defined. Therefore, a brief description is provided.

1.1 History of the Study of ''Reward''

The study of the neurobiology of reward began more than 50 years ago when Olds and Milner (1954) reported that rats would press a bar to receive electrical stimulation in certain areas of the brain. In this initial study, animals were reported to make more than 700 bar presses/h, but many self-stimulation studies since then have reported more than 100 responses/min (e.g., Wise, 2004). Subsequent "intracranial self-stimulation" studies singled out the medial forebrain bundle as being crucial for positive reinforcement from electric shock (Olds and Olds, 1969). From these studies, it was concluded that there were "rewarding" areas in the brain that were referred to as "pleasure centers" of the brain. The concept of a "reward system" in the brain followed from these important observations.

During this same time period, Teitelbaum and Epstein (1962) demonstrated that electrolytic lesions of the lateral hypothalamus caused aphagia, and adipsia. This phenomenon was called the "lateral hypothalamic syndrome," and animals were shown to exhibit extreme sensory neglect, which contributed to the failure to eat or drink during early stages of recovery (Levitt and Teitelbaum, 1975). It was the work of Ungerstedt, which first demonstrated that the neurotransmitter dopamine was playing an important role for both intracranial self-stimulation and the lateral hypothalamic syndrome.

In his research using the selective catecholamine neurotoxin 6-hydroxydopamine, Ungerstedt showed that when dopamine neurons in the midbrain are neurochemically destroyed, the result is severe akinesia, aphagia, and adipsia (Ungerstedt, 1971). A few years earlier, investigators in the same laboratory in Sweden, had shown that catecholamine neurons from the midbrain project via the medial forebrain bundle through the lateral hypothalamus to the striatum, NAcc, amygdala, and medial prefrontal cortex (Anden et al., 1966). Thus, most of the deficits found in the lateral hypothalamic syndrome were caused by the destruction of axons from dopamine neurons in the midbrain that project through the lateral hypothalamus on their way to their forebrain targets.

As the pieces of the puzzle began falling into place, it was generally accepted that the reinforcing properties of intracranial self-stimulation, drugs of abuse, and natural rewards were mediated by the activation of the ascending dopamine pathway, and in the absence of dopamine these things were not rewarding. As Wise (1984) summarized, "The notion that cocaine and amphetamine can centrally activate natural reward mechanisms and that they owe their reinforcing action to such activation . . . is consistent with the fact that these agents have the traditional properties of conventional reinforcers . . . In both cases the central reinforcer can be more powerful than more "natural" reinforcers, even in cases of acute need; access to psychomotor stimulant reinforcement . . . or to electrical brain stimulation . . .can cause self starvation to the point of severe weight loss."

Nevertheless, from early in the discussion it has been clear that dopamine is not the only mediator of reward. Going back to self-stimulation as a tool to uncover the neurobiological mechanisms of reward, there are some areas of the brain where animals will respond for self-stimulation, yet discrete dopamine lesions at these sites do not block responding (for a discussion see Wise, 1978). In a later review of the role of dopamine in reward, Wise and Rompre (1989 p. 220) concluded, "While the evidence is strong that dopamine plays some fundamental and special role in the rewarding effects of brain stimulation, psychomotor stimulants, opiates, and food, the exact nature of that role is not clear. One thing is clear: Dopamine is not the only reward transmitter, and dopaminergic neurons are not the final common path for all rewards" (Wise and Rompre, 1989). Therefore, a discussion of the neurochemistry and molecular biology of reward must involve a discussion of many neural systems.

1.2 Definitions

Before we go much farther, it is necessary to define some of the terms that are used in the study of reward.

1.2.1 Reward Versus Reinforcement

In the psychological literature "reward" is used as a noun to refer to an object or incentive that an animal or individual will work to receive. A natural reward is an unconditioned stimulus that has some intrinsic value. Rewarding is used to refer to the properties attributed to a stimulus that gives value to an animal or individual. A reinforcer is any natural reward or conditioned stimulus that when associated with a behavior, increases the probability that the given behavior will be repeated. When Wise (1984) postulated that drugs of abuse like amphetamine and cocaine "activate natural reward mechanisms, and that they owe their reinforcing action to such activation," he was referring to activation of neural systems that respond to natural rewards.

Berridge and Robinson (2003) argue that to understand the neurobiology of reward one must begin to dissect or parse reward into its psychological components. They identify these components as: (1) learning; (2) affect or what they refer to as "liking"; and (3) motivation or "wanting". In other words, an individual *learns* that a stimulus is rewarding due to its *hedonic or affective characteristics* and *how much these characteristics are valued or wanted* by the individual. For some stimuli, the first time an animal encounters the item it is rewarded (e.g., the intrinsic value of a good tasting food item is immediately recognized by an animal or individual). For the example of a good tasting food item, the animal learns that something that looks like the item tastes good. The visual stimuli associated with the item (color, shape, size, etc.) are not

rewarding until the animal has tasted the food. The neuroanatomical and neurochemical systems that respond to and adapt with changes in reinforcement history are discussed in more detail below.

1.2.2 The Role of Learning and Memory in Reward

With all rewards, an animal must learn whether something is rewarding. Food preferences are learned by eating the food, or through interaction with an animal that has eaten a novel food (Galef and Whiskin, 2003). Sexual experience results in changes in motivational and consummatory aspects of sexual behavior in male rats (Pfaus et al., 2001) and female rats (Jenkins and Becker, 2003a, b). Other stimuli acquire rewarding properties by association with external or internal primary reinforcers.

Are there stimuli that are so powerful that they are immediately approached and sought after even in animals that have never had contact with the item before? There is one example of this that comes to mind: pheromones. Pheromones produced by the female silk moth will attract male silk moths from miles away. In some mammals, there are clearly powerful effects of pheromones on mating behavior. The male hamster will not mate without an intact vomeronasal organ, demonstrating the important role of chemosensory input for behavior in the hamster. There is still a role for learning in the effects of pheromones in the male hamster, as the neural systems activated by female hamster pheromones are different in sexually experienced and naïve male hamsters (Westberry and Meredith, 2003). In addition, only experienced male hamsters can be trained to bar press for access to female hamster vaginal secretions (Coppola and O'Connell, 1988). Therefore, in mammals, even with highly potent natural rewards, some experience with the stimulus is important for it to acquire rewarding properties.

As summarized by Robinson and Berridge, "Individuals are guided to incentive stimuli by the influence of Pavlovian stimulus–stimulus (S–S) associations on motivational systems, which are psychologically separable from the symbolic cognitive systems that mediate conscious desire, declarative expectancies of reward, and act-outcome representations. Prefrontal and other cortical areas primarily mediate cognitive forms of desire and act-outcome representations, whereas NAcc-related circuitry (especially dopamine-related systems) plays a more important role in Pavlovian-guided attributions of incentive salience" (Robinson and Berridge, 2003). The study of the neurochemistry and molecular biology of reward involves the integration of neural systems that mediate learning and memory, with the neural systems that attribute value to a stimulus.

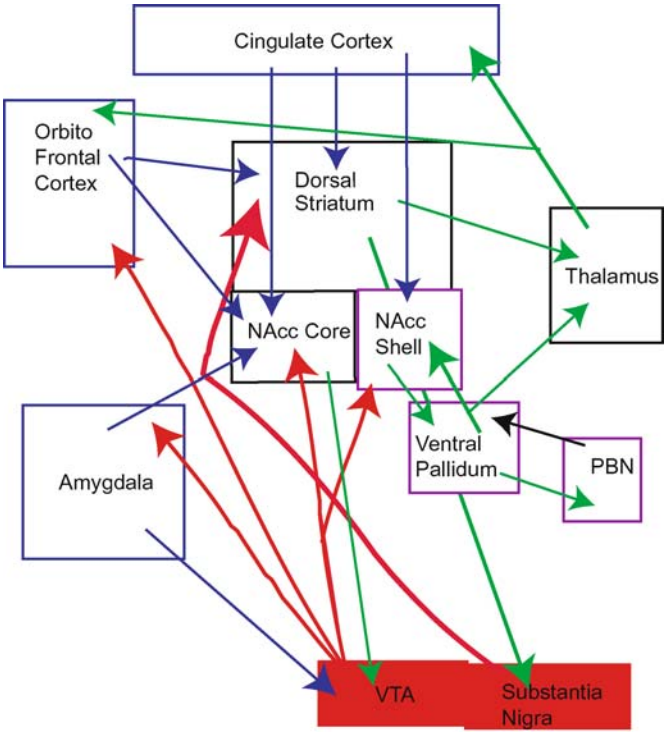
As indicated in the quotation above, the neural systems that are implicated in the neurobiological changes associated with learning include the orbitofrontal cortex, cingulate cortex, and the amygdala (*Figure 20-1*). These brain regions are activated by the rewarding stimuli (for review see Berridge and Robinson, 2003) and have been shown to exhibit electrophysiological and morphological neuroadaptations following treatment with drugs such as cocaine, amphetamine, or morphine (Cador et al., 1989; Everitt et al., 1989; Robinson and Kolb, 1997, 1999; Robinson et al., 2001; Volkow et al., 2002; Carelli et al., 2003). Although other brain regions are involved in learning associated with reward, these areas of the brain are most consistently implicated. It should also be noted that these brain regions may also be important for the interpretation of the hedonic and motivational value of stimuli.

1.2.3 Hedonic Value Versus Motivational Value ("Liking" Versus "Wanting")

It is generally assumed that the reason we work for natural rewards is that these rewards have intrinsic hedonic value. We like the way something tastes or how it makes us feel and that is the basis for the rewarding value of natural rewards. This is not always true, of course. Sometimes we eat food because we are hungry, even though we do not really like the taste. Sometimes we drink because we are thirsty, not for the hedonic value of water. As we shall see, with sexual behavior in the female rat (for example), the act of engaging in sex may be rewarding only under certain conditions. Both the internal state of the animal (hunger, thirst, hormone primed to be sexually receptive, etc.) and the environmental conditions in which an event occurs can affect the hedonic value of a natural reward or conditioned stimulus (Rolls, 2004).

Figure 20-1

Simplified schematic of the neural systems important for reward. Of course, no brain region is involved in only one aspect of reward. Cortical areas and the amygdala are also implicated in "wanting." Habit learning is likely to take place in the dorsal striatum and NAcc. There are also serotonin connections from the raphe nucleus to the shell of the NAcc and acetylcholine projections from the pedunculo pontine nucleus to the VTA involved in the regulation of reward. Red arrows: dopamine projections; Green arrows: GABA projections; Blue arrows: glutamate Projections; Black arrows: unknown or multiple; Blue boxes: important for the learning components of reward; Purple boxes: important for "liking"; Black boxes: important for "wanting." NAcc, nucleus accumbens; PBN, parabrachial nucleus



For the reasons discussed above, and others, the hedonic value of a stimulus is not the only property of a stimulus that can make it rewarding. Berridge and Robinson have termed the other component of reward as "wanting" or "incentive salience" (Robinson and Berridge, 1993; Berridge and Robinson, 2003). "Incentive salience is a motivational, rather than an affective, component of reward. Its attribution transforms mere sensory information about rewards and their cues (sights, sounds, and smells) into attractive, desired, riveting incentives. The sight of food, drugs, or other incentives is merely a sensory configuration of shape and color that is not intrinsically motivating. Attribution of incentive salience to a percept or other representation is what is suggested here to make it a "wanted" target of "motivation" (Berridge and Robinson, 2003).

Berridge and Robinson have written extensively in support of separate neural systems for "wanting" or incentive salience and "liking" or intrinsic hedonic value (Robinson and Berridge, 1993; Berridge and Robinson, 1995; Berridge, 1996; Berridge and Robinson, 1998a, b; Robinson and Berridge, 2000, 2001; Berridge and Robinson, 2003; Robinson and Berridge, 2003). They propose that the ascending dopamine system mediates incentive salience or "wanting" for a reward, whereas "liking" is mediated primarily by the actions of endogenous opioids and gamma-aminobutyric acid (GABA) acting in the shell of the NAcc, the

parabrachial nucleus (PBN), and ventral pallidum (Berridge and Winkielman, 2003; Robinson and Berridge, 2003). Their argument is based on evidence that rats will continue to exhibit and learn new hedonic responses after dopamine depletion; therefore, dopamine is not necessary for hedonic attributes of a stimulus.

Changes in dopamine activity in NAcc, however, can change the incentive salience attributed to a cue for a reward, so that animals will work harder for a reward if dopamine activity is enhanced. This is true even when conditions are such that there can be no contribution from the hedonic value of the reward. (Berridge and Winkielman, 2003; Robinson and Berridge, 2003). These data and results from laboratories with alternative views will be discussed in more detail later as the neurochemistry of the reward system is discussed.

In addition to separate neural systems for "wanting" and "liking," there is evidence that separate neuronal populations respond to different types of reward. Neurons in NAcc have been shown to selectively respond to cocaine versus water or food reinforcers (Carelli et al., 2000; Carelli, 2004). Neurons in NAcc and amygdala show adaptations as a cue or stimulus changes in value through learning (Carelli et al., 2003; Peters et al., 2003; Carelli, 2004). Furthermore, stimuli acquire value through association with both positive and negative outcomes, and the NAcc is involved in the acquisition of both types of information (Schoenbaum and Setlow, 2003; Setlow et al., 2003).

1.2.4 The Neurobiology of the Reward System

The areas of the brain that are thought to be important for the neurobiology of motivation are illustrated in *Figure 20-1*. While no diagram can do justice to the complexity and subtleties of the relations among these brain regions, this figure will allow the reader to follow the discussion. At the core of the reward system are the ascending dopamine systems that project from the substantia nigra to the dorsal striatum and from the ventral tegmental area (VTA) to the NAcc, amygdala, and frontal cortex. As initially hypothesized by Robinson and Berridge (2003), these dopamine systems are necessary for incentive salience or wanting.

The NAcc is composed of the core and shell, which differ in their afferent input and efferent projections. The hippocampus projects to both core and shell, with the dorsal subiculum projecting to the core and ventral subiculum projecting to the shell. Prelimbic prefrontal cortex projects to the core of the NAcc whereas infralimbic and piriform cortex project to the shell (Brog et al., 1993). Specific subcompartments of the amygdala also project to the core versus shell (Wright et al., 1996). Both core and shell receive input from dopamine neurons in the VTA, and this input is topographically organized. The output from the NAcc core connects to the ventral pallidum, subthalamic nucleus, and substantia nigra, while the shell projects more to the subcortical limbic regions including the VTA, ventral medial pallidum, and lateral hypothalamus.

The NAcc core appears to be important for cocaine-seeking behavior that is acquired using conditioned reinforcers, but lesions of the core did not affect acquisition of responding for cocaine under continuous reinforcement conditions (Ito et al., 2004). On the other hand, if one looks at what happens in the NAcc after repeated exposure to cocaine, there is increased dendritic branching in the core and the shell of the NAcc only in animals that exhibited behavioral sensitization. Animals that were exposed to the same amount of cocaine, but did not develop behavioral sensitization had increased dendritic branching only in the shell of the NAcc (Li et al., 2004). Thus, the core of the NAcc exhibits structural plasticity under conditions where behavioral sensitization occurs.

The NAcc shell in association with the ventral pallidum and PBN is thought to be important for the hedonic value of stimuli or "liking" (Berridge and Robinson, 2003). Selective excitotoxic lesions of the NAcc shell do not impair drug self-administration or the acquisition of cocaine-seeking behavior, but do attenuate the psychostimulant effects of cocaine (Ito et al., 2004).

Information from the core and the shell of the NAcc is integrated at the level of the thalamus. Cortical areas (amygdala, and orbitofrontal, perhaps the cingulate cortex) are important for learning the association between a CS and reward as well as for mediating changes in the incentive salience of stimuli.

1.3 Summary

The study of reward has been focused on the ascending dopamine systems for many years, but it is now clear that complex relations among multiple neurotransmitter systems mediate reward. Neural systems important for reward include brain areas that are important for learning whether a stimulus is rewarding or it is associated with a rewarding stimulus (e.g., prefrontal cortex and NAcc). In addition, it is thought that there are separate neural systems that mediate "wanting" and "liking" for a stimulus. The ascending dopamine systems are thought to be necessary for "wanting" but not liking. It is proposed that liking is mediated by the NAcc shell in association with ventral pallidum and PBN.

2 The Neurochemistry of Reward

2.1 Food Reward

2.1.1 Dopamine

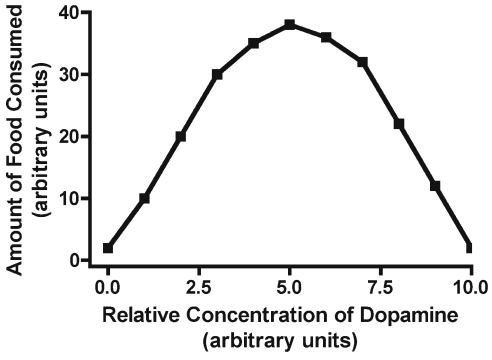
Most discussions of the neurochemistry of feeding behavior and food reward begin with a discussion of the role of dopamine in feeding behavior. This idea follows from the work of Teitelbaum (discussed earlier), who showed that lesions of the ascending dopamine pathway in the lateral hypothalamus resulted in profound aphagia and adipsia. What Teitelbaum also showed, however, is that when rats with lateral hypothalamic lesions were fed a highly palatable food they could recover from these lesions, and would eventually eat standard laboratory rat chow without a restoration of dopamine function. Therefore, while dopamine clearly plays a role in feeding behavior, there are other neurotransmitters involved.

Evidence supporting a role for dopamine in feeding behavior includes studies investigating the rewarding effects of sham-fed sucrose. Dopamine increases in dialysate from the NAcc in response to sucrose, and previous experience with sucrose enhances this effect (Smith, 2004). Dopamine antagonists decrease sucrose intake as a function of the concentration of sucrose, suggesting that dopamine in the NAcc is important for the rewarding aspects of sucrose. Depletion of NAcc dopamine with 6-hydroxydopamine, however, does not affect the hedonic response to sucrose in the taste reactivity test (Berridge et al., 1989). Furthermore, Wyvell and Berridge (2001) demonstrated that sensitization of animals with repeated amphetamine did not increase the hedonic impact of sucrose, but did increase responding for sucrose in response to a previously paired conditioned stimulus. These results taken together suggest that sensitization of the ascending dopamine system with amphetamine increases the incentive salience or "wanting" for sucrose.

It may seem counterintuitive, but other evidence in support of a role for dopamine in feeding behavior comes from the widespread use of amphetamine for the treatment of obesity. Amphetamine stimulates dopamine release and blocks dopamine reuptake. So it seems that an excess of dopamine decreases feeding behavior, just the opposite of what happens when endogenous dopamine increases. This indicates that there is an inverted U-shaped curve relationship between dopamine release and feeding behavior, with dopamine release facilitating feeding behavior at physiological levels and inhibiting feeding at pharmacological levels (*Figure 20-2*). In support of this idea, mice with reduced expression of the dopamine transporter, which elevates intracellular dopamine, are hyperphagic and exhibit behaviors consistent with an increase in "wanting" for sucrose, without an increase in "liking" for sucrose (Pecina et al., 2003). On the other hand, in mice that cannot make norepinephrine or epinephrine due to the lack of dopamine-β-hydroxylase, amphetamine reduces food intake equally well as in wild-type mice (Cannon et al., 2004). This effect is not blocked by the dopamine antagonist haloperidol, even though locomotor behavior was suppressed. These results indicate that there had not been compensation during development by D2 dopamine receptors mediating the hypophagia induced by amphetamine, and that hypophagia was not a secondary consequence of enhanced locomotor activity preventing feeding behavior (Cannon et al., 2004). In contrast, mice lacking dopamine are resistant to the hypophagic effects of amphetamine and will actually increase food intake after amphetamine (these animals require supplementation with l-dopa for normal food intake; Cannon et al., 2004).

Figure 20-2

Hypothetical relationship between dopamine release and food consumption. As the concentration of dopamine in the synapse increases, there is initially an increase in food consumption. After reaching the asymptote, additional increases in dopamine result in decreased food consumption



Using extracellular recording from dopamine neurons in the substantia nigra and VTA of awake monkeys, Schultz has shown that dopamine neurons initially fire in response to delivery of a juice reward. If the reward is paired with a predictive stimulus (CS) dopamine neurons come to fire with the CS (Schultz and Romo, 1990; Schultz, 1992; Schultz et al., 1992, 1993; Schultz, 1997; Fiorillo et al., 2003; Tobler et al., 2003). Dopamine neurons are also activated by rewards that are considered more valuable than would have been predicted by the CS, uninfluenced by rewards that occur as predicted, and depressed by rewards that are worse than predicted (Schultz, 2004). Schultz has suggested that the dopamine signal is important for risk taking behavior, rather than being related to the type of reward (such as food). As uncertainty in reward value increases, there is a greater increase in dopamine neuron firing (Fiorillo et al., 2003). These data can be summarized as indicating that dopamine neurons fire in response to a learned (or unlearned) reward or CS and code information about reward value and reward predictability.

If dopamine activity is reduced with a low dose of a dopamine receptor antagonist or depletion of dopamine in the NAcc, food intake and affective responses to food tastes are not affected, but behaviors emitted to gain access to food are suppressed (Berridge, 1996). Similarly, infusion of selective D1 or D2 dopamine receptor antagonists into the NAcc core or shell of food-restricted rats has no effect on food intake, but will suppress locomotor activity usually associated with hunger (Kelley, 2004). Kelley (2004) hypothesizes that dopamine plays a broad role in adaptive motor behavior and learning, rather than a specific role in food intake. Salamone (Salamone and Correa, 2002) finds that NAcc dopamine depletions decrease an animal's likelihood of engaging in instrumental responding that has a high cost-benefit ratio. He proposes that NAcc dopamine is important for maintaining effort in instrumental responding over time in the absence of primary reinforcement (Salamone and Correa, 2002). This interpretation is not inconsistent with dopamine coding reward value or "wanting."

2.1.2 GABA and Glutamate

Research on the roles of GABA, glutamate and the endogenous opiates in feeding behavior has been reviewed recently, so the reader is referred to that excellent article (Kelley, 2004). The Kelley lab has shown that neurons in the NAcc shell are important for modulating feeding behavior. Antagonists of glutamatergic AMPA receptors (but not NMDA antagonists) in the shell induce the immediate onset of feeding behavior. Inhibition of the NAcc shell with the GABA-A agonist muscimol or the GABA-B agonist baclofen also induces feeding (Kelley, 2004). These data suggest that corticolimbic glutamatergic input to the NAcc shell is involved in inhibition of feeding, and that GABA released with feeding is important for self-inhibition of competing behaviors, and enhanced feeding behavior.

2.1.3 Endogenous Opiates

Opioid agonists stimulate food intake and antagonists depress feeding behavior. It has been suggested that opioids are important for taste palatability or how much the animals like a food substance (Kelley et al., 2002). Opioid stimulation of the NAcc induces feeding behavior. Conversely, regular feeding of animals with a highly palatable food can result in down regulation of striatal enkephalin gene expression (Kelley, 2004).

When areas of the NAcc that are important for feeding behavior were mapped, the caudal region of the shell was found to contain the opioid neural circuits where morphine activation is sufficient to increase responding on the taste reactivity test, which indicated enhanced "liking" for food (Berridge, 2003). As reviewed by Berridge (2003), opiate drugs will also enhance how much an animal eats and rats will work for morphine infusion into the NAcc. So, opioid systems in the NAcc are involved in both "liking" and "wanting" for food reward.

2.2 Drugs of Abuse

Drugs of abuse have been used extensively in research to tap into the reward system(s). This is not to say that drugs of abuse activate the exact same neural systems that are activated by natural rewards. As White (1996) points out, drugs such as amphetamine and morphine, when given systemically, can simultaneously cause a conditioned place preference and a conditioned taste aversion. These simultaneous effects are thought to be due to the actions of these drugs at multiple regions in the brain. For example, conditioned place preference for amphetamine requires the lateral nucleus of the amygdala, the NAcc, and the tegmental pedunculo pontine nucleus. In contrast, conditioned taste aversions can be induced by amphetamine in the area postrema and blocked by lesions of the basolateral amygdala (White, 1996). So, the use of drugs of abuse to investigate the neural mechanisms of reward can be informative, but it is important to keep in mind that these drugs are having many other actions in the brain as well.

2.2.1 Dopamine

Psychomotor Stimulants. During microdialysis in the NAcc, dopamine increases in both the shell and core during intravenous cocaine self-administration. Noncontingent CS presentation led to increased dopamine only in the NAcc core (Ito et al., 2000). Using a second-order schedule of reinforcement, dopamine in the dorsal striatum is also increased (Ito et al., 2002). These authors suggest that dopamine in the NAcc core may be involved in the acquisition of the CS–cocaine association, but that once the association is established, other neural systems, including dopamine in the dorsal striatum take precedence (Ito et al., 2002).

When dopamine antagonists are given to animals that are lever pressing for brain self-stimulation, or other rewards, responding declines over time (Wise, 2004). The animals initiate responding normally and then the behavior drops off. A sensory challenge can reinstate responding, suggesting that the decline in behavior is not due to the effect of the drug on motor activity. Wise (2004) concludes, "most normally rewarding stimuli fail to serve as effective reinforcers in dopamine-compromised animals.

Psychomotor stimulant drugs, such as cocaine, amphetamine, and methylphenidate act by blocking dopamine reuptake at the dopamine transporter and thereby increasing the amount of dopamine available at postsynaptic receptors (Schenk, 2002). Amphetamine acts at the dopamine transporter to increase dopamine release (Fischer and Cho, 1976). Amphetamine is also active at norepinephrine and serotonin transporters, although within the striatum, it is the action of amphetamine at the dopamine transporter that accounts for most of the behavioral effects of amphetamine (Heikkila et al., 1975; Raiteri et al., 1975).

Amphetamine also redistributes dopamine from within vesicles to the cytosol where it promotes reverse transport out of the neuron through the mechanism of exchange diffusion (Sulzer et al., 1995). This is an active, energy-dependent process that derives its energy from the effect of amphetamine as a weak base that

results in a pH gradient that promotes reverse transport (Sulzer et al., 1993), and from the polarization of the neuronal membrane: transporter activity increases with increased membrane polarization (Kanner, 1983).

Cocaine has equivalent affinities at the dopamine transporter, norepinephrine transporter, and serotonin transporter, but it is the binding potency at the dopamine transporter that is correlated with the effects of cocaine in tests of reward (Kuhar et al., 1988). The hypothesis that the monoamine transporters were involved in the effect of cocaine lead to the cloning of these transporter genes and the development of animals with overexpression, underexpression, or knockout of this gene. As discussed by Uhl et al. (2002), the subsequent experimental use of these animals demonstrated that the dopamine transporter is necessary for cocaine-induced locomotor behavior above an already elevated baseline of locomotor activity. On the other hand, dopamine transporter knockout mice express a normal conditioned place preference for cocaine and will learn to self-administer cocaine (Sora et al., 1998; Uhl et al., 2002).

Interestingly, double knockouts of the dopamine transporter and the serotonin transporter do not show a conditioned place preference for cocaine, whereas double knockouts of the serotonin transporter and the norepinephrine transporter have an enhanced conditioned place preference for cocaine. The results with the various monoamine transporter knockouts illustrate that cocaine can produce its rewarding effects by acting at multiple sites, and through multiple mechanisms. These results also suggest that there are both rewarding and aversive aspects of cocaine's action being mediated by the coordinated actions of blocking different transporters. Animals with double knockouts of the dopamine transporter and the serotonin transporter have reward deficits, while double knockouts of the serotonin transporter and the norepinephrine transporter do not exhibit conditioned aversion with cocaine (Uhl et al., 2002). Of course, experiments with animals that have been genetically altered since birth must be interpreted cautiously as there may be considerable adaptation during development as a result of the altered gene expression. It will be important to determine if the areas of the brain identified as important for conditioned place preference and conditioned taste aversion in knockout animals also mediate the rewarding and aversive effects of cocaine in the wild-type mice.

Opiates. Considerable evidence supports a role for dopamine in the reinforcing value of opiates. In animals depletion of dopamine in the VTA or NAcc, the acquisition or maintenance of heroin or morphine reinforcement are abolished, as are conditioned place preferences for these drugs; D1 dopamine receptor antagonists also decrease the rewarding value of opiates (Shippenberg and Herz, 1987, 1988; Shippenberg et al., 1993; Xi and Stein, 2002). Studies using in vivo microdialysis have shown that morphine induces a significant increase in extracellular dopamine in the NAcc (Leone et al., 1991; Pothos et al., 1991). The exact role of dopamine in opiate-induced reward remains a topic of discussion, but it seems clear that dopaminergic mechanisms are involved to some degree.

Nicotine. Nicotine is thought to increase dopamine release by acting at presynaptic dopamine receptors to increase the rapidly releasable pool of dopamine (Turner, 2004). In striatal slices from guinea pig brains, nicotine enhances dopamine release during phasic, but not tonic activity (Rice and Cragg, 2004). In corticostriatal slices from mouse brain, nicotine depresses dopamine released by stimuli inducing tonic firing, but increases dopamine released from stimuli emulating phasic firing (Zhang and Sulzer, 2004). These results suggest that nicotine enhances incentive salience during periods of dopaminergic activation.

2.2.2 Glutamate

The presence of glutamate afferents to the VTA and NAcc suggests an interaction between dopamine and glutamate in the mediation of the effects of both natural rewards and drugs of abuse. The effects of glutamate are mediated by receptor subtypes from both metabotropic and ionotropic receptor classes (*Table 20-1*). The significance of these receptor classes is that the ionotropic receptors can modulate rapid excitatory neurophysiological responses (Chuhma et al., 2004) as well as mediate plastic changes in synaptic contacts (Carroll and Zukin, 2002). The metabotropic receptors are linked to classic intracellular signaling pathways that can regulate protein phosphorylation and transcription, which may also lead to long-term plasticity (Schoepp et al., 1999).

Table 20-1
Organization of Glutamate Receptor Subtypes

Receptor class	Receptor subtype	Receptor subunits	Signaling
Ionotropic[1]	AMPA Receptors	GluR1-4	$Na^+/K^+/(Ca^{2+})$ influx[2]
	NMDA Receptors	NR1	$Ca^{2+}/Na^+/K^+$ influx
		NR2A-D	$Ca^{2+}/Na^+/K^+$ influx
		NR3A	$Ca^{2+}/Na^+/K^+$ influx
Metabotropic	Group I	mGluR1/5	Gq; IP_3 activation
	Group II	mGluR2/3	Gi/o; Adenylyl cyclase inhibition
	Group III	mGluR4/6-8	Gi/o; Adenylyl cyclase inhibition

[1]Kainate receptors are not included here as their role in reward-related processes is uncertain
[2]Permeability to Ca^{2+} is inhibited if the R2 subunit is present

There are three groups of metabotropic glutamate receptors (Groups I–III) containing eight receptor subtypes. Group I receptors (mGluR1/5) are Gq coupled, whereas group II receptors (mGluR2/3) and group III receptors (mGluR4/6–8) are Gi/o coupled. The ionotropic glutamate receptors are referred to by the ligands they preferentially bind (NMDA versus AMPA), giving rise to a series of NMDA (NR1-3) and AMPA receptor (GluR1-4) subtypes based on the subunits that comprise the receptors (*Table 20-1*). The combination of inputs from different forebrain regions and multiple receptor types offers a remarkably complicated array of means through which glutamate can impact reward processes. Still there are some clear patterns in the mechanisms through which glutamate can mediate reward-related processes.

Psychomotor Stimulants. In addition to the regulation of dopamine neurotransmission, drugs of abuse produce changes in synaptic levels of glutamate. For example, acute treatment with amphetamine increases extracellular levels of glutamate in the VTA and NAcc (Xue et al., 1996; Wolf, 1998; Wolf et al., 2000). The effects of amphetamine on glutamate release, at least in the VTA, depend on efferents from the prefrontal cortex (Li et al., 1999). Repeated amphetamine administration does not increase glutamate release; however, stimulated glutamate release is enhanced with sensitization (Wolf, 1998; Giorgetti et al., 2001).

Less is known about the effects of cocaine on glutamate release. Chronic cocaine elevates glutamate levels in the VTA (Kalivas and Duffy, 1998), but not in the NAcc (Robinson et al., 1997). Oddly, aspartate concentrations, which can be used as an indication of glutamate release, did increase in the NAcc following chronic cocaine (Robinson et al., 1997). Another potential (though certainly indirect) measure of glutamate neurotransmission is the abundance of glutamate in presynaptic nerve terminals. Glutamate immunoreactivity was measured in the NAcc and VTA in response to either acute or chronic cocaine administration (Meshul et al., 1998; Kozell and Meshul, 2001, 2003, 2004). Acute cocaine decreased glutamate staining in terminals in both the shell and core of the NAcc, an effect that persisted in the core, but not in the shell. This effect was not found in glutamate terminals in either the VTA or prefrontal cortex. Chronic cocaine increased glutamate immunoreactivity in the VTA, and the effect was magnified in behaviorally sensitized animals. After withdrawal, however, VTA glutamate was increased in the nonsensitized cocaine-treated animals. Despite the minimal evidence for a link between cocaine and glutamate release, these results are consistent with the findings from experiments with amphetamine. At the same time, it does not appear that presynaptic glutamate content is related to the development of sensitization following cocaine administration (Kozell and Meshul, 2004).

One way that drugs such as amphetamine or cocaine may impact glutamate neurotransmission is by acting at metabotropic or ionotropic glutamate receptors. In one electrophysiological study, VTA metabotropic glutamate receptor postsynaptic inhibitory potentials were dramatically inhibited by amphetamine, whereas ionotropic receptor-mediated postsynaptic currents were not affected (Paladini et al., 2001). When the relative contributions of currents derived from AMPA and NMDA receptors were parsed; however, amphetamine produced an increase in the ratio of AMPA:NMDA currents in the VTA relative to saline controls (Faleiro et al., 2004).

Chronic treatment with cocaine increased both GluR1 and NR1 (but not GluR2/3) content in the VTA one day after the last cocaine injection (Churchill et al., 1999). This effect was restricted to behaviorally

sensitized animals, and was gone 3 weeks later. In the NAcc there was no difference between cocaine-sensitized animals in GluR1 or NR1 subunits one day after treatment termination. Three weeks later, however, GluR1 levels increased in sensitized rats, with GluR2/3 and NR1 subunits still unchanged. The lack of effect of chronic cocaine on NR1/2A-2C receptor levels immediately after treatment has also been seen by other investigators (Yamaguchi et al., 2002).

Withdrawal from amphetamine produced a complex pattern of changes in AMPA receptor subunit expression that depended on the period of withdrawal and the neural region (Lu and Wolf, 1999). First, no changes in GluR2/3, GluR2/4, or GluR4 subunit expression were seen at any time point. In the NAcc, there was no change in GluR1 nor in GluR2 expression after 3 days of withdrawal, but at 14 days of withdrawal, GluR2 levels decreased in both the NAcc shell and core, but GluR1 levels decreased only in the NAcc shell. In the prefrontal cortex, only GluR1 expression was affected, with a decrease in subunit levels at 3 days of withdrawal, normalizing by 14 days of withdrawal.

Paradoxically, NMDA and AMPA agonists and antagonists both increase locomotor activity (Kelley and Throne, 1992; Burns et al., 1994; Danysz et al., 1994; Leriche et al., 2003; David et al., 2004), possibly through interactions with dopamine D2 and/or D3 receptors (Choi et al., 2000; Leriche et al., 2003; David et al., 2004). Amphetamine directly infused into the core of the NAcc also increases locomotor activity, but these effects of amphetamine are blocked by intraNAcc pretreatment with either an NMDA receptor agonist or an antagonist (Kelley and Throne, 1992; David et al., 2004). Pretreatment with an AMPA receptor agonist or antagonist produced a similar attenuation of amphetamine's effects (Vanover, 1998; David et al., 2004). This overall pattern of results is seen with both cocaine and amphetamine treatment (Pulvirenti et al., 1994).

One possible resolution to this apparent paradox is that glutamate receptors are found both on dopaminergic presynaptic terminals and on postsynaptic dopaminergic target neurons (David et al., 2004). Another variable often overlooked in these paradigms is the environment in which the drugs are given. One notable study tested the ability of NMDA receptor antagonists to counteract the sensitizing effects of repeated amphetamine treatments (Battisti et al., 2000). In this case, the antagonists were effective when the animal was tested in the same environment in which the amphetamine was administered, but not when the animals were tested in a novel environment. If locomotor activity is dependent on dopamine neurotransmission, then the integrated outcome of modulating both dopamine release and postsynaptic responsiveness in a context-sensitive manner could differentially regulate locomotor activity.

Similar to the studies on ionotropic glutamate receptors, the locomotor stimulating effects of pharmacological agents targeting the metabotropic glutamate receptors have been evaluated. Injections of group II mGluR antagonists either systemically or in the NAcc will antagonize the increases in activity produced by amphetamine administration (Cartmell et al., 2000; Kim et al., 2000; Breysse et al., 2002; David and Abraini, 2003). The effect of group I antagonists on amphetamine or cocaine stimulated locomotor behavior are similar to that of antagonizing Group II receptors. Group I antagonists block the effects of amphetamine or cocaine on activity in some studies (David and Abraini, 2003; Herzig and Schmidt, 2004), but not in another (Kim et al., 2000).

Though locomotor activity typically is a property associated with the rewarding effects of drugs of abuse, group I antagonists affect reward differently for individual drugs. Cocaine, amphetamine, and morphine-related reward processes are inconsistently disrupted by group I antagonists (Darracq et al., 2001; Popik and Wrobel, 2002; McGeehan and Olive, 2003; Herzig and Schmidt, 2004; Kim et al., 2005). Another way to look at this question is to examine expression of receptors following drug sensitization (Mao and Wang, 2001). Of group I receptors, a sensitizing amphetamine regimen increases mGluR1 expression in the NAcc, an effect that disappears during withdrawal. In contrast, amphetamine experience decreased mGluR5 expression in the NAcc, and this effect persisted during a period of drug withdrawal. Why mGluR5 receptor expression is elevated in the NAcc during withdrawal from a sensitizing cocaine regimen (Ghasemzadeh et al., 1999) is unclear. Thus, the effects of sensitization on mGluRs depend on the particular drug administered as well as the pattern of administration. Consequently, it seems unlikely that activation of metabotropic glutamate receptors forms a common mechanism for the behavioral consequences of drug exposure.

Opiates. Acute morphine treatment had a bidirectional effect on ionotropic glutamate receptor subunits in the core of the NAcc (Jacobs et al., 2005). Three days after injection there was a decrease in expression of NR1, NR2B/2C, and GluR1-4 subunits as measured by the real time PCR. By 21 days there appeared to be a compensatory rebound as expressions of NR1, NR2A-D, NR3, and GluR1-4 were significantly elevated compared with saline-treated controls. It is clear that these drugs produce a complicated pattern of changes in glutamate ionotropic receptors, a pattern that may depend on time after drug administration and brain region. Further, the degree to which fluctuations in receptor subunits contribute to active or silent synapses needs to be evaluated (Nakayama et al., 2005). Still, the suggestion that increased expression of GluR1 mediates sensitization to repeated drug exposure (Carlezon and Nestler, 2002) warrants further study.

Reward Learning. Besides the glutamate modulation of the sensitization of locomotor responses to drugs of abuse, the role of glutamate in more conventional learning paradigms has been assessed. In a conditioned place preference paradigm, inhibition of glutamate release through systemic treatment with riluzole prevented conditioned place preference to either morphine or amphetamine (Tzschentke and Schmidt, 1998). Further, NMDA antagonists blocked either the acquisition or reinstatement of conditioned morphine place preference (Harris and Aston-Jones, 2003; Ribeiro Do Couto et al., 2005). A role for specific subunits of the NMDA receptor was evaluated by intracranial passive immunization to the NR1, NR2A, or NR2B subunits (Narita et al., 2000). The effectiveness of inactivation of each of the subunits was demonstrated by increased NMDA-induced seizure threshold. Subunit specificity for conditioned place preference for morphine was demonstrated in that inactivation of the NR2B subunit eliminated conditioned place preference, whereas inactivation of the other subunits was without effect. Similar effects of AMPA and NMDA antagonists were seen with cocaine-induced place preference, though the effectiveness of these agents was limited to infusions in the VTA (Harris and Aston-Jones, 2003), a site specificity also noted for morphine-induced place preference (Harris et al., 2004). Oddly, systemic administration of MS-153, a reported activator of the glutamate transporter, also antagonized conditioned place preference to cocaine, morphine, or methamphetamine (Nakagawa et al., 2005). A simple explanation for this discrepancy awaits further study.

Instrumental learning tasks appear to be facilitated by glutamate. Spatial memory as measured in a radial arm maze is disrupted by treatment with NMDA or AMPA antagonists (Klein et al., 2004) and enhanced by drugs that prolong AMPA receptor mediated currents (Davis et al., 1997). NMDA antagonists will interfere with instrumental responses for food or response to novel objects when infused into the NAcc or related structures (Maldonado-Irizarry and Kelley, 1994; Andrzejewski et al., 2004; Kelley, 2004). Likewise, GluR2 subunit knockout mice a disruption in instrumental responding to a food reward (Mead and Stephens, 2003). Glutamate activity does not seem to be sufficient in this regard, instead requiring an interaction between dopamine and glutamate receptor activation (Smith-Roe and Kelley, 2000). One means through which glutamate affects instrumental responding is through a discrimination of responses directed at cues related to the value of the reward. In particular, animals treated with NMDA or AMPA antagonists respond strongly to cues associated with reward, but lose the ability to selectively respond to the cue signaling the reward of greater value (Giertler et al., 2005).

2.2.3 GABA

GABA is a ubiquitous neurotransmitter that is present in both interneurons and in long-projecting neurons in the mesolimbic circuitry (Van Bockstaele and Pickel, 1995). Besides the potential role of these neuronal types in the mediation of reward, GABA has two classes of receptors, the ionotropic $GABA_A$ and metabotropic $GABA_B$ receptors (Matsumoto, 1989; Bowery, 1993). Both receptor subtypes are coexpressed through most regions of the brain (Bowery, 1993), though different patterns of localization of the receptor subtypes are found due to circuitry and cellular localization. $GABA_A$ and $GABA_B$ receptors occur pre and postsynaptically, with the presynaptic receptors acting as autoreceptors and modulating the release of other neurotransmitters (Bowery, 1993). The implication here is that the

functional consequences of GABA neurotransmission will depend on receptor subtype and location (e.g., Akiyama et al., 2004).

In general, GABA neurotransmission is thought to be inhibitory to the rewarding effects of drugs of abuse or natural stimuli (Ikemoto and Wise, 2004). Consequently, one therapeutic approach taken to antagonize the rewarding effects of drugs is the administration of gamma vinylGABA (GVG). GVG is an irreversible inhibitor of GABA transaminase (an enzyme that degrades GABA). Treatment with GVG results in prolonged elevation of synaptic GABA. Rats sensitized to repeated cocaine administration have reduced GABA release (e.g., Jung et al., 1999). Further, overexpression of the GABA transporter leads to a reduction in reward efficacy of morphine (Hu et al., 2003). Therefore, sustained elevations of GABA antagonize reward processes.

Several examples illustrate this conclusion. GVG dose-dependently depressed cocaine self-administration when given within 3 h of access to cocaine (Kushner et al., 1999). The GVG was without effect if administered the previous day. Also, drugs like cocaine reduce the threshold for intracranial brain stimulation, and GVG given in conjunction with cocaine restores the brain stimulation threshold (Kushner et al., 1997). An interesting outcome of conditioned place preference studies is that GVG antagonizes conditioned place preference to cocaine, but it is without effect on conditioned place preference to a food reward (Dewey et al., 1998). On the other hand, GVG does antagonize bar pressing for food (Kushner et al., 1999). In fact, as discussed above, GABA neurotransmission plays a very different role in food-related reward (Berridge, 1996; Kelley and Berridge, 2002; Berridge and Robinson, 2003).

The generalization of the role of GABA in reward processes is complicated by the fact that there are regional differences in the responsiveness to GABAergic agents both between brain regions and within brain regions (Berridge, 2003). In addition, at the cellular level there are bidirectional effects of both $GABA_A$ and $GABA_B$ receptor stimulation (Cruz et al., 2004; Ikemoto and Wise, 2004; Laviolette and van der Kooy, 2004). For $GABA_A$ receptor mediated processes, it seems that the effects on reward are a function of both dopamine-dependent and dopamine-independent processes, which may mediate both excitatory and inhibitory signaling mechanisms (Laviolette and van der Kooy, 2001, 2004).

In the case of $GABA_B$ signaling, it appears that GABA could differentially alter cellular activity based on the efficacy of the coupling of receptors to functional ion channels. Dopamine and GABA neurons in the VTA differ in the subunit composition of G-protein-gated inwardly rectifying potassium channels, with a much lower efficiency of coupling in dopamine versus GABA neurons (Cruz et al., 2004). Therefore, the passage of information through dopaminergic or GABAergic neurons depends on the concentrations of extracellular GABA and the GABA receptor subtype. Coupling of $GABA_B$ receptors to G-proteins could be one of the mechanisms mediating these differences in signaling efficacy. The reported effects of chronic amphetamine on $GABA_B$ coupling to G-proteins make this a likely candidate for plastic changes underlying reward-related events (Zhang et al., 2000).

Another link to $GABA_B$ receptors in reward is the observation that the effects of GVG on reward-related processes are antagonized by a $GABA_B$ antagonist (Ashby et al., 1999). Baclofen, a commonly used $GABA_B$ receptor agonist, prevents the elevation in extracellular dopamine (a hallmark effect of drugs of abuse) following nicotine, cocaine, or morphine treatment (Fadda et al., 2003; Jayaram and Steketee, 2004). When placed directly in the VTA, baclofen prevents the locomotor sensitizing effects of repeated morphine treatment (Leite-Morris et al., 2004) and self-administration of cocaine (Brebner et al., 2000). Besides diminishing responsiveness to primary rewards, baclofen also prevents responsiveness to drug-related cues (Hotenspiller and Wolf, 2003; Kaplan et al., 2003).

Collectively, these results contribute to the view that drugs of abuse may modulate GABA responsiveness in a way that influences both dopamine and glutamate release (Giorgetti et al., 2002). For example, systemic or local administration of heroin or morphine inhibits neuronal activity in the NAcc where the majority of neurons are GABAergic, and administration of drugs that activate GABA-B receptors blocks heroin self-administration in a dose-dependent manner (Xi and Stein, 1998a, 2002). Furthermore, sensitization with cocaine results in an increase in the basal extracellular concentrations of GABA and desensitization of GABA-B receptors (Xi et al., 2003). One possibility is that the output of medium spiny GABA projection neurons mediate the rewarding effects of drugs of abuse, as inhibition of GABA activity by dopamine or directly by some drugs of abuse is necessary for drugs to be rewarding (Xi and Stein, 1998a, 2002).

2.2.4 Opioids

In the central nervous system (CNS) there are three classes of opiate receptors: μ, σ and κ. Morphine and heroin act primarily at μ-opiate receptors, and animals will self-administer selective μ agonists. Endogenously, endorphins and enkephalins act at μ or σ receptors. On the other hand, κ agonists tend to lack reinforcing effects or produce conditioned place aversions, and the endogenous ligand is dynorphin (Xi and Stein, 2002). Reward mediated by μ-opioid receptors is hypothesized to be mediated primarily via actions on dopamine, GABA, and perhaps glutamate neurons. Activation of opioid receptors in the VTA inhibits GABA release, and as a result of the release of inhibition on VTA dopamine neurons there is an increase in dopamine release in the NAcc (Leone et al., 1991). Opioid receptors on GABA neurons in the NAcc can similarly inhibit GABA release and enhance dopamine release (Xi and Stein, 1998b, 2002). So, activation of opioid receptors by morphine or heroin is hypothesized to produce rewarding effects through secondary actions on other neurotransmitter systems.

2.3 Summary

Table 20-2 presents a simplified summary of the role of different neurotransmitters in food reward and drug abuse. It should be noted that the relationship between relative dopamine concentrations and consumption of food or drugs of abuse is the same. On the other hand, both glutamate and GABA have different effects on feeding behavior versus intake of drugs of abuse. This suggests that glutamate and GABA are indirectly modulating reward behavior, and different factors contribute to the effects of these neurotransmitters on feeding versus responding for drugs of abuse.

Table 20-2

Summary of neurotransmitter effects on responding to natural and drug-related rewards. Indications of changes in a particular category reflect how increased activity in that neurotransmitter system affects an animal's response for either a natural reward (e.g. food) or for drugs (e.g. cocaine)

Neurotransmitter	Natural reward (Food intake)	Drug-related reward
Dopamine	↑ Responding[1]	↑ Responding[1]
Glutamate	↓ Responding[2]	↑ Responding
GABA	↑ Responding	↓ Responding
Opiates	↑ Responding	↑ Responding[3]

[1]Bell-shaped dose response curve: initially there is increased food intake or operant responding for drugs of abuse as dopamine concentrations increase, then decreased food intake and decreased self-administration as dopamine concentrations increase further

[2]However, glutamate *increases* cue salience

[3]Effects are mediated through other neurotransmitters

3 Cellular and Molecular Mechanisms of Reward

Inherent in reward processes, whether through natural behaviors, laboratory paradigms, or pharmacological agents, are variations in behavioral expression. The assumption is that the underlying behavioral plasticity is a corresponding neural plasticity and that the artificially induced neural plasticity is mediated by neural processes used in behavioral plasticity. A prominent example of the later is hippocampal long-term potentiation studied as a mechanistic basis for learning. Of significance here is that long-term potentiation can also be demonstrated among neurons in the mesolimbic system and that there are common molecular mechanisms for long-term potentiation in the hippocampal and mesolimbic systems.

In this section, we review some of the cellular and molecular adaptations thought to mediate plasticity in reward systems.

3.1 Interaction Between Drugs of Abuse and Natural Rewards

An ongoing assumption is that drugs of abuse activate neural pathways underlying natural rewards. Both types of processes seemingly activate common neural pathways and utilize similar cellular mechanisms (Nestler, 2002). Nonetheless, this does not automatically mean that the underlying mechanisms are isomorphic to drugs of abuse and natural rewards. One way in which this isomorphism was demonstrated was through the parity of experience in one modality with consequent adaptations in the behavioral responses in the other. This approach began with a rather clever experiment by Mitchell and Stewart (1990). In this study, male rats were given a sensitizing regimen of morphine in either their home cage or in a novel arena. Saline was administered in a complementary manner. The rats were tested for copulatory behavior in either their home cage or in the previously unfamiliar arena. All rats received equal morphine exposure. Copulatory parameters were enhanced only in the arena (either the home cage or the unfamiliar cage) in which the males had previously received morphine, compared to copulation in the arena in which the animals had received saline. Following this study, others showed that prior exposure to sensitizing amphetamine treatments also had a positive impact on copulation in males (Fiorino and Phillips, 1999a, b). In further support of these findings, Barr et al. (1999) found an inhibition of copulation when male rats were tested during withdrawal from a sensitizing amphetamine regimen.

It may not be surprising that potent pharmacological agents like morphine and amphetamine could alter the nervous system in a way that affects the display of a natural behavior, such as sexual behavior. Perhaps more dramatic are studies showing that prior experience with a natural behavior can sensitize the animal's behavioral response to an initial drug exposure. In one paradigm, animals experience an aggressive encounter in which they are defeated. This stressful social experience enhanced the behavioral responses to amphetamine or cocaine in animals that were previously drug-naïve (Marrow et al., 1999; Miczek, 2004; Miczek et al., 2004; de Jong et al., 2005). Both social defeat and aggression induce a stress response. Furthermore, stress can enhance the behavioral response to drugs of abuse. It is possible, therefore, that the initial response to amphetamine or cocaine is altered by the stress hormones and the behaviors per se are not directly involved (Miczek et al., 2004). Results from similar studies with natural reinforcers support the interpretation that such behavioral experiences do sensitize neural systems underlying responsiveness to drugs (Bradley and Meisel, 2001).

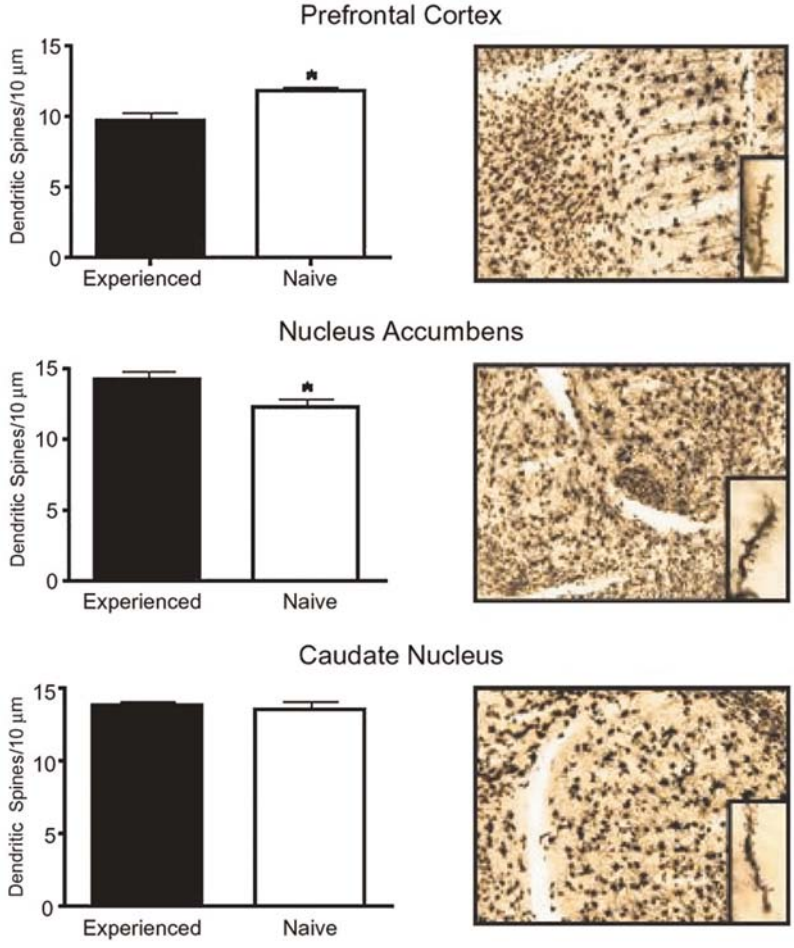
3.2 Alterations in Dendritic Structure

One consequence of experience with both drugs of abuse and natural rewards is changes in dendritic structure, particularly in the NAcc and prefrontal cortex. The plasticity of dendritic structure and particularly that of dendritic spines is linked to the dynamic regulation of intrinsic cytoskeleton proteins, whose expression is a function of synaptic activity (Carlisle and Kennedy, 2005). The drugs of abuse, amphetamine (Robinson and Kolb, 1999; Robinson et al., 2002; Li et al., 2003), cocaine (Robinson and Kolb, 1999; Robinson et al., 2002; Norrholm et al., 2003; Li et al., 2004), morphine (Robinson and Kolb, 1999; Robinson et al., 2002), or nicotine (Brown et al., 2000; Brown et al., 2001) all affect dendritic length and/or spine density compared to that of controls, with some differences in the pattern of dendritic changes for individual drug treatments (*Figure 20-3*).

Chronic treatment (3–5 weeks) with either amphetamine or cocaine increased both total dendritic length and dendritic spine densities in medium spiny neurons of the NAcc and caudate, as well as in the apical dendrites of layer III pyramidal neurons of the prefrontal cortex (Robinson and Kolb, 2004). For the NAcc, these changes are seen in both the shell and core subregions. With the exception of Li et al. (2003), all spine density measurements were taken from the distal dendritic branch. Li et al. (2003) confirmed that the changes in spine density indeed occur only in the distal branches and not in the more proximal dendritic

Figure 20-3

An illustration of the effects of sexual experience on dendritic structure. Sexual experience in female hamsters produced region specific effects on spine density in the medial prefrontal cortex, NAcc significantly decreased spine density (left panel) in the terminal branches of the apical dendrites of prefrontal cortex pyramidal neurons, while increasing spine density on terminal branches of accumbens medium spiny neurons. Sexual experience had no effect on caudate medium spiny neurons



branches of the medium spiny neurons of the NAcc and caudate. Robinson et al. (2001) performed an interesting twist on this approach using animals self-administering cocaine. In this paradigm animals pressed a bar to receive intravenous cocaine for a 7 week period. The same pattern of dendritic changes was observed in the NAcc, indicating that the morphological changes could be produced when the self-administered drugs are related to specific effects of cocaine in the brain. Supporting this conclusion was the observation that additional rats bar pressing for food pellets over this same time period had no change in dendritic measurements (Robinson et al., 2001). On the other hand, only changes in the NAcc core are specific to animals that had shown behavioral sensitization (Li et al., 2004). In this experiment, animals were treated with cocaine in a novel environment or their home cage. Animals that received cocaine in the home cage did not sensitize, while animals treated with cocaine in the novel environment did. Both groups showed increased branching in the NAcc shell, while only the sensitized group had increased branching in

the NAcc core (Li et al., 2004). These findings indicate that cocaine induces increased branching in the NAcc shell, independent of behavioral changes, whereas dendritic branching changes in the NAcc core are related to behavioral sensitization.

Nicotine injections over a period of 5 weeks produced a somewhat different pattern of dendritic response (Brown and Kolb, 2001). For the NAcc, the pattern was the same as that of amphetamine and cocaine. That is, there was an increase in both dendritic length and spine density. In the pyramidal cells of the prefrontal cortex, spine density increased in both the basilar and apical dendrites. On the other hand, the dendritic length increased in the basilar, but not in the apical dendrites of the prefrontal cortex neurons.

In contrast to drugs having stimulant properties, chronic morphine treatment reduced dendritic length and spine density in neurons of both the NAcc and prefrontal cortex (Robinson and Kolb, 1999; Robinson et al., 2002). Like the effects seen with cocaine, it did not matter whether the morphine was injected or self-administered by the rat.

One interesting feature of these experiments is the persistence of the drug effects on dendritic morphology. Though a time course of dendritic changes has not been established (after all these are heroic anatomical studies), the delay between drug administration and sacrifice has been as short as 2 days (Norrholm et al., 2003) and as long as 3.5 months later (Li et al., 2003). Consequently, the structural changes appear relatively soon after at least the cessation of drug administration, but are retained even in the absence of further drug administration.

The absence of an effect of bar pressing for food on dendritic morphology would suggest that these structural changes are a consequence of the pharmacological actions of the drugs rather than an inherent plasticity of these neurons and activation of afferent pathways. Nevertheless, several recent studies indicate otherwise. Induction of a salt appetite through diuretic treatments followed by consumption of saline led to an increase in dendritic length in medium spiny neurons of the shell of the NAcc (Roitman et al., 2002). There was no effect on spine density, though as the authors note the static spine density coupled with an increase in dendritic length would yield an increase in total numbers of spines. Fiorino and Kolb (2003) found that dendritic length increased in both apical and basilar dendrites of prefrontal cortex pyramidal neurons following sexual experience in male rats. In contrast, there was a decrease in dendritic length in medium spiny neurons of the NAcc. Spine densities were not reported in this study. In a similar study in female hamsters (Mullins et al., 2004), spine density was increased in the NAcc, but decreased in apical dendrites of prefrontal cortical neurons following sexual experience. There was no difference between experienced and naive hamsters in spine density in medium spiny neurons of the caudate nucleus. Total dendritic length was not measured. One interesting speculation derived from this work is that comparisons between the drug effects and those following natural behaviors may offer insight into the pathways and neurotransmitters recruited by different behaviors.

3.3 Synaptic Mechanisms

Considerable research effort has been aimed at discovering molecular mechanisms mediating drug-induced sensitization and natural rewards. Based on our foregoing discussions, we can look for clues to these mechanisms from observations of behavioral sensitization, structural (particularly dendritic spine) alterations, and dopamine/glutamate interactions related to both repeated drug treatments and experience with natural rewards. The predominant approach has been that of hypothesis testing, in which individual endpoints are measured in response to particular treatment conditions. Recently, a discovery approach has been taken using DNA microarrays to broadly screen differences in gene expression across experimental conditions (Gonzalez-Nicolini and McGinty, 2002; Backes and Hemby, 2003; McClung and Nestler, 2003; Sokolov et al., 2003; Yuferov et al., 2003; Bradley et al., 2005). In many cases, we can identify the "usual suspects" in these cellular and molecular mechanisms, though there are some unsuspected signaling pathways at work here as well. Because the goal of the microarray analyses is to generate "hypotheses," the value of this approach will only be known following future experimental tests of these hypotheses. For this review, we will focus on the results of the conventional approach.

Both presynaptic and postsynaptic mechanisms of dopamine neurotransmission have been explored, with the obvious candidates emerging. Increases in extracellular dopamine following repeated experience with drugs or natural behaviors are certainly related to neuronal firing rate (Floresco et al., 2003). Still, the sensitized and cross-sensitized responses to drugs and natural behaviors suggest that these augmented synaptic levels of dopamine include changes in dopamine autoreceptor and transporter function. To be fair, for both functions contradictions exist in whether repeated drug treatments yield prolonged effects. Some of these contradictions have been resolved based on methodological differences in route or timing of drug administration (Henry and White, 1991; King et al., 1994; Henry et al., 2002). Regarding autoreceptor function, the ability of autoreceptor agonists to inhibit dopamine release is reduced in animals sensitized to cocaine or amphetamine (Ackerman and White, 1990; Pierce and Kalivas, 1995; Pierce et al., 1995; Jones et al., 1996; Chen et al., 1999). The reduction in autoreceptor responsiveness is a product of both receptor sensitivity and overactivity of pertussis toxin-sensitive effector mechanisms (e.g., Bates et al., 1991). In fact, infusions of pertussis toxin into the NAcc sensitize the locomotor response to an acute cocaine challenge (Hummel and Unterwald, 2003).

Parallel to autoreceptor changes, effects of drugs on dopamine transporters could also augment synaptic concentrations of dopamine. Repeated administration of methamphetamine, amphetamine, or cocaine yields consistent decreases in NAcc uptake of exogenously applied dopamine, mRNA for the dopamine transporter, increased transporter turnover, or decreased transporter binding sites (Cass et al., 1993; Masserano et al., 1994; Boulay et al., 1996; Hitry et al., 1996; Letchworth et al., 1997, 2001).

On the postsynaptic side, chronic drug administration has been reported to produce transient increases in dopamine D1 receptor binding (Alburges et al., 1993; Bonhomme et al., 1995), long-term increases in D1 binding (Unterwald et al., 1996), decreases in D1 receptor binding (DeMontis et al., 1993), or no effect on D1 binding (Nestby et al., 1997). A similar lack of congruence is seen in dopamine D3 receptor regulation (Chiang et al., 2003; Le Foll et al., 2003).

In addition to dopamine receptor resistance to repeated drug treatments, G-protein levels are not altered by a sensitizing drug regimen. Perrine et al. (2005) administered cocaine to rats for 14 days, after which the rats displayed sensitized locomotor responses. Although there was some pattern of alterations in mRNA expression, protein levels of Gαs, Gαolf, Gαo, or Gαi1 were unchanged in either the NAcc, prefrontal cortex, or striatum after 1, 3, or 14 days of cocaine exposure. In contrast, repeated treatments with drugs (Roseboom et al., 1990; Van Vliet et al., 1993; Schoffelmeer et al., 1996; Unterwald et al., 1996) or sexual experience (Bradley et al., 2004) enhance cAMP accumulation through dopamine D1 receptor stimulation. These latter findings suggest that although levels of dopamine D1 receptors and their cognate G-proteins are not affected by drug administration or experience with a natural reward, the coupling of the receptor/G-protein complex to downstream signaling pathways, for example through RGS protein inhibition (Rahman et al., 2003), is more efficacious. In support of this interpretation are the findings that (1) intracerebral administration of forskolin, a direct activator of adenylyl cyclase, facilitates locomotor sensitization to cocaine (Schroeder et al., 2004) and (2) cAMP-dependent protein kinase A inhibition blocks conditioned place preference to amphetamine (Beninger et al., 2003).

Besides dopamine signaling, NMDA receptor activation will lead to a biochemical cascade that can affect activity of dopamine neurons. The two most notable consequences of calcium entry through NMDA receptors are the activation of the calcium/calmodulin system along with the activation of the MAP kinase pathway (Adams et al., 2000; Licata et al., 2000). Increased intracellular calcium levels through NMDA receptors, or for that matter through L-type calcium channels increase calmodulin activity, which in turn activates calcium/calmodulin protein kinase (CaMKII). CaMKII thereby phosphorylates CREB, which leads to an increase in gene expression. Calmodulin will also activate raf, which forms an entry point into the MAP kinase system. Further, the MAP kinase pathway is activated through phospholipase C mediated pathways as well as binding to cell-surface growth factor receptors such as receptor tyrosine kinase.

What makes this system so notable with respect to reward-related processes is that cAMP accumulation through G-protein coupled receptors (e.g., dopamine D1 receptors) also provides an entry into the MAP kinase pathway. This interaction becomes more salient with the demonstration of a reciprocal regulation of the phosphorylation of DARPP-32 through dopamine and NMDA receptor activation (Valjent et al., 2005).

Collectively, this system is key to the sensitizing effects of drugs of abuse and natural rewards. A host of manipulations, including stimulation of L-type calcium channels, administration of brain-derived neurotropic factor (an endogenous ligand for receptor tyrosine kinase), elimination of DARPP, blockade of protein kinase C, or direct manipulations of the MAP kinase pathway illustrate the importance of these signaling systems in reward (e.g., Horger et al., 1999; Licata et al., 2000; Zachariou et al., 2002; Gerdjikov et al., 2004).

Not clear from the foregoing discussion is how these transient events lead to long-term changes in neural and behavioral plasticity. One proposed resolution to this question was the discovery of the transcription factor deltaFosB (Kelz et al., 1999; McClung and Nestler, 2003). Because deltaFosB expression is stable over long periods of time, repeated neuronal stimulation produces an incremental accumulation of this protein. Elevated deltaFosB increases the sensitivity of the cells to further stimulation (e.g., by cocaine) meaning a higher level of behavioral output. As would be expected from this hypothesis, overexpression of deltaFosB yields a sensitized response to cocaine (Colby et al., 2003). Rounding things out, NMDA receptor activity can regulate the protein kinase Cdk5 (Wei et al., 2005). Cdk5 regulates NMDA receptor activity, calmodulin, protein kinase A, and DARPP-32 dephosphorylation (Bibb, 2003). Cdk5 may link these processes to the formation of dendritic spines, serving a common function in the biochemical and structural plasticity of dopamine responsive neurons.

3.4 Summary

An individual's experience with both drugs and natural rewards produces alterations in behavior that reflect changes in underlying neural systems. The commonality of these neural alterations is predicted by the reciprocal effects of drugs and natural experiences on an individual's future reaction to drugs or behavioral expression. Indeed, these experiences are represented by a morphological and biochemical plasticity that encompasses several brain regions, several neurotransmitter systems, and interacting signaling pathways. At the same time, there are important differences in the cellular and molecular responses to drug exposure and one's ongoing natural behaviors. One goal of future research will be to disentangle the complexity of these experiential effects to distinguish those neural responses forming the basis for behavioral flexibility from the pathological corruption of these pathways leading to addiction.

4 Sex Differences in Reward

Very little research has investigated sex differences in reward systems, except for some recent work investigating sex differences in drug abuse. There is some research on sexual motivation in male and female rats, but studies that directly investigate differences between males and females are rare. Nevertheless, as will be discussed below, there are sex differences in and hormonal influences on drug taking behavior, the behavioral response to psychomotor stimulants, sexual motivation, and feeding behavior.

The differences between males and females in the modulation of natural rewards are in part due to the modulation of these behaviors by ovarian hormones. Estradiol decreases feeding behavior and in combination with progesterone activates sexual behavior. In other words, there is day-to-day variation in the value of natural rewards in females. As a consequence of the ovarian cycle, the reward system in females is rarely in a state that is maximally activated by stimuli. In fact, the rewarding value of many stimuli is in a state of constant variation, due to hormonal changes of the estrous cycle. In males, enhanced testosterone secretion that occurs in response to some behaviors may be rewarding, in addition to the rewarding value of the stimulus. As a consequence, sex differences in steroid secretion may affect the neurochemical tone in reward pathways differentially between males and females. Similarly, the salience of external stimuli (e.g., food or conspecifics) may fluctuate as a function of hormonal state. These variations in activity of reward pathways would be expected to impact the individual's response to pharmacological agents that similarly activate these neural pathways. And in fact this is the case. If the goal of motivated behaviors is the activation of internal reward processes rather than the homeostatic biological mechanisms that are necessary for survival

and reproduction, these behaviors serve a homeostatic function. Evolutionary pressures led to a situation that optimized the link between reward and homeostasis.

Regulation of behaviors optimizes activation of reward pathways with reproduction, regulation of metabolic fuels, electrolyte balance, and the secondary consequences of the rewarding value of behavioral activity. Again, this would suggest that there are both points of convergence and divergence between the sexes in the responsiveness of these reward pathways. Thus, in females when drugs of abuse drive neural activity in the reward system day after day, the system shows greater changes than seen in males, because the effect of the drugs is more dramatic. It is not just the magnitude of the drug effect, but that the drug effect occurs repeatedly without waxing and waning. The ways in which males and females differ, as well as the dramatic influences of ovarian hormones on these behaviors, may provide us with new paradigms to tease apart the neurochemical and molecular mechanisms mediating reward.

4.1 Sexual Behavior

Sexual behavior has both appetitive (motivational) and consummatory components. This has been demonstrated most elegantly by experiments from the Everitt laboratory (Everitt and Stacey, 1987; Everitt, 1990). In experiments using a second-order schedule of reinforcement, Everitt and collaborators demonstrated that male rats would bar press for access to a sexually receptive female rat. They went on to show that bar pressing for access to the female rat (i.e., sexual motivation) was abolished by lesions of the basolateral amygdala. In contrast, lesions of the preoptic area had no effect on operant responding for access to the female, but when the female rat was available, the male does not copulate with her (Everitt and Stacey, 1987; Everitt, 1990). These experiments clearly demonstrated that there are distinct neural substrates necessary for sexual motivation versus sexual ability. Furthermore, when amphetamine was delivered to the NAcc of the male rat with basolateral amygdala lesions, bar pressing for access to the female was reinstated. (Everitt, 1990). Since in the rat there are projections from the basolateral amygdala to the NAcc, dopamine in the NAcc was implicated in sexual motivation.

Subsequently, a number of investigators have demonstrated that dopamine increases in the NAcc of male rats in anticipation of gaining access to a sexually receptive female rat. (Pfaus et al., 1990; Pleim et al., 1990; Pfaus and Phillips, 1991; Damsma et al., 1992). Furthermore, both male and female rats exhibit an increase in extracellular concentrations of dopamine in the NAcc during sexual behavior (Pfaus et al., 1990; Mermelstein and Becker, 1995; Pfaus et al., 1995).

Sexual behavior in the female rat is unique in that it is not rewarding to the female under traditional laboratory testing conditions (Oldenberger et al., 1992; Paredes and Alonso, 1997; Paredes and Vazquez, 1999; Martinez and Paredes, 2001; Jenkins and Becker, 2003b). In the laboratory, copulation has historically been studied under conditions where contacts are initiated by the male who engages in a series of mounts and intromissions that ultimately lead to an ejaculation (Bermant, 1961; Adler, 1969). Under these conditions, the male controls the rate of copulation and he will intromit with a female at a relatively rapid rate.

On the other hand, if the female is given a place where she can escape from the male, she will establish longer latencies between sexual contacts (Adler, 1969, 1978; McClintock, 1984; Erskine et al., 1989). In the wild, rats engage in mating in groups of several females and males, and males are able to achieve relatively rapid intromissions with different females. The females, in turn, achieve their preferred rate of copulation by withdrawing from the male and then returning after the preferred interval (McClintock, 1984). This behavior of the females, of withdrawing and then returning to the male after copulatory contacts is known as pacing behavior (Erskine et al., 1989). Pacing behavior allows the female to control both the rate and duration of the copulatory bout. Importantly, sexual behavior is rewarding to the female rat when she achieves her preferred rate of copulation (Paredes and Alonso, 1997; Paredes and Vazquez, 1999; Martinez and Paredes, 2001; Jenkins and Becker, 2003b), whether or not she is actively pacing the rate of copulation (Jenkins and Becker, 2003a).

