Preface

Behavioral neuroscience was not covered extensively in the second edition of the Handbook of Neurochemistry, published in 1983. That was nearly a decade before the formation of the international society, which named itself after this discipline, the International Society for Behavioral Neuroscience, and it was even longer before the inception of the Society for Behavioral Neuroendocrinology, which focuses on a subfield of behavioral neuroscience. The progress that has been made in the study of the cellular and molecular underpinnings of behavior was almost unimaginable in 1983. The field has prospered thanks to development in novel drugs, genetic models, and related molecular techniques, neuroanatomical techniques, including *in situ* hybridization histochemistry, new immunocytochemical techniques, real time PCR, microarrays, and more sophisticated behavioral analysis.

This volume is filled with a tremendous amount of history that documents the coming of age of behavioral neuroscience. Learning the history and following the development of a field are often an important part of understanding an area of science, and many of the authors have elaborated extensively on the history of their field. Though behavioral neuroscience has advanced tremendously in recent years, impediments to progress still remain in this field. For example, behavior still occasionally takes a back seat to the study of simpler physiological endpoints, such as the control of ovulation. Yet, it is the more complex regulation of behavior and the interactions of the environment on it that allow for fertilization, without which, ovulation would be irrelevant. In his memorable biography of the field of hormones and behavior, Frank Beach (1981) explained some of the background for bias against studies of behavior. He also provided what is perhaps one of the most noteworthy examples of this bias against studying behavioral endpoints. In 1935, Edward Dempsey, working in William C. Young's group, made the heretic proposal that sequential exposure to estradiol and progesterone was necessary to induce the expression of estrous behaviors in female guinea pigs. This made no sense at the time since it was widely believed that the source of progesterone was the corpus luteum, most definitely formed after ovulation, long after the animal's estrous behavior had commenced. Beach recounts that Edgar Allen, a co-discoverer of estradiol, suggested that Young would be "well-advised to give up behavior and return to his more promising early studies on physiology of the epididymis." It was to be another 30 years before novel biochemical procedures would be developed, which would prove Dempsey, Young and colleagues correct; progesterone was being secreted from another source before the formation of the corpus luteum. Behavioral studies had indeed informed physiology.

Throughout this volume, you will find examples of dogmas that ultimately did not hold water (the timing of progesterone secretion during the estrous cycle just discussed is but one example). Time and time again, throughout the history of science, scientists who have questioned dogma have been subjected to ridicule or derision for their actions. Win or lose, the dogma fight is always worth waging, and it is good science. If the dogma represents truth, it will stand; if not, it will eventually topple, but usually not without significant battle. I dedicate this volume to all scientists who have at one point or another challenged dogma in their work.

In this volume, I have collected in one place the expertise of numerous authorities in the diverse field of behavioral neuroscience. A volume of this size does not allow for an exhaustive treatment of the neurochemistry, neuroendocrinology, and molecular neurobiology of behavior; rather it is a sampling of some fascinating areas within the realm of behavioral neuroscience. Moreover, because of my personal bias, these

areas of behavioral neuroscience often have an important, well-developed, endocrine slant. To appreciate how much space a comprehensive treatment of the entire field would require, consider that a comprehensive coverage of the subfield, the relatively narrow field of behavioral neuroendocrinology, was recently accomplished admirably in a discipline-defining, five-volume, and nearly 4,000 page work, which was edited by Donald W. Pfaff et al.

It is impossible to acknowledge here each of the authors and all of the important findings of the fields that they represent. Suffice it to say that tremendous progress has been made in the study of reproductive behaviors, affiliative and aggressive behaviors, bird song, sex differences, the hypothalamo-pituitary-adrenal axis, stress, ingestive behaviors, fear, cognitive function, reward, rhythms, and sleep. The book starts at the beginning with reproduction and ends appropriately with sleep. Between those two basic, life-generating and restorative activities, tremendous progress in all of these fields is described.

Recent changes in the funding climate have affected many areas within behavioral sciences. For example, the National Institutes of Health have shifted emphasis to more translational research; in some cases, at the expense of more basic research. This volume is filled with examples of basic research that have led to a better understanding of the human brain and behavior. I hope that it serves as testament to the indispensable value of basic research, as well as translational research, in behavioral neuroscience.

Frank Beach ended his biography of the field of behavioral endocrinology with the following passage: "Scientists with doctorates in psychology study development of progesterone receptors in neurons of the rat hypothalamus while other investigators initially trained in pharmacology invent elegant behavioral measures of sexual motivation in the estrous female. These developments appear to represent more than a mere borrowing of techniques by one discipline from another. Instead they seem to reflect progress toward recognition of common goals and shared theoretical interests. If such indeed is the case, behavioral endocrinology may well be a discipline *in statu nascendi*," that is, a discipline in a state of being born. He could have said the same about behavioral neuroscience. I submit that the discipline of behavioral neuroscience has become a fully developed discipline with investigators answering questions that truly run the gamut from molecular to behavioral and all levels in between.

I am immensely grateful to all who contributed to this volume. Writing a comprehensive review of a field, even one's specialty, is time-consuming and laborious, and it invariably takes time away from other worthy tasks. My job of convincing colleagues to contribute to this volume was made relatively easy because previous versions of the Handbook of Neurochemistry have been well received, and have often served as landmark volumes in their respective fields. It is my hope that the authors will be well compensated for their work with the satisfaction of knowing that their reviews will be read and that, as their areas evolve, progress can be updated and followed in the electronic version of the Handbook.

5 Relationship Between Sexually Dimorphic Hypothalamic Morphology and Male-Typical Sexual Behavior and Partner Preference 22

Abstract: Berthold, working in the mid-nineteenth century, first published data linking the endocrine secretions of the rooster testes to the display of masculine courtship behavior. Since then hundreds of experiments have been published showing that testosterone is the endocrine signal produced by the Leydig cells of the testes, which in male mammals contributes both to the activation of mating behavior in adulthood and to the organization during perinatal life of neural mechanisms that control this behavior. The broader topic of the neural basis of male sex behavior has recently been reviewed (Hull et al., 2002). Therefore, the present review will concentrate selectively on neuroendocrine variables that control the adult activation as well as the perinatal development of brain mechanisms controlling male-typical sexual motivation, courtship, penile erection, and coital behaviors, with an emphasis on common mammalian models including the rat, mouse, hamster, ferret, and monkey. A common theme to all of these studies is that testosterone exerts its actions in the neural systems controlling male-typical sexual behavior both by acting directly via neural androgen receptors and after neural aromatization to estradiol or 5α−reduction to dihydrotestosterone. Estradiol, in turn, affects neural morphology and function via estradiol receptors of the alpha- or beta-subtypes, whereas dihydrotestosterone, like testosterone, acts via androgen receptors. The evidence reviewed indicates that there are many similarities and a few differences among mammalian species, including higher primates, in the principles of neuroendocrine regulation that control the development and expression of male sexual behavior.

List of Abbreviations: AOB, accessory olfactory bulb; AR, androgen receptor; ArKO, aromatase knockout (mouse); ATD, 1,4,6-androstatriene-3,17-dione (aromatase blocker); BNST, bed nucleus of the stria terminalis; CA, cyproterone acetate; CBP, cAMP response element binding protein; COX-2, cyclooxygenase 2; CPP, conditioned place preference; DA, dopamine; DHT, dihydrotestosterone; DHTP, dihydrotestosterone propionate; DNA, deoxyribonucleic acid; DOPAC, 3,4-dihydroxy-phenylacetic acid; E, estradiol; E25, embryonic day 25; EB, estradiol benzoate; ER, estrogen receptor; F1, first generation; GABA, gamma amino butyric acid; GnRH, gonadotrophin releasing hormone; HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome; INA-3, third interstitial nucleus of the anterior hypothalamus; IR, immunoreactivity; LS, lumbar spinal cord; MeA, anterior amygdaloid nucleus; MN-POA/AH, (sexually dimorphic) male nucleus of the preoptic area/anterior hypothalamus (ferret); MPOA/AH, medial preoptic area/anterior hypothalamus; mRNA, messenger ribonucleic acid; MSH, melanocyte stimulating hormone; NO, nitric oxide; NOS, nitric oxide synthase; OHF, hydroxyflutamide; P, progesterone; PGE2, prostaglandin E2; POE, parent of origin effect; POM, sexually dimorphic medial preoptic nucleus (quail); PR, progesterone receptor; sc, subcutaneous; SDN, sexually dimorphic nucleus; SPFp, subparafascicular nucleus ; SRC-1, steroid receptor co-activator 1; Sry, sex determining region of the Y chromosome; T, testosterone; Tfm, testicular feminization; TH, tyrosine hydroxylase; TP, testosterone propionate; VMH, ventromedial hypothalamic nucleus; VNO, vomeronasal organ; WT, wild type