In support for a role for dopamine in sexual reward, female rats only exhibit an increase in NAcc dopamine if they can achieve a preferred rate of intromissions. This can be accomplished by either the

female actively controlling or "pacing" the rate of copulation or if the experimenter removes the male and then returns it to the female's chamber at appropriate intervals during copulation (Mermelstein and Becker, 1995; Becker et al., 2001). Female hamsters also exhibit an increase of dopamine in dialysate during sexual behavior (Meisel et al., 1993). Achieving the preferred rate of copulation is important for the female rat to optimize the rate of vaginocervical stimulation received from a male which activates a neuroendocrine reflex that is necessary for pregnancy to occur (Adler, 1969; McClintock and Adler, 1977; Adler, 1978; McClintock, 1984; Erskine, 1989).

It should be noted that females engaged in sexual behavior at their preferred pacing interval had greater increases in dopamine in dialysate from the NAcc than did animals in which the male rat was removed and then returned to the female's chamber either too rapidly or much later (Becker et al., 2001). Furthermore, dopamine increases in the NAcc occurred prior to coital stimulation when intromissions are received at the female's preferred pacing interval, but not when coital stimulation occurred under other conditions (Jenkins and Becker, 2003a). Thus, increases in NAcc dopamine are not induced by coital stimulation or escape from/removal of the male rat. Instead, dopamine increases occur in anticipation of coital stimulation that occurs at a specific interval. These data support the hypothesis that dopamine increases in the NAcc signal the impending receipt of coital stimulation at the female's preferred pacing interval.

Is the increase in dopamine in the NAcc necessary for a female to find sexual behavior rewarding? In hamsters, pretreatment of females with D2-dopamine receptor antagonist raclopride blocked conditioned place preferences for the place in which mating occurred (Meisel, 1996). On the other hand, Paredes found that pretreatment with the dopamine antagonists flupentixol or raclopride did not block conditioned place preference induced by paced mating in female rats (Garcia-Horsman and Paredes, 2004), while naloxone treatment prevented establishment of conditioned place preference induced by paced mating (Paredes and Martinez, 2001). These results suggest that activation of D2 dopamine receptors is not necessary for sexual behavior to be rewarding, but μ-opioid receptor mediated activation, with the downstream effects on GABA, dopamine, and glutamate neurotransmission is important for sexual motivation in the female rat. The study by Garcia-Horseman and Paredes (2004) used relatively low dose of raclopride, so it is possible that in the reward circuit this dose was not sufficient to completely block the effect of dopamine. Alternatively, if sexual reward can be dissociated into "wanting" and "liking," it is possible that the way the conditioned place preference test is conducted (animals are placed into the test apparatus for training immediately after receiving an ejaculation) is particularly sensitive for "liking." This interpretation would be consistent with the findings, as dopamine is thought to be important for "wanting," while GABA and opioid systems are important for "liking."

Sexual behavior of the female rat requires new considerations and interpretations of the role of dopamine in reward. Female rats find sexual behavior rewarding and have increased NAcc dopamine when they engage in sex at their preferred interval (Mermelstein and Becker, 1995; Paredes and Alonso, 1997; Becker et al., 2001; Martinez and Paredes, 2001). Sex that is rewarding has been shown to be associated with the triggering of a neuroendocrine reflex necessary for pregnancy (Adler, 1974; Gilman et al., 1979; Erskine et al., 1989). One possibility is that the changes in dopamine observed here represent a coupling of the sexual interaction and its physiological consequences, both of which may be necessary for sexual behavior to be rewarding. In other words, increases in dopamine predict the receipt of coital stimulation, but only when the coital stimulation occurs at such a rate that triggers the neuroendocrine reflex necessary for successful pregnancy to occur. Coital stimulation is known to induce the release of oxytocin in rats and other species (Flanagan et al., 1993). The neuroendocrine reflex that is activated in the female rat results in the release of prolactin (Erskine, 1995). Since oxytocin is thought to induce the release of prolactin, one possibility is that the activation of the intrahypothalamic neurons necessary for coital-induced release of oxytocin also enhances dopamine release in the NAcc.

4.2 Drug Abuse

The evidence for sex differences in drug abuse and drug taking behavior has been the subject of recent reviews (Lynch et al., 2002; Carroll et al., 2004; Roth et al., 2004), so this review will be brief. Cocaine abuse

by women has increased in the last decade so that of the 1.8 million Americans who use cocaine, approximately 30% are now female (Wetherington and Roman, 1995). According to a recent report, 9% of women aged 12 and above have used cocaine. The only illicit drug used more by women is marijuana (28% have used marijuana) (Kandel et al., 1995). Among women who have used cocaine, prevalence of lifetime dependence for cocaine is 14.9 ± 2.0% (mean ± S.D.). This is in contrast to the case with alcohol where 79% have used it, but only 9.2 ± 0.8% have developed lifetime dependence (Kandel et al., 1995). The use of all illicit drugs has been increasing among women in the past decade, and stimulant drug use and dependence among women, in particular, is a growing public health concern (Wetherington and Roman, 1995; Lynch et al., 2002; Carroll et al., 2004).

Psychomotor Stimulants. Sex differences in the pattern of cocaine abuse and behavioral responses to cocaine indicate that the pattern of cocaine use and the onset of addiction to cocaine are more rapid in women than men (Carroll et al., 2004). Women begin using cocaine and enter treatment at earlier ages than men (Griffin et al., 1989; Mendelson et al., 1991) and have more severe cocaine use at intake than men (Kosten et al., 1993). Furthermore, cocaine cues induce more drug craving in female than male addicts (Robbins et al., 1999). Collectively, these results suggest that women may be more sensitive to the addictive properties of cocaine than men.

Basic research on the role of sex and ovarian hormones in the neurochemical and behavioral responses to acute and repeated exposure to drugs of abuse also finds sex differences. In order to investigate sex differences, the issues involved are complex (Becker et al., 2005). First, adult males and females do not differ solely in their genetic composition, but also in the hormones secreted by their gonads and the patterns of hormone secretion (i.e., females exhibit a cyclic release of estradiol and progesterone, while males exhibit a tonic release of testosterone). These patterns of hormone release are a consequence of hormone exposure during sexual differentiation of the brain. This means that there are three different ways that males and females can be different: (1) sex differences independent of the milieu of gonadal hormones in the adult, due to developmental sex differences in the brain, which are driven either by secretions from the fetal gonads or due to cell-autonomous sexual differentiation; (2) sex differences in effects of gonadal hormones in the adult acting on a sexually dimorphic brain; and (3) sex differences due to the different hormones produced by males and females.

The acute behavioral response to psychomotor stimulants that rodents exhibit can reflect both sex differences and can be modulated by gonadal hormones in males and females. Furthermore, the effect of repeated exposure to psychomotor stimulants results in behavioral sensitization. Behavioral sensitization can be different in males and females, and can also be differentially affected by gonadal steroid hormones. In humans, these factors are intermingled because chronic cocaine use can disrupt and even cause cessation of a woman's menstrual cycle (Mello, 1995). In such women, estradiol may play a role in acquisition of drug taking behaviors, but not in maintenance of these behaviors (because in women with amenorrhea the serum concentrations of estradiol are extremely low).

Research on rodents and humans indicate that the behavioral effects of drugs of abuse and the psychomotor stimulants, in particular, are both sexually dimorphic and modulated by the gonadal steroid hormones (e.g., Gordon, 1980; Hruska and Silbergeld, 1980; Becker and Ramirez, 1981; Di Paolo et al., 1981; Joyce et al., 1982; Dluzen and Ramirez, 1984; Becker and Beer, 1986; Di Paolo et al., 1986; Hruska, 1988; Van Hartesveldt et al., 1989; Dluzen and Ramirez, 1990; Bazzett and Becker, 1994; Lynch et al., 2002; Sell et al., 2002; Carroll et al., 2004). If one considers sensitization of amphetamine or cocaine-induced psychomotor behavior to be the absolute increase in the behavioral response exhibited when two tests are compared, females exhibit more robust sensitization than do intact males (Robinson et al., 1982; Robinson, 1984; Camp and Robinson, 1988a, b; van Haaren and Meyer, 1991; Forgie and Stewart, 1994).

The preponderance of evidence indicates that ovariectomy (OVX) of female rats does not affect the induction or expression of sensitization to amphetamine (Robinson et al., 1982; Robinson, 1984; Camp and Robinson, 1988a, b; Forgie and Stewart, 1994). Yet in some studies, OVX females do not exhibit significant sensitization of cocaine-induced locomotor activity when intact females or gonadal hormone treated females do (van Haaren and Meyer, 1991; Sircar and Kim, 1999). Furthermore, estradiol treatments in OVX rats enhance sensitization of locomotor activity induced by amphetamine or cocaine

(Peris et al., 1991; Forgie and Stewart, 1994). Thus, it is possible that variability in the behavior of intact female rats across the estrous cycle may obscure the effects of ovarian hormones on the induction and/or expression of sensitized psychomotor behaviors in experiments where intact and OVX rats are compared. Effects of ovarian hormones are likely to be seen more clearly when females are OVX and treated with estradiol.

Female rats have also been shown to acquire cocaine self-administration more rapidly than males (Lynch and Carroll, 1999; Carroll et al., 2002; Roth et al., 2004), and cocaine self-administration in female rodents varies across the estrous cycle (Lynch et al., 2000). Female rats will work harder for cocaine (by making more lever presses for an infusion of cocaine) during the estrous phase of the cycle than during other phases of the cycle, and females work harder than male rats (Roberts et al., 1989). In contrast, sucrose self-administration does not vary across the estrous cycle (Hecht et al., 1999).

Estradiol administration to OVX females affects many psychostimulant drug-induced behaviors, including self-administration (Verimer et al., 1981; Peris et al., 1991; Morissette and Di Paolo, 1993; Thompson and Moss, 1994; Grimm and See, 1997; Becker, 1999; Sircar and Kim, 1999; Quinones-Jenab et al., 2000; Freeman et al., 2001). For example, Hu et al. (2004) found that in OVX female rats, exogenous estradiol treatment alone was sufficient to facilitate acquisition of cocaine self-administration. Estradiol-facilitated cocaine self-administration has also been found in other studies (Roberts et al., 1989; Freeman et al., 2001).

In contrast to estradiol, the subjective effects of psychomotor stimulant drugs are negatively correlated with salivary progesterone levels (White, 2002). Furthermore, in rodents, progesterone inhibits cocaine-mediated behaviors, such as estradiol-enhanced locomotor activity and sensitization of cocaine-induced stereotyped behavior, compared to OVX females treated with estradiol. Recently, it was reported that concurrent administration of progesterone with estradiol counteracts the effect of estradiol on acquisition of cocaine self-administration behavior (Jackson et al., 2005). Therefore, over the course of the estrous cycle, and perhaps across the menstrual cycle, there are peaks and valleys during which females are more or less susceptible to the reinforcing properties of cocaine.

Castration (CAST) of males has been reported to enhance sensitization of amphetamine- or cocaine-induced psychomotor behavior (e.g., Robinson, 1984; Camp and Robinson, 1988a, b), although this result has not been found consistently (van Haaren and Meyer, 1991; Forgie and Stewart, 1994). It has been hypothesized that if CAST enhances the induction and/or expression of behavioral sensitization, testosterone treatment should reverse this effect. This is not the case, however, as testosterone treatment has not been found to affect behavioral sensitization in CAST males (Forgie and Stewart, 1994). Furthermore, there is no effect of CAST on acquisition of cocaine self-administration behavior and a dose of estradiol that enhances self-administration in female rats has no effect on cocaine self-administration behavior in male rats. Thus, the effects of estradiol on the acquisition of cocaine self-administration are sexually dimorphic. There are also sex differences in the maintenance of cocaine self-administration, and in the reinstatement of responding after abstinence (Roth et al., 2004). It should be noted that sex differences are most robust at lower doses of cocaine, and at higher doses of cocaine, differences between males and females are less evident.

Opiates, Nicotine, and Alcohol. There are also sex differences in humans and laboratory animals in acquisition, maintenance, and relapse seen with other drugs of abuse. This literature has been reviewed extensively, so the review here will be brief. The reader is referred to recent reviews for additional information (Lynch et al., 2002; Roth et al., 2004).

In laboratory animals, not all studies find a sex difference in self-administration of opiates (heroin, morphine, and fentanyl). When there is a sex difference, females tend to acquire self-administration more rapidly and take more drugs during the maintenance phase (see *Table 20-1* in Roth et al., 2004). In humans, however, there is no sex difference found in the pattern of opiate use (Lynch et al., 2002). Female rats also acquire nicotine self-administration more rapidly than males, and will work harder to receive nicotine than males (reviewed in Lynch et al., 2002; Roth et al., 2004). Women report shorter intervals between cigarettes, and find it more difficult to quit smoking than men (reviewed in Lynch et al., 2002; Roth et al., 2004).

Fewer women than men abuse alcohol (7–12% versus 20%), yet the frequency that young women are becoming intoxicated on alcohol is rising, and the medical consequences of chronic alcohol consumption

are more severe for women than for men (Almeida et al., 1998; Devaud et al., 2003). It has also been suggested that women become addicted to alcohol more rapidly than do men (Lynch et al., 2002). In laboratory animals, there are sex differences in the development of and recovery from ethanol dependence. Female rats have decreased seizure threshold following withdrawal and have a more rapid return to the control level of seizure susceptibility (Devaud and Chadda, 2001). Devaud and colleagues have found that ethanol administration affects $GABA_A$ and NMDA receptor subtypes differently in male and female rat brain, and the direction of the sex difference varies among brain regions (Devaud and Alele, 2004). Whether the sex differences in the effects of alcohol and $GABA_A$ and NMDA receptors mediate sex differences in the long-term consequences of alcohol dependence is not known. Further research in the clinical setting and the laboratory is needed to clarify the causes and extend our understanding of the nature of the sex differences.

4.3 Summary

It is clear from this brief discussion that there are sex differences in the reward system. Studies of the response to cocaine in gonadectomized male and female rats suggest that there is an underlying sex difference due to sexually dimorphic development of the brain that, in part, mediates the sex difference in reward behavior. In addition, there are effects of gonadal hormones that modulate the reward system. In particular, estradiol enhances the rewarding value of drugs, whereas progesterone counteracts the effect of estradiol.

5 General Principles and Significance

The principles governing the motivation to engage in behaviors motivated by natural rewards are the same as those governing disorders such as drug abuse and other pathological conditions. In general, activation of dopamine release in the NAcc is an internal cue that tells an animal that something desired is available (or is soon to be available). We conclude, as others have, that this dopamine signal is associated with enhanced incentive salience or "wanting" of the desired stimulus. Glutamate and GABA neurons modulate dopamine release, providing input related to context and motivational state. GABA and endogenous opioids also provide information about the hedonic value of the stimulus or "liking."

Sex differences in motivation and motivational systems may provide key insights into the fundamental processes mediating the switch from natural rewards to pathological behaviors, such as drug addiction. We argue that knowledge of sex differences in reward processes is essential for the development of appropriate therapeutic approaches. A rational therapeutic treatment must accommodate differences between males and females.

8 Concluding Remarks 794

Abstract: Cognitive function – the ability to learn, retain, and recall information – changes over the lifespan and shows some sexual dimorphism. These patterns of cognitive ability appear to depend, in part, on the changing/different mileu of circulating steroid hormones. This review examines the extent to which steroid hormones, gonadal, and adrenal, influence cognitive function. First, emerging studies indicate that estrogens (directly secreted or derived from androgens) and glucocorticoids (cortisol in humans and corticosterone in most rodents) exert programming effects on cognition during the perinatal period which are subsequently expressed at adulthood. At adulthood, hormones also promote or impair cognition, depending on the specific hormone, the sex of the subject, and the situation/function examined. Finally, steroids appear to be important contributors to age-related losses in memory function. Hormonal actions on cognition, like their well-described effects on homeostatic function, rely on specific genomic activations of neurons via morphological and neurochemical mechanisms in brain areas underlying memory function. Newer evidence also suggests that estrogens rapidly activate signal transduction pathways via membrane receptors to enhance memory. Using classic, posttraining paradigms for assessing learning and memory, these rapid effects of estrogen on neural function have been shown to reflect enhancements in the consolidation of memory. While it is clear that hormonal effects on cognition are not generally large, this review posits that hormonal influences are nonetheless pervasive throughout the lifespan and provide fundamental, important regulation over higher order neural function, i.e., the intellectual/cognitive realms of life.

1 Introduction

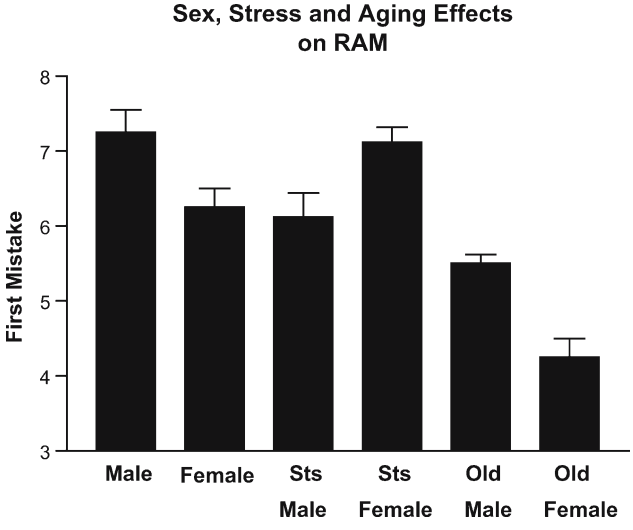
The emergence and progress of neuroendocrine research during the latter half of the 20th century demonstrated without question that numerous hormones act within specific sites of the mammalian brain to regulate homeostatic functions critical for life. Previously, the pituitary was thought to be the site for regulation of hormonal secretions and actions. Thus, it was surprising when endocrine studies demonstrated that hypothalamic and preoptic area sites were responsible for hormonal regulation of ovulation and sexual behavior (Everett, 1965; Gorski, 1971). Currently, endocrine glands that synthesize centrally acting hormones include – but are not limited to – the gonads, adrenal gland, thyroid gland, gut, and pancreas (van Wimersma Greidanus and Rigter, 1989; Nelson, 2005). Thus, hormones acting in the brain regulate such diverse functions as reproduction and growth, and hormones also influence ingestion and the sleep–wake cycle (Nelson, 2005). Traditionally, this regulation has involved hormonal action at brain sites and systems that are not involved in complex, higher order brain function, for example at sites in hypothalamic, limbic, and spinal cord areas.

Current neuroendocrinological research, driven by advances in molecular biology and technology, suggests that hormones also impact higher order brain functions such as mood and psychiatric symptoms (Ostlund et al., 2003; Payne, 2003), cognitive function (Luine and Harding, 1994; Dohanich, 2002), and bonding/affiliation (Carter et al., 1997). These effects are mediated by hormonal actions at additional sites and/or neural systems in cerebral cortex, basal forebrain, hippocampus and striatum which are responsible for complex, higher order neural function. Thus, hormones may not only regulate homeostatic/housekeeping functions of the central nervous system (CNS), but they may also influence the intellectual/cognitive realms of life.

This review will examine and discuss evidence for steroid hormone – adrenal and gonadal – influences on cognitive processes. The primary focus is on basic research in rodents but pertinent, relevant data in primates/humans, will also be provided in order to highlight the relevance of the animal data. Hormonal influences on cognition will be examined over the lifespan as it is important to note that hormones exert potent influences during critical developmental periods before birth, during the neonatal period, at puberty and adulthood, and also impact the aging process. While hormonal influences on cognition at each period of development are not generally large, the accumulation of effects across the life span are particularly evident in old age, especially in females who experience the greatest age-dependent changes in circulating hormones. *Figure 21-1* highlights sex differences and the effects of stress and aging on performance of the spatial memory task, radial arm maze, in rats (see Section 4.3 for specific information on the radial arm maze task).

Figure 21-1

Sex, stress, and aging affect radial arm maze performance in rats. Performance of the spatial memory task, radial arm maze, is shown in male and female rats of various ages and after chronic stress. Bars are the average ± SEM of the choice where the subject made the first mistake (larger numbers indicate better performance). Young males and females (2–3 months) served as controls or received daily restraint for 21 days. Old rats were 22–24 months old. Chronic stress impairs young male performance but enhances female performance. Both aged males and females are impaired as compared to young controls, and aged females show the worst performance of all groups. Data are combined from a number of studies and are for illustrative purposes only as no statistical tests were performed to test group differences. See the original studies for details and statistical analyses. Data from Luine and Rodriguez (1994), Luine et al. (1994), Luine and Hearns (1990), Bowman et al. (2001)



2 The Endocrine Brain – Mechanisms and Sites for Steroid Hormone Modulation of Neural Function

2.1 Hormonal Activation Through Intracellular Receptors

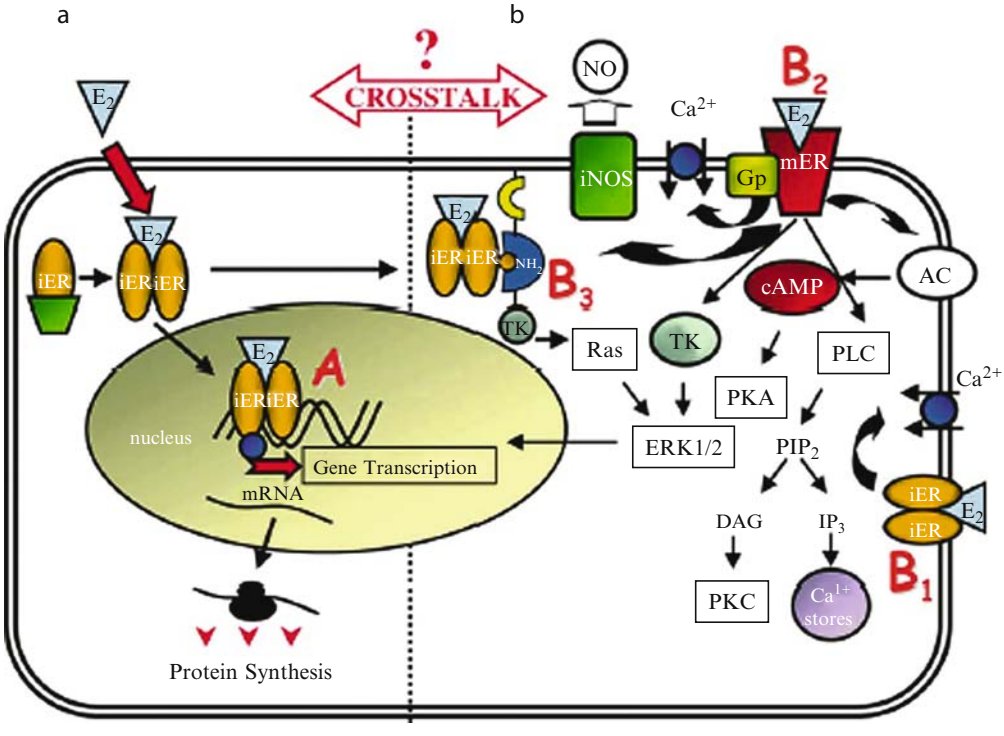
Receptors for the gonadal hormone estradiol were first identified and characterized from the uterus approximately 40 years ago and subsequently identified in specific brain sites (see Jensen and Jacobson, 1962 for review). Recently, a second type of estrogen receptor has been identified and receptors binding

estradiol are currently designated as estrogen receptor alpha (ERα) and estrogen receptor beta (ERβ) (Kuiper et al., 1997). Both receptors are ligand-dependent transcription factors and through interactions at specific sites on DNA, initiate a cascade of intracellular reactions culminating in unique physiological responses within estrogen target tissues like uterus, breast, osteoclasts, and neurons of the brain (*Figure 21-2*). *Figure 21-2* also illustrates that recent studies show hormonal activations by estrogens through membrane receptors. This mechanism is discussed further in Section 2.4. See McEwen and Alves (1999) for a detailed description of genomic mechanisms for estrogen action in the CNS.

Receptors for glucocorticoids (cortisol in humans and corticosterone in most rodents) and mineralocorticoids (aldosterone) as well as other gonadal hormones like progesterone and testosterone were identified around the same time as the estrogen receptor, and all are now known to be part of the steroid super family of receptors which also includes vitamin D (Tsai and O'Malley, 1994; Smith and

Figure 21-2

Diagram of possible mechanisms by which estradiol may act in neurons to alter function and thereby enhance memory. (a) Genomic pathway through classical cytosolic/nuclear receptors acting as nuclear transcriptional factors. This pathway would be present in only the soma of neurons. (b) Nongenomic pathway mediating rapid effects via signal transduction mechanisms through unusual membrane receptor (B2) or classical cytosolic/nuclear receptor spanning through plasma membrane (B1) or through multiproteic complex associated to the inner part of plasma membrane (B3). Nongenomic pathways could be present in the soma, in dendritic spines, or in nerve terminals. E_2: estrogens; iER: classical cytosolic/nuclear ER; mER: membrane ER; Gp: G protein; iNOS: inducible nitric oxide synthase; NO: nitric oxide; TK: tyrosine kinases; AC: adenylate cyclase; SH2: Src homology domain; PLC: phospholipase C; PKA: protein kinase A; ERK1/2: ERKs 1/2; DAG: diacyl glycerol; IP3: inositol 3-phosphate; PKC: protein kinase C; cAMP: cyclic adenosin monophosphate; PIP2: phosphatidyl inositol bisphosphate. Reprinted from Luconi M, Forti G, Baldi E. 2002. Genomic and nongenomic effects of estrogens: molecular mechanisms of action and clinical implications for male reproduction. *J Steroid Biochem Molec Biol* 80, with permission from Elsevier



O'Malley, 2004). Like estrogen receptors, adrenal steroid receptors have a unique distribution within the brain and act as ligand-dependent transcription factors to alter neural function (See deKloet et al., 1994 for details). When steroids are bound to their respective receptors, they initiate new protein synthesis through interactions with specific sites on DNA and in this way influence function in their target neurons (*Figure 21-2*).

2.2 Brain Areas Involved in Steroid Effects on Cognition

Brain areas which mediate cognition in animals and humans include, but are not limited to, frontal cortex, basal forebrain, hippocampus, amygdala, and striatum (see Section 3.1 for details) and in these areas, estradiol, testosterone, progesterone, and adrenal hormones exert wide ranging effects (see below). It is noteworthy, in this context, that ERβ is found in several cortical areas, including frontal cortex, and the hippocampus (Mitra et al., 2003). In contrast, ERα is present at low levels in these areas (Shughrue et al., 1997). Thus, current theories hypothesize an important role for ERβ in cognitive function (Rissman et al., 2002), a hypothesis requiring further testing and confirmation (see Section 4.3).

The foundation for glucocorticoid effects on learning and memory was laid with the remarkable demonstration in the early 1970's that ^{3}H-corticosterone was avidly deposited within pyramidal neurons of the hippocampus when it was administered to adrenalectomized rats (McEwen et al., 1968). Subsequently, receptors for glucocorticoids have been measured in areas subserving both the stress response and cognitive function (van Steensel et al., 1996; Helm et al., 2002); thus providing a strong context for stress influences on cognition. Influences of estrogen on cognition stemmed from the demonstration that cognitive loss in Alzheimer's disease derived from loss of cholinergic neurons and that estrogen activated cholinergic neurons in this circuit through genomic activation by estrogen receptors (Luine et al., 1975, 1994; Luine, 1985; Wickelgren, 1997). Current studies have amplified these observations of steroid hormone influences on cognitive function (Gibbs and Aggarwal, 1998).

2.3 Morphological and Neurochemical Effects of Steroids

At the morphological level, steroids regulate the structure of dendrites, spines, and synapses in brain regions critical for memory. For example, estradiol treatment to ovariectomized (Ovx) rodents increases the number of dendritic spines in CA1 hippocampal pyramidal neurons (Gould et al., 1990; Woolley and McEwen, 1992; Li et al., 2004), and estradiol and testosterone both increase the density of spine synapses in CA1 pyramidal neurons (Leranth et al., 2000; MacLusky et al., 2005). Cortical neurons and terminals have received less investigation, but Kritzer and Kohama, (1998) and Markham and Juraska (2002) found that hormone induced plasticity is present in these areas as well. Recent studies have confirmed estrogen-dependent influences on spines, synapses, or neural markers in nonhuman primates (Leranth et al., 2002; Hao et al., 2003; Tang et al., 2004; Voytko and Tinkler, 2004). Moreover, estradiol administration is also associated with increased neural cell birth in the dentate gyrus of the hippocampus (Tanapat et al., 1999).

Stress hormones also regulate morphological structure in CNS; however, these effects are generally opposite to gonadal hormone effects. Chronic restraint stress or corticosteroid administration is associated with a pruning of the apical dendritic arbor of CA3 pyramidal neurons as well as layer III frontal cortex pyramidal neurons (Watanabe et al., 1992; McEwen, 2001; Wellman, 2001). In cases of severe and prolonged stress, neuronal loss in the hippocampus has been reported (Uno et al., 1989); however, this effect awaits further validation.

Using neurochemical techniques, estrogens, progestins, and glucocorticoids have been shown to affect activity in a variety of neuronal systems: the basal forebrain–hippocampal cholinergic system, serotonergic cell bodies and terminals, monoaminergic terminals and δ-amino-butyric acid (GABA) containing interneurons and projecting systems (see McEwen and Alves, 1999; Bowman et al., 2003 for reviews). The synthesis and release of a number of trophic factors and/or their receptors are also affected by gonadal hormones in sites subserving memory and include BDNF, NGF, IGFII, and others (Gibbs and Aggarwal, 1998; Gibbs, 1999). Thus, direct genomic activation of diverse neural circuits by hormones has been demonstrated.

In summary, steroid hormones exert a wide range of effects on neural function and these effects may in turn influence cognitive function. Genomic actions at the cell nucleus by the hormones result in long-lasting, sustained effects on neural function. Thus, it is likely that genomic changes subserve developmental hormone effects, which exert life-long actions in programming sex-dependent functions and sex-dependent differences in functions. In adults, genomic effects also likely underlie changes over the menstrual and estrous cycles, and during aging. Alterations in neural function during aging may also derive from sustained down regulation of genomic function by age-related decreases in circulating gonadal hormones. This notion is expanded and elaborated upon in the following sections.

2.4 Hormonal Activations Through Membrane Receptors

Recently, estrogen receptors have been identified in extranuclear sites, primarily the membrane, in peripheral tissues like the breasts and epithelial cells, and in the CNS (Levin, 2002; Toran-Allerand et al., 2002). See *Figure 21-2*. During development, nonnuclear receptors appear in areas of the cerebral cortex of mice (Toran-Allerand et al., 2002). These receptors, in contrast to classically identified ERα and β receptors, mediate rapid hormonal effects (sec to min) through signal transduction pathways (see Levin, 2002 for review and details). While the extranuclear presence of receptors in neurons remains to be validated, several studies indicate putative estrogen receptors (whether they are ERα or β, or another different receptor remains to be determined) in membranes of cell bodies, axons, spines, presynaptic terminals, and near postsynaptic neurotransmitter receptors (*Figure 21-2*; Blaustein, 1992; Milner et al., 2001; Towart et al., 2003). Thus, the possibility is raised that estradiol, or other steroids, could exert rapid changes in cognitive and other functions through these receptors.

As the demonstration of nonnuclear steroid receptors is recent, their role in brain function is currently unclear. Changes in several signal transduction pathways, for example, MAP kinase (mitogen-activated protein kinase), CREB (cAMP response element-binding protein), and several immediate, early genes have been shown within minutes following estrogen in vitro and in vivo (Toran-Allerand et al., 1999, 2002; Bi et al., 2000, 2001; Singh, 2001;Wade et al., 2001; Znamensky et al., 2003). See *Figure 21-2* for schematic of the relationship between these pathways. Interestingly, estrogen-dependent enhancements in recognition memory have been demonstrated within 4 h, an effect which may be extragenomic (Luine et al., 2003; see Section 4.5). The membrane receptors may also cross-talk with the genomic receptors to amplify or modify hormonal effects (See *Figure 21-2*). However, it remains unclear, at this time, to what extent nongenomic mechanisms of hormone action contribute to neural function and enhancement of cognition.

3 The Cognitive Brain – Mediation of Learning and Memory

3.1 Sites for Learning and Memory

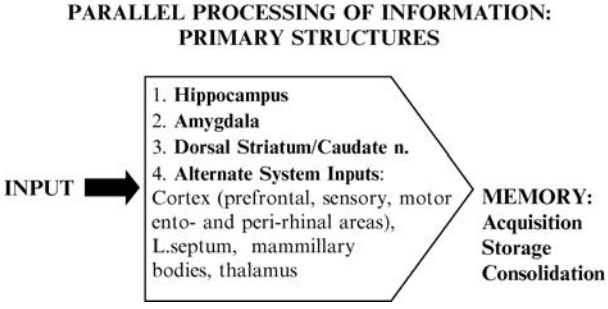
Cognition represents a complex, multidimensional set of intellectual functions whose component processes are subserved by specific, yet interrelated, brain sites. In this context, no generally accepted framework for the acquisition, consolidation, and retention of memory has been agreed upon and a number of neural substrates of memory, "memory molecules," have been delineated, but which may be most important and how the molecules are coordinated is still generally unclear (but see Bailey et al., 2004; Ge et al., 2004). However, some agreement as to brain areas/systems necessary for cognition exists, and several different theories link these critical brain sites together in diverse ways. Thus, as a detailed description of the neural, chemical, or anatomical bases for cognitive function is still not available, neuroendocrinologists are unable to delineate how hormones might alter memory. Nonetheless, a brief synopsis of currently held notions of cognition and how hormones might intervene to alter cognitive function follows.

At a minimum, brain areas incorporated into theories of cognition function include the hippocampus, dorsal striatum (basal ganglia), amygdala, and several cortical areas (Ennaceur and Aggleton, 1994; Packard et al., 1994; Ennaceur et al., 1997). Most researchers have hypothesized multiple "memory systems" which

operate in parallel to process information; however, the exact number varies. White and McDonald (2002) recently reviewed evidence for three systems relying on "three central structures," the hippocampus, the matrix compartment of the dorsal striatum (caudate putamen), and the amygdala (*Figure 21-3*). All

Figure 21-3

The concept of parallel processing of information as reviewed by White and McDonald (2002). Three systems, which have as primary structures the hippocampus, amygdala, and dorsal striatum/caudate putamen and which may receive input from an alternate system (cortex, lateral septum/mammillary bodies, and thalamus), function independently to facilitate learning. Each system receives input which leads to learning and memory formation, but each system processes that information differently (processing style). These systems influence behavior/memory in either a cooperative or competitive manner, but all systems lead to storage of information (memory) that influences future processing of similar information



systems access the same information at acquisition, but each is specialized to take in and process a different kind of relationship between stimuli, responses, and reinforcers which flow through it. In contrast, Steckler et al. (1998) posited two parallel systems for recognition memory in rats. Network I is essential for the processing of nonspatial/item recognition memory processes and incorporates the cortical association areas, the rhinal cortices, the mediodorsal thalamic nucleus, and prefrontal cortical areas. Network II comprises the hippocampus, mammillary bodies, anterior thalamic nuclei and medial prefrontal areas, and is suggested to be pivotal for the processing of spatial recognition memory.

3.2 Mechanisms for Learning and Memory

Current hypotheses of cognitive function are congruent with the concept of memory consolidation as originally advanced at the beginning of the 20th century by the laboratory of Muller and Pilzecher (see McGaugh, 2000 for discussion), which hypothesized that newly acquired information or memories (short-term memory) were consolidated into long-term memory. The exact nature of this process still remains unclear, but see discussion below. McGaugh and coworkers have highlighted the critical role of the amygdala in the consolidation, but not necessarily the storage, of all forms of memory in multiple brain areas (McGaugh, 1989; Packard et al., 1994; Roozendaal et al., 2004).

In relation to the action of steroids within current tenets of memory function, it is notable that nuclear or other receptors for steroids are present in the four key brain's areas underlying cognitive function (described above). However, the strongest association of steroids with retention of memory is found with spatial memory functions of the hippocampus. This relationship is present for gonadal hormones (see Section 4) and for adrenal hormones (see Section 5).

Progress on the molecular/neurochemical basis of memory is spearheaded by elegant studies of the Kandel (Bailey et al., 2004) and Tully (Ge et al., 2004) groups. While details of these studies are beyond the scope of this review, several signal transduction pathways which may form the basis of short-term and long-term memory have been identified in aplysia, the fruit fly, and in some cases, rats or mice. Integral to this

process is CREB and other signal transduction pathway intermediaries like MAP kinase and the immediate early genes cJun and cFos (See *Figure 21-2*). Recent studies in brain show that estrogen affects these signal molecules (Bi et al., 2000, 2001; Znamensky et al., 2003; Akama and McEwen, 2003) and coupled with the identification of estrogen receptors outside of the nucleus in cortex, striatal, and hippocampal areas, it can be hypothesized that gonadal hormones may influence consolidation of memory through these signal transduction pathways (See *Figure 21-2*).

In summary, a strong basis for hormones influencing cognition can be advanced as the structures critical for memory express receptors which bind and mediate steroid hormone action (McEwen, 2001; de Kloet, 2004). The looming challenge is for neuroendocrinologists and cognitive scientists to collaborate in designing experiments to test critical hypotheses: a new field of cognitive neuroendocrinology?

4 The Sexual Brain – Gonadal Hormone Influences on Cognition

Gonadal hormones initiate reproduction and attendant sexual behaviors in males and females through central regulation of the hypothalamic/pituitary/gonadal axis. Neuroendocrinological research in the past 50 years has documented the roles and neural sites of estrogens, progestins, and androgens in the activation and maintenance of these events (the sexual brain). The breadth and depth of this research has established that hormonal regulation of these reproductive functions resides within the CNS (see Micevych and Hammer, 1995).

4.1 Gonadal Hormone Activation of Cognition

Recent studies have extended observations on hormonal effects in brain and suggest that gonadal hormones also modulate neural areas responsible for complex, higher order function (Luine, 1994; Luine, 1997; McEwen et al., 1995; McEwen and Alves, 1999; Dohanich, 2002). While this hypothesis has not received widespread investigation, a body of evidence is building. Studies demonstrating gonadal hormone modulation of cognitive processes are highlighted in the following sections.

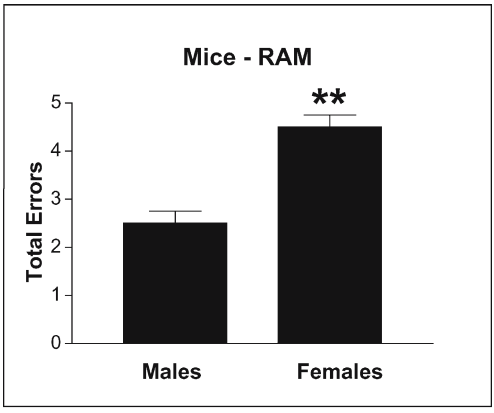
4.2. Sex/Gender Differences in Cognition

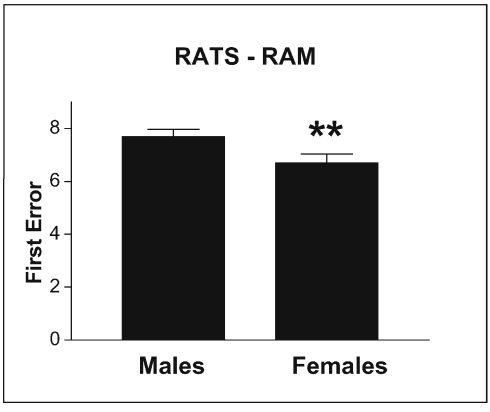
In adults, an initial observation suggesting gonadal hormone influences on cognitive function was that males and females differ in performance of some tasks/tests requiring memory. For example, men outperform women in tasks requiring spatial contexts (Hampson, 1990). This pattern of male gender superiority is also seen in rodents where males show better performance on radial arm maze (Williams et al., 1990; Luine and Rodriguez, 1994) and object placement (Beck and Luine, 2002; Bisagno et al., 2003). See *Figures 21-1* and *21-4* for illustration of radial arm maze performance in male and female, rats and mice. Women are superior to men in various aspects of verbal memory (Hampson, 1990; Nelson, 2005); however, such tasks cannot be assessed in rodents, and nonhuman primates have not been investigated.

Sex differences in memory tasks are not large (usually less than a standard deviation unit), but these differences suggest that gonadal hormones, estrogens, androgens, or both, influence function since different circulating levels of these hormones are found in the sexes (It remains possible that genetic differences, presence or absence of specific genes on the Y chromosome which only males possess, may also be responsible/contribute. Little research has addressed this difficult question (but see Arnold, 2004). An additional, important question which has not been widely investigated in relation to these sex differences is whether the differences are due to gonadal hormones acting during development (organizing/programming effect) to establish long-lasting neuroanatomical, chemical, and/or functional sex differences (Matsumoto, 1999). Developmental/organizational effects of gonadal hormones on cognitive function are detailed next in Section 6. Alternatively, sex differences in cognitive function may arise from differences in circulating hormones that act on neurons to influence their function (activational effect) (McEwen, 2001). Moreover, sex differences in cognitive function may depend on both organizational and activational effects of hormones, and genes on the Y chromosome may also contribute. The extent and

Figure 21-4

Male rodents perform the radial arm maze task more accurately than females. Performance is shown in young male and female mice (*top* panel) and rats (*bottom* panel). In mice, females make more errors to complete the tasks than males. In rats, the females make their first error on earlier choices than males. Rat data from Luine and Rodriguez (1994). Mice data is from Kneavel, Christakos and Luine, unpublished. Student's *t*-test value is **$p < 0.01$





importance of gonadal hormone influences on cognition, i.e., learning and memory, remains somewhat controversial in both animals and humans, but a growing literature providing support for this idea is reviewed below.

4.3 Estrogens Enhance Spatial Memory Tasks in Rodents

In rats and mice, a variety of memory tasks relying on different reinforcements or contingencies (for example, the aversive stimulation of electric shock), measuring various types of memory (for example, spatial or visual memory) and which assess acquisition (learning) or memory (long- or short-term, working versus reference) or both, have been investigated in relation to possible gonadal hormone influences on their performance. In Dohanich (2002), a comprehensive list of these tasks, their primary properties in relation to learning and memory, and the effects of gonadal hormones can be found.

Spatial memory is the most widely assessed form of memory in rodents, and a variety of tasks have been developed for its measurement. These are strongly hippocampal-dependent tasks that rely on the innate ability of rodents to know and defend a territory by utilization of salient environmental landmarks to establish a cognitive map which resides within hippocampal neurons or networks (Mumby et al., 2002).

In the widely applied radial arm maze, subjects receive a food reward at the end of arms of the maze (mazes include from 8–17 arms). This task takes advantage of the natural foraging strategy of rats, and the ability to complete the task without reentering arms depends on building a cognitive map of the cues around the maze, and remembering the arms entered using the cues. The Morris water maze uses a similar spatial context, but subjects learn the location of one, nonvisible platform from which to escape onto from a rat-sized, swimming pool. Several studies show acute or chronic estradiol treatment to Ovx rats or mice enhances, during acquisition, the performance of the radial arm maze and Morris water maze task (Luine and Rodriguez, 1994; Sandstrom and Williams, 2001; Daniel et al., 1997; Luine et al., 1998; Daniel and Dohanich 2001). When subjects have acquired the contingency rules of the specific task, often referred to as reference memory, estradiol appears to cease enhancing performance (Williams et al., 1994; Luine et al., 1998; Fader et al., 1999) and may even impair performance of the radial arm and Morris water maze, although the data are inconclusive and interactive effects with progesterone have not been properly controlled (see Dohanich, 2002 for discussion). When performance of the radial arm maze, Morris water maze and recognition memory tasks are configured to measure working memory (to use and remember within trial information) or short-term memory, then estradiol administration to Ovx subjects usually enhances these spatial memory tasks. *Figure 21-5* shows that estradiol enhances performance of the spatial memory task, object placement, in Ovx mice when the hormone is given 24 h before testing. Recognition memory tasks such as object placement rely on the observation that rodents seek novelty. When a delay is interspersed between presentation of new and old objects (object recognition) or objects in new or old locations (object placement), memory can be assessed by determining whether the subject spends more time exploring the new object or location than the old (Ennaceur and Aggleton, 1994; Ennaceur et al., 1997).

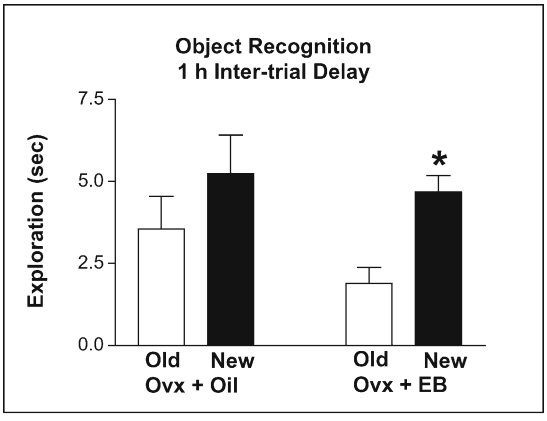
Results from a recent study provide a provocative interpretation for the lack of estrogen enhancement in several Morris water maze studies (Frick et al., 2004). Stress, engendered by forced swimming in the face of drowning, may interfere with possible mechanisms underlying estrogen effects, i.e., estrogen-dependent increases in spine density in hippocampal CA1 pyramidal neurons may be blocked in estrogen-treated subjects which swam in the water maze (Frick et al., 2004; see Section 5 for further discussion of stress effects on memory). Nonetheless, when spatial memory tasks are applied to gonadally intact rats experiencing regular estrous cycles, a less clear picture of estrogenic influences also emerges. For acquisition parameters, proestrous rats are often impaired (Frye, 1995; Warren and Jaraska, 1997; Bowman et al., 2001), a result which is inconsistent with estrogen's enhancement of spatial memory in Ovx rats because proestrous rats have high estradiol levels. It should be noted that gonadally intact rats experience daily, hourly and moment to moment changes in gonadotropins, gonadal hormones and adrenal hormones depending on the estrous cycle day. Thus, estrous cycle studies in relation to cognitive function are difficult to implement and complex to interpret. In addition, estrogen levels are high only on early proestrus and decline concomitant with a rise in progestins. Thus, time of memory assessments on proestrus may be critical. Other studies fail to show performance changes over estrous cycle days (Berry et al., 1997; Stackman et al., 1997), but these studies assessed reference memory, a paradigm where estrogen administration in Ovx models also appears generally ineffective (see Dohanich, 2002 for discussion). Recent studies also indicate that strategy selection or memory system utilized (*Figure 21-3*) may change depending on the presence or absence of specific hormones and thereby impact performance (Korol, 2004; Daniel and Lee, 2004). Clearly, further studies of spatial memory in intact females are necessary and should include measurements of acquisition, reference and working memory components as well as several time points during each estrous cycle day in tasks which minimize stress to the subjects and allow assessment of performance style.

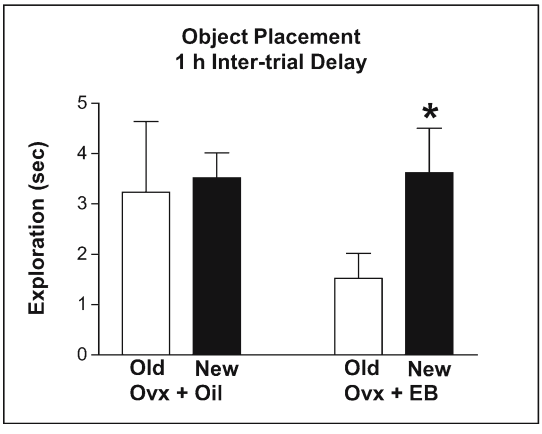
4.4 Estrogens Enhance Performance of Specific Memory Tasks in Humans

In humans, spatial memory shows both sexual dimorphisms (see above) and sensitivity to hormonal fluctuations. Young, premenopausal women who have undergone ovarian removal or treatments to lower estradiol because of gynecological problems, show a decline in some aspects of memory, an effect which is prevented by estradiol replacement (Sherwin, 2003). Likewise, some studies in women treated with antiestrogens (tamoxifen or raloxifen) for estrogen-sensitive breast cancer show some cognitive/memory

Figure 21-5

Estradiol enhances object recognition and placement in ovariectomized mice. Ovariectomized mice received sesame oil or estradiol benzoate (5 μg SC) 24 h before testing. Groups consisted of 10 mice. The delay between sample trial (T1) and the recognition trial (T2) was 1 h. *Top* panel is performance of object recognition and *bottom* panel is object placement. Data analyzed by ANOVA (object × treatment) and differences between old and new location tested within groups by paired *t*-test, *$p < 0.05$. Luine, Gordon and McEwen, unpublished. See Li et al. (2004) for other published studies in mice





losses as well as postmenopausal women who have little circulating estrogen (Sherwin, 2002; Nelson et al., 2002; Maki and Resnik, 2001). These results suggest that circulating estradiol may promote memory function in adult women. Yet, like rodents, examination of cognitive function over the menstrual cycle gives a conflicting array of information. Tests where women excel compared to men were enhanced during the period when estrogens are high while tasks where men are better than women were worse under high hormonal conditions (Kimura, 1992). The same considerations and caveats for examining memory over the estrous cycle appear germane to the menstrual cycle.

4.5 Estrogens Enhance Nonspatial Memory Tasks in Rodents

While spatial memory tasks provide a convenient measure for memory function and a sensitive read-out for hippocampal function in relation to memory, spatial tasks do not necessarily assess higher order memory or executive function which rely on cortical sites (Ennaceur and Aggleton, 1994; Ennaceur et al., 1997, Mumby et al., 2002). Other memory tasks or tests like visual and verbal memory require complex integration of

hippocampal circuits with cortical areas that receive and store sensory information and a knowledge base. Thus, effects of gonadal hormones on associative learning (conditioning, for example, as in active or passive avoidance or eye blink) or on object recognition may also be informative and relate more closely to primate cognitive processes. Avoidance conditioning and T-maze performance is sensitive to circulating estrogen levels in rats and mice (Dohanich et al., 1994; Singh et al., 1994; Gibbs, 2000; Rhodes and Frye, 2004). Recognition memory, in which subjects are tested for the ability to discriminate between familiar and unfamiliar objects or objects in familiar or unfamiliar locations, is also enhanced by administration of estradiol or other estrogens to Ovx rats (Luine et al., 2003) or mice (*Figure 21-5*; Li et al., 2004). These tasks share the common property of assessing short-term memory or working memory. This aspect of memory is in contrast to most spatial tasks which are commonly configured to measure reference memory or acquisition. Interestingly, Sandstrom and Williams (2001, 2004) reported that performance of the spatial memory task, Morris water maze, is enhanced by estrogen treatment when the task is configured to measure working memory.

4.6 Posttraining Activation of Memory by Estrogens

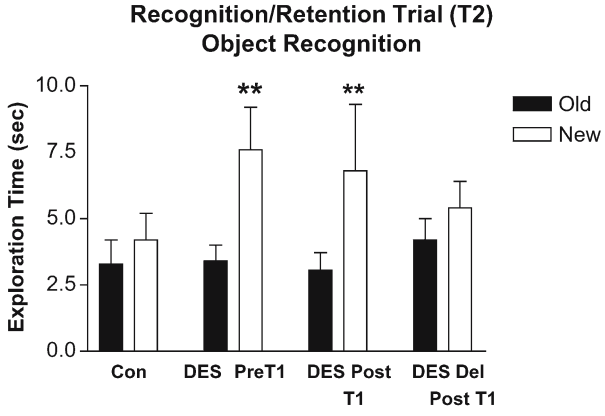
Consistent with the demonstration of putative, nonnuclear steroid receptors in brain (*Figure 21-2*), rapid enhancements in performance of memory tasks by estradiol treated rats have been recently demonstrated. Recognition memory (object or place) was enhanced 4.5 h following estradiol or diethylstilbestrol (DES, synthetic estrogen) administration to Ovx rats (Luine et al., 2003). Behavioral effects were consistent with the stereochemistry of estrogen binding at membrane sites, 17α-estradiol as well as 17β-estradiol, were effective (Toran-Allerand et al., 1999, 2002; Wade et al., 2001). In contrast, genomic responses to estradiol are activated only by 17β isomers, and 17α estrogens have extremely low potencies (Kuiper et al., 1997). Supporting these novel behavioral findings, Rhodes and Frye (2004) reported that inhibitory avoidance is also enhanced by estradiol within 4 h after treatment.

The short latency of above responses to estrogens allows for investigating whether enhanced performance of memory tasks is due to hormonal actions on performance/psychological parameters like motivation, arousal, and explorative effects which indirectly enhance performance or whether hormones act directly on mnemonic mechanisms (see Packard, 1998; McGaugh et al., 1989; McGaugh, 2000). Such experiments utilize a posttraining paradigm for assessment of memory function, i.e., drugs or hormones are given following the rats' learning of the location of a platform in the water maze or after subjects have explored objects in object recognition and placement tasks. This paradigm is based on the idea that after a training or sample trial, new information requires consolidation and that drugs or hormones could influence memory storage processes during the period immediately training. This hypothesis was confirmed, beginning in the 1960s, by McGaugh (2000), who found that immediate posttraining injections of specific drugs could facilitate memory in rats. An important additional finding was that the effectiveness of posttraining treatments was time-limited; only treatments given 1–2 h after training/sampling trials were effective, and treatments given later were not effective. Moreover, enhancements after immediate, but not delayed, posttrial injections rule out the possibility that enhancing effects derive from nonmnemonic effects (Packard et al., 1994; Packard, 1998).

Evidence that estrogens act on consolidation of memory has been provided in four memory tasks – water maze, inhibitory avoidance, object recognition, and object placement. For object recognition and placement, immediate, but not delayed, subcutaneous (SC) injections of 17β-estradiol, diethylstilbestrol (DES), or 16α-iodoestradiol after the sample trial enhanced discrimination 4 h later in Ovx rats (*Figure 21-6*; Luine et al., 2003). In the water maze, subcutaneous or intrahippocampal estrogens given immediately following, but not 2 h after, the training trials enhanced the ability of Ovx or castrated rats to locate the hidden platform (Packard and Theather, 1997a, b). Likewise, estradiol administration to Ovx rats immediately, but not 1, 2, or 3 h posttraining, increased crossover latencies as compared to vehicle for inhibitory avoidance (Rhodes and Frye, 2004). Thus, the temporal relationship between hormonal application and performance enhancement is consistent with augmentation of mnemonic processes. It is interesting that an increase in spine synapse density in hippocampal CA1 pyramidal neurons has also

Figure 21-6

Diethylstilbestrol (DES) enhances object recognition when given before or immediately after the sample trial (posttrain paradigm). The time spent exploring the old object (closed bars) and the new object (open bars) in the recognition/retention trial (T2) is shown. Ovariectomized subjects received vehicle (control) or DES (15 μg/kg) 30 min before T1 (pre T1), immediately following T1 (DES post T1) or 1 h post T1 (DES del post T1). (Controls were collapsed for pre and post T1). Only DES given before T1 or immediately post T1 enhanced recognition. The intertrial delay was 4 h. Data analyzed by ANOVA (object × treatment) and differences between time spent at old and new location tested within groups by paired *t*-test, $^{**}p < 0.01$. This result shows that an estrogen enhances mnemonic function. Data from Luine et al. (2003)



been reported 30 min following injection of estradiol; both 17α and β-estradiol are effective, but the α form is more potent (MacLusky et al., 2005). Increased synapse density may provide the neural substrate underlying the mnemonic enhancements as both processes share similar dose–response curves and ligand specificities. Consistent with this hypothesis, results by Li et al. (2004) show that an increase in mushroom type spines in the hippocampal CA1 region of mice by estradiol occurs with the same dose regimen and time course as an enhancement in object placement performance.

While these memory data and possible activation of signal transduction mechanisms for estradiol action provide a new avenue for hormonal effects, possible relationships to cognition in humans are totally unknown. However, the considerable differences in steroid efficacies and target tissue responses between nuclear and nonnuclear receptor mediated processes may be valuable for designing new programs of hormone replacement following menopause or in aged subjects (see the aged brain, Section 7).

4.7 Other Gonadal Hormones and Memory

It is notable that few studies have examined whether progestins, the other major gonadal hormone secreted by the ovaries, influence cognitive function. In rodents, progesterone reaches high levels on proestrus, and in primates, it remains elevated for most of the luteal portion of the menstrual cycle (Becker et al., 2005). Progestins can act as classical progestational agents through binding to nuclear progestin receptors to initiate transcription and as neurosteroids through local metabolism. Thus, progestins provide a rich context for possible effects on cognitive function. Due to the paucity of studies, the role of this hormone in learning and memory remains unknown, but, like its effects in other hormone target tissues and neurons, progestins could synergize with or oppose estrogenic effects as well as exert progestational effects. While androgens have clear growth (and cancer) promoting properties in peripheral target tissues, a pivotal role in regulation of reproductive function, and influence aggression, previous studies have shown little influence on cognitive function. However, recent studies have shown that testosterone enhances performance of some cognitive tasks in rats (Roof and Heavens, 1992; Kritzer et al., 2001; Daniel et al., 2003) and men (Yaffe et al.,

2002; Edinger et al., 2004). Clearly, androgens, like progestins, require further investigation in relation to cognition.

4.8 Conclusion: Gonadal Hormones Influence Cognition

Overall, compelling support for the view that gonadal hormones influence cognitive function in adult animals and humans is now extant: foremostly, female rodents and women exhibit a variety of substantial differences from male rodents and men in aspects of cognitive function. Moreover, gonadal hormones, the most documented being estradiol, enhance performance of many memory tasks and mnemonic processes. On the other hand, results from a substantial body of experiments do not support this view or suggest alternative effects. The continued application and refinement of neuroendocrine research strategies will ultimately resolve these differing views concerning the extent to which gonadal hormones influence cognition.

5 The Coping Brain – Adrenal Hormone Influences on Cognition

Over the lifespan, animals as well as humans are presented situations requiring rapid and judicious responses. For animals, an example is a deer leaping and sprinting to escape from predators. Humans, at this juncture in our evolution, not only face similar life threatening situations like war, natural disasters, accidents, and abuse, but also psychologically stressful situations at the workplace and home. Does the release of corticosterone (most rodents) or cortisol (primates) from the adrenals assist, impede, or not affect the performance of daily tasks and/or remembrance of salient events? From the commonly heard phrases "pumped up, burned out, or stressed out" it might be inferred that stress, the hallmark of which is high circulating levels of adrenal steroids, affects people's functioning or at least their view of their own functionality. What is the evidence for glucocorticoid influences on adult cognitive function?

5.1 Acute Stress Effects

The response to stress is characterized by rapid and large outpourings of hypothalamic, pituitary, and adrenal hormones, which provide a positive impact on brain and body for coping with acute stressors and which attempt to restore homeostasis (the fight or flight response, the details of which have been widely described previously; See also *Table 21-1*). There does not appear to be a general pattern in cognitive

Table 21-1
Effects of stress on physiological function

→	→
Time Course	

responses to acute stress although many responses are enhanced. Acute foot shock enhances several conditioning paradigms in male rats (Shors et al., 1992; Shors, 2001) but impairs recognition (Baker and Kim, 2002) and spatial memory (Diamond et al., 1999). These effects are rapid in onset and may last up to a few days. Responses to acute stress in female rodents are less investigated, but results suggest sex differences in the response. Acute stress impairs eye blink conditioning in females while it enhances such conditioning in males (Wood and Shors, 1998), and performance of some spatial memory tasks is enhanced in female rats but impaired in male rats following acute stress (Conrad et al., 2004).

5.2 Chronic Stress Effects

When stress continues for an extended period (chronic stress), hormonal-dependent, adaptive responses become maladaptive, and subjects suffer negative consequences from the extended secretion of adrenal steroids (see *Table 21-1* and Nelson, 2005). In an effort to determine possible consequences of chronic stress on cognition, various stressors (restraint, immobilization, noise, lights, cold water) were applied to rats and mice over days and weeks, and effects on performance of cognitive tasks determined. Performance of several spatial memory tasks, radial arm maze (*Figure 21-1* and Luine et al., 1994), Y-maze (Conrad et al., 1996), object placement (Beck and Luine, 1999, 2002) and Morris water maze (Park et al., 2001; Kitraki et al., 2004) is impaired in male rats following these chronic stress regimens. Some nonspatial tasks including recognition memory are also impaired following daily chronic restraint stress (Beck and Luine, 1999, 2002 and see *Figure 21-7*). Chronic stress effects are not large and appear reversible. That is, cognitive function returns to prestress or control levels in a few days to a few weeks.

5.3 Sex Differences in Chronic Stress Effects on Cognition

Not surprisingly, less information is available for females, rodent or human, but chronic stress appears to affect this sex quite differently than males. Daily restraint to female rats for the same period as males, 21 days, results in enhanced female performance of a number of spatial memory tasks: object placement (Beck and Luine, 2002), Y-maze (Conrad et al., 2003), radial arm maze (Bowman et al., 2001, 2002 and see *Figure 21-1*) and Morris water maze (Kitraki et al., 2004). This change in performance following stress is opposite to that in males receiving the same stress. In addition, no effects of chronic stress were noted on object recognition in females (Beck and Luine, 2002; Bisagno et al., 2004), whereas males were impaired on this task (Beck and Luine, 1999, 2002). See *Figure 21-7* which shows effects of chronic stress on the performance of male and female rats in the object recognition task. If female rats are stressed for a longer period (28 days) or Ovx, then enhanced performance is no longer present following stress (Bowman et al., 2001). Interestingly, when males receive a shorter stress, 13 days of daily restraint, radial arm maze performance is enhanced (Luine et al., 1996). These differences in cognitive responding between the sexes may be due to a right shift in the female curve of the continuum from adaptive to maladaptive effects of stress (*Table 21-1*; Bowman et al., 2003). This shift may result from sex differences in processing by adrenal steroid receptors (De kloet et al., 1999; de Kloet, 2004). The shift may also result from the presence in females of higher levels of circulating estrogens which may provide neuroprotection through antioxidant or antiapoptotic effects and/or upregulation of trophic factors (Garcia-Segura et al., 2001; Wise et al., 2001) as well as through direct activation of the brain areas mediating cognition (see Section 4).

5.4 Morphological and Neurochemical Effects of Stress

The paradigm of 21 days of daily restraint stress is associated with some sexually dimorphic morphological effects in the hippocampus. In males, stress or corticosterone administration is associated with decreased dendritic branches and length in CA3 pyramidal neurons (Watanabe et al., 1992; Coburn-Litvak et al., 2004) and frontal cortex (Wellman, 2001). These hippocampal changes are not present in stressed females

Figure 21-7

Chronic restraint stress impairs object recognition in male, but not female, rats. Young male (*top* panel) and female (*bottom* panel) rats received daily restraint stress for 6 h/day for 21 days or only handling (control). The time spent exploring the old (solid bars) and new (open bars) objects in the recognition/retention trial is shown. The intertrial delay between sample trial (T1) and the recognition/retention trial was 4 h. Data were analyzed by two-way ANOVA (object × treatment) and differences in time spent between old and new object tested within groups by paired *t*-test, *$p < 0.05$. Stress impaired male, but not female, performance on the task. Data from Beck and Luine (2002)

(Galea et al., 1997). Acute stress also has opposite effects in males and females on spine density in CA1 (Shors et al., 2001). In addition, receptors for glucocorticoids are increased in males and decreased in females following chronic stressors (Kitraki et al., 2004; de Kloet, 2004). Monoamines are also altered in the CA3 subfield of the hippocampus: levels of 5-HT and NE were increased in females, but not males, whereas males showed increased levels of GABA (Luine, 2002). Thus, stress appears to affect the male and female hippocampus differently in terms of behavioral output and neuroanatomical and neurochemical properties.

5.5 Stress and Human Cognition

While less is known concerning effects of stress on humans, acute stress can exert either impairing or enhancing effects on memory depending on the temporal context, the relationship of the stress to the task, and the sex of the subject (Kudielka et al., 1998; Wolf, 2003). The Trier social stress test causes acute stress and assessment of memory immediately following this paradigm using word recall found no significant stress effect, but male cortisol levels were correlated with performance; thus, the subjects with highest increases in cortisol had lowest performance (Wolf et al., 2001). No such correlation between cortisol levels and performance was found in women. Processing of emotionally influenced memory storage may also differ between the sexes but follow a different pattern than non-emotion based memories (Cahill, 2001).

While difficult to study in humans, chronic stressors such as stays in boot camps, catastrophic illnesses, or death of spouses result in some form of impaired cognitive function; Posttraumatic stress disease sufferers or those who have experienced extended, high secretions of cortisol show similar deficits (Seeman et al., 1997; McEwen, 2000; Wolf, 2003).

5.6 Conclusion: Adrenal Hormones Influence Cognition

Stress, given both acutely and chronically, appears to affect cognitive function in rodents and in humans. Surprisingly, qualitative and quantitative sex differences in the response appear prominent even though few studies have assessed cognition in females. Since stress has increased for all segments of society, the long-term effects of stress on cognition should become all the more apparent in this new century.

6 The Fetal/Neonatal Brain – Programming of Adult Cognitive Function

Previous discussions of steroid hormone effects on cognition in humans and rodents have highlighted sex differences in performance of memory tasks and sex differences in the effects of both gonadal and adrenal hormones (see Sections 4 and 5, above). The perinatal developmental period (pre and postnatal) is critical for establishing patterns of brain function and sex differences in these functions. Research beginning in the 1950s established that sex differences in reproductive function (both behavior and gonadotrophin secretion) depend on the presence of gonadal hormones in order to establish a male or female adult pattern of function (Matsumoto, 1999). Hormonal secretions from the testes of fetal and newborn males act within the brain to establish phenotypic male behaviors and a tonic pattern of HPG axis hormonal secretions. On the other hand, phenotypic female patterns – behavior and cyclic patterns of HPG axis hormonal secretions – are inherent in the brain and expressed without secretions from the ovary.

6.1 Perinatal Gonadal Hormone Influences

Perinatal events such as secretion or lack of secretion, of gonadal hormones also program sex specific aspects of the HPA axis and its response to stress in adulthood (Patchev et al., 1995; McCormick et al., 1998; Patchev and Almeida, 1998). For example, males and females show differences in circulating levels of adrenal steroids and their receptors in the brain (Handa et al., 1994; MacLusky et al., 1996; Bowman et al., 2004). Surprisingly, few studies have addressed whether sexual differences in cognition are dependent on perinatal hormonal secretions from the gonads, the adrenals, or both. However, Williams et al. (1990) found that sex differences in radial arm maze performance (males are better than females) were abolished if males were castrated immediately after birth or if females were given estradiol immediately following birth. These results suggest that cognitive sex differences may be programmed similarly to reproductive behaviors, that is, through aromatization of testosterone to estrogen within the brains of males.

6.2 Perinatal Glucocorticoid Influences

During development, as well as in adulthood, the HPG and HPA axes interact to influence brain function. For example, stressing pregnant dams causes a premature cessation and decline in testicular secretions in male fetuses which is accompanied by incomplete masculinization and some feminization of sexual behaviors (Reznekov et al., 2001). Likewise, the HPA axis responds to the effects of early hormonal exposure to adrenal steroids (McCormick et al., 1998; Bowman et al., 2004), and the ability to successfully respond to stress at adulthood, that is, maintain glucocorticoids at a low level, appears to depend on perinatal stress exposure.

Recent studies show a similar pattern of prenatal stress effects on cognitive function as on sexual behavior: stressed males' spatial memory performance is lower than control males' performance (Szuran et al., 1994, 2000; Bowman et al., 2004) and stressed females' performance is improved, and not different, from control male performance (Bowman et al., 2004). Interestingly, prenatally stressed females appear masculinized in other brain properties in addition to spatial memory: anxiety and basal and stress induced corticosterone levels (Bowman et al., 2004). Taken together these results suggest that androgens, as well as corticosterone, may be released from the adrenal gland following stress and alter neural function in females (Frye and Wawrzykci, 2003; Bowman et al., 2004). Prenatal stress is also associated with alterations in monoamines and metabolites at adulthood in areas of the brain associated with cognition, frontal cortex and hippocampus (Bowman et al., 2004; See *Figure 21-8*). Thus, the prenatal hormonal milieu presumably exerts powerful organizing effects on development of cognitive function. While these hormonally driven, prenatal effects leave a permanent imprint through adulthood on neural and behavioral function, they have received little study.

7 The Aged Brain – Cognitive Loss and Steroid Hormones

With advancing age, most aspects of cognitive function suffer some degree of deterioration, ranging from modest declines in healthy individuals to devastating losses in people with neurodegenerative diseases associated with aging like Alzheimer's and Parkinson's (McEwen et al., 1995; Fillit and Luine, 1997). See also *Figure 21-1* which illustrates age-related memory declines in radial arm maze performance in male and female rats.

7.1 Gonadal Hormones and Cognition During Aging

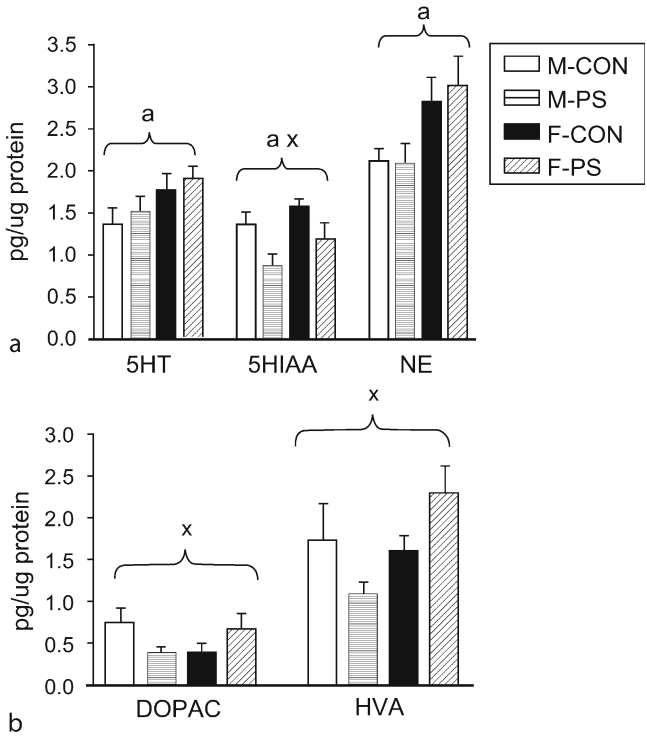
Ascribing a specific role for hormones or other parameters to age-related cognitive loss is difficult because all factors are confounded by the aging process itself. Nonetheless, it is notable that in postmenopausal women, gonadal hormone levels plummet to near undetectable levels, and testosterone levels in men, starting at approximately 50 years, decline 30–60% (Yaffe et al., 2000, 2002; Sherwin, 2002). Thus, hormones that tend to promote cognitive function (gonadal) are lower in aged individuals.

In relation to neurodegenerative disease, some evidence suggests that estradiol replacement postmenopause, is associated with either a delay in the onset or a prevention of Alzheimer's disease (Tang et al., 1996; Slooter et al., 1999). Postulated neuroprotective, antioxidant, or antiaging effects of estrogen in brain may be responsible for this effect (Wise et al., 2001; Garcia-Segura et al., 2001).