1 Introduction

Contemporary textbooks of behavioral endocrinology (Nelson, 2000; Becker et al., 2002) list the first formal experiment in this field as having been carried out at the University of Gottingen, Germany by Arnold A. Berthold (Berthold, 1849), who demonstrated that castrating young male chickens prevented the development of crowing, sexual behavior, and secondary sex characteristics, including a red comb. By contrast, castrated chickens that were implanted with a testis (either one of their own or from another male) showed normal male-typical development of a comb along with courtship and sexual behaviors. The implanted testes were vascularized and they produced sperm along with an endocrine product that stimulated the observed behavioral changes, including mating. Many years later it was found that testosterone (T), secreted by Leydig cells of the testes, was the relevant endocrine signal that caused all of these behavioral and somatic effects. These early observations laid the groundwork for a myriad of experiments, conducted mainly in avian and mammalian species, on the actions of T in both the nervous system and in other androgen-sensitive target tissues including the prostate gland and penis. Androgens can act directly in the brain to facilitate the expression of numerous social behaviors, including mating. Through its action on

another androgen-sensitive tissue, the penis, androgen also indirectly affects the patterning of mating behavior. This chapter concentrates on the actions of T, and its metabolites estradiol (E) and 5α−dihydrotestosterone (DHT), in the adult and/or fetal brain that contribute to male-typical sex partner preference, sexual arousal including penile erection, and the control of courtship and mating behaviors in male mammals. The reversible, adult (so-called activational), the permanent perinatal (so-called organizational), and the pubertal actions of testosterone and its neural metabolites on neural mechanisms controlling male-typical sexual behavior are considered. Experimental findings from several vertebrate species including rat, ferret, mouse, hamster, quail, monkey, and human are used to illustrate the relevant principles of neuroendocrine regulation. Extensive reviews of the literature on the neuroendocrine and neurochemical regulation of male sexual behavior (Hull et al., 2002), as well as of brain and behavioral sexual differentiation (Wallen and Baum, 2002; De Vries and Simerly, 2002), appeared in 2002. I therefore concentrate here on studies concerning the neuroendocrine regulation of masculine sexual behavior that were either not highlighted in those reviews or have been published since 2001.

2 Methods of Studying Appetitive versus Consummatory Components of Male Sexual Behavior as well as Erectile Function

A distinction between the neuroendocrine mechanisms controlling appetitive and consummatory components of male-typical sexual behaviors is emphasized throughout this review. Much research using animal models has concentrated on the different neuroendocrine mechanisms controlling sexual motivation, penile erection, and mating behavior per se. The most common model system is the male rat in which mating performance has been observed during interactions with an estrous female. In this situation, a receptive female is placed in a chamber with the male being tested, and the observer records the occurrence of mounts with pelvic thrusting, penile intromissions, and ejaculations over time. In rats, as in many rodent species, the male displays a series of discrete mounts of the female partner that are accompanied by very brief penile erection, pelvic thrusting, and intromission into the vagina. The male dismounts after each intromission. After 5 to 15 such mounts with intromission, the male ejaculates a copulatory plug composed of secretions of the prostate, seminal vesicle, and coagulating gland and sperm from the testes. Deposition of this copulatory plug against the female's cervix ensures that sperm will pass into the uterus, thereby increasing the likelihood that fertilization of ova will occur in the female's fallopian tubes. Receipt of a minimal number of intromissions from the male over a particular period insures the activation of a neuroendocrine reflex in female rodents, which is needed to stimulate prolactin secretion from the pituitary gland. Prolactin then stimulates the corpora lutea of the ovaries to produce the progesterone needed to establish pregnancy (Erskine, 1995).

Significant species variations exist in the behavioral patterns displayed by male vertebrates during mating. For example, many species of fish perform stereotyped courtship movements that entice the female to deposit eggs in a nest, whereupon the male positions himself over these eggs and deposits his sperm without any physical contact with the female. Male birds exhibit a wide variety of courtship displays, including vocalization (crowing or singing), strutting, mounting, and deposition of sperm through direct cloacal contact with the female. The pattern of mating displayed by the male rhesus monkey resembles that shown by the male rat, as described earlier. By contrast, the male ferret mates by grasping the female's neck, mounting, and exhibiting episodes of pelvic thrusting (accompanied by penile erection). Once the erect penis is inserted into the female's vagina, thrusting ceases, and the intromission is maintained for up to 1.5 h, even after ejaculation occurs. This intromissive stimulation activates a neuroendocrine reflex in females leading to the pituitary secretion of luteinizing hormone (LH) and subsequent ovulation (Carroll et al., 1985). Specific patterns of masculine courtship and coital behavior have evolved in different species (Dewsbury, 1972) to maximize the chances of reproductive success.

Recording the frequency or timing the duration of neck grip, mounting, intromission, and ejaculation provides a useful index of masculine coital performance. However, these variables provide only partial insight into an animal's level of sexual motivation. Sexual motivation is a construct that refers to the inclination of an individual to seek out and approach a partner for the purpose of mating. Masculine sexual

motivation has been studied in several different ways. These include (Stone et al., 1935) monitoring the willingness of male rats to cross an electrified grid to gain access to an estrous female, as well as latencies of males to approach an estrous female tethered in the goal box of a straight runway (Beach and Jordan, 1956; Bolles et al., 1968; Lopez et al., 1999). Another approach has been to require rats to press a lever in a Skinner box to gain access to an estrous female (Beck, 1971). A shortcoming of this method is that subjects' operant responses occurred at a low rate under a continuous reinforcement schedule, and when the female became available, the resulting sexual interaction disrupted subjects' operant lever-pressing behavior. Everitt et al. (1987) improved on this procedure by providing male rats with a conditioned secondary reinforcer (a red light) that was initially associated with access to an estrous female that dropped into the male's compartment from an overhead location. This procedure led to high levels of lever pressing by male subjects in order to illuminate the conditioned stimulus. Although some interesting data were obtained using this method, it also had certain disadvantages in that considerable pretraining was needed for subjects to acquire the task, and various experimental manipulations could influence task performance by affecting subjects' motivation to lever press for the conditioned stimulus as opposed to the unconditioned sexual stimuli.

The method of measuring runway-approach latencies is insensitive and the method of training animals to press a lever for access to a goal stimulus is tedious. As a compromise, numerous investigators have chosen to assess the subjects' preference to approach and interact with any one of two different social stimuli that are tethered to the opposite ends of a 3-compartment box or in the goal boxes of a T- or Y-shaped maze. This method has also been used to provide a choice between volatile odors from anesthetized conspecifics and physical access to these animals. Such an approach has been used to assess the preference of rats (Vega Matuszczyk et al., 1988), hamsters (Johnson and Tiefer, 1972), ferrets (Stockman et al., 1985), and mice (Bakker et al., 2002) for same-sex versus opposite-sex conspecifics. This method has also been extensively used (Winslow et al., 1993) to establish the roles of vasopressin and oxytocin in monogamous pair bonding in male and female prairie voles, respectively. The motivation of male ferrets to approach same-sex conspecifics in a T-maze was studied after the placement of lesions in the sexually dimorphic preoptic/anterior hypothalamic region (Paredes and Baum, 1995). More recently, this method was adapted so that volatile odors from same-sex versus opposite-sex conspecifics could be presented in an air-tight Y-maze, with the aim of establishing the role of body odorants in heterosexual mate recognition in ferrets of both sexes (Kelliher and Baum, 2001). Avian species use visual signals to identify preferred mating partners, and the time that male quail spend approaching a window to view a receptive female has been taken as an index of their sexual motivation (Balthazart et al., 1998).

Sexual motivation in male rats and mice has been assessed using bilevel test chambers. Males' level-changing behavior increased significantly when subjects were tested in the presence of an estrous—as opposed to an anestrous—stimulus female (Mendelson and Pfaus, 1989). Anosmic male rats showed less level changing in the presence of an estrous female (Van Furthand Van Ree, 1996b), implying that males' motivation to approach the female resulted from their attraction to volatile estrous odors. Male rats showed significantly less level-changing behavior within a few minutes following ejaculation with an estrous female (i.e., during the postejaculatory interval) (Van Furth and Van Ree, 1996a), providing further evidence that this behavior is a useful index of the males' sexual motivation. Male rats that were treated with dopamine (DA) receptor blockers also showed significantly less level-changing behavior in the presence of an estrous female (Pfaus and Phillips, 1991), implying that the activation of DA neurons normally augments masculine sexual motivation and reward.

A simple method for assessing the rewarding characteristics of drugs of abuse (e.g., heroin, cocaine, amphetamine) has been to demonstrate that the administration of a particular drug in a compartment (distinctive because of its color, odor, and/or floor texture), which was initially not preferred by a subject, causes the subject to prefer that compartment as a result of repeated pairing of its physical features with receipt of the drug (Mucha et al., 1982). Male rats learn a conditioned place preference (CPP) for the opportunity to mate with an estrous female (Miller and Baum, 1987). This type of CPP was less evident in male subjects that had no control over the rate at which an estrous female allowed mounting and intromission behaviors to occur (Martinez and Paredes, 2001).