In healthy, aged women from the Baltimore Longitudinal Study of Aging, gonadal hormone replacement was associated with better maintenance of many aspects of cognitive function (see Maki and Resnick, 2001, for example), a result also shown in several other studies (Gibbs and Aggarwal, 1998; Yaffe et al., 2000). However, results of the recent Women's Health Initiative (WHI) trial supported by NIH and other trials have not replicated these results (Zec and Trevidi, 2002). In addition, hormonal replacement with either conjugated equine estrogens (CEE) alone (Anderson et al., 2004) or in combination with medroxyprogesterone (MPA) (Wassertheil-Smoller et al., 2003) showed some unexpected, deleterious effects in subjects. CEE was associated with a small increase in stroke while CEE+MPA subjects show an increased incidence of breast cancer and cardiovascular complications. Endocrinologists have pointed out that this population of women was generally older (67% were age 60–79) and heavier (69% were overweight or

Figure 21-8

Prenatal stress is associated with altered expression at adulthood of frontal cortex monoaminergic activity. Data are expressed as pg/μg protein (mean ± SEM). Group differences are identified by main effect of sex (a) and the sex X prenatal treatment interaction (x). Females had higher levels of NE ($p < 0.006$) and 5HT ($p < 0.05$) than males, regardless of prenatal treatment. 5HIAA levels were influenced both by sex (higher in females, $p < 0.001$) and the sex X treatment interaction (lowest in PS males, $p < 0.02$). Dopamine activity, as indexed by HVA ($p < 0.03$) and DOPAC ($p < 0.03$) metabolite levels, was influenced by the sex X treatment interaction, with lowest levels observed in PS males and highest levels in PS females. From Bowman et al. (2004). Sexually dimorphic effects of prenatal stress on cognition, hormonal responses, and central neurotransmitters. *Endocrinology* 145: 3778–3787. Copyright 2004, The Endocrine Society



obese) than populations in other epidemiological studies like the Baltimore study. In addition, 74% had never used hormone replacement and were thus estrogen-deficient for more than a decade. These risk factors may have contributed to the untoward cardiovascular and other effects. The use in this trial of widely prescribed replacement drugs (CEE and MPA), not estradiol or progesterone, may have also been problematic (See Turgeon et al., 2004 for a discussion of these studies). Thus, the WHI study has discouraged use of estrogens in postmenopausal women. The implementation of better hormone formulations, different modes of administration, and initiation of therapy at the menopause may provide a better hormonal replacement outcome, one consistent with positive effects of estrogen in animal models (see above) and in premenopausal women (Sherwin, 2003).

7.2 Adrenal Hormones and Cognition During Aging

Compounding the decline of gonadal hormones, the level of basal, circulating glucocorticoids tends to increase with aging (McEwen et al., 1995), and high levels of these steroids, for extended periods in rodents and humans, are associated with poorer cognitive performance (See Section 5). Aged individuals

therefore possess a hormonal mileu, high glucocorticoids and low gonadal hormones, not optimal for cognition. Thus, the ability to maintain cortisol at a low level has been linked to maintenance of cognitive function and "successful" aging (Lupien et al., 1999), and treatments or behaviors which maintain low cortisol levels may be beneficial to cognitive function and a slowing of aging. However, some recent studies have not supported the idea that high cortisol is linked to poor cognitive performance in aged individuals (See Wolf, 2003 for discussion).

7.3 Hormonal Therapy for Age-Related Memory Loss

Since hormones influence neurons over the entire life cycle, the use of hormonal derivatives or "designer" hormones to promote memory in aged individuals would appear to offer advantages. The goal would be to eliminate the cancer promoting and cardiovascular damage that estrogens may exert but still take advantage of growth promoting and neuroprotective effects. The development of such selective receptor modulators (SRMs; Smith and O'Malley, 2004), especially selective estrogen receptor modulators (SERMs) is promising in this regard, and raloxifene (Evista), the second generation of such drugs has proven effective for osteoporosis without unwanted effects in the uterus or breast, but raloxifene unfortunately appears largely inactive in neural tissue (Tierney and Luine, 1997). Estrogens that act through membrane receptors offer promise as well because 17α-estrogens are more potent than the 17β-estrogens, and 17α-estrogens show little cancer promoting properties (See Luine et al., 2003; MacLusky et al., 2005 for more discussion). These estrogens may offer new routes for treatment of memory loss and neurodegenerative disease.

The blocking of deleterious effects from elevated glucocorticoids might also be advantageous in aged populations. To date, little progress on identifying selective glucocorticoid receptor modulators (SGRMs) or related antagonists has been made. Interestingly, gene therapy has recently shown promise in an animal model. A viral amplicon, containing a chimeric glucocorticoid receptor ligand-binding domain fused to the estrogen receptor DNA binding domain, was placed in the rat hippocampus. The size of a lesion after neurological damage was reduced by 63% (Kaufer et al., 2004) and the viral vector attenuated acute stress-dependent impairments in object recognition memory (Ferguson et al., 2004). Thus, neuroprotective effects of estrogen appear to have mitigated deleterious effects of glucocorticoids.

8 Concluding Remarks

Steroid hormones influence cognitive function in animal models and humans over the entire life span. Some hormonal influences on memory appear to be mediated directly through actions on neurons and circuits subserving memory and on memory consolidation itself while other mnemonic changes may be indirect and result from hormonal influences on psychological/performance parameters. Clearly, further research on how cognition is altered by hormones is critical. Increased knowledge of the substrates and the circuits responsible for acquiring and maintaining memories would provide neuroendocrinologists the information upon which to develop novel, hormonally based therapies (SRM drugs-selective receptor modulator drugs) or specific hormone–gene targets to enhance cognitive function. Hormonal or genetic based interventions could promote recovery from strokes or injury and also intervene in preventing or attenuating age- and neurodegenerative disease-related memory losses.

Acknowledgments

Research in the author's laboratory is supported by NIH grants RISE, GM60665; SCORE, GM60654; MIDARP, DA12136, and RCMI, RR03037. Advice and discussions with Gary Dohanich in the preparation of this manuscript is greatly appreciated. Dedicated work by former and current students Kevin Beck, Rachel Bowman, Deveroux Ferguson, Luis Jacome, Govini Mohan, Marisa Gordon, and Shannon Richards are gratefully acknowledged.

1 Introduction

Virtually all organisms studied to date, from bacteria to humans, possess an internal clock that has an intrinsic period of approximately 24 h. This endogenous pacemaker drives circadian rhythms ("circa" = about, "dies" = a day) of myriad biological processes, from cell metabolism to behavioral state. Although the anatomical location and genetic components of the pacemaker differ among species, all circadian systems can be described by a three-component model that includes: (1) the pacemaker, a molecular clock that has a period of approximately 24 h and that continues to oscillate even in the prolonged absence of any timing cues, (2) an input pathway that conveys environmental time cues to the pacemaker, and (3) output pathways by which the pacemaker can influence biochemistry and behavior (Takahashi et al., 2001). This review focuses on mammalian circadian rhythms, and covers the anatomical and molecular basis for the master pacemaker, the neurochemical processes responsible for pacemaker entrainment, and the diverse systems involved in pacemaker output.

2 Historical Background

2.1 Discovery and Properties of the Circadian System

The rotation of the earth and the accompanying cycle of day and night produce a clear and dependable external time cue, known as a "zeitgeber" ("time giver"). Changes in light intensity are particularly important for photosynthetic organisms, and the ability to predict energy (light) availability is an advantageous adaptation that enables organisms to coordinate photosynthesis and nitrogen fixation to the appropriate time of day. Accordingly, circadian rhythms were first observed and studied in plants. It was long assumed that daily variations such as leaf movement and petal opening occurred in response to external stimuli, but in the early 1700s Jean Jacques d'Ortous de Mairan conducted an insightful experiment demonstrating the existence of an endogenous timekeeper. de Mairan placed heliotrope plants, which open and close their leaves in a circadian manner, in total darkness, and documented a persistence in the rhythm of leaf movement despite the absence of photic timing cues (de Mairan, 1729). Later, Carolus Linnaeus, the creator of the modern taxonomical system, took advantage of the circadian regulation of petal opening to create a "circadian garden," with each hour represented by a flower that opened at a particular time of day (von Marilaun, 1895). Since that time, endogenous circadian rhythms have been identified in a wide variety of organisms, allowing for the prediction and testing of hypotheses related to the properties of circadian systems.

Primary to the function of endogenous circadian rhythms is the ability to be entrained, or synchronized to the phase and periodicity of the external world (Pittendrigh, 1981). In fact, because endogenous rhythms have a period of nearly, but not exactly, 24 hours, a periodic external signal (zeitgeber) is required to adjust the period and phase of the internal rhythm to that of the environment. For entrainment to occur, the endogenous system must be able to adopt and maintain a stable phase angle relationship to the zeitgeber; if the zeitgeber shifts, the endogenous system must also shift until it reaches the same phase relationship with the external signal as before (for an in-depth review, see Daan and Aschoff, 2001). A stable phase

relationship occurs when the period of the endogenous oscillator closely matches the period of the environment, and includes a mechanism for phase adjustment. The maintenance of a stable phase relationship allows for predictive homeostasis: the endogenous system gains the ability to anticipate changes in the environment and to adjust behavior and physiology accordingly. An important property of entrainment is that the response of the internal system to the zeitgeber depends on the phase at which the zeitgeber occurs. This effect, which is represented as a phase response curve, can be defined by administering brief entraining stimuli at different phases under otherwise constant conditions and measuring the resulting phase changes (Daan and Aschoff, 2001). In nocturnal rodents, for example, a brief light pulse administered during the early subjective night results in a phase delay in activity rhythms, whereas a light pulse administered during the subjective night results in a phase advance (Pittendrigh, 1981). For the majority of organisms, the dominant zeitgeber is the light–dark (LD) cycle; however, in the absence of a LD cycle, other environmental cues, such as cycles in temperature, feeding, or social activity, can entrain endogenous rhythms (Gwinner, 1966; Engelmann et al., 1974; Edgar and Dement, 1991). Even in the presence of a LD cycle, nonphotic cues may help to stabilize entrainment to the environment (Amir and Stewart, 1996).

The methods used to study mammalian circadian rhythms have remained essentially unchanged since rigorous study began in the early 1950s. Model organisms—generally rats, hamsters, or mice—are placed within an environment where the LD conditions can be regulated, and the properties of circadian rhythms are monitored by observing one or more circadian-regulated activities, such as wheel running, drinking, or feeding. These activities represent the output of the internal pacemaker, and, as such, can be used to measure the properties of the endogenous clock. In some cases, animals are placed under constant conditions (constant dark, DD, or constant light, LL) to observe rhythms in the absence of entraining cues; the length of the cycle of rhythms observed under DD reflects the "true," or steady state, period (τ) of the internal pacemaker, and animals under constant conditions are said to be "free running." In the majority of experiments, animals are maintained on a cycle of 12 h light, 12 h dark (LD 12:12); where, by convention, lights-on is known as ZT0 and lights-off as ZT12. Under constant conditions, circadian time (CT) 0 to CT12 is the subjective day, and CT12-24 is the subjective night.

In the 1920s, Richter documented endogenous circadian rhythms in the rat by measuring locomotor and drinking activity, and showed that activity rhythms could be entrained either by light or by feeding (Richter, 1922, 1967). Richter found that rats, which are nocturnal, restrict the majority of both drinking and locomotor activities to the actual or subjective night. Johnson documented similar circadian, environmentally entrained activity in mice (Johnson, 1926). Later, Aschoff and Wever extended Richter's findings to humans, demonstrating the presence of endogenous circadian rhythms in humans by isolating subjects in an underground bunker and observing the persistence of circadianly organized activity in the absence of any entraining signals (Aschoff, 1965; Wever, 1979).

2.2 Identification of the Suprachiasmatic Nucleus

Although multiple examples of mammalian circadian rhythms—including the sleep–wake cycle, locomotor activity, and endocrine rhythms—had been identified in the mid-1900s, little was known about how such rhythms were controlled. Rhythms were remarkably persistent, continuing after such insults as anesthesia and seizures, and were not perturbed by the removal of candidate pacemakers such as the adrenal and pineal glands. The sheer number of physiological systems showing circadian rhythmicity suggested that either there was a single master pacemaker that drove and coordinated slave oscillators throughout the body, or that peripheral systems contained individual clocks that were phase-coordinated by cross talk between systems (Pittendrigh, 1960). Then, in the 1970s, anatomical tracing of the retinohypothalamic tract (RHT), the source of photic input to the circadian system, led two separate groups of researchers to identify a hypothalamic area known as the suprachiasmatic nuclei (SCN) as the region responsible for all measurable rhythms, including activity, sleep, and drinking (Moore and Eichler, 1972; Stephan and Zucker, 1972; Menaker et al., 1978). Stephan and Zucker electrically lesioned one or both SCN nuclei and found that bilateral SCN lesions resulted in arrhythmicity, whereas unilateral SCN lesions resulted only in a reduction

in the amplitude of circadian drinking rhythms (Stephan and Zucker, 1972). Working independently of Stephan and Zucker, Moore and Eichler found that bilateral SCN lesions resulted in the loss of circadian corticosterone rhythms in rats (Moore and Eichler, 1972).

The SCN quickly became the focus of intense interest among circadian biologists, and further evidence of the role of the SCN as master pacemaker was soon reported. Inouye and Kawamura demonstrated that the SCN pacemaker functioned autonomously by using knife-cuts to isolate SCN tissue *in vivo* and subsequently measure multiunit electrical activity (MUA) within the SCN and other brains regions (Inouye and Kawamura, 1979). In SCN-intact animals, the amplitude of electrical activity in the brain had been shown to have a clear circadian rhythm, with firing rates peaking during the day in the SCN and during the night in other brain tissues. In SCN-isolated animals, electrical activity continued in a rhythmic manner in the SCN but became arrhythmic in non-SCN areas, indicating that the SCN contains a self-sustained pacemaker, and that neural outputs from the SCN are responsible for driving the circadian organization of electrical activity in other parts of the brain. These results supported those from experiments conducted by Schwartz and Gainer, who showed that the uptake of 14-C-deoxyglucose is rhythmic in the SCN, with peak uptake occurring during the day, but that uptake in other brains regions is nonrhythmic (Schwartz and Gainer, 1977).

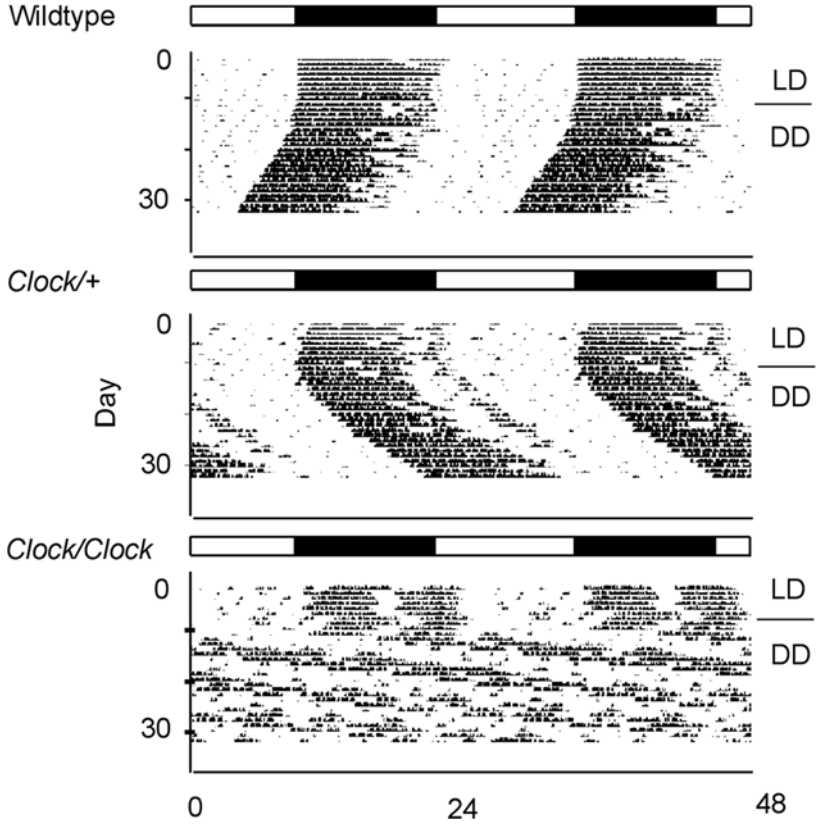
2.3 Use of Mutant Animal Models to Study the Circadian System

The identification of a region as a pacemaker requires not only that the putative pacemaker shows autonomous rhythms, but that it can also drive and sustain rhythms throughout the body. In a series of papers using a circadian mutant hamster, Ralph and Menaker showed both that the SCN was the master pacemaker and that the period length of circadian rhythms in mammals was genetically determined. During the observation of circadian behavior in individual animals from a particular shipment of hamsters, Ralph and Menaker identified a single hamster that had a shortened period of free-running wheel-running activity: the normal period for hamsters in DD is approximately 24.1 h, but the free-running period of the mutant hamster was only 22 h (Ralph and Menaker, 1988). Subsequent breeding experiments showed that this mutation, which was named "*tau*," was autosomal and acted in a semidominant fashion, such that the homozygous offspring of the heterozygous founder had a free-running period of 20 h. Ralph and Menaker then showed that they could make a genetic *tau* mutant run with a normal 24-h period by transplanting the SCN from a wild-type embryo into the third ventricle of an SCN-lesioned mutant (Ralph et al., 1990). The converse was also true: a genetically wild-type animal could be made to show the circadian phenotype of a *tau* mutant if the wild-type animal was SCN-lesioned and then implanted with the SCN from a mutant hamster.

The genetic control of the circadian timing signal thus established, the hunt was on for genes involved in the mammalian pacemaker. Although advances in the identification of genes regulating circadian rhythms had been made in nonmammalian models (Sargent and Woodward, 1969; Feldman and Hoyle, 1973), the first breakthrough in mammals did not occur until the mid-1990s, when Vitaterna and colleagues identified a mouse with abnormal circadian activity during a screen for ENU-induced circadian mutants (Vitaterna et al., 1994). The founder mouse had a free-running period almost an hour longer than normal, and, like the *tau* mutant, the responsible mutation turned out to be semidominant: mice homozygous for the subsequently identified *Clock* gene mutation had a free-running period of almost 4 h longer than normal, and often became arrhythmic after about 2 weeks in constant darkness (Vitaterna et al., 1994) (*Figure 22-1*). The identification of the gene responsible for the *Clock* mutant phenotype was crucial, as it provided an entrée into the genetic underpinnings of the mammalian pacemaker (Antoch et al., 1997; King et al., 1997). Other core circadian genes were subsequently identified, and it was ultimately shown that neurons in the SCN of all mammalian species studied thus far contain a cell-autonomous molecular feedback loop composed of positive and negative elements that cycle with a rhythm of approximately 24 h. The molecular mechanism of circadian clocks is discussed in detail later in this chapter. Briefly, CLOCK and its binding partner BMAL1 form the positive limb of the loop by driving the transcription of a number of genes, including *Period1*, *Period2*, *Cryptochrome1*, and *Cryptochrome2*, which form the negative limb of the loop by

Figure 22-1

Circadian Wheel-Running Activity in Wild-Type and Clock Mutant Mice. Activity records of wheel-running behavior from wildtype, *Clock*/+, and *Clock/Clock* mice in 12 h lights:12 h dark (LD) and constant darkness (DD). Records are double-plotted. Courtesy of K. Shimomura



inhibiting their own transcription. Turnover of the negative limb proteins allows CLOCK:BMAL1-induced transcription to begin anew (Lowrey and Takahashi, 2000). The biochemical components of the clock have since been shown to be rhythmically expressed in many other tissues, including liver and pituitary, but the SCN remain the only tissue capable of phase-coordinating the circadian activity of oscillators throughout the body (Brown and Schibler, 1999; King and Takahashi, 2000; Lowrey and Takahashi, 2004; Yoo et al., 2004).

3 Structure and Function of the SCN

3.1 Rhythmic Properties of the SCN

The SCN are bilateral nuclei, each made up of approximately 10,000 neurons, that reside in the anterior hypothalamus immediately superior to the optic chiasm and lateral to the third ventricle (*Figure 22-2*). As described earlier, previous studies showed that neurons in the SCN exhibit rhythmic patterns in glucose utilization and electrical activity, with both measures peaking during the day. These electrical and metabolic rhythms persist under constant conditions, and, *in vivo*, are phased similarly in both diurnal and nocturnal

Figure 22-2

Anatomical Location of the Suprachiasmatic Nuclei. The SCN are bilateral nuclei located at the base of the anterior hypothalamus, superior to the optic chiasm and lateral to the third ventricle. This coronal section from an adult mouse brain has been hybridized with an oligonucleotide probe for *Period2*, a core clock gene that is highly expressed and rhythmic in the SCN

animals. Some of the first studies of electrical activity measured output from multiple neurons; more recently, several groups have recorded circadian rhythms in electrical activity, calcium concentration, and membrane conductance in isolated SCN neurons, indicating that these rhythms are an intrinsic property of individual cells and are not dependent on functional interneuronal connections (Welsh et al., 1995; Gillette et al., 1995b).

MUA measurements from SCN slices have shown that the rhythm of spontaneous neuronal activity has a periodicity of approximately 24 h (Bos and Mirmiran, 1990). Even when SCN slices are cultured for many weeks, rhythmic spontaneous activity is stably maintained, despite the absence of humoral and endogenous time cues normally present *in vivo*. Application of agents such as tetrodotoxin (TTX), a sodium channel blocker, inhibits neuronal activity and, if administered *in vivo*, rhythmic locomotor activity, but spontaneous firing reappears after washout with the phase unchanged (Schwartz et al., 1987). This indicates that neuronal activity is not required for continued function of the pacemaker within individual cells, although more recent studies have shown that disrupting electrical activity does reduce the amplitude of oscillation (Yamaguchi et al., 2003). *In vivo* studies using electrodes implanted in the brains of freely moving hamsters support the *in vitro* findings, showing that MUA in the SCN peaks during the day, and, moreover, has a period that matches the period of free-running locomotor activity. Yamazaki and colleagues measured MUA from wild-type and *tau* mutant hamsters, and found that, though the period of MUA was 24 h in wild-types, the period of MUA in *tau* mutants was only about 20 h, similar to the period of activity measured by wheel running (Yamazaki et al., 1998).

Other measures of neuronal properties also show circadian rhythmicity in SCN slices. In addition to glucose metabolism and electrical activity, intracellular calcium levels peak during the day, although calcium rhythms occur only in the cytoplasm and not in the nucleus. Using optical imaging of the Ca^{+2}-sensitive dye Fura2-AM in acute slices, Colwell determined that calcium rhythms are present in SCN sections removed from animals maintained in DD, suggesting that changes in rhythmic calcium concentration are regulated by the internal pacemaker, rather than dependent on external cues (Colwell, 2000a). More recently, Ikeda and colleagues transfected organotypic SCN cultures with a calcium-sensitive fluorescent protein and determined that the length of the Ca^{+2} period matches that of the MUA, but is phase-advanced in comparison to the MUA (Ikeda et al., 2003). Unlike rhythmic MUA, which can be blocked by TTX, Ca^{+2}

fluctuations continue in the absence of electrical activity. Thus, Ca^{+2} rhythms are driven by the intracellular clock, rather than by neuronal activity (Shibata and Moore, 1993; Ikeda et al., 2003).

3.2 SCN Neurons as Cell-Autonomous Pacemakers

A major advance occurred when individual SCN neurons were found to have many of the same rhythmic properties as SCN slices. Studies of spontaneous activity, membrane resistance, and, more recently, circadian gene expression in individual neurons indicate that between 75% and 99% of SCN neurons possess oscillatory characteristics (de Jeu et al., 1988; Yamaguchi et al., 2003). In 1995, Welsh and colleagues measured rhythmic spontaneous activity from individual SCN neurons cultured on fixed microelectrode arrays and found that single cell rhythmicity can be stably maintained for weeks (Welsh et al., 1995). Furthermore, as had been shown in whole slices, application of TTX for up to 2.5 days inhibited neuronal activity, but did not stop each neuron's internal clock. Surprisingly, the activity of individual neurons within the same culture was not necessarily in phase, a finding that has since been replicated many times (Gillette et al., 1995a). Both acute and long-term measurements of individual SCN neurons have shown that there is a wide distribution of phase and period between different neurons from the same SCN. In measurements from dissociated cells in culture, the intrinsic periods among individual neurons may differ by up to 8 h, whereas measurements from cells in organotypic SCN cultures show a period range of up to 5 h suggesting that intact neuronal connections, though not necessary for the generation of rhythmicity, do contribute to phase-coupling (Herzog et al., 1997, 2004; Honma et al., 1998). Despite the range of periods within single cells, the mean period for the entire SCN is equivalent to the species-specific period in locomotor activity (Liu et al., 1997; Herzog et al., 1998).

To understand how multiple oscillators with different periods can produce a behavior with a single stable ~24-h period, circadian biologists have used theoretical models of oscillators. In these models, each neuron represents a single oscillator with an individual period and phase, and synchronous output is achieved through chemical and/or electrical coupling among neurons. In support of this hypothesis, several groups have shown that the period of locomotor activity represents the mean period of all neurons sampled from a single SCN (Liu et al., 1997; Yamazaki et al., 1998). For example, in the *tau* mutant hamster, the range of periods expressed by individual neurons depends on genotype. Liu and colleagues measured the period of electrical activity from individual SCN neurons cultured from wild-type hamsters and from hamsters homozygous for the *tau* mutation and found that periods in wild-type neurons ranged from 20 to 25 h with a mean of ~24 h, whereas periods in *tau* mutant neurons ranged from 16.5 to 21.5 h with a mean of ~20 hours (Liu et al., 1997). Thus, the mean neuronal activity period length for each genotype is equal to the period of free-running locomotor activity, as wild-type hamsters have a period of 24 h and *tau* mutant homozygotes have a wheel-running period of approximately 20 h. Yamazaki and colleagues later confirmed these findings by measuring the period of electrical activity in SCNs of freely moving wild-type and *tau* mutant hamsters (Yamazaki et al., 1998).

The production of mice with targeted knockout or induced mutations of specific core clock genes has provided approaches to investigate the underpinnings of rhythmic neuronal activity. Using chimeric mice made of cells from wild-type and *Clock/Clock* mice, Low-Zeddies and Takahashi showed a direct correlation between the period of circadian wheel-running activity and the percent of SCN cells carrying the *Clock* mutation: the greater the percent of mutant cells in the SCN, the longer the behavioral period (Low-Zeddies and Takahashi, 2001). Herzog and colleagues, also using *Clock* mutant mice, found that neurons isolated from heterozygous mice, which have a free-running activity period of approximately 24.7 h, show a lengthened period of spontaneous activity, whereas neurons from homozygous mutants, which become arrhythmic under constant conditions, have arrhythmic spontaneous activity (Herzog et al., 1998). Similarly, the deletion of the *Cryptochrome 1* and *Cryptochrome 2* genes, part of the negative limb of the core pacemaker, results in arrhythmicity of both locomotor and neuronal activity under constant conditions (Albus et al., 2002).

A relatively new method of studying the characteristics of individual oscillatory cells within the SCN has arisen from the development of transgenic mouse and rat strains that produce a molecular reporter, such as

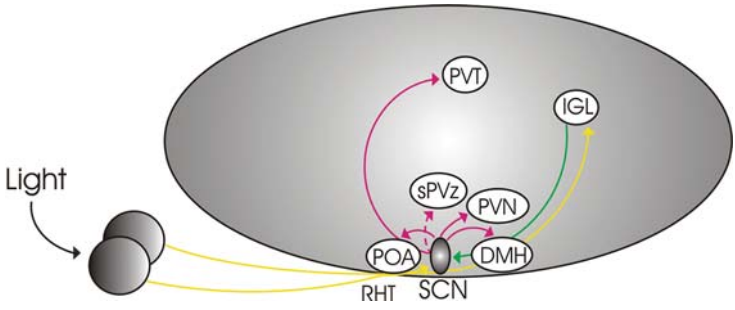
luciferase, under the control of rhythmic promoters from the *Per1* and *Per2* genes (Yamazaki et al., 2000; Yamaguchi et al., 2003; Yoo et al., 2004). Studies measuring rhythms in luciferase luminescence under the control of the *Per1* promoter have confirmed that between 75% and 100% of SCN cells have intrinsic oscillators, and that these oscillators exhibit a range of periods and peak times (Quintero et al., 2003; Yamaguchi et al., 2003). In the transgenic models, mean bioluminescence peaks during the day, similar to the peak in electrical activity, and the mean period for individual neurons is the same length as the period of locomotor activity. Recently, one group used neurons containing the *Per1*-luciferase transgene to confirm and extend previous electrophysiological findings regarding the lack of an effect of inhibition of electrical activity on the endogenous clock. Yamaguchi and colleagues, using bioluminescence imaging of SCN slice cultures, found that the application of TTX does not prevent rhythmic luciferase expression in individual neurons (Yamaguchi et al., 2003). However, TTX application does damp mean circadian luciferase expression across an entire slice. By analyzing luciferase expression at the single-cell level, it was found that that TTX-induced damping resulted from a combination of the desynchronization of individual neurons and a reduction, but not elimination, of luciferase amplitude within individual cells. This indicates that, while neuronal activity is not mandatory for intrinsic expression of the molecular pacemaker, it is important for the synchronization of individual cells. These results also suggest that TTX-sensitive sodium channels are somehow important to the coupling of neuronal activity that is required to generate a stable, coherent output from the SCN. Gap junctions have also been implicated in neuronal coupling in the SCN, but the molecular mechanism underlying activity coupling remains relatively unknown (Colwell, 2000b).

3.3 Shell versus Core: the Division of Labor Within the SCN

Although rhythmic neurons are distributed throughout the SCN, functional and anatomical studies suggest that the nuclei contain two major divisions known as the shell and the core (Leak and Moore, 2001). Although there are some species-specific differences, the shell and core are organized in a similar manner across mammals (Moore et al., 2002). The core is immediately superior to the optic chiasm, and it receives the majority of afferents from the visual system. Studies have shown direct connections between retinal ganglion cells (RGC) and neurons within the core; this pathway is known as the RHT, and is the primary pathway for phase-resetting photic stimuli (Moore and Lenn, 1972) (*Figure 22-3*). The core also receives photic input via an indirect pathway involving the intergeniculate leaflet (IGL) (Moore and Card, 1994).

Figure 22-3

Major Efferent and Afferent SCN projections. Model depicts a sagittal cross section of mouse brain. Light is detected by the retinal neurons at the back of the eyes, which communicate to the suprachiasmatic nuclei (SCN) directly via the retinal hypothalamic tract (RHT) and indirectly via the intergeniculate leaflet (IGL). As the master coordinator of circadian timing, the SCN communicates via neuronal projections to important regulatory regions of the brain such as the mPOA, the dorsomedial hypothalamus (DMH), the paraventricular nucleus (PVN) and the paraventricular nucleus of the thalamus (PVT). The SCN may also communicate with the subparaventricular zone (sPVz) via secreted factors (dashed line)



In addition to receiving RHT input, a defining characteristic of the core is its high level of vasoactive intestinal peptide (VIP) expression: 26% of SCN neurons express VIP, and these neurons reside almost exclusively in the core. Core neurons also preferentially express neurotensin and gastrin-related peptide (GRP) (Moore et al., 2002). Neurons within the core densely innervate each other and the neurons in the shell, but account for only a minority of projections from the SCN to other brain regions (Watts et al., 1987). Recent studies using several different retrograde tracers indicate that the only regions innervated by the core are the subparaventricular zone of the hypothalamus, thalamic nuclei, and the peri-suprachiasmatic area immediately adjacent to the SCN (Leak and Moore, 2001).

An abundance of evidence suggests that the core is responsible for responding to and integrating photic cues. Electron microscopic studies have shown that RHT terminals make direct contact with the VIP- and GRP-expressing core neurons (Ibata et al., 1989; Tanaka et al., 1997), and that these same neurons respond to light pulses by upregulating expression of the immediate early genes (IEGs) *c-fos*, *egr3,* and *junB* (Romijn et al., 1996; Castel et al., 1997; Beaule and Amir, 1999). Furthermore, light-induced expression of the clock gene *Per1* occurs mainly within core neurons, particularly those expressing GRP and/or VIP (Yan et al., 1999; Kulhman et al., 2003). In hamsters, light-induced *Per1* and *Per2* expression is further restricted to a small population of calbindin-positive neurons within the core that only express the *Per* genes after light exposure at night (Silver et al., 1996b).

The shell, which, in most mammals, fully encapsulates the core, receives the majority of its inputs from the core. Shell neurons make few projections back to the core, but are responsible for the majority of SCN efferents (Swanson and Cowan, 1975). Retrograde tracing studies have shown that shell neurons make monosynaptic connections to the medial preoptic area of the hypothalamus (mPOA), the dorsomedial (DMH) and ventromedial (VMH) hypothalamus, the paraventricular thalamic nuclei (PVT), the lateral septum, and the bed nucleus of stria terminalis (BNST), among others (Leak and Moore, 2001). Multisynaptic efferents connect shell neurons to endocrine organs such as the pituitary and pineal glands, and to the autonomic nervous system (ANS). Shell neurons are characterized by high expression of vasopressin (AVP) and calretinin (Moore et al., 2002). AVP is of particular interest, as its expression in the SCN is directly controlled by core clock genes and RNA levels are rhythmic even under constant conditions (Lee et al., 2001). Thus, AVP is a likely candidate for relaying timing signals from the SCN to other brain regions (Kalsbeek and Buijs, 2002).

The pattern of neural connections into, out of, and within the SCN suggests a relatively simple subdivision of labor in which the core receives photic input—the major phase resetting environmental cue—and integrates this input via activation of IEGs and their downstream genes, and regulation of *Per1* and *Per2* expressions and protein turnover (Ginty et al., 1993; Okamura et al., 1999; Yamazaki et al., 2000; Kornhauser et al., 2002). The core then conveys phase-resetting information to the shell, which is responsible for the majority of SCN efferents. SCN output, both humoral and neuronal, phase-coordinates circadian activity throughout the brain and periphery.

4 Photic and Nonphotic Input to the SCN

4.1 Overlapping Roles of Rods, Cones, and Retinal Ganglion Cells

In mammals, entrainment to an environmental LD cycle sets the phase of behavioral activity and rest cycles, fluctuations in body temperature and hormone levels (e.g., melatonin), and circadian gene expression patterns. The entrainment of mammalian circadian rhythms has been shown to require photoreceptive cells within the eye, as enucleation (removal of the eyes) prevents entrainment to a LD cycle as well as attenuates the response to light in constant darkness (Nelson and Zucker, 1981; Foster et al., 1991). The retina acts as the light-sensitive region of the eye and is composed of multiple neuronal cell layers that capture light and transmit image-forming and nonimage-forming signals to other areas of the brain. The photoreceptor cells are primarily responsible for mammalian visual perception and are organized into two major classes: rods, which are responsible for vision in dim light, and cones, which mediate color vision. Due to differential expression of the opsin photopigments, rod and cone cells are receptive to distinct wavelengths of light.

In rod cells, rhodopsin predominates and is maximally stimulated by light of approximately 500 nm wavelength. Cone cells are classified based on their distinct action spectra peaks. Humans have three distinct classes of cones, UV or short wave (S), middle wave (M) and long wave (LW), whereas rodents have only M- and S-type cones (Neitz and Neitz, 2001). Wavelengths of 360 nm (blue/UV) and 510 nm (green) light maximally stimulate the S and M cone opsins, respectively (Jacobs, 1993; Foster, 1998). Studies in rodents have shown that phase shifting of wheel-running activity is most sensitive to light near 500 nm wavelength, so it is plausible that classic photoreceptor cells may also communicate light input for circadian entrainment purposes (Takahashi et al., 1984; Provencio and Foster, 1995).

Spontaneous mutants and genetically altered rodent models have proven to be useful in determining how distinct retinal cells are involved in circadian photic entrainment. Mice that are homozygous for the *rd/rd* mutation, which results in gradual rod and cone degeneration, retain the ability to entrain to an LD cycle and to respond to night-time light with melatonin suppression (Foster et al., 1991; Provencio et al., 1994; Lucas et al., 1999). Another transgenic mouse line, *rdta*, which displays complete loss of rods and most cones by 28 days of age, is also able to entrain to an LD cycle (McCall et al., 1996; Lupi et al., 1999). However, these mice exhibit some circadian abnormalities, such as a slightly shorter free-running period in DD and an increased sensitivity to phase-shifting light pulses, suggesting that rod/cone input may play a role during the development of circadian rhythms (McCall et al., 1996). Because some cone cells remain in the *rd/rd* and *rdta* mutants, it was long thought that these photoreceptors were responsible for photic input to the SCN. However, in 1999, two groups working independently crossed the *rd/rd* or *rdta* mutants to a strain of mice lacking cones (*cl*) to produce mice that completely lacked rods and cones (Freedman et al., 1999; Lucas et al., 1999). The offspring retained the ability to entrain to an LD cycle and phase shift both melatonin and wheel-running activity in response to a light pulse, indicating that neither rods nor cones are necessary for photic regulation of circadian rhythms.

Recently, another class of retinal neurons known as RGCs has been identified as a mediator of photic stimulation and communication to the SCN. Berson and colleagues found that certain RGCs are intrinsically light-sensitive: neither blocking neuron–neuron communication from rods or cones, nor isolating individual rat RGCs prevented the cells from firing in response to light stimulation (Berson et al., 2002). In addition, RGCs are not as sensitive to light levels as rods and cones: they are slow to react to increased light intensity, but then respond continuously without adapting over a relatively long period of time (seconds to minutes). These results correlate with the predicted characteristics of the mammalian circadian photoreceptive system based on the findings that hamsters required a relatively high threshold of light intensity and long duration of light exposure to maximally phase-shift wheel-running activity (Takahashi et al., 1984). As further evidence for the role of RGCs in circadian entrainment, Wee and colleagues characterized circadian activity in a mouse line rendered deficient in the majority of RGCs by the disruption of *Math5*, a gene necessary for RGC differentiation. *Math5*$^{-/-}$ mice do not have an observable RHT and are unable to entrain to a LD cycle (Brown et al., 2001; Wang et al., 2001; Wee et al., 2002; Brzezinski et al., 2005). These studies provide strong evidence that RGCs are the retinal cells primarily responsible for mediating photic input to the circadian system.

4.2 Biochemical Effectors of Photic Input: Opsins and Cryptochromes

4.2.1 Opsins

The molecular basis for mammalian light detection has been extensively studied in rodent rods and cones. Mammalian photoreceptor opsins are transmembrane receptors that contain a lysine residue in the third transmembrane domain, which binds the light-sensitive chromophore, 11-cis-retinal (vitamin A), through a Schiff-base linkage. Once exposed to light, the chromophore is converted to all-trans-retinal, which induces a conformational change in the opsin protein. Intracellularly, photoreceptor opsins are coupled to guanine nucleotide-binding proteins (G-proteins) by their third cytoplasmic loop. The light-activated conformational change in the opsin activates the bound G-protein and subsequent signaling pathways required for visual perception. Rod cells, which represent 97% of mouse photoreceptors (Young, 1985),

are dependent on the retinal pigment epithelium (RPE) layer to isomerize the chromophore back to 11-cis-retinal. The chromophore is then transported back to the photoreceptor cells where it reassociates with the photo-bleached opsins and awaits reactivation by light.

In 1998, Provencio and colleagues discovered a novel opsin in the photosensitive dermal melanophores of *Xenopus laevis*, which they named melanopsin (Provencio et al., 1998). Two years later, they described the identification of melanopsin in human retina, and localized the mRNA to the amacrine and ganglion cell layers in both mouse and monkey retina (Provencio et al., 2000). Phylogenetic comparisons revealed that both amphibian and mammalian melanopsin were more similar to invertebrate opsins than to vertebrate isoforms at the amino acid level: mammalian opsins contain a lysine residue in the third transmembrane domain responsible for chromophore binding, but melanopsin sequences contain an aromatic residue substitution (tyrosine). Therefore, melanopsin, like invertebrate opsins, may be able to retain the covalently linked chromophore, allowing for repeated interconversion between the two states and eliminating the dependency on the RPE for chromophore supply. Recent findings have shown that exogenously expressed melanopsin does indeed exhibit both inherent photosensitivity and photoisomerase activity (Melyan et al., 2005; Panda et al., 2005). These features make melanopsin a likely candidate for a circadian photoreceptor, as melanopsin-containing cells can autonomously function in widely dispersed regions.

In 2002, a series of elegant studies were published characterizing both melanopsin and the RGCs that express the photopigment. Provencio and colleagues (2002) identified what they termed an 'expansive photoreceptive net' in the mouse inner retina by immunolabeling flat mount sections with antiserum against melanopsin. The melanopsin-labeled cells were present in the RGC layer, and dendrites from the cells extended to different regions of the retinal inner plexiform layer, creating an extensive network capable of receiving photic stimulation. Gooley and colleagues (2001) used retrograde tracing to show that, in rats, the majority of melanopsin-containing RGCs project to the SCN through the RHT, and the majority of RGCs that project to the SCN contain melanopsin. These studies indicate that melanopsin-containing RGCs have a wide dendritic network for efficient photic capture, can fire in response to sustained increases in light, and project to the SCN—necessary characteristics for mediators of circadian entrainment. However, subsequent knockout experiments showed that mice with a null mutation of the melanopsin gene (*Opn4*) had a subtle defect in light-induced phase shifts, but were capable of entraining to an LD cycle and had a normal free-running activity period (Panda et al., 2002b; Ruby et al., 2002).

The results obtained with *Opn4* knockout mice indicated that compensation by the rods, cones, and/or another photoreceptor could occur in the absence of melanopsin. Hattar and colleagues (2003) definitively showed that RGCs, rods, and cones are the only cells required for normal circadian entrainment. The authors first examined the action spectrum for phase-shifting circadian wheel-running activity in rodless, coneless mice (*rd/rd cl*), and observed a maximal effect of light of approximately 481 nm wavelength, which corresponds to the wavelength required for maximal stimulation of endogenous melanopsin-expressing RGCs in the rat, as well as exogenous melanopsin-expressing *Xenopus* oocytes (Berson et al., 2002; Panda et al., 2005). Interestingly, mice that are rendered functionally deficient in all three major photoreceptor pathways (*Gnat1*$^{-/-}$ *Cnga3*$^{-/-}$ *Opn4*$^{-/-}$) could not entrain to an LD cycle, although they exhibited a normal free-running period. Thus, circadian entrainment is mediated by the three major photoreceptive systems in the mammal: rods, cones, and melanopsin-containing RGCs. Recent findings have begun to elucidate the intracellular biochemical pathways through which melanopsin may function, as Panda and colleagues (2005) have shown that the $G\alpha_q/G\alpha_i$ family of G-proteins and the transient receptor potential (TRP) subfamily C (TRPC) channel are involved in light-dependent activation of melanopsin-expressing *Xenopus* oocyte membrane currents.

4.2.2 Cryptochromes

In plants, blue-light photoreceptors known as cryptochromes (*Crys*) transduce sunlight, which is required for a variety of functions such as growth and reproduction. Cryptochromes are distinct from opsin photopigments in that they do not use vitamin A as a chromophore. Instead, vitamin-B based FAD and folate are the bound cofactors required for light sensitivity (Kavakli and Sancar, 2002). The discovery of

mammalian *Cry* homologs *Cry1* and *Cry2* and their expression in retinal cell layers, including the ganglion cells, made these proteins potential candidates for the circadian photoreceptors (Miyamoto and Sancar, 1998). In addition, a study from Sancar's group showed that vitamin-A dependent opsins may not be required for circadian entrainment, as mice that were fed a vitamin-A-deficient diet and genetically lacked the serum retinol transport protein could still respond to light by upregulating *Per2* in the SCN (Thompson et al., 2001). However, mammalian *Cry*s exhibit maximal light absorption at 420 nm wavelength, shorter than that required for maximal circadian response (~500 nm) (Hsu et al., 1996). Furthermore, mice that carried null mutations of both *Cry* genes (*Cry1*$^{-/-}$, *Cry2*$^{-/-}$) respond to an LD cycle (van der Horst et al., 1999; Vitaterna et al., 1999). However, Selby and colleagues crossed *Cry* double knockout mice with *rd/rd* mice and found that triple mutant mice (*Cry1*$^{-/-}$, *Cry2*$^{-/-}$, *rd/rd*) were unable to entrain to a LD cycle, suggesting that the cryptochromes are also involved in circadian entrainment (Selby et al., 2000). As both *Cry* genes and melanopsin are expressed in the RGC layer, it is possible that they are both involved in stimulation of these neurons and may act in concert. The ability of these retinal cells to compensate for the loss of one or even two of the retinal photoreceptive systems indicates the crucial role of environmental input to the circadian system.

4.3 Neurotransmitters and Intracellular Pathways

As previously described, RGCs project to neurons in the core region of the SCN through the RHT. Upon light stimulation, RGCs fire and release neurotransmitters—primarily glutamate and pituitary adenylate cyclase activating polypeptide (PACAP)—that can act on the SCN. Both glutamate and PACAP have been observed in RHT neurons that terminate in the SCN, and receptors for both these neurotransmitters (NMDA and non-NMDA type glutamate receptors, PAC1, and VPAC2) are expressed in the SCN (Cagampang et al., 1998a, b; Hannibal, 2002). Studies examining the role that these neurotransmitters play in transmission of photic signal have relied primarily on the phase-shifting effects of light pulses on animals housed in DD. Pulses of light given to nocturnal rodents during the early subjective night, or active phase, result in a delay in the circadian phase, whereas light pulses given during late subjective night result in phase advances (Daan, 1977). Light administered during the subjective day usually does not alter phase. Phase shifting can be detected by changes in the time of wheel-running activity onset, the electrical firing rate of explanted SCN tissue, and/or expression of the circadian clock genes *Per*1 and *Per*2 in the SCN.

In vitro, application of glutamate or NMDA to SCN slice preparations induces a phase shift in the electrical firing rate of SCN neurons (Ding et al., 1994; Shibata et al., 1994). *In vivo*, light pulses or injection of NMDA near the SCN produce similar phase shifts in wheel-running behavior, whereas injection of glutamate receptor antagonists can block the phase-shifting effects of light on wheel-running behavior (Colwell et al., 1990, 1991; Colwell and Menaker, 1992; Mintz et al., 1999). Evidence also points to a role for PACAP in light-induced phase shifts, as PACAP immunoreactivity in the SCN is almost completely lost following enucleation in hamsters (Hannibal et al., 1998). Microinjection of PACAP into the SCN produces phase shifts in both wheel-running activity and neuronal firing rates, and PACAP antagonists attenuate light-induced phase shifts (Harrington et al., 1999; Piggins et al., 2001; Minami et al., 2002; Bergstrom et al., 2003). Recently, Colwell and colleagues found that PACAP-deficient mice show attenuated phase shifts in wheel-running activity in response to light (Colwell et al., 2004). Therefore, both glutamate and PACAP appear to communicate the photic signal directly to the SCN neurons.

PACAP and glutamate may also modulate one another's ability to evoke a postsynaptic response. Glutamate normally induces a phase advance in SCN slice firing rate when administered at late subjective night, and a phase delay when administered at early subjective night. However, Chen and colleagues showed that treatment of SCN slices with PACAP blocked the normal glutamate-induced phase advance at CT19, but potentiated the glutamate-induced phase delay at CT14 (Chen et al., 1999). Defining the light-induced regulation and interactions of the two major neurotransmitters of the RHT may help explain why light has differential phase-shifting properties at distinct points throughout the circadian cycle. The characterization of this modulation, especially with respect to time of day, will further our understanding of the complex mechanisms that regulate phase-shifting input to the SCN.

RHT input to SCN neurons results in the activation of several intracellular signaling pathways, including the calcium/calmodulin kinase (CAMK), ERK/MAP kinase, and protein kinase A (PKA) pathways. All these kinases can activate the cAMP response element (CRE) CRE-binding protein (CREB) transcriptional pathway, which regulates many cellular processes. Obrietan and colleagues used transgenic mice expressing a CRE-β-galactosidase construct to show that both reporter gene activity and endogenous CREB phosphorylation exhibit a circadian rhythm in the SCN (Obrietan et al., 1999). It has since been shown that three amino acids, serines 133, 142, and 143, on CREB are important for activation by light and glutamate (Ginty et al., 1993; Gau et al., 2002; Kornhauser et al., 2002), as mutation of Serine 142 results in an attenuation of light-induced phase shifts of wheel-running activity and *Per1* gene expression (Gau et al., 2002).

Phosphorylated CREB also regulates the expression of IEGs such as *c-fos* in response to light stimulation. *C-fos, Per1,* and *Per2* all contain CRE sites in their promoter regions, and injection of an oligodeoxynucleotide CRE decoy into the SCN inhibits light or glutamate-induced phase shifts of wheel-running activity and *Per1* gene expression. This suggests that CRE/CREB-mediated transcriptional activation plays an important role in photic entrainment (Ginty et al., 1993; Tracnickova et al., 2002; Tischkau et al., 2003). Expression of *Per1* and *Per2* mRNA, which is normally low during the night, is rapidly induced by light exposure at night/subjective night, but is not induced by light exposure during the subjective day (Shearman et al., 1997). Thus, the regulation of the *Period* genes may be key to behavioral phase-shifting in response to light.

4.4 Nonphotic Input Modulates Circadian Rhythms

In addition to light, external cues such as activity/exercise and social behavior can modulate SCN-dependent circadian rhythms (Edgar and Dement, 1991). Anatomical and pharmacological studies have shown that nonphotic input to the SCN is communicated by the IGL and raphe nuclei, and is mediated primarily by the neurotransmitters neuropeptide Y (NPY) and serotonin (5-HT), respectively (Yannielli and Harrington, 2004). Application of either NPY or 5-HT during the subjective day results in phase advances of circadian rhythms of wheel-running activity and SCN gene expression (Yannielli and Harrington, 2004). However, these neurotransmitters mediate their effects through separate molecular pathways: NPY acts through the NPY Y1, Y2 and Y5 receptors to activate PKC and to elicit phase shifts, whereas the 5-HT family of receptors mediates serotonin-induced phase shifts through PKA and potassium channel activation (Yannielli and Harrington, 2004).

Nonphotic input to the SCN not only has a direct influence on circadian rhythms, but can also modulate the phase-shifting effects of light, and vice versa. Both NPY and serotonin can inhibit light-induced phase shifts during subjective night, with serotonin likely acting through 5HT1A/7 and 5HT1B receptors (Pickard et al., 1996; Weber et al., 1998; Yannielli and Harrington, 2004). Interestingly, though the 5HT1A/7 receptors are located on SCN neurons, the 5HT1B receptors are localized to RHT axons. Activation of these presynaptic receptors decreases glutamatergic excitatory postsynaptic currents (EPSCs) in the SCN, suggesting that serotonin modulates light-induced phase shifts by regulating both the stimulatory effects of the RHT and the cellular response of SCN neurons (Pickard et al., 1999; Smith et al., 2001). NPY has been shown to inhibit both *in vivo* light responses and NMDA-induced phase advances of spontaneous firing rate in SCN slice preparations (Yannielli and Harrington, 2000, 2001a, b). Y5 receptor antagonists block the inhibitory effects of NPY on light-induced wheel-running phase shifts, in addition to potentiating light-induced phase advances in the absence of exogenous NPY (Yannielli et al., 2004; Yannielli and Harrington, 2001a, b). This suggests that the NPY pathway normally acts to restrict the shifting effects of light during subjective night, perhaps as a way to fine-tune the effects of phase-shifting stimuli.

A recent study has uncovered a mechanism coupling the photic and nonphotic pathways in the SCN. *Dexras1*, a guanine nucleotide exchange factor, shows a circadian pattern of expression in the SCN, with mRNA levels peaking in early subjective night, and DEXRAS1 guanine nucleotide exchange activity increases in response to NMDA stimulation of cortical neurons (Fang et al., 2000; Panda et al., 2002a;

Takahashi et al., 2003). Cheng and colleagues found that mice lacking the *dexras1* gene exhibit attenuated phase delays and MAPK pathway component phosphorylation in response to light pulses, and also exhibit dramatically increased phase advances when placed in a novel environment (Cheng et al., 2004). SCN preparations from *dexras1*$^{-/-}$ mice exhibited an increased sensitivity to NPY blockade of NMDA-induced firing rate phase shifts compared with sections from wild-type mice, implying a role for *dexras1* in nonphotic input (Cheng et al., 2004). These results provide evidence for a common molecular pathway that can receive and respond to photic and nonphotic stimuli to appropriately adjust an organism's circadian rhythm to environmental cues.

5 The Molecular Clock

Many of the advances in our understanding of the molecular pacemaker have come either from the identification of mammalian homologs of circadian genes in other organisms, or from the induced or targeted disruption of individual clock genes (Lowrey and Takahashi, 2004). Beginning with the identification of the *Clock* gene in 1997, the number of confirmed mammalian clock genes has rapidly risen to include six core genes necessary for generating rhythmicity and a number of other genes that modify pacemaker characteristics (Takahashi, 2004; Lowrey and Takahashi, 2004). In the present chapter, we define the core clock genes as those necessary for pacemaker function, mutation or deletion of which results in an extreme phenotype such as molecular and behavioral arrhythmicity. In contrast, clock-modifying genes are not essential for the generation of rhythmicity, but do play a role in regulating the properties of circadian rhythms (Takahashi, 2004).

At its most basic level, the molecular circadian clock present within each SCN neuron is composed of a transcription–translation loop: two proteins, CLOCK and BMAL1 (also known as MOP3) induce the transcription of four other genes, *Per1, Per2, Cry1,* and *Cry2*, which, after translation, dimerize, re-enter the nucleus, and inhibit their own transcription (King and Takahashi, 2000) (*Figure 22-4*). Following turnover of the inhibitory proteins, the transcription–translation cycle resumes. This molecular cycle occurs over a period of approximately 24 h, and continues indefinitely with a stable period in the absence of any input.

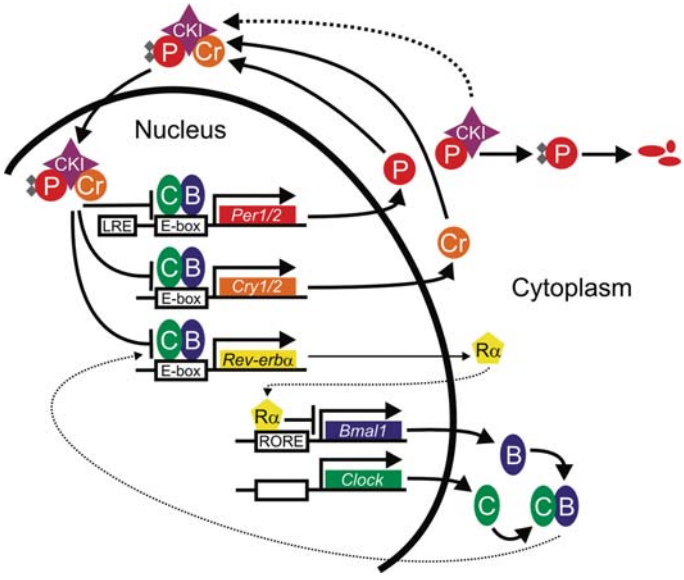
5.1 *Clock* and *Bmal1/Mop3*

As previously described, the *Clock* mutant mouse was discovered in 1994 during a screen for ENU-induced mutations that resulted in abnormal circadian phenotypes (Vitaterna et al., 1994). Following the identification and characterization of the mutant phenotype, Vitaterna and colleagues determined that the responsible mutation mapped to a single locus on mouse chromosome 5. King and colleagues (1997) used positional cloning to characterize and map the *Clock* gene. The *Clock* gene spans almost 100 kb and has at least two splice variants, both of which have 23 exons (King et al., 1997). The resulting protein is a member of the basic helix-loop-helix (bHLH) PAS (Period-Arnt-Sim) transcription factor family, and shares high homology with bHLH-PAS member NPAS2 and lower homology with other family members such as ARNT, HIFα, and SIM1. CLOCK has a bHLH domain, important for DNA binding, PAS-A and PAS-B domains, which are involved in protein–protein dimerization, and a C-terminus glutamine-rich region associated with transactivation of the transcription initiation complex. It is within this glutamine-rich region that the single base-pair mutation responsible for the *Clock* mutant phenotype occurs: an A–>T transversion at the exon–intron junction 3′ to exon 19 results in a 51-amino acid internal deletion (King et al., 1997). The *Clock* mutation has a dominant negative functional effect: the mutant CLOCK protein is able to bind to other transcription factors and to DNA, but is unable to initiate transcription, resulting in neuronal and behavioral arrhythmicity under constant conditions (King et al., 1997; Gekakis et al., 1998; King and Takahashi, 2000).

Bmal1, another bHLH-PAS family member, was discovered when Weitz and Takahashi used a yeast two-hybrid screen to identify CLOCK-binding partners (Gekakis et al., 1998). Both *Clock* and *Bmal1* are highly

Figure 22-4

The Circadian Transcription–Translation Feedback Loop. The proteins CLOCK, BMAL1/MOP3, PERIOD1 and 2, and CRYPTOCHROME1 and 2 make up the core of the molecular circadian pacemaker. CLOCK and BMAL1 dimerize and activate the transcription of the *Period* and *Cryptochrome* genes, the protein products of which inhibit their own transcription following homo- and heterodimerization. There are a number of other proteins, including CK1ε and REV-ERB α, that can regulate the speed at which the pacemaker runs by regulating transcription or protein turnover of the core clock genes. Reprinted by permission of Annual Review of Genetics and Human Genomics



expressed in the SCN; although *Clock* expression is not rhythmic, *Bmal1* expression is regulated in a circadian manner with peak expression during the subjective night (CT15-CT18) (Shearman et al., 2000b). BMAL1 and CLOCK heterodimerize and, like other bHLH-PAS proteins, bind to an E-box element on genomic DNA. This E-box sequence, CACGTGA, is involved in the induction of gene transcription by bHLH-PAS transcription factors, and E-boxes have since been identified in the promoter regions of many circadian genes (Hogenesch et al., 1998; Panda et al., 2002a). Mice with a targeted disruption of *Bmal1* lack both rhythmic *Per1* and *Per2* mRNA expression in the SCN and rhythmic locomotor activity in constant darkness (Bunger et al., 2000).

5.2 The *Period* and *Cryptochrome* Paralogs

The CLOCK:BMAL1 heterodimer induces coordinated transcription of *Per1*, *Per2*, *Cry1*, and *Cry2*, which have been shown, through the use of knockout mice, to be the essential components of the core circadian mechanism. The *Period* paralogs and the *Cryptochrome* paralogs are homologous to genes known to be essential to circadian rhythms in other organisms, including *Drosophila*. The *Per* genes, members of the PAS family, are highly enriched in the SCN, and are rhythmically expressed with peak *Per1* mRNA expression around CT6, peak *Per2* mRNA expression at ZT9, and peak protein expression of both approximately 3–6 h phase-delayed to mRNA expression (Zylka et al., 1998; Zheng et al., 2001). The PER proteins have been shown to homodimerize, and to heterodimerize with each other and with both CRY1 and CRY2 (Griffin et al., 1999; Bae et al., 2001; Zheng et al., 2001). Dimerization occurs in the cytoplasm

and results in the exposure of a nuclear localization sequence (NLS) and subsequent nuclear entry, where the dimers inhibit CLOCK:BMAL1-induced gene transcription (Kume et al., 1999).

Mice with a targeted deletion of either the *Per1* gene or the *Per2* gene display a free-running period approximately 1 h shorter than normal, and in the case of *Per2* show a loss of rhythmicity during extended periods in DD (Zheng et al., 1999, 2001; Bae et al., 2001). *Per1/Per2* double knockouts exhibit locomotor arrhythmicity immediately upon introduction to DD, indicating that while the molecular pacemaker continues to function—albeit somewhat impaired—with one normal *Period* gene, the loss of both *Period* genes completely disrupts pacemaker function (Bae et al., 2001; Zheng et al., 2001). However, there are important phenotypic differences between *Per1* and *Per2* knockouts: *Per1* deletion has little effect on *Per2*, *Cry1*, or *Bmal1* mRNA expression, but reduces the level of CLOCK protein expression, whereas *Per2* deletion results in a reduction in the amplitude of both *Per1* and *Per2* gene expressions (Bae et al., 2001). Furthermore, *Per2* knockout mice have a shorter free-running period than the *Per1* knockout mice, and the majority of *Per2* knockout mice lose circadian rhythmicity with prolonged time in constant darkness (Zheng et al., 1999). It has been proposed that *Per2* regulates *Bmal1* transcription, which might explain why *Per2* knockout mice have a more severe phenotype than *Per1* knockouts (Shearman et al., 2000a). Microarray analysis also indicates that *Per1* and *Per2* have differential effects on clock-controlled genes (Zheng et al., 2001). Unlike *Per1* and *Per2*, a third paralog, *Per3*, does not appear to be necessary for circadian behavioral rhythms, as *mPer3* knockout mice show only a slightly shortened period and no change in rhythmic clock gene expression (Shearman et al., 2000a). PER3 does not appear to interact with the CRY proteins, perhaps explaining why it cannot compensate for the loss of both *Per1* and *Per2* (Lee et al., 2004).

Like the *Period* genes, *Cryptochromes 1* and *2* are orthologs of core circadian genes in *Drosophila* (Kume et al., 1999). CRY1 and CRY2 strongly inhibit CLOCK:BMAL1-induced transcription, and have been shown to dimerize with each other and with the PER proteins (Kume et al., 1999). *Cry1* and *Cry2* are rhythmically expressed in the SCN, with mRNA expression peaking toward the end of the subjective day, and are unaffected by nighttime light exposure (Okamura et al., 1999; van der Horst et al., 1999). CRY1 and CRY2 are present in both the retina and the SCN, and are likely involved in the photic entrainment pathway.

Cry1 and *Cry2* loss-of-function mutations have opposite effects on circadian period: the mutation of *Cry1* results in an ∼1-h shortening of the free-running period, whereas the mutation of *Cry2* results in an ∼1-h lengthening of the period in mice (van der Horst et al., 1999; Thresher et al., 1998). This suggests that *Cry1* and *Cry2* have overlapping functions as core clock components, but opposite functions in affecting period length. As might be predicted from their behavioral effects, *Cry1* and *Cry2* differentially regulate *Period* gene expression. Deletion of *Cry1* results in an earlier peak of *Per1* and *Per2* expression in the SCN, as would be expected from the shortened period of locomotor activity, and may blunt light-induced *Per1* expression at night (Okamura et al., 1999) (Vitaterna et al., 1999). Deletion of *Cry2* results in a delayed peak of *Period* gene expression, but has no effect on light-induced *Per1* expression (van der Horst et al., 1999). Similar to *Per1/Per2* double knockouts, *Cry1/Cry2* double knockouts become arrhythmic in DD. *Per1* and *Per2* levels were found to be elevated and arrhythmic in *Cry1/Cry2* knockouts; further investigation has shown that the CRY proteins are potent inhibitors of the CLOCK:BMAL1 complex via protein:protein interactions (Okamura et al., 1999; Vitaterna et al., 1999).

5.3 *Rev-erbα*, *Timeless*, and Other Modifiers of the Circadian Pacemaker

The mutation of *Clock*, *Bmal1*, both *Per1* and *Per2*, or both *Cryptochrome* genes results in behavioral arrhythmicity in the absence of entraining cues. However, there are a number of other proteins that are not essential for sustaining rhythmicity, but do affect the length or properties of the molecular clock. These genes include enzymes such as *Casein Kinase 1ε*, which regulates PER accumulation by phosphorylation, and transcription factors such as *Rev-erbα,* which regulates the transcription of *Bmal1* (Takahashi, 2004; Lowrey and Takahashi, 2004). Lowrey and colleagues (2000) used positional syntenic cloning to identify a

mutation in the *Casein kinase 1ε* gene as the cause of the shortened period length in *tau* mutant hamsters. *CK1ε* is a serine/threonine protein kinase that normally phosphorylates cytoplasmic PER1 and PER2, resulting in PER degradation. The mutant version of *CK1ε* fails to effectively phosphorylate the PERIOD proteins, allowing PER to accumulate more rapidly than normal (Lee et al., 2001). This effectively shortens the molecular cycle, resulting in the shortened activity period observed in *tau* mutants.

The transcription factor *Rev-erbα* has recently been shown to couple the positive and negative limbs of the core pacemaker by regulating a component of the positive limb. *Rev-erbα* mRNA is highly rhythmic in the SCN, and expression levels peak early in the subjective day (Ueda et al., 2002). Expression is induced by the CLOCK:BMAL1 complex binding to an E-box sequence on the *Rev-erbα* promoter, but, unlike the *Period* and *Cryptochrome* genes, *Rev-erbα* feeds back to inhibit transcription of *Bmal1* and other genes that have retinoic acid related orphan receptor response elements (ROREs) within their promoters (Ueda et al., 2002; Sato et al., 2004). Preitner and colleagues (2002) determined that the *Bmal1* promoter contains two ROREs that bind *Rev-erbα*. In addition to being regulated by CLOCK:BMAL1, expression of *Rev-erbα* is negatively regulated by PER2, and levels of *Rev-erbα* mRNA are high and nonrhythmic in *Per2* knockout mice. Because of its role in repression of *Bmal1* expression, *Bmal1* levels are constitutively high in *Rev-erbα* knockout mice. However, locomotor activity is only slightly shorter in the knockouts, indicating that rhythmic expression of *Bmal1* is not essential for proper pacemaker function (Preitner et al., 2002).

The role of a third candidate gene, *Timeless*, is still under investigation. *Timeless* is a core component of the *Drosophila* molecular clock, and flies carrying a null mutation of timeless (tim^{01}) are arrhythmic, but the function of the mammalian homolog has been difficult to ascertain because deletion of *Tim* results in embryonic lethality (Gotter et al., 2000). However, Barnes and colleagues have recently used *in vitro* knockdown of *Tim* to suggest a circadian function for the gene (Hastings et al., 1999; Barnes et al., 2003). Application of antisense oligodeoxynucleotides against *Tim* to SCN slices results in the disruption of rhythmic VIP expression and phase-shifts spontaneous neuronal activity when applied during the subjective day (Barnes et al., 2003; Tischkau et al., 2003). Barnes and colleagues suggest that previous attempts to study *Tim* have been confounded by the abundance of a short, nonrhythmic isoform of the protein, and that it is the less-abundant full-length isoform that is transcribed rhythmically and contributes to normal *Period* and *Cryptochrome* expression.

In addition to *CK1k1ε, Rev-erbα*, and *Timeless*, there are several other genes that may modify period length but whose functions have not been studied as extensively. These include: (a) albumin D-element binding protein (DBP), a member of the PAR family of basic leucine (bZip) transcription factors, expression of which is induced by the CLOCK:BMAL complex (Ripperger et al., 2000; Yamaguchi et al., 2000b); (b) *Dec1* and *Dec2*, bHLH transcription factors that are rhythmically expressed in the SCN and inhibit CLOCK:BMAL1-induced transcription of *Per1* by competing for E-box binding and/or directly binding to BMAL1 (Honma et al., 2002); (c) *Math5*, a helix-loop-helix protein that is involved in RHT development and the deletion of which results in both the inability to entrain to an LD cycle and an ∼1-h lengthening of the free-running period (Wee et al., 2002); and (d) *Rab3a*, a ras-associated protein that regulates synaptic vesicle trafficking and mutation of which results in a shortened free-running period (Kapfhamer et al., 2002). Also of interest is *Npas2*, the bHLH-PAS family member most similar to *Clock* (King et al., 1997). Although NPAS2 does not appear to play a role in pacemaker activity in the SCN, it is expressed throughout the forebrain and forms a transcription initiation complex with BMAL1, the DNA-binding activity of which is regulated by redox state (Rutter et al., 2001). NPAS2 may therefore be involved in the entrainment of the pacemaker by food, linking cellular redox state to the circadian pacemaker.

In summary, the core clock genes are the basis for the cell-autonomous molecular clock observed in SCN neurons. CLOCK, BMAL, the PERIODs, and the CRYPTOCHROMEs form an autoregulatory loop that functions with or without external cues. However, the time required for the loop to run full-circle can be regulated by a number of other proteins that act as transcription factors or phosphatases. As the CLOCK:BMAL complex drives transcription of core component genes, it also induces or inhibits transcription of numerous other genes, some of which are themselves transcription factors and some of which may be directly involved in circadian phenotypes observed at the cellular level, such as neuropeptide expression and membrane conductance (Panda et al., 2002a).

5.4 Transcriptional and Functional Regulation of Clock Genes I: Transcription

Circadian expression of genes can be controlled at one or more of three levels: (1) at the level of gene expression, as in the induction or inhibition of transcription, (2) at the level of protein function through mechanisms such as phosphorylation and dimerization that regulate protein activity or cellular localization, or (3) at the level of protein degradation, with rhythmic proteins targeting other proteins for removal. Of these three mechanisms, the best studied is transcriptional control, and it also appears to be the most important means of regulating circadian gene/protein expression.

The primary mechanism of circadian control over gene expression occurs via CLOCK:BMAL1 binding at specific E-box elements located within the regulatory regions of a number of clock-controlled genes. E-boxes are hexameric DNA sequences, CANNTG, recognized by all bHLH transcription factors; the sequence preferentially recognized by the CLOCK:BMAL complex is (G/T)G(A/G)A*CACGTG*ACCC (Hogenesch et al., 1998; Panda et al., 2002a). The primacy of the E-box to circadian transcription was first recognized in flies, when it was shown that an E-box-containing 69-bp region of the *per* promoter was enough to induce robust circadian transcription of a reporter gene (Hao et al., 1997); indeed, a multimer of the E-box plus the 6-bp immediately 5′ and 3′ could also produce circadian transcription (Darlington et al., 2000). In mammals, *Per1* has 5 circadian E-boxes in the 6.8 kb upstream to the transcription start site. These E-boxes are necessary for circadian transcription and act in an additive manner: mutation of all but one upstream E-box results in greatly reduced, but still rhythmic, transcription, whereas mutation of all five results in low, nonrhythmic transcription of a reporter gene (Hida et al., 2000; Yamaguchi et al., 2000a).

A number of other clock-controlled genes also contain E-boxes within their promoter regions. By using microarrays to analyze gene expression in the SCN and liver over 48 h, Panda and colleagues identified 127 cycling transcripts, 9 of which contained a CACGTGA sequence within the 10 kb upstream to the transcription start site (Panda et al., 2002a). However, a number of clock-controlled genes, such as *Per2*, do not contain a canonical E-box within the promoter, suggesting that there are other, as-yet unidentified sequences involved in circadian transcription, and that there are sequences other than the canonical CACGTGA sequence that are necessary for regulating CLOCK:BMAL1 binding. Indeed, a variant of the circadian E-box has recently been identified by Yoo and colleagues, who found that the majority of the circadian transcription of *Per2* can be accounted for by a noncanonical CACGTT sequence 20 bp upstream of the *Per2* transcription start site (Yoo et al., 2005). Chromatin immunoprecipitation shows that this E2 sequence, like the canonical E-box, constitutively binds the CLOCK:BMAL1 dimer *in vivo*, and a 210-bp E2-containing enhancer sequence is sufficient for driving *in vivo* luciferase rhythms in transgenic mice (Yoo et al., 2005). Further investigation may show that the E2 element is as important as the canonical E-box for regulating genome-wide circadian transcription.

E-box sequences are relatively common throughout the genome, yet only a subset of genes with E-box-containing promoters is transcribed rhythmically. To identify non-E-box regions involved in circadian transcription, Munoz and colleagues compared the promoter regions of two genes, *vasopressin* (AVP) and *cyclin-b* (CYC) (Munoz et al., 2002). Both promoters contain a single CACGTG sequence, but expression of AVP in the SCN is rhythmic and controlled by CLOCK:BMAL, whereas expression of CYC is not rhythmic (Hwang et al., 1995; Jin et al., 1999). In addition to showing that CYC transcription is not affected by CLOCK:BMAL, suggesting that there are sequences adjacent to the E-box that increase or decrease a promoter's affinity for CLOCK:BMAL, Munoz found that the AVP promoter has lower affinity than the CYC promoter for the universal E-box factor USF. This leads to the hypothesis that nonrhythmic E-box containing genes combine a low affinity for CLOCK:BMAL1 with a high affinity for constitutively expressed transcription factors, whereas rhythmic genes have a lower affinity for constitutive transcription factors and a high affinity for CLOCK:BMAL1 (Munoz et al., 2002). Additional regulation of circadian transcription likely occurs via both spatial control of transcription factor expression and concentration-dependent competition by other bHLH transcription factors.

Although Munoz identified several E-box-like sequences in the AVP promoter as possible enhancers for CLOCK:BMAL1 binding, there are still no non-E-box sequences known to confer transcriptional rhythmicity. However, the cAMP-responsive element (CRE) has been identified as important for light-dependent

induction of the *Period* genes, and, as described earlier, the RORE plays a role in the regulation of rhythmic *Bmal1* expression (Tracnickova et al., 2002; Tischkau et al., 2003). The ROREs in the *Bmal1* promoter appear to have a bidirectional effect on *Bmal1* expression depending on which transcription factors are present: whereas *Rev-Erb* α inhibits *Bmal1* transcription via RORE binding, the orphan nuclear receptor RORα induces *Bmal1* transcription (Preitner et al., 2002; Ueda et al., 2002; Najima et al., 2004; Sato et al., 2004). Recently, Ueda and colleagues classified circadian transcriptional regulators into three groups: those that act via E/E1-boxes, those that act on ROR elements, and those that act on DBP/E4BP4 elements (Ueda et al., 2005). They showed that the rhythmicity, amplitude, and phase of circadian gene expression can be fine-tuned by the combination of one of more of these elements regulating the expression of transcriptional activators and repressors. Given that microarray studies have indicated that a large number of transcription factors exhibit rhythmic expression, it is possible that the CLOCK:BMAL complex only directly regulates rhythmic expression of genes with E-box-like promoter sequences, and that the rhythmic expression of all other clock controlled genes is dependent on the rhythmic expression of transcription factors, such as *Dbp*, downstream of CLOCK:BMAL transcriptional activity (Panda et al., 2002a; Hayes et al., 2005).

5.5 Transcriptional and Functional Regulation of Clock Genes II: Posttranslational Regulation

The presence and activity of core clock genes are regulated at the protein level by several mechanisms, including the timing of translation, spatial localization, phosphorylation, and degradation. Although transcriptional regulation allows for gross control of the availability of clock genes, transcript processing also appears to be regulated. For example, peak *Per* gene expression occurs around CT6 in the SCN, and PER and CRY protein levels peak at approximately CT12 (Kume et al., 1999; Field et al., 2000; Shearman et al., 2000b; Maywood et al., 2003). Thus, the negative loop component protein levels are phase-delayed with respect to mRNA expression by about 3–6 hours. Shearman and colleagues (2000b) suggested that *Bmal1* had a similar translational delay of 4–6 h, which would result in peak BMAL1 protein at the approximate time of *Per* gene induction. However, a later study using mouse liver extracts found very little delay between the peak time of *Bmal1* mRNA and protein expression, suggesting that as-yet-unknown factors may regulate the rate at which core clock genes are translated, affecting the bioavailability of the resulting proteins for dimerization (Lee et al., 2001).

Following translation, clock proteins must dimerize and re-enter the nucleus to regulate transcription of other genes. Nuclear entry is associated with protein phosphorylation, which may regulate both spatial localization and degradation. Lee and colleagues (2001), using mouse liver extracts to characterize the levels and localization of core circadian clock proteins, observed that the molecular weights of several core clock proteins showed a circadian rhythm. From CT15-03, higher molecular weight forms of PER1 and PER2 appeared, peaked, and then gradually diminished. BMAL1 and CLOCK also exhibited fluctuations in molecular weight over the 24-h period. By treating proteins immunoprecipitated from liver extracts with protein phosphatase, the authors determined that the changes in molecular weight were due to phosphorylation of these clock components. Lee and colleagues (2001) also showed that phosphorylation was associated with nuclear accumulation, as the phosphorylated forms of core clock proteins predominated in the nuclear fractions. Little phosphorylated CLOCK or BMAL1 was observed in the cytoplasm, suggesting that phosphorylation either results in, or occurs immediately after, nuclear entry.

Currently, two isoforms of casein kinase 1 (CK1ε and CK1δ) are the only kinases specifically known to play a role in the mammalian circadian clock. The mutation in the *tau* hamster results in an arginine-to-cysteine amino acid substitution in the substrate-binding region of the CK1ε protein, resulting in reduced CK1ε activity and decreased phosphorylation of the PER proteins (Lowrey et al., 2000). A later human genetic study correlated a mutation in *Per2* with familial advanced sleep phase syndrome (FASPS), in which affected individuals awake very early in the morning (Toh et al., 2001). The mutation was mapped to Serine 662, an acceptor site for CK1ε phosphorylation. Thus, the interaction of PER2 and CK1ε appears to be an evolutionarily conserved mechanism required for proper circadian function. In addition, CK1δ, a homolog of CK1ε, is expressed in the SCN and has been shown to associate with and phosphorylate mPER1 and

mPER2 (Vielhaber et al., 2000; Camacho et al., 2001; Ishida et al., 2001). More recently, a missense mutation (T44A) in the gene encoding CK1δ was also shown to result in FASPS in humans (Xu et al., 2005). The region downstream of the CK1ε-binding site in the PER1 protein contains various acceptor residues which, when phosphorylated, can mask the nuclear localization sequence and prevent the protein from entering the nucleus (Vielhaber et al., 2000). Retention of PER proteins in the cytoplasm makes them more susceptible to degradation; therefore, mutations that reduce PER phosphorylation appear to shorten the circadian cycle by increasing the rate of PER dimerization and nuclear accumulation.

Several other core clock proteins, including BMAL1, CRY1, and CRY2, may also be regulated by phosphorylation, possibly by components of the MAPK pathway (Sanada et al., 2002, 2004). Because the MAPK pathway is thought to play a role in communicating photic input to the SCN, it is possible that photic control of circadian rhythms is partially mediated by clock protein phosphorylation. Future studies will undoubtedly add to the list of protein kinases that modify and regulate known clock components.

Phosphatase-mediated removal of phosphate groups also appears to be involved in clock component regulation. Butcher and colleagues showed that the MAPK phosphatases MKP-1 and -2 are expressed in mouse SCN and acutely regulate light-induced MAPK activity; similar results were obtained by Hoyashi and colleagues, who used chick pineal gland as a model (Hayashi et al., 2001; Butcher et al., 2003). In *Drosophila*, protein phosphatase 2A has been implicated in directly regulating dPER by stabilizing the protein in central clock neurons (Sathyanarayanan et al., 2004). The modification and regulation of circadian clock proteins by the addition or removal of phosphate groups is therefore crucial to the timing and plasticity of circadian function.

A third mechanism of control at the protein level involves regulation of the formation of heterodimer complexes by the limitation of component availability. Because *Bmal1* mRNA levels fluctuate over a 24-h period while *Clock* mRNA levels remain constant, it had been proposed that BMAL1 is the rate-limiting factor in the positive arm of the molecular clock feedback loop (Shearman et al., 2000b). However, overexpression of a *Clock*-containing bacterial artificial chromosome (BAC) in transgenic mice resulted in a shortened free-running period, suggesting that under normal conditions, CLOCK is either not in excess of BMAL1 or not completely functionally available (Antoch et al., 1997). It has also been shown that CLOCK nuclear localization is dependent on BMAL1, as no CLOCK immunoreactivity is detected in nuclear fractions from *Bmal1*-deficient mouse liver tissue (Kondratov et al., 2003). If these results are representative of all tissues, the *Bmal1* knockout mouse model may also be considered functionally deficient in CLOCK, due to the lack of CLOCK nuclear translocation. Regarding the negative limb components, CRY proteins have been shown to be in molar excess of PER proteins and are present in the cytoplasm throughout the day in liver extracts, leading Lee and colleagues to suggest that that PER proteins are the limiting factors in the negative limb of the feedback loop (Lee et al., 2001). In support of this, although CRY is present in the cytoplasm of *Per* double knockouts, very little CRY protein can be detected in nuclear extracts from livers of *Per1/2* double knockouts (Lee et al., 2001).

A final mechanism of protein regulation is degradation or turnover. Based on *in vitro* studies, it is clear that phosphorylation of circadian clock proteins precedes and most likely triggers the degradation process. The exact mechanism for this is still unknown, but two recent studies provide evidence that the 26S ubiquitin-mediated proteosome pathway is involved in the regulation of clock gene activity (Yagita et al., 2002; Kondratov et al., 2003). The 26S pathway of degradation begins with the addition of multiple ubiquitin polypeptide units onto lysine residues of the substrate protein by a family of proteins known as ubiquitin ligases (E1, E2, and E3). Once polyubiquitylated, the protein is targeted to the 26S-proteasome, where it is proteolytically cleaved and degraded. Yagita and colleagues found that mouse embryonic fibroblast (MEF) cells from *Cry1/2* knockout mice had very little PER2 in the nucleus, but when the cells were treated with a specific inhibitor of 26S proteosome-mediated protein degradation (MG132), a dramatic increase in nuclear and cytoplasmic PER2 was observed (Yagita et al., 2002). Additionally, coexpression of *Cry1* prevented ubiquitylation of PER2 in COS7 cells in a dose-dependent manner, and the presence of PER2 reduced ubiquitylation of CRY1. CLOCK and BMAL1 levels may also be regulated by ubiquitylation: Antoch's group has shown that phosphorylation of BMAL1 is dependent on CLOCK: BMAL1 dimerization, and that this dimerization triggers rapid degradation of the CLOCK protein (Kondratov et al., 2003). Furthermore, inhibition of the 26S pathway in HEK 293 cells results in CLOCK

nuclear accumulation, indicating that CLOCK is normally degraded via a proteosome-dependent mechanism after it has heterodimerized with BMAL1 and translocated to the nucleus. Interestingly, multiple members of the ubiquitin-mediated degradation pathway (ubiquitin-conjugating enzymes, ubiquitin-like proteins, and proteosome subunits) exhibit circadian regulation of mRNA expression, suggesting that the degradation of circadian clock proteins (as well as other proteins) may also be circadianly regulated (Panda et al., 2002a).

Increasing efforts in the circadian field are being directed at understanding how fluctuating protein levels, protein modification, and core clock component localization regulate cellular pathways and subsequent tissue physiology. In addition to regulating the transcription of genes involved in cellular output pathways, the core clock proteins may directly interact with ion channel proteins or other proteins involved in regulating neuronal activity. By elucidating the spatial and temporal regulation of protein function, we will increase our understanding of the control over circadian physiology and behavior of an organism.

6 Neuronal and Humoral Output from the SCN

The fundamental function of the SCN is to transmit time-of-day information to the rest of the body. For this to occur, the molecular pacemaker within each SCN neuron must be translated into an output signal—such as a change in neuronal excitability or neurotransmitter production—that can be communicated to other brain regions that directly or indirectly regulate activity at the systems level. Molecularly, this requires a change in the expression, localization, or stability of proteins involved in neuronal communication. Recent gene expression studies have identified a number of candidates that are rhythmically expressed and are known to be involved in pathways associated with neural output. These genes include neurotransmitter receptors, such as the vasopressin receptor (*Avpr1a*), which regulates neuron response to incoming signals, ion channel proteins, such as the large conductance Ca-channel potassium channel (*mSlo*), which affects neuronal excitability, and neuropeptides and secretory factors, such as secretogranin III (S*cg3*) and vasopressin (*Avp*), which affect the communication of neurons with one another (Panda et al., 2002a). These changes occur at the single-cell level, but through coupling of individual SCN neurons, produce time-of-day dependent changes in the properties of the SCN as a whole. The SCN effects changes in the periphery via neuronal and humoral outputs to other regions of the brain, such as the hypothalamus and the pineal gland, that then regulate physiological and behavioral processes.

6.1 Hypothalamic Projections

The most abundant group of SCN efferents are the projections to other nuclei in the hypothalamus. Kalsbeek and Buijs have grouped SCN targets in the hypothalamus into three categories: endocrine neurons such as GnRH neurons, which directly control pituitary function; interneurons, which likely act as integrators of circadian and noncircadian information and regulate endocrine neuron function; and autonomic neurons, which regulate the function of the peripheral nervous system (Kalsbeek and Buijs, 2002). SCN communication has been shown to occur through both direct neuronal connections and humoral mechanisms: when a transplanted SCN is placed inside a membrane that allows for the release of diffusible factors but prevents the establishment of synaptic connections, certain rhythms, such as locomotor activity, are restored, but many endocrine rhythms are not (Lehman et al., 1987; Silver et al., 1996a; Meyer-Bernstein et al., 1999).

As described earlier, SCN efferents generally express AVP or VIP, and arise primarily from the ventrolateral shell. These neuropeptides are thought to be the primary messengers of the timing signal, and changes in AVP and VIP signaling have been shown to be important in the regulation of endocrine function (Kalsbeek and Buijs, 2002). However, circadian wheel-running behavior appears to be regulated differently from endocrine function, and two other molecules, TGF-α and prokineticin-2 (PK2), have been identified as involved in controlling circadian locomotor activity (Kramer et al., 2001; Cheng et al., 2002).

The following section addresses the molecular mechanisms of circadian regulation of three specific processes: the hypothalamic-pituitary-gonadal axis (HPG) in the female, the hypothalamic-pituitary-adrenal (HPA) axis, and locomotor activity.

6.2 The Hypothalamic-Pituitary-Gonadal (HPG) Axis

Although reproduction in the male is generally not under circadian control—except for seasonally regulated breeders such as hamsters—the female reproductive axis is under SCN control in all mammals, and the components of the axis are well understood. The gatekeepers of reproductive physiology are gonadotropin-releasing hormone (GnRH) neurons, which are diffusely distributed throughout the mPOA of the anterior hypothalamus (Wray and Hoffman, 1986). GnRH neurons act as integrating stations, receiving input from the SCN (signaling time of day), from the ovaries (signaling follicular readiness via estradiol and progesterone production), and from fat pads (signaling nutrient availability) (Evans et al., 1994; Hamann and Matthaei, 1996; Magni et al., 1999). On the afternoon of proestrus, which occurs every 4–5 days in mice and rats, incoming signals coordinate GnRH neuronal activity, inducing a bolus of GnRH release into the portal hypophysial circulatory system. GnRH stimulates the pituitary to release the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which induce ovulation and follicular recruitment. The ovaries produce the hormones estradiol and progesterone, which feed back to regulate GnRH release via steroid receptors on interneurons and on GnRH neurons themselves (Peterson et al., 2003).

The role of the SCN in controlling GnRH neuron activity was first suggested by SCN ablation studies that resulted in vaginal acyclicity and cessation of reproductive function and later confirmed by tract-tracing studies showing direct projections of SCN neurons to GnRH neurons (Brown-Grant and Raisman, 1977; Van der Beek et al., 1997; Wiegand et al., 1980). The GnRH surge occurs only on the afternoon of proestrus, around the light–dark transition, and if release is inhibited by phenobarbital administration on the morning of proestrus, it will occur exactly 24 h later (Everett and Sawyer, 1950). It has been suggested that the SCN transmits a daily signal to GnRH neurons that permits GnRH release when other factors, such as estradiol and progesterone levels, are also permissive (Levine et al., 1991, 1995).

The neuropeptides AVP and VIP have both been implicated in the circadian control of LH release (Kalsbeek and Buijs, 2002). Electron microscopy and immunohistochemical studies have shown that VIP-containing SCN projections directly contact GnRH neurons; the population of GnRH neurons receiving VIP input is the same population that is preferentially activated (*c-fos* expressing) on the afternoon of proestrus (Van der Beek et al., 1994; Smith et al., 2000). In middle-aged female rats, VIP-mediated transmission is lower, possibly contributing to the altered LH surge profile characteristic of early reproductive senescence (Krajnak et al., 2001). AVP expression is circadianly controlled, elevated in the hypothalamus immediately before GnRH release, and capable of inducing an LH surge in SCN-lesioned rats (Gillette and Reppert, 1987; Jin et al., 1999; Palm et al., 1999). Furthermore, estrous cyclicity is abnormal in the Brattleboro rat, a strain that does not synthesize AVP (Boer et al., 1981). The *vasopressin* promoter contains an E-box element with a CLOCK-binding sequence (CACGTG), and *vasopressin* is transcribed in the same phase as other CLOCK-controlled genes such as *Per1* and *Per2*. In male *Clock* mutant mice, circadian transcription of *vasopressin* in the SCN is damped, as is transcription of the *Per1* and *Per2* genes (Jin et al., 1999). Because AVP secretion is stimulatory to GnRH release, we have recently hypothesized that reduced SCN-derived AVP output from the SCN may account for the lack of a coordinated proestrus LH surge in *Clock* mutant mice (Miller et al., 2004).

Certain aspects of pregnancy are also under circadian control. Following ovulation, the corpus luteum (CL) of the ovulated oocyte begins producing progesterone. The CL will quickly recede unless mating occurs. The mating stimulus triggers twice-daily circadian-regulated prolactin release that maintains the CL for approximately 10 days following copulation (Barkley et al., 1978). Maintenance of the progesterone-producing CL is an absolute requirement of pregnancy: if prolactin secretion is interrupted during pregnancy, progesterone levels drop and the developing fetuses are reabsorbed (Smith, 1980). Several studies have linked the control of postcopulatory prolactin release to vasopressinergic transmission from

the SCN, presumably via contacts to dopaminergic neurons that regulate prolactin release from the pituitary, and we have recently described mid-gestational pregnancy failure in *Clock/Clock* females that is likely due to abnormal prolactin release during early- and mid-pregnancy (Palm et al., 2001; Miller et al., 2004). Finally, parturition is temporally restricted to the nighttime/early morning in rodents, although the interplay of maternal and fetal circadian rhythms that control the timing of birth is poorly understood (Rowland et al., 1991; Muglia, 2000).

6.3 The Hypothalamic-Pituitary-Adrenal (HPA) Axis

The adrenal cortex regulates organismal response to stress by releasing steroid hormones and catecholamines, and adrenal gland function is controlled both by the hypothalamic-pituitary axis and by the ANS. Under normal conditions, the hypothalamus is the primary modulator of adrenal function, resulting in basal corticosterone release that is low during the behaviorally inactive period and rises before the onset of activity. Under stressful conditions, the sympathetic nervous system releases norepinephrine, which stimulates the adrenal glands to produce epinephrine.

The role of AVP in SCN regulation of adrenal function can be surmised both by the daily timing of AVP and corticosterone release, and by changes in adrenal function following infusion of a vasopressin receptor antagonist into the dorsomedial hypothalamus (DMH) (Inouye, 1996). As described earlier, AVP is released rhythmically into the hypothalamus and CSF by neurons projecting from the SCN. In rats, AVP release is highest during the early day (ZT2-4), when corticosterone levels are at a nadir, and as AVP release decreases later in the day, corticosterone levels rise (de Boer and Van der Gugten, 1987; Gillette and Reppert, 1987). Tract-tracing and electron microscopy studies have shown that AVP-containing neurons project from the SCN to the paraventricular nucleus (PVN) and the dorsomedial hypothalamus (DMH), the location of the corticotropin-releasing hormone (CRH) neurons that stimulate pituitary release of corticotropin (ACTH) (Kalsbeek and Buijs, 2002). Although there are few direct AVP-CRH synapses, SCN fibers densely innervate interneurons that likely regulate CRH neuron activity (Kalsbeek et al., 1992). Functional studies have shown that, in SCN-lesioned rats, AVP infusion into the PVN results in rapid inhibition of corticosterone levels, likely via actions on GABA-ergic PVN neurons (Kalsbeek et al., 1992; Hermes et al., 2000). The effects of a vasopressin receptor antagonist vary with time of day: in rats, infusion during the morning results in a rapid increase in plasma corticosterone, whereas treatment during the early evening or night has no effect on corticosterone release (Kalsbeek et al., 1996).

It has recently been shown that the SCN can also regulate adrenal activity by way of a multisynaptic autonomic pathway, suggesting that autonomic output from the SCN modulates adrenal responsiveness to ACTH. Retrograde tracing following injection of pseudorabies virus into the liver or spinal cord shows that SCN neurons make third-order synaptic connections with both sympathetic and parasympathetic autonomic neurons (Buijs et al., 1999, 2003). SCN projections to preautonomic neurons in the PVN are separated into parasympathetic and sympathetic branches, but there appears to be no regional separation within the SCN, and SCN projections to both branches are primarily vasopressinergic, raising the question of how a single signal can regulate opposing outputs. Buijs and colleagues (2003) suggest that vasopressinergic outputs to the PVN may have different cotransmitters, such as GABA or glutamate, depending on which branch of the ANS is innervated. If this is the case, the SCN may regulate ANS control of adrenergic function by simultaneously stimulating the parasympathetic nervous system and inhibiting the sympathetic nervous systems.

6.4 Locomotor Activity

Although the measurement of wheel-running activity has been the gold standard for insight into the circadian pacemaker for almost a century, we have only recently begun to understand the molecular mechanisms behind circadian control of locomotor activity. SCN transplant studies involving encapsulated SCN explants indicated that the factor(s)controlling activity had to be diffusible, as transplants could

restore locomotor rhythms without establishing neural connections, but the first advance in molecular knowledge occurred only when a Harvard group conducted a systematic screen to look at the behavioral effects of factors secreted from the SCN (Silver et al., 1996a; Kramer et al., 2001). Kramer and colleagues performed a yeast-secretion trap on a hamster SCN cDNA library to identify previously unknown secreted factors, and these factors were then infused into the third ventricle of freely moving hamsters though wheel-running activity was monitored. Kramer was looking for locomotor inhibitory and excitatory factors that functioned downstream of the molecular pacemaker, specifically affecting wheel running without resetting the underlying circadian clock. This screen identified the candidate peptide transforming growth factor-alpha (TGFα), which, upon application, completely blocked wheel-running activity for the duration of the infusion. When TGFα application was halted, wheel-running activity reappeared with the predicted phase and period, indicating that the cessation of circadian locomotor activity was not due to an effect on the circadian pacemaker (Kramer et al., 2001).

There are several characteristics that make TGFα a prime candidate for transmission of a locomotor control signal. First, TGFα is expressed in the SCN in a rhythmic manner, with peak expression during the inactive phase and trough expression during the active phase, as would be expected of a locomotor inhibitory factor. Second, the TGFα receptor, epidermal growth factor receptor (EGFR), is highly expressed in the subparaventricular zone (SPZ), a target area for SCN projection neurons that is spatially close enough to the SCN to receive diffusible factors, and lesions of which disrupt locomotor activity (Watts et al., 1987; Lu et al., 2001). Finally, mice with the *waved-2* mutation, which decreases the activity of the EGFR by approximately 90%, exhibit excessive daytime activity but have a normal activity period length (Kramer et al., 2001).

More recently, a second candidate molecule has been identified (Cheng et al., 2002). Prokineticin 2 (PK2) is a cysteine-rich protein that is expressed rhythmically in the SCN in a manner similar to TGFα and the *Period* genes, with peak expression during the inactive period and trough expression during the active period. The PK2 promoter contains 4 E-boxes and a CRE, the CLOCK:BMAL1 complex induces PK2 transcription, and expression is negatively regulated by PERIOD and CRYPTOCHROME proteins. The PK2 receptor, a G-protein coupled receptor, is expressed in several regions that receive SCN projections, including the paraventricular thalamic nucleus (PVT), the PVN, and the DMH, although there are no PK2 receptors in the SPZ, the target for TGFα activity. Finally, administration of PK2 into the third ventricle in rats shows that PK2 administration at CT14, during the active period, suppresses wheel-running activity (Cheng et al., 2002). It is interesting to note that both candidate molecules for the control of the SCN over locomotor activity are inhibitory, suggesting that activity is the basal state and the function of the SCN is to restrict activity to an appropriate time period.

Two other molecules, DBP and histidine decarboxylase (HDC), have been shown to affect circadian locomotor activity. Both mice with a targeted deletion of HDC and mice lacking DBP, a PAR leucine transcription factor that is rhythmically expressed in the SCN, display significantly reduced locomotor activity (Lopez-Molina et al., 1997; Abe et al., 2004). However, both mutants also display altered free-running periods, suggesting that these proteins are either involved in regulating the core molecular clock, or are part of a feedback mechanism from behavior to the SCN. Finally, Shimomura and colleagues have exploited the differences in circadian behavior among inbred mouse strains to identify candidate genes involved in circadian phenotype, including activity amplitude. This genome-wide approach involving quantitative trait locus analysis (QTL) of circadian phenotypes in C57BL/6J x BALBc/J F2 hybrids has identified two loci, *Activity-1* and *Activity-2*, linked to changes in circadian activity level, although the associated genes have yet to be cloned (Shimomura et al., 2001).

6.5 Peripheral Oscillators

In additional to regulating physiology and behavior via endocrine and neural output, the SCN also modulates physiology by phase-coordinating oscillators that are present in peripheral cells. Until recently, it was commonly believed that the oscillator in the SCN and the oscillators in peripheral tissues functioned in a master–slave relationship, with the autonomous pacemaker in the SCN driving peripheral oscillators.

In the absence of the SCN, peripheral oscillators would quickly run down. However, new data indicate that this model is incorrect, and that peripheral oscillators are in fact autonomous, continuing to oscillate even without SCN input (Yoo et al., 2004). Therefore, the function of the SCN appears to be to phase-coordinate oscillators in peripheral tissues.

Following the cloning and identification of the core mammalian clock components, it was found that genes such as *Per1* and *Bmal1* were expressed almost ubiquitously throughout the organism, and that expression was rhythmic in almost every tissue, including liver, lung, muscle, and kidney (Balsolobre et al., 1998; Reppert and Weaver, 2001). Balsolobre and colleagues (1998) showed that a serum shock could induce rhythmic transcription of *Per1* and *Per2* in cultured Rat-1 fibroblasts, and that such oscillations could be sustained for approximately 3 days with a stable period of 22.5 h. Later, Yagita and colleagues (2001) found that serum shock of NIH3T3 fibroblasts induced robust rhythmic expression of *Bmal1*, the *Period* genes, and *Cry1*, with the *Bmal1* and *Per* expression levels antiphase to each other and *Cry1* peak expression delayed relative to peak *Per1* expression by 4–8 h, as is observed in SCN neurons. The period of clock gene expression in peripheral tissues is regulated by genotype: MEFs from *Cry1* knockout mice, which have a shortened free-running period of locomotor activity, show short periodicity of *Dbp* expression, whereas MEFs from *Cry2* knockout mice, which have a lengthened activity period, have a lengthened periodicity of *Dbp* expression. MEFs cultured from *Cry1/Cry2* double knockout mice, which are arrhythmic under constant conditions, showed constitutively high, nonrhythmic *Dbp* expression (Yagita et al., 2001).

The SCN primarily regulates peripheral oscillators via endocrine output. Balsolobre and colleagues (2000) showed that the glucocorticoid hormone analog dexamethasone could induce rhythmic *Period*, *Cry*, and *Dbp* expression in Rat-1 fibroblasts. Furthermore, mice injected with dexamethasone showed transient *Per1* induction in the liver in a CT-dependent manner: injections at ZT14 and ZT21, after normal peak *Per1* expression, resulted in phase delays of *Per1* and *Dbp* expression, whereas injections at ZT1, before the normal *Per1* peak, phase-advanced *Per1* and *Dbp* expression (Balsolobre et al., 2000). Importantly, the effects of dexamethasone on clock gene expression in the liver occurred in the absence of any effects on *Per1* expression in the SCN, indicating that glucocorticoids function downstream of the SCN to regulate peripheral clocks.

Although the SCN is the primary phase-coordinator of peripheral rhythms, recent studies have shown that peripheral oscillators can be uncoupled from the SCN by the application of stimuli, such as restricted feeding, that bypass the SCN (Damiola et al., 2000; Stokkan et al., 2001). Damiola and colleagues (2000) maintained mice on a normal LD12:12 cycle, but restricted food availability either to the dark or to the light phase. *Period*, *Cry1*, and *Rev-Erbα* gene expression in livers from mice fed at night showed a normal rhythm and phase angle of expression, with peak peripheral clock gene expression phase delayed by ~8 h relative to peak gene expression in the SCN. However, clock gene expression in livers from mice restricted to day-time feeding was 8–12 h out of phase with that of from night-time fed mice, although there was no effect of day-time feeding on the phase of rhythmic gene expression in the SCN (Damiola et al., 2000). Restricted feeding appears to phase shift peripheral tissues via global circulating signals, as tissues not directly involved in food response, including heart and lung, also show phase shifts in clock gene expression following restricted feeding. However, the nature of the entraining signal is unknown: although glucocorticoids can phase shift peripheral rhythms, Stokkan and colleagues (2001) have suggested that, although the pattern of corticosterone secretion changes during restricted feeding, the new peak of corticosterone occurs at a time when peripheral tissues are refractory to the phase-shifting effects of glucocorticoids.

The ability of peripheral clocks to be uncoupled from SCN regulation reflects the physiological role of peripheral oscillators. The SCN restricts certain behaviors, such as locomotor activity and reproductive receptivity, to the night, when nocturnal rodents can best avoid prey and are most likely to have conspecific interactions. However, peripheral clocks in organs such as the liver and pancreas, both involved in feeding, must be able to respond whenever food is available. Peripheral circadian gene expression plays a crucial role in many biochemical pathways, as microarray experiments have shown that up to 10% of the genes expressed in all organs studied shows rhythmic transcription profiles (Akhtar et al., 2002; Panda et al., 2002a; Storch et al., 2002). In keeping with the different functions that individual organs perform, comparisons of rhythmic gene expression between the SCN, heart, and liver show that the majority of genes that are rhythmic in one tissue are not rhythmic—and sometimes not even expressed—in the other

tissues. Out of approximately 650 cycling transcripts in mouse SCN and liver, Panda and colleagues found that only 28 genes were rhythmic in both tissues, including genes like *Per2* that were already known to be involved in the clock mechanism (Panda et al., 2002a). Although the function of some of the 28 genes is unknown, it is likely that all are involved either in the regulation of the core molecular clock or in the basic circadian cellular outputs.

Observation of peripheral molecular clocks at the level of the individual cell has shown that rhythms can persist for weeks or months in the absence of the SCN, although individual cells may drift out of phase with each other. Yoo and colleagues (2004) developed a reporter mouse that carries the luciferase gene fused to the 3′ end of the *Per2* gene, so that luciferase is under the same transcriptional and posttranscriptional regulation as *Per2*. Unlike earlier work that involved transgenes using the *Per1* promoter fused to the *luciferase* gene, all of which had shown that rhythms in explanted peripheral tissues damped after several days, Yoo found that all explanted tissues, including pituitary, lung, lung, kidney, and tail, showed robust rhythms that persisted for up to 20 days. Furthermore, peripheral tissues removed from behaviorally arrhythmic SCN-lesioned animals showed rhythmic oscillations, although there were significant differences in tissue phase within and among animals (Yoo et al., 2004). Thus, the Yoo study suggests that it is time to revise our understanding of the role the SCN plays: rather than driving peripheral rhythms, SCN output is responsible for phase-coordinating the oscillators within peripheral cells and tissue.

7 Conclusion

The tissue-specific regulation of circadian gene expression indicates that many specialized processes are under circadian control; presence of cell-autonomous oscillators in almost every cell type studied and the extent of circadian regulation of the SCN and peripheral transcriptomes suggest that the ability to time-regulate physiological functions is extremely beneficial evolutionarily. Under normal circumstances, the SCN is entrained by a predictable LD cycle, and subsequently phase-coordinates peripheral oscillators to organize behavior and physiology appropriately. In nocturnal rodents, physiological processes such as metabolism and ovulation are restricted to the dark period, when feeding and mating are most likely to occur, and behaviors such as locomotor activity—important in food gathering—and estrus behaviors, crucial for mating, are also restricted to the night, when the risk of predation is lower. However, in situations when nonphotic zeitgebers are out of phase with photic cues, peripheral tissues are able to respond by functioning independently of the SCN.

Although humans have escaped from the confines of the LD cycle imposed by the earth's rotation, we are still subject to the regulation of physiology by the SCN. This regulation is normally only obvious to us as the sleep–wake cycle, but also becomes apparent following circadian disruptions such as shift-work and long-distance travel, which have been linked to gastric disruptions, disrupted reproductive function, mood disorders, and even a heightened risk of cancer (Hastings et al., 2003). However, based on the genome-wide circadian regulation of gene expression observed in mice, it is likely that circadian rhythms in humans have a multitude of more subtle effects that may turn out to be important. A new field, chronotherapeutics, recognizes that there are CT-dependent changes in both disease processes and the ability to metabolize therapeutic drugs; if this field is successful, we may be able to make circadian gene regulation work in our favor even while defying the natural LD cycle.

1 Introduction

From ancient times, humans have appreciated the role of specific organs in regulating behavior and physiological function, particularly the reproductive organs. The practice of castration of animals and men has been used to control behavior and fertility since earliest written records exist. In this chapter, we briefly review some history of how we came to appreciate the influence of hormones on behavior, the control of many of those hormonal systems by the brain, and how the exquisite timing of many behavioral events involves an interaction between the circadian mechanism (described in Chapter 22) and the neural control of hormones.

1.1 Historical Background on Neuroendocrine Relationship to Behavior

The earliest record of manipulation of behavior by manipulating hormones is described in ancient texts such as the Bible and writings of Aristotle (384–322 BCE). Aristotle compared the effects of castration of birds and of mammals (including humans). He noted that removal of the testes resulted in reduction of male typical traits such as the crowing of the rooster, the deep voice of the human male, the aggressive behavior of male ungulates during the breeding season, and the sexual interest in most males. Understanding the role of the testis in production of male specific traits led humans to consume testes, or eventually inject testicular extracts, in an attempt to regain and maintain masculine traits. Similar treatments were used on animals. These attempts to make use of the masculinizing, androgenic substances from the testis to improve strength, sexual prowess and fertility are little different from the use of androgenic compounds today.

The first successful experimental manipulation of an endocrine gland that resulted in behavioral changes was reported in 1849 by A.A. Berthold. He systematically gonadectomized roosters and noted the loss of crowing behavior, loss of size and color of the comb and wattle, and loss of male-male aggression and sexual interest. When he put a single testis back into the caponized rooster and restored these traits to normal, he concluded that the testis must secrete a substance into the blood that maintains male behavior and secondary sex characteristics.

Around the same time, other scientists began to demonstrate that a number of physiological problems were related to atrophy of various glands and recovery could occur by replacement with extracts from the glands. For example, Thomas Addison (1855) described a human condition (now called Addison's disease) associated with deterioration of the adrenal cortex, and Murray (1891) prepared emulsions of sheep thyroid glands that helped patients suffering from hypothyroidism (Turner and Bhagnara, 1971).

The birth of the field of Endocrinology occurred around 1902–1905 (Bayliss and Starling, 1902) with studies demonstrating the secretion of pancreatic juices into the gut without assistance of the nervous system. Over the next 30 years, researchers discovered most of the glands that produce the key hormones that are recognized today as modulating growth, metabolism, energy storage and release, and reproduction in both sexes. The field boomed from the 1940s as new hormones were isolated and their biochemical and physiological properties were described. During this same period of time, the role of the hypothalamus in controlling the release of hormones was coming to be appreciated. Harris (1937) demonstrated that electrical stimulation of the hypothalamus could induce ovulation in the rabbit. From the 1930s to early 1950s researchers tried to determine the relationship between the brain and pituitary in controlling testes and ovaries. By 1932, Moore and Price proposed a model of pituitary control of the gonads with gonadal steroids negatively regulating pituitary secretions to maintain a balance in the male and cyclicity in the female. They conveniently ignored the evidence of neural mediation of gonadal function from copulation-induced ovulation and the effects of other external factors, such as season of the year, on gonadal function. Their model was soon called into question by studies that moved the pituitaries to other locations in the body, demonstrated that they were still healthy, but no longer stimulated gonadal function (Hohlweg and Junkmann, 1932). G. W. Harris continued this line of research, theorizing that hypothalamic neurons must produce secretions that entered the hypophyseal portal vasculature to regulate the release of pituitary

hormones. Eventually, he and his colleagues demonstrated the existence of what we now know as gonadotropin-releasing hormone (GnRH) and its control over pituitary LH and FSH release, which in turn controlled ovarian function. In a 1955 monograph, Harris summarized the results of more than 20 years of research demonstrating that the hypothalamus, pituitary, and gonads each produced their own secretions which influenced the activity of the tissues above them, such that pituitary hormones had a negative effect on GnRH release from the hypothalamus, and ovarian or testicular hormones had a negative effect on production of GnRH, LH and FSH.

The marvelous experiments of Harris quickly led other researchers to demonstrate similar relationships. Schally (1968) demonstrated with in vitro systems the release of corticotrophin releasing hormone (CRH) that controlled pituitary adrenal corticotrophic hormone (ACTH) release, and ultimately glucocorticoid (cortisol or corticosterone, CORT) release from the adrenal. While Harris was widely recognized for his contribution in proving the existence of the hypothalamic control over pituitary hormone release, it was ultimately Andrew Schally who received the Nobel Prize in 1977 for Physiology and Medicine for his work on these principles; Harris simply did not live long enough (died in Nov, 1971). In his acceptance speech and later writings, Schally frequently cited the path-breaking work of Harris, and many felt that Harris would also have received the prize had he lived.

The final leap forward in our understanding of the role of hormones and their neural controls opened in 1959 with the publication by Phoenix et al. (1959) demonstrating that gonadal steroids during embryonic life not only organized the secondary genital tissues, but also organized the central nervous system. They found that female guinea pigs exposed to androgens during a specific period of maximal sensitivity lost the ability to express estrous behavior. Research during the 1960s with altricial, muroid rodents (rat, mouse, hamster) demonstrated that similar organizing effects could occur postnatally as well as prenatally. By the early 1970s, researchers (Beach, 1971; Goy and Goldfoot, 1973) were introducing and clarifying the concepts of organizational and activational effects of steroid hormones, as well as critical (or sensitive) periods for masculinization and defeminization of behavior, and showing that those principles generalized to a wide variety of species. Books began to appear in the early 1980s that summarized the rapidly advancing field of Neuroendocrinology and its relationship to behavior (Goy and McEwen, 1980; Pfaff, 1980; Adler, 1981; Adler, et al., 1985). This relationship is now well established and represented in the second edition of two popular text books by Becker et al. (2002) and Nelson (2000).

The recognition that biological rhythms influence the neurohormonal control of behavior and physiology is, at once, quite old and relatively new. As mentioned earlier, from most ancient times humans have recognized the seasonal changes in behavior and reproductive activity of the animals and plants around them. The manipulations of testes and androgens, described earlier, made it clear that seasonal control of reproduction came about by altering the secretions from the gonads. However, it is only in the last 50 years, and primarily since the early 1970s when radioimmunoassays were developed that allowed the measurement of blood concentrations of hormones, that the circadian nature of these secretions and their influence on behavior has been clear (Moore-Ede et al., 1982).

1.2 Goal of this Chapter

The goal of this chapter is to describe the relationship between the circadian mechanism and neuroendocrine axes. Hormones such as insulin, glucagon, and gastrin are important for physiologic functions that affect behavior; their secretion is not primarily controlled by the central nervous system. This chapter focuses on a few hormones whose release is directly controlled by the brain and which have large effects on behavior. We will examine how the circadian rhythms generated by the suprachiasmatic nucleus (SCN) are transmitted to endocrine tissues so as to organize the temporal patterns of release of several hormones. We begin with melatonin, released by the pineal gland, which is under direct neural control of the SCN. We then examine the role the SCN plays in regulating release of hypothalamic factors that control the pituitary, and ultimately gonadal and adrenal tissues. This is not meant to be an exhaustive review of all neuroendocrine mechanisms that are influenced by the SCN. Instead, we look at exemplars of direct and indirect control of circadian hormone secretion and its impact on behavior.

2 Circadian Rhythms and Neuroendocrine Control

2.1 Overview of Circadian Control of Hormone Release

Dorothy T. Krieger edited the first book that seriously examined the range of circadian rhythms exhibited by the endocrine system (1979). This came after a period of rapid development of radioimmunoassays (RIAs) used by researchers such as Weitzman and co-workers (1966, 1971, 1974, 1976; Hellman et al., 1970) to quantify the episodic release of hormones, such as cortisol. In Krieger's book, a chapter by one of the founders of the field of chronobiology, Jurgen Aschoff (1979), describes the daily pattern of release of cortisol, growth hormone, aldosterone, prolactin, testosterone, thyrotropin, LH and FSH in humans. The examples are illustrative of one of the key features of the circadian system: while it regulates many physiological and behavioral processes very precisely, the rhythms have a great variety of relationships to one another and the LD cycle. For example, in the diurnal human, cortisol, aldosterone, prolactin, and testosterone peak late at night or at dawn. In contrast, growth hormone, thyrotropin, melatonin and LH are elevated during the dark, with the first three peaking near the onset of sleep. Only melatonin has the same phase relationship to the LD cycle in essentially all vertebrates, rising during the night and falling during the day. The remaining hormone patterns vary between species, often as a function of whether they are diurnal or nocturnal.

To determine whether any daily rhythm is circadian, that is, endogenously produced with an approximately 24 h period, the animal must be housed in conditions without information about time of day (i.e., constant conditions such as constant darkness, DD, or constant light, LL). If the daily rhythm persists, then it can be described as truly circadian. Some daily hormone rhythms are not directly coupled to the SCN, but are rather driven by other systems; for example, growth hormone is only released during slow wave sleep. If sleep is prevented, the daily rhythm of growth hormone disappears. However, many of the hormones with a major influence on behavior are circadian.

Once a rhythm is determined to be circadian, the next obvious question to answer is what environmental cues are synchronizing, or entraining, the circadian rhythm to a 24 h period. Not surprisingly, given that the endogenous period is close to 24 h, the same as that of the earth's rotation, the 24 h light: dark (LD) cycle provides the most potent source of entraining signal ("zeitgeber" from the German for "time giver"). Other non-photic signals, such as regular food intake, social interactions, and exercise can also produce entraining effects on circadian rhythms, but light is by far the dominant signal. Chapter 21 describes, in great depth, how circadian rhythms are generated and how they are controlled by light. For our purposes, it is important to note that some tissues outside the SCN also have endogenous circadian rhythms. In mammals, these oscillating tissues (including the adrenal cortex, for example) are considered to be slave oscillators since, under stable environmental conditions, the SCN indirectly controls their daily activity. In mammals, the SCN receives direct retinal input through the retinohypothalamic tract that maintains entrainment of the endogenously rhythmic cells with the LD cycle. Interestingly, in nonmammalian species, even among non-mammalian vertebrates, it is common for more than one tissue to have its own photoreceptors that can entrain the circadian activity of that tissue independently of all other tissues. One such well-described tissue is the pineal gland, which produces the daily rhythm of melatonin. However, in mammals, the pineal, as well as all other endocrine systems with circadian release patterns, is under direct or indirect control of the SCN.

The importance of the SCN for maintaining internal synchronization of endocrine and other physiological processes is best understood when we examine the consequences of internal desynchronization in humans who make transmeridian trips (jetlag; rapid shift in the phase relationship to the LD cycle) or have jobs with rotating shift schedules (Klein et al., 1972; Tapp and Natelson, 1989). Jet lag can cause myriad physical, emotional, and psychiatric problems in humans (Winget et al., 1984; Cho et al., 2000; Cho, 2001; Katz et al., 2001). Some of the symptoms of jetlag, such as ulcers, depression, and emotional distress, are also commonly associated with stress and an increase in cortisol secretion. In women, the timing of reproductive events, including the preovulatory LH surge, is linked to the LD cycle (Kapen et al., 1973; Ewards, 1981; Seibel et al., 1982; Testart et al., 1982; Hoff et al., 1983). Frequent disruptions of circadian

rhythms in women are correlated with disruptions in reproductive function. Female shift workers have a higher risk of having low birth weight babies, spontaneous abortion, and subfecundity, and can experience irregular menstrual cycles accompanied by changes in secretion patterns of ovarian and pituitary hormones (Scott, 2000; Knutson, 2003; Lohstron et al., 2003). Female flight attendants have similar negative reproductive outcomes. Additionally, sleep disturbance, a common side effect of disrupted circadian rhythms, in late pregnancy is associated with increased labor duration and increased likelihood of medical intervention (cesarean section) (Lee and Gay, 2004). The problems with labor are most likely due to a disruption in the nightly rise in oxytocin release that prepares the uterus for labor in the last weeks of pregnancy (Hirst et al., 1993).

As mentioned earlier, the circadian control of hormone release can occur in one of several ways. In the following sections, we discuss the direct neural pathway between the SCN and the pineal gland of mammals that controls the nightly release of melatonin. Other circadian hormone release patterns are modulated more indirectly. The circadian control of ovulation and estrous behavior in female rodents, and perhaps some other female mammals, occurs because time of day information from the SCN is integrated with other important information about the internal state of the female (e.g., energy balance, age, recent pregnancy or parturition) and the state of the environment (e.g., season of the year, presence of appropriate mate) at the GnRH cells in the hypothalamus. In some cases, part of the integration includes endogenous circadian oscillations within a part of the complex axis, as occurs with the adrenal cortex and perhaps GnRH cells.

2.2 Neural Control of Melatonin Release

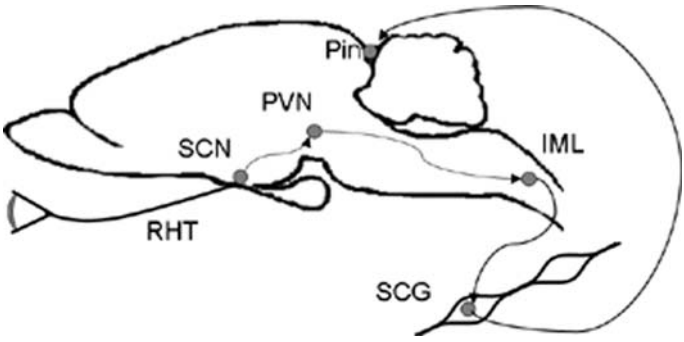
One of the most pervasive sets of behavioral changes are those associated with preparation for the winter in temperate zone species. Among vertebrates, these changes include migration, hibernation, molting of outer coverings, changes in color, cessation of reproduction, decreases in aggression, and alterations in aggregation patterns. Increasing or decreasing the amount of light each day (photoperiod) can induce estrus in the non-breeding season (ferrets—Bissonette, 1932; field voles—Baker and Ranson, 1932; sheep—Yeates, 1949), as well as a host of other changes. Rusak and Morin (1976) demonstrated that SCN lesions prevent short day lengths from causing regression of the testis. Rusak and Morin concluded that the SCN controlled seasonal changes by altering the circadian release of melatonin because of two earlier findings: (1) Axelrod (1974) had demonstrated that nerves from the superior cervical ganglion (SCG) synapse near blood vessels around the pineal gland, and (2) Moore and Klein (1974) found that the circadian rhythm of the enzyme necessary for production of melatonin (pineal N-acetyltransferase) was abolished by lesions of the SCN.

Subsequently, Turek and Campbell (1979) demonstrated that administration of melatonin to a hamster when it was housed in long day lengths could, like a shortening of the photoperiod, cause testicular regression. In the early 1980s, anatomical work by Klein et al. (1983) and endocrine work by Goldman et al. (1981) demonstrated that the SCN sends efferents to the paraventricular nucleus (PVN), which projects to the SCG, which synapses on blood vessels near the pineal gland, and that manipulation of day length directly affects melatonin release. Interruption of this circuitous pathway at any location blocks the daily rhythm of melatonin release. Goldman et al. (1984, 1991; Elliott et al., 1989) demonstrated that the duration of the melatonin signal, whether exogenously produced during the day or naturally produced during the night, determines whether the animal interprets the photoperiod as being long or short. Virtually all seasonal changes in behavior and physiology have subsequently been connected to the circadian pattern of melatonin release. Even circannual rhythms are synchronized to a 12 month period by seasonal changes in the circadian pattern of melatonin (Woodfill et al., 1994; Hiebert et al., 2000).

Further evidence of the circadian nature of melatonin release is the persistence of the rhythm in animals living in DD (Illnerova and Vanecek, 1983; Sun et al., 2002, 2003). Because of the minimal number of synapses between the SCN and the pineal gland, the melatonin rhythm has frequently been used as a marker of SCN function. Earlier it was thought that shifts in the LD cycle "instantaneously" altered the function of SCN (Moore-Ede et al., 1981), however melatonin rhythms very clearly do not recover within the

Figure 23-1

Pathway by which the SCN controls the production and secretion of pineal melatonin. Axons from the eye, via the retinohypothalamic tract (RHT), synapse on ventral–lateral cells of the suprachiasmatic nucleus (SCN). The SCN projects to the paraventricular nucleus of the hypothalamus (PVN), which in turn projects to the intermediolateral column (IML) of the spinal cord. The IML projects to neurons in the superior cervical ganglion (SCG) of the sympathetic nervous system, which ultimately project to the pineal gland where it regulates the synthesis of melatonin



1–2 days expected based on the SCN models (Illnerova and Vanecek, 1983; Humlova and Illnerova, 1992). Recent reports analyzing the response of melatonin rhythms (Liu and Borjigin, 2005) and *per* gene transcription in the SCN (Nagano et al., 2003) to phase shifts of the LD cycle reinforce how tightly melatonin is driven by the SCN, and that both take a number of days to recover from a shift.

Because melatonin is thought to be a completely passive system, driven only by the neural signals from the SCN, one would expect to find that the SCN and melatonin require approximately the same amount of time to recover from a shift. Liu and Borjigin (2005) used in vivo microdialysis with a 10 min sampling schedule to detect changes in pineal melatonin release after phase delays of 3, 6, or 12 h. Their data demonstrate that recovery of melatonin entrainment, like the SCN (Nagano et al., 2003) takes several days to achieve. The process occurred in three steps. First, there was a rapid shift of the melatonin onset at lights-out within 1–2 cycles, much as the ventral–lateral SCN shifted (Nagano et al., 2003). Secondly, the fall in melatonin at the end of the dark phase shifted rapidly for 3–4 days, overshooting the correct phase so that melatonin was still elevated during the early lights-on phase. And lastly, a period of several days passed (increasing with increasing size of the shift), when, both, the rising and the falling phases of the melatonin rhythm make small adjustments to reach a steady state. The initial large shift that brought the melatonin rhythm close to entrainment after 1–3 days correlates with the initial rapid shift of the ventral–lateral SCN, while the slow final resolution of the entrained phase correlates with the slower dorsal–medial SCN recovery time (Nagano et al., 2003). It is interesting that in each case, the melatonin rhythm lags behind that of the SCN by 1–2 cycles. The *rPer1* rhythm from the shifting dorsal–medial SCN does not appear to overshoot the entrained phase, as the melatonin rhythm does. Since the in situ study of the SCN did not collect data from animals for every day during the recovery period after the shift, and the intervals of collection were 2 h, it remains possible that the dorsal–medial SCN also phase shifts too far initially, and then returns to the correct phase. The precision of the melatonin rhythm most likely provides a more fine-tuned analysis of the time it takes for the SCN to recover completely from a shift in the LD cycle than does the *rPer1*data (Nagano et al., 2003; Liu and Borjigin, 2005).

2.3 Effects of Melatonin on the SCN

The interaction between the SCN and the pineal is not as unidirectional as the data mentioned earlier would suggest. Although early studies demonstrated that pinealectomy did not alter entrained or free-running

rhythms (Quay, 1968), later work demonstrated that pinealectomy of rats and hamsters enhanced the rate of recovery from a shift in the LD cycle (Quay, 1970; Finkelstein et al., 1978). Furthermore, pinealectomized rats housed in LL quickly produced only ultradian (no circadian) rhythms (Cassone, 1992), and pinealectomy enhanced splitting of activity rhythms in hamsters housed in LL (Aguilar-Roblero and Vega-Gonzalez, 1993). Redman et al. (1983) demonstrated that daily injections of melatonin at the same time of day could entrain circadian rhythms in animals free-running in DD. Cassone et al. (1986) then demonstrated that the effect was apparent with physiological levels of melatonin and that saline injections at the same time of day had no effect on the free-running rhythms of the animals.

The mechanism underlying these effects is still unknown, although melatonin receptors are present in the SCN of some mammals, and the numbers of receptors varies across the day (Gauer et al., 1993; 1994a, b; Weaver et al., 1993). Two species with reduced or undetectable numbers of melatonin receptors in the SCN (adult Syrian hamsters and mink) also do not entrain to injections of melatonin (Hastings et al., 1992; Bonnefond et al., 1993). Thus melatonin receptors in the SCN may be necessary for entrainment feedback effects.

To summarize, the SCN controls the circadian pattern of melatonin secretion in mammals by a four synapse pathway. Melatonin has multiple effects on physiology and behavior, and therefore represents one indirect pathway through which the SCN can influence physiology and behavior. The SCN is also the target through which melatonin can entrain circadian rhythms. It seems likely that the rates and patterns of phase recovery for the clock rhythms in the dorsal–medial SCN and for the rhythms in melatonin secretion from the pineal gland following a shift in the LD cycle is a consequence of interactions between these neural and endocrine structures, respectively.

3 Circadian Mechanisms Regulating the LH Surge and Estrous Behavior

Successful reproduction requires coordinated timing of male and female behavior so that sperm arrives soon after the egg is expelled from the follicle and is ready for fertilization. For males, the temporal coordination is relatively simple. During times of post-pubertal life, when females are available to be inseminated, they produce relatively continuous secretion of high levels of one primary hormone (testosterone), and a steady supply of sperm. Such a male is in a position to take advantage of opportunities to mate whenever they arise. For a female, the process is far more complex. She must develop mechanisms that will couple the occurrence of her sexual behavior to the LH surge at a time when the follicles are ready for ovulation, and the uterus must be prepared to receive and nurture an embryo. The nature of the mechanisms coordinating these events varies considerably across species. For example, ovulation can be spontaneous or induced, and it may or may not be tightly regulated by a circadian time-keeping system. Here we focus on the role of endogenous circadian timekeeping mechanisms responsible for the temporal coordination of estrus-related events in mammals. The system is bidirectional, in that it involves not only circadian mechanisms that regulate hormone secretion, but also influences of those hormones on the circadian system. We focus first, and primarily, on the role of the circadian system in the regulation of neuroendocrine events associated with estrus, and then turn briefly to consider how ovarian hormones can feed back to influence circadian systems.

The two initial events that the circadian system helps to coordinate are the occurrence of the surge of secretion of LH from the anterior pituitary gland that triggers ovulation, and mating behavior that makes possible the fertilization of the eggs that have been released by that ovulation. Both of these events require a period of exposure to steroid hormones secreted by the ovary. These secretions, over time, prepare the brain so as to lead females to seek out and solicit reproductive males, and respond to male advances with receptive behavior. Steroid hormones also prepare the brain to emit the signals that ultimately lead to ovulation. Specifically, ovulation is triggered by a surge in the release of LH from the anterior pituitary, which is promoted by the release of GnRH from the hypothalamus into the median eminence. This basic system can be considered a part of the positive limb of the hypothalamic–pituitary–gonadal (HPG) axis. The negative side of this axis involves a system of feedback through which the pituitary hormones [luteinizing hormone (LH) and follicle stimulating hormone (FSH)] inhibit the hypothalamic production of GnRH, and the

ovarian hormones (progesterone-P and estradiol-E) inhibit both the pituitary and the hypothalamus. The last basic element of this system key to understanding ovulation is a fascinating switch from a negative to a positive response by the GnRH neurons to rising estradiol concentrations as the follicles develop. That is, just before the GnRH and LH surge occurs, the GnRH neurons change, such that they respond to estradiol by increasing rather than decreasing the release of GnRH. This switch from a negative to a positive feedback effect of estradiol is a phenomenon that has puzzled neuroendocrinologists for years and, more recently, has drawn the attention of mathematicians who have begun to model the process. However, we bypass that mystery here and focus, instead, directly on the role of the circadian timekeeping system in the regulation of the events leading to ovulation and mating behavior. These events are primed by steroid hormones, but they are also influenced by, and in some species depend upon, signals from the circadian time-keeping system. Indeed, disruption of genes intrinsic to the molecular clock can lead to reductions in fertility (Chappell et al., 2003).

To understand just how a signal from the circadian system might regulate estrus, it is important to first consider the nature of the GnRH cells that the SCN signals must ultimately reach, as these cells represent a final common pathway upon which many kinds of signals converge to regulate reproductive physiology and behavior. The GnRH neurons are large bipolar cells that are few in number and diffusely distributed in a network that crosses traditional cytoarchitectonic boundaries (Silverman et al., 1994). The rostral extent of their distribution begins in the septum and diagonal band of Broca, and they become most concentrated caudal to that in the medial regions of the preoptic area of the hypothalamus (POA). In some species, such as rats and hamsters, they continue caudally to the end of the optic chiasm, while in others, such as guinea pigs and rhesus monkeys, they continue through the arcuate nucleus (Silverman et al., 1994). The diffuse nature of their distribution has made it difficult to identify the afferents to the GnRH cells. One approach that has been taken is to examine details of synapses on their cell bodies, which has revealed the nature of the peptides and transmitters impinging on them. However, probably the best characterized afferents of the GnRH neurons are those through which the circadian information reaches them.

Direct evidence that GnRH cells are rhythmic has been obtained through studies of Fos expression, and in situ hybridization and direct measurements of GnRH. Fos expression within GnRH neurons peaks late in the light phase on the day of proestrus; this peak coincides with the LH surge in rats (Lee et al., 1990; van der Beek et al., 1994) and guinea pigs (King et al., 1998), but occurs immediately after the surge in hamsters (Doan and Urbanski, 1994). A peak at the time of the LH surge in Fos expression within GnRH neurons has also been seen in the diurnal grass rat during a post partum estrus, approximately 12 h out of phase with its occurrence in the nocturnal rodents (McElhinny et al., 1999). The rhythm in Fos expression in GnRH neurons appears to be endogenous in both nocturnal lab rats and diurnal grass rats (Mahoney et al., 2004).

3.1 The Circadian System is Involved in the Triggering of the LH Surge

A clear role for the circadian timekeeping in the direct regulation of the LH surge has been established in closely related murid rodents, with short cycles, that ovulate spontaneously but do not have a spontaneous luteal phase (rats, hamsters, and mice). The development of our understanding of this fascinating interplay between steroids and circadian signals has its origins in a 1950 paper by Everett and Sawyer (1950). These investigators injected intact female rats with pentobarbital at different times on the day of proestrous, and found that there was a critical phase of the daily rhythm during which the drugs could block ovulation, and the delay was not simply for the duration of the anesthesia, but rather, it lasted for 24 h (reviewed in Rusak and Zucker, 1979b). This study provided evidence that there is a critical phase of the daily rhythm during which a daily neural signal triggers ovulation. The same method has been used to establish that the postpartum LH surge of rats is also triggered by a precisely timed daily signal (Fox and Smith, 1984). This conclusion has been bolstered by many kinds of experimental evidence. For example, Legan and Karsch (1975) implanted ovariectomized (OVX) rats with silastic capsules and found that LH surges occurred every day at approximately the same time, 3–4 h before lights-out; estrogen-treated OVX mice are similarly only able to surge around lights off, regardless of when the steroid stimulation occurs

(Bronson and Vom Saal, 1979). The postpartum LH surge of rats also occurs 3–4 h before lights-off and is also gated by a time-keeping system such that appropriately timed injections of pentobarbital lead to a 24 h delay (Fox and Smith, 1984).

The question of whether the phase of the daily signal is determined by cues from the environment or from an endogenous time-keeping system was addressed by Alleva et al. (1971), who found that when hamsters were kept in constant light, they had free-running "quadradian" rhythms in the occurrence of a variety of indices of the estrous cycle including gonadotropin release, with periods that were four times those of their circadian rhythms. Since these early studies, compelling evidence has accumulated from a variety of very different studies. For example, when the period of the circadian rhythm of hamsters was lengthened by administering deuterium oxide (heavy water), the period of the estrous cycle increased proportionally in hamsters (Fitzgerald and Zucker, 1976). When hamsters were maintained in LL and their wheel-running rhythms split into two bouts in antiphase relationships, they developed two surges per day, approximately 12 h apart (Swann and Turek, 1985). When rats were exposed to LL for long periods, their behavioral rhythms became disorganized, and under these conditions the animals ceased having regular estrous cycles and became induced ovulators (Brown-Grant et al., 1973). While the role of the circadian system in the LH surge has been well established in some rodents, this system has less direct control over the surges, and may be less essential, in some other species, including sheep and rhesus monkeys, and diurnal species with a spontaneous LH surge and a spontaneous luteal phase (Jackson et al., 1975; Tersawa et al., 1984).

3.2 The SCN

Even before it was clearly established that the murid rodent's LH surge is regulated by a circadian "gate," and before the relationship between the SCN and circadian rhythms had been clearly established, Critchlow (1963) (reviewed in Rusak and Zucker, 1979) proposed that a retinohypothalamic tract projecting to the SCN mediates the entrainment of the estrous cycle by the LD cycle. This conclusion was based on the finding that SCN lesions led to constant estrus and acyclicity in females. Since that time, many lesion studies have led to the same basic conclusion, although the details of the nature of the effects of the lesions have varied (Stetson and Watson-Whitmyre, 1976; Gray et al., 1978b; Wiegand et al., 1980; Kawakami and Arita, 1981; Meyer-Bernstein et al., 1999b). Differences in the size of lesions and the degree to which they altered projections to the anteroventral preoptic area (AVPV), an area slightly rostral to the SCN, may account for the discrepancy. When Wiegand et al. (1980) produced tiny lesions in different regions along the rostral–caudal axis from the SCN to the AVPV (which they refer to as the medial preoptic nucleus), they found that the LH surge of rats was blocked if the lesion destroyed either the SCN or the AVPV. However, even as the SCN lesions disrupted ovulation in response to E alone, small LH surges did occur in response to E plus P injections. Animals were unable to surge in response to any hormone treatment when the AVPV was destroyed. This work led to the notion that under intact conditions a "surge generator" in the AVPV integrates circadian signals from the SCN with information on levels of steroid hormones to determine whether a surge will occur.

As noted previously, the circadian system plays less of a role in the regulation and generation of the surge of some species, and in these cases the SCN, not unexpectedly, is not as critical. In both guinea pigs and rhesus monkeys, knife cuts that severed the SCN from the caudal population of GnRH neurons did not interfere with the ability to produce an LH surge (Butler and Donovan, 1971; Krey et al., 1975). It is also the case that in some species, including humans, females may typically produce LH surges at a specific time of day, even if it can be generated at any time. In these cases, it is not yet known whether the normal circadian timing of ovulation is important to fertility.

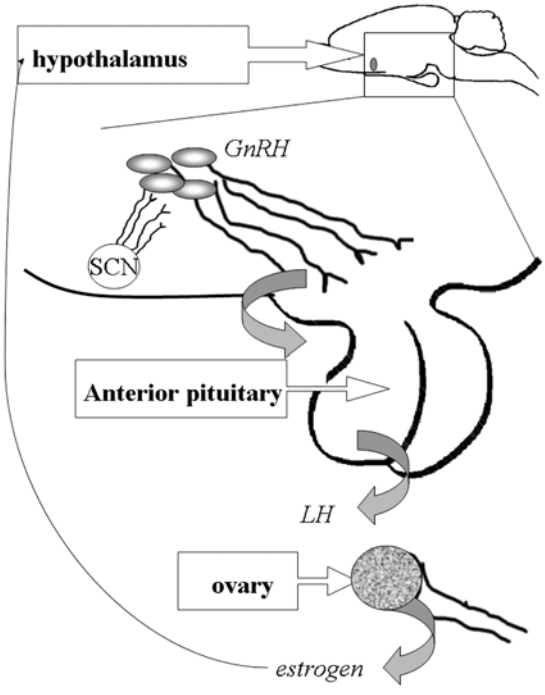
It should also be noted that the region immediately dorsal to the SCN, the lower subparaventricular zone (LSPV), may contribute to the temporal organization of reproductive events. The LSPV receives a massive input from the SCN and projects to many of the same targets as the SCN (Watts and Swanson, 1987; Morin et al., 1994), including cells that contain GnRH and ER (De La Iglesia et al., 1995; Watson et al., 1995; van der Beek et al., 1997), and is rhythmic (Schwartz et al., 2004), and in OVX lab rats, lesions of the LSPV result in an increase in tonic levels of LH (Doecke et al., 1982).

3.3 Signals from the SCN to the GnRH Neurons

More recent studies of murid rodents have been aimed at examining which specific pathways emanating from the SCN communicate temporal information to GnRH neurons. At a very general level, the SCN can get its message out via traditional neural efferents and also via an as yet unidentified diffusible substance (Silver et al., 1996). The possibility that a diffusible signal might serve to communicate temporal information from the SCN to its targets has been tested most carefully in hamsters. This notion was first suggested by the finding that although SCN lesions abolished wheel running rhythms, core knife cuts that severed all fibers into and out of the SCN did not (Silver and LeSauter, 1995). The hypothesis was further supported by the finding that behavioral rhythms could be restored in SCN-lesioned animals by transplants of fetal SCNs into the third ventricle of lesioned animals even when the transplanted tissue was encapsulated in a material through which neural processes could not pass (Silver et al., 1996). It thus seems that, although traditional efferents may contribute to behavioral rhythms, the rhythms do not depend on them. It should be noted, however, that this model has not been tested in other species and may not apply to rats (Nunez and Casati, 1979; Nunez et al., 1985).

In the case of neuroendocrine rhythms, the situation appears to be different. Here, the data suggest that a diffusible signal is not sufficient for the generation of the rhythms. The issue has been addressed in a number of ways. In rats, knife cuts that severed the lateral, dorsal, and caudal connections of the SCN eliminated estrous cycles, suggesting that neither a diffusible signal nor the rostral pathway is sufficient (Nunez and Casati, 1979). More recently, Myer-Bernstein et al. (1999) used SCN transplants in hamsters to address the question of which rhythms can and cannot be restored in SCN-lesioned animals. These

Figure 23-2
Proposed direct pathway by which the SCN may regulate the timing of GnRH (gonadotropin-releasing hormone) release into the portal vasculature around the pituitary. GnRH then stimulates the surge of luteinizing hormone (LH) that causes ovulation



investigators found that transplants that restored wheel-running rhythms in female hamsters did not bring back estrous cycles or the ability of OVX females to surge in response to E. This study also found that rhythms in pineal, gonadal, and adrenal function of males could not be restored by the grafts. These results suggest that, although a diffusible factor might contribute to neuroendocrine rhythms, these rhythms are dependent on neural pathways connecting the SCN to its various targets.

A recent study by de la Iglesia et al. (2003) provides further compelling evidence that a neural rather than a humoral signal is central to circadian regulation of the GnRH system. This study examined patterns of laterality in GnRH neuron function of hamsters with split activity rhythms. As noted previously, splitting involves the dissociation of both a single daily activity bout and a single LH surge into two that are in an antiphase relationship, with smaller peaks in activity and LH, respectively, approximately 12 h apart (Swann and Turek, 1985). In these animals, the two bilaterally paired SCN also exhibited antiphase relationships with respect to their rhythms in PER, one of the proteins intrinsic to the circadian clock. In split hamsters, rhythms in FOS within GnRH neurons on the two sides of the brain were also in an antiphase relationship relative to each other, further indicating that axonal outputs of the SCN, which are primarily ipsilateral, rather than a diffusible factor, trigger the activation of the GnRH neurons (de la Iglesia et al., 2003).

Axons emanating from the SCN could theoretically influence the GnRH neurons via indirect pathways, perhaps via ER-containing cells in the AVPV, or through direct projections. Tract-tracing studies have revealed the existence of a direct pathway in rats (van der Beek et al., 1997a), hamsters (De La Iglesia et al., 1995), and Nile grass rats (unpublished data). In hamsters and grass rats, these projections have only been examined at the light level, but in rats they have been clearly verified with electron microscopy. Estimates of the numbers of GnRH neurons receiving SCN input in these species are 11–19% for hamsters and lab rats, and 60% for grass rats. The majority of GnRH cells contacted by SCN efferents in these species are located in the region of the organum vasculosum of the lamina terminalis (OVLT) and the POA of lab rats and grass rats, and in the diagonal band of Broca (DBB) and POA of hamsters (de la Iglesia et al., 1995; van der Beek et al., 1997).

Recent data from Kallo et al. (2001) raise the possibility that GnRH neurons receiving direct input from the SCN could themselves represent one site at which circadian signals converge with feedback signals from ovarian steroids to provoke an ovulatory surge in LH. This is based on their observation that ER-beta is ordinarily present in over 50–65% of GnRH cells in the POA of lab rats, but that when they are exposed to high levels of E, as occurs prior to the surge, this percentage drops to 26–46% (depending on the time and dose of E administration), potentially leading to a decrease in negative feedback effects of E. If these cells are among those receiving input directly from the SCN, this could heighten their response to a circadian signal, enabling a surge of GnRH release into the hypophyseal portal system to occur.

3.4 VIP and VP

The question of which SCN cells and transmitters convey temporal signals to GnRH neurons has received considerable attention in recent years. Two of the best understood signaling peptides found in SCN efferents are vasopressin (VP) and vasoactive intestinal polypeptide (VIP) (Moore et al., 2002). These peptides are present in a large proportion of SCN cells and their axons, and they appear to play important roles in the regulation of rhythms in glucocorticoids, feeding and drinking, as well as reproduction (Salisbury et al., 1980; Buijs et al., 2003). These populations of cells are different with respect to their inputs and outputs as well as some of their functional characteristics. Within the hypothalamus, VIP cell bodies, which are present in every species that has been examined, are concentrated in the "core" region of the SCN, where they receive direct input from the retina but exhibit rhythms in the absence of an LD cycle. Cells containing VP are located in the "shell" of the SCN which is different from the core with respect to its inputs and its intrinsic connections as well as its rhythms. Both populations of cells appear to be involved in communicating from the SCN to GnRH neurons. Somewhat conflicting evidence exists, however, regarding whether these peptides have inhibitory or excitatory effects on the ovulatory surge in GnRH and, subsequently, LH (Vijayan et al., 1979; Stobie and Weick, 1989; Weick and Stobie, 1992). The discrepancies are most likely due to variations in methodology with respect to the route of administration of the various agents, the specific

agents administered, and the doses and animal models used (van der Beek, 1996; Palm et al., 1999b). Here we highlight some of the data bearing on the respective roles of VIP and VP, and then consider some of the attempts to develop models that may account for them.

Evidence of a role for VIP as an efferent signal emanating from the SCN comes from a variety of studies, both correlational and experimental. In female lab rats, hamsters, and grass rats, contacts between VIP fibers and GnRH cells have been seen using light level microscopes (Van Der Beek et al., 1998; Kriegsfeld et al., 2002; Mahoney and Smale, 2005). In lab rats, SCN lesions eliminated most of these contacts (Van der Beek et al., 1993), and the presence of synapses between VIP terminals and GnRH neurons has been verified with electron microscopy (van der Beek et al., 1997). Triple immunocytochemical labeling has also revealed that approximately 50% of GnRH cells that expressed Fos at the time of the surge are contacted by VIP fibers (van der Beek et al., 1994). These appositions are more numerous in females, which produce a surge at regular intervals, than in males, which are unable to generate one (Horvath et al., 1998b). A role for VIP is also indicated by the presence of VIP2 receptors on GnRH neurons, both in vivo and in vitro (Smith et al., 2000; Olcese et al., 2003).

The issues become somewhat less clear and the data less consistent when one considers effects of experimental manipulations intended to block or increase availability of VIP. Although VIP administered into the ventricles of lab rats has been reported to stimulate the release of LH in some conditions (Vijayan et al., 1979), other studies have found that administration of VIP inhibits LH (Alexander et al., 1985; Stobie and Weick, 1989; Weick and Stobie, 1992). Experimental disruption of VIP, however, delayed and attenuated the surge in two studies. In one, the production of VIP was disrupted by antisense administered into the SCN (Harney et al., 1996), and in the other, anti-VIP antisera was delivered into the lateral ventricle just before the expected onset of the surge (van der Beek, 1999). Several potentially confounding variables may account for the discrepancies, such as differences in the timing of experimental manipulations of the system (discussed in van der Beek et al., 1999).

VP cell bodies are found in a number of brain regions, including the PVN, making interpretations regarding their relationship to the circadian system more problematic. A role for VP as a potential efferent signal of the SCN was first suggested by the discovery of rhythms in its release into the cerebral spinal fluid that peak during the day in both nocturnal and diurnal mammals; these rhythms were abolished by SCN lesions (Reppert et al., 1987). More recently, rhythms in VP release within the SCN of rats have been documented via microdialysis (Kalsbeek et al., 1995). These VP rhythms also peak during the day, during the critical period 2 h before the LH surge, when it can be blocked by administration of barbiturates (see above).