In addition to the above-mentioned methods for measuring sexual motivation and mating performance, per se, several model systems have been established in which to study the neuroendocrine regulation

of penile erection in mammals. In many commonly studied laboratory species, penile erections can be easily observed and counted "in copula" with the use of a mirror for ventral viewing during mating sessions with a female conspecific. More detailed measurements of erectile function, including monitoring blood pressure increments in the penile corpora cavernosa that are associated with erection induced by electrical stimulation of the cavernosal nerve, have been made in studies using anesthetized male rats (Lugg et al., 1995; Marin et al., 1999) and rabbits (Traish et al., 1999). Numerous experiments have also been conducted in which erectile function was studied "ex copula" in awake male rats during whole body restraint and retraction of the penile foreskin coupled with continuous pressure at the base of the penis (Hart, 1967). Finally, erection has also been studied ex copula by placing an awake male rat down wind from an estrous female whereupon noncontact, psychogenic erections induced by volatile chemosensory signals from the female are observed using a ventrally placed mirror (Sachs, 1997).

3 Activation of Male-typical Sexual Behavior and Penile Erection by Testosterone and its Neural Metabolites, Estradiol and Dihydrotestosterone

3.1 Effects of Castration and Systemic Administration of Steroids or Antagonist Drugs

With one notable exception (discussed later in detail), studies conducted over the past 75 years have established the indispensable role of the testicular steroid hormone, T, in promoting the activation of both appetitive and consummatory components of sexual behavior among infra primate mammalian species (Hull et al., 2002). Thus, castration of male rodents (e.g., rats, mice, hamsters, and guinea pigs) inevitably leads to a steady decline over a period of several weeks in ejaculation, followed by a decline in mounting and approach of an estrous female. Administration of T immediately after castration will maintain high levels of male-typical mating behavior, and this treatment will readily restore mating in castrated males even when treatment is begun many months after the postcastration disappearance of sexual behavior. Evidence will be considered suggesting that T, either acting itself or after metabolism in the brain into E or DHT, plays a permissive role in the sense that it facilitates the display of appetitive and consummatory sexual behaviors in response to olfactory, visual, and/or genital–somatosensory stimuli derived from a sexually receptive estrous female. In the absence of circulating T, these same stimuli lack the ability to elicit sexual behaviors. Adult male rats normally have circulating levels of T that range from 1 to 3 ng/ml; however, sexual behavior can be readily maintained in castrated rats by s.c. administration of very low doses of T that result in plasma levels of <1.0 ng/ml (Damassa et al., 1977). Higher circulating levels of T are required to restore mating in long-term castrate males. Male mammals normally begin displaying mating behavior around the time of puberty, when testicular production of T and the production of mature sperm is established (55–65 days postnatal in male rats). The first display of sexual behavior can be significantly advanced by daily administration of testosterone priopionate (TP) to prepubertal male rats (Stone, 1940; Baum, 1972), and the doses of TP required for these effects are considerably higher than those needed to maintain or restore mating in adult castrated males. In male hamsters that were castrated either prepubertally or after the age of puberty, s.c. administration of different doses of T (pellets given s.c.) activated all aspects of mating in the adult, but not the prepubertal males (Meek et al., 1997), suggesting that males' ability to respond behaviorally to T increases as they pass through the age of puberty.

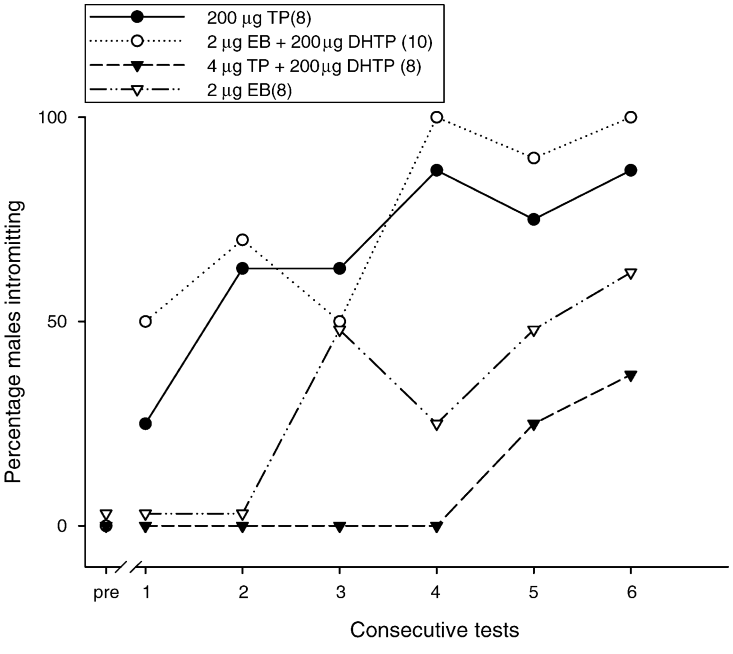
Early in the history of contemporary behavioral neuroendocrinology, Beach argued that the activational effect of T on male rats' sexual behavior reflected the increased size and sensitivity of somatosensory receptors on cornified papillae of the glans penis (Beach and Levinson, 1950). Evidence that this peripheral action of T—presumably acting via the androgen receptor (AR) agonist actions of its metabolite, DHT—cannot account for the behavioral effects of T, came from the observation (McDonald et al., 1970; Feder, 1971; Whalen and Luttge, 1971) that administration of DHT to castrated male rats failed to activate mating behavior, whereas it stimulated the growth of the prostate gland and other accessory sex organs, including the penis, up to levels characteristic of testes-intact controls. By the early 1970s, it also became apparent that

DHT and T are specifically bound, with high affinity, in the male rat hypothalamus (Kato and Onouchi, 1973). It was subsequently shown (Vreeburg et al., 1975) that specific, high-affinity hypothalamic binding of the androgen metabolite, E, also occurs in male rats. In subsequent years the AR and the ERα were cloned, and mRNAs for each type of receptor were found to be expressed in the hypothalamus and amygdala (among other regions) of male rats (Simerly et al., 1990). Early studies also established that T can be aromatized to E (Naftolin et al., 1972) and reduced to DHT (Denef et al., 1973) in the rat hypothalamus and amygdala. These facts strongly pointed to a neural action of T and/or its androgenic or estrogenic metabolites in the activation of masculine sexual behavior.

In contrast to the inability of systemic treatment with DHT, by itself, to activate mating in male rats, two studies (Davidson, 1969; Sodersten, 1973a) demonstrated that s.c. injections of estradiol benzoate (EB) into castrated male rats restored appreciable levels of male sexual behavior, especially mounting and intromission, along with an occasional ejaculation response. Administration of EB prepubertally to male rats activated precocious expression of mounting and intromission behaviors even more readily than a prepubertal treatment with TP (Baum, 1972). As shown in *Figure 1-1*, combined s.c. administration of 2 μg EB and 200 μg DHTP activated all components of sexual behavior in castrated male rats as readily as

Figure 1-1

Combined s.c. administration to castrated male rats of estradiol benzoate (EB)+dihydrotestosterone propionate (DHTP) duplicated the activational effects of testosterone propionate (TP) on sexual behavior. The percentage of males showing intromission behavior with an estrous female is shown before (pre) and after the onset of daily injections of different hormones. Similar data (not shown) were obtained for the occurrence of ejaculation. Group Ns are given in parentheses. Adapted from Baum and vreeburg (1973)



200 μg TP itself. By contrast, combining a low dose of TP (4 μg/rat/day) with the same high dose of DHTP stimulated only low levels of mating behavior (Baum and Vreeburg, 1973). Similar results were also obtained by other investigators (Larsson et al., 1973; Feder et al., 1974). An obvious explanation for the

combined action of E and DHT was that E acted on neural mechanisms that control appetitive and pre-ejaculatory components of the behavior, whereas DHT acted in the penis to promote the genital sensory inputs needed in order for intromissions to trigger ejaculation. Interestingly, the ability of s.c. injections of DHT to augment mounting behavior in castrates that were given EB concurrently was not reduced by pudendal nerve transaction (Lodder and Baum, 1977). Pudendal nerve transaction interrupted sensory inputs from the penis to the spinal cord; thus, the result obtained implies that there are central activating effects of DHT on the expression of sexual behavior in addition to any facilitation of mating due to a stimulation of penile sensory responsiveness.

A wealth of information (Hull et al., 2002) has appeared assessing the respective roles of E and DHT in the activation of sexual behavior in a variety of vertebrate species. For example, in male hamsters the conversion of T to E may not be required for the activation of sexual behavior in that s.c. administration of the aromatase inhibitor, Fadrozole, failed to inhibit the expression of any aspect of male sexual behavior (Cooper et al., 2000). This outcome contrasts with a similar study in male rats (Bonsall et al., 1992) in which systemic Fadrozole treatment dramatically inhibited sexual behavior. Similar effects had been obtained in early studies (Christensen and Clemens, 1975; Beyer et al., 1976) in response to the administration of other aromatase inhibitors to male rats. Likewise, s.c. treatment with Fadrozole reduced the number of anticipatory level changes shown by male rats in anticipation of the presentation of an estrous female (Roselli et al., 2003), in addition to reducing mating behavior. In the latter study, s.c. administration of E reversed these inhibitory effects of Fadrozole treatment, further affirming the essential role of E as a mediator of T's activational effect on appetitive as well as some consummatory components (mounting, intromission) of mating in the male rat.