VP fibers make contacts with GnRH neurons in the hypothalamus of female lab rats, hamsters, and grass rats, as well as primates (Thind et al., 1991; Horvath et al., 1998; Abizaid et al., 2004). In lab rats, there is a sex difference in the number of VP contacts with GnRH neurons in the diagonal band of Broca such that males actually have more than females (Palm, 2001), and the number of contacts is reduced by lesions of the SCN, suggesting that at least some of this input comes from cells within the SCN (Palm et al., 1999a).

As with VIP, some studies in which VP has been administered to laboratory rodents suggest an inhibitory role, and others suggest an excitatory one (reviewed in Palm et al., 1999a). The most recent work used reverse microdialysis to deliver relatively minute quantities of VP specifically into the POA; this generated an LH surge in SCN-lesioned rats (Palm et al., 2001a). This work also found that the effect of VP occurred when its administration began at ZT 8 but not when it began at ZT 0 or ZT 4. Further evidence that VP may stimulate the release of GnRH comes from the finding that administering it into the POA induced GnRH release (Funabashi et al., 2000).

At least two studies have directly compared VP and VIP with respect to their potential roles in the regulation of the surge. In one, Krajnak et al. (1998) evaluated mRNA rhythms in the SCN of male and female rats. The rising phases of the rhythm in VIP mRNA occurred 8–12 h earlier in female than male rats, whereas VP mRNA rhythms were the same. This pattern is consistent with the possibility that a relatively early rise in production, and perhaps release, of VIP may be important for the initiation of the LH surge. The potential roles of VIP and VP have also been investigated in vitro. Funabashi et al. (2000) found that when preoptic area tissue and the SCN were cultured together, GnRH, VP, and VIP were all released

rhythmically. Most importantly, the GnRH rhythms were tightly coupled to those of VP but not VIP. They also found that administration of VP stimulates the release of GnRH from cultured cells in a dose-dependent manner.

As one can see from the above considerations of the respective roles of VIP and VP, the data are somewhat conflicting. Several explanations have been offered. On the basis of the sex difference in rhythms in its mRNA, Krajnak et al. (1998) suggested that VIP plays an important role in the timing of the surge. However, although the presence of the sex differences may suggest a role for VIP, the absence of a sex difference in rhythms in VP mRNA does not argue against the possibility that VP plays an important role. Palm et al. (1999) attempted to account for the data by suggesting that VP plays an important role in the initiation of the surge, but that it can only do this during a brief window of time determined by the release of VIP. This hypothesis is difficult to reconcile with the fact that in vitro rhythms in VP release are tightly coupled to those of GnRH, which occurs at all phases of the rhythms in VIP (Funabashi et al., 2000). Funabashi et al. (2000) suggest that the data are consistent with a model, whereby VP mediates the effect of the clock on the LH surge and any effect of VIP is through its actions within the SCN, where it modulates entrainment. This model offers no explanation for the function of the VIP contacts on GnRH cells, or for the dramatic sex difference in VIP mRNA rhythms within the SCN, which is not paralleled by a sex difference in entrainment. Clearly, although these SCN efferents are likely to play a role in the generation of the LH surge, the exact nature of that role remains to be elucidated.

3.5 Molecular Oscillators Within GnRH Neurons

A fascinating new part of the story of circadian regulation of GnRH comes from recent discoveries of molecular oscillators in brain regions beyond the SCN (Reppert and Weaver, 2002). For example, Abe et al. (2002) found in vitro rhythms in *Per1* that persisted for approximately 3–5 cycles in 11 isolated brain regions. There are now several reports of in vivo *r*hythms of PER proteins in several brain regions outside the SCN in male rats, including the bed nucleus of the stria terminalis (BNST) and the centromedial and basolateral amygdala (Amir et al., 2004; Waddington Lamont et al., 2005). This work was conducted with adult males, but there is also evidence of molecular oscillators within regions of the brain beyond the SCN in female rats, specifically within neuroendocrine cells (Gillespie et al., 2003; Kriegsfeld et al., 2003; Sellix et al., 2006). The suggestion that oscillations in the expression of clock genes occur within GnRH cells has come from in vitro studies of GT1–7 cell lines (Chappell et al., 2003; Gillespie et al., 2003; Olcese et al., 2003). Gillespi et al. (2003) demonstrated mRNA rhythms for several clock genes in this cell line after the cells had been synchronized with serum shock; the phase relationships among these rhythms were similar to those seen in cells within the SCN of intact animals. The GnRH gene was expressed rhythmically in these cells, and experimentally altering patterns of expression of two of the clock genes led to changes in the pattern of GnRH secretion from these cells (Chappell et al., 2003). These data raise the tantalizing possibility that GnRH neurons represent "slave" oscillators entrained by the SCN, perhaps allowing for greater flexibility in the phase of rhythms in GnRH expression (de la Iglesia, 2006). This might also account for the reduced fertility apparent in mice with a mutation in *Cry*, an important element of the clock (Dolatshad et al., 2004; Kenneway et al., 2006).

3.6 Circadian Influences on GnRH Neurons via ER-Containing Cells

Another way in which the circadian system could influence estrus-related events is via the production of rhythms in responsiveness to ovarian hormones, as estradiol and progesterone have a major influence on both the LH surge and sex behavior in rodents. Here we focus on estrogen receptors (ERs), as more is known about the input of ER-containing neurons to the SCN. Numbers of ERs have, in fact, been reported to change across the day. An early indication that this might be the case came from examination of cytosolic binding to E in tissue containing the hypothalamus, POA, and amygdala from OVX female rats put to death

across the day (Roy and Wilson, 1981). This binding underwent 24 hour rhythms with a peak just before lights-out and a trough in the middle of the dark period, at ZT 18. The amplitude of the rhythm was relatively low, with peak values approximately 30% higher than trough values. A similar rhythm has been reported in OVX hamsters (O'Connor et al., 1985). The functional significance of these rhythms is unclear, as the receptors are highest after the period during which behavioral and neuroendocrine functions are maximally sensitive to circulating E.

More recent work has focused on where in the hypothalamus ovarian hormones might interact with circadian signals to promote the surge. Much of this work has focused on the AVPV, which contains a high concentration of ERs and PRs and, as noted earlier, is essential for the generation of the surge (Tersawa et al., 1980; Tersawa et al., 1984). Watson and Langub (1992) discovered that VP fibers form synapses on ER-immunocytochemically labeled cells in the AVPV, raising the possibility that VP cells within the SCN project to ER neurons in that region. Watson et al. (1995) then directly addressed the question of whether the SCN projects to ER cells in the AVPV by delivering an anterograde tracer into the SCN of lab rats and then staining the tissue for visualization of ERs. Labeled fibers were observed in the AVPV, where they formed synapses with cells containing ERs; injections of the tracer that were restricted to the LSPV also revealed such synapses. Evidence that the SCN projects to ER-containing neurons has also been obtained in hamsters where, using light-microscopy, contacts were seen on 8–30% of ER-containing cells (De La Iglesia et al., 1995). These data suggest that AVPV cells that contain ERs and receive input from the SCN may be a site at which rising levels of E converge with the circadian signal that triggers the LH surge. The resulting signal could be carried from the AVPV through its direct projections to GnRH neurons (Gu and Simerly, 1997). Some of the effects of VIP or VP or both on the GnRH and LH surge, described above, might occur through projections from the SCN to the AVPV (Chappell, 2005).

Recent data have pointed to the SCN as another possible site for the integration of circadian and steroid signals. This possibility is suggested by evidence that ER-beta is present in the SCN, where rhythms in its mRNA with a sharp peak at ZT 4 have been documented (Wilson et al., 2002). This peak could theoretically contribute to a rhythmic gating of the GnRH/LH surge. This could happen, for example, if there were a time lag between the elevated ER mRNA and elevated protein in the SCN, and a further lag between the rise in ER-beta protein and the time at which the binding of E to ER promotes a functional change in the cell. Such a sequence of steroid-induced events might then facilitate the production of the circadian signal thought to be emitted around this time.

It is clear that a great deal has been learned over the years about the influence of the circadian system on the LH surge. However, it should also be clear from the above discussion that the full story has not yet come together, that many interesting questions about these mechanisms remain, and that there is still a great deal of room for speculation.

3.7 Rhythms in Sex Behavior

An integration of signals from the circadian system and steroid hormones is also important for another critical estrus-related event: sex behavior. The mechanisms exquisitely timing the surge would be irrelevant if that surge were not tightly coupled to female sexual behavior. Not surprisingly, therefore, animals do exhibit rhythms in their copulatory behavior, with diurnal rodents typically mating during daylight hours and nocturnal rodents displaying mating behavior throughout the dark period (reviewed in Mahoney and Smale, 2005b). In lab rats, estrous behavior continues to occur during subjective night even when animals are housed in constant lighting conditions, and these rhythms are abolished by lesions of the SCN (Gray et al., 1978a; Hansen et al., 1978a; Hansen, 1979; Hansen et al., 1979; Eskes, 1984; Meyer-Bernstein et al., 1999a).

Daily rhythms in female sexual behaviors appear to be due to temporal patterns of change in steroid hormone secretion, as well as changes in responsiveness to these hormones (Hansen et al., 1978b). Ovariectomized lab rats implanted with estradiol capsules and tested for sexual behavior three days later had peak lordosis quotients (LQ, position of arched back and deflected tail by the female that allows male to successfully mate), indicative of heightened sexual behavior, during the dark, and the lowest LQs during the

light portion of the LD cycle (Hansen et al., 1978b; Hansen et al., 1979). Not all studies of lab rats have found daily rhythms in sexual behavior, perhaps because different strains of rats have been used in these studies (Erskine et al., 1980). In diurnal female grass rats primed with E and P at different times of day, rates of sexual behavior three hours after hormone injections were highest one hour before the lights came on, as is the case for intact females in estrus (Mahoney and Smale, 2005b). Nocturnal and diurnal female rodents thus appear to have rhythms in responsiveness to steroid hormones that are 12 h out of phase with one another. The mechanisms responsible for that difference are unknown, but it is tempting to speculate that they involve differences within ER-containing neurons that receive input from the SCN.

This possibility is related to a more general question that emerges from consideration of whether efferent signals from the SCN that regulate behavior are conveyed through a process of diffusion, or whether they are carried along more traditional axonal pathways (Silver et al., 1996). Transplant studies (above) have provided evidence that a diffusible signal is essential and sufficient for the generation of behavioral rhythms. However, those studies have focused on patterns of general activity, feeding or drinking, rather than reflexive behaviors expressed in more specialized circumstances. In the case of lordosis, the fact that the reflex is modulated by estradiol, and that the SCN projects onto ER-containing cells in regions involved in its regulation, suggests the possibility that axonal outputs, rather than diffusible signals, may be key.

3.8 Ovarian Steroids Affect the Circadian System

Until now, we have been considering the ways in which the circadian system can influence reproductive processes and behavior. It is also important to appreciate how the neuroendocrine system can also alter circadian timekeeping systems. Gonadal hormones act early in development to promote sex differences in circadian systems, as well as again in adulthood to modulate these systems, across the estrous cycle as well as over the course of pregnancy and lactation (e.g., Rosenwasser et al., 1987). Here we discuss effects of ovarian secretions associated with the estrous cycle as an example of how hormones may feed back to the circadian system. Direct and indirect evidence for effects of E and P on circadian rhythms has been obtained from a range of species, including carnivores and primates, but the best understood species are rodents, reviewed here.

An initial appreciation of how ovarian hormones can influence the phase and period of circadian systems began with observations by Morin et al. (1977) of changes in the onset of activity that correlated with the estrous cycle of female hamsters kept in a light–dark cycle. A "scalloping" effect was seen whereby the onset of daily wheel running occurred earlier on days 3 and 4 of the estrous cycle than on days 1 and 2, when animals were kept in LL as well as in an LD cycle. Evidence that rising levels of E were responsible for the advance was provided by the observation that in OVX females, subcutaneous implants of estradiol advanced the phase angle of entrainment and shortened the period of the rhythm in free-running conditions; the changes in phase may have been due to the changes in the period. Estradiol implants have also been reported to help maintain synchrony of rhythms of female hamsters kept in constant conditions that commonly lead to dissociated activity rhythms such as those seen in the case of splitting (described above; Morin, 1980; Morin and Cummings, 1982). Administration of E also reduces variability in the onset of activity of free-running hamsters, an effect that is counteracted by P (Takahashi and Menaker, 1980). Very similar effects have been seen in female rats (Albers et al., 1981), although they are strain- and housing specific. It has been suggested that E may shorten the period of the activity rhythm and trigger the LH surge by acting on common circadian mechanisms (Fitzgerald and Zucker, 1976). The function of the circadian regulation of responsiveness to E may be to speed up the clock in a manner that helps ensure that a female is awake and active when she needs to find a mate (Takahashi and Menaker, 1980). It could be quite costly for a short-lived rodent to miss out on the opportunity to mate on the day of estrus, as she may then have to wait 4–5 more days, which is not an insignificant portion of the reproductive life of such rodents.

Another species in which dramatic effects of hormones on rhythms have been seen is the *Octodon degus* (degu), a diurnal, hystricomorph rodent from South America. These females have a 21 day estrous cycle

which, unlike those of rats and hamsters, has a spontaneous luteal phase. Pronounced changes in patterns of daily rhythms and in their phase angles of entrainment to an LD cycle are associated with the estrous cycle, and rates at which the rhythms can adjust to phase shifts in a LD cycle are modulated by ovarian hormones (Labyak and Lee, 1995). As with hamsters, the cyclic effects of E and P on entrained phase disappear with ovariectomy, and phase is altered by replacement hormones. However, unlike the hamster, it does not appear that either hormone is directly altering the underlying period of the circadian mechanism (Labyak and Lee, 1995; Jechura and Lee, 2004). Interestingly, in both hamsters and degus, the sex difference in circadian period is determined by exposure to postnatal estrogen. This occurs perinatally in the hamster (Albers et al. 1981; Davis et al. 1983), but long after puberty in the degu (Hummer et al., in press).

Over the years, since the effects of steroid hormones on behavioral and physiological rhythms were discovered, it has become clear that these hormones have myriad activational effects on a variety of features of the SCN, such as on the presence of gap junctions and associated proteins (Shinohara et al., 2003). Most recently, it has been shown that E influences the molecular clock within the SCN, as well as in the uterus. Nakamura et al. (2005) found that E treatment led to an advance in the peak and a decrease in the amplitude of the *Per2* rhythm, but no change in *Per1*, within the SCN of OVX rats. Interestingly, E induced a biphasic rhythm in *Per1* and *Per 2* within the uterus of these animals, significantly altering phase relationships between rhythms in the SCN and uterus. Effects of E on the clock within the SCN could occur indirectly through the ER-alpha containing cells afferent to the SCN, noted above (De La Iglesia et al., 1995), or directly through ER-beta containing cells within the SCN (Wilson et al., 2002).

4 Circadian Rhythms in Neuroendocrine Dopamine Neurons and Prolactin

Prolactin (PRL) is an anterior pituitary hormone that plays a critical role in a far-ranging suite of behavioral and physiological functions, from the promotion of "water drive" in amphibians and crop sack development in birds to a variety of osmoregulatory functions in all vertebrate classes. In mammals, its role has been best studied in the context of female reproduction, where, as the name implies, one of its functions is to promote lactation. The secretion of prolactin from the anterior pituitary is regulated by the release of both inhibitory and stimulatory factors. Stimulatory factors may include oxytocin, thyrotropin releasing hormone, VIP and VP. The latter two factors may exert their effects on PRL secretion via their release into the hypothalamus, where they may act as neuromodulators, as well as through their direct effects on the pituitary gland. The primary inhibitory factor is dopamine (DA), whose synthesis is regulated by the enzyme tyrosine hydroxylase (TH). DA from TH-producing cells reaches the anterior pituitary directly through axons projecting from the hypothalamus to the median eminence, as well as indirectly through its release into the intermediate and posterior lobes of the pituitary; it travels from these lobes to the anterior pituitary through short portal blood vessels.

Rhythms in PRL secretion are evident in females under a variety of reproductive conditions, as reviewed by Freeman et al. (2000). In pregnant and pseudopregnant animals, the rhythms vary somewhat across species. In rats, a bimodal pattern of prolactin secretion is evident for the first ten days of pregnancy, until the placenta matures and begins to secrete its own luteotrophic hormone, at which time the prolactin secretion, initially necessary for maintenance of pregnancy, drops precipitously, and then remains low until the end of pregnancy. A circadian pattern of PRL release is less clear during lactation, when the stimulation a mother receives from her nursing offspring becomes the primary determinant of the pattern of secretion of the hormone. When animals are not pregnant or lactating, prolactin secretion varies systematically as a function of the stage of the estrous cycle and the time of day. Here we focus on the circadian control of the peri-ovulatory PRL surge in the nonpregnant female rat, the best studied model for the circadian regulation of this hormone.

In rats, the preovulatory surge of prolactin parallels that of LH, and is similarly regulated by a circadian signal from the SCN in the context of rising levels of E. As is true of the LH surge, the PRL surge is blocked by lesions of the SCN (Kawakami et al., 1980), which may influence circadian timing of release through VIP and VP signals. As with LH, the PRL surge requires high levels of E, whose effects appear to be mediated

primarily by ER-alpha- and ER-beta-containing cells located in the POA. In rats, P enhances the magnitude of the PRL surge as it does for LH. However, the mechanisms controlling the PRL surge are quite different from those controlling the LH surge in some important ways. The primary hypothalamic factor influencing PRL release is DA, which has an inhibitory rather than a stimulatory effect on its secretion, and DA release is reduced rather than increased at the time of ovulation. The circadian signals involved must therefore, directly or indirectly, inhibit the release of DA from the hypothalamus.

Studies of the circadian regulation of prolactin by DA have focused on three primary populations of TH neurons, whose roles are described in Moore and Lookingland (1995). These include TH-producing neuroendocrine cells referred to as the periventricular hypophyseal DA (PHDA) neurons. These cells represent a subset of the A14 group of TH neurons and project to the intermediate lobe of the pituitary where they play a role in the regulation of melanocyte stimulating hormone (MSH). A second group of neuroendocrine DA cells are the tuberohypophyseal TH neurons (THDA neurons), a subset of A12 neurons; these cells are located in the anterior part of the arcuate and the periventricular region. THDA neurons are thought to project to the posterior neural lobe of the pituitary. A third group of neuroendocrine DA cells are referred to as the tuberoinfundibular neurons (TIDA neurons), and represents another subset of the A12 neurons. These are located in the dorsomedial arcuate, caudal to the THDA neurons. These cells release DA into the median eminence (ME) and play a major role in the regulation of prolactin secretion from the anterior pituitary. Research on the question of what might generate a circadian rhythm in prolactin secretion has focused on these three populations of TH neurons.

Evidence that neuroendocrine TH neurons are rhythmic comes from examination of patterns of DA turnover in the pituitary of OVX animals, as well as expression of immediate early genes in TH cells. DA turnover in all three lobes of the pituitary was rhythmic in animals kept in LD cycles as well as in DD, though the patterns were somewhat different in these two conditions (Sellix and Freeman, 2003). Immunohistochemical studies of the immediate early gene FRA have enabled investigators to determine which TH neurons change around the time of the PRL surge (Hoffman et al., 1994; Lerant and Freeman, 1997). Hoffman et al. (1994) first reported a decline in FRA expression within TIDA neurons across the day of proestrous, suggesting that a decrease in their activity precedes the PRL surge. More detailed analyses showed a decrease in FRA within all three groups of neuroendocrine DA cells (THDA and PHDA, as well as TIDA neurons) in both OVX females and intact females on the day of proestrus (Lerant and Freeman, 1997). Interestingly, the decrease occurred in OVX females, despite the fact that PRL secretion did not change over the course of the day in these animals. Lerant and Freidman (1997) suggest that the apparent paradox may reflect increased responsiveness of the pituitary to inhibitory factors, such as DA, over the course of the day, or a change in stimulatory signals that act in parallel with the inhibitory neuroendocrine DA neurons (NDA neurons) or both. Another possibility is that a dissociation develops between mechanisms responsible for an increase in FRA and a change in DA secreted by these cells.

As is the case with GnRH neurons, tract-tracing studies are consistent with the hypothesis that rhythms in NDA neurons may be regulated by both direct and indirect input from the SCN. Horvath (1997) provided evidence for direct projections by showing contacts between fibers labeled with an anterograde tracer subsequent to its injection into the SCN, and cell bodies labeled by a retrograde tracer injected into the peritoneal cavity; (the tracer is picked up by terminals in the pituitary and carried back to neuroendocrine cells in the hypothalamus). Indirect input from the SCN to TH neurons was suggested by the observation that it projects to hypothalamic regions afferent to these neurons, including those in the POA (Watts et al., 1987). As with the circadian regulation of GnRH cells, VP and VIP appear to be important signals communicating temporal information along pathways from the SCN, directly or indirectly or both, to the NDA neurons.

Several lines of evidence suggest that the SCN may convey some temporal information directly to NDA neurons through the release of VIP. VIP fibers form synapses on NDA neurons, which express a VIP2 receptor (Gerhold et al., 2001). Interestingly, the number of contacts between VIP fibers and NDA neurons was elevated by treatment with E and P (Gerhold et al., 2001). VIP may also influence these neurons indirectly, as injections of VIP into the preoptic area stimulate PRL release (Akema et al., 1988). Blocking the signal by administering VIP antisera into the medial preoptic area may also block the normal rise

of PRL (van der Beek et al., 1999; but see Harney et al., 1996). Two studies have been conducted using delivery of VIP antisense into the SCN to evaluate its role in the regulation of the PRL surge, and have lead to somewhat conflicting results. In the first, which looked at PRL as the endpoint, the rhythm was not affected (Harney et al., 1996), and in the second, the expression of FRA within NDA neurons was significantly decreased at ZT 13 but not at ZT 1 (Gerhold et al., 2002). These authors did not mention the earlier antisense study, and the reasons for the apparent discrepancy are unclear. Gerhaold et al. (2002) suggest that VIP, coming from the SCN, may help shape PRL rhythms by inhibiting NDA neurons on the evening of proestrus, leading to decreased release of DA and, consequently, increased secretion of prolactin.

A role for VP release from SCN terminals in the regulation of the PRL surge has recently been suggested by Palm et al. (2001). These investigators found that delivery of VP into the POA by reverse microdialysis on the afternoon of proestrus, when VP release normally declines, blocked the PRL surge in OVX female rats treated with E (Palm et al., 2001b). These investigators suggest that, under intact conditions, the drop in secretion of VP from SCN terminals in the POA may help to promote the rise in PRL at that time. It is not yet clear how VP might act under physiological conditions, as attempts to influence PRL release by administration of one VP receptor antagonist, V1aR, were unsuccessful. Nevertheless, when taken together, it appears that an increase in release of both VP and VIP from SCN terminals into the POA and onto NDA neurons may contribute to the circadian regulation of the periovulatory surge in PRL secretion by triggering a decrease in DA secretion. This is especially interesting, as the same SCN outputs appear to trigger an increase in release of GnRH at this time.

Another important part of the mechanism generating circadian rhythms of PRL release may involve rhythmic mechanisms intrinsic to DA neurons. One of the more exciting recent developments relating to rhythms in prolactin is the discovery in female rats, of rhythms in PER1 and PER2 in several populations of cells that contain TH. In the PHDA neurons, Sellix et al. (2006) found a PER1 rhythm with a peak that occurred at ZT 12, and a PER2 rhythm that peaked between ZT 6 and ZT 12. In the THDA neurons, Sellix et al. (2006) found a PER2 rhythm in cells with a peak between ZT 6 and ZT 12; PER1 was present in this group of cells, but was not rhythmic in them. In the TIDA neurons, which are most important for the regulation of prolactin secretion, PER1 peaked at ZT18, and PER2 was highest at ZT 6 and 12 (Sellix et al., 2006). Another study of clock mechanisms in TH neurons, combined TIDA and THDA cells for analysis of PER1 protein and found significantly higher levels in female mice euthanized at ZT 10 than at ZT 22 (Kriegsfeld et al., 2003).

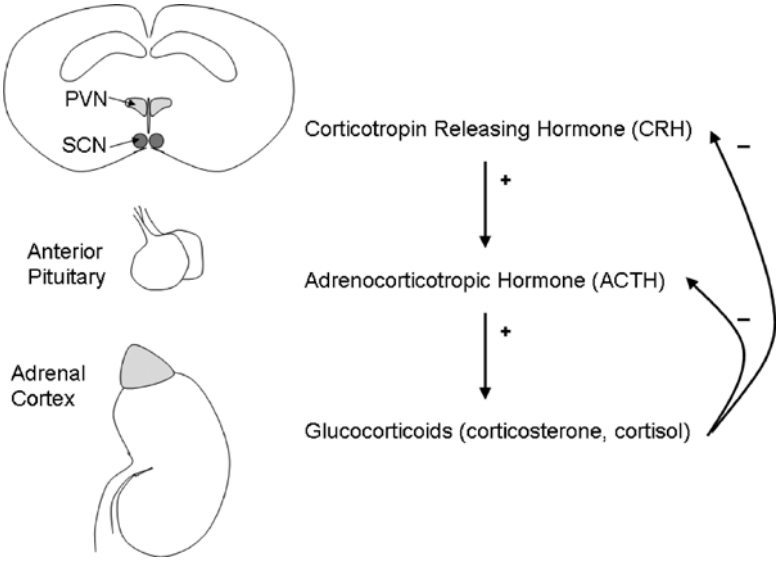
5 Circadian Rhythms in the Hypothalamic–Pituitary–Adrenal Axis

Activation of glucocorticoids by stressful stimuli is an adaptive mechanism that serves many functions (Sapolsky et al. 2000). The underlying circadian pattern of the hypothalamic–pituitary–adrenal (HPA) activity keeps this system in tune with the environment. Chronically elevated glucocorticoid levels, however, can have detrimental effects on an organism and change its response to novel stressors. Species typically produce predominantly either corticosterone or cortisol (CORT) from the adrenal cortex, although a few produce both. Interestingly, chronically elevated CORT levels and circadian or sleep disturbances tend to coexist in a myriad of human diseases. The following section outlines the basic features of the HPA axis, anatomy and interactions with the circadian axis, which when disrupted correlates with many stress-related disorders. Chapters 13, 14, and 15 examine the stress axis in much greater detail. The focus of this section is on its relationship with the circadian axis.

In response to stressful or challenging stimuli (henceforth referred to as "stressors"), the activity in the sympathoadrenal system (SAS) and HPA-axis is increased. The SAS releases norepinephrine and epinephrine at synaptic terminals and into the bloodstream, respectively, and is largely responsible for the initial, so-called "fight or flight" response to a stressor. The HPA-axis is also activated, and has the potential to lead to more long-lasting effects. Chronic exposure to the same stressor can result in an inhibited CORT and ACTH response (e.g., habituation) compared to those of stress-naive animals

Figure 23-3

The mechanism by which the daily circadian release of glucocorticoids is controlled by the SCN. The SCN projects to the PVN which releases corticotrophin-releasing hormone (CRH) into the portal vasculature to cause the release of adrenocorticotropic hormone (ACTH). ACTH, in turn, controls the release of corticosterone/cortisol from the adrenal cortex. The glucocorticoids have a negative feedback effect at the pituitary and PVN, as well as effecting other brain areas not shown in the diagram



(Dobrakovova et al., 1993; Campmany et al., 1996; Bhatnagar et al., 2002; Bhatnagar et al., 2004; although see Pitman et al., 1988). Habituation following chronic stress, however, is coupled with an enhanced response (facilitation) to novel heterotypic stressors (Bhatnagar and Meaney, 1995; Bhatnagar and Dallman, 1998; Johnson et al., 2002); a more robust CORT and ACTH response is observed following acute presentation of the novel stimulus (Scribner et al., 1991; Bhatnagar and Dallman, 1998). The sympathoadrenal system also appears to be modulated by chronic stress (Dobrakovova et al., 1993; Terrazzino et al., 1995).

Activation of the HPA-axis by a stressor results in release of CRH from the PVN of the hypothalamus, and CRH then stimulates the pituitary to secrete adrenocorticotropic hormone (ACTH). Hypothalamic AVP release tends to enhance this response (Antoni, 1993) while oxytocin tends to suppress it (Swaab et al., 2005). ACTH then stimulates the adrenal cortex to release glucocorticoids. Under normal conditions, the resulting increase in CORT then feeds back at the level of the hypothalamus and pituitary to down-regulate production and release of CRH and ACTH, thus ultimately slowing its own production (Ziegler and Herman, 2002).

Glucocorticoids exert their effects by binding to mineralocorticoid (MR, or Type 1) and glucocorticoid (GR, or Type 2) receptors (De Kloet et al., 1998). Low, basal levels of CORT result in only activation of MR, for which CORT has a higher affinity, to regulate metabolism. The heightened levels of CORT, induced by stress, tend to result in activation of GR, allowing an organism to respond to the stressor by mobilizing glucose and suppressing energetically costly functions that are not of immediate importance, such as immune function and some reproductive functions (Sapolsky et al., 2000; Charmandari et al., 2004). When the HPA axis has been activated repeatedly for prolonged periods of time, a suite of serious health problems can develop. In addition, further glucocorticoid release can become resistant to suppression via negative feedback.

5.1 Anatomy of the HPA Axis

The PVN receives direct, excitatory input from the brainstem (McKellar and Loewy, 1981; Cunningham and Sawchenko, 1988). These projections are catecholaminergic in nature, with norepinephrine stimulating the hypophysiotrophic cells of the PVN (Itoi et al., 1994; Itoi et al., 1998). This allows for a fast HPA response to so called "systemic stressors," challenges that present an immediate, physical threat to homeostasis.

The PVN also receives indirect input from a number of limbic system structures, including the hippocampus and amygdala (Herman, et al., 2003). These limbic inputs are thought to be involved in activation of "processive" stressors (Herman and Cullinan, 1997). These are the "psychological" stressors that are learned through experience, such as fears and anxieties related to potential threats. The dominating presence of GRs in the hippocampus (Han et al., 2005) makes that brain area a likely player in the process of glucocorticoid negative feedback to the PVN.

Inputs from hypothalamic areas, including the BNST (Cullinan et al., 1993, 1996), medial preoptic area (MPOA) (Cullinan et al., 1996), subparaventricular zone (Roland and Sawchenko, 1993), and SCN (Watts et al., 1987) are also present in the PVN. The BNST both excites and inhibits the HPA axis via GABA synapses in the PVN (Herman and Cullinan, 1997). The BNST also acts as a relay station to the PVN (Herman et al., 2005), receiving innervation from limbic and brainstem nuclei that influence PVN activity (Weller and Smith, 1982; Cullinan et al., 1993). The MPOA, providing inhibitory input to the PVN (Cullinan et al., 1996; Viau and Meaney, 1996), is a likely point of interface for the HPA and HPG axes, thus allowing for integration of the reproductive and stress systems. The subparaventricular zone contributes GABAergic inhibition to the PVN (Roland and Sawchenko, 1993) and, being a recipient of input from the SCN (Abrahamson and Moore, 2001), is likely to play a role in circadian regulation of the HPA axis. The SCN innervates a number of other hypothalamic nuclei that also receive input from the PVN (Cullinan et al., 1996; Abrahamson and Moore, 2001) and also projects directly to the parvocellular PVN (Boudaba et al., 1996; Abrahamson and Moore, 2001).

The thalamus also provides important input to the PVN. Sensory information is relayed through thalamic nuclei to provide stress-related information to the PVN. Through projections to the PVN, the posterior paraventricular nucleus of the thalamus (PVTh) plays a role in HPA response to chronic stress (Bhatnagar and Dallman, 1998), and provides another mechanism of circadian control of the HPA axis.

5.2 Daily Rhythms in the Adrenal Axis

The HPA axis provides an excellent example of the hierarchical control of circadian rhythms (e.g., Aschoff, 1981; Moore-Ede et al., 1982; Panda and Hogenesch, 2004). On the one hand, the adrenal gland appears to generate its own rhythms that are then entrained by the SCN. The rhythm in adrenal secretion of CORT appears to act, in turn, as a zeitgeber for other peripheral organs, such as the liver, without having a feedback effect on the SCN (Balsabore et al., 2000; LeMinh et al., 2001; Gachon et al., 2004).

5.2.1 The Circadian Adrenal Gland

The adrenal gland was the first tissue outside the SCN in mammals that was reported to have the ability to oscillate independently. The earliest direct evidence that the adrenal cortex produced endogenous circadian oscillations was provided by adrenal glands cultured in vitro for several days. These glands maintained a nearly 24 h period of CORT release into the culture medium for several days (Andrews and Folk, 1964; Andrews, 1968; Shiotsuka et al., 1974). Subsequently, Moore and Eichler (1972) demonstrated a dramatic dampening of the circadian pattern after SCN lesions, suggesting that, at least in vivo, the adrenal circadian rhythm requires an input of circadian information from the SCN. However, as Davidson et al. (2005) point out, these early conclusions of dependence upon the brain for rhythmicity may have been erroneous, since they were based on the averaged data from groups of animals whose adrenal glands could have produced

free-running rhythms following SCN lesions. Moore and Eichler (1972) also collected blood samples at only four times each day, so that even the individual rhythms of the animals might have looked dampened if not collected before a free-running rhythm emerged.

Recent studies using mouse knockins of luciferase attached to the clock genes *mPer1* or *mPer2*, have demonstrated that many peripheral tissues have strong circadian oscillations in vivo and in vitro (Yamazaki et al., 2000; Yoo, et al., 2004; Ishida et al., 2005). The protein produced by the gene construct can be visualized by the bioluminescence of the luciferase when exposed to an appropriate light source. Yamazaki et al. (2000) found that the oscillations of mPer1:luciferase in peripheral tissues (liver, lung, and skeletal muscle) dampened after only 2–7 days in culture while the SCN continued to oscillate for 32 days. The same laboratory subsequently found that the peripheral oscillations last as long as do the SCN oscillations when a mPer2:luciferase construct is monitored rather then Per1 (Yoo et al., 2004). It is unclear why the clock gene used should make such a difference, but the only laboratory to recently report on adrenal clock gene activity used the mPer1:luciferase construct (Ishida et al., 2005). They found that light was able to induce *mPer1* and *mPer2* only in the cortex of the adrenal gland. When animals were housed in DD, the circadian rhythm of Per1 bioluminescence persisted. Not surprisingly, when the animals had their SCNs lesioned, light no longer elicited a rapid increase in Per. However, they did not examine whether SCN-lesioned animals continued to express a daily bioluminescence rhythm of Per in the adrenal cortex (or CORT secretion) in individual animals. Thus, although the technology is available to answer the question of whether the adrenal cortex oscillates endogenously, the current data leave that question open for future research.

It seems likely that the adrenal gland is capable of producing endogenous oscillations, as many of the tissues outside the brain that express clock genes are able to continue oscillating for an extended time. Those tissues now include cornea, pituitary, liver, kidney, and lung (Yoo et al., 2004). Additionally, CORT rhythms seem capable of re-setting the period of clock genes in several peripheral tissues acting through GR, including liver, kidney, and heart (Balsalobre et al., 2000; LeMinh et al., 2001). Thus, whether the adrenal is capable of oscillating independently is still an open question that deserves attention.

5.2.2 Circadian Control of HPA Axis

The HPA axis is tightly regulated by the circadian system under stable entrained conditions. There is an underlying rhythm to the production of CRH, ACTH, and CORT (Ixart et al., 1977; Kaneko et al., 1981; Atkinson and Waddell, 1997), and this rhythm differs between chronotypes. Nocturnal species typically reach peak glucocorticoid levels just before lights-off (Ixart et al., 1977; D'Agostino et al., 1982; Muglia et al., 1997); diurnal animals' glucocorticoid levels peak around the time of lights-on. This rhythm of glucocorticoid secretion is controlled by the rhythm of ACTH (review by Panda and Hogenesch, 2004). In nocturnal rodents, vasopressin release from the SCN appears to exert inhibitory control upon the HPA-axis, which could reflect part of a mechanism by which the SCN entrains oscillators in the adrenal gland that generate rhythms in CORT secretion (Kalsbeek et al., 1992).

The adrenal gland also appears to receive information from the SCN via sympathetic brainstem nuclei (Buijs et al., 1999). This raises the possibility that the SCN might influence CORT secretion in a manner that is independent of the HPA axis. While the basic rhythm in CORT secretion appears to be driven by the pattern of ACTH release, there may also be a contribution from the sympathetic nervous system (England and Arnhold, 2005).

5.2.3 Circadian Disruptions Elicit Stress Responses

Alterations of the LD cycle, typical of transmeridian travel or shift-work, can result in increased glucocorticoid secretion in a number of species (Cho et al., 2000; Leproult et al., 2001; Sei et al., 2003; Ishida et al., 2005). In lab rats, light can also suppress adrenal function more directly, in a manner independent of the circadian system (Buijs et al., 1999). In contrast to findings from mice, in which a light pulse stimulated an

increase in CORT secretions (Ishida et al., 2005), Buijs et al. (1999) found a suppression of CORT in rats when light was presented close to the onset of darkness (ZT14). Interestingly, both sets of investigators attributed the change in glucocorticoid levels not to HPA activation, but to sympathetic innervation of the adrenal by the SCN (Buijs et al., 1999; Ishida et al., 2005).

Data from human studies provide support for an interaction between disruption of the circadian system and alterations in HPA functioning. Both, long-term transmeridian travel (Cho et al., 2000) and exposure to a light pulse (Leproult et al., 2001), result in elevated CORT levels. However, in one study, a phase-shift failed to produce statistically significant increases in mean CORT levels, although a trend towards such, as well as an abbreviated quiescent period, was observed (Caufriez et al., 2002). Additionally, desynchrony of the rhythms of ACTH and cortisol following a shift in the LD cycle (Desir et al., 1981) further suggests that circadian manipulations can have an effect on the human HPA axis.

The rodent literature points to a link between glucocorticoid activation and recovery time following a photic phase-shift. The time it takes female rats to reentrain following a shift in the LD cycle is positively correlated with their CORT reactivity under entrained conditions (Weibel et al., 2002). This suggests that HPA activation resulting from the phase-shift could be contributing to interindividual variability in reentrainment rate. This hypothesis is further supported by the finding that adrenalectomy can accelerate reentrainment (Sage et al., 2004).

5.3 Glucocorticoids Affect Circadian Rhythm Expression

There is a large body of evidence supporting a role for glucocorticoids in the timing of circadian systems. Glucocorticoids can induce mouse *Per1* expression in a number of peripheral tissues (Balsalobre et al., 2000; Yamamoto et al., 2005), but not the SCN (Balsalobre et al., 2000). Although it has been thought that the SCN is insensitive because of a lack of GR (Rosenfeld et al., 1988, 1993), we have recently labeled cells with GR in both the ventral–lateral and dorsal–medial SCN of rats and found that a light pulse during the night elicits c-FOS expression within those GR-containing cells (Lee and Mohawk, unpublished data). In addition, there is induction of cFOS in the SCN following glucocorticoid administration (Briski et al., 1997). CRH-deficient mice lack the normal rhythm of μ-opioid receptor expression in the brain, and this rhythm can be reinstated by administration of exogenous CORT (Yoshida et al., 2005). Together, these data suggest that the circadian rhythm of CORT may act as a zeitgeber for both peripheral tissues and for some CNS structures, and may influence SCN function.

The effects of stress on a stable (entrained or free-running) circadian system do not appear to be robust, as it does not result in altered free-running period (Barrington et al., 1993; Meerlo et al., 1997). However, stress can have a reliable effect on another important parameter of a circadian rhythm, its amplitude. Decreases in the amplitude of body temperature rhythms in rats have been seen following both social stress (Meerlo et al., 1997) and footshock (Kant et al., 1991). Chronic, intermittent cold stress can also decrease the amplitude of body temperature rhythms in rats (Bhatnagar and Dallman, 1999). Surgical stress increases rats' heart rates and the amplitude of their body temperature rhythms (Harper et al., 1996). There is also minimal evidence of an ability of stress and glucocorticoids to affect phase angle of entrainment. Injection of dexamethasone, a glucocorticoid agonist, has been shown to have some effect on the entrained phase angle in free-running rats; however, dexamethasone was only effective at high doses (Horseman and Ehret, 1982). Restraint stress does not have an effect on the phase angle of entrainment of locomotor activity rhythms in rats (Barrington et al., 1993) or mice (Yamamoto et al., 2005), but has been shown to cause phase delays in rhythms of free-running hamsters (Van Reeth et al., 1991; Rosenwasser and Dwyer, 2002).

5.4 Glucocorticoids Alter Recovery from Phase Shifts of the Light Cycle

In contrast to the minimal effect of CORT on entrained circadian rhythms, it appears to have a major impact on the rate of recovery from shifts in the LD cycle. We found that recovery of locomotor activity

synchronization is altered by restraint stress in the diurnal rodent *Octodon degus* (degu) and the nocturnal rat. Sixty minutes after the new lights-on, animals underwent 60 min of restraint stress. The number of days it took each animal to reentrain its activity rhythms to the new LD cycle was recorded and compared to the number of days it took the animal to reentrain under control conditions. When subjected to restraint stress, degus and rats took 20–30% longer to reentrain their activity rhythms than did controls that also experienced the shifted light cycle, but not the restraint stress (Mohawk and Lee, 2005; Mohawk, 2006). In a second experiment, suppression of the CORT response in the diurnal degu with either a daily injection of metyrapone (blocks synthesis of CORT from progesterone) or dexamethasone (blocks CORT by negative feedback) for the first five days after the shift in the LD cycle, decreased the number of days required to recover stable entrainment by 33% (Mohawk et al., 2005). We also found that on the third day after the shift in the light cycle, CORT levels were elevated relative to the previous baseline.

We subsequently conducted a series of experiments to examine the immediate HPA axis response to a phase shift, with and without concurrent restraint stress (Mohawk, Pargament and Lee, submitted). We measured CORT and ACTH release in male rats exposed to light, occurring 6 h before the normal lights-on (ZT18). A light pulse resulted in increased CORT and ACTH, and restraint (in the dark) or light (without restraint) induced the same rise in CORT. Interestingly, CORT released in response to both stressors presented simultaneously was approximately 40% greater than the response to either stressor alone. These data support the hypothesis that a photic phase-shift elicits an HPA response, in addition to any sympathetic immediate light-induced effect on the adrenal cortex (Ishida et al., 2005). The magnitude of this rise may play a role in recovery of normal circadian entrainment after destabilization, suggesting that either CORT has an impact on SCN function in this state, or that recovery of stable entrainment of activity, feeding and other endocrine rhythms outside the CNS may be slowed by the need to integrate the signals from the SCN and the adrenal.

Humans experiencing circadian desynchrony suffer from a variety of symptoms (Winget et al. 1984; Katz et al., 2001), which are commonly correlated with glucocorticoid activation (Stephens, 1980; Munck et al., 1984). It could be that the change in the LD cycle itself, as supported by the data presented herein, is partly responsible for the change in glucocorticoid levels and resulting symptoms. Keeping CORT levels constant following an LD shift may result in faster recovery of normal entrainment for humans, as it does in rodents (Sage et al., 2004; Mohawk et al., 2005). The additive effect of restraint and light on CORT levels leads us to speculate that keeping stress at a minimum around the time of a phase-shift could be important for health and reestablishing normal circadian entrainment. It may be possible to employ pharmacological manipulation to reduce CORT to improve entrainment of shift-workers and recovery of transmeridian travelers.

6 Conclusion

The timing of a variety of daily behaviors is controlled directly or indirectly by the SCN. Some behaviors, such as activity or wake cycles and changing EEG patterns during sleep, are controlled primarily be neural outputs from the SCN. However, a variety of behaviors are dependent upon the endocrine state of the animal. In addition to responses to destabilizing events (such as a sudden ingestion of food) that restore homeostasis, most endocrine glands also demonstrate stable circadian release patterns that anticipate daily changes in the behavioral needs of the animal. In this chapter, we discussed four such rhythms that have wide ramifications on behavior and physiology: melatonin, GnRH/LH, prolactin, and glucocorticoids.

Exactly how the circadian mechanism communicates with these neuroendocrine systems has slowly come into focus, with the control of melatonin being best understood. There are still several pieces of information that are unknown. To what extent does each of the secretory cells oscillate independently of the SCN, and are they synchronized by the SCN rather than being passively driven? Clearly, in mammals, the pineal gland has become a completely passive organ; however, the same is not at all clear for GnRH cells, the pituitary, or adrenal cortex. Davidson et al. (2005) argue that most tissues outside the brain that have oscillating clock genes are likely able to oscillate independently, but that the SCN normally maintains the internal synchrony between these tissues and the outside world. Others see this as less likely for the

endocrine system than for peripheral tissues that can be synchronized by endocrine tissues (Buijs and Kalsbeek, 2001; Schibler and Brown, 2005). They suggest that the abdication of endogenous oscillation by the pineal might also be true for other endocrine tissues. The research tools are available that allow us to determine which hypothesis is correct.

Lastly, it is important to take note that the maintenance of stable entrainment is no longer unidirectional. That is, while the SCN does act as a conduit for light-controlled circadian rhythms, the oscillations generated throughout the body have an impact on SCN function. Melatonin can be used to entrain circadian rhythms, and the finding of receptors in the SCN of animals sensitive to such entrainment suggests that such feedback may be important. Estrogen released as a function of circadian stimulation of GnRH neurons alters some clock gene-related activity and connections among cells within the SCN at the same time that behavior is altered on the day of estrus. Elevated glucocorticoids during recovery from a light-induced circadian disruption may compete with the SCN for control of peripheral tissues, thereby extending the period of desynchrony. Thus, the stability of circadian neuroendocrine rhythms is the result of a network of bi-directional information between the SCN and the endocrine glands.

Acknowledgements

We wish to acknowledge the assistance of Dr. Megan Mahoney, Dr. Daniel Hummer and soon to be Dr. Jennifer Mohawk, without whose data and assistance this chapter would never have been completed. The authors were supported by NIMH: MH05333 (LS), NSF: IBN-0130977 (LS), NIMH: MH069518 (TML), NSF: IBN-0212322 (TML).

5 Questions for Future Research 884

Abstract: Neurophysiological and neurochemical mechanisms regulating wakefulness and sleep are reviewed. Wake-active brain areas include the noradrenergic locus coeruleus, the serotonergic dorsal raphe, the dopaminergic ventral tegmental area, cholinergic cells in pontomesencephalic nuclei and basal forebrain (BF), the histaminergic posterior hypothalamic area, and the hypocretin/orexin cells in the lateral hypothalamus. Glutamate is also an important mediator in waking mechanisms. Sleep-active neurons have been found in the ventrolateral preoptic hypothalamic region, and are GABA/galaninergic. These neurons inhibit waking mechanisms. Adenosine is an important homeostatic regulator of sleep, acting on BF neurons to induce sleep. NO production in the BF forebrain through induction of inducible NO synthase has been found to be part of the regulation of recovery sleep after sleep deprivation, involving also local adenosine release. NO influences sleep regulation also through other brain areas. Prostaglandins released in the leptomeninges may also induce sleep through adenosinergic mechanisms. Future research should include studying the role of glial cells in sleep regulation. Also, sleep need is use-dependent, depending especially on cortical neuronal activity, but it is not yet known how this information is conveyed to the homeostatic regulatory mechanisms in the BF.

List of Abbreviations: ACh, acetylcholine; AD, adenosine; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, a glutamate agonist; ARAS, ascending reticular activating system; BF, basal forebrain; CRH, corticotropin-releasing hormone; CSF, cerebrospinal fluid; DPR, D type of prostanoid receptor, PGD_2 receptor; DR, dorsal raphe; EEG, electroencephalogram; GABA, gamma-aminobutyric acid; GHRH, growth hormone-releasing hormone; 5-HT, 5-hydroxytryptamine, serotonin; Hcrt, hypocretin = orexin; IL-1, interleukin-1; KO, knockout; LC, locus coeruleus; LDT, laterodorsal tegmental nucleus; L-NAME, NG-nitro-L-arginine methyl ester, a NOS inhibitor; MAO, monoamino-oxidase; NMDA, N-methyl-D-aspartic acid, a glutamate agonist; NOS, nitric oxide synthase (nNOS, eNOS, iNOS); NREM, non-REM (sleep); OX, orexin = hypocretin; PCPA, para-chlorophenylalanine; PGD, prostaglandin, e.g. PGD_2; PGO waves, ponto-geniculo-occipital waves; PPT, pedunculopontine nucleus; PVN, paraventricular nucleus; R, used for receptor (e.g., OX_2R, $5HT_{1A}R$); REM, rapid eye movements (sleep); SCN, suprachiasmatic nucleus; SN, substantia nigra; SWS, slow wave sleep (part of NREM sleep); TM, tuberomamillary; TNFα, tumor necrosis factor alpha; VLPO, ventrolateral preoptic nucleus; VTA, ventral tegmental area

1 Introduction

1.1 What is Sleep?

Sleep is a physiological state during which the subject's ability to react to external stimuli is considerably diminished. Sleep in vertebrates is defined as a specific pattern of electric activity of the brain cortex as measured by electroencephalogram (EEG). During waking, the cortical activity is desynchronized resulting in low-amplitude, high-frequency EEG. On falling asleep the cortical activity gets synchronized, and the amplitude of the EEG waves increases, while frequency decreases (*Figure 24-1*). Sleep consists of two main phases: nonREM (NREM) and REM sleep. NREM is the quiet sleep phase during which EEG waves are high and low-frequent, and depending on species, it is further divided to 2–4 stages (e.g., in humans S1, S2, S3, and S4) describing the intensity of NREM sleep. REM sleep is characterized by high-frequency and low-amplitude EEG (as in waking), but muscle tone, which is high in waking, and decreased in NREM sleep, is further decreased. In the course of night, these states alternate regularly in a highly regulated and composed manner constituting the sleep cycles.

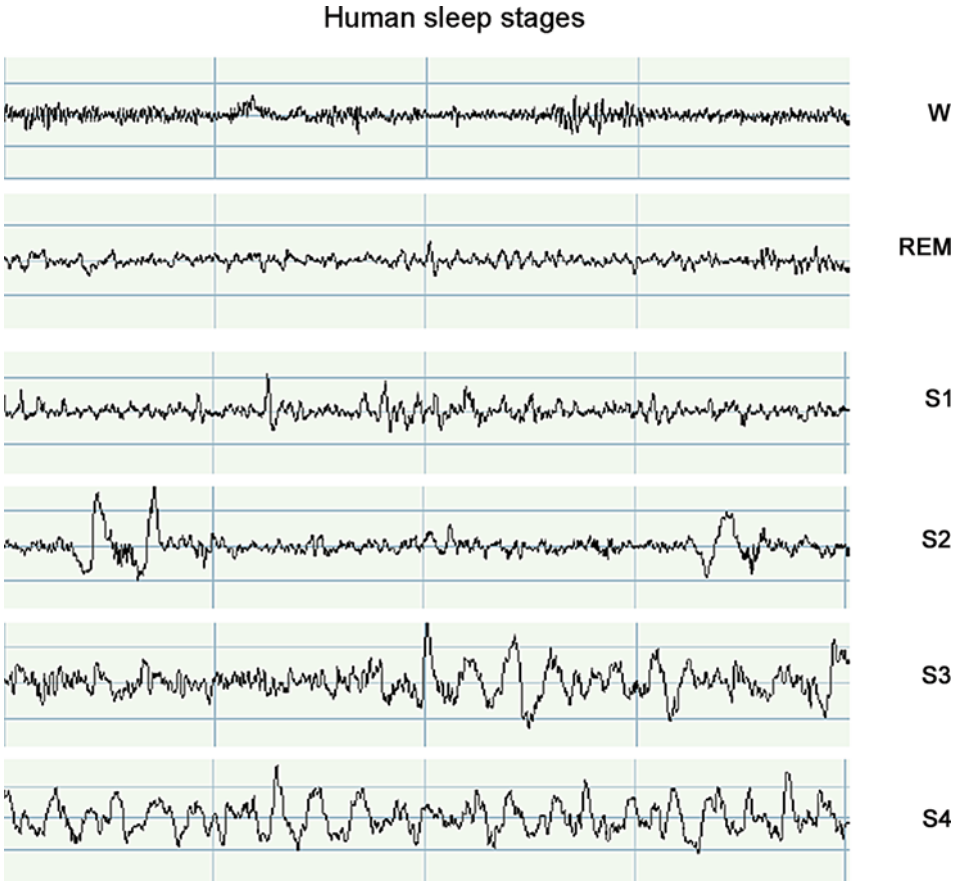
Sleep is homeostatically regulated, which means that a prolonged period of wakefulness is followed by a prolonged period of sleep (Borbély, 1982). The neural substrate(s) and the molecular correlates of sleep, and sleep regulation have been a subject for systematic research for less than 50 years. Considering this, we have managed to reach a considerable understanding of these mechanisms.

1.2 The Emergence of Neurochemistry of Sleep and Wakefulness

The neuroanatomical substrates of sleep–wake regulation were largely known even before contemporary neurochemistry revealed the transmitters involved. The influenza pandemic of 1917–1919 not only killed

Figure 24-1

Human sleep stages. The EEG wave amplitude increases from waking through the sleep stages S1–S4 being largest in stages S3 and S4 (=slow-wave sleep). The frequency of the wave decreases simultaneously. During REM sleep the EEG gets desynchronized as in waking, and is characterized by low-amplitude and high-frequency waves



tens of millions of people, but also left some patients in a sleep-like coma, encephalitis lethargica. In a series of studies, von Economo described autopsy findings from these patients (von Economo, 1923, 1930). Loss of viable neurons was found in the posterior hypothalamus and the rostral mesencephalic area. These areas were thus concluded to be necessary for waking, and this view has held. Some patients, on the other hand, displayed insomnia, and their lesion was in the anterior hypothalamus and preoptic area, still considered major sleep-inducing areas.

A major leap was the discovery by Moruzzi and Magoun (1949) that electrical stimulation in cats of the mesencephalic region called "reticular formation" induced waking, and its lesion led to constant sleep. For these studies, a crucial technique was the EEG, first described in animals by Caton (1875) and in further detail in humans by Berger (1929). Although arousal was signaled by low-amplitude fast waves, sleep was characterized by high-amplitude slow waves. The area whose stimulation led to EEG arousal was termed the "ascending reticular activating system" (ARAS), and was assumed to be activated by collaterals of sensory input signals, but lesion studies soon showed that interruption of the afferent sensory input did not prevent the wakefulness, whereas destruction of the ARAS did (Lindsley et al., 1950). Sleep was initially seen simply as deactivation of the ARAS (passive sleep theory), either through fatigue or through the accumulation, during wakefulness, of some unknown chemical substances.

The accumulation in the brain of some sleep-inducing substance(s) was proposed independently by Ishimori (1909) and by Legendre and Piéron (1910). CSF (Legendre and Piéron, 1910) or brain homogenate (Ishimori, 1909) from sleep-deprived dogs was found to induce sleep in recipient animals. As ultrafiltration or heating destroyed the somnogenic action of CSF, the "hypnotoxin" was assumed to be a protein (Legendre and Piéron, 1911). This concept of thinking about sleep regulation and the pioneering findings preceded the modern analysis of sleep-inducing substances, pursued, e.g., in the laboratories of Pappenheimer (Pappenheimer et al., 1975), Krueger (Krueger, 1985), and Inoue (Honda et al., 1984).

Chemical mediation in synapses was not a concern of the physiologists at that time. Since the publication of the evidence that acetylcholine (ACh) acts as a mediator of nerve impulses in the heart (Loewi, 1921), the concept of chemical synapses was soon extended to efferent transmission in both the autonomic and the somatic peripheral nervous system (Dale, 1936). Dale had pointed out that acetylcholine could have different actions at different synapses (muscarinic and nicotinic) (Dale, 1914). He mentioned that the basal ganglia are rich in acetylcholine, predicting a possible chemical mediation even in the central nervous system (Dale, 1936). It was finally recognized that acetylcholine has a role in the CNS and that it affects excitability (Feldberg, 1950; Hughes and Robinson, 1951; Hebb, 1957). If the ARAS maintained waking, sleep could then result from the depletion of acetylcholine. Gamma-aminobutyric acid was later proposed as an inhibitory transmitter (Purpura et al., 1957; Krnjevic and Schwartz, 1966), but not linked to the induction of sleep.

Noradrenaline was shown to be the peripheral sympathetic neurotransmitter (von Euler, 1946), and subsequently effects of catecholamines on the CNS were described (Kety, 1959; Rothballer, 1959). The breakthrough for the concept of multiple central neurotransmitters was the demonstration of catecholamine-containing cell bodies in the brain, by use of the histofluorescence technique (Dahlström and Fuxe, 1964). By placing lesions at various levels of the brain, Ungerstedt was able to map the projection systems of the dopaminergic and noradrenergic systems (Ungerstedt, 1971). The glyoxylic fluorescence technique allowed mapping without making lesions (Lindvall and Björklund, 1974). The complexity of systems and pathways projecting from the brain stem to the forebrain became apparent.

1.3 The General Structure of the Wakefulness/Sleep System

The passive sleep theory is not entirely compatible with the structure of normal sleep, which consists of sleep cycles as sign of active regulation of sleep stages. Recently, it has also become evident that in addition to nuclei that maintain wakefulness, we also have brain areas where cells are more active during sleep than during waking.

The structures of the waking promoting/maintenance system and that putting us to sleep have interesting differences. The waking system consists of several clearly defined nuclei in the midbrain and the pons, with specific neurotransmitters and long projections that reach virtually all parts of the brain (*Figure 24-3*). Neuronal activity in these nuclei is high during waking and decreases during NREM sleep.

The sleep-active neurons lie in the preoptic area and ventrolateral preoptic nucleus (VLPO) of the hypothalamus (Sherin et al., 1996). Analogously with the waking system, also these neurons send widespread projections to distant brain areas, and notably to the wakefulness-regulating nuclei. This structure implies a reciprocal inhibition model for regulation of sleep and wakefulness: during waking the waking-promoting nuclei inhibit the sleep-active neurons and vice versa. An interesting difference from the waking system is that there are several potent sleep-inducing molecules, which originate from diffuse brain structures, and not necessarily only from neurons. These substances have known roles in energy metabolism [e.g., adenosine (AD) and NO], immune function (e.g., cytokines and NO) and hormonal regulation (e.g., GHRH). Whether these molecules act through the sleep-active cells, or by inhibiting the wake-active cells, is presently under investigation.

2 Neurochemistry of Waking

2.1 The Noradrenergic System in Sleep–Wake Regulation

Noradrenaline-containing neurons have their cell bodies in the pons and medulla, in cell groups designed A1–A7, as they did not conform to previously identified anatomical nuclei (Dahlström and Fuxe, 1964).

The major cell group is A6 in the dorsomedial pons, called the locus coeruleus (LC). A4 is close to A6. Also in the pons are the dorsolateral A7 and the ventrolateral A5. In the medulla, A1 is found ventrolaterally and A2 dorsomedially. The noradrenergic cell groups form two projection systems: a dorsal fiber bundle from the locus coeruleus group including A6 and the adjacent A4, projecting to the thalamus, cerebellum, entire neocortex and hippocampus, and a more ventral projection from A1, A2, A5, and A7 to the hypothalamus and preoptic areas (Moore and Bloom, 1979).

Most studies on noradrenergic involvement in sleep have been on neurons in the LC and its immediate vicinity. The firing of LC neurons is state-dependent, decreasing during periods of drowsiness and transitions into sleep (Chu and Bloom, 1974). The bulk of LC neurons fire most intensely in waking, more slowly during slow wave sleep, and cease firing during REMS (Aston-Jones and Bloom, 1981a). Furthermore, changes in their firing rate anticipate the change in vigilance state, pointing to a state-regulatory role. Their activity appears reciprocal to that in neighboring cholinergic cell groups (Hobson et al., 1975).

By comparing the results of pharmacological manipulations and localized brain stem lesions, Jouvet concluded that slow-wave sleep (SWS) and paradoxical (REM) sleep are regulated by different mechanisms, and that tonic and phasic components of REM sleep are also separately regulated, by monoaminergic and cholinergic mechanisms (Jouvet, 1967). Further studies implicated noradrenaline, possibly together with acetylcholine in the maintenance of tonic cortical arousal, and the locus coeruleus area as crucial for the induction of paradoxical (REM) sleep (Jouvet, 1972). It appeared, however, that the effects of lesions are not permanent, but are compensated with time, indicating a more modulatory than imperative role of noradrenaline on sleep–wake states (Jones et al., 1977).

Within waking, LC neuronal firing increases in response to novel sensory stimuli (Foote et al., 1980; Aston-Jones and Bloom, 1981b). Further study has shown that the LC is not only tonically more active during wakefulness, but also phasically activated by stimuli and by behavioral tasks involving selective attention (Rajkowski et al., 1994).

Stress responses are accompanied by increases in noradrenaline turnover and increased LC neuronal activity (Valentino and Foote, 1988). CRH neurons in the paraventricular nucleus (PVN) of the hypothalamus have an important projection to the LC, and intraventricular CRH increases the tonic activity of LC neurons (Valentino and Foote, 1988), as also direct microdialysis of CRH into the LC (Asbach et al., 2001). On the other hand, stress increases the noradrenaline release increases in the PVN, which further activates CRH release (Pacak et al., 1995). Such reciprocal stimulation might serve to increase stress responsivity during chronic or repeated stress, although otherwise repeated stress leads to development of some LC tolerance (Berridge and Waterhouse, 2003).

Noradrenergic projections act on target neurons via a multitude of membrane receptors (Berridge and Waterhouse, 2003). α_1 receptors act on the phosphoinositol system and increase intracellular Ca^{++}. α_2 receptors activate a G_i protein, decreasing cAMP. β_1 receptors act on a G_s protein, increasing cAMP. β_2 receptors have been found presynaptically on noradrenergic neurons and facilitate noradrenaline release from these.

Noradrenaline has a complex modulating effect on target neurons (Berridge and Waterhouse, 2003). In general, the spontaneous firing rate decreases, while the ability to react to afferent stimuli is enhanced, which increases the signal–noise ratio of the response. However, this effect follows an inverted U-type function, as the signal–noise improvement is maximal at a moderate noradrenaline concentration, and decreases with higher or lower noradrenaline. This relationship has been found in the thalamocortical projection cells, in the hippocampus, cerebellum, auditory, and visual cortices, etc. Both excitatory and inhibitory synaptic functions may be enhanced by noradrenaline.

In the context of sleep function, it is interesting that noradrenergic projections appear essential for the memory- and plasticity-related gene expressions (Cirelli and Tononi, 2004). Thus, noradrenaline release during alert wakefulness has a crucial role for the potentiation of synaptic plasticity related to experience and learning.

2.2 The Serotonergic System in Sleep–Wake Regulation

Cell bodies of serotonergic neurons are found in several nuclei in the brain stem midline (raphe), which can be divided into a rostral and a caudal group, depending on whether their projections are mainly ascending

to the forebrain or descending to the spinal cord. The rostrally projecting group (B4–B9) comprises the median raphe, pontine raphe, and dorsal raphe nucleus (DR, B7); whereas the caudally projecting group (B1–B3) includes nucleus raphe magnus and nucleus raphe pallidus (Dahlström and Fuxe, 1964). For sleep–wake regulation, DR is the most interesting.

The serotonergic influence on waking was initially thought to be inhibiting, as lesions or pharmacological depletion of serotonin caused insomnia (Jouvet, 1972), and stimulation of raphe nuclei induced behavioral inhibition during waking (Jacobs et al., 1973). This view was difficult to reconcile with studies on unit activity. Like LC neurons, serotonergic DR neurons fire during waking at a regular slow rate of 2–3 spikes/s, more slowly in NREM sleep, and they cease firing in REM sleep (McGinty and Harper, 1976; Trulson and Jacobs, 1979). The neurons are stimulated by sensory stimuli (Trulson and Jacobs, 1979; Heym et al., 1982). Some neurons are activated by specific motor patterns during wakefulness (Jacobs and Fornal, 1991). Serotonin release at the terminals is in parallel with the firing rate, as shown by in vivo microdialysis (Jacobs et al., 1990; Portas et al., 1996). It thus appears that serotonin is released mainly during wakefulness. In addition, local cooling of DR induces NREM sleep and REM sleep, while suppressing waking (Cespuglio et al., 1976).

The early notion that serotonin opposed noradrenaline and favored sleep was favored by experiments showing that pharmacological depletion of serotonin with PCPA caused chronic insomnia (Jouvet, 1972). During this, sustained pontogeniculooccipital (PGO) wave activity supported the absence of serotonin (Petitjean et al., 1985). Repletion of serotonin with 5-HTP immediately caused the PGO waves to disappear, indicating resynthesis of serotonin, but only after a delay of 30 min did NREM sleep, and after 1 h REM sleep reappear, pointing to a delayed action of serotonin. As the reappearance of REM sleep was inhibited by administration of chloramphenicol, it was deduced that at least in the case of REM sleep, the delayed action was mediated by a neurohormone (Jouvet, 1982; Petitjean et al., 1985). A similar indirect effect of serotonin on NREM sleep was also hypothetized.

Serotonin (5-hydroxytryptamine, 5-HT) receptors in the brain include the group of 5-HT_1 receptors (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}), which are mainly inhibitory through inhibition of adenylate cyclase, and the group of 5-HT_2 receptors (5-HT_{2A}, 5-HT_{2C}), which are mainly excitatory through the PLC system. Inhibitory autoreceptors are of the 5-HT_1 type. 5-HT_2 receptor antagonists induce SWS (Idzikowski et al., 1987; Dugovic and Wauquier, 1987), some also enhancing EEG slow waves (Landolt et al., 1999) and some not (Dijk et al., 1989). However, 5-HT_{2C} receptor knockout mice have more wakefulness, but also a greater response to sleep deprivation than wild-type mice, which indicates several roles for serotonin in sleep regulation (Frank et al., 2002) or might indicate adaptation in the knockout mice (Adrien et al., 2004).

5-HT_{1A} receptor agonists will inhibit DR neurons (Fornal et al., 1994) and have been shown to favor sleep in man (Seifritz et al., 1996), although large doses will increase waking and inhibit sleep (Monti and Monti, 2000). 5-HT_{1A} receptor antagonists, when infused into DR, will block inhibitory autoreceptors and increase DR activity (Bjorvatn et al., 1998). As suppression of DR activity is a prerequisite for REM sleep, local infusion of 5-HT_{1A} antagonist also suppresses REM sleep (Sorensen et al., 2000). Cataplexy, which resembles the atonia during REM sleep, is also suppressed by 5-HT_{1A} agonists in dogs (Nishino et al., 1995). Mice with a constitutional knockout of either 5-HT_{1A} or 5-HT_{1B} receptors have higher amounts of REM sleep than wild-type mice (Boutrel et al., 1999, 2002). In wild-type mice, either 5-HT_{1A} or 5-HT_{1B} agonist decreased and 5-HT_{1A} or 5-HT_{1B} antagonist increased REM sleep. Thus both receptor types contribute to REM sleep control. The REM sleep-depressing effect of the serotonin reuptake inhibitor citalopram is seen in wild-type and 5-HT_{1B} knockout mice, but not in the 5-HT_{1A} knockouts (Monaca et al., 2003). Serotonin transporter knockouts have increased REM sleep, maybe indicating decreased sensitivity of 5-HT_{1A} and 5-HT_{1B} receptors (Adrien et al., 2004). Monoaminoxidase A knockouts, again, have decreased REM sleep, comparable to the effect of MAO-A inhibitor drugs (Adrien et al., 2004). In constitutional knockouts, adaptive processes often make the interpretation of results complicated.

The serotonergic system is activated in conditions of stress. Considerable release of serotonin takes place in the hypothalamus during immobilization stress of the rat, which is accompanied by REM sleep rebound following an initial period of waking (Cespuglio et al., 1995). Combined with the fact that the immediate effects of serotonin activity is inhibition of sleep, and especially REM sleep, this has led to the concept of serotonin-stimulated events eventually leading to the release of sleep-promoting peptide factors

and rebound sleep (Jouvet, 1999). Such sleep-promoting peptides may include pro-opiomelanocortin-derived peptides (Cespuglio et al., 1995).

2.3 The Dopaminergic System in Sleep–Wake Regulation

Cell bodies of dopaminergic brain stem neurons are located in three areas: the substantia nigra (SN, A10), the adjacent ventral tegmental area (VTA, A9), and several small groups in the hypothalamus (A12, A13, A14). The ascending projections are part of the median forebrain bundle; and whereas SN projects mainly to the striatum, VTA projects to the cerebral cortex and basal forebrain (BF) (mesocortical and mesolimbic system). The hypothalamic nuclei have short connections within the hypothalamus and mainly control neurohormone output there and in the hypophysis (a well-known function is the inhibition of prolactin secretion).

The dopaminergic output from SN to striatum mainly facilitates motor activity. Dopaminergic output from VTA to nucleus accumbens is related to reward behavior. However, the neuronal unit activity of dopaminergic neurons in SN and VTA does not appear correlated to sleep–wake state as such (Trulson et al., 1981; Steinfels et al., 1983; Trulson and Preussler, 1984), whereas nondopaminergic neurons fire more during REM sleep and active movement (Miller et al., 1983). Dopaminergic neurons thus differ from other monoaminergic systems. It is also remarkable that a variety of stimuli are ineffective in affecting the firing rate of SN neurons (Strecker and Jacobs, 1985), whereas VTA neurons are significantly excited by stress (Trulson and Preussler, 1984). It would seem that the mesencephalic dopamine system is not primarily a sleep–wake-regulating system. Despite this, pharmacological manipulations cause important changes in vigilance (Monti, 1982; Wauquier, 1983), possibly because of the positive effects on affect and motor activity. Thus, nonspecific dopamine agonists like apomorphine at low doses favor sleep, while large doses prevent sleep. Corresponding opposite biphasic dose effects are seen with dopamine receptor antagonists (Monti, 1982).

2.4 The Cholinergic System in Sleep–Wake Regulation

Two groups of cholinergic neurons are of interest: a posterior one in the ponto-mesencephalic area (Ch5–6), and a rostral one in the basal forebrain (Ch1–4) (Mesulam et al., 1983). These cells are characterized immunohistochemically by their content of cholinacetyltransferase (ChAT) (Vincent and Reiner, 1987) (*Figures 24-2* and *24-3*).

2.4.1 Pontomesencephalic Nuclei

The laterodorsal tegmental nucleus (LDT, Ch6) is situated immediately medially from the LC, and lateral to the DR. The pedunculopontinenucleus (PPT, Ch5) is situated laterally to the LC, in the peribrachial area (and sometimes called area X). For many purposes, the LDT and PPT can be considered together, although LDT is more involved in muscle atonia during REM sleep, and PPT is more involved in the rapid eye movements.

The dendrites of LDT–PPT neurons extend into neighboring areas (Jones, 1990), and there is considerable reciprocal activity between the cholinergic cells and the noradrenergic and serotonergic ones. It is also apparent that sensory fibers ascending through the brain stem may influence LDT–PPT neurons. The major efferent projections are to the thalamus and into the hypothalamus and basal forebrain (Steriade et al., 1988; Jones and Cuello, 1989; Losier and Semba, 1993; Ford et al., 1995). The posterior cholinergic system thus innervates the rostral one.