It must be noted that despite the wealth of data pointing to a role of E metabolites of T in the activation of sexual motivation and aspects of mating behavior in the male rat, there are several studies that continue to implicate T in the control of these behaviors. Thus, systemic injections with the potent AR blocker, Flutamide, to castrated, T-treated rats blocked the restoration of mounting, intromission, and ejaculation behaviors (Gladue and Clemens, 1980b), although only intromission and ejaculatory responses were blocked by Flutamide treatment of male rats in other studies (Sodersten et al., 1975; Gray, 1977). As DHT, given by itself, fails to augment even mounting behavior in rats, these workers concluded that T may act at ARs to facilitate appetitive courtship responses and consummatory components of this behavior. This view is supported by another study (McGinnis and Dreifuss, 1989), which compared the nuclear occupation of AR and ER in several hypothalamic and amygdaloid regions of castrated male rats that were treated with E, DHT, T, or E + DHT. Although a low dose of E + DHT treatment resulted in nuclear AR and ER occupation levels that were comparable to those of T-treated castrates, these particular doses of E and DHT failed to activate even mounting behavior in castrated rats. Treatment with higher doses of E, either alone or combined with DHT, activated higher levels of mounting, with some intromission and ejaculation behavior. Based on these results, the authors argued that T itself, and not E, is primarily responsible for the activation of male sex behavior in rats.

There is a small literature suggesting that progesterone (P), acting via neural progestin receptors (PR), may contribute in male vertebrates to the activation of male-typical courtship and mounting behaviors. When given in moderate doses, P activated all facets of sexual behavior in castrated male lizards (Young et al., 1991; Lindzey and Crews, 1992), although treatment with T had greater and longer-lasting stimulatory effects on males' courtship behaviors than P (Sakata et al., 2003). Likewise, administration of P to castrated male rats partially duplicated the activational effects of T on mating behavior, and this effect of P was blocked by concurrent administration of a PR antagonist, suggesting that the effects of P were mediated by its action at PR as opposed to AR (Witt et al., 1995). Gonadally intact male mice with a homozygous null mutation of the PR showed significantly lower mount frequencies than WT controls, and heterozygous mutant males were less responsive to the activational effect of T following castration (Phelps et al., 1998). This latter finding points to the interesting possibility that PR activation may somehow contribute to the activational effects of T on the expression of male-typical sexual behaviors. More research will be required to characterize the nature of any such relationship.

3.2 Species and Genotype Variations in the Effects of Castration and Hormone Replacement on Male Sexual Behavior

With the exception of one particular hybrid mouse strain (details given later), male rodents reliably display a progressive loss in all aspects of sexual motivation, mating, and erectile function within a few weeks after castration and the resultant deprivation of circulating T, regardless of whether or not subjects had received coital experience prior to castration (Hull et al., 2002). Considerably more variability in the display of sexual behavior has been reported in males of two carnivore species, the dog (Hart, 1968; Beach, 1970) and cat (Rosenblatt and Aronson, 1958), especially when castration was carried out after subjects had received mating experience. In these instances, mating persisted in some individuals for many months after castration. By contrast, in another carnivore, the ferret, castration reliably led to a disappearance of mating within one month in all males tested (Lambert and Baum, 1991). Perhaps not surprisingly, castration of male rhesus monkeys failed to disrupt mating performance in some individuals. In contrast to the rat, administration of DHTP duplicated the facilitatory effect of TP on ejaculation capacity in castrated rhesus monkeys (Phoenix, 1974) whereas administration of EB failed to influence mating in castrated monkeys (Phoenix, 1978; Michael et al., 1990). This observation raised doubts about a possible contribution of T aromatization to the activation of sexual behavior in male primates. More recently, however, it was reported (Zumpe et al., 1993) that systemic administration of the aromatase inhibitor, Fadrozole, to gonadally intact male cynomolgus monkeys significantly reduced all aspects of mating, including ejaculation after 2 weeks of treatment. This effect of Fadrozole treatment was partially reversed by concurrent treatment with E, raising the possibility that aromatization of T to E plays some role in the activation of sexual behavior in male primates just as it does in several species of rodent.

Adult castration of human males had variable effects on sexual behavior in different individuals (Heim and Hursch, 1979), although average levels of erectile function, sexual fantasies, and intercourse were reliably reduced in groups of men within 6 weeks after the inhibition of testicular T production by administration of a GnRH antagonist drug (Bagatell et al., 1994). These behavioral effects were reversed by concurrent treatment with T plus the GnRH antagonist. However, administering an aromatase inhibitor failed to reduce this latter activational effect of T treatment, providing no evidence that the conversion of T to E contributes to sexual arousal or performance in adult men. This conclusion must be tempered, however, by the absence of any independent confirmation that the particular aromatase inhibitor administered by these investigators had its intended effects on the neural conversion of T into E. Indeed, a more recent clinical study (Carani et al., 1999) of a single man with a spontaneous mutation in the *Cyp* 19 aromatase gene suggests that the E may contribute to sexual arousal and performance in adult men. This individual had a male-typical gender identity and a heterosexual orientation (he was married to and reported having sex with a woman). Administration of T over several months failed to influence the incidence of sexual intercourse, masturbation, or erotic fantasies; however, each of these variables was increased after an equivalent period of E treatment. More clinical studies are needed to determine conclusively whether the aromatization of T to E plays an essential role in the regulation of sexual motivation and mating performance in higher primates including man. Regardless of the outcome of such studies, the available comparative evidence supports the early suggestion of Frank Beach (1942b) that the degree to which males of different species depend upon gonadal hormones for its ability to display courtship and mating behaviors is inversely correlated with the degree of cerebral cortex development. An exception to this rule is now discussed.

Male mice, like other rodents, typically stop pursuing and mating with an estrous female within a few weeks after castration. However, McGill and Tucker (1964) initially made the serendipitous observation that the male F1 hybrid offspring produced by mating a female C57BL/6J with a male DBA/2J mouse (B6D2F1 males) were surprisingly resistant to the effects of castration on the display of all aspects of male sexual behavior, including ejaculation. Subsequent studies of this particular F1 hybrid strain of male mice (McGill and Haynes, 1973; Clemens et al., 1988; Coquelin, 1991) showed that all aspects of sexual behavior continued to be expressed after castration over the subsequent lifespan (upto 2 years) in some individuals. Several studies have explored a possible endocrine basis for the persistence of mating capacity in B6D2F1 mice, following castration. Castration in these animals, as in other genotypes, caused a profound reduction

in circulating levels of T (Clemens et al., 1988; Sinchak et al., 1996) and in removal of the adrenal glands, in addition, castration of B6D2F1 male mice failed to disrupt the postcastration maintenance of mating behavior (Thompson et al., 1976). Some evidence raises the possibility that the persistence of sexual behavior in castrated B6D2F1 males depends on the activational effects of E, which continues to circulate in very low concentrations in this as well as other mouse strains even after castration (Sinchak et al., 1996). Administration of the aromatase inhibitor, ATD, to castrated B6D2F1 significantly reduced the expression of sexual behavior (Sinchak et al., 1989). No explanation was provided for why B6D2F1 males, unlike other mouse strains, are so highly responsive to the activating effects of the low circulating levels of E that persist after castration. One hint of a possible mechanism stems from the early observation (McGill and Manning, 1976) that there is a parent of origin effect (POE) in the ability of mating to persist in male mice following castration. Thus, this persistence of mating capacity was seen only in the F1 male offspring of a female C57BL/6J with a male DBA/2J; male F1 offspring of the reverse parentage (female DBA/2J $\times$ male C57BL/6J) stopped mating within a few weeks after castration. Many POEs have been attributed to the differential expression (genomic imprinting) of autosomal genes, depending on whether particular alleles are inherited from the mother or the father of the individual being studied (Isles et al., 2002). Future studies of the possible contributions of a small set of imprinted genes to the activational effects of E on neural mechanisms controlling sexual arousal and mating performance could provide insights into the mechanism that allows B6D2F1 male mice to continue to display sexual behavior after castration.

3.3 Effects of Hypothalamic Implantation of T, E, DHT or Antagonist Drugs on the Expression of Sexual Behavior

Several early experiments (Brookhard and Dey, 1941; Hillarp et al., 1954; Soulairac and Soulairac, 1956) established that destructive lesions of the medial preoptic area/anterior hypothalamus (MPOA/AH) disrupted the display of sexual behavior in male rats and guinea pigs. These studies, which appeared well before the advent of knowledge about the hypothalamic localization of T-metabolic enzymes or AR and ER, led shortly thereafter to a preliminary study (Fisher, 1956) that showed that intra-hypothalamic implantation of T-activated sexual behavior in castrated male rats. More than a decade later several studies were published that corroborated and extended these findings. Davidson (1966) reported that small amounts of TP, implanted into the anterior and posterior hypothalamus, were effective in restoring sexual behavior in castrated male rats. Subsequently, more detailed studies showed that implanting TP in the MPOA/AH more effectively restored sexual behavior than implanting TP in the posterior hypothalamus (Lisk, 1967; Johnston and Davidson, 1972; Kierniesky and Gerall, 1973). Such activational effects of TP implanted directly into the MPOA/AH of castrated rats could not be explained by leakage of T into the general circulation (Smith et al., 1977). Activational effects of MPOA/AH implants of TP on masculine courtship behavior were also reported in several other species including the domestic fowl (Barfield, 1969), the ring dove (Barfield, 1971), the Barbary dove (Hutchison, 1974), the quail (Balthazart and Surlemont, 1990), the mouse (Matochik et al., 1994), and the ferret (Tang and Sisk, 1991), thereby illustrating an activational effect of this steroid on male sexual behavior in a range of avian and mammalian species.

As already explained, combined systemic injections of E and DHT activated mating behavior in castrated male rats as effectively as injections of T (Baum and Vreeburg, 1973; Larsson et al., 1973). Several studies implicate E, formed locally in the MPOA/AH from circulating T, as a sex steroid that acts on neurons in this particular brain region to activate masculine sexual behavior. Thus, implants of E into the MPOA/AH restored sexual behavior in castrated male rats (Christensen and Clemens, 1974; Davis and Barfield, 1979), thereby duplicating the effect of T when implanted into this region. The results of these experiments are complemented by studies in which infusion of aromatase-inhibiting drugs such as ATD (Christensen and Clemens, 1975) or Fadrozole (Clancy et al., 1995) into the MPOA/AH of male rats inhibited the ability of exogenous or endogenous T to activate male-typical sexual behavior. Likewise, when the aromatase inhibitor, ATD, was bilaterally implanted into the sexually dimorphic nucleus (POM) of the MPOA/AH, the activation of copulatory behavior induced by a systemic T treatment in castrated male quail was completely blocked (Balthazart et al., 1990). This inhibition of coital behavior was accompanied by an

inhibition of the aromatase activity in the MPOA/AH. Moreover, implants of a synthetic estrogen (diethylstilbestrol) into the MPOA/AH restored copulatory behavior in castrated quail, whereas implantation of a nonaromatizable androgen (methyltrienolone) lacked consistent activational effects on courtship behavior (Balthazart et al., 1990). These workers also found that the activational effects of systemic T treatment were blocked by POM implants of either an antiandrogen (Flutamide) or an antiestrogen (Tamoxifen). The authors concluded that estrogenic metabolites of T are produced in the sexually dimorphic POM of male quail, where they selectively activate the expression of sexual behavior. Two additional studies point to a similar conclusion in male rats. In one study (Vagell and McGinnis, 1997), infusion of the aromatase inhibitor, Fadrozole, into the lateral ventricle, blocked the ability of systemic T to restore ejaculation. This inhibition of T-induced mating by central administration of Fadrozole was reversed in other castrated males that also received an s.c. capsule containing a low dose of E. In another study (Clancy et al., 2000), systemic administration of Fadrozole to gonadally intact male rats effectively reduced mounting and ejaculation; however, bilateral implantation of E directly into the MPOA/AH effectively reversed the inhibitory effect of systemic Fadrozole on mating performance. These results confirm the specific role of T aromatization in the activation of mating performance, including mounting, intromission, and ejaculation. Interestingly, however, administration of a low systemic dosage of E to castrated males, by itself, failed to activate sexual behavior (Vagell and McGinnis, 1997). This suggests that the activational effects of E on mating may depend on the concurrent, synergistic action of an androgen, acting via neural androgen receptors. In contrast to its effect on mating performance per se, icv administration of Fadrozole failed to attenuate the activational effect of T on males' preference to approach an estrous as opposed to an anestrous stimulus female. This latter result suggests that males' motivation to seek out an estrous female may depend on the effects of T itself, as opposed to its estrogenic metabolite.

An initial attempt to attenuate the activational effect of T on ejaculation in castrated male rats by implanting the antiandrogen, cyproterone, into the MPOA/AH failed; if anything, implanted males showed higher levels of mating than cholesterol-implanted controls (Block and Davidson, 1971). Several subsequent studies using more potent AR receptor antagonists, including flutamide or its active metabolite, hydroxyflutamide (OHF), have provided more definitive evidence of a role of T, and/or DHT, acting via AR, in promoting aspects of sexual partner preference and mating performance in male rats. In an earlier study (McGinnis et al., 1996), implantation of OHF into the MPOA/AH prevented the restoration of sexual behavior (mounting and ejaculation) in castrated rats that received s.c. T capsules concurrently. In a subsequent study (McGinnis et al., 2002), this inhibitory effect of OHF was most reliably obtained when implants were placed in the rostral portion of the POA. Implanting OHF into the posterior POA did not disrupt T-induced mating behavior, whereas it did reduce males' preference to seek out an estrous as opposed to an anestrous female. This latter effect may have resulted from a leakage of OHF into caudal regions of the hypothalamus. Indeed, in a more recent study (Harding and McGinnis, 2004) implantation of OHF into the ventromedial hypothalamic nucleus (VMH), but not the MPOA/AH, significantly reduced the preference of castrated, T-treated male rats to approach an estrous versus an anestrous female and blocked the establishment of a CPP response for the opportunity to mate with an estrous female. As in previous studies by this group, implantation of OHF into the MPOA/AH attenuated the activational effect of T on mating behavior, whereas it failed to affect either partner preference or males' ability to learn a CPP response for access to an estrous female. Further evidence of the role of a male's VMH in male-typical sexual motivation was provided by the observation that bilateral implants of TP into this brain region stimulated approach to an estrous as opposed to an anestrous female without facilitating mating behavior per se (Harding and McGinnis, 2003).

As already explained, the enzyme 5α−reductase is expressed in the rat hypothalamus and in other subcortical brain regions (Denef et al., 1973), raising the question of whether any of the reported effects of AR blockade (after hypothalamic administration of OHF) reflect an antagonism of DHT action or that of T itself. In one study (Butera and Czaja, 1989), s.c. administration of DHT when combined with implantation of either T or of DHT into the MPOA activated equivalent levels of mating behavior in castrated male rats. In the majority of studies, however, neither systemic administration of DHT nor intra-hypothalamic implants of this androgen succeeded in activating sexual behavior. Thus, systemic administration of

DHT (McDonald et al., 1970; Feder, 1971; Whalen and Luttge, 1971), a nonaromatizable synthetic AR agonist, R1881 (Baum et al., 1987), or direct administration of DHT into the MPOA/AH (Johnston and Davidson, 1972; Baum et al., 1982b) failed to activate mating behavior in castrated male rats, suggesting that any contribution of hypothalamic AR activation to the expression of masculine sexual behavior is caused by T itself. Further support for this conclusion is also drawn from the observation (Bradshaw et al., 1981) that concurrent administration of a 5α-reductase inhibitor, 17β-testosterone carboxylic acid, failed to attenuate mating induced in castrated male rats by T, even though this treatment did significantly reduce T-stimulated increments in prostate and seminal vesicle weights.

Studies conducted in males of several different infraprimate mammalian species, including the rat (Carr et al., 1965; Kelliher et al., 1999), mouse (Wysocki et al., 1982), hamster (Powers et al., 1979), and ferret (Kelliher and Baum, 2001) have implicated odor cues emitted from the urine and/or scent glands of estrous females in male-typical patterns of sex partner preference and masculine sexual arousal. Extensive neuroanatomical evidence (Wood, 1997) has established the existence of projections from odor receptors in the vomeronasal organ (VNO) to the accessory olfactory bulb (AOB). Mitral cells from the AOB project to the medial amygdala, which in turn sends projections to the principal nucleus of the bed nucleus of the stria terminalis (BNST) and the MPOA. Afferents from the main olfactory bulb also gain access to this VNO projection to the hypothalamus via axonal projections to the anterior cortical amygdaloid nucleus (Scalia and Winans, 1975). By monitoring the expression of the immediate-early gene, c-fos, it has been possible to show that body odors (e.g., urine and vaginal secretions in rats and hamsters, respectively) activate neurons in each of the above-mentioned brain regions projecting to the MPOA/AH (Fiber et al., 1993; Bressler and Baum, 1996). Experiments in male hamsters (Fiber and Swann, 1996) and male rats (Paredes et al., 1998a) showed that administration of T enhanced the number of Fos-immunoreactive (IR) cells in the VNO-projection circuit that were induced by exposure to odors from opposite-sex conspecifics. Wood and Newman (1995b) provided evidence that such steroidal enhancement of olfactory processing contributes to the activation of sexual behavior in castrated male hamsters. Unilateral implantation of T into the MPOA/BNST successfully activated mating in subjects in which the ipsilateral olfactory bulb was intact; removal of the olfactory bulb ipsilateral to the T implant prevented the activation of sexual behavior. It is noteworthy that previous work by these same investigators (Wood and Newman, 1993) had demonstrated that many of the Fos-IR neurons activated in the MPOA and BNST of male hamsters after they mated with a female also coexpressed AR. More recent studies carried out in rat (Greco et al., 1998a, 1998b) and mouse (Shah et al., 2004) showed that mating-induced Fos expressing neurons located in several extra-hypothalamic sites including the cortical–medial amygdala express AR and/or ERα.