Neurons in the PPT area were found to burst in advance to the PGO waves, which are related to REMs, and these neurons were assumed to be PGO wave generators (McCarley et al., 1978). In addition, many nonbursting (tonically firing) neurons in the LDT–PPT area were found to be most active either during

Figure 24-2
The anatomical localization of the basal forebrain (BF) and the ventrolateral preoptic nucleus (VLPO). In a horizontal section of a rat brain, the VLPO and BF are localized in the ventral part of the brain, close to each other. AC = anterior commissure

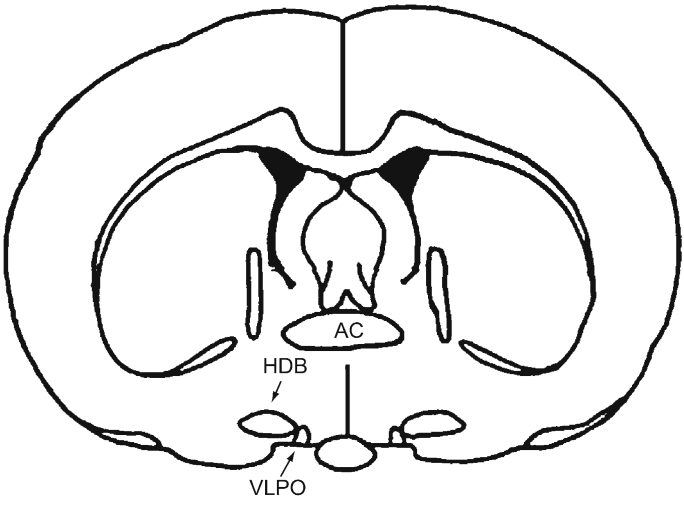


Figure 24-3
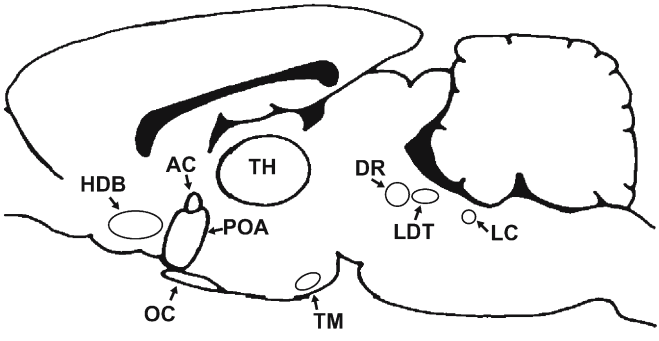
The localization of the waking active and sleep-active nuclei in the rat brain. Waking-active: LC = locus coeruleus, DR = dorsal Raphe nucleus, TM = tuberomamillary nucleus, LDT = laterodorsal nucleus; sleep-active: POA = preoptic area; HDB = horizontal limb of the diagonal band of Broca; TH = thalamus; OC = optic chiasm



REM sleep or both during waking and REM sleep; their activity increased before the EEG desynchronization (El Mansari et al., 1989; Steriade et al., 1990). This indicated a role for cholinergic brain stem neurons in thalamocortical activation which is different from the noradrenergic, serotonergic, and histaminergic neurons. All of these are active in waking, but silent in REM sleep. The effects on thalamic relay neurons consist in depolarization through both nicotinic and muscarinic receptors (McCormick, 1989), in addition to disinhibition through a hyperpolarization of reticular thalamic neurons (McCormick and Prince, 1986). A curious phenomenon is the production, by systemic administration of the muscarinic receptor blocker atropine, of slow waves and spindles in the EEG, while the animal is still awake (Bradley, 1968).

LDT–PPT neurons may be excited by local injections of glutamate, histamine, adrenaline and noradrenaline (Koyama and Sakai, 2000). Microinjections of glutamate at 0.3 and 1.0 μg into the LDT of cats

increased REM sleep without decreasing wakefulness, whereas 3.0 μg increased wakefulness at the expense of both NREM and REM sleep (Datta and Siwek, 1997). A similar dose-relationship was found for glutamate injections into the PPT of the rat (Datta et al., 2001b), and it was found that the cortical activation was mediated though NMDA receptors (Datta et al., 2001a), but REM sleep through kainate receptors, apparently excited by projections from glutamatergic neurons in the pontine reticular formation (Datta et al., 2002). In addition, microinjection of hypocretin/orexin (Hcrt/OX) into the LDT increased the time spent waking and decreased REM sleep in the cat (Xi et al., 2001).

Cholinergic neurons from LDT–PPT project to the medial pontine reticular formation (Shiromani et al., 1988). It has been shown earlier that injections of the cholinergic muscarinic receptor agonist carbachol into the pontine reticular formation induces long-lasting muscle atonia and other REM sleep-like signs in cats, whereas the effect is more variable and involves more brain stem areas in rats (Amatruda et al., 1975; Baghdoyan et al., 1984; Taguchi et al., 1992; Boissard et al., 2002). Carbachol activates G-proteins in the corresponding brain stem areas through several muscarinic receptor types (Capece et al., 1998), and M2 subtype receptors located both postsynaptically and as presynaptical autoreceptors seem to be the most prominent regulators of REM sleep-like signs (Baghdoyan et al., 1998). Similarly, microinjection of the acetylcholine esterase inhibitor neostigmine into the pontine reticular formation enhances REM sleep (Coleman et al., 2004), whereas microinjection of an inhibitor of ACh transport into terminal vesicles decreases REM sleep and prevents the REM sleep-enhancing effect of neostigmine (Capece et al., 1997). During electrical stimulation of the PPT, acetylcholine release was increased in the pontine region where carbachol injection induces REM sleep-like signs (Lydic and Baghdoyan, 1993). Evidently, the cholinergic input from LDT–PPT can induce muscle atonia through pontine reticular glutamatergic neurons, which in turn excite glycinergic, inhibitory neurons in the medullary magnocellular nucleus (Lai and Siegel, 1988). It was shown long ago that this medullary portion of the reticular formation inhibits muscle tone (Magoun, 1950).

PGO waves, which originate in the LDT/PPT area and normally precede REM sleep episodes, are increased by pharmacological agents increasing REM sleep, including cholinomimetics or drugs antagonizing noradrenergic or serotonergic activity (Callaway et al., 1987). Microinjection of carbachol into the peribrachial region of the pontine tegmentum induced sustained PGO activity, followed by a long-lasting REM sleep (Datta et al., 1992; Datta, 1995). The PGO generator area extends more caudally in the pons than the general REM sleep-inducing area (Datta et al., 1998). Several other transmitter sytems modulate the cholinergic PGO wave generator (Datta, 1997).

2.4.2 Basal Forebrain

Basal forebrain is a heterogenous region in the ventral region of forebrain adjacent to preoptic, supraoptic, and rostral infundibular levels of the hypothalamus including the cholinergic cell groups Ch1–4 as defined by Mesulam (Mesulam et al., 1983). The magnocellular cholinergic neurons project widely to the limbic system and the cortex providing most of the cholinergic cortical innervation (Jones, 2004). The cholinergic cells are located interdispersed in several nuclei, from rostral to caudal: the medial septum, the vertical and horizontal diagonal bands of Broca, the magnocellular preoptic are, the substantia innominata and the nucleus basalis of Meynert (Cullinan and Zaborszky, 1991). Even though the BF was originally named according to the cortically projecting magnocellular cholinergic neurons, these neurons are a minority and actually outnumbered by 2:1 the rat BF by GABAergic neurons, which have cortical projections as well. In addition, there is a substantial proportion of unidentified cortically projecting neurons (Gritti et al., 1993; Gritti et al., 1997).

The exact role of the basal forebrain cholinergic neurons in the regulation of sleep is less clear than that of the LDT/PPT neurons, but several experiments suggest that such a role exists. The cholinergic cortically projecting neurons release ACh which excites the cortical neurons and thus stimulates cortical activation (McCormick and Prince, 1986; McCormick, 1992). This ACh release has been shown to be highest during waking and REM sleep (Marrosu et al., 1995). Furthermore, lesions of the BF have been shown to disrupt sleep patterns of both cats and rats (Szymusiak and McGinty, 1986; Buzsaki et al., 1988), and the discharge

rates of the presumed cholinergic neurons have been shown to be highest during waking and REM sleep while being lowest during SWS in both cats and rats (Szymusiak and McGinty, 1986; McGinty and Szymusiak, 1989; Alam et al., 1999). The cholinergic cells of the BF are thus waking-active, and are regarded to be important in cortical arousal. The BF is also part of the extrathalamic ventral pathway from the brain stem reticular activating system to the cerebral cortex (Steriade, 1996; Jones, 2004).

The basal forebrain/preoptic area of the hypothalamus is an important target area for endogenous sleep-inducing substances, as discussed later (adenosine, NO, and protaglandins); but presently it is not clear which of these effects, if any, are mediated through cholinergic neurons, as opposed to GABAergic and other neurons in the BF.

2.5 The Histaminergic System in Sleep–Wake Regulation

Histaminergic cell bodies are found exclusively in the tuberomamillary (TM) nuclei in the ventrolateral posterior hypothalamus. von Economo's finding that lesions in the posterior hypothalamus caused somnolence (von Economo, 1923, 1930) is in accordance with present knowledge of the arousing action of histamine, although other types of sleep–wake-related neurons are also found in this area (Steininger et al., 1999).

The histamine neurons receive inputs from many forebrain and brain stem systems, including the ventrolateral posterolateral preoptic area, where GABAergic/galaninergic sleep-active neurons are found (Sherin et al., 1998). Afferent inputs to the tuberomamillary area include cholinergic inputs from the basal forebrain area, dopaminergic hypothalamic input, and various peptidergic hypothalamic inputs (Yoshimoto et al., 1989). The histaminergic neurons project diffusely to all brain regions (Panula et al., 1989). Like other monoaminergic neurons they fire most intensely during wakefulness, less during SWS, and are minimally active during REM sleep (Steininger et al., 1999; Vanni-Mercier et al., 2003).

Postsynaptic receptors mediating arousal are type H_1, and the activity of TM neurons is negatively influenced by H_3 autoreceptors. Thus administration of centrally active H_1 antagonist drugs inhibit waking (Lin et al., 1988; Monti, 1993), whereas H_3 receptor antagonists increase it (Lin et al., 1990; Monti, 1993). These effects have been confirmed in single-unit recordings of TM neurons (Vanni-Mercier et al., 2003).

Efferents of histaminergic TM neurons project to major waking-promoting centers, including noradrenergic neurons of the locus coeruleus and cholinergic neurons in the basal forebrain, as well as to the sleep-promoting preoptic/anterior hypothalamic area (POAH) (Panula et al., 1989). Depletion of histamine in POAH caused a decrease, and histamine injections an increase in waking of cats, and the effect of histamine was blocked by both H_1 and H_2 antagonists (Lin et al., 1994). Using in vivo microdialysis, Strecker et al. (2002) showed that the extracellular levels of histamine in the POAH of cats were highest during waking, intermediate during NREM sleep, and lowest during REM sleep, in accordance with the single neuron activity studies. However, the latter study did not show any increase in histamine levels during sleep deprivation, indicating that histamine does not convey information about sleep pressure to the POAH sleep-promoting area.

In vitro, histamine depolarizes thalamic relay neurons through H_1 receptors, which decrease the potassium current (McCormick and Williamson, 1991). Electrical stimulation of the tuberomamillary nucleus strengthened the processing of visual stimuli in the thalamic lateral geniculate nucleus, indicating promotion of sensory input as one wakefulness-related effect of histamine (Uhlrich et al., 2002). H_2 receptor-mediated inhibition through increased chloride conductance may be related to dampening of sleep-type thalamic activity and facilitate the transition to wakefulness (Lee et al., 2004).

Mice constitutively lacking the histamine-synthesizing enzyme histidine decarboxylase had a slight increase in REM sleep, less theta rhythm in the EEG during waking, and less waking at lights-off (Parmentier et al., 2002). Most interestingly, these mice had less arousal when moved to a new environment, and fell asleep in a few minutes, unlike controls. This indicates that histamine has a role in maintaining the brain in a wake state following behavioral challenge, a role that is not compensated by other systems even when constitutively absent.

2.6 The Hypocretin/Orexinergic System in Sleep–Wake Regulation

The other major waking-promoting system in the posterior hypothalamus consists of perifornical neurons scattered in the lateral posterior hypothamalic regions, containing a peptide called hypocretin (de Lecea et al., 1998) or orexin (Sakurai et al., 1998). The same gene codes for two forms of the peptide: hypocretin 1 and 2 or orexin A and B, the latter of which is degraded very fast and has thus been studied less. Hcrt/OX neurons project diffusely in the brain (Peyron et al., 1998), and innervate other major waking-promoting systems, e.g., the noradrenergic (Horvath et al., 1999) and the basal forebrain cholinergic system (Eggermann et al., 2001). Hcrt/OX also excites neurons of the thalamocortical projection (Bayer et al., 2002) and tuberomamillary histaminergic neurons (Bayer et al., 2001). Single neurons recorded in vivo in the Hcrt/OX neuronal area were wake-active or wake-REM sleep-active (Alam et al., 2002), but they could not be chemically identified.

Two receptor types (OX_1R and OX_2R) mediate the synaptic actions of Hcrt/OX, and both receptors are sensitive to both peptides, although OX_2R is tenfold as sensitive to Hcrt-2/OX-B than to Hcrt-1/OX-A (Sakurai et al., 1998). Both receptors mediate the same type of synaptic action. It was originally found that Hcrt/OX was excitatory on postsynaptic neurons (de Lecea et al., 1998). It raises cytoplasmic calcium via a G-protein mechanism, and can act both pre- and postsynaptically (van den Pol et al., 1998). Interestingly, local glutamate neurons are excited by Hcrt/OX, and in turn serve to excite Hcrt/OX neuons, which provides a means for synchronizing the activity of these latter (Li et al., 2002).

Hcrt/OX was initially found to increase food consumption (van den Pol et al., 1998), but the multiple projections suggested other regulatory actions also (Peyron et al., 1998). It was then found that knockout of the Hcrt/OX gene caused narcolepsy in mice (Chemelli et al., 1999), and that narcolepsy in dogs is caused by a mutation in the OX_2R gene (Lin et al., 1999). Human narcoleptics have an 85–95% reduction in the number of Hcrt/OX neurons (Thannickal et al., 2000). Hypocretin 2-saporin lesions of the posterior hypothalamus increased sleep to an extent correlating with the loss of Hcrt/OX neurons (Gerashchenko et al., 2001). It has become obvious that Hcrt/OX is necessary for the maintenance of consolidated periods of waking, and that its lack fragments waking and increases the propensity for sleep induction (Kilduff and Peyron, 2000). It has been shown that GABAergic neurons in the ventrolateral basal forebrain area control Hcrt/OX neurons, which might be part of the sleep-induction mechanism (Alam et al., 2005).

2.7 Glutamatergic Involvement in Sleep–Wake Regulation

It has been estimated that 75% of the excitatory synapses in the CNS are glutamatergic. It could thus be of no surprise if glutamatergic transmission were crucial in the regulation of wake and sleep. However, its ubiquity would make it difficult to assign specific roles to this transmitter. In addition, glutamatergic neurons may be either local interneurons or projecting neurons.

Short-latency projections to the thalamus from midbrain reticular formation locations, where no noradrenergic or cholinergic neurons are found, indicate possibly amino acids as the transmitter (Steriade and Glenn, 1982; Steriade et al., 1990). Glutamate as a transmitter in brain stem reticular neurons is indicated by immunohistochemical studies (Jones, 1995). Glutamate affects thalamic neurons by exciting thalamocortical relay cells, but inhibiting thalamic reticular cells (McCormick, 1992; Cox and Sherman, 1999). Metabolic glutamate receptors with long-lasting effects are involved in some cases (Cox and Sherman, 1999; Schwarz et al., 2000).

The basal forebrain is also the target of glutamatergic projections from the lower brain stem, including the reticular formation, locus coeruleus, raphe nuclei, and LDT/PPT, as shown by immunohistochemistry (Carnes et al., 1990) Furthermore, glutamatergic projections from the pontine reticular formation mediate muscle atonia during REM sleep (Lai and Siegel, 1988). It is thus apparent that glutamatergic transmission may influence many aspects of wake–sleep regulation.

Some anesthetics apparently act by suppressing glutamatergic transmission, others by enhancing GABAergic transmission, which may have the secondary effect of decreasing glutamate transmission. The anesthetic action of ketamine has been explained by a specific blocking effect on NMDA receptors

(Yamamura et al., 1990). Several other anesthetic agents, including halothane, isoflurane, and thiopental apparently also antagonize ionophoric (AMPA or NMDA) glutamate receptors (Carla and Moroni, 1992). Another cellular target for anesthetics is glutamate uptake into astrocytes, which normally terminate glutamate action by removing it from the synaptic cleft. In vitro, ketamine had no effect on glutamate uptake into astocytes, whereas this was a mechanism of action of halothane, isoflurane, and some other volatile anesthetics (Miyazaki et al., 1997). In conclusion, therefore, decreasing glutamate transmission may impair waking, and this may be a prominent target for the development of anesthetics.

3 Neurochemistry of Sleep

3.1 Adenosine

Adenosine is a ubiquitous molecule, directly associated with energy metabolism, but which also functions in cellular communication and regulation of neural activity. Adenosine mediates its effects via specific receptors, namely A_1, A_{2A}, A_{2B}, and A_3 (Fredholm et al., 2001). The receptors differ in their affinity to adenosine, their distribution and function. The A_1 and A_{2A} are the high-affinity receptors, as they are activated at nanomolar adenosine concentrations, while the A_{2B} and A_3 are activated only at micromolar concentrations. Functionally, the A_1 and A_3 are negatively coupled to adenylate cyclase by $G_{i/o}$ and $G_{q/11}$ proteins and their activation leads to a decrease in the intracellular cAMP levels, while the A_{2A} and A_{2B} are positively coupled to adenylate cyclase by G_s, G_{olf}, $G_{q/11}$, and $G_{15/16}$, and consequently their activation has an opposite effect on the cAMP levels (Fredholm et al., 2000).

The A_1 receptor is the most abundant and widely expressed of the adenosine receptors in the CNS, being most prominent in the hippocampus, cerebellum, and cortex as shown by both mRNA expression studies and immunohistochemical staining (Rivkees et al., 1995). The net effect of A_1 activation is a reduction in transmitter release presynaptically and postsynaptic hyperpolarization (Haas and Selbach, 2000).

The A_{2A} receptor has a more localized expression in the CNS, being concentrated in the striatum, the nucleus accumbens, the olfactory tubercle, and the lateral segment of globus pallidus (Parkinson and Fredholm, 1990) with a low expression throughout the rest of the CNS. The A_{2A} receptor activates the adenylate cyclase pathway and seems to increase neurotransmission, but its role is not only stimulatory (Cunha, 2001). The A_{2B} and A_3 have a low expression in the CNS (Dixon et al., 1996). They are activated only at extreme concentrations of adenosine in pathological conditions, and their physiological role is not clear (Haas and Selbach, 2000).

The first report on the hypnogenic properties of adenosine was that injections of adenosine into the lateral ventricle induced sleep-like behavior in the cat (Feldberg and Sherwood, 1954). Two decades later the same phenomenon was noted in dogs (Haulica et al., 1973). Since then adenosine has been in the focus of sleep research, and its hypnotic properties have been noted repeatedly as both adenosine and its agonist induce sleep in rodents (Virus et al., 1983; Radulovacki et al., 1984; Ticho and Radulovacki, 1991a) and cats (Portas et al., 1997). Furthermore, the most widely used psychoactive stimulant in the world, caffeine, is an adenosine receptor antagonist (Fredholm et al., 1999). It has been shown that unilateral infusion of A_1 receptor antagonist cyclopentyl-1,3-dimethylxanthine (CPT) into the BF of cats and rats increases waking and decreases sleep (Strecker et al., 2000). Most experiments suggest that sleep is induced through A_1 receptors (Ticho and Radulovacki, 1991b; Benington et al., 1995; Schwierin et al., 1996; Portas et al., 1997), while there is also evidence for participation of the A_{2A} receptors (Matsumura et al., 1994; Urade and Hayaishi, 1999; Maquet et al., 1992).

A_{2A} agonists into the subarachnoid space under the rostral basal forebrain induces sleep (Satoh et al., 1996, 1999).

Extracellular adenosine concentrations increase during both increased neuronal activity and increased metabolism (Pull and McIlwain, 1972; Van Wylen et al., 1986; Mitchell et al., 1993). On the other hand, metabolic activity in the brain is higher during wakefulness than sleep, as measured by glucose utilization, cerebral blood flow, and oxygen consumption in humans (Maquet et al.,1990; Madsen et al., 1991; Maquet

et al., 1992; Madsen, 1993), and extracellular glucose and lactate concentrations in rats (Netchiporouk et al., 2001).

Thus, it could be expected that adenosine concentrations vary during the sleep–wake cycle. It was first shown that the extracellular adenosine levels were lower during the rest phase and higher during the active phase in the hippocampus and neostriatum of rats (Huston et al., 1996). The first direct evidence for state-dependency was published in 1997, when it was shown using in vivo microdialysis that the extracellular adenosine levels were higher during SWS than during waking in the cholinergic magnocellular BF and the thalamus of cats (Porkka-Heiskanen et al., 1997). Later this phenomenon was shown to be present also in the cortex, the dorsal raphe nucleus, the pedunculopontine tegmental area (PPT) and the preoptic hypothalamic area (Porkka-Heiskanen et al., 2000). Recently, the state-dependency and the circadian variation have been further confirmed in the BF of both young and old rats (Murillo-Rodriguez and Blanco-Centurion, 2004).

As prolonged wakefulness continues to make demands on the neuronal metabolism, it can be expected that adenosine levels would increase. Indeed, increased adenosine levels have been measured in the BF of cats and rats during prolonged wakefulness (Porkka-Heiskanen et al., 1997; Basheer et al., 1999). This effect is site specific since adenosine levels increase only in the BF and transiently in the cortex (Porkka-Heiskanen et al., 2000). Furthermore, it has been shown with combined in vivo microdialysis and unit recording that infusion of adenosine into the BF of rats and cats decreases the unit activity of the cortically projecting wake-related neurons (Alam et al., 1999; Thakkar et al., 2003a). These data strongly suggest that adenosine is an endogenous sleep-regulating substance, acting specifically in the basal forebrain by decreasing the activity of the wake active, presumably cholinergic projection neurons, and thus decreasing cortical activity and promoting sleep.

One scenario to explain the role of adenosine in sleep regulation is through its connection to energy metabolism (Benington and Heller, 1995). The continuous activity of the wakefulness-promoting cells in the basal forebrain imposes a burden on the mitochondrial energy production capacity during wakefulness. When wakefulness is prolonged, these cells start to suffer from an energy deficit, resulting in increased glycolysis and elevations in extracellular concentrations of lactate, pyruvate, and adenosine. The enhanced extracellular concentration of adenosine contributes to the increased sleep propensity and promotes the transition from wakefulness to sleep. This view is supported by the finding that experimentally induced energy depletion in the BF induces sleep that resembles recovery sleep (Kalinchuk et al., 2003). We have proposed that the cholinergic cells of the basal forebrain are particularly vulnerable to the effects of energy depletion, and act as fuses, triggering adenosine release and forcing the brain to sleep (Kalinchuk et al., 2003, 2006a).

The effects of adenosine in the BF appear to be mediated predominantly through A_1 receptors (Basheer and Shiromani, 2001; Basheer et al., 2001a,b; Thakkar et al., 2003b). A_1 agonists decrease and antagonist increased the neuronal discharge rate in the cholinergic mesopontine LDT/PPT by causing hyperpolarization of identified cholinergic cells (Rainnie et al., 1994). Combined microdialysis and unit recording studies have shown that infusion of A_1 agonist into the BF decrease, and infusion of A_1 antagonist increase single unit activity of wake-active neurons in both cats and rats (Alam et al., 1999; Thakkar et al., 2003a). Recently it has been shown that bilateral infusion of antisense to the A_1 receptor mRNA decreases NREM sleep and induces wakefulness (Thakkar et al., 2003a). When considering the evidence presented earlier, the A_1 receptors have an important role in the homeostatic regulation of sleep in the BF.

However, in the immediate vicinity of the BF, effects of adenosine on sleep have been reported to take place through A_{2A} receptors. For details, please, see the Section 3.5 later in this chapter.

3.2 Cytokines

Cytokines are chemical messengers (low molecular weight proteins), which communicate information between the cells (intercellular messengers). Originally, they were described in connection with immune functions, and the communication within this system is best known. They are secreted through autocrine,

paracrine, and endocrine routes, and are involved in the regulation of host defense, cell growth, differentiation, cell death, angiogenesis, and development and repair processes. Injurious stimuli usually initiate the production of cytokines, though they can also be produced constitutively (Vitkovic et al., 2000), and possibly act as neuromodulators.

In addition to their originally defined function as regulatory molecules of the immune system, cytokines regulate a number of other physiological functions, including hormonal secretion and stress. Typically, cytokines rarely act alone, but in concert with other cytokines, forming a network of activity. Of the multitude of cytokines, particularly IL-1 and TNFα have been well assessed in sleep regulation.

Injections of IL-1 beta will increase NREM sleep, while inhibition of IL-1 beta inhibits it [for review see Krueger et al. (2001)]. TNFα induces NREM sleep in several species, including rabbits, mice, sheep, and rats (Shoham et al., 1987; Fang et al., 1997; Dickstein et al., 1999; Kubota et al., 2002), while its inhibition decreases it (Takahashi et al., 1996). In rats, highest levels of both IL-1beta and its mRNA appear in the hypothalamus in the early phase of lights-on (Taishi et al., 1997), when also NREM sleep is maximal. Also, in humans the blood level of IL-1 is maximal at sleep onset (Moldofsky et al., 1986), and its mRNA hypothalamic levels undergo diurnal variation (Bredow et al., 1997). Sleep deprivation decreases IL-1beta mRNA in the hypothalamus (Mackiewicz et al., 1996). Sleep deprivation increases TNFα levels in the hypothalamus (Krueger et al., 2001).

The above cited data suggest a role for cytokines not only in the regulation of the pathologically increased sleep in infection [for review see Opp and Toth (2003)]; but also in the regulation of spontaneous sleep–wake cycle and sleep homeostasis. As the induction of cytokines is part of the early host defense reaction, frequently elicited by immunological challenge, it will be of importance to clarify whether the sleep response is an integral part of such defense. Induction of iNOS during prolonged wakefulness (Kalinchuk et al., 2006b), as well as the induction of heat shock proteins (Terao et al., 2003) and unfolded protein response (Naidoo et al., 2005), imply that this might be the case.

3.3 Nitric Oxide

Nitric oxide (NO) is a gaseous intercellular signaling molecule that regulates both physiological and pathophysiological processes in the CNS (Garthwaite and Boulton, 1995). NO is produced by three nitric oxide synthases (NOS). Neuronal (nNOS) and endothelial (eNOS) types are regulated by intracellular Ca^{2+} levels and they are constitutively expressed, producing small amounts of NO. The third type, iNOS, is regulated at the transcriptional and posttranscriptional levels, and is normally present in the brain only in trace amounts (Nathan and Xie, 1994a). Immunological challenge (Nathan and Xie, 1994b), as well as stressful stimuli including oxygen/glucose deprivation (Moro et al., 1998) and immobilization (Madrigal et al., 2001), activate expression of iNOS, which induces rapid (Harada et al., 1999) and relatively large increases in NO concentration. Excessive synthesis of NO by iNOS has been implicated as a contributing factor for a number of pathological conditions, including acute and chronic neurodegenerative diseases and diabetes (Gross and Wolin, 1995).

nNOS immunopositive neurons are distributed throughout the brain. Dense staining is found in the cortical interneurons, hypothalamic supraoptic and paraventricular nuclei and in the pontine LDT/PPT nuclei and cerebellum. eNOS is predominantly located in the endothelial cells of the blood vessels, and iNOS is induced mainly in the glial cells. The main pathway for NO effects is the cGMP pathway: NO binds to soluble guanylyl cyclase (sGC) activating cGMP production. NO also directly affects the mitochondrial energy metabolism (Brorson and Zhang, 1999).

In the cortex NO release, as measured using voltammetry, is highest during waking, and decreases during NREM and REM sleep (Burlet and Cespuglio, 1997), while in the nucleus raphe dorsalis the changes were opposite (Cespuglio et al., 2004). In the rat thalamus NO levels were highest during waking and REM sleep and lowest during NREM sleep (Williams et al., 1997). In mice with targeted disruptions of nNOS, REM sleep is decreased, while in the iNOS KO mice REM sleep was increased, but NREM in the late dark period was decreased (Chen et al., 2003). nNOS exhibits a circadian rhythm in the rat pineal gland (Spessert and Rapp, 2001) being maximally expressed during the dark phase, and NO production, measured as NO2-,

showed a robust circadian rhythm in the SCN (Mitome et al., 2001) and whole brain (Tunctan et al., 2002) with higher NO release during the dark period.

REM sleep deprivation modifies the circadian variation in nNOS expression while there were no changes in iNOS activity (Clement et al., 2004). In recent experiments, total sleep deprivation for 3 h induced iNOS, and when this induction was prevented during sleep deprivation with a specific iNOS inhibitor, recovery sleep was abolished (Kalinchuk et al., 2006b). This suggests that NREM recovery sleep is produced by an increase in NO through iNOS induction.

Most studies using either systemic or icv administration of NOS inhibitors report decreases in sleep (Kapas et al., 1994b; Dzoljic et al., 1996), though increase has also been reported (Dzoljic and de Vries, 1994). NO donors administrated icv have been reported to increase sleep (Kapas and Krueger, 1996). The interpretation of the results obtained by systemic administration is complicated by the voltammetric measurement of NO in the brain after administration of L-NAME, the most frequently used nonspecific NOS inhibitor, showing that the inhibitor has no effect on the brain NO levels (Burlet et al., 1999).

Local microinjections of NOS inhibitors into the LDT/PPT reduce REM sleep (Kapas et al., 1994a; Datta et al., 1997; Leonard and Lydic, 1997; Hars, 1999), while NO donors increase it. Administration of NOS inhibitors into the dorsal raphe nucleus also decreased REM sleep (Burlet et al., 1999; Monti et al., 2001). Interestingly, pretreatment with either a GABA-A or adenosine A1 receptor agonist partially prevented the effect of L-NAME in the dorsal raphe nucleus (Monti et al., 2001).

Taken together these data strongly suggest a role for NO in regulation of sleep and particularly in the regulation of recovery sleep. Of particular interest is the induction of iNOS during prolonged wakefulness in the BF. As iNOS is not expressed in the brain under normal conditions, it suggests that prolonged wakefulness evokes the host defense reaction, and as part of it, sleep is induced.

3.4 GABA

GABA is the main inhibitory neurotransmitter in the brain. GABA neurons are either local interneurons, or project to more distant areas, e.g., GABAergic neurons in the BF. A role for GABA in sleep regulation is suggested by the notion that the most frequently used hypnotics, benzodiazepines, act through GABA binding site, though the exact mechanism of the action has not been clarified (Möhler, 2001)

GABA neurons are widely distributed in the brain, but presently two main sites of action have been proposed to explain the effects of the GABAergic neurons on sleep: the reticular thalamic nucleus, which is part of the reticulo-thalamic circuit, and which has been proposed to be central in the generation of cortical EEG delta (Steriade et al., 1991) and spindle activity (Steriade et al., 1987). A more recent finding, that in the preoptic area of hypothalamus there are sleep active neurons as defined by electrophysiological measurement (Alam et al., 1997) or by using c-fos activation as an indicator of cellular activity (Sherin et al., 1996). These neurons are GABAergic and in the VLPO nucleus they are colocalized with galanin, another inhibitory neuromodulator (Sherin et al., 1998). These neurons send projections to the waking-promoting monoaminergic (locus coeruleus and raphe nuclei) and histaminergic (tuberomamillary nuclei) cell groups (Sherin et al., 1998; Steininger et al., 2001), and they appear to be essential for the production of sleep, since lesion of the VLPO cells reduced the amount of NREM and REM sleep to about half (Lu et al., 2000). VLPO neurons are inhibited by monoamines (Gallopin and Saper, 2000), suggesting a reciprocal inhibition model: during wakefulness the monoamines inhibit the sleep-active VLPO neurons, and during sleep the VLPO neurons inhibit the wake-active monoaminergic neurons (McGinty and Szymusiak, 2000).

GABA concentrations, measured using in vivo microdialysis, were high in the posterior hypothalamus during sleep (Nitz and Siegel, 1997a), while in the dorsal raphe and locus coeruleus the highest GABA levels were measured during REM sleep (Nitz and Siegel, 1997b), suggesting that GABA has a specific role in the shutting off the monoaminergic nuclei during REM sleep.

One neurotransmitter regulating the activity of the VLPO neurons appears to be adenosine, through disinhibition of these neurons (Chamberlin et al., 2003), suggesting a dual role for adenosine in sleep induction in the BF/hypothalamic area: inhibition of the waking-active (presumably cholinergic) neurons through A_1 receptors and disinhibition of the sleep-active GABAergic cells through A_{2A} receptors.

3.5 Prostaglandins

Of the several members of the prostaglandin family, prostaglandin D_2 (PGD_2) has the most sleep-promoting properties. In the brain PGD synthase, a key enzyme in PGD_2 metabolism, is predominantly localized in the leptomeninges (Urade et al., 1993). PGD_2 concentrations are higher during the light period, and particularly during NREM sleep, and sleep deprivation increases it (Ram et al., 1997). PGD_2 injected in the preoptic area (POA) of rats (Ueno et al., 1982), and icv in monkeys (Onoe and Hayaishi, 1988) increased SWS. DPR prostaglandin receptor binding was found to be localized in this area (Yamashita et al., 1983), while immunoreactivity for DPR antibody was found to be most intense in the leptomeninges on the ventral surface of the basal forebrain (Mizoguchi and Hayaishi, 2001).

PGD_2 receptor activation-induced release of adenosine exerts its somnogenic effects via the A_{2A} adenosine receptor in the subarachnoid space below the rostral basal forebrain (Matsumura et al., 1994; Urade and Hayaishi, 1999; Mizoguchi and Hayaishi, 2001; Hayaishi, 2002). Infusion of PGD_2 into the subarachnoid space increased the local extracellular adenosine concentration. Data supporting the somnogenic effects of both PGD_2 and A_{2A} agonists are induction of c-fos immunoreactivity in the ventrolateral preoptic area, this region has been suggested to be involved in promoting sleep by inhibiting the ascending histaminergic arousal system of the tuberomammillary nucleus (Scammell et al., 1998; Sherin et al., 1998; Scammell et al., 2001). Infusion of the A_{2A} agonist CGS 21680 in the subarachnoid space increased SWS, and both A_{2A} agonist- and PGD_2-induced sleep were blocked by the A_{2A} antagonist, KF17837. These data provide the pharmacological evidence for the role of the A_{2A} receptor in mediating the somnogenic effects of PGD_2 (Satoh et al., 1996; Satoh et al., 1999) suggesting that PGD_2-induced release of adenosine in a specific area of subarachnoid space below the rostral forebrain, leads to A_{2A} receptor-mediated effects. The sleep-inducing effects of the PGD_2 and A_{2A} agonists have been localized in the VLPO (Scammell et al., 1998, 2001).

Several experiments thus suggest that PGD_2 has sleep-modulating effects. Interestingly, the effects are localized in the same BF/hypothalamic regions where also other sleep-active substances exert their effects. PGD_2 appears to act through adenosine, particularly through A_{2A} receptors. As also cytokines and NO can increase adenosine release, one of the key questions is whether adenosine is the common key molecule, through which the other sleep-active molecules affect sleep, or whether each of these molecules has a separate mechanism to modulate sleep.

4 Summary

The sleep-promoting substances consist of a variety of endogenous substances, which have regulatory roles in other physiological regulatory systems, as energy metabolism, immune responses and hormonal regulation. These molecules also have a wide interconnecting network, with partly common intracellular signaling pathways. The details of the orchestration of this network to produce the regulation of the spontaneous sleep–wake cycle and the response to prolonged wakefulness are currently one of the most important topics of research within the sleep research community.

5 Questions for Future Research

1. Does the induction of (NREM) sleep take place mainly by activating the sleep-active neurons in the VLPO, or does it take place by inhibiting the wake-active (cholinergic) neurons in the BF, or is it a combination of these?
2. Several substances have (NREM) sleep-inducing effects in the BF/hypothalamic area, and all of them are able to induce adenosine release. Is the effect of these substances on sleep based on their ability to release adenosine, or do they have adenosine-independent mechanism to affect the activity of the sleep/waking active neurons?

3. So far, sleep research has concentrated solely on neuronal activity. However, it is evident that substances like adenosine, nitric oxide and cytokines can be released also by glial cells. The role of glia in regulation of sleep needs to be addressed.
4. Sleep need (the homeostatic component of sleep regulation) appears to be use-dependent, particularly cortical activity-dependent, but the executive mechanism of sleep induction appears to be localized in the basal forebrain/hypothalamic area. How is the information of cortical neuronal activity conveyed to the subcortical areas, and which signaling molecules participate in this?
5. Research on the recently found wake-active cell group, the hypocretin/orexin cells, continues actively.

25 Neuroendocrinology of Sleep

A. Steiger

1 Introduction 897

2 Hypothalamo–Pituitary–Somatotrophic System 899
2.1 Basic Activity 899
2.2 Sleep in Disorders of the HPS System 900
2.3 Effects of HPS Hormone Administration on the Sleep EEG 900
2.3.1 Growth Hormone-Releasing Hormone 900
2.3.2 Growth Hormone, Insulin-Like Growth Factor-1 903
2.3.3 Somatostatin 903
2.3.4 Ghrelin and GH Secretagogues 904
2.4 Animal Models of HPS System Changes 906
2.5 Interactions of HPS System and Orexin 906
2.6 Summary 906

3 Hypothalamo–Pituitary–Adrenocortical System 907
3.1 Basic Activity 907
3.2 Sleep in Disorders with Pathological Changes of HPA Activity 908
3.3 Effects of Changes of Sleep–Wake Behavior on HPA Hormones 909
3.4 Effects of HPA Hormone Administration on the Sleep EEG 911
3.4.1 Corticotropin-Releasing Hormone 911
3.4.2 Vasopressin 913
3.4.3 Adrenocorticotropic Hormone 913
3.4.4 Cortisol, Synthetic Glucocorticoid and Mineralocorticoid Receptor Ligands 913
3.5 Animal Models of HPA System Changes 915
3.6 Summary 915

4 Hypothalamo–Pituitary–Thyroid System 916
4.1 Basic Activity 916
4.2 Sleep in Hypothyroidism and Hyperthyroidism 916
4.3 Effects of Thyrotropin-Releasing Hormone Administration 916
4.4 Summary 916

5 Insulin 916
5.1 Basic Activity 916
5.2 Effects of Insulin Administration 917

6 Prolactin 917
6.1 Basic Activity 917
6.2 Sleep in Prolactinoma 917
6.3 Effects of Hormone Administration 918
6.3.1 Prolactin 918
6.3.2 Prolactin-Releasing Peptide 918
6.3.3 Vasoactive Intestinal Polypeptide Interaction with Prolactin and Sleep 918
6.4 Animal Models of Changed Prolactin Activity 919

7 Other Peptides 919
7.1 Cortistatin 919
7.2 Galanin 920
7.3 Neuropeptide Y 920
7.4 Neuropeptide S 920
7.5 Pituitary Adenylate Cyclase Activating Polypeptide 920
7.6 Substance P 921

8 Melatonin 921
8.1 Basic Activity 921

Abstract: Sleep is a time of distinct activity in various endocrine systems. Two major methods of sleep research are the sleep electroencephalogram (EEG) and the assessment of sleep-related endocrine activity (e.g., by collection of hormone profiles). The combination of these methods in human subjects and in animal models helps to elucidate the interaction of sleep EEG and hormones in normal and pathological sleep. Such simultaneous investigations showed a bidirectional interaction between the electrophysiological and the neuroendocrine components of sleep. Certain hormones (neuropeptides and steroids) play a specific role in sleep regulation and some peptides (growth hormone-releasing hormone [GHRH], galanin, ghrelin, neuropeptide Y) promote sleep, at least in males, whereas others (corticotropin-releasing hormone [CRH], somatostatin) impair sleep. A reciprocal interaction of GHRH and CRH plays a keyrole in sleep regulation. GHRH promotes nonrapid-eye-movement sleep (NREMS), at least in males and stimulates GH secretion, whereas CRH maintains wakefulness and enhances the secretion of ACTH and cortisol. Changes in the CRH:GHRH ratio in favor of CRH contribute to shallow sleep, elevated cortisol secretion, and blunted GH levels during depression and normal ageing. However, CRH-like effects of GHRH were found in women, as sleep is impaired, and ACTH and cortisol are elevated after this peptide. Besides peptides, steroids are involved in sleep regulation. Cortisol appears to promote rapid-eye-movement sleep (REMS). This finding points to a REMS-promoting effect of cortisol. Similarly, $GABA_A$ receptors are targets of various neuroactive steroids, which exert specific effects on sleep. The changes of sleep EEG in women after menopause and the beneficial effect of estrogen replacement therapy suggest a role of estrogen in sleep regulation.

List of Abbreviations: ACTH, adrenocorticotropic hormone; CNS, central nervous system; CRH, corticotrophin-releasing hormone; DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate; EEG, electroencephalogram; FSH, follicle stimulating hormone; 5-HT-3, 5-hydroxytryptamine type 3; GABA, gamma-aminobutyric acid; CSF, cerebrospinal fluid; GH, growth hormone; GHRH, growth hormone-releasing hormone; GHRP-6, growth hormone-releasing peptide-6; GHS, growth hormone secretagogue; GR, glucorticoid receptor; HPA, hypothalamo-pituitary-adrenocortical; HPS, hypothalamo-pituitary-somatotrophic; IGF-1, insulin-like growth factor-1; iv, intravenous; MR, mineralocorticoid receptor; NREMS, nonrapid-eye-movement sleep; NPS, neuropeptide S; NPSR, neuropeptide S receptor; NPY, neuropeptide Y; OX-A, orexin-A; OX-B, orexin-B; PACAP, pituitary adenylate cyclase activating polypeptide; PRA, plasma renin activity; REM, rapid-eye-movement; REMS, rapid-eye-movement sleep; SWA, slow wave activity; SWS, slow wave sleep; THDOC, deoxycorticosterone-3-alpha, 21-dihydroxy-5-alpha-pregnan-20-one; TRH, thyrotropin-releasing hormone; TSH, thyroid stimulating hormone; VIP, vasoactive intestinal polypeptide

1 Introduction

Sleep is a time of distinct activity in various endocrine systems. Two major methods for the investigation of sleep in various species including humans are the sleep electroencephalogram (EEG) and the assessment of sleep-related endocrine activity (e.g., by collection of hormone profiles) during the night or during 24 h, respectively. The combination of these electrophysiological and neuroendocrinological methods in human subjects and in animal models helps to elucidate the interaction of sleep EEG and hormones in physiological and pathological sleep. Such simultaneous investigations of sleep EEG and hormone secretion were performed in female and male normal control subjects from adulthood to senescence, in patients with psychiatric, particularly affective, with endocrine and sleep disorders, under baseline conditions, after manipulation of the sleep–wake pattern (e.g., sleep deprivation), and after administration of synthetic and endogenous compounds acting at the central nervous system (CNS), particularly neuropeptides and neuroactive steroids. Furthermore, related animal models were studied, including administration of hormones, sleep deprivation, surgery of adrenal glands, and transgenic animals with changes of endocrine activity. These studies showed a bidirectional interaction between the electrophysiological and the neuroendocrine components of sleep. Particularly, it was demonstrated that certain hormones play a specific role in sleep regulation.

Human sleep is characterized by the cyclic occurrence of periods of nonrapid-eye-movement sleep (NREMS) and rapid-eye-movement (REM) sleep (REMS). During the first NREMS period, the major portion of slow wave sleep (SWS) occurs. Correspondingly, in EEG spectral analysis (Borbély et al., 1981; Trachsel et al., 1992; Steiger et al., 1993), the major portion of slow wave activity (SWA) is found in the first sleep cycle. The secretion of various hormones shows distinct patterns as described in detail in the corresponding chapters below. In short, during the first half of the night the growth hormone (GH) surge preponderates, whereas adrenocorticotropic hormone (ACTH) and cortisol levels are low. In contrast, during the second half of the night ACTH and cortisol concentrations are high, whereas GH release is low (*Figure 25-1*) (Weitzman, 1976). This pattern suggests (i) a reciprocal interaction of the hypothalamo-pituitary-somatotrophic (HPS) and the hypothalamo-pituitary-adrenocortical (HPA)

Figure 25-1

systems (the corresponding peripheral endpoints are GH and cortisol, respectively) and (ii) the existence of common regulating factors of the sleep EEG and the nocturnal hormone secretion. Indeed, there is good evidence, that a reciprocal interaction of the key hormones of the HPS and HPA systems, GH-releasing hormone (GHRH) and corticotropin-releasing hormone (CRH) plays a major role in sleep regulation. This issue is described in detail below.

A sexual dimorphism of sleep-endocrine activities was reported in young normal humans. Cortisol secretion is higher in female than in male subjects. Most men show a single GH peak near to sleep onset, whereas in women characteristically a presleep GH surge and one or more additional GH peaks are found during the second half of the night (Antonijevic et al., 1999a). Sleep EEG (Bliwise, 1993) and nocturnal

hormone secretion (Van Coevorden et al., 1991) change throughout the life span. In females, the menopause is a major turning point towards impaired sleep (Ehlers and Kupfer, 1997), whereas in men, the sleep quality declines continuously during ageing.

The one hormone, which is most clearly linked to the NREMS–REMS cycle, is renin. Plasma renin activity (PRA) shows oscillations of about 90 min period strongly linked to the NREMS–REMS cycles. PRA reaches its peak during NREMS and its acrophase during REMS periods (Brandenberger et al., 1988). In particular, a link between SWS and the peaks of renin secretion was observed. Also, in rats, PRA is low in REMS and high in NREMS (Obál et al., 1994).

Leptin, the protein product of the obese (*ob*) gene is released from adipocytes in the periphery. It acts within the hypothalamus and reduces food intake (Tomaszuk et al., 1996). The maximum of serum leptin is found between 0000 and 0400 h. An inverse relationship exists between leptin and cortisol particularly in women (Licinio et al., 1997; Antonijevic et al., 1998). Leptin levels are higher in women than in men (Deuschle et al., 1996; Saad et al., 1997). Ghrelin, which is the first peptide identified as an endogenous ligand of the GH secretagogue (GHS) receptor was delineated as the orexigenic counterpart of leptin in the energy balance (Horvath et al., 2001). For the relationship of ghrelin to sleep, please see Section 2.3.4.

2 Hypothalamo–Pituitary–Somatotrophic System

2.1 Basic Activity

GH stimulates tissue growth and protein anabolism. These effects are mediated in part by insulin-like growth factor-1 (IGF-1). The synthesis and the secretion of GH is promoted by GHRH and inhibited by somatostatin. Recently, ghrelin was identified as an additional stimulus for GH release (Kojima et al., 1999). Synthetic GHSs were already known before the cloning of the GHS receptor. All these components of the HPS system were shown to participate in sleep regulation.

Whereas about one third of GH is released during daytime in humans, the major peak of GH secretion during 24 h occurs near to sleep onset. This GH surge is associated to the first period of SWS (Quabbe et al., 1966; Takahashi et al., 1968; Steiger et al., 1987). In one study, GH concentrations were determined every 30 sec in normal young male subjects. Maximal GH secretion was reported within minutes after the onset of SWS (Holl et al., 1991). A close temporal relationship was found between GH secretion and SWA (Gronfier et al., 1996). However, GH may be released prior to sleep onset in normal human subjects (Steiger et al., 1987).

The GH surge appears to be widely sleep dependent and is suppressed during sleep deprivation (Sassin et al., 1969; Beck et al., 1975). However, in sleep-deprived, but relaxed normal young male subjects in supine position, an unchanged nocturnal GH peak was observed (Mullington et al., 1996). This finding corroborates the view that lying relaxed is sufficient to trigger the nocturnal GH surge. On the other hand a weak circadian component in the regulation of GH release was delineated. During the second half of the night, GH levels are low. Similarly, it was shown that about one third of SWS periods are not associated with GH secretion (Van Cauter et al., 1992). Already during the third decade of the life span, distinct parallel decreases of SWS, SWA, and GH secretion start. In males near to the onset of the fifth decade, the GH pause occurs. From then on, GH release is nearly absent. In females, the GH pause is related to menopause.

In several animal species (rhesus monkeys, adult rats, goats, cows, and dogs), an episodic release of GH, but no link between sleep and GH secretion was found (reviewed in: Quabbe et al., 1981; Laurentie et al., 1989). However, in calves (Fabry et al., 1982) and in growing pigs (Dubreuil et al., 1988) a relationship between the sleep–wake cycle and GH release was reported. In lambs, the highest GH production rate occurred during SWS and REMS (Laurentie et al., 1989). In contrast, in immature rats a correlation between GH concentration and the duration of sleep during the preceding 10 min was found (Kawakami et al., 1983).

Hypothalamic GHRH mRNA depends on a circadian rhythm. In rats, the highest concentration is found at the onset of the light period when sleep propensity reaches its maximum in these night active

animals (Bredow et al., 1996). Furthermore, hypothalamic GHRH contents display sleep-related variations with low levels in the morning, increases in the afternoon (peak at the transition from the light to the dark period) and decreases at night (Gardi et al., 1999). Calcium levels in GABAergic neurons cultured from rat fetal hypothalamus increased when perfused with GHRH (De et al., 2002). It is thought that many hypothalamic GHRH responsive neurons are GABAergic.

2.2 Sleep in Disorders of the HPS System

In patients with isolated GH deficiency, SWS was reduced in comparison to normal control subjects, whereas total sleep time and NREMS stages 1 and 2 increased (Åström and Lindholm, 1990). In addition, a decrease in SWA was found in these patients (Åström and Jochumsen, 1989). In children with psychosocial dwarfism, the amount of SWS was low. After several weeks in a new environment, during recovery of growth, sleep quality improved, and particularly SWS increased (Guilhaume et al., 1982). The multiple sleep latency test, a method to examine daytime sleepiness, was in the normal range in patients with acquired GH deficiency (Schneider et al., 2005).

Excessive GH levels are found in patients with acromegaly. In these patients, obstructive sleep apnea syndrome is frequent due to hyperplasia of their upper airway soft tissue (Hart et al., 1985). However, in patients with acromegaly without sleep apnea, daytime sleepiness and an abnormal sleep structure are also found. One year after adenectomy, REMS and SWS time increased in a sample of these patients (Åström and Trojaborg, 1992). In this study, EEG power spectrum analysis was used to calculate sleep energy. At baseline, REMS and SWS energy were higher before than after adenectomy.

2.3 Effects of HPS Hormone Administration on the Sleep EEG

2.3.1 Growth Hormone-Releasing Hormone

GHRH is an important endogenous sleep-promoting substance. The GHRH receptor gene is found in the mouse in the region of chromosome 13 linked to SWA (Franken et al., 2001). Intracerebroventricular administration of GHRH increases SWS in rats and rabbits (Ehlers et al., 1986; Obál et al., 1988) (*Figure 25-2*). The same effect is found when GHRH is injected into the medial preoptic area in rats (Zhang et al., 1999) or intravenous to rats (Obál et al., 1996).

Similarly, after repetitive hourly iv bolus injections of GHRH between 22:00 and 01:00 h, SWS and GH secretion increased and cortisol levels were blunted in young normal men (Steiger et al., 1992). Mimicking the pulsatile endogenous release appears to be a crucial methodological issue, because sleep remained unchanged after GHRH infusion in normal controls (Marshall et al., 1999) (*Figure 25-3*). Sleep promotion in young male subjects by GHRH was confirmed after iv (Kerkhofs et al., 1993; Marshall et al., 1999) and intranasal (Perras et al., 1999a) administration. The effects of GHRH on human sleep were investigated in three states with a change of the GHRH/CRH ratio in favor of CRH—(i) the second half of the night in young normal men, (ii) in elderly normal men and women, and (iii) in patients with depression. (i) Repetitive iv bolus injections of GHRH during the early morning hours (each hour from 04:00 to 07:00) prompted no major changes of sleep EEG. GH increased whereas HPA hormones remained unchanged (Schier et al., 1997). (ii) At daytime, the response of GH to GHRH is reduced in older men (Iovino et al., 1989). Similarly only a weak sleep-promoting effect of repetitive iv administration of GHRH (hourly from 22:00 to 01:00) was found in healthy elderly women and men. The first NREMS period was prolonged and the number of awakenings decreased. GH levels increased slightly but significantly whereas cortisol levels remained unchanged (Guldner et al., 1997). Furthermore, intranasal administration of GHRH in elderly subjects had only a relatively weak sleep-promoting effect (Perras et al., 1999b). In a pilot study, the hypothesis was tested that after priming (e.g., iv GHRH every 2 days for 12 days) the sleep-promoting effect of GHRH would be restored in the elderly. The study results in two subjects do not support this hypothesis

Figure 25-2

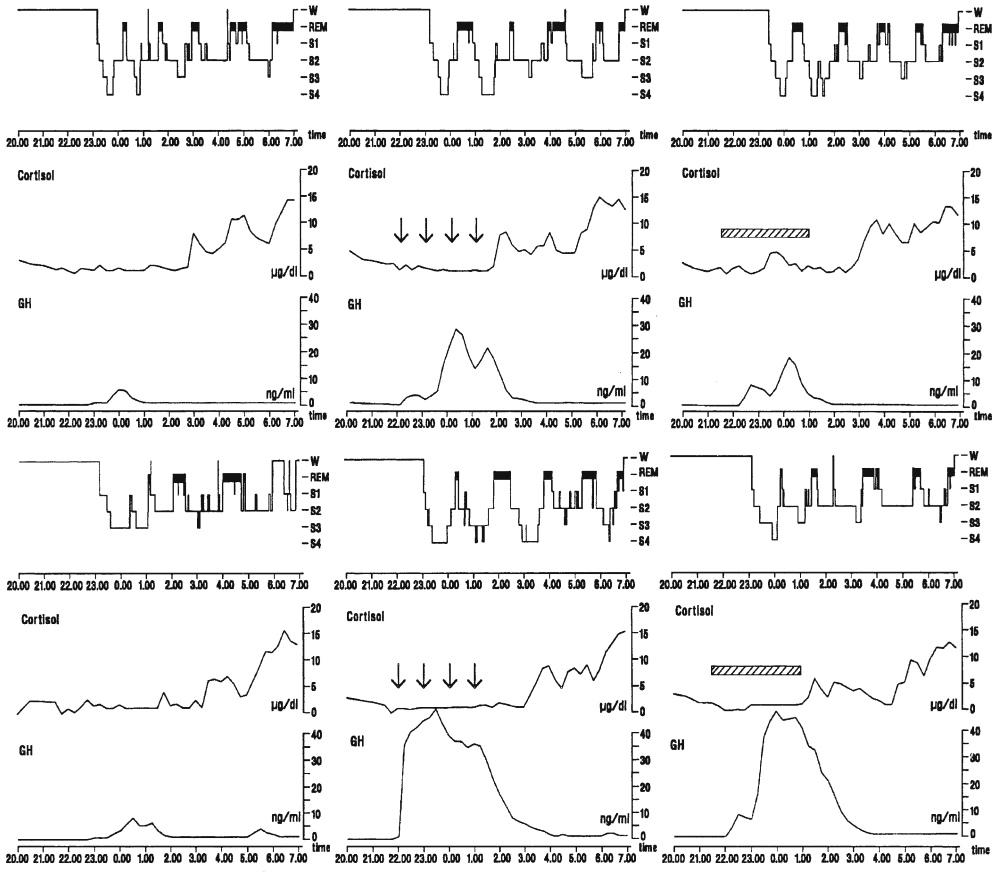
(Murck et al., 1997b). (iii) The influence of pulsatile iv administration of GHRH during the first few hours of the night (22:00 to 01:00) was examined in drugfree patients of both sexes with depression (age range 19–76 years) and in normal controls matched for age and gender. A sexual dimorphism in the response to GHRH was found. In male patients and controls GHRH decreased. ACTH levels during the first half of the night and cortisol levels during the second half of the night decreased. In contrast, these hormones were enhanced in females, regardless of whether they were healthy or depressed. Similarly, NREMS and particularly stage 2 sleep increased and wakefulness decreased in male patients and controls whereas opposite sleep-impairing effects were found in women. These data corroborate a reciprocal antagonism of GHRH and CRH in males (see Section 23.3.4.1), whereas a synergism of GHRH and CRH is suggested in females. The latter issue may contribute to the increased prevalence of mood disorders in women (Antonijevic et al., 2000b, c). In the rat, NREMS decreases and sleep latency increases when GHRH is inhibited by receptor antagonists (Obál et al., 1991). Similarly, NREMS is reduced after intracerebroventricular administration of antibodies to GHRH (Obál et al., 1992b). In humans however, sleep remained unchanged after a GHRH antagonist (Jessup et al., 2004).

Sleep deprivation is a major stimulus for sleep (Borbély et al., 1981; Borbély et al., 1984; Franken et al., 1991). There is good evidence that GHRH mediates this effect. GHRH antibodies antagonized sleep promotion after sleep deprivation in rats (Obál et al., 1992b). Similarly, microinjections of a GHRH antagonist into the area preoptica of rats inhibited the sleep rebound after sleep deprivation (Zhang et al., 1999). Eight hours of sleep deprivation prompted a distinct depletion of hypothalamic GHRH and very low hypothalamic GHRH contents at the end of the experiment (Gardi et al., 1999), whereas hypothalamic GHRH mRNA increased after sleep deprivation in rats (Toppila et al., 1997; Zhang et al., 1999). It is thought that the high rate of release stimulates transcription of GHRH mRNA. The rise in hypothalamic GHRH mRNA concentration is associated with decreases in hypothalamic somatostatin

Figure 25-3

From: Marshall, L., Mölle, M., Böschen, G., Steiger, A., Fehm, H.L., Born, J.: Greater efficacy of episodic than continuous growth hormone releasing hormone (GHRH) administration in promoting slow wave sleep (SWS). *Journal of Clinical Endocrinology & Metabolism*, 81 (1996) 1009-1013. Copyright 1996, The Endocrine Society



levels (Zhang et al., 1998). GHRH receptor mRNA and GHRH binding declined by 50% in the hypothalamus of rats after 8 h of sleep deprivation. In contrast, pituitary GHRH receptors remained unchanged. Characteristically marked exposure of GHRH receptors to GHRH induces downregulation (Bilezikjian et al., 1986). Therefore, it is thought that a robust intrahypothalamic release explains the downregulation of hypothalamic GHRH receptors. The unchanged pituitary GHRH receptor mRNA and binding suggests that excessive GHRH release into the pituitary vessels does not occur during sleep deprivation (Obál, Jr. and Krueger, 2004).

In mice, viral infections induce excess NREMS. The role of the GHRH receptor in this effect was tested. After influenza A infection, the duration and intensity of NREMS increases in mice with normal phenotype, whereas NREMS and EEG delta power decreases in the GHRH receptor deficient *lit/lit* mice. These findings show that GHRH signaling is involved in the NREMS response to influenza infection (Alt et al., 2003).

2.3.2 Growth Hormone, Insulin-Like Growth Factor-1

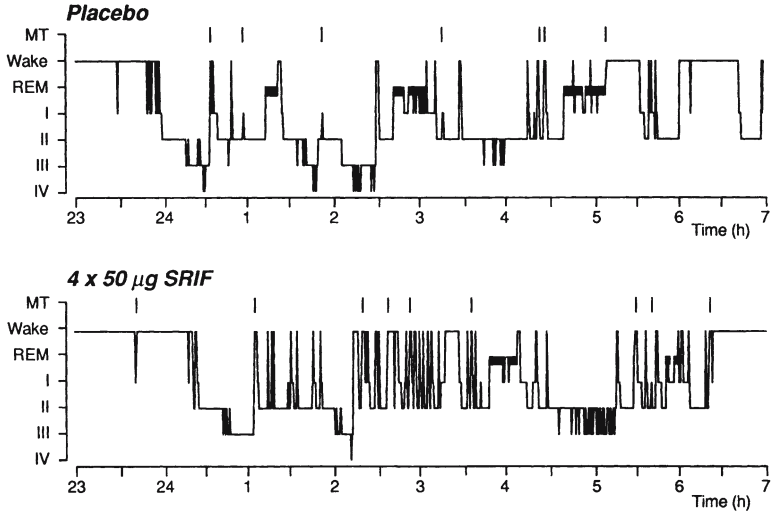
Negative feedback inhibition of GHRH after administration of GH in humans (Mendelson et al., 1980), cats (Stern et al., 1975), and rats (Drucker-Colin et al., 1975; Obál, Jr. and Krueger, 2004), or higher dosages of intracerebroventricular IGF-1 (Obál et al., 1999) decrease NREMS. On the other hand, GH antagonism impairs sleep (Obál et al., 1997a). Low dose intracerebroventricular IGF-1 stimulated NREMS in rats (Obál et al., 1998). Sleep remained unchanged after chronic GHRH substitution to patients with acquired GH deficiency (Schneider et al., 2005).

2.3.3 Somatostatin

After, intracerebroventricular somatostatin selective increases of REMS were reported in rats (Danguir, 1986). In contrast, in rats systemic intracerebro-ventricular administration of the somatostatin analogue, octreotide decreased NREMS and GH secretion (Beranek et al., 1999). Similarly, SWS was reduced and intermittent wakefulness was enhanced in young normal men after subcutaneous administration of octreotide (Ziegenbein et al., 2004). Octreotide is known to be long acting and more potent than exogenous somatostatin. This explains why somatostatin impaired sleep in normal elderly female and male controls after repetitive iv administration (Frieboes et al., 1997) (*Figure 25-4*), whereas it had no effect in young normal men after repetitive and single iv injections (Parker et al., 1974a; Steiger et al., 1992; Kupfer et al., 1992). In cats and

Figure 25-4

Sleep pattern in one subject after placebo and SRIF. MT, movement time; REM, rapid eye movement sleep; I-IV, NREMS stages 1-4. From: Frieboes R-M et al.: Somatostatin impairs sleep in elderly human subjects. Neuropsychopharmacology (1997) 16: 339-345. (with permission)



rats, somatostatin inhibits GABAergic transmission in the sensory thalamus via presynaptic receptors (Leresche et al., 2000). It was suggested that this mechanism contributes to the decrease of NREMS after somatostatin. All these data point to a reciprocal interaction of GHRH and somatostatin in sleep regulation similar to their relationship in the regulation of GH release. The same dose of somatostatin, which was not effective in young men impaired sleep in the elderly probably due to a decline of endogenous GHRH during ageing. The finding that infusion of the somatostatin antagonist arginine enhanced SWS in normal elderly

male subjects supports this theory. It is thought that in this experiment the action of endogenous GHRH was facilitated (Steiger et al., 2002).

2.3.4 Ghrelin and GH Secretagogues

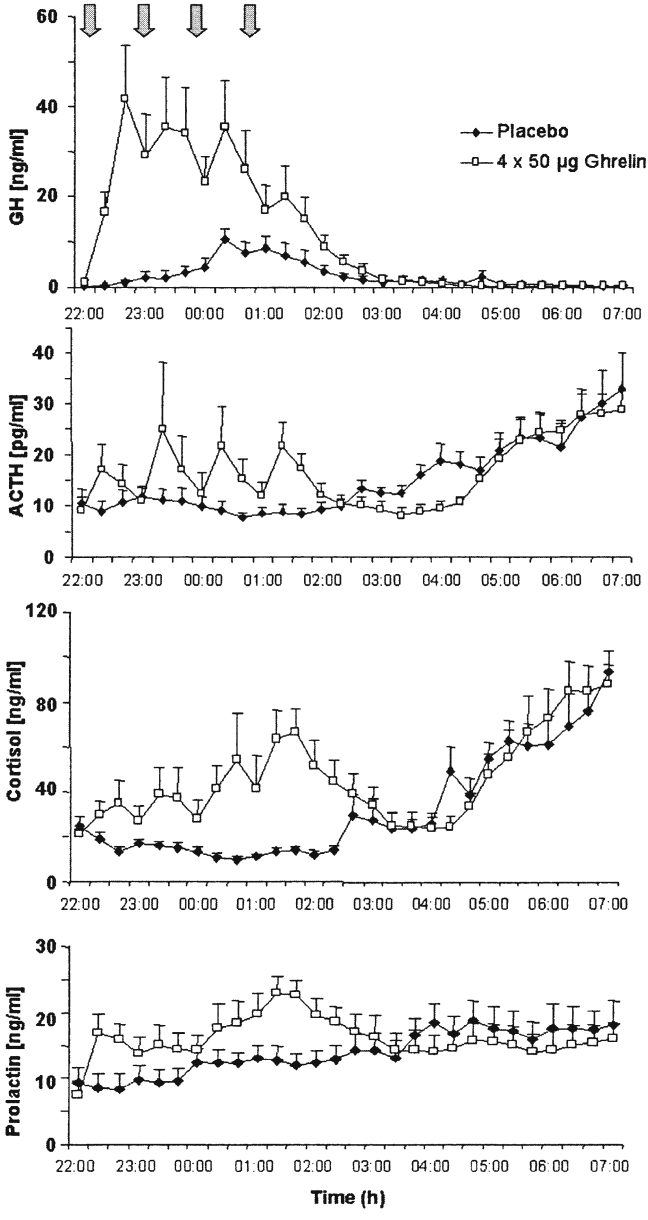
Similar to the effects of GHRH, repetitive iv administration of ghrelin (22:00 to 0100) enhanced SWS and GH in young normal men (Weikel et al., 2003). In contrast to the effects of GHRH, which blunted cortisol in young men (Steiger et al., 1992), ACTH and cortisol increased, particularly during the first half of the night after ghrelin (Weikel et al., 2003). After the first injection of ghrelin, the response of GH was most distinct and the increase of cortisol was relatively low. In contrast, the fourth injection prompted the highest response of cortisol and the lowest of GH (*Figure 25-5*). The pattern of hormone changes after ghrelin resembles the effects of repetitive iv administration of the synthetic GHSs GH-releasing peptide-6 (GHRP-6) (Frieboes et al., 1995) and hexarelin (Frieboes et al., 2004). These findings suggest that ghrelin acts as an interface between the HPA and the HPS systems. The sleep-EEG effects of GHRP-6 and hexarelin however differed from the changes after ghrelin. After GHRP-6 sleep stage 2 increased (Frieboes et al., 1995), whereas after hexarelin SWS and SWA decreased, probably due to a change of the GHRH/CRH ratio in favor of CRH (Steiger, 2002). In mice, ghrelin promoted NREMS (Obál et al., 2003). An intact GHRH receptor was shown to be the prerequisite for this effect, as in mice with nonfunctional GHRH receptors sleep remained unchanged after ghrelin. Oral administration of the GHS MK-677 for 1 week had a distinct sleep-promoting effect in young men and only a weak effect in elderly controls (Copinschi et al., 1997).

Bodosi et al. (2004) investigated the relationships among plasma ghrelin and leptin concentrations and hypothalamic ghrelin contents and sleep and feeding. In order to do this, rats were examined in three conditions: (i) free-feeding rats with normal diurnal rhythms, (ii) feeding restricted to the 12-h light period, and (iii) 5 h of sleep deprivation at the beginning of the light period. Plasma ghrelin and leptin concentrations displayed diurnal rhythms. (i) The ghrelin peak preceeded and the leptin peak followed, the major daily feeding peak in the first hour after dark onset. (ii) The rats showed vigorous eating in the first hour of the light period after food restriction. The diurnal rhythm of ghrelin and leptin reversed in such a way that they maintained their relationship with respect to one another and to feeding activity. The ghrelin peak continued to preceed the feeding peak. Consequently, the ghrelin maximum was found towards the end of the dark period. The leptin peak followed the major feeding activity. The nocturnal ghrelin peak during restrictive feeding was almost double of that of the diurnal ghrelin peak in rats on normal feeding conditions. REMS decreased throughout the light period and increased during the dark period. (iii) Sleep deprivation did not change leptin concentrations, but it stimulated plasma ghrelin concentrations and induced eating. Hypothalamic ghrelin was highly responsive to sleep deprivation, displaying biphasic variations. Ghrelin contents of the hypothalamus increased during sleep deprivation and returned to baseline after sleep deprivation. These results suggest a strong relationship between feeding and the diurnal rhythm of leptin and a major influence of feeding on the diurnal rhythm of ghrelin. The variations in the hypothalamic ghrelin contents point to an association with the sleep–wake activity in rats.

Furthermore, studies in humans contribute to the understanding of the relationship between sleep–wake-behavior and ghrelin levels. Dzaja et al. (2004) compared interactions of sleep and ghrelin levels in young normal men who were semirecumbent during 24 h. When they were allowed to sleep, they showed a sharp increase of ghrelin levels by sleep onset, which was followed by a decline throughout the night. This nocturnal rise of ghrelin was blunted when the subjects were sleep-deprived. Another study suggests gender differences in the nocturnal secretion of ghrelin. Ghrelin levels were determined between 20:00 and 07:00 in normal female and male control subjects who were active during daytime. Ghrelin concentrations differed during the interval between 20:00 and 23:00, when subjects were allowed to sleep. In males, there was a continuous rise of ghrelin concentrations between 20:00 and 23:00. In females, however, ghrelin levels were at 20:00 already in the same range as during the sleeping period. No relationships between ghrelin and sleep stages or the nocturnal secretion of GH, cortisol, and ACTH was found (Schüssler et al., 2005b). In a large sample of more than 1,000 subjects, the interaction between sleep and ghrelin morning levels was investigated. Short sleep time was associated with higher ghrelin levels

Figure 25-5

Time course of nocturnal plasma hormone concentrations. Copyright The American Physiological Society



(Taheri et al., 2004). Similarly, the comparison between extended (12 h) and restricted (4 h) sleep time during 2 days each showed at daytime increases in ghrelin levels, self-rated hunger and appetite, and a decrease in leptin after sleep restriction (Spiegel et al., 2004).

2.4 Animal Models of HPS System Changes

In the so-called supermice, the giant transgenic mice, the metalothionine-1 promoter stimulates expression of rat GH (Mt-rGH mice). Therefore, plasma GH is permanently elevated and secretion pulses are absent. Behavioral observation showed that these mice spend more time sleeping than normal mice (Lachmansingh and Rollo, 1994). Sleep recording showed that during the light period, the amount of NREMS is modestly higher and REMS is almost doubled in these mice compared to normal mice, whereas sleep does not differ between groups at night. Also after sleep deprivation, the MT-rGH mice sleep more than normal mice (Hajdu et al., 2002). In dwarf rats with deficits in the central GHRHergic transmission and reduced hypothalamic GHRH, NREMS is reduced compared to control rats (Obál et al., 2001). In dwarf homozygous (*lit/lit*) mice with nonfunctional GHRH receptors, the amounts of NREMS and REMS are lower than in normal control mice. In the dwarf mice, infusion of GH by Alzet minipumps leads to normalization of REMS, but not of NREMS within 9 days. Similar to ghrelin, GHRH, and the somatostatin analogue octreotide exert no effect on sleep EEG in dwarf mice. These results suggest that (i) GHRH deficiency is associated with decreases in NREMS, (ii) decreases in GH lead to decreases in REMS, (iii) the actions of GHRH, ghrelin, and octreotide on sleep EEG require intact GHRH receptor signaling (Obál, Jr. and Krueger, 2004).

2.5 Interactions of HPS System and Orexin

The orexins (OX-A and OX-B) are derived from their common precursor prepro-orexin. Orexins participate in the sleep regulation (see the chapter by Porkka-Heiskanen and Stenberg in this volume). Recent findings suggest an interaction between OX-A, GHRH, and somatostatin in the regulation of sleep, food intake, and GH release. In patients with narcolepsy, who show orexin deficiency, changes of the circadian pattern of GH secretion were reported, pointing to a disruption of GHRH release (Overeem et al., 2003). Lopez et al. (2004) studied the interaction of these peptides in rats. In situ hybridization showed a decrease of GHRH mRNA levels in the paraventricular nucleus of the hypothalamus after OX-A treatment without changes in the arcuate nucleus. The somatostatin mRNA content in the hypothalamus increases GH-dependently after OX-A. In animal models of GH deficiency, hypophysectomized rats and dwarf Lewis rats GHRH mRNA levels in the paraventricular nucleus of the hypothalamus are reduced.

2.6 Summary

All components of the HPA system participate in sleep regulation. GH is widely sleep dependent. GH administration promotes REMS. The influence of GHRH, ghrelin, and somatostatin on sleep EEG corresponds to their role in the regulation of GH release, at least in male subjects. In the rat, hypothalamic GHRH mRNA and hypothalamic GHRH and ghrelin contents display sleep-related changes. GHRH mRNA peaks at the onset of the light period. GHRH promotes NREMS in several species including humans, in male gender. In women, however, GHRH impaired sleep as NREMS decreases and wakefulness increases. Studies on GHRH effects on sleep in female laboratory animals are lacking. Furthermore, GHRH participates in sleep promotion during recovery sleep after sleep deprivation. The sleep-promoting effects of GHRH declines during ageing. In contrast, the impairing effect of somatostatin increases during ageing. These changes appear to contribute to the age-related decline of SWS and GH. Similar to GHRH, ghrelin enhances NREMS in young normal men and in mice. The effects of GHRH and ghrelin on HPA hormones in males are opposite. After GHRH, ACTH and cortisol decrease in males, whereas these hormones increase

in females. In women, GHRH enhances ACTH and cortisol levels. Intact GHRH receptors appear to be the prerequisite of the effects of ghrelin and of the somatostatin analogue octreotide on sleep. Decreased GHRH acitivity may explain that SWS is lower in dwarfs than in normal controls. Similarly, feedback inhibition of endogenous GHRH may contribute to the decrease of SWS in patients with acromegaly.

3 Hypothalamo–Pituitary–Adrenocortical System

3.1 Basic Activity

The HPA system mediates the reaction to acute physical and psychological stress. This stress reaction is a prerequisite for survival of the individual. It starts with the release of CRH from the parvocellular neurons of the paraventricular nucleus of the hypothalamus. This results in the secretion of ACTH from the anterior pituitary and finally, in the secretion of cortisol (in humans) or corticosterone (in rats) from the adrenocortex. Various cofactors contribute to this cascade (reviewed in: Holsboer, 1999).

In rats, CRH gene transcription levels increase during the dark period, when the animals are active and decrease in the morning and throughout the light period (Watts et al., 2004). In humans during sleep, both the nadir and the major portion of the secretion of ACTH and cortisol occur. The first few hours of the night contain their quiescent period. Between 02:00 and 03:00 h, the first pulse of cortisol occurs. It is followed by further pulses until awakening (Weitzman, 1976; Born and Fehm, 1998). Whereas ACTH is the prime regulator of nocturnal cortisol secretion in humans, the secretion of ACTH and cortisol may dissociate. A complete lack or a minor ACTH burst before the cortisol morning peak was found in about 40% of normal controls (Fehm et al., 1984). Similarly, the pulse concomitants for nocturnal ACTH with cortisol were 47% and for cortisol with ACTH pulses were 60% (Krishnan et al., 1990). During the quiescent period, the major amounts of SWS and the GH peak both occur.

One approach to examining these interactions in more detail is to analyse the relationships in the course of the NREMS–REMS cycle and of cortisol secretion during normal sleep. An association between a decrease in cortisol levels and REMS periods was observed, particularly during the first four sleep cycles. For the fifth sleep cycle, however, increasing cortisol levels during REMS were reported (Fehm et al., 1993). A novel statistical method, event history analysis, was used to assess the effects of cortisol on the transition between sleep stages in normal human control subjects. The aim of this analysis is to assess the instantaneous probabilities of transitions between sleep stages, provided they are influenced by both various time-dependent factors (e.g., hormone secretion) and the history of the process. High cortisol levels facilitated the transition intensity of (i) waking to sleeping around 2 h after sleep onset, (ii) NREMS to REMS around 6 h later, (iii) sleep stage 1 or 2 to SWS around 2, 4 or 6 h later, and (iv) SWS to sleep stage 1 or 2 about 2 h later. Furthermore, high cortisol concentrations at the beginning of REMS periods favored the change to NREMS, whereas later the influence of cortisol on a change became weaker (Yassouridis et al., 1999).

The relationships between cortisol, EEG spectral activity, and by two measures of heart rate variability, the activity of the autonomic nervous system were examined in normal controls (Gronfier et al., 1999). EEG delta power (SWA) was the greatest during the quiescent period of the HPA system. During the period of pulsatile release, the cortisol secretory variations were concomitant with, or anticipated opposite variations 10–20 min later in SWA. Sleep deepening was associated with decreasing cortisol concentrations and low or decreasing sympathetic tone. In contrast, a lightening of sleep was accompanied by increases in cortisol and sympathetic tone. REMS was associated with a decrease in cortisol secretory rates preceding REMS onset and high autonomic activity. An association between the duration of spontaneous sleep and HPA hormone levels was found in normal male subjects, ACTH and cortisol were higher in subjects with short sleep time when compared to subjects with long sleep time (Späth-Schwalbe et al., 1992).

The genetic factors that contribute to the pattern of cortisol secretion were studied in monozygotic and dizygotic pairs of male, normal twins. Genetic control was found for the timing of the cortisol nadir and for the proportion of overall temporal variability associated with pulsatility. In contrast, for the 24-h mean and the timing of the morning acrophase, environmental effects were identified (Linkowski et al., 1993).

Controversial reports exist on the effect of age on HPA hormones. Elevated and unchanged cortisol levels have both been reported in the elderly. The study including the largest sample of normal human adults over a lifetime reported age-dependent increases of mean cortisol levels and of the nadir and selectively in women, of the acrophase. The rhythmicity of cortisol was preserved in the elderly, but the amplitude was dampened and the morning rise was advanced (Van Cauter et al., 1996).

3.2 Sleep in Disorders with Pathological Changes of HPA Activity

In Addison's disease, the capacity of the adrenal glands to produce corticosteroids is severely reduced. Only a few case reports exist on sleep EEG in these patients. No major disturbances of their sleep were found (Gillin et al., 1974; Krieger and Glick, 1974). Addison's patients were compared intraindividually under two conditions, either continuous hydrocortisone replacement or short-term hydrocortisone withdrawal. After hydrocortisone replacement, REMS latency was shortened, and REMS time and intermittent wake time were increased in comparison to withdrawal. These findings suggest that cortisol may be needed to facilitate the initiation and maintenance of REMS (Garcia-Borreguero et al., 2000). In contrast to Addison's disease, hypercortisolism and disturbed sleep are frequent symptoms in Cushing's disease and in depression. It is very likely that common factors underlie the pathophysiology of these changes. Excessive cortisol levels are produced in Cushing's disease, either of central, or peripheral origin. In these patients, SWS is decreased (Krieger and Glick, 1974; Shipley et al., 1992). In one study, in addition, disturbances of sleep continuity (increased sleep latency, enhanced waketime) and REMS (shortened REMS latency, elevated REM density, a measure for the amount of rapid-eye-movement during REMS) were reported (Shipley et al., 1992).

Similar symptoms are frequently observed in depression, whereas the dysregulation of the HPA system is more subtle in affective disorders. Characteristic sleep-EEG findings in depressed patients are disturbed sleep continuity (prolonged sleep latency, increased number of awakenings, early morning awakening), a decrease of NREMS (decreases of stage 2 sleep and SWS, in younger patients a shift of the major portion of SWS from the first to the second sleep cycle), and REMS disinhibition (shortened REMS latency, prolonged first REMS period, elevated REM density) (reviewed in: Ehlers and Kupfer, 1987); (Steiger et al., 1989). Well-documented endocrine changes include signs of (i) HPA overactivity (reviewed in: Holsboer, 1999) and (ii) HPS dysfunction (reviewed in: (Steiger et al., 1989). Most sleep-endocrine studies in depressed patients report elevated cortisol and ACTH (Linkowski et al., 1987; Steiger et al., 1989; Antonijevic et al., 2000c) throughout the night or throughout day and night (24 h) (Linkowski et al., 1987), respectively, in comparison to normal controls, whereas the circadian pattern of cortisol is preserved. This finding is in contrast to its disappearance due to excessive hypercortisolism in Cushing's disease (Weitzman, 1976). A positive correlation between age and cortisol concentrations was found particularly in female patients with depression (Antonijevic et al., 2000c). Elevated cortisol plasma and norepinephrine cerebrospinal fluid (CSF) levels throughout 30 h, but normal ACTH plasma and CRH CSF levels, were reported in a sample of depressed patients (Wong et al., 2000). GH was blunted in most (Steiger et al., 1989; Jarrett et al., 1990; Voderholzer et al., 1993), but not in all (Linkowski et al., 1987) studies. These findings suggest a causal relationship between shallow sleep, low GH, and HPA hyperactivity in depression. Furthermore, there are similarities in the sleep-endocrine changes during depression and during normal ageing (*Figure 25-1*).

Three studies compared sleep-endocrine activity longitudinally between acute depression and recovery. One study showed a decrease of ACTH and cortisol during 24 h and a normalisation of REMS in adult patients after recovery (Linkowski et al., 1987). As some of the patients received tricyclic antidepressants, which are known to suppress REMS (Steiger, 2002) at the examination during recovery it is difficult to differentiate between the effects of remission and of drugs. Intraindividual comparison of adult patients who were drugfree at least 14 days before each examination (Steiger et al., 1989) confirmed a decrease of cortisol levels after recovery. The pathological sleep EEG and low GH levels, however, remained unchanged. Stage 4 sleep even decreased (Steiger et al., 1989). Both studies corroborate that HPA hypersecretion is a state marker of depression in adult patients. In contrast, sleep EEG and 24 h cortisol profiles of prepubertal depressed children did not differ from children with nonaffective psychiatric disorders and normal controls.

Cortisol hypersecretion was found only in 4 of the 45 young patients with depression. These were restudied after recovery. Only one of them showed persistence of hypersecretion (Puig-Antich et al., 1989). These findings show that abnormalities of sleep EEG and of cortisol secretion are infrequent in prepubertal children with depression. This is in line with the view that ageing and depression exert synergistic effects on sleep-endocrine activity (Antonijevic et al., 2000c). The decrease of cortisol after recovery resembles the normalization of pathological results of challenge tests of the HPA system and of CRH CSF levels after remission (reviewed in: Holsboer, 1999). The persistence of most sleep-EEG (Kupfer et al., 1993) and GH changes (Jarrett et al., 1990) after recovery has been confirmed over a period of 3 years. Obviously, cortisol levels normalize independently from the sleep architecture. Hence, hypercortisolism in depression is not secondary to shallow sleep. Interestingly, patients with primary insomnia had increased nocturnal cortisol and a shorter quiescent period than the controls (Vgontzas et al., 2001; Rodenbeck et al., 2002).

Young individuals with insomnia had higher 24-h ACTH and cortisol secretion than controls. Patients with a high degree of objective sleep disturbance (shortened sleep time) secreted more cortisol than those with a low degree. In another sample, however, nocturnal cortisol levels did not differ between patients with insomnia and controls, whereas their melatonin levels were blunted (Riemann et al., 2002). Salivary cortisol after awakening is decreased in patients with primary insomnia (Backhaus et al., 2004). The authors discussed that this decrease may be due to nocturnal cortisol activation after an increased number of nocturnal awakenings.

It appears likely that the metabolic disturbances during acute depression result in a biological scar as reflected by the persisting changes of sleep EEG and of GH levels in remitted patients. This hypothesis is supported by the results of a study of male patients who survived severe brain injury (Frieboes et al., 1999). Several months later, their cortisol levels did not differ from normal controls, whereas their GH levels and sleep stage 2 time were lower. Obviously, there are similarities between the sleep-endocrine pattern of patients after injury and of remitted depressed patients. Whereas cortisol levels were normal at the time of the examination in this study, it appears likely that either HPA overactivity due to stress under the intensive care situation after brain injury or treatment with glucocorticoids in some patients contributes to the changes of sleep EEG and of GH levels.

Only two studies deal with sleep-endocrine activity in psychiatric disorders other than depression. Hypercortisolism was also found in patients with mania (Linkowski et al., 1994). Enhanced cortisol levels during the first few hours of the night were observed in patients with schizophrenia. In these patients, sleep latency was prolonged and REMS was reduced (Van Cauter et al., 1991b).

In obstructive sleep apnea syndrome, during an episode of apnea upper airway constriction, progressive hypoxemia due to asphyxia, autonomic, and sleep-EEG arousal occur. Buckley and Schatzberg (2005) hypothesized that obstructive sleep apnea causes activation of the HPA system through autonomic activation, awakening, and arousal. This HPA activation may be a risk factor in the development of the metabolic syndrome in untreated obstructive sleep apnea. Furthermore, the authors proposed that HPA hyperactivity may contribute to the pathophysiology of obstructive sleep apnea in hypertension.

3.3 Effects of Changes of Sleep–Wake Behavior on HPA Hormones

Weitzman and colleagues (Weitzman, 1976) did pioneering work as they used nonpharmacological manipulations as sleep deprivation and nocturnal awakenings in studying the interaction between sleep EEG and hormones. Their work led to the still valid conclusion that the pattern of cortisol secretion is widely dependent on a circadian rhythm, whereas manipulation of the sleep–wake pattern prompts subtle changes in HPA secretion. A similar approach is provided by studies on the effects of environmental changes.

In the first investigation by Weitzman and colleagues, normal subjects underwent a repetitive 3 h sleep–wake cycle for 10 consecutive days. Each cycle consisted of 2 h wakefulness and 1 h sleep. Finally, cortisol levels were consistently lower during the interval with sleep than during the period awake in each cycle, independently of circadian time (Weitzman, 1976). In a 4-day protocol, a baseline investigation was followed by sleep deprivation. On day 3, the subject was allowed to sleep 12 h later than usual. On day 4,

he slept again at his usual sleeping time. During the first 4 h after sleep onset cortisol levels were reduced, even when sleep took place during the interval when the subject was usually awake (Weitzman et al., 1983). During free running conditions with an average 25 h period, a phase advance of the circadian cortisol rhythm was observed in controls. Cortisol was secreted in large amounts prior to sleep onset. Immediately after sleep onset, cortisol levels decreased sharply for the next 2–3 h (Weitzman et al., 1981).

Various studies investigated HPA activity at several intervals during and after partial and total sleep deprivation. During the night of sleep deprivation, either enhanced or unchanged cortisol concentrations were reported. In the recovery night, after one night of sleep deprivation, cortisol levels were unchanged in young and elderly normal controls compared to baseline conditions (Murck et al., 1999). In one study, patients with depression were investigated during three consecutive nights, before, during, and after sleep deprivation. During the night of sleep deprivation, cortisol levels increased and returned to baseline values during the recovery night (Voderholzer et al., 2004). In the evening of the day after partial or total sleep deprivation, cortisol was elevated in normal controls (Leproult et al., 1997). Similarly, evening cortisol was higher when sleep in normal young men was restricted to 4 h per night for 6 days (Spiegel et al., 1999). In the recovery night, after four nights with restricted sleep, cortisol was blunted during the second half of the night (Follenius et al., 1992). A delayed sleep onset in normal controls prompted a later occurrence of the cortisol rise (Fehm et al., 1993). In rats, 72 h of sleep deprivation resulted in increases in CRH levels in the striatum, limbic areas, and pituitary, whereas hypothalamic CRH was reduced. Significant decreases in CRH binding were reported in the striatum and in the pituitary (Fadda and Fratta, 1997). In vivo microdialysis in rats showed a marked rise in free corticosterone levels in the brain during sleep deprivation (Penalva et al., 2000). Rats were sleep-deprived during intervals up to 92 h. ACTH and corticosterone plasma levels increased from 24 h of sleep deprivation and decreased during the recovery period. After 24 h of recovery, ACTH dropped below baseline levels remaining low until 96 h of recovery (Andersen et al., 2005). All these data point to an enhanced HPA activity during awakenings and sleep deprivation and to a relative decrease of HPA activity during sleep.

The HPA acrophase appears to be linked with the termination of sleep at the morning. The expectation of waking up at a certain time induces a marked increase in ACTH before the end of sleep (Born et al., 1999). This was shown in normal subjects. Lights were switched off at midnight after they had been told that they would be awakened either at 06:00 (once) or at 09:00 (twice). During one of the latter nights, they were allowed to sleep until 09:00. To their surprise the other night, they were awakened at 06:00. When anticipating being awakened at 06:00, distinct increases in ACTH levels before waking were found compared to the condition of unexpected awakening. Arousal from sleep in each of the three conditions prompted increases in ACTH and cortisol concentrations. This change points to an adaptive response to the stress of waking. The increase of ACTH prior to the expected time of waking suggests that anticipation exists also during sleep. This anticipatory increase in ACTH may facilitate spontaneous waking.

The effects of an acute shift of the sleep–wake cycle on cortisol secretion were studied in normal controls. Cortisol secretion was compared during nocturnal and during daytime sleep intraindividually. The 24 h cortisol secretion did not differ between both conditions. The 24 h hormone profiles of the first day were compared to those of the second day of the sleep shift. On this day, the quiescent period was delayed. This finding suggests that an abrupt sleep shift after 2 days can change the circadian pattern of cortisol (Goichot et al., 1998). Cortisol secretion was shown to be relatively stable to environmental changes. After a flight from Europe to the USA, it took 2 weeks for the cortisol pattern of normal control subjects to be totally adapted to the new sleep schedule (Desir et al., 1981). Dissociation of sleep and cortisol rhythm during the first few days after long distance travel are thought to contribute to the symptoms of jet lag.

The interaction between cortisol pulses and SWA was studied in two groups of normal subjects, one group with night sleep (23:00–07:00) and the other with day sleep delayed by 8 h (07:00–15:00). The study showed that SWA may occur in the absence of cortisol pulses, as during the first 3 h of the night. On the other hand, cortisol pulses may occur without any concomitant variations of SWA during wakefulness. When SWA and cortisol are present simultaneously, they are negatively correlated. Cortisol changes precede variations in SWA by about 10 min. This findings show that cortisol and SWA can oscillate independently

from each other, but when they occur at the same time, they are oscillating in phase opposition (Gronfier et al., 1998).

In shift workers, even a long-lasting resistance of the cortisol rhythm to adapting totally to an inverted sleep–wake schedule was reported. Young male night workers who had been on night-shift regularly for at least 2 years were compared to matched day-active male controls. In each group, sleep EEG and hormone secretion were investigated during the usual sleep time (07:00–15:00 in the night workers or 23:00–07:00 in the controls respectively). Furthermore, hormone secretion was examined during the usual work time. Whereas sleep EEG did not differ distinctly between groups, cortisol levels were enhanced in the night workers during the usual sleep time. Conversely, during usual work hours, cortisol was blunted in this sample. Obviously, the quiescent period of cortisol persists during the daytime in night workers (Weibel and Brandenberger, 1998).

Light is the major environmental factor which influences the timing of neuroendocrine rhythms via the suprachiasmatic nucleus. This is corroborated by experiments in which 24 h hormone profiles were determined in normal control subjects on two separate occasions, once after they were chronically exposed to simulated short (8 h) "summer nights" and once after they were chronically exposed to simulated long (14 h) "winter nights". During the "winter nights" the duration of the period of rising cortisol levels was longer than during the "summer nights" (Wehr, 1998). It is likely that the physiological responses to seasonal changes in the duration of days and nights are suppressed in people living in modern civilization, in which they are exposed to artificial light after dark or to artificial darkness during the daytime. Bright light was shown to be a stimulus for cortisol in humans. Normal control subjects were kept on bed-rest with enforced wakefulness in dim light. Early morning (05:00–08:00), but not afternoon (13:00–16:00) exposure to bright light resulted in increased cortisol levels (Leproult et al., 2001).

3.4 Effects of HPA Hormone Administration on the Sleep EEG

3.4.1 Corticotropin-Releasing Hormone

Various preclinical and human studies show that the administration of HPA hormones or their antagonists affects sleep. After intracerebroventricular administration of CRH, SWS decreases in rats (Ehlers et al., 1986) and rabbits (Opp et al., 1989). Even following 72 h of sleep deprivation CRH reduces SWS in rats. Furthermore, sleep latency is prolonged and REMS increases (Marrosu et al., 1990). Repetitive hourly iv injections of 4×50 μg CRH (22:00–01:00) in young normal men has a similar effect on NREMS as SWS and REMS decrease. Furthermore, the GH surge is blunted, and cortisol levels increase during the first half of the night (Holsboer et al., 1988; Tsuchiyama et al., 1995). Similarly, after an iv dose of 100 μg CRH, SWS decreased and sleep stages 1 and 2 increased in young normal male subjects (Tsuchiyama et al., 1995). As mentioned before, the time interval, the dosage, the age, and the protocol of the administration of peptides appear to be crucial methodological issues. For example, after continuous nocturnal infusion of CRH, the sleep EEG remains unchanged (Fehm et al., 1993). Moreover, hourly iv injections of 10 μg CRH (08:00–18:00) fail to induce sleep-EEG changes during the following night (Kellner et al., 1997), whereas melatonin levels decrease. This finding supports the reciprocal interaction between HPA activity and melatonin secretion. After a single iv bolus of CRH in young healthy men EEG activity in the sigma frequency range increases throughout the first three sleep cycles, both after administration during the first SWS period and during wakefulness (Antonijevic et al., 1999b). This finding is in line with the observations (i) that EEG sigma activity increases throughout the night arbitrarily in parallel to the increase in HPA activity and (ii) that the activities of the HPA system and of the EEG sigma range are greater in young women than in young men (Antonijevic et al., 1999a). A dose of CRH, which was not effective in young normal men, impaired sleep in middle-aged normal men (Vgontzas et al., 2001). This observation suggests that the vulnerability of sleep to CRH increases during ageing, similar to the finding mentioned before, that the same dose of somatostatin impairs sleep in the elderly (Frieboes et al., 1997), but not in young subjects (Steiger et al., 1992).

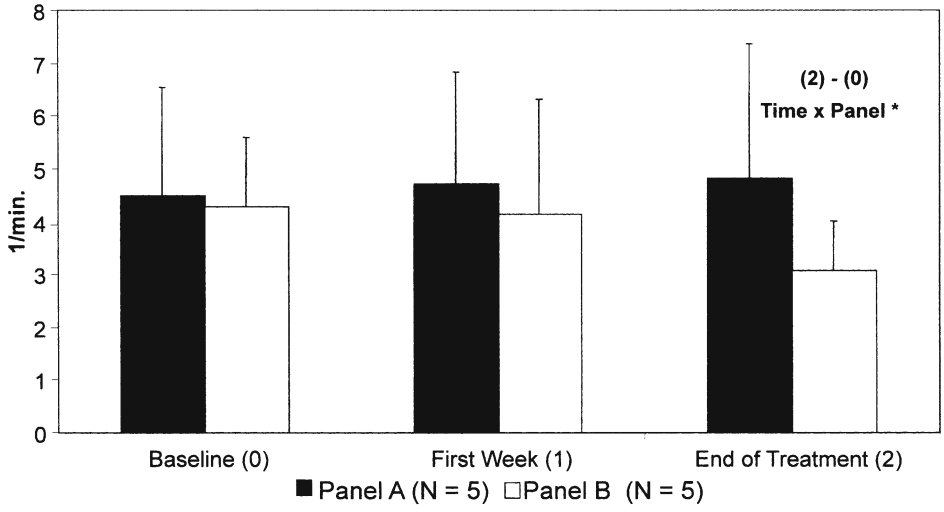
Two studies investigated sleep-EEG changes after CRH antagonists in rats and reported conflicting results. After administration of two different CRH antagonists, α-helical CRH and astressin, before the dark period, wakefulness is reduced in a dose-related manner, whereas the time courses for these effects differ between drugs (Chang and Opp, 1998). α-helical CRH is effective during the first 2 h after administration. Astressin however is effective during hours 7 to 12 after injection. Administration of the substances before the light period does not prompt any effect. These findings support the view that CRH contributes to the regulation of physiological waking periods. In contrast, in another study (Gonzalez and Valatx, 1997) an effect of α-helical CRH was found only in stressed animals. In these rats REMS was enhanced and decreased to values of the nonstressed condition after the substance was injected. In sleep-deprived rats, α-helical CRH diminished the REMS rebound but not the SWS rebound during recovery sleep. The authors suggested that stress acting via CRH is the major factor inducing the REMS rebound after sleep deprivation (Gonzalez and Valatx, 1998).

In rats, kindling of the amygdala at light onset decreases SWS and REMS and enhances corticosterone plasma levels. Intracerebroventricular administration of the CRH antagonists astressin or alpha-helical CRH antagonized the decrease of SWS after kindling in a dose-dependent manner and blocked the increase of corticosterone (Yi et al., 2004). Central increases of CRH are likely to mediate the changes of SWS and corticosterone after kindling.

Some of this preclinical work (Marrosu et al., 1990; Gonzalez and Valatx, 1997; Gonzalez and Valatx, 1998) supports the hypothesis that CRH promotes REMS. From the study in normal humans, the influence of endogenous CRH on REMS is uncertain, however, as CRH suppresses REMS (Holsboer et al., 1988). Furthermore, in normal male controls alpha-helical CRH prompt CRH-agonistic and CRH-antagonistic effects as well on sleep-endocrine activity (Held et al., 2005). Studies on the sleep-EEG effects of ACTH and cortisol help to differentiate the central and peripherally mediated sleep-EEG changes after CRH in humans (see below). The role of CRH in normal and physiological sleep regulation is further elucidated by a study on the effects of CRH receptor-1-antagonism in patients with depression (Held et al., 2004). After a 4 week trial with the substance R121919, the characteristic sleep-EEG changes in patients with depression were counteracted, as the number of awakenings and REM density decreased and SWS increased (*Figure 25-6*).

Figure 25-6

REM-density analysis of variance (1/min) of the three examinations (baseline, first week, end of treatment) compared for panel A (n = 5) and panel B (n = 5). Panel B showed a significant reduced REM-density at the end of the treatment period ((2)-(0), time × panel*). The significance value was *p < 0.05. Reprinted from Journal of Psychiatric Research, 38, Held K. et al., Treatment with the CRH-receptor-antagonist R121919 improves sleep-EEG in patients with depression, 129-136, Copyright 2004, with permission from Elsevier



These results support the view that (i) CRH is involved in the pathophysiology of sleep-EEG changes during depression including REMS disinhibition and that (ii) CRH-1-receptor antagonism helps to treat symptoms of depression including impaired sleep.

3.4.2 Vasopressin

The neuropeptide vasopressin is the major cofactor with CRH in the activation of the stress reaction (Holsboer, 1999). Intracerebroventricular administration of vasopressin increases wakefulness in rats (Arnauld et al., 1989). After acute infusion of the peptide to humans stage 2 sleep increased and REMS decreased (reviewed in: Perras et al., 1999b). Studies with pulsatile administration of this peptide are lacking. Surprisingly, chronic intranasal vasopressin for 3 months improves sleep in normal elderly subjects (Perras et al., 1999b). In detail, total sleep time, SWS and, in the second half of the night, REMS increased. The authors suggested that this treatment may compensate for an age-related decrease in vasopressin content of the suprachiasmatic nucleus or that vasopressin could act by stimulating the expression of central corticosteroid receptors.

Finally, the responsiveness of ACTH and cortisol to their secretagogues during sleep and during wakefulness were compared in normal male control subjects. During sleep, particularly during SWS in the first three hours of the night, the HPA stimulating effect of CRH and vasopressin was blunted (Born and Fehm, 1998).

3.4.3 Adrenocorticotropic Hormone

Nocturnal infusions of ACTH suppress REMS in normal controls (Gillin et al., 1974; Fehm et al., 1993), while cortisol and GH increases (Born et al., 1989). Ebiratide is a synthetic ACTH (4–9) analogue. It shares several behavioral effects of ACTH but does not influence peripheral hormone secretion. Accordingly, after repetitive iv administration of ebiratide, GH and cortisol levels remain unchanged in young male controls. A set of sleep-EEG changes is found after ebiratide corresponding to a general CNS activation. Sleep onset increases and during the first third of the night, awake time is elevated and SWS decreases, whereas REMS remains unchanged (Steiger et al., 1991). These findings support the view that the blood–brain interface is no obstacle for CNS effects of iv administered neuropeptides, because ebiratide induces sleep-EEG changes in the absence of effects on peripheral hormone secretion.

3.4.4 Cortisol, Synthetic Glucocorticoid and Mineralocorticoid Receptor Ligands

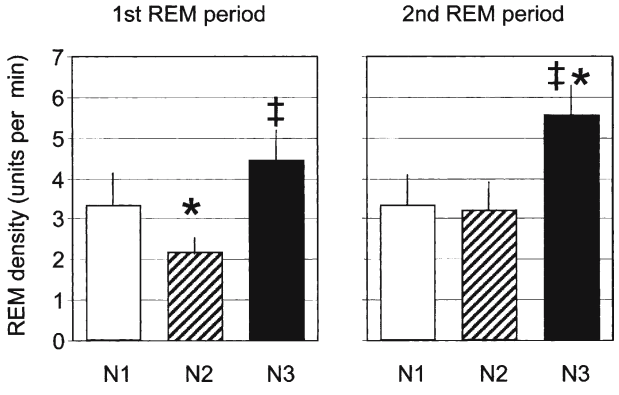
Since the pioneering work of Gillin, it has been known that certain synthetic and endogenous steroids affect sleep (Friess et al., 1995b). Also continuous nocturnal (23:00–07:00) infusion of cortisol (Born et al., 1991) and pulsatile iv administration (hourly from 17:00–07:00) increases SWS (Friess et al., 1994) and SWA (Friess et al., 2004) and decreases REMS in young normal controls. In a second study, GH levels increased after cortisol. Similarly, SWS, SWA, and GH increase and REMS decreases in analog protocols with pulsatile iv administration of cortisol in normal elderly male subjects (Bohlhalter et al., 1997) and in patients with depression (Schmid et al., 2000). As CRH (Holsboer et al., 1988) and cortisol exert opposite effects on SWS (Born et al., 1991; Friess et al., 1994) and GH levels (Friess et al., 1994; Bohlhalter et al., 1997), it appears unlikely that these effects are mediated by stimulation of cortisol. In contrast, these changes may be explained by negative feedback inhibition of endogenous CRH. Because CRH (Holsboer et al., 1988), ACTH (Born et al., 1989), and cortisol (Born et al., 1991; Friess et al., 1994, 1995b) diminish REMS in contrast to ebiratide, REMS suppression may be mediated by cortisol after each of these hormones. This hypothesis is supported by the observation that the inhibition of cortisol synthesis by metyrapone reduces SWS and cortisol levels in normal controls, whereas REMS is not affected (Jahn et al., 2003). In this experiment, endogenous CRH was probably enhanced, as ACTH was distinctly elevated.

As an alternative to CRH feedback inhibition, action on the central cortical steroid receptors was suggested as a way in which cortisol modulates sleep (Born et al., 1991). Two types of these receptors occur in the CNS, the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR). Because in normal controls the MR antagonist, canrenoate, reduces SWS, whereas the mixed MR and GR agonist, cortisol, enhances SWS and inhibits REMS, it was hypothesized that the MR regulates SWS, whereas the GR regulates REMS. This theory is challenged however, because (i) in another study MR agonists and antagonists did not modulate sleep EEG (Friess et al., 1995b), (ii) SWS is increased in elderly controls after cortisol, although the number of MRs is known to decrease distinctly during ageing (Bohlhalter et al., 1997), (iii) MRs and GRs coexist frequently in cells as heterodimers (see below).

In contrast to the effects of acute cortisol administration, treatment of female patients with multiple sclerosis with the GR agonist methylprednisolone during 9 days resulted in shortened REMS latency, increased REM density and a shift of the major portion of SWS from the 1st to the 2nd NREMS period. These changes resemble the sleep-EEG disturbances in depression (Antonijevic and Steiger, 2003) (*Figure 25-7*).

Figure 25-7

REM density during corticosteroid treatment. REM density during the first REMS period decreased significantly after acute high dose treatment with glucocorticoids (N2, hatched bars) compared to baseline (N1, open bars), but increased after prolonged corticosteroid treatment (N3, filled bars) compared to N2. For the second REMS period, REM density was not changed after acute treatment (N2, hatched bars), but significantly increased after prolonged treatment (N3, filled bars) compared to both baseline (open bars) and N2. Values are means ± SEM. N1 = before treatment (baseline), N2 = day 2 of high dose corticosteroid treatment, N3 = day 10 of corticosteroid treatment REM period = REMS period. ‡ = significant difference compared to N2, * = significant difference compared to N1. Reprinted from *Psychoneuroendocrinology*, 28, Antonijevic I.A. & Steiger A., Depression-like changes of the sleep-EEG during glucocorticoid treatment in patients with multiple sclerosis, 780-795, Copyright 2003, with permission from Elsevier



Administration of the mixed GR and progesterone receptor antagonist mifepristone is another approach to modulate the HPA system. In a single case study after oral administration of mifepristone, ACTH and cortisol levels were enhanced in young normal male subjects. Sleep quality was disrupted distinctly with increases of sleep latency and intermittent awake time and decreases of SWS and REMS time. This pilot study was extended in a set of experiments on the effects of GR and MR antagonists in normal controls (Wiedemann et al., 1994). These subjects participated in four protocols: (i) placebo only; in the other protocols before the examination nights dexamethasone was given orally, the following day at 14:00 either (ii) placebo or (iii) the MR antagonist spironolactone, or (iv) mifepristone were administered orally. After pretreatment with dexamethasone sleep EEG remained unchanged. After the combination of dexamethasone with spironolactone, REMS is diminished. Dexamethasone followed by mifepristone results in

decreases of SWS and REMS and an increased number of awakenings. Pretreatment with dexamethasone suppresses ACTH and cortisol secretion. Mifepristone, but not spironolactone counteracts this effect.

Finally, the effects of mifepristone, the progesterone receptor agonist megestrol acetate, and placebo were compared (Wiedemann et al., 1998). Mifepristone and megestrol exert opposite effects on hormone levels, but compound their impairing effects on sleep quality. HPA hormones increase in the morning, and GH decreases after mifepristone, whereas megestrol exerts inverse effects. Again, mifepristone disturbs sleep, and megestrol selectively suppresses REMS. The combination of these substances increase wakefulness and shallow sleep and decreases REMS. It is thought that these effects are mediated by an interaction of GR and progesterone receptors. The precise evaluation of the function of corticosteroid receptors becomes puzzling with the discovery that receptor complexes, composed of both MRs and GRs mediate genomic effects on CNS activity (for discussion, see Bohlhalter et al., 1997).

3.5 Animal Models of HPA System Changes

In rats, it was investigated whether changes in the secretion of corticosterone contribute to the circadian variations in sleep–wake behavior. One week before the start of the experiment, rats were adrenalectomized and substituted with subcutaneous 21-day constant release corticosterone pellets, while another group of animals was sham-operated. In rats, after adrenalectomy and corticosterone replacement, the levels of this hormone remain at about 100 ng/ml throughout the day, whereas in the sham-operated control group, corticosterone levels range between peak values of about 240 ng/ml in the evening and minimal concentration of about 20 ng/ml in the morning. Slightly more, but shorter REMS episodes occur in the experimental group compared to the controls. Hence, the tonic levels of corticosterone exert negligible effects on spontaneous sleep–wake behavior (Langebartels and Lancel, 2000).

In another study, the effects of surgical adrenalectomy and subsequent corticosterone replacement were tested in rats under several conditions: before surgery, 14 days after adrenalectomy, which is known to elevate endogenous CRH; after corticosterone replacement in physiological dosage designed to restore CRH levels, or at a supraphysiological dosage suppressing CRH. Adrenalectomy reduces the amplitude of the diurnal rhythms of maximal and average sleep bout lengths. In the EEG power spectra after adrenalectomy, power from 1 to 4 Hz decreases, whereas power from 9 to 12 Hz increases. Physiological corticosterone replacement reverses some of these effects. Supraphysiological corticosterone replacement decreases NREMS. The finding suggests that adrenalectomy and supraphysiological corticosteroid replacement each altered sleep architecture without affecting sleep homeostasis (Bradbury et al., 1998).

In the Lewis rat, the synthesis and the release of CRH is reduced due to a hypothalamic gene defect in comparison to the Fisher 344 and Sprague–Dawley rat strains. Lewis rats spend less time awake and more time in SWS than the intact strains. REMS does not differ between strains. After intracerebroventricular administration of CRH, waking is enhanced similarly in Lewis and Sprague–Dawley rats (Opp, 1997). Obviously, the mechanisms mediating the response to exogenous CRH are not disturbed in the Lewis rats. Vice versa, spontaneous wakefulness of rats is reduced by a CRH antisense oligodeoxynucleotide (Chang and Opp, 2004). A role in the maintenance of wakefulness and sleep-disturbing effects of CRH are confirmed by these studies.

3.6 Summary

In contrast to GH, ACTH, and cortisol are widely dependent on a circadian rhythm. During the night, both their nadir and their acrophase occur in humans. Nocturnal awakenings and sleep deprivation result in increases of HPA hormone levels. CRH and ACTH administration impairs sleep. Various studies in humans and laboratory animals support the view that CRH is involved in the maintenance of wakefulness. Some but not all studies suggest a role of CRH in the promotion of REMS. In addition, cortisol may enhance REMS. HPA overactivity contributes distinctly to the pathophysiology of depression, including the sleep-EEG changes in affective disorders. It is thought that a reciprocal interaction of GHRH and CRH plays a key role

in sleep regulation. During depression (CRH overactivity) and during normal ageing (reduced GHRH activity), the GHRH:CRH ratio is changed in favor of CRH. This appears to contribute to the similar changes of sleep-endocrine activity during an episode of depression and during normal ageing.

4 Hypothalamo–Pituitary–Thyroid System

4.1 Basic Activity

The secretion of thyroid stimulating hormone (TSH) and of the thyroid hormone thyroxin is related to circadian rhythm (Chan et al., 1978; Brabant et al., 1987). The minimum levels of TSH occur during the daytime. The level of TSH rises during the night and reaches its maximum by midnight. Then TSH levels decline during the early morning hours. The course of thyroxin release is opposite to that of TSH. Thyroxin concentrations are low during the night and increase during daytime. One study reported declining TSH levels during REMS periods (Follenius et al., 1988).

4.2 Sleep in Hypothyroidism and Hyperthyroidism

Changes of sleep–wake behavior are well-known symptoms of disorders of the thyroid gland. From clinical practice, it is well established that hyperthyroidism is linked with insomnia. In contrast, fatigue occurs frequently in patients with hypothyroidism. Therefore, it is astonishing that only a few data on sleep EEG in these diseases are available. One study reported reduced SWS in patients with hypothyroidism in comparison to normal controls. These changes normalized after therapy (Kales et al., 1967).

4.3 Effects of Thyrotropin-Releasing Hormone Administration

Pulsatile iv administration of thyrotropin-releasing hormone (TRH) decreases sleep efficiency and prompts the advanced occurrence of the cortisol morning rise in young normal male control subjects. All other sleep-EEG, cortisol, and GH variables remained unchanged (Hemmeter et al., 1998).

4.4 Summary

TSH and thyroxin are related to a circadian rhythm. Whereas changes of sleep–wake behavior in hypo- and hyperthyroidism are well known, there is only one study in this field. In patients with hypothyroidism, SWS was reduced. TRH exerts only a weak effect on sleep EEG as sleep efficiency decreases.

5 Insulin

5.1 Basic Activity

Insulin stimulates glucose uptake in adipocytes and skeletal muscles. Both, circadian rhythmicity and sleep, influence the profiles of glucose and the insulin secretion rate throughout 24 h. This results in higher mean levels during nocturnal sleep (Van Cauter et al., 1991a). Furthermore, slow oscillations with a periodicity of 50–150 min occur in animals and humans for both glucose and insulin secretion rate. To determine whether these oscillations are influenced by sleep, a sample of young normal subjects was investigated twice over 24 h during continuous enteral nutrition, once with a normal nocturnal sleep from 23:00 to 07:00 h, and once with a shifted daytime in sleep from 07:00 to 15:00 h. The amplitude of glucose and the insulin secretion rate oscillations increased distinctly during the sleep periods, whatever time they were performed,

whereas the influence of the time of the day was not significant. Hence, the increased amplitude of glucose and insulin secretion rate oscillations is related to sleep rather than to the time of the day (Simon et al., 1994).

5.2 Effects of Insulin Administration

Systemic insulin injection (Sangiah et al., 1982), as well as intracerebroventricular insulin infusion during 3 days (Danguir and Nicolaidis, 1984), prompts increases of NREMS in rats. Rats with experimental diabetes mellitus show decreases of NREMS and REMS. Their sleep normalizes after systemic insulin infusion (Danguir, 1984).

6 Prolactin

6.1 Basic Activity

Prolactin is a circulating hormone and a neuroprotein as well. Prolactin is localized particularly in the hypothalamus (review: Roky et al., 1995). In humans, the prolactin level rises after sleep onset and reaches its peak during the second or the last third of the night (Weitzman, 1976). In contrast to various other hormones, prolactin is affected neither by normal ageing (Van Coevorden et al., 1991) nor by an episode of depression (Steiger and Holsboer, 1997b). During the recovery night after sleep deprivation, prolactin levels increase both in young and in elderly normal subjects (Murck et al., 1999).

A relationship between the pattern of prolactin secretion and the NREMS–REMS cycle was found in humans. Prolactin nadirs occur during REMS periods and prolactin levels rise during NREMS periods (Parker et al., 1974b). Furthermore, a temporal relationship between SWA and prolactin secretion was found in young human subjects (Parker et al., 1974b). Decreased dopaminergic inhibition of pituitary prolactin release is thought to lead to the increase of prolactin secretion during NREMS. However, a positive correlation between sleep cycles and plasma prolactin concentrations was not confirmed by another study (Van Cauter et al., 1982). A study on the circadian influences of sleep–wake and light–dark cycles on prolactin release suggests that the nocturnal rise in prolactin is not sleep-associated, but rather is rest dependent (Wehr et al., 1993). In normal human controls, the prolactin secretory rate is elevated throughout the sleep period independently from sleep quality. In this study, experimentally impaired sleep did not change prolactin release (Spiegel et al., 1994).

In Sprague–Dawley and Wistar rats, maximum plasma prolactin concentrations occur at the dark period. In another strain, however, prolactin pulses were observed at the end of the light period (review: Roky et al., 1995). In all, the timing of prolactin release appears to differ between species. In humans, prolactin is released during the night. Most studies suggest that prolactin is not sleep-associated but rather is dependent.

In the twin study mentioned before (Section 3.1), the genetic and environmental influences on prolactin release during waking and sleep were investigated (Linkowski et al., 1998). Baseline daytime prolactin concentrations are partially under genetic influence, whereas the amplitude and overall wave shape of the secretory profile at daytime are genetically determined. The secretory response to a standardized sleep/circadian stimulus is also partly genetically controlled.

6.2 Sleep in Prolactinoma

In patients with hyperprolactinoma, SWS is increased selectively when compared to normal controls (Frieboes et al., 1998). This symptom appears to be unique when compared to other endocrine disorders, which are linked with impaired sleep.

6.3 Effects of Hormone Administration

6.3.1 Prolactin

Prolactin administration promotes REMS in cats, rabbits, and rats. After subcutaneous injection of prolactin, REMS increases in rabbits. The same effect is found after intrahypothalamic injection of prolactin in rats (Roky et al., 1994). In addition, systemic administration of prolactin during the light period stimulates REMS. In contrast, injection of prolactin during the dark period inhibits REMS (Roky et al., 1993). The REMS-promoting effect of prolactin was also found in pontine cats after hypophysectomy (Jouvet et al., 1986). An experimental prolactin-secreting tumor under the kidney capsule leads to long-term hyperprolactinemia in rats, and to an increase in nocturnal REMS, whereas REMS during the day decreases progressively (Valatx et al., 1994). In adult rats bearing juvenile rat anterior grafts under the capsule of the kidney, a distinct increase in REMS and enhanced duration of NREMS with a trend to increased SWA was found (Obál et al., 1992a). Likewise, systemic or intrahypothalamic injection of antiserum to prolactin decreases REMS in rats (Roky et al., 1994; Obál et al., 1997b). Similarly, intrahypothalamic injection of prolactin antiserum to rats decreases REMS. These data point to promotion of REMS after prolactin in rats. The increase of prolactin in these studies differs from the excessive hyperprolactinemia in patients with prolactinoma who showed increased SWS but unchanged REMS (Frieboes et al., 1998). The effects of a moderate increase of prolactin on human sleep have not been investigated so far.

6.3.2 Prolactin-Releasing Peptide

Intracerebroventricular infusion of prolactin-releasing peptide prompts in a dose-dependent manner different effects on sleep and hormone secretion in rats. At 0.1 nmol, REMS and plasma prolactin increase, whereas GH is blunted. After a dose of 1.0 nmol, NREMS and REMS increase, whereas 10.0 nmol enhances only NREMS (Zhang et al., 2001).

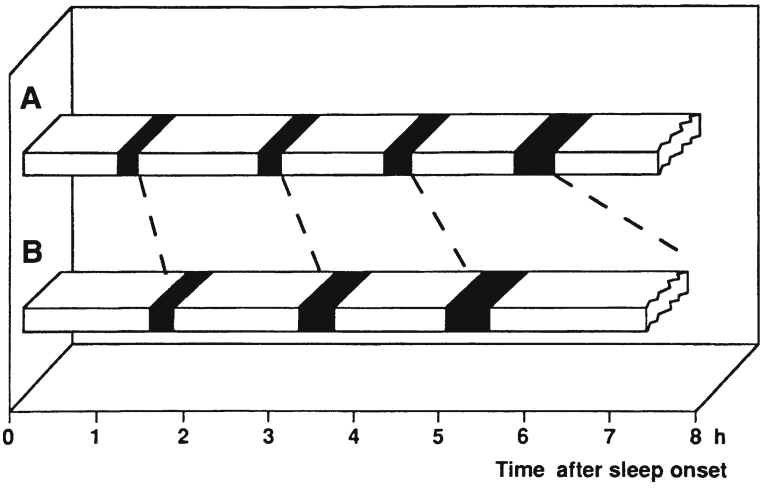
6.3.3 Vasoactive Intestinal Polypeptide Interaction with Prolactin and Sleep

In addition, vasoactive intestinal polypeptide (VIP) enhances REMS after intracerebroventricular administration in laboratory animals (Drucker-Colin et al., 1984). When VIP was given to rats during the dark period, NREMS and REMS increased (Riou et al., 1982; Obál et al., 1994). Similarly, VIP microinjections into the pontine reticular tegmentum enhance REMS in rats. This effect lasts up to 8 days (Bourgin et al., 1997). It is thought that interaction with the cholinergic system mediates the enhancement of REMS. This view is corroborated by the observation, that VIP microinjections into the oral pontine tegmentum enhance REMS in rats (Bourgin et al., 1997).

The REMS-promoting effect of systemic VIP was inhibited by immunoneutralisation of circulating prolactin in the rat. Therefore, it is thought that stimulation of prolactin is involved in the promotion of REMS after VIP (Obál et al., 1992a). VIP antibodies neutralized a REMS-promoting substance that accumulated in the CSF of sleep-deprived cats (Drucker-Colin et al., 1988). Subsequently, an increase of VIP was found in the CSF of REMS-deprived cats (Jimenez-Anguiano et al., 1993). After central administration of VIP antibodies (Riou et al., 1982) or a VIP antagonist to rats (Mirmiran et al., 1988), REMS decreases.

In young normal human male subjects, two doses of VIP exert different effects (Murck et al., 1996). After pulsatile administration of 4×10 µg VIP from 22:00 to 01:00, prolactin levels decrease, whereas sleep EEG remains unchanged. In contrast, after the higher dose of 4×50 µg VIP, prolactin levels increase. Furthermore, the NREMS–REMS cycles are decelerated (*Figure 25-8*). Each of the NREMS and REMS periods is prolonged, the cortisol nadir appears advanced, and the GH surge is blunted (Murck et al., 1996). These findings suggest that VIP exerts a specific effect on the temporal organization of the NREMS–REMS cycle and the sleep-related hormone secretion including the timing of the cortisol nadir. VIP appears to

Figure 25-8
Summarized sleep cycles on basis of conventional sleep electroencephalographic analysis under placebo (A) and 4 × 50 μg VIP (B); n = 10. Open bar, NREMS period; solid bar, REMS period. From: Murck, H., Guldner, J., Frieboes, R.M., Schier, T., Wiedemann, K., Holsboer, F., Steiger, A.: VIP decelerates nonREM-REM cycles and modulates hormone secretion during sleep in men. *American Journal of Physiology*, 271 (Regulatory, Integrative and Comparative Physiology 40) (1996) R905-R911. Copyright The American Physiological Society



affect the circadian clock, resulting in prolonged sleep cycles, and the early occurrence of the cortisol nadir. The blunted GH surge may be the consequence of advanced elevated HPA activity. It is unclear whether the effects of systemic VIP are the same as the actions of intracerebral administration of VIP. The mechanisms of promotion of REMS by intracerebral VIP may differ from the sleep response to systemic VIP. For example, systemic VIP did not reach the brain stem, whereas it may reach the hypothalamus and modulate activity of the suprachiasmatic nucleus, as suggested by the findings in humans.

6.4 Animal Models of Changed Prolactin Activity

In genetically hypoprolactinemic rats, a decrease of REMS was reported (Valatx and Jouvet, 1988). However, in this study the recordings were done at room temperature. For these hairless rats, this temperature means a cold environment, and cold exposure may cause the decrease of REMS. In a warm environment, sleep durations of these rats did not differ from normal rats, whereas their circadian sleep–wake rhythm was changed. The circadian SWS rhythm remained unchanged, whereas the circadian REMS rhythm was reversed (3/4 during the night, 1/4 during the day) (Roky et al., 1995).

7 Other Peptides

7.1 Cortistatin

The brain-specific peptide cortistatin is highly homologous to somatostatin, whereas it is a product of a gene different from the somatostatin gene (de Lecea et al., 1997; Spier and de Lecea L., 2000). In contrast to somatostatin, which is widely distributed in the brain, cortistatin is localized mainly in the cerebral cortex and in the hippocampus (de Lecea et al., 2002). After intracerebroventricular administration of cortistatin to rats, NREMS increased distinctly (de Lecea et al., 1996). This finding suggests that the effects of cortistatin and somatostatin (see above) on sleep are opposite.

7.2 Galanin

Galanin is a peptide that is widely located in the mammalian brain and coexists in neurons with various peptides and classical neurotransmitters participating in sleep regulation. Furthermore, it stimulates GH via GHRH in man (Davis et al., 1987). Sleep in the rat remains unchanged after intracerebroventricular administration of galanin, whereas REMS deprivation induced galanin gene expression (Toppila et al., 1995). After repetitive iv administration of galanin to young normal male subjects, SWS and the duration of REMS periods increase, whereas the secretion of GH and cortisol remain unchanged (Murck et al., 1997a). A cluster of GABAergic and galaninergic neurons was identified in the ventrolateral preoptic area, which is thought to stimulate NREMS (Saper et al., 2001).

Galanin or placebo was given iv to patients with depression during a steady state of antidepressive therapy with the tricyclic trimipramine. After galanin is administered, REMS latency increases, and the severity of depression as measured by the Hamilton Depression Scale decreases. These findings suggest an acute antidepressive effect of galanin (Murck et al., 2004).

7.3 Neuropeptide Y

In sleep regulation, neuropeptide Y (NPY), besides GHRH, appears to be a physiological antagonist of CRH. NPY exerts a dual action on the HPA system. After intracerebroventricular administration, low doses of NPY suppress corticosterone in the rat, whereas higher doses enhance corticosterone and ACTH (Harfstrand et al., 1987). Similarly, increases of hypothalamic CRH levels after NPY (Haas and George, 1989), as well as a CRH antagonistic action of NPY were described. NPY is found in several neuronal circuits in the CNS, and NPY actions may greatly vary with these action sites.

Similarly, opposite effects of CRH and NPY were found in animal models of anxiety (reviewed in Steiger and Holsboer, 1997a). After intracerebroventricular administration of NPY to rats, EEG spectral activity changes in a similar manner to the effects of benzodiazepines (Ehlers et al., 1997a). The prolongation of sleep latency by CRH is antagonized in a dose-dependent manner by NPY in rats (Ehlers et al., 1997b). In young normal male subjects, repetitive iv administration of NPY decreases sleep latency, the first REMS period, cortisol and ACTH levels, and increases stage 2 sleep and sleep period time (Antonijevic et al., 2000a). In patients with depression of both sexes, with a wide age range and age-matched controls, the sleep latency is shortened, and prolactin levels increase after NPY, whereas cortisol and ACTH levels and the first REMS period remain unchanged (Held et al., 2006). These data suggest that NPY participates in sleep regulation, particularly in the timing of sleep onset as an antagonist of CRH acting via the $GABA_A$ receptor.

7.4 Neuropeptide S

Neuropeptide S (NPS) was recently described as a peptide that potently modulates wakefulness and may also regulate anxiety. NPS acts by activating its cognate receptor (NPSR). The NPSR mRNA is found widely in the brain, including the amygdala and the midline thalamic nuclei. NPS is expressed in a cluster of cells located between the locus coeruleus and Barrington's nucleus. Central administration of NPS in rats increased dose-dependent wakefulness and decreased SWS and REMS in a dose-dependent manner (Xu et al., 2004).

7.5 Pituitary Adenylate Cyclase Activating Polypeptide

Pituitary adenylate cyclase activating polypeptide (PACAP) is a member of the VIP family. Intracerebroventricular injection of PACAP at dark onset enhanced REMS (Fang et al., 1995). In young normal male subjects, however, after pulsatile iv administration of PACAP, the distribution of SWS and REMS changed during the night. SWS decreased during the first and increased during the fourth sleep cycle. The ratio of

REMS to NREMS sleep decreased during the fourth sleep cycle. GH and cortisol remained unchanged, whereas prolactin increased by trend during the first half of the night (Antonijevic et al., 1997).

7.6 Substance P

The neuropeptide substance P is a tachykinin acting as an excitatory neurotransmitter and/or neuromodulator. Microinjection of substance P into the ventrolateral preoptic area of rats enhances SWS. This effect is blocked by a phospholipase C inhibitor and by 3-mercaptopropionic acid, an inhibitor of GABA synthesis and release (Zhang et al., 2004). Whereas this study suggests sleep-promoting effects of substance P, in young normal male subjects, repetitive iv administration of substance P increased wakefulness, stage 1 sleep, REMS latency and cortisol and TSH levels. GH decreased after substance P. It is thought that these results point to a central arousing effect of substance P in humans (Lieb et al., 2002).

8 Melatonin

8.1 Basic Activity

Melatonin secretion is related to the light–dark cycle. Melatonin levels are maximal during the dark period in light active and in dark active species as well. It is thought that melatonin is primarily a neuroendocrine transducer promoting an increased propensity for "dark appropriate" behavior. Hence, it is suggested that melatonin is only a hypnotic in light active species (van den Heuvel et al., 2005).

8.2 Effects of Melatonin Administration

Study results on a beneficial effect of melatonin in young and elderly subjects are ambiguous (Zhdanova et al., 1997; Baskett et al., 2001; Zhdanova, 2005; van den Heuvel et al., 2005). A possible side effect of long-term treatment with melatonin is a blunting of sexual steroids in men and women. So far, there is a lack of sufficient data from clinical studies in order to recommend melatonin as a hypnotic. Some studies suggest that due to phase-shifting properties, melatonin may be helpful in the treatment of rhythm disturbances, like jet lag and disturbed rhythms in blind patients (Zhdanova et al., 1997; Sack et al., 2000).

9 Gonadal Hormones

9.1 Basic Activity

In young females during puberty, highest values of estradiol occur between 14:00 and 16:00 h, and lowest values are found during the night (Boyar et al., 1976). In a small group of adult women, no clear interaction between estradiol levels and sleep was observed (Alford et al., 1973). In males, testosterone rises constantly throughout the night (Weitzman, 1976).

9.2 Sleep in Women

In women, the menstrual cycle, pregnancy, and the menopause reflect distinct changes in endocrine activity and have some impact on sleep regulation. Only few studies have addressed these issues so far. Most studies on sleep regulation and sleep disorders were performed selectively in men or in male animals. One of the reasons why females are not included in such studies is because of the variability of the menstrual cycle (Kimura, 2005). On the other hand, women experience sleep problems more often than men do.

9.2.1 Menstrual Cycle Effects on Sleep

In normal women, sleep EEG was recorded every second night throughout one entire menstrual cycle. The percentage of REMS tended to be higher in the early follicular than in the late luteal phase, and the percentage of NREMS showed higher values in the luteal compared to the follicular phase. In NREMS, EEG power density in the upper frequency range of the sleep spindles (14.25–15.0 Hz) exhibits a large variety across the menstrual cycle, with maximum in the luteal phase (Driver et al., 1996). Normal cycling female rats show significantly less REMS during proestrus nights than during metestrus and diestrus nights, whereas no changes in daytime sleep patterns are found across the estrous cycle (Fang and Fishbein, 1996).

9.2.2 Sleep in Pregnancy

Sleep EEG was recorded in nine healthy women during each trimester of pregnancy. Waking increases from the second to the third trimester, whereas REMS decreases from the first to the second trimester. In NREMS, a progressive reduction of power density occurs (Brunner et al., 1994). Between the third trimester of pregnancy and 1 month postpartum, REMS latency decreases (Lee et al., 2000). In the rat, during pregnancy, nocturnal NREMS increases across the entire period, whereas REMS is enhanced only during the early period. After pregnancy, enhanced sleep returns to baseline (Kimura et al., 1998) (*Figure 25-9*).

9.2.3 Sleep Changes during Menopause

A distinct decline in the sigma frequency range is reported in women during the menopause, whereas in men these changes occurred more gradually (Ehlers and Kupfer, 1997). After menopause, sleep-endocrine changes associated with depression are accentuated. This hypothesis is supported by a comparison of sleep-endocrine activity in pre- and postmenopausal women with depression and in matched controls. Cortisol is enhanced in the postmenopausal patients, whereas it decreases in postmenopausal controls. Sleep-EEG changes namely disturbed sleep continuity is characteristically associated with depression. A decrease in SWS and an increase of REM density are prominent in post- but not in premenopausal patients. An inverse correlation exists between the decline in SWS and in sleep continuity and follicle stimulating hormone (FSH) secretion in patients with depression. These observations suggest a role of menopause for these sleep-EEG changes. In premenopausal patients, however, a shift in SWS and SWA from the first to the second NREMS period was found, which was not related to age or hormone secretion (Antonijevic et al., 2003).

9.3 Effects of Gonadal Hormone Administration

9.3.1 Gonadal Hormone Administration in Adults

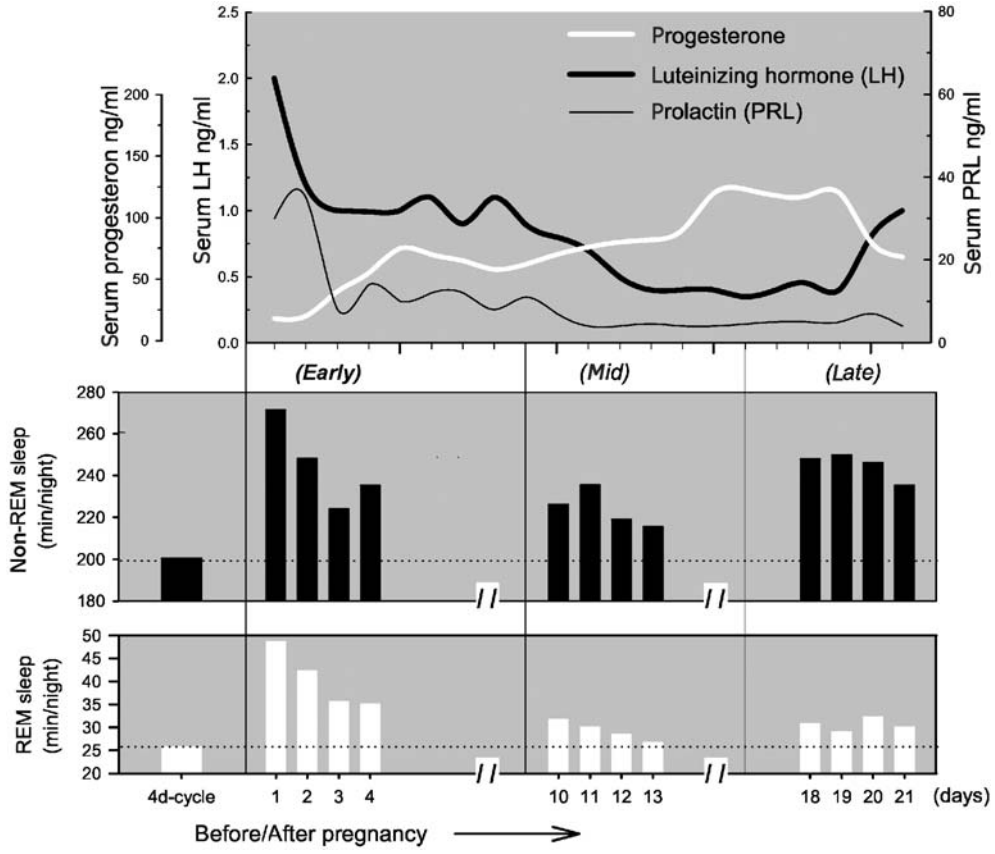
Administration of gonadal hormones to adult animals exerts minimal effects on sleep or on sex differences in sleep (Manber and Armitage, 1999). Similarly, only weak effects of high chronic dosages (80–100 mg) of estradiol in transsexual men who underwent cross-gender therapy to women were found. Stage 1 sleep increased in these patients (Künzel et al., 2000).

9.3.2 Hormone Replacement Therapy

In postmenopausal women, estrogen replacement therapy by skin patch (50 μg of estradiol per day) enhances REMS and reduces intermittent wakefulness during the first two sleep cycles. The normal decrease

Figure 25-9

Endocrine changes and sleep patterns during pregnancy in the rat. Upper panel shows circulating concentrations of luteinizing hormone (LH), prolactin (PRL), and progesterone; lower two panels show changes in nocturnal NREMS (nonREM sleep) (*middle*) and REMS (REM sleep) (*bottom*) relative to the baseline in estrous cycle



in SWS and SWA from the first to the second cycle is restored (Antonijevic et al., 2000d). These data suggest that estrogen treatment after menopause can help to restore the normal sleep-EEG pattern in women. For the effects of progesterone replacement, please see Section 10.2.2 below.

9.4 Animal Models—Ovariectomy, Castration

REMS is enhanced during the night and is reduced during daytime in adult female rats with ovariectomy, whereas SWS is increased in particular during the night. After subsequent estradiol replacement, the circadian pattern of sleep–wake behavior was restored by reducing the amount of REMS during the night (Colvin et al., 1969). After castration, REMS increases in neonatal mice. This effect is reversed after administration of testosterone (Yang and Fishbein, 1995).

10 Neuroactive Steroids

10.1 Introduction

Certain steroids, so-called neuroactive steroids, exert direct effects only on neuronal membranes and thereby rapidly affect CNS excitability (Paul and Purdy, 1992). It is thought that their effect on neuronal excitability is mediated by the gamma-aminobutyric acid $(GABA)_A$-receptor complex. However, classical steroid hormones including progesterone may also act as functional antagonists at the 5-hydroxytryptamine type 3 (5-HT-3) receptor, a ligand-gated ion channel or at distinct glutamate receptors (Rupprecht, 2003). Neuroactive steroids were found to be involved in the regulation of anxiety, memory, and sleep. Glial cells are capable of synthesizing certain neuroactive steroids independently of peripheral steroid sources (Jung-Testas et al., 1989). Various neuroactive steroids exert specific effects on sleep EEG in humans and rats.

10.2 Effects of Neuroactive Steroids Administration on the Sleep EEG

10.2.1 Pregnenolone, Pregnenolone Sulfate

When an oral dose of 1 mg pregnenolone is given to young normal male controls, it exerts sleep-EEG changes resembling the effects of a partial inverse agonist at the $GABA_A$ receptor, as SWS increases, and EEG power in the spindle frequency range decreases (Steiger et al., 1993) (*Figure 25-10*). Similarly in rats after subcutaneous pregnenolone at the beginning of the light period, SWA increases (Lancel et al., 1994). Intraperitoneal administration of pregnenolone sulfate in rats, however, increases REMS (Darnaudery et al., 1999).

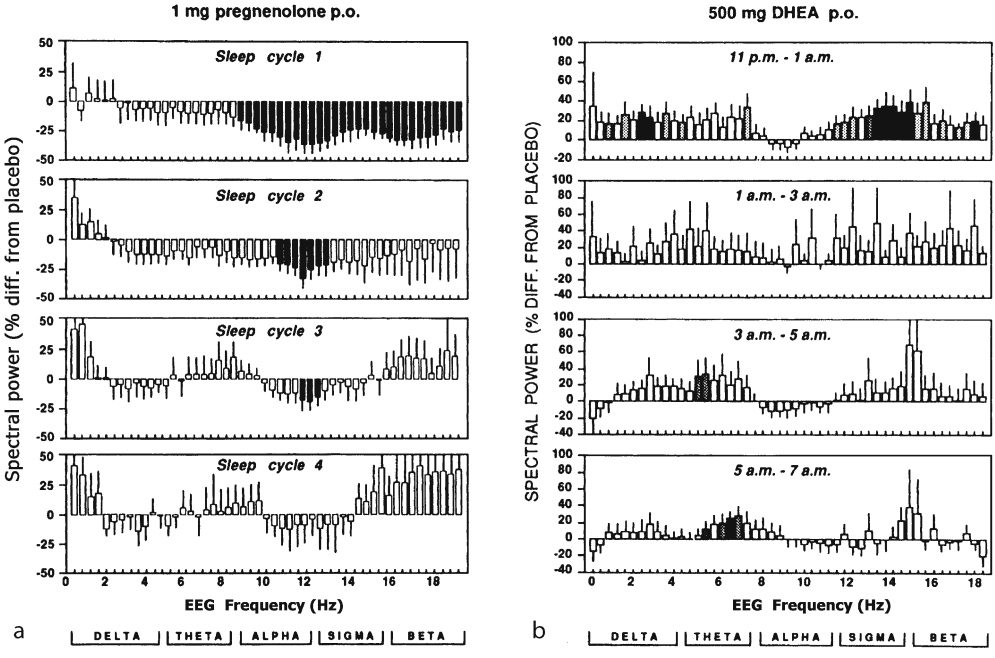
10.2.2 Progesterone, Allopregnanolone

A dose-dependent hypnotic effect of iv progesterone was reported as early as in 1954 (Merryman et al., 1954). After oral progesterone, in normal young men NREMS, especially stage 2 sleep, increases, and SWA decreases (Friess et al., 1997). Furthermore, EEG power in the higher frequency range (>15 Hz) tended to be elevated. In this study, a distinct interindividual variability in the bioavailability of progesterone and consequently in the time course of the concentrations of its metabolite allopregnanolone was found. Therefore, two subgroups were formed, one with an early peak and one with a late peak of allopregnanolone. The time course of this peak is associated with the changes in the EEG power spectra. The initial increase in the EEG activity in the spindle and alpha range in the first few hours of sleep is restricted to the subjects with an early allopregnanolone peak, whereas the decrease of SWA occurred mainly in those showing a later peak of this metabolite. The sleep-EEG changes after administration of progesterone in humans are similar to those induced by agonists at the $GABA_A$ receptor, e.g., benzodiazepines and appear to be mediated in part via the conversion of progesterone into allopregnanolone.

In women, progesterone levels decrease after menopause. Subchronic progesterone replacement increases REMS and decreases intermittent wakefulness in postmenopausal women (Schüssler et al., 2005a). Intraperitoneal administration of three doses of progesterone at the onset of the dark period in rats prompts dose-dependent decreases of NREMS latency, wakefulness and REMS and increases of REMS latency and of preREMS, an intermediate state between NREMS and REMS. Furthermore, EEG activity decreases in the lower frequencies and increases in the higher frequencies. Sleep-EEG effects of two doses of intraperitoneal allopregnanolone itself were studied in rats (Lancel et al., 1997). Both doses reduced NREMS latency and the higher dose increases preREMS. Furthermore, in NREMS EEG activity decreased in the lower frequencies ($\leq$7 Hz) and increased in the higher frequencies ($\geq$13 Hz). These data confirm benzodiazepine-like effects of allopregnanolone on sleep.

Figure 25-10

Sleep-state-specific electroencephalogram (EEG) power spectra after administration of pregnenolone (panel a, left; n = 6) and dehydroepiandrosterone (panel b, right; n = 7) in healthy male control subjects. Bars show deviation (mean ± SEM) from placebo level (=100%) in each frequency bin (0.38 Hz). Panel A; EEG power spectra of NREMS during sleep cycles: solid bars denote significant differences between placebo and pregnenolone (two-sided Bonferroni t-test, nominal $p < 0.05$). Panel B; EEG power spectra of REMS during 2-h periods of night sleep: solid bars denote significant differences between placebo and dehydroepiandrosterone (two-sided Bonferroni MANOVA, nominal $p < 0.05$), shaded bars indicate tendency ($p < 0.01$). Reprinted from Advances in Neuroimmunology, 5, Friess, E., Wiedemann, K., Steiger, A., Holsboer, F., The hypothalamic–pituitary–adrenocortical system and sleep in man, 111-125., Copyright 1995, with permission from Elsevier



10.2.3 Deoxycorticosterone-3-Alpha, 21-Dihydroxy-5-Alpha-Pregnan-20-One (THDOC)

The ring A reduced metabolite of deoxycorticosterone-3-alpha, 21-dihydroxy-5-alpha-pregnan-20-one (THDOC) is found in the brain. It has been shown to be a barbiturate like ligand of the GABA receptor complex. In the rat, sleep EEG was investigated after THDOC alone and in combination with the benzodiazepine flurazepam. THDOC exerted dose-dependent sleep-inducing effects including shortened sleep latency and increased NREMS. Flurazepam had similar effects and decreased REMS. There were no significant interaction of THDOC and flurazepam except in REMS latency. The findings point to a sedating effect of THDOC (Mendelson et al., 1987).

10.2.4 Dehydroepiandrosterone, DHEA Sulfate

A single oral dose of dehydroepiandrosterone (DHEA) increases selectively REMS in young normal men (Friess et al., 1995a) (*Figure 25-10*). This finding corresponds to a mixed $GABA_A$ agonistic/antagonistic effect. After intraperitoneal DHEA sulfate (DHEAS), a dose-dependent effect on EEG power was observed in rats. A 50 mg/kg DHEAS augmented EEG power in the spindle-frequency range, whereas 100 mg/kg

DHEAS had the opposite effect. Sleep architecture remained unchanged after either dosage of DHEAS (Schiffelholz et al., 2000).

11 Conclusions

The data reviewed in this chapter show that a bidirectional interaction between sleep EEG and endocrine activity is well established. Various hormones (particularly neuropeptides and neuroactive steroids) exert specific effects on the sleep EEG in several species including humans. Vice versa, changes of sleep–wake behavior result in changes of endocrine activity.

In *Figure 25-11*, a model of peptidergic sleep regulation in humans is proposed. It appears that some peptides (GHRH, galanin, ghrelin) promote sleep, at least in males, whereas others (CRH, somatostatin) impair sleep. The reciprocal interaction of the neuropeptides GHRH and CRH plays a key role in sleep regulation. GHRH promotes NREMS, at least in males, and stimulates GH secretion, whereas CRH maintains wakefulness and enhances the secretion of ACTH and cortisol. Related to its role in the maintenance of wakefulness, it impairs sleep. Changes in the CRH:GHRH ratio in favor of CRH contribute to shallow sleep, elevated cortisol secretion and blunted GH levels during depression and ageing. On the other hand, GHRH participates in sleep promotion after sleep deprivation. Interestingly, recent data suggest CRH-like effects of GHRH in women, as sleep is impaired, and HPA hormones are elevated after GHRH in females. Several findings, particularly the effects of the CRH-1 receptor antagonist, R121919, in patients with depression, and some studies on the effects of CRH antagonists in the rat model suggest that CRH also promotes REMS, whereas other studies failed to support this view. NPY is another endogenous antagonist of CRH. Its major role appears to be in the timing of sleep onset. Similar to their reciprocal role in sleep regulation, GHRH and somatostatin exert opposite effects on sleep EGG, at least in males. Somatostatin is another sleep-impairing peptide. Besides GHRH, galanin and ghrelin were shown to promote SWS. Intact GHRH receptors are the prerequisite for sleep promotion by ghrelin. In contrast to GHRH, ghrelin stimulates HPA hormones in males and may act as an interface between the HPA and HPS systems. Galanin is colocalized with GABA in the ventrolateral preoptic nucleus. Many hypothalamic GHRH responsive neurons are GABAergic. Galanin, ghrelin, and GHRH may either act in a synergistic fashion or these peptides may be part of a cascade resulting in the promotion of NREMS. Probably, GABAergic neurons mediate the effects of these peptides. On the other hand, thalamic GABAergic transmission is thought to be involved in the sleep impairing effect of somatostatin. Whereas the aforementioned peptides either promote or impair sleep, VIP appears to be involved in the temporal organization of sleep. In young normal men after VIP, the NREMS/REMS cycle is decelerated, probably by action at the suprachiasmatic nucleus. In contrast, VIP is thought to promote REMS in animals via prolactin.