3.4 Extra-Hypothalamic Sites of Sex-Steroid Activation of Male Sexual Behavior

The suggestion (Wood, 1997; Newman, 2002) that T or its metabolites E and/or DHT act in the medial amygdala (MeA) to facilitate the transmission of olfactory information to the hypothalamus, with a resultant stimulation of approach, sexual arousal, and mounting of an estrous female is supported by numerous experiments in which sex hormones have been implanted directly into this temporal region of male rodents. Unilateral implants of T into the MeA stimulated approach and mounting of an estrous female in male hamsters (Wood and Newman, 1995a), and the facilitation of sexual behavior seen after such implants was not further enhanced by combined MeA and MPOA/AH implants of T (Coolen and Wood, 1999). These results point to a distributed network of steroid-sensitive neurons (Cottingham and Pfaff, 1986) that independently amplify and transmit sexually relevant chemosensory inputs. As already described, olfactory bulbectomy carried out ipsilaterally, but not contralateral to, a unilateral T implant into the MPOA and/or BNST, disrupted mating behavior in castrated male hamsters (Wood and Newman, 1995b). When T was implanted unilaterally into the MeA instead of the hypothalamus of castrated male hamsters, surgical removal of the olfactory bulb that was either ipsilateral or contralateral to the implant blocked the activation of sexual behavior (Wood and Coolen, 1997), suggesting that bilateral olfactory inputs are required at the level of the MeA where they are amplified and transmitted into the hypothalamus

by steroidal actions. Implantation of T into the MeA of castrated male rats augmented the display of penile erections shown in response to odors emitted from estrous females (Bialy and Sachs, 2002), suggesting that the steroidal enhancement of olfactory processing may also facilitate sexual arousal. Implantation of E, but not DHT, into the MeA of castrated male hamsters duplicated the activational effects of T on the display of approach and mounting of an estrous female, but not intromission and ejaculation (Wood, 1996). Likewise, implantation of E into the MeA of castrated male rats stimulated mounting behavior (Rasia-Filho et al., 1991) and implantation of E into the MeA of gonadally intact male rats that received the aromatase inhibitor, fadrozole, s.c., stimulated mounting, but not intromission and ejaculation (Huddleston et al., 2003). One interpretation of these results is that estrogen-sensitive neurons in the MeA respond to E, formed via the local aromatization of T, to facilitate the sexual arousal induced by olfactory signals from estrous females. Whereas neither systemic (McDonald et al., 1970) nor intracranial (MPOA or MeA) (Johnston and Davidson, 1972; Wood, 1996) administration of DHT by itself stimulated sexual behavior in castrated male rats, implanting DHT into the MeA of castrated male rats given concurrent s.c. implants of E, stimulated all aspects of sexual behavior including ejaculation (Baum et al., 1982b). No such stimulation was seen in groups of castrated, E-primed males that received DHT implants in the MPOA/AH. These results are consistent with the suggestion (Baum and Vreeburg, 1973) that both estrogenic and 5α reduced androgenic metabolites of T contribute to the activation of mating behavior in the male rat by acting in the brain. Further evidence that DHT affects sexual behavior by acting neurally, as opposed to solely at the level of penile sensory receptors stems from the observation (Lodder and Baum, 1977) that denervating the penis by cutting the pudendal nerves failed to diminish the ability of DHT, given concurrently with E to castrated male rats, to stimulate mounting behavior. In the event that DHT (as opposed to T) is the behaviorally active AR ligand that normally facilitates mating behavior in gonadally intact animals, it would appear that it occurs in brain regions other than the MPOA/AH. It is possible that the synergistic action of E and DHT reflects an up-regulation of AR synthesis (Handa et al., 1987), and a resultant enhancement of the behavioral effects of DHT (or of T) at these ARs in sites such as the MeA or BNST. In this regard it is interesting to note that the distribution of AR was significantly reduced in the BNST of male mice bearing a null mutation for ERα (Wersinger et al., 1997).

The MeA and BNST (also referred to as the "extended amygdala" (Alheid and Heimer, 1988)) contain steroid-sensitive neurons that amplify olfactory inputs to the MPOA/AH, which are thought to enhance masculine sexual motivation and sexual arousal including penile erection. On the other hand, somatosensory inputs associated with achieving intromission with an estrous female are apparently conveyed to the MPOA/AH via a polysynaptic pathway that originates in laminae 7 and 10 of lumbar spinal cord segments L3 and L4 (Ju et al., 1987) and includes the parvocellular subparafascicular nucleus (SPFp) of the posterior thalamus (also known as the central tegmental field) (Simerly and Swanson, 1986). Significant increases in the number of Fos-IR neurons were noted in the SPFp of male rats after they achieved intromissions, with a maximal level of Fos seen after a series of intromissions leading to ejaculation (Baum and Everitt, 1992; Veening and Coolen, 1998). Many of the same neurons in the SPFp that express Fos after intromissions and ejaculation coexpress AR (Greco et al., 1998b), raising the question of whether androgenic facilitation of mating may depend, in part, on a steroidal action in these neurons. Indeed, earlier studies (Brackett and Edwards, 1984; Maillard and Edwards, 1991) showed that thalamic lesions that included the SPFp disrupted the expression of sexual behavior in male rats as reliably as lesions of the MPOA/AH.

Coolen and coworkers (Truitt and Coolen, 2002; Truitt et al., 2003) provided evidence that a cluster of lumbar spinal (LS) neurons, which project to the thalamic SPFp nucleus may comprise an "ejaculation generator" in male rats. Mating with ejaculation stimulated Fos-IR in neurons of the LS (Truitt and Coolen, 2001), and in another study (Greco et al., 1999) many of the mating-induced Fos-IR neurons in the LS, which were retrogradely labeled by fluorogold injected into the thalamic SPFp, also coexpressed AR. Targeted destruction of spinal LS neurons in male rats by intrathecal administration of the neurotoxin, saporin (which was conjugated to substance P, thereby causing it to bind with high affinity to neurokinin receptors expressed on LS neurons), eliminated ejaculatory capacity without disrupting males' capacity to mount and intromit with estrous females (Truitt and Coolen, 2002). These results point to a spinal mechanism whereby AR activation by either T and/or DHT may facilitate the processing of penile sensory inputs associated with erection and intromissions that lead to ejaculation.

3.5 MPOA/AH Sex Steroid–Dopamine Relationships in the Control of Male Sexual Behavior

Several lines of pharmacological and neurochemical evidence have established a link between the activational effects of T (perhaps acting via its aromatized metabolite, E) on mating and a facilitation of activity in dopaminergic neurons that are located in the dorso-lateral hypothalamus and in zona incerta, and that terminate in hypothalamic regions including the MPOA/AH and the paraventricular nucleus (Dahlstrom and Fuxe, 1964). The earliest evidence of such a link derived from a study (Malmnas, 1977) showed that systemic injections of the nonspecific dopamine (DA) agonist, apomorphine, reversed the postcastration decline in mating performance otherwise seen in male rats. Similar results were later obtained by administering apomorphine either systemically or into the MPOA/AH (Scaletta and Hull, 1990). Conversely, either systemic (Baum and Starr, 1980) or intra MPOA/AH (Pehek et al., 1988) administration of mixed D1 and D2 type DA receptor antagonist drugs attenuated steroid-activated sexual behavior in male rats.