Besides peptides, steroids are involved in sleep regulation. Acute administration of cortisol promotes SWS in normal human controls, probably via feedback inhibition of CRH. Furthermore, cortisol suppresses REMS in humans, whereas REMS decreases after short-term withdrawal of hydrocortisone substitution in Addison's patients. This finding points to a REMS-promoting effect of cortisol. Similarly, subchronic administration of the GR agonist methylprednisolone in patients with multiple sclerosis prompted a set of sleep-EEG changes resembling those in patients with depression including REMS disinhibition. These findings suggest that physiological cortisol levels contribute to REMS maintenance and that a synergism of elevated CRH activity and enhanced glucocorticoid levels participates in the development of REMS disinhibition and changes of SWS during depression. $GABA_A$ receptors are also targets of various neuroactive steroids, which exert specific effects on sleep. Pregnenolone promotes SWS in humans and rats. In postmenopausal women, progesterone decreases intermittent wakefulness. Progesterone, most likely via allopregnanolone, acts similarly to benzodiazepine hypnotics in humans and rats. In contrast, DHEA promotes REMS in humans. Finally, the changes of sleep EEG after menopause and the beneficial effect of estrogen replacement therapy point to a role of estrogen in sleep regulation.

The effects of CRH-1 receptor antagonism in depression, of arginine vasopressin in the elderly and of estrogen and progesterone replacement therapy in the menopause are promising hints for a clinical application of research in this exciting area.

Figure 25-11

Model of peptidergic regulation. CRH, corticotropin-releasing hormone; GHRH, growth hormone-releasing hormone; NPY, neuropeptide Y; SRIF, somatostatin. Characteristic hypnograms and patterns of cortisol and GH secretion are shown in a young and in an elderly control subject and in a depressed patient. It is thought that GHRH is released during the first half of the night, whereas CRH preponderates during the second half of the night. GHRH contributes to the high amounts of GH and SWS after sleep onset, whereas CRH is linked with cortisol release und REM sleep in the morning hours. Neuropeptide Y (NPY) is a signal for sleep onset. In addition to GHRH, galanin and ghrelin are sleep promoting factors, whereas somatostatin is a sleep impairing factor. During depression (CRH overactivity) and during normal ageing, similar changes of sleep-emdocrine activity occur. It is thought that changes in the GHRH/CRH balance in favour of CRH play a key role in these alterations. Chlomipramine, 5-HT reuptake inhibitor, 57
Chloride channels, 63
p-Chlorophenylalanine, 5-HT synthesis inhibitor, 38, 57
Cholecystokinin (CCK), 38, 75 , 153, 165, 166, 172, 668
Cholecystokinin receptor 1 (CCK-1), 153, 166
Cholecystokinin receptor 2, (CCK-2), 153, 166
Cholecystokinin receptor A, (CCK-A), 153, 166
Cholecystokinin receptor B, (CCK-B), 153, 166
Choline acetyltransferase (CHaT), 153, 171
Choline acetyltransferase, ACh synthetic enzyme, 61
Choline, ACh precursor, 38, 61, 62
Cholinergic, 171
Cholinergic agonist, 71
Cholinergic antagonist, 71
Chromatin
– chromatin structure, 603–605, 609
– cytosine methylation, 608
– demethylation, 604–606, 609, 611–613
– DNA methyltransferases, 604
– histone acetylation, 604
– histone modifications, 604
Chromosome, 2, 15, 16
Cialis (tadalafil), PDE 5 inhibitor, 65
Circadian rhythms, 801–804, 806, 809, 810, 813–815, 820, 823, 826, 838, 850–856
– animal models of, 804, 805
– clock genes, 874, 855, 857
– genes, 815–821
– history of, 802, 803
– oscillator, 847, 855
– period (Per), 838, 850, 853–856
– slave oscillator, 838, 847
Circadian time, 802, 803
Circumventricular organs (CVOs), 646, 649, 650, 655, 660, 664, 665, 673
– area postrema (AP), 649, 665, 673
– organum vasculosum lamina terminalis (OVLT), 649–652, 656, 663, 664, 669, 673
– sensory, 647–649, 652
– subfornical organ (SFO), 649, 673
cis-Flupenthixol, DA antagonist, 44, 47, 52
Citalopram, an SSRI, 58
Cloacal contact, 3
Clock mutant mouse, 814, 815
Clonidine, α_2 receptor agonist, 55, 56
CNQX, AMPA antagonist, 38, 63
Coactivators, 111, 122
– amphetamine, 741, 742, 745, 747, 749–752, 754, 756, 757, 759, 761, 762
– cocaine, 741, 742, 744, 747–758, 760–763,
– steroid receptor, 103, 104, 106, 117, 119, 121, 123–126
Cognition, 776, 779, 780, 782, 783, 787–789, 791–794
COMT, catechol-O-methyltransferase
– expression in violent patients with schizophrenia, 303
– heightened aggression in knockout mice, 294, 298, 301
Conditioned olfactory stimuli, 44
Conditioned place preference, 2, 4, 747, 448, 751, 752, 757, 760
– drugs of abuse, 740, 747–753
Congenital adrenal hyperplasia, 479
Consolidation, 722, 731, 732
– models for
– "C" theory, 731

– multiple trace theory, 732
– standard model, 732
– purpose of, 733
Copulatory behavior, 39, 40, 45, 46, 51, 52, 56, 66, 67, 71, 97, 98, 100, 106, 111, 119, 126, 128, 131
CREB, 106, 117, 122, 123
Copulatory plug, 42
Core clock genes, 807, 809, 814, 817, 819
– *bmal1/Mop3*, 814, 815
– *Clock*, 814, 815
– *cryptochrome 1*, 807, 812, 814–816, 820, 825
– *cryptochrome 2*, 807, 812, 814–816, 820, 825
– *period 1*, 808, 809, 812–820, 822, 825, 826
– *period 2*, 808–820, 822, 825, 826
– *period 3*, 816
Corpus cavernosum, 14, 56, 60, 61, 65, 74
Corticosteroid secretion
– circadian rhythm, 517, 518
– glucocorticoid negative feedback of, 518
Corticosterone, 261, 268, 662, 663, 776, 778, 789, 788, 789, 792
Corticotrophin releasing factor (CRF), 153, 168
Corticotropin releasing factor/ hormone, 268, 269
Corticotropin releasing hormone (CRH), 75, 911–913
– ACTH release, 531
– extrahypothalamic, 525
– gene expression, 519, 522
– HPA axis regulation by, 519, 520
– paraventricular nucleus, 516
– secretion, 518, 519, 521–526, 530
– urocortins, 531, 532
Corticotropin, 911–913
Cortisol, 269, 271, 776, 778, 788, 791, 794, 913–915
Cortistatin, 919
Cox-2 enzyme, 21
CPEB, 776, 780, 782
– binding protein, 106, 117, 123
– role in intermediate-term memory, 727
– role in synaptic tagging, 731
CRH antagonist, 912, 920, 926
CRH, 873
Critical period, 391, 395
– crystallization, 381, 394, 395
– sensitive period, 376, 392
– sensorimotor period, 376, 378
CTOP, h-D-phe-cys-tyr-D-trp-orn-thr-pen-thr-nh_2, 153, 164
Cushing's disease, 908
Cycle
– estrous, 97–101, 106, 113, 114, 116, 126, 128
Cyclic 3′,5′-adenosine monophosphate (cAMP), 153, 164, 174
Cyclic guanosine monophosphate (cGMP), 38, 64, 66, 67, 153, 173, 174
Cyclooxygenase -2, -3, 467–469
Cyp-19 gene, 8, 18
Cyproterone, 10, 20
– cytokines, 881, 882, 884
D_1 DA receptors, 38, 45–48, 67
D_2 DA receptors, 38, 45, 47, 67
D_3 DA receptors, 38, 45
D_4 DA receptors, 38, 45
D_5 DA receptors, 38, 45
DA neurotoxin, 52
DAMGO, h-tyr-d-ala-gly-n-met-phe-glycinol-enkephalin, 153, 161
DARPP32, 122, 123, 125, 174
– deactivation, 871
Defeminization, 463, 466, 467, 469, 470
Defensive aggression
– kindling and, 295
– neurocircuitry of, 306, 315
Dehydroepiandrosterone (DHEA), 340, 344, 346, 347, 355–358, 361, 362
Delaquamine, α_2 receptor antagonist, 55
Dendrites, 754–756
Dendritic remodeling, 578, 581–586
Dendritic shafts, 488
Dendritic spines, 488
Depression, 901, 908–910, 912–914, 917, 920, 922, 926
Desensitization
– progesterone-induced, 98, 99, 116
Detumescence, 54, 56
Diagonal band of broca, 166
Diencephalon
– anteroventral periventricular nucleus, 490
– arcuate nucleus, 490
– lateral habenular nucleus, 490
– medial preoptic area, 488
– paraventricular nucleus, 490
– periventricular zone, 490
– sexually dimorphic area, 489, 491
– suprachiasmatic nucleus, 490, 491
Diethylstilbestrol (DES), 786, 787
Dihydrotestosterone propionate, 6, 8
Dihydrotestosterone, 3, 5–15, 50, 65, 66, 69, 99
Dihydroxyphenylalanine decarboxylase, 170
Dihydroxyphenylalanine, 170
5,7-Dihydroxytryptamine (5,7-DHT), 5-HT neurotoxin, 38, 60
5α-dihydroprogesterone (αDHP), 153, 173
Dog, 8
Dominance
– function, 288
– behavioral displays and, 288
Domperidone, DA antagonist, 43, 45
Dopamine (DA), 4, 13, 14, 17, 43–55, 122–125, 129, 130, 153, 169, 170, 219, 267, 268, 740–743, 745–752, 850–852, 855
– antiaggressive effects of antipsychotic medications, 302, 304
– anticipatory rises, 304, 306
– cell bodies containing, 875
– distribution in the song system, 441, 442
– function in the control of song, 441, 442, 445
– increased levels in brains of aggressors, 303, 304
– *in vivo* microdialysis, 305, 308
– melanocyte stimulating hormone (MSH), 851
– mesolimbic system, 224–226
– nigrostriatal system, 222, 224, 225
– periventricular hypophyseal dopamine (PHDA), 851, 852
– receptor subtypes and aggression, 304
– receptors, 205, 224–229
– role in maternal behavior, 224–226
– tyrosine hydroxylase (TH), 850
– tuberoinfundibular dopamine (TIDA), 851, 852
– tuperohypophyseal dopamine (THDA), 851, 852
Dopamine agonist, 43
Dopamine receptors
– antiaggressive effects of agonists and antagonists, 304
– density in violent patients, 302
– disruption by knock-out, 303, 304
– motor routines and, 304
– opiate withdrawal and, 304
Dopamine transporter
Dopamine-and-cAMP-regulated-phosphoprotein, 122, 123, 125
Dopamine-β-hydroxylase, 170, 291, 301
Dorsal gray commissure, 56, 61, 72
Dorsal noradrenergic bundle, 55
Dorsal raphe nucleus, 57
Dorsal striatum, 43, 54, 60

Double-depletion hypothesis, 645
– thirst additivity, 658–659
DPDPE, ([d-pen2, d-pen2]-enkephalin), a selective dop agonist, 153, 161, 162
Drosophila melanogaster
– and dNPF, 250
– and Rovers versus sitters, 252
– and social burrowing, 250
– *dg2/for*, 252
– cAMP mutants of, 728
– olfactory learning in, 716
– role of mushroom bodies, 716
"dry mouth" theory, 644
Dwarfism, 900
Dynorphin a, 162
Dynorphins, 67, 68
Early experience
– postnatal handling, 603
– maternal care, 608
Ebiratide, 913
E-box enhancer element, 815, 818, 822
Ejaculation, 3–8, 10, 12, 17–20, 22, 39, 40, 97, 100, 101, 126, 128, 129
Electrophysiology, 389, 393
Encephalitis lethargica, 871
Endocannabanoids
– glucocorticoid feedback and, 515, 519
Endocytosis, 68, 69
Endogenous opioid peptides (EOP), 153, 159, 163, 166
β-endorphin, 153, 160–164
Endorphins, 67
Endothelial NOS (eNOS), 38, 64, 65
Enkephalinase inhibitor, 68
Enkephalins, 67–69, 153, 161, 162
Entorhinal cortex
– input to hippocampus, 720
– output from hippocampus, 720
– role in spatial memory, 721
Entrainment, 802, 803, 809–813, 816, 817, 838, 840, 841, 843, 847, 849, 850, 856–858
ENU mutagenesis, 804, 814
Environmental signals, 398
– adrenocorticoids, 399
– catecholamines, 399
– endocannabinoids, 399
– gonadal steroids, 399
– photoperiod, 398, 399
– seasons, 398, 399
Epigenetics
– cross-fostering studies, 606
– environmental programming, 612, 613
– maternal effects, 605, 606, 612
Erection, 3–15
Escalated aggression
– selected breeding and, 290, 291, 293
– frustration, omission of scheduled reinforcement, 292, 293
– social provocation, instigation, priming, 293, 294
Estradiol benzoate, 6
Estradiol, 3, 5–15, 25, 41, 50, 51, 66, 68, 69, 98–102, 104–121, 123–128, 130, 131, 153–175, 758, 761–763, 776–780, 784–788, 791–793
– actions of, 466–470, 472–477
– synthesis of, 464
17 β-estradiol benzoate (EB), 153, 157, 158
Estradiol/Estrogens, 212, 213
– and maternal behavior, 202–207, 209, 214, 215
– and maternal motivation, 216, 219
– effects on mesolimbic dopamine system, 228, 229
– effects on nigrostriatal dopamine system, 227, 228
– receptors and maternal behavior, 211
Estrogen receptor α (ERα), 43, 153, 426–428, 446, 776, 778,
Estrogen receptor β (ERβ), 153, 426, 428, 776, 778
Estrogen receptors, 345, 351, 353, 355, 464, 469, 470, 472, 474, 847
Estrogen, 10, 12, 16–19, 21, 22, 25, 38, 40, 41, 43, 66, 114, 119, 123, 153, 157, 163, 175, 626–628, 842, 847, 850, 858
– antagonist, 100, 105, 106, 111, 112, 123
– receptor, 102–108, 117, 118
– and maternal behavior, 254, 255
– and social recognition, 257, 258
– estradiol (17β), 339, 353, 354, 541, 542
Estrous behavior, 122
Estrous cycle, 98–101, 106, 113, 114, 116, 126, 128, 758, 762
Estrus
– postpartum, 201–203, 209, 211, 213
Ethanolamine-O-sulfate, $GABA_A$ agonist, 64
Eticlopride, D_2/D_3 receptor antagonist, 45
Ex copula measures of penile function, 41, 42
Explicit memory
– definition of, 718
– entorhinal cortex involvement in, 721
– hippocampus involvement in, 719, 720
– role of medial temporal role in, 718, 719
Extinction
– definition of, 734
– role of ERK in, 734
– role of prefrontal cortex in, 734
Extracellular depletion, 644, 672
– hemorrhage, 647, 659, 662
– hyperoncotic colloid, 645, 659
– hypovolemia, 645, 647, 652, 654, 656–661, 663, 667–669, 672
Fadrozole, 7–10, 12
Fear conditioning, 690–694, 696–698, 700–702
– contextual memory for, 718
– cued memory for, 718
– role of amygdala, 718
– trace conditioning, 718
Fear, 572, 578, 580–584
Feeding behavior, 745, 747, 753, 758
Feeding, 745–747, 753, 758,
Female aggression
– maternal aggression, 290
– rivalries and fertility suppression, 290
Feminine sexual behavior, 97, 98, 100–102, 104–107, 110, 111, 113, 114, 118–126, 131, 132
Feminization, 466, 467, 470
Ferret, 3, 4, 8, 9, 11, 18–20, 22, 23, 25
Flesinoxan, $5\text{-}HT_{1A}$ agonist, 58,
Fluoxetine, an SSRI, 57, 71
Flutamide, 7, 10, 19, 20
Follicle stimulating hormone (FSH), 38, 66
Foreskin, 5
Forgetting, 734
Fos immunoreactivity (FOS-ir), 51
Fos, 11, 12, 117, 122–124, 128, 130, 131
FosB, 254
Free-running period, 814, 810, 811, 816, 817, 820, 824, 825
Frontal cortex, 779, 789, 792, 793
Fruit flies, 291
G protein-coupled receptor (GPCR), 153, 159, 163, 164, 169, 170, 172
GABA, 21, 22, 63, 64, 314, 315, 527, 668, 674, 743, 746, 751–753, 760, 763
– anti-aggressive effects of GABA agonists, 295
– anti-convulsants and, 295
– distribution in the song system, 438

– drugs of abuse, 752, 753
– feeding behavior, 746, 753
– function in the song system, 439
– GAD and aggression, 295
– in hypothalamus, 295, 308
– lower levels in aggressive individuals, 295
– modulation by 5-HT, 315
GABA receptors, 752
GABA, distribution in brain
– α_1 selective agonists and antagonists effects on aggression, 300
– effects on astrocytes, 474
– Positive allosteric modulators
– alcohol, 298
– individual differences, 300
– prior history with, 300
– benzodiazepines
– clinical management of aggression, 298, 300
– effects in laboratory animals, 298
– modulation by experience and context, 298, 300
– "paradoxical" effects, 298
– neurosteroids, 298, 299
– effects in isolated versus socially-housed mice, 299, 300
– role in lh secretion, 472
– sex differences in, 472, 473–474
– synthetic enzymes for, 472
– subunits and aggression, 298, 300
– thalamus, 883
– VLPO, 883
$GABA_A$ receptors, 63, 64
$GABA_B$ receptors, 63, 64
GAD (glutamic acid decarboxylase)
– anabolic steroids and, 297
– in hypothalamus, 295
Galanin, 38, 73, 74, 76, 153, 168, 920
Galanin-like peptide (GALP), 38, 73, 153, 168
Gamma amino butyric acid (GABA) (see GABA)
GAP-43, 467, 469,
Gene expression
– aromatase, 395, 397, 400
– CREB, 391
– ERK, 391
– Expressed Sequence Tag (EST), 403
– fox-P2, 402
– habituation, 387
– immediate early gene, 383, 387–389
– *in situ* hybridization, 383
– microarray, 403, 404
– NMDA receptor, 395
– retinaldehyde dehydrogenase, 395
– role in learning, 385, 387–389
– synelfin, 381, 395
– synuclein, 395
– *zenk*, 383, 389, 391, 394, 398, 402
– zRalDH, 382
Gene variation and social behavior variation
– in voles, 260–264
– in *C.elegans*, 249–252
– in *D. melanogaster*, 250
Genital stimulation, 131
Genomic effects, 778, 788
Genomic imprinting, 9
GH secretagogues, 904–906
Ghrelin, 624, 899, 904–906
GHS-R, 624
Gill-withdrawal reflex in *Aplysia*
– classical conditioning of, 716
– habituation of, 730
– sensitization of, 715
Glossopharyngeal, 657
– afferents, 647, 657
– nerve, 644, 648, 649, 656, 657, 673
Glucocorticoid negative feedback, 518
– adrenocorticosteroid receptor regulation of, 520, 521
– non-genomic mechanisms, 542
Glucocorticoid receptor, 914
– glucocorticoid receptor promoters, 601–603, 606–612
– glucocorticoid receptor gene transcription, 609
– hippocampus, 597, 602, 603, 605, 606, 610
– localization, 516
– mRNA expression, 599–602
– regulation, 516
– role in negative feedback, 516
Glucocorticoids, 573–581, 586, 646, 654, 655, 662
– corticosterone, 662, 663
Glucose dialysis, 645
Glutamate receptors, 749, 750
– AMPA, 746, 749, 750
– AMPA subtype, 712
– kinate subtype, 712
– metabotropic, 748–750
– metabotropic subtype, 713
– NMDA, 749–751
– NMDA subtype, 713
– role in long-term potentiation, 711
– table of, 753
Glutamate transporter, 751
Glutamate uptake inhibitors, 62
Glutamate, 62–64, 76, 153, 166, 171, 172, 174, 528, 529, 746, 748–752, 756, 760, 763, 870, 876, 877, 879, 880
– anticonvulsants and, 295
– distribution in the song system, 438
– feeding behavior, 746
– function in the control of song, 438
– higher brain levels in aggressive individuals, 295
– imbalance with GABA, 294, 295
– in hypothalamus, 295
– "limbic dyscontrol" and, 294
– NMDA receptors
– competitive and non-competitive effects on aggression, 297
– motor impairment, 297
– relevance of prior experience and intensity of aggression, 297
– subunit expression after aggression, 297
– olfactory stimuli and, 295, 296
– vesicular glutamate transporter and HAA, 314
Glutamic acid decarboxylase (GAD), 153, 172
– synthetic enzyme for GABA, 63
Gonadal hormones, 778–783, 786–788, 791–794
Gonadotropin-releasing hormone (GnRH), 38, 66, 72, 73, 76 , 153, 166, 167, 172, 174
Growth hormone, 898
Growth hormone-releasing hormone, 900–902
Growth hormone-releasing peptide, 6, 904
GTP binding proteins (G-proteins), 62
Guanethidine, peripheral NE depleter, 56
Guanylyl cyclase, 38, 64, 66
Habenula and maternal behavior, 208, 209
Haloperidol, DA antagonist, 43, 44, 47, 55
Hamster, 4, 5, 7, 11–13
H-D-phe-cys-tyr-D-trp-orn-thr-pen-thr-nh_2, 153
Heat termination, 99, 115–117
Heat, 98, 99, 103, 114–117, 128–130
Hexarelin analog peptides, 75
Hexarelin, 904
Hippocampus, 55, 70–72, 384, 385, 464, 575–582, 584–587, 711, 714, 715, 718–721, 727, 728, 730–735, 744, 776, 779–781, 789, 790, 792, 794
– de novo steroidogenesis by, 461
– information flow through, 714, 720, 721

– input from entorhinal cortex, 720, 721, 728
– output to cortical association areas, 720
– structure of, 720, 721, 728, 735
– role in learning and memory, 475, 477
– sex differences in, 475–477
Histamine, 525–526
– cell bodies containing, 878
– receptors for, 878
Homeostatic reflexes, 642
Honeybee (see *Apis mellifera*), 252, 253
Hormone-independent activation, 124
Hormones, 38, 40–42, 69, 70, 76, 97–99, 101, 107, 116, 127, 128, 489, 501
– and maternal behavior, 200–215
– androgen, 488, 492, 493, 495, 499
– corticosteroids, 500
– dihydrotestosterone, 492–495, 497
– and maternal motivation, 215–217, 219
– effects on mesolimbic dopamine system, 228, 229
– effects on nigrostriatal dopamine system, 227, 228
– estradiol, 488, 492, 493, 495, 497
– estrogen, 492, 493, 495
– gonadotropic hormone, 488
– progesterone, 493, 495
– sex, 99, 131
– steroid, 100, 102–104, 108, 118, 120, 122–126, 130, 131
– testosterone, 488, 492–495, 497–499, 502
Hpa axis, 573, 574, 577–579, 582
5-HT_{1A} receptors, 38
5-HT_{1B} receptors, 38
5-HT_{2C} receptors, 38
Humans, 344, 358, 359, 362
Hybrid mice, 8
Hydrational challenges, 668
– hemorrhage, 647, 659, 662
– hypertension, 651, 653, 660
– hypertonic saline, 645, 648–652, 657, 659, 665–667, 671
– hyperoncotic colloid, 645, 659
– hypovolemia, 645, 647, 652, 654, 656–661, 663, 667–669, 672
– intraperitoneal dialysis, 647
– polyethylene glycol, 651, 653, 659, 661
6-Hydroxydopamine, 741, 745
Hydroxyflutamide, 10
5-hydroxyindole acetic acid (5-HIAA), 5-HT metabolite, 59
Hydroxylamine, NO donor, 67
3β-hydroxysteroid dehydrogenase, 153
11-hydroxysteroid dehydrogenase-1 and 2, 576
5-Hydroxytryptamine (5-HT), serotonin, 38
5-Hydroxytryptophan, 5-HT precursor, 57–59
Hyperthyroidism, 916
Hypnotoxin, 872
Hypocretin (orexin), 877, 879
Hypothalamic-pituitary-adrenal axis (HPA axis), 268, 269
Hypothalamic-pituitary-adrenocortical axis
– acute stress regulation, 523, 524, 532
– basal regulation, 543, 544
– chronic stress regulation, 548
– definition of, 515
Hypothalamo-pituitary adrenocortical system, 907–911
Hypothalamo-pituitary-somatotrophic system, 899–907
Hypothalamus, 6, 9–11, 13, 21, 24, 108, 112–117, 122, 124, 125, 128, 131, 153–159, 164–174, 645, 655, 663, 670
– arcuate nucleus, 546
– attack area, 295, 296
– behaviors controlled by, 471
– control of gonadotropin secretion, 471, 472
– medial preoptic area, 543, 547
– NMDA receptor subunit expression after aggression, 297
– peri-PVN region, 522, 527, 535, 544, 546
– posterior hypothalamus, 878, 879
– preoptic area, 873
– sex differences in, human, 478
– tuberomamillary nuclei, 878
– vasopressin and 5-HT interactions in, 313, 314
– ventrolateral preoptic nucleus (VLPO), 872
– ventromedial, 109, 111, 118, 119, 121, 130
– ventromedial nucleus of, 105, 107, 110, 120
Hypothalmic-Pituitary-Adrenal (HPA) axis, 852–856
– adrenal corticotrophic hormone (ACTH), 852, 853, 855–857
– corticosterone, 852, 853
– corticotropin-releasing hormone (CRH), 853, 855, 856
– cortisol, 852, 856
– glucocorticoids, 852, 853, 856–858
Hypothalmic-Pituitary-Gonadal (HPG) axis, 841, 854
– follicle stimulating hormone (FSH), 837, 838, 841
– gonadotropin-releasing hormone (GnRH), 841–848, 851
– luteinizing hormone (LH), 841, 844
– ovary, 841
– testis, 836, 839
Hypovolemic thirst, 645, 657, 658
– angiotensin II, 651
– caval ligation, 651, 659
– nephrectomy, 652, 657
– polyethylene glycol, 651, 653, 659, 661
– renin, 645, 646, 649, 652–655, 657, 658, 661, 664, 667–670
Hysterectomy
– effects on maternal behavior, 201, 206, 214
Immediate early genes, 809, 813, 851
– *c-fos*, 382, 383, 856
– FRA, 851, 852
– learning state, 388, 389
– memory strength, 387, 389
– neuromodulator systems, 391
– regulation by CREB, Elk-1, and ERK, 391
– *zenk*, 382, 383
Immunocytochemistry, 51, 54–56, 60–62, 66, 67, 71
Implicit memory, 710, 714–718
– definition of, 714, 715
– gill-withdrawal reflex in *Aplysia*
– classical conditioning of, 716, 717
– habituation of, 715, 716
– sensitization of, 715
– role of cAMP in, 716, 717
– role of serotonin in, 716, 717
In situ hybridization, 55
In vivo voltammetry, 52
Indomethacin, 21
Inositol triphosphate (IP_3), 38, 56, 164
Insulin, 620–629, 631
– glucose homeostasis, 621, 622
IRS–1, 622, 623
Insulin-like growth factor-1 (IGF1), 153, 173, 899, 903
Interleukin-1 (IL-1), 882
Intermediate-term memory
– requirement for protein synthesis, 727
– role of CPEB in, 727
– role of PKMzeta in, 727

Intermediolateral cell column, 56, 72
Internal milieu, 642
Intracavernous pressure, 52, 55, 59, 65, 67, 70, 72
Intracerebroventricular, 153, 162
Intrathecal, 54–57, 60, 61, 64, 67, 69, 70
Intromission, 3, 4, 6, 7, 10, 12, 13, 16–22, 39, 43, 45, 47, 54, 57, 61, 62, 69, 73, 75, 97, 100, 101, 126–129
Ionotropic glutamate receptor (GLuR), 62, 153, 172
Ischiocavernosus muscle of penis, 55, 61, 63
Isoforms
– estrogen receptor, 102–108, 117, 118
– progestin receptor, 112–114
Isoproterenol, β adrenergic agonist, 55
Japanese quail, 353
Jun, 122–124
Kainate receptors, 38
Kidneys, 644, 646
– renal rennin, 654
– sodium excretion, 644, 662, 665
– water excretion, 644
Kinase, 103, 107, 118, 122–125
– MAP, 122
– mitogen activated protein, 117
Knock-out (null) mice, 670
Knockout mice
– aggressive phenotypes, 291, 315, 316
– 5-HT disturbances in, 312
– influence of background strain and rates of aggression, 290
Knockouts
– progestin receptor, 111–113
Lactation, 199, 201–207, 211–213, 216, 226, 227
Lamina terminalis, 649, 652, 656, 663, 664, 673
– anteroventral third ventricle (AV3V), 650, 673
– median preoptic nucleus (MePO), 651, 663–665, 669, 671, 674
– organum vasculosum of the lamina terminalis (OVLT), 649–652, 656, 663, 664, 669, 673
– subfornical organ (SFO), 649, 651, 652, 656, 663, 664, 667–669, 671, 673, 674
L-arginine, NO precursor, 65, 66,
Lateral hypothalamic area (LHA), 53, 54, 60
Lateral hypothalamus, 740, 741, 744, 745
– medial Forebrain Bundle, 740, 741
– syndrome, 740, 741
Lateral parabrachial nucleus (LPBN), 656, 666, 673
– serotonin, 656, 673
Lateral septum, 257, 259, 264, 265
Laterodorsal tegmental nucleus (LDT), 875–877, 881, 883
L-dopa, 14
L-DOPA, DA precursor, 43
Leptin, 620–629, 631, 899, 904, 906
– arcuate nucleus, 624
– hypothalamus, 621, 623–626, 630
– PI3K, 627
– STAT-3, 621, 622
– SOCS-3, 621, 622
Leu-enkephalin, 67
Lever pressing, motivation test, 40
Levitra (vardenafil), PDE 5 inhibitor, 65
LHRH, 460, 471–473
Licking, 198–200, 207, 208, 213, 217, 224–226,
Ligand-independent activation, 104, 124–126, 129–131
Light:Dark Cycle (LD), 803, 809–812, 817, 826, 838–841, 843, 845, 849–851, 855–857
Liking, 740–747, 760, 763
Limbic system
– amygdaloid nucleus, central, 531
– amygdaloid nucleus, medial, 516
– bed nucleus of the stria terminalis, 527, 531, 535, 536, 543, 544, 547
Limbic system, 670
L-name, 153, 164
L-NAME, NOS antagonist, 63
L-NMMA, NOS antagonist, 65, 66, 70
Locus coeruleus, 55, 873, 878, 879, 883
Locus heterogeneity, 253
Long-term depression (LTD)
– definition of, 711
– eyeblink response, 714
– requirement for calcineurin in, 714
– role of cerebellum in, 714
Long-term memory
– persistent PKA activity in, 728
– requirement for transcription factor activation, 729, 730
– requirement for morphological changes, 730, 731
– role of CaMK in, 728–730
– role of CREB in, 729–731
– role of ERK in, 727–730
– synaptic tagging in, 731
Long-term potenitation (LTP)
– activation of silent synapses, 726
– definition of, 711
– kinase activation in, 725, 728
– role of glutamate receptors in, 713, 714
Long-term potentiation consolidation, 692–694, 696–698, 700
Lordosis, 97–102, 107, 111, 113, 114, 116, 118–129, 153–175, 466
Lordosis quotient (LQ), 155–159, 172, 173
Lordosis reflex, 153, 155–175
Low pressure receptors (baroreceptors), 656–658, 660
– atrial distension, 658
– loading, 657, 658
– unloading, 657, 658
– vena cava constriction, 647, 648, 657
L-sulpiride, D_2 receptor antagonist, 67
Ltp, 692–694, 696–698, 700
Luteinizing hormone (LH), 153, 157, 166, 167
Luteinizing hormone releasing hormone/gonadotropin releasing hormone (LHRH/GnRH), 153, 166, 167
LY-171555, D_2 receptor agonist, 67
Magnocellular PVN neurons, 70, 71
Major Histocompatability Complex genes, 256, 257
Major urinary proteins, 256, 257
Male sexual behavior, 464, 466–470, 476, 477
MAO-A (monoamine oxidase A), 303, 304, 311
– heightened aggression associated with polymorphism in humans, 303
– heightened aggression in knockout mice, 301
– relationship to norepinephrine, serotonin and aggression, 301
MAP Kinase, 122
MAP kinase, 776, 780, 782
MAPK, 117, 122–124, 125
Masculinization
– definition of, 466, 467
– mechanisms controlling, 469, 470
– sensitive period for, 469
Maternal behavior
– in rodents, 253–256
– in sheep, 260, 261
Maternal behavior, 197–229
Mating, 100–102, 122, 126–131
MBP10, melanocortin MC-4 receptor antagonist, 70
MC-3 receptor (melanocortin receptor-3), 70

MC-4 receptor (melanocortin receptor-4), 70,
MC-4 receptor knockout mice, 70
Mc4 receptor, 164
mCPP, 5-$HT_{2C/1D}$ agonist, 59
Medial amygdaloid nucleus, posterodorsal part (MeApd), 153
Medial preoptic area and maternal behavior, 248, 254–257, 260, 261
Medial preoptic area (MPOA), 38, 40, 45, 46, 56, 59, 61, 62, 64, 65, 68, 73, 74, 160, 161, 163, 165–172, 851, 854
Medial preoptic nucleus (MPN), 153, 154
Medial raphe nucleus, 57
Medial raphe, 169
Median eminence, 72
Mediobasal hypothalamus, 165, 169, 172
Megestrol acetate, 915
Melanocortin (MC) receptors, 70
Melanocortin receptor 1–5, 153
Melanocortins, 153, 164, 625, 626
– α-MSH, 625, 626
Melanocyte stimulating hormone (αMSH), 153, 164
Melanotan-II, melanocortin MC-4 receptor agonist, 70
Melatonin receptors, 432
Melatonin, 809, 810, 839–841, 858
Membrane receptors, 117
Membrane steroid receptors, 117, 124
Memory, 776–794
Menstrual cycle, 761, 762
3-mercaptopropionic acid (3-MPA), $GABA_A$ antagonist, 64
Mesencephalon
– dorsal raphe nucleus, 490
– midbrain central gray, 490, 496
– peripeduncular nucleus, 490
– substantia nigra, 502
Mesocorticolimbic dopamine tract, 38, 60, 76
Metabotropic glutamate receptors, 62
Metencephalon, locus coeruleus, 490, 496
Met-enkephalin, 67, 69
Methoxamine, α_1 receptor antagonist, 56
Methylphenidate, 747
– dopamine antagonists, 745, 747, 760,
– glutamate, 760
Methylprednisolone, 914, 926
Methysergide, 5-HT antagonist, 57, 60
Metyrapone, 913
MHC genes (see Major Histocompatability Complex genes)
MHPG (methoxy-4-hydroxyphenylethylene glycol), 301
– CSF content and aggression, 301
Microarray, 248, 252, 253
Microdialysis, 13, 48, 50–54, 59, 60, 62, 63, 66
Microsatellite, 265, 266, 271
Mifepristone, 914, 915
Mineralocorticoid receptor, 913–915
– localization, 520
– regulation, 520
– role in negative feedback, 518, 537
Mineralocorticoid, 651
– aldosterone (Aldo), 642, 645, 649, 654, 655, 658–662, 673
– antagonists, 654, 659, 668, 672
– deoxycorticosterone acetate (DOCA), 659, 664, 667
Mitogen activated protein kinase, 117
MK-801, NMDA antagonist, 62, 63
Molt, 350, 354, 355
Monkey, 3, 8, 14
Monoamine oxidase B (MAO B), 52
Monoamines, 790, 792
Monogamy, 261–265, 267–271
Monosodium glutamate (MSG), 153, 172
Morphiceptin, μ agonist, 68
Morphine, 747, 748, 750–754, 762
– feeding behavior, 747, 753
– opiates, 741, 746–748, 751, 753, 762
– sexual behavior, 754, 759, 760
Morphine, μ agonist, 68
Morris water maze, 784, 786, 789
Motivation, 197–229
– hormone effects on, 215–217, 219
Motivation, 3, 4, 7, 8, 10, 12, 14, 16, 17, 23
Motivation, 97, 121
– sexual, 101, 102
Mount, 97, 98, 100, 102, 121, 126–128
Mounting, 3–7, 10–12, 14, 16–22
Mounts, 39, 49, 55, 60, 62, 65, 69, 73, 75
Mouse, 3, 8, 9, 11
Multiunit electrical activity, 802, 804, 806
MUPs (see Major Urinary Proteins)
Muscarine, muscarinic agonist, 45, 61
Muscarinic acetylcholine receptor (mAchR), 153
Muscarinic agonist, 45, 61
Muscarinic antagonist, 45, 61
Muscimol, 172
Muscimol, $GABA_A$ agonist, 63, 64
Naloxone, 159–162
Naloxone, opiate antagonist, 52, 67, 69
Naltrexone, opiate antagonist, 67
Narcolepsy, 879
Nephrectomy, 652, 657
Nerve, 5, 7, 12, 14, 15
Nest construction, 198, 199, 203, 207–209, 214, 220, 226
Neural Plasticity, 740, 753
Neuroendocrine, 3, 4, 21, 25
Neurogenesis, 378
– and song learning, 397
– BDNF, 389, 397, 398
Neurohypophysial peptides
– oxytocin, 533
– vasopressin, 532
Neurokinin, 153, 167
Neurokinin-1 receptor (substance p receptor) (NK1), 153, 167
Neuroleptics (*see Antipsychotics*)
Neuronal NOS (nNOS), 64–66
Neuropeptide S, 920
Neuropeptide Y (NPY), 38, 75, 153, 163, 164, 623–625
Neuropeptide Y receptor-like protein (NPR-1), 249–251
Neuropeptide Y, 920
Neuropeptide y-y1 receptor (NPY-Y1), 163, 164
Neuropeptide, 153, 154, 159, 163, 165–167, 172, 174
– angiotensin II, 533
– atrial natriuretic peptide, 535
– calcitonin gene-related peptide, 537–538
– cholecystokinin, 533
– cocaine-amphetamine related transcript, 538
– C-type natriuretic peptide, 535
– galanin, 535, 536
– ghrelin, 539
– glucagon-like peptide 1, 515
– GnRH, 122–124, 126, 130
– melanocortins, 539, 540
– neuropeptide B, 540
– neuropeptide W, 540
– neuropeptide Y, 534
– neurotensin, 535
– orexins, 540
– somatostatin, 536, 537
– substance P, 537
– vasoactive intestinal peptide, 543
Neurosteroids
– allopregnanalone, 346
– dehydroepiandrosterone, 344, 346, 347, 361, 362
– role of gamma aminobuteric acid, 347
Neurosteroids, 154

Neurotoxin, 671, 672
– 6-hydroxydopamine (6-OHDA), 671
Neurotransmitter, 38, 42, 43, 76, 103, 115, 126, 646, 668–671, 673
– cholecystokinin, 489, 501–502
– dopamine, 122–125, 129, 130, 502, 503
– norepinephrine (NE), 670, 671
– serotonin, 488, 503
– serotonin (5-HT), 656, 673
– somatostatin, 503
– substance P, 489
– vasoactive intestinal polypeptide, 503
– vasopressin, 489–503
– vasotocin, 495–498
Nicotine, 748, 752, 754, 756, 762
Nicotinic acetylcholine receptor (nAchR), 153, 171
Nigrostriatal dopamine tract, 54
Nitric oxide (NO), 14, 38, 50, 64–67, 153, 154, 164, 173, 174, 261, 262, 540
– eNOS (endothelial), 882
– iNOS (inducible), 882, 883
– nNOS (neuronal), 882, 883
– release, 882, 883
– synthases (NOS)
Nitric oxide donor, 65–67
Nitric oxide synthase (NOS), 50, 51, 63–65, 67, 70, 72, 153, 164, 174
NMDA receptors, 62, 63, 286, 296
– motor impairment, 297
– relevance of prior experience and intensity of aggression, 297
– subunit expression after aggression, 297
N-methyl-d-aspartic-acid (NMDA), 153, 172
N-nitro-l-arginine-methyl-ester (L-NAME), 153
nNOS knockout mice, 65
Nociceptin opioid receptor (NOP, ORL-1), 153
Nociceptin, orphanin FQ (OFQ), 153, 162, 167
Nomifensine, DA reuptake inhibitor, 46
Non-breeding season, 344, 345, 349–351, 354–357
Noncontact erections, 42, 47, 52, 57, 59, 63, 65–67, 69, 71
No-net-flux, 49
Non-genomic effects, 778, 780
Noradrenaline
– cell bodies containing, 882
– receptors for, 882
Noradrenergic agonist, 46
Noradrenergic antagonist, 46, 56
Nor-binaltorphimine, κ antagonist, 68
Norepinephrine (NE), 38, 43, 44, 55, 56, 76, 153, 170, 171, 286, 445, 670, 671, 745, 747, 748
– α2 receptors and aggression, 291, 302
– β-blockers and anti-aggressive agents, 301
– actions in AV3V, 671
– ascending pathways, 671
– CSF metabolite and aggression, 301
– distribution in the song system, 441
– effects in raphé nuclei, 308
– facilitation of thirst, 670, 671
– feeding, 670
– "fight or flight" response, 300
– function in the control of song, 441
– general arousal, 301
– genetic manipulations of, 301, 315, 316
– heightened aggression in transporter knockout mice, 294
– in cat defensive aggression, 301
– levels in MAOA knockout mice, 291
– tricyclic antidepressants, 301
Norepinephrine/Noradrenaline, 257, 259, 260
NOS, nitric oxide synthase
– heightened aggression in nNOS knockout, 315, 316
– reduced aggression in eNOS knockout, 291
NREM sleep, 870
Nucleus accumbens (NAc), 38, 40, 43, 52–54
– hormone effects on, 222–226, 228, 229
Nucleus accumbens, 13, 256, 263, 740, 743
– core, 744, 747, 749–751, 754–756
– role in reward, 749
– shell, 743–747, 749, 750, 754–756
Nucleus of the solitary tract (NTS), 655, 665
Nucleus paragigantocellularis (nPGi), 38, 60
Nucleus, 102, 122, 128
– ventromedial hypothalamic, 105, 107, 109–111, 118–121, 130
Nursing, 198–200, 207–209, 215, 220, 224–226
Object placement, 782, 784, 785, 787, 789,
Object recognition, 785–787, 789, 790, 794,
Odortype, 256, 257
8-OH-DPAT, 5-HT_{1A} agonist, 58– 60
7-OH-DPAT, D_3 receptor agonist, 45
Olfaction, 11, 12, 18, 25
– and maternal behavior, 200, 210
– in *C.elegans*, 250–252
– in maternal care
– rodents, 254, 255
– sheep, 260, 261
– in pair bonding, 262
– in social recognition, 256–260
Olfactory bulbectomy, 50
Oligonucleotides, 21
Oligonucleotides, antisense, 106, 111, 117, 124, 125
Operant conditioning
– to measure maternal motivation, 218
Opiate receptors, 753
Opiate withdrawal
– heightened aggression and, 304
– increased sensitivity of DA agonists, 304
– increased sensitivity of NMDA receptor antagonists, 304
Opioid octapeptide, 69
Opioid peptides, 153, 159
– beta-endorphin, 529, 530
– dynorphin, 530
– enkephalin, 530
– nociceptin (Orphanin FQ), 530
Opioid receptor, 153, 159–161
Opioid receptor-like receptor-1 (ORL-1), 159
Opioids and bonding, 260
Opioids, 52, 67–69, 75, 747, 753, 763
– feeding behavior, 747
– orexin (hypocretin)
– cell bodies containing, 78
– receptors for, 878
Orexin, 906
Orexin/hypocretin, 74, 76
Organizational effects, 488, 494
Organizational versus activational effects, 340–342
Organizational/activational hypothesis, 461, 462
Orphanin FQ (nociciptin), 67
Osmosensitive cells, 650, 673
Osmotic pressure, 644, 646
– "osmoreceptor", 645, 646, 648–650, 664, 673

Ovariectomized and adrenalectomized, 153
Ovariectomized/ovariectomy (OVX/ADX), 153, 157, 164
Ovariectomy, 761
– effects of, 343, 361
Ovaries
– hormones and maternal behavior, 201–203, 210, 213, 216, 217, 227–229
Ovulation, 98, 131
Oxotremorine, muscarinic agonist, 61
Oxytocin, 38, 52, 57, 64, 67, 70–72, 76, 153, 164, 165, 174, 228, 229, 260, 261
– and maternal behavior, 205, 206, 208, 212, 215, 253–256, 260
– and social recognition, 257–259
– and pair bonding, 262–264, 266, 268
– and humans, 270–273
– oxytocin receptors and maternal behavior, 212–213
Pacing, 97, 100–102, 119, 121, 126–129, 759
Paracopulatory behaviors, 97, 99–102, 111, 127
Parasympathetic, 38, 45, 47, 48, 55, 58–61, 64, 65, 72, 76
Paraventricular nucleus of the hypothalamus (PVN), 38, 51, 254–255, 258, 261, 264, 839, 840, 846, 853, 854
Paraventricular nucleus of the thalamus (PVTh), 854
Paraventricular nucleus
– ACTH secretagogues, 516
– median eminence, 516, 519, 528
– subdivisions, 522
– vascularity, 517
Parent of origin effect, 9
Partner preference, 3, 10, 11, 17, 18, 22–25, 101, 102, 261, 262, 264–269
Parturition, 198, 200–206, 208, 211–213, 215–217, 225, 226
Parvocellular PVN neurons, 71,
Pavlovian conditioning, 715, 716
Pedunculopontine tegmental nucleus (PPT), 875, 877, 881, 882
Peg3, 255
Pelvic nerve, 3, 16, 17
Penile function, 41, 42
Penis, 2, 3, 5, 7, 12, 14
Periaquaductal gray (PAG) (also midbrain central gray - MCG), 153, 155, 156, 161, 162, 167–169, 171, 172, 174, 175
Periaqueductal gray, and maternal behavior, 209, 210, 212, 215
Perifornical lateral hypothalamus, 74
Peripheral oscillators, 824–826, 838
Phase response curve, 803
Phase-shifting, 810–814, 817, 825
– glutamate, 812, 813
– neuropeptide Y, 813, 814
– phase response curve, 803
– pituitary adenylate cyclase activating polypeptide, 812
– serotonin, 813
Phase-shifting, 856, 857
Phenoxybenzamine, α receptor antagonist, 56
Phentolamine, α_2 receptor antagonist, 55
Phenylephrine, αreceptor agonist, 56
Phenylethanolamine n-methyl-transferase, 170
Pheromones, 3, 8, 11, 16, 18, 19, 21
Phosphodiesterase 5 (PDE 5), 38, 64
Phospholamban, calcium pump inhibitor, 64
Phosphoprotein, dopamine-and-cAMP-regulated, 123
Photoperiod, 398, 399
Physiological challenges (stressors), 643
Physiological functions, 501, 503
– cardiovascular, 496
– fever, 498
– osmoregulation, 496
– ovarian cycles , 488
– thermoregulation, 496, 499
Pigtail macaques, 269, 270
Pilocarpine, muscarinic agonist, 61
Pituitary adenylate cyclase-activating polypeptide (PACAP), 153, 174
Pituitary, 488, 490, 503, 515–548, 836, 837, 839, 841, 842, 844, 850, 853, 855
Place preference learning, 4
Place-preference test, motivation test, 40
Plasticity, 629, 630
– proteoglycans, 629
– syndecans, 629
pMPPI, 5-HT_{1A} antagonist, 59
Polyethylene glycol, 651, 653, 659, 661
Portal vein, 649, 650
Post train paradigm, 787
Postejaculatory behavior, 39, 40
Post-ejaculatory plug, 3–5, 7, 8, 10, 12, 17–20
Post-translational protein regulation, 819–821
– dimerization, 819, 820
– degradation, 820, 821
– localization, 819–821
– phosphorylation, 819, 820
Prazosin, α_1 receptor antagonist, 56
Precopulatory behavior, proceptive behavior, 39
Precopulatory behavior, species-specific displays, 39
Preference, partner, 101, 102
Prefrontal cortex, 296, 305, 306, 575, 577–580, 584, 587, 718, 722, 723, 744, 745, 749, 750, 754–757
– and motivation, 221
– connections with amygdale, 286, 295
– functions of, 313
– regulation of 5-HT release, 308, 309, 316
– role in extinction, 722
– role in retrieval, 722, 723
– role in working memory, 722, 723
– site of interactions with 5-HT, 313, 316
Pregnancy, 200–206, 208, 210–217, 219, 222, 225–228
Premature ejaculation, 57, 65
Prenatal, 776, 792, 793,
Preoptic area (POA), 4, 9, 21, 22, 347, 351–355, 842, 843, 846, 851, 854, 871–873, 878, 883, 884
– control of gonadotropin secretion, 471, 472
– role in maternal behavior and motivation, 207, 208, 221
– sex differences in, 474
β-preprotachykinin (PPT), 153, 167
Primates
– macaques, 358–361
– baboons, 358, 360, 361
Proceptive behavior, 97
Prodynorphin, 67, 72
Progestative behavior, 97, 100, 119, 132
Progesterone, 153–155, 157–168, 170–174, 254, 255, 260, 270, 758, 761–763, 778, 789, 784, 787, 793, 842, 847, 857
– and maternal behavior, 202–205, 213, 214
– and maternal motivation, 216, 219
– antagonist, 111, 112, 114, 121, 124, 129, 131
– effects on mesolimbic dopamine system, 229
– effects on nigrostriatal dopamine system, 227, 228
– progesterone receptor (PR), 848
– progesterone receptors and maternal behavior, 211, 212

– -induced refractory period, 115–117, 121
– receptor, 111, 122
– receptor isoforms, 112, 114
– receptor knockouts, 111
Progesterone receptor, 153, 157–159, 163, 167, 170, 173, 174
Progesterone receptor knock out (PRKO), 153, 174
Progestins, 99, 108–118, 122, 123, 129–131, 541, 542
Proglumide, CCK receptor antagonist, 75
– projection from midbrain, 740
Prolactin, 57, 75, 76, 268, 917–919
– and maternal behavior, 201–207, 215, 248, 253, 254, 256, 260
– and paternal behavior in primates 270
– receptor expression in female rat brain, 212
Prolactinoma, 917
Prolactin-releasing peptide, 918
Proopiomelanocortin (POMC), 38, 67, 153, 164
Prostaglandin E_2 (PGE_2), 21, 22, 38, 74, 153, 172
– role in masculinization, 467–469
– synthesis of, 467
Prostaglandins, 153, 172, 173, 884
– PGD_2, 884
Prostate, 2, 3, 5, 11
Protein kinase, 103, 123–125
– mitogen activated, 117
Protein kinase A (PKA), 38, 64, 118, 153, 165, 174, 713, 724, 725
– phosphorylation of CREB, 714, 729, 730
– role in gill withdrawal reflex, 725
– role in long-term memory, 727, 728
Protein kinase C (PKC), 107, 165
– isoforms of, 726
– role in long-term memory, 727, 728
Protein kinase G (PKG), 38, 64
Protein kinase Mzeta, 727, 728
– role in intermediate-term memory, 728
Proteosome, 26S, 115–117, 123
26S proteosome, 115–117
Pseudorabies virus, 168
Psychomotor stimulants, 741, 747, 749, 758, 761
PT-141, melanocortin MC-4 receptor agonist, 70
Puberty, 5, 17, 345, 346, 358, 359
Puberty, second organizational period, 40, 41
Pudendal motor neurons, 60
Pudental nerve, 7, 12
PVN (paraventricular nucleus of hypothalamus), and maternal behavior, 208
Quail, 3, 4, 9, 10
Quinelorane, D_2/D_3 receptor agonist, 45
Quinpirole, D_2 receptor agonist, 45, 46, 52
5alpha reductase
– distribution in the songbird brain, 428, 429
– seasonal changes, 434–437
R121919, 912
Raclopride, D_2 antagonist, 47, 58, 59
Radial arm maze, 776, 777, 782–784, 789, 791, 792
Raphe nuclei, 874, 879, 883
– dorsal raphe, 874
Rauwalscine, α_2 receptor antagonist, 55
Receptivity
– estrogen, 105, 106
– membrane, 108, 125, 117
– progestin, 99, 115, 116, 129, 130
– sexual, 97–99, 102, 105, 106, 108, 114–117, 119–121, 125, 127–130
– steroid, 120, 121, 125
Receptor, 489
– androgen, 488, 492, 493, 495, 499
– angiotensin, 656
– antidiuretic, 496
– chemoreceptors, 647
– estrogen, 492, 493, 495
– mechanoreceptors, 647, 650, 656
– osmoreceptors, 645, 646, 648–650, 664, 673
– progesterone, 493, 495
– receptors, 745–747, 753
– reward, 740–754, 756
– sodium, 642–644, 649–653, 664
– tachykinin, 664, 672
– v1a, 496, 498, 500, 502
– vasopressor, 496
Reductase
– 5α, 353, 354
– 5β, 353–355
Reflex, 642, 648, 663, 665
Refractory period
– progesterone-induced, 115–117, 121
Relative refractory period, 40
Relaxin, 646, 655, 656
REM sleep, 870, 871, 873–879, 882–884
Renin, 899
Renin-angiotensin system (RAS), 646, 649, 652–654, 660, 668–670
– brain, 668–670
– circulatory (classic; renal), 669
– tissue, 669
Retina, 808–812, 816
– ganglion cells, 808, 809, 812
– photopigments, 809, 811
– photoreceptor cells, 809–811
– wavelength sensitivity, 809–812
Retinohypothalamic tract, 803, 808–813, 817, 838, 840, 843
Retrieval, 198–200, 207–209, 214–217, 224–226
– role of prefrontal cortex in, 718, 722
Rett's syndrome, 271
Reward, 4, 216–219, 222–224, 740–754, 756–763
– hedonic value, 742–744
– primary reinforcer, 740, 742
– reinforcement, 742, 744, 748
– reward System, 740, 744, 758, 759
– role of learning and memory, 742
– sex differences, 758
Rhesus macaques, 269, 270
Rho-kinase, 56
Rhythmic behavior, 805–807
– drinking, 803, 804
– locomotor, 823, 824
RO60–0175, 5-HT_{2C} agonist, 59
Rodents
– hamsters, 342–348
– mice, 340, 342, 344–348, 353
– rats, 340, 342, 344–346, 348, 353
Sacral parasympathetic nucleus, 61, 72
Salt appetite
– adrenalectomy, 652–654, 661, 664
– depletion-induced, 651, 654, 659, 664
– mineralocorticoid-induced, 662, 663
– synergy hypothesis, 646, 654, 659, 660, 662
Saporin neurotoxin, 12
Satiety, 39, 40, 43, 64
SCH 23390, D_1 receptor antagonist, 46, 47, 67
Schizophrenia, 271
Scopolamine, muscarinic antagonist, 61
Seasonal neuroplasticity, 423, 432–434
Seasonal rhythms, 839
Seasonal
– photoperiodic control of, 343, 344

– melatonin involvement in, 343, 344
– effects of pinealectomy, 343
Seizure disorders and aggression
– inter-ictal rage, 295
– kindling, 295
– "limbic dyscontrol", 294
– neurotoxin exposure, 295, 311
Selective serotonin reuptake inhibitors (SSRIs), 38, 57
Selegiline, MAO B inhibitor, 52
Self-stimulation, 740, 741, 747
– history, 740, 742
– intracranial, 740, 741
– reinforcing properties, 741, 762
Seminal vesicle, 57, 65
Sensitive period
– humans, 463
– primates, 462
– rodents, 462
Sensitization, 744, 745, 749–752, 755–757, 761, 762
– amphetamine, 745, 749–751, 754, 761, 762
– cocaine, 744, 749, 750, 752, 757, 761, 762
– dendritic structure changes, 754, 755
– increases in extracellular dopamine, 757
– morphine, 750–752
– nicotine, 748
Septum and maternal behavior, 209, 210, 212, 213
SERM, 776, 794
Serotonin, 153, 164, 168, 169, 524, 656, 673, 743, 747, 748
– behavioral specificity of agonist effects. 287, 306, 308
– 5-HT_1 receptors
– agonist effects on aggression and 5-HT levels, 311
– behavioral specificity, 311, 316
– control over glutamate and GABA release, 314, 315
– pre- and post-synaptic distribution, 309, 311, 315
– 5-HT_2 receptors
– antiaggressive effects of resperidone, 311
– control over glutamate and GABA release, 314, 315
– lack of behavioral specificity, 311, 316
– interactions with
– cortical GABA and glutamate, 314–316
– hypothalamic vasopressin, 313, 314
– mesolimbic dopamine, 313
– inverse correlation between aggression and CSF metabolite, 306
– peripheral markers of function, 308
– prolactin response to pharmacological agonists, 308
– receptor families
– serotonin transporter, 291, 311–312
– acute versus chronic effects in animals, 312
– cell bodies containing, 874
– effect on allopregnanolone levels, 312
– human gene polymorphisms, 312
– lateral parabrachial nucleus (LPBN), 656, 658, 664–668
– reduced aggression in knockout mice, 315
– SSRI treatments in humans, 312
– raphé
– median and dorsal, 315
– receptor specific effects on aggression, 287, 294–316
– receptors for, 874
– region specific changes during and after aggression, 288–289
– tryptophan depletion and heightened aggression, 308
Serotonin (5-hydroxytryptamine, 5-HT), 38, 53, 57, 76
Serotonin antagonist, 57
Serotonin receptors, 5-ht1–5, 153
Sertoli cells, 501
Sex behavior, 847–849
– lordosis, 848, 849
Sex chromosomes, 492
– XX, 494, 500–502
– XY, 494, 500–502
Sex differences
– genomic basis of, 396
– gonadal steroids, role of, 396
– gynandromorphy, 396
– in the song control system, 432–434
– neurosteriod synthesis, 396
– song control nuclei, role of, 396
Sex steroids, 339, 350, 354–356
Sexual behavior, 754, 759, 760
– feminine, 97, 98, 100–102, 104–107, 110, 111, 113, 114, 118–126, 131, 132
– sexual ability, 759
– sexual motivation, 758–760
Sexual differentiation, 791
Sexual efficiency, 40
Sexual experience, 40, 44, 51, 66, 69, 73, 76
Sexual motivation, 40, 44–47, 49, 51, 52, 57, 60, 65, 68, 74, 76, 101, 102
Sexual orientation, 503
Sexual proceptivity, 97
Sexual receptivity, 97–99, 102, 105, 106, 108, 114–117, 119–121, 125, 127–130
Sexually dimorphic nucleus
– analog in humans, 470
– behavioral significance of, 470
– role of cell death, 470, 471
– volumetric sex differences in, 461
Sham drinking, 659
Short-term memory, 722, 725–728, 735
– activation of silent synapses in, 726
– in *Aplysia*, 725, 726
– role of PKA in, 725, 726, 728
– role of NMDA in, 725, 726
– role of PKC in, 725, 726
SHU 9119, MC-3/MC-4 receptor antagonist, 70
Sildenafil (Viagra), PDE 5 inhibitor, 65, 67
Simulated territorial aggression, 350, 353, 357
– territoriality, 354–356
SKF 38393, D_1 receptor agonist, 45–47, 67
SKF 81292, D_1 receptor agonist, 45
Sleep deprivation, 897, 899, 901, 904, 906, 910–912, 917, 926
Sleep, 394
– definition, 870
– deprivation, 874, 878, 882–884
– homeostasis, 882
– regulation, spontaneous, 882
– regulation, prolonged wakefulness, 881, 882
Sleep-active nuclei, 876
Smooth muscle, 56, 64, 70, 71, 74
SND 919, D_2/D_3 receptor agonist, 45
Social factors
– influence on gene expression, 398
– influence on song, 398
Social recognition
– rodents, 256–260, 264, 268, 275
– sheep, 260
Sociogenomics, 252
Sodium channels, 652
– Na_x, 652

Sodium depletion, 646, 651, 654, 655, 659, 660, 664, 665, 667, 668, 672
– glucose dialysis, 645
Soliciting behavior, 97, 100
Somatosensation, and maternal behavior, 199, 200, 207
Somatostatin, 903, 904
Song control nuclei
– anterior forebrain pathway, 376, 393
– area X, 376, 378
– discovery of, 378
– HVC, 376, 378, 382, 384, 393, 397, 398
– HVC-RA pathway, 376, 378, 392, 393, 396
– LMAN, 378, 382, 384, 393–395
– NCM, 376, 390, 397
– nomenclature, revised, 376–379
– RA, 376, 378, 381, 382, 384
– song motor control pathway, 396–398
– steroid hormone receptors, 378, 396
– *zenk*, 383, 384, 398, 399
Song control system, 438, 441, 443, 444
– basic anatomy, 421–423
– seasonal neuroplasticity, 432–434
Song learning, 395, 396
– anterior forebrain pathway (AFP), role of, 376, 392–395
– caspase-3, 391
– critical period, 391
– efference copy, 395
– habituation, 387, 389–391
– LTD and LTP, 393
– memory strength, 387, 389
– NMDA receptors, 393
– song production learning, 376, 391–395
– song recognition learning, 376, 385–391
– tutor, 376, 385, 386
– *zenk* gene, 383, 384, 389–391, 394, 398–400
Song preferences
– memory strength, 387
– significance, 389
Song, function of, 375, 376
Songbird, 351
– canary, 375, 379, 398, 402
– chickadee, 383, 385
– estrilidine, 382

– guinea pigs, 488, 496
– hamsters, 495, 496, 498, 655, 659
– humans, 496, 498, 503, 646, 656, 662, 668, 672
– Japanese quail, 495, 497
– lizards, 495
– marmoset, 496
– mice, 489, 492, 494, 495, 500–502
– mouse, 651, 652, 654, 669, 670
– primate, 496
– rainbow trout, 496
– rat, 651, 652, 656, 657, 659, 663, 669–672
– rough-skinned newts, 495
– sheep, 653–655, 657, 660–664, 669
– turtle, 495
– vole
– meadow vole, 495
– prairie vole, 493, 495, 499, 500
– zebra finches, 488
Sperm, 2, 3, 5
Spinal cord, 38, 52, 54–57, 60, 61, 64, 67, 69, 70, 72, 73, 76
– sexually dimorphic nucleus of the bulbocavernosus, 488
Spiperone, D_2 antagonist, 46, 58
Spironolactone, 914, 915
Splanchnic circulation, 649
Spontaneous erections, 41, 71
Squirrel monkeys, 264, 269, 274
SRC-1, 103, 106, 107, 124
SRM, 776, 794
Sry gene, 15, 16
Sry, 500–503
SSRI, selective serotonin reuptake inhibitor, 312
– acute versus chronic effects in animals, 312
– effect on allopregnanolone levels, 312
– effect on human aggression, 312
Steroid hormone, 5, 17, 21, 837, 841–843, 848, 849
– estrogen, 842, 847, 850, 858
– glucocorticoids, 845, 852, 853, 856–858
– progesterone, 842, 847, 857
– testosterone, 838, 841
Steroid
– androgen, 394, 396
– aromatase, 396, 397, 400, 402
– estradiol, 396–398
– estrogens, 378, 382, 396, 397, 400
– retinoid, 381
– steroid hormone receptors, 378, 397, 400, 402
– steroid synthesis, 378, 397
– hormones, 100, 102–104, 108, 118, 120, 122–126, 130, 131
– receptor coactivators, 104, 106
– receptor coregulators, 104
– receptors, 104, 108, 117, 121, 123–126
Steroidogenesis, 461, 462, 471
Stimulation, 99–101, 120, 121, 125, 127, 128, 130
– genital, 131
– vaginocervical, 98, 126, 129
Stress hormones, 573, 575, 581
Stress, 168, 169, 572–587, 776, 777, 779, 784, 788–793, 873, 875, 882
– adrenocorticotropic hormone, 344
– corticosterone, 357
– cortisol, 346
– glucocorticoids, 346
– hypothalamic-pituitary-adrenal axis, 596, 597
– hypothalamo-pituitary-adrenal axis, 346
– negtaive feedback, 598–599
Stress, acute
– psychogenic, 546
– systemic, 546

Stress, chronic
– facilitation, 548
– habituation, 548
Striatum, 209, 221, 222, 225–228, 741, 743, 744, 747, 757, 776, 779–781
Stroke, 503
Subparafascicular nucleus of the thalamus (SPFp), 73
Substance p, 153, 167, 168
Substantia nigra
– and maternal behavior, 214,
– hormone effects on, 222, 225–227
Suprachiasmatic nucleus properties, 805–807
– calcium concentration, 806
– core, 804, 807–809, 812, 814–817, 819–821, 824–826
– gene expression, 807, 809, 813, 816, 818, 819, 821, 825, 826
– glucose uptake, 805
– peptide expression, 817
– shell, 808, 809
– spontaneous firing rate, 813
Suprachiasmatic nucleus, 837, 840
Sympathetic, 38, 45, 47, 55, 56, 58, 60, 65, 72
Synapses
– axosomatic, 465
– dendritic spine, 467, 469, 474, 475
– density of, 465, 467, 468, 474, 475, 476
– sex differences in, 465, 475
Synaptic plasticity, 573, 579, 585, 586, 587
Synergy hypothesis, 646, 654, 659, 660, 662
Tachykinin, 167, 672
– peptides, 650, 652, 656, 671
– receptors, 672
– substance p, 672
Tadalafil (Cialis), PDE 5 inhibitor, 65
Tail pinch, 44, 68
Tau mutant hamster, 806, 807, 817
Telencephalon
– anterior commissure, 503
– bed nucleus of the stria terminalis, 489, 490
– CA1, 499
– hippocampus, 496, 499
– medial amygdaloid nucleus, 489
– planum temporale, 503
– song control nuclei, 488
– ventral pallidum, 500
Territorial aggression
– function in mice, 288, 289
– laboratory housing and, 288, 289
Testes, 2, 3, 5, 15, 16, 25
– regression, 342
– spontaneous recrudescence, 342, 343
Testosterone propionate, 5
Testosterone, 2, 3, 5–17, 19, 21, 40, 41, 44–46, 49–51, 56, 58, 62, 65, 66, 68, 70, 73, 74, 287, 778, 779, 787, 791, 792
– obligatory role in lizards, snakes, fish, and birds, 287
– prior behavioral experience reduces effects of castration, 287
Tetrahydrothienopyridine, D_1 receptor agonist, 38, 47
Tetrodotoxin, 806–808
THIQ, melanocortin MC-4 receptor agonist, 70
Thirst
– additivity, 658, 659
– double-depletion hypothesis, 645, 672
– "dry mouth" theory, 644
Threodihydroxyphenylserine, NE precursor, 55
Thyreotropin-releasing hormone, 916
Thyroid releasing hormone, 174
Thyroidism, 916
Thyrotropin releasing hormone (TRH), 38, 60
Thyroxin, 916
Titi monkeys, 269
Touch-based erections, 42, 44–47, 52, 55–58, 61, 64–68
Transcription factors
– DNA binding, 605
– effect of CpG methylation, 606
– NGFI-A (zif-268, egr-1), 601, 603, 606–612
Transcription-translation feedback loop, 815
Transgenic
– mice, 669, 670
– rats, 669
Transient receptor potential (TRP), 650–652
– ion channels, 650, 651
– transporter, 745, 747, 748, 757
– TRPV1, 652
– TRPV4, 651
Tryptophan hydroxylase, 5-HT synthetic enzyme, 57
Tryptophan, serotonin precursor, 57,
Tuberomamillar nuclei, 876, 878, 879, 883
Tumor necrosis factor alpha (TNFα), 882
Two-process model, 874
Tyrosine hydroxylase, 13, 14, 170, 502
Tyrosine, 170
U-50,488, κ agonist, 68
Ultrasonic vocalizations, 48, 62
Urbach-Wiethe disease, 272
Urethrogenital reflex, 42, 57, 60, 62
Vagal, 649, 657
– afferents, 647, 657
– nerve, 644, 648, 649, 656, 657
Vaginocervical stimulation, 98, 126, 129
– vanilloid receptor family, 651
Vardenafil, (Levitra), PDE 5 inhibitor, 65
Vasoactive intestinal peptide (VIP), 38, 74, 174, 442, 443, 809, 817, 821, 822, 845–848, 850–852, 918, 919
Vasopressin, 52, 72, 153, 165, 291, 308, 313, 314, 642, 651, 671, 809, 818, 821–823, 845–847, 850–852, 913
– actions in hypothalamus, 308, 313
– and paternal care, 264, 265
– and social recognition, 257, 259
– and pair bonding, 263–266, 268
– and humans, 270–272
– arginine vasopressin (AVP), 853
– facilitation of aggression, 313, 314
– regulation by 5-HT, 313, 314
– V1aR receptor, 852
Vasopressin-1a receptor, v1a, 153
Ventral horn motoneurons, 61
Ventral horn of spinal cord, 56
Ventral noradrenergic bundle, 55
Ventral noradrenergic bundle, lateral tegmental tract, 170
Ventral pallidum, 264–267
Ventral tegmental area (VTA), 38, 43, 69, 74, 255, 256, 261, 272, 273, 744
– and maternal behavior, 207, 213, 215
– hormone effects on, 222–226, 228–229
Ventrolateral medulla, 671
– A1/C1, 671
– norepinephrine, 670, 671
Ventromedial hypothalamic nucleus, 10
Ventromedial hypothalamus, 107, 118–121
– and maternal behavior, 210, 212–215
Ventromedial nucleus of the hypothalamus, 105, 107, 110, 120, 153, 154
Viagra (sildenafil), PDE 5 inhibitor, 65
Viral vector gene transfer, 248, 259
Visceral (viscera), 657, 663, 673, 674

– neuraxis, 663, 668, 673, 674
– receptors, 673
– sensory nerves, 657
VLPO, 872, 876, 883
VMN, 105, 107, 109, 110, 114, 118–121, 127, 130, 131
VNX, vomeronasal organ removed, 73
Vocalization, 376, 383, 393, 399
– neural control of, 375
Voles, 261–271, 274
Vomeronasal organ, 11, 38, 73, 742
– pheromones, 742
– role in mating, 742
Wanting, 740–747, 760, 763
Water deprivation, 644, 650–652, 657–659, 670
– cell volume, 644, 647
– plasma volume, 644, 645, 658
WAY 100635, 5-HT_{1A} antagonist, 58
Western immunoblot, 74
Whole-genome sequencing, 375
Withdrawal, 749, 750, 754, 763
Working memory, 722–725, 733
– definition of, 722
– requirement for dopamine, 722–724
– role of calcineurin in, 725
– role of calcium signaling in, 725
– role of PKA in, 723
– role of prefrontal cortex, 722
World Health Organization (WHO), 286
– statement on violence, 286
X inactivation, 501
X-maze, motivation test, 40, 47, 52, 65
Y-maze, 4, 18
Y-maze, 789
Yohimbine, α_2 receptor antagonist, 55, 56, 58
Zeitgeber, 802, 803, 826
– α-Melanocyte stimulating hormone (α-MSH), 38, 69, 76
– β-blockers
– β-Endorphin, 67, 69, 70
– γ-amino butyric acid (GABA), 153, 172
– δ opioid receptors, 67
– Δ-opioid receptor (DOP), 153
– κ opioid receptors, 67
– μ-opioid receptors, 67, 68
– Actions at 5-HT_{1A} receptors, 301
– Anti-aggressive effects of, 301
– K-opioid receptor (KOP), 153, 159
– M-opioid receptor (MOP), 153
– Motor impairments, 301