Establishing a direct link between the action of T, sexually arousing signals from an estrous female, and neurochemical indices of DA function in the MPOA/AH of male subjects has been a difficult task. Early studies (Simpkins et al., 1980, 1983; Gunnet et al., 1986) suggested that DA turnover in the MPOA/AH, which was measured by the rate of decline of DA concentrations after systemic treatment with the tyrosine hydroxylase inhibitor, $\alpha-$methylparatyrosine, was reduced in castrated male rats by T treatment. Another study (Baum et al., 1986) revealed no effect of castration, with or without T replacement, on the concentrations of DA, its neural metabolite DOPAC, or the ratio of DOPA/DA (an index of DA release) in male rats. Similar negative results were obtained in groups of castrated males that were killed 10 min after exposure to the sight, sound, and odors of an estrous female. Subsequently, different groups of investigators used in vivo electrochemical recordings (Mas et al., 1990) and in vivo microdialysis (Pfaus et al., 1990; Pleim et al., 1990) to document significant increases in the extracellular levels of DA in the nucleus accumbens of gonadally intact male rats while they engaged in mating behavior with an estrous female. Increased DA release in the nucleus accumbens was also seen in males that were simply exposed to odors from estrous females (Mitchell and Gratton, 1991, 1992). Likewise, in vivo microdialysis studies subsequently established that extracellular levels of DOPAC (Fumero et al., 1994) as well as DA itself (Hull et al., 1995; Sato et al., 1995) were significantly increased in the MPOA of gonadally intact and castrated, T-treated male rats while they were exposed to an estrous female. Likewise, exposure to odors emitted from an estrous female significantly augmented both DA and DOPAC concentrations in the paraventricular nucleus of gonadally intact male rats (Melis et al., 2003). There was a close correlation between increases in MPOA levels of DA that were shown in response to distal cues from estrous females, and the subsequent display of mating behavior when given access to an estrous female (Hull et al., 1995). Castrated males given no T replacement rarely mated with estrous females, and these males did not show increases in MPOA levels of DA in response to the presence of a female (Hull et al., 1995). In a subsequent study (Putnam et al., 2001) a close correlation was seen between the ability of T replacement to restore mating behavior in castrated male rats and to allow exposure to distal cues from an estrous female to elevate extracellular DA levels in the MPOA. Castrated male rats only mustered a significant MPOA DA response to the presence of an estrous female if they were treated with T or with E + DHT. Castrated males given only E showed no such DA response, although they did display mounts and intromissions (no ejaculation) when given access to a female (Putnam et al., 2003). This result implies that AR activation is required in order for signals from an estrous female to augment DA release from terminals in the male's MPOA. As already explained, implanting either T or DHT into the MeA augmented mating behavior in male hamsters and rats, respectively, and it is possible that these behavioral responses reflect an activation of DA release in the MPOA that is driven by inputs to this hypothalamic region from the MeA. Evidence supporting this conclusion derives from the observations (Dominguez et al., 2001) that excitotoxic lesions of the medial amygdala disrupted mating in male rats, whereas infusion of a DA agonist into the MPOA restored this behavior. Also, lesions of the MeA blocked the increases in extracellular DA levels in the MPOA otherwise observed in male rats after they were exposed to distal signals from an estrous female.

The studies just summarized support the notion that a steroid-induced facilitation of the responsiveness of hypothalamic and/or ventral tegmental DA neurons to olfactory cues from estrous females

contributes to sexual arousal and the display of male-typical sexual behavior. Further support for this view stems from a study (Szczypka et al., 1998) using male mice in which a null mutation of the tyrosine hydroxylase (TH) gene eliminated the capacity to produce DA and in which TH expression was selectively rescued in noradrenergic neurons by daily injections of the DA precursor, L-DOPA. These authors noted that mutant DA-/-males, unlike wild type controls, showed high levels of mounting behavior as well as aggression toward either female or male cagemates immediately after the daily injection of L-DOPA. Castration of mutant males led to a reduction in the display of both mounting and aggressive behaviors. Subsequent administration of T stimulated higher levels of mounting in DA-/-mutants than in wild type control males (all of which continued to receive daily injections of L-DOPA). These results suggest that nondopaminergic neurochemical mechanisms must exist, which mediate at least some of the facilitatory effects of T and/or E on masculine sexual motivation and mating performance.

3.6 Androgenic Facilitation of Penile Erectile Function

A complete description of the neural innervation of the penis and the neurochemical control of erectile function can be found in the recent review by Hull et al. (2002). The present review is confined to a consideration of the role of T and its androgenic metabolite, DHT, acting via ARs, in the regulation of erectile functions in rat and rabbit.

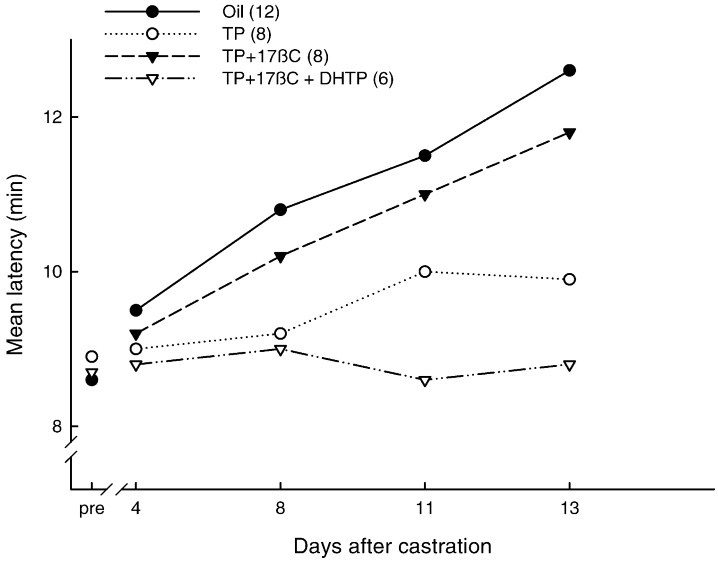
Electrical stimulation of the MPOA/AH reliably elicits penile erection in rat (Giuliano et al., 1996) and monkey (Maclean et al., 1959), due to a complex modulation of parasympathetic (tumescence promoting) and sympathetic (tumescence inhibiting) inputs to the smooth muscle lining of the corpora caveronsa of the penile shaft as well as the corpus spongiosum that surrounds the urethra and extends distally into the glans penis. Erection can also be induced by electrical stimulation of the cavernosal nerve in rat (Lugg et al., 1995; Marin et al., 1999) and rabbit (Traish et al., 1999), and in both models castration reduced the stimulation-induced erection (indexed by increases in intracavernosal blood pressure), whereas T replacement reversed this effect. A similar modulation of stimulation-induced penile erection was observed in male mice after the administration of the melanocortin 4 receptor agonist, THIQ, which is a synthetic analog of the natural ligand for melanocortin receptors, α−MSH (Van der Ploeg et al., 2002). Systemic injections of the melanocortin receptor agonist into wild type male mice enhanced erections induced by cavernous nerve stimulation; however, no such enhancement was seen in male mice with a null mutation of the melanocortin 4 receptor. More research is needed to determine what, if any, interaction exists between the facilitatory actions of androgen and melanocortin receptor activation on erectile responsiveness.

A hormonal modulation of erectile function was also observed in an early study (Hart, 1967), which showed that severing the spinal cord of male rats at the midthoracic level greatly increased the display of penile erections as well as dorsal flips when subjects were tested in the ex copula restraint paradigm with constant pressure being applied to the base of the penis. As in the electrical stimulation paradigm, castration reduced the occurrence of erections in these spinal rats, and administration of T reversed this effect, suggesting that the steroid acted at sites distal to the level of the spinal section to enhance erectile function. Subsequent studies established that ex copula erections displayed by male rats tested either in the restraint paradigm (Hart, 1973; Gray et al., 1980; Meisel et al., 1984) or in the noncontact paradigm in the presence of odors from an estrous female (Manzo et al., 1999) were reliably activated in castrated rats by administration of either T or DHT, but not by E. As shown in *Figure 1-2*, administration of the 5α-reductase inhibiting drug, 17β-testosterone carboxylic acid, significantly attenuated the activational effect of T on erection frequency (restraint paradigm) in castrated rats (Bradshaw et al., 1981). This effect was reversed by administering DHT, suggesting that this metabolite of T plays an essential role in facilitating erectile function, probably acting via androgen receptors (AR) that are expressed in the corpora cavernosa (Takane et al., 1991).

Several lines of evidence suggest that DHT facilitates erectile function by augmenting the activity of nitric oxide synthase (NOS; both the neural and endothelial isoenzymes), which catalyzes the formation of nitric oxide (NO) in nerve terminals in the endothelial lining of the penile corpora caversosa. In one study

Figure 1-2

Administration of the 5α-reductase inhibitor, 17β-testosterone carboxylic acid (17β−C) significantly attenuated the activational effect of a low dose (8 μg/100 g body weight) of testosterone propionate (TP) on the display of *ex copula* penile erections in castrated male rats. The frequency (Freq) of erections is shown 4 and 2 days prior to as well as 4–13 days after castration and the onset of daily s.c. injections of the different hormone treatments or sesame oil vehicle. Group Ns are given in parentheses. Adapted from Bradshaw et al. (1981)



(Lugg et al., 1995) castration of male rats significantly reduced NOS activity in penile cytosols, whereas administration of T or DHT reversed this effect. Combined treatment with T and the 5α-reductase inhibiting drug, Finasteride, duplicated the effect of castration on NOS activity, suggesting that the stimulatory effects of T on enzyme activity are mediated by DHT. This profile of steroidal regulation of NOS activity was paralleled by the effects of these treatments on the maximal degree of intracavernosal pressure shown in response to electrical stimulation of the cavernosal nerve. Again, blocking 5α-reductase activity completely blocked the stimulatory effect of T on stimulation-induced erection (Lugg et al., 1995). In another study (Marin et al., 1999) electrical stimulation of the cavernosal nerve stimulated erection in anesthetized male rats, and augmented the extracellular levels of NO, measured by in vivo electrochemistry, in the corpora cavernosa. Again, castration reduced stimulation-induced erectile responses and associated levels of NO, and administration of T to castrated rats reversed these reductions. Western blot analysis showed that castration reduced the content of both the neural and endothelial isoforms of NOS in the corpora cavernosa, and administration of T reversed this effect of castration (Marin et al., 1999).

4 Sex Steroids, Acting Perinatally in the Male Brain, "Organize" Neural Mechanisms Controlling Male-Typical Mating Behavior

Much evidence (Arnold, 2002; Wallen and Baum, 2002) indicates that the differentiation of male-typical courtship behaviors in mammalian species results from the perinatal neural actions of T, and/or its neural metabolite, E, after the fetal differentiation of testes in response to the expression of the Y chromosome *Sry* gene in the embryonic genital ridge. In this respect, the hormonal control of the development of neural mechanisms controlling masculine sexual behavior parallels the androgenic control of male-typical differentiation of the internal and external genital structures (Jost, 1970). Several studies have recently explored

the possibility that genes expressed on the Y chromosome may also contribute directly to male-typical aspects of brain and behavioral sexual differentiation (Arnold et al., 2004). These studies used mice in which the *Sry* gene was deleted from the Y chromosome and in some cases was expressed via an autosome. By expressing *Sry* via an autosome it was possible to generate XY^{-}*Sry* (Sry deleted from the Y chromosome and instead expressed off an autosome) and XX*Sry* (Sry expressed off an autosome) mice in which testes developed as in normal XY males. Also, XY^{-} mice (*Sry* deleted from the Y chromosome without autosomal expression) with ovaries (females) were generated along with normal XX females. Sexually dimorphic aspects of male-typical courtship behavior, including time spent sniffing an anesthetized female and the display of mounting and thrusting behaviors, were associated with the presence of testes (males) and ovaries (females) as opposed to the presence or absence of Y chromosome genes other than *Sry* (De Vries et al., 2002). There were no differences in any aspect of male-typical courtship behaviors between males (mice with testes) in which Y chromosome genes were present (i.e., XY and XY^{-}*Sry*) and those in which they were absent (i.e., XX*Sry*). By contrast, XY males that possessed Y chromosome genes in addition to *Sry* had a more masculine vasopressin innervation of the lateral septal region than XX males. These results suggest that purely endocrine, as opposed to direct genetic factors, controls the differentiation of the male-typical neural mechanisms controlling courtship and mating behaviors. The available evidence suggests that the critical endocrine signal controlling behavioral masculinzation is T, secreted perinatally from the testes. As reviewed later, this androgen organizes neural mechanisms controlling male-typical behavior via either a direct action at neural AR or after its neural aromatization to E and subsequent actions at neural receptors ERα or ERβ.

4.1 Contribution of Testosterone (T) Acting via Androgen Receptor (AR)

Naturally occurring mutations in the androgen receptor gene (AR) have been studied in humans, rats, and mice for many years. The resultant androgen insensitivity or testicular feminization (tfm) syndrome involves an absence of normal male-typical external and internal genital development in genetic (XY) male individuals, combined with an inhibition of internal female-typical duct development due to the secretion of Mullerian inhibiting hormone by the fetal testes. These tfm individuals, who are typically assigned the female gender at birth, are reared as girls, and live as women in adulthood, present a complex profile of psychosexual characteristics. In woman with complete androgen insensitivity syndrome who had undergone castration and surgical vaginal enlargement followed by estrogen therapy as teenagers there was subsequently a high level of satisfaction with their female assignment and sex of rearing coupled with a heterosexual orientation (Wisniewski et al., 2000). The majority of the 20 androgen insensitive women studied also reported that they were satisfied with their sexual and romantic lives. In an early study (Beach and Buehler, 1977) tfm male rats showed deficient pelvic thrusting, intromissive, and ejaculatory behaviors when tested while gonadally intact or after treatment with TP. By contrast, Olsen (1979) reported that administration of TP, EB, or EB + DHT activated mounting, pelvic thrusting, and intromission-like behaviors but not ejaculation in tfm male rats after castration in adulthood. One inference drawn from these observations is that the brain mechanisms controlling the motivation to seek out, mount, and intromit with a female do not rely on AR activation, either perinatally or in adulthood. Instead, E formed perinatally and/or in adulthood via the neural aromatization of T may promote a degree of male-typical brain sexual differentiation that enables male rats that lack AR expression to show these components of sexual behavior.

In an early study (Olsen, 1992) tfm male mice showed no male-typical mating behavior in tests with estrous females, although mounting behavior was displayed in 25% of these same mice when they were treated with EB or with EB + DHT. More recently it was found (Bodo and Rissman, 2004) that tfm male mice showed mounting and pelvic thrusting behavior as readily as WT control males and females following adult gonadectomy and E treatment, whereas the preference to approach soiled bedding from an estrous female as opposed to a gonadally intact male was significantly reduced in tfm compared with WT males. Transgenic mice have been produced with a null mutation of the AR gene (Sato et al., 2004). As in tfm males, male-typical external genital development was completely inhibited in AR null mutant (ARKO)

males. When tested with estrous females, gonadally intact ARKO males, like tfm males (Olsen, 1992), showed no sexual behavior. Following gonadectomy and treatment with E, however, approximately 40% of ARKO males displayed mounting, pelvic thrusting, and intromission-like behaviors toward estrous females whereas 80% of WT control males showed these behaviors following castration. Neither WT controls nor ARKO males displayed lordosis behavior in response to mounts from a stud male after castration and E treatment. This latter result implies that the perinatal defeminization of the male brain occurred despite the absence of AR signaling, presumably as a result of the actions of estrogen formed perinatally via the neural aromatization of T. Interestingly, perinatal administration of DHT to WT mice significantly enhanced their subsequent capacity to display male-typical sexual behaviors (including ejaculation-like behavioral responses) toward estrous females after gonadectomy and treatment with either DHT or E in adulthood (Sato et al., 2004). However, this behavioral facilitation of perinatal DHT treatment was absent in ARKO females, leading the authors to conclude that AR activation normally contributes to the perinatal differentiation of neural circuits that control male-typical mating behaviors. As will be seen, a body of other recent evidence suggests that E receptor α (ERα) signaling in the perinatal brain also makes an essential contribution to the differentiation of male-typical sexual behavior.

4.2 Contribution of E, Aromatized in Brain from T, Acting via E Receptor (ER) α and β

In early studies (Booth, 1977a; Sodersten, 1978), neonatal administration of the anti-estrogen MER-25 to male rats led to later deficits in their capacity to achieve ejaculation even though their mounting and intromission behaviors were normal. A similar behavioral profile was observed in male mice with a null mutation of ERα. Thus, homozygous null mutant ERα−knockout (ERαKO) male mice that were gonadectomized and treated with TP showed significant reductions in their capacity to achieve ejaculation, even though they often pursued and mounted, and occasionally intromitted with estrous females (Wersinger et al., 1997; Ogawa et al., 1998; Rissman et al., 1999). Mount latencies were lengthened in ERαKO males, suggesting a deficit in male-typical sexual motivation. Confirmation of this impression was obtained in additional studies (Wersinger and Rissman, 2000a; Imwalle et al., 2002), in which ERαKO male mice, unlike WT controls, spent very little time investigating chemosensory cues emitted from estrous females, even though they clearly were able to detect these signals. Still further evidence of a deficit in motivation, as opposed to an inability to show the motor patterns associated with mating, was provided by the report (Wersinger and Rissman, 2000b) that systemic administration of the dopamine receptor agonist, apomorphine, reliably stimulated all aspects of mating, including ejaculation, in ERαKO males, which had been castrated and given T in adulthood.

A second type of E receptor, ER-β [Kuiper, 1966 #221], was discovered shortly after ERαKO mice were first produced. A homozygous mutation of the ER-β led to the creation of ERβKO male mice which, when tested while gonadally intact with estrous females, showed no deficits in mating behavior (Ogawa et al., 1999), and indeed, were fertile (Krege et al., 1998). However, a recent developmental study (Temple et al., 2004) showed that gonadally intact ERβKO males first mated with estrous females at an older age than WT control males. Thus, estrogenic signaling via ERβ may control the timing of behavioral puberty. Perhaps not surprisingly, a double null mutation of both types of estrogen receptor gene eliminated mating behavior in male mice tested while gonadally intact (Ogawa et al., 2000). However, after castration and s.c. treatment with T plus icv administration of the dopamine agonist, apomorphine, 75% of double mutant ERαβKO males displayed mounting behavior, and 50% showed intromission behavior, although none ejaculated (Burns-Cusato et al., 2004). These results are consistent with the conclusion that estrogen signaling, primarily acting via the ERα, contributes to either the organization during perinatal development or to the activation of neural circuits that control sex discrimination, heterosexual partner preference, or sexual arousal. Insofar as the mutations in the AR as well as both types of ER are present in transgenic mice from the earliest stages of development right on into adulthood (the time when sex behavior tests are administered), it is impossible, based on these model systems, to distinguish between possible organizational versus activational deficiencies in steroid hormone signaling to explain observed

deficits in the mating behavior of different mutant mice. A future solution to this problem may be the development of "inducible knockout" transgenic mice in which AR or ER genes are only rendered functionless under the influence of a drug (e.g., tetracycline) or some other pharmacological or environmental stimulus. In lieu of such models, the availability of transgenic mice with a null mutation of the *Cyp*19 gene (Fisher et al., 1998), which encodes the enzyme for estrogen biosynthesis, aromatase, has provided an attractive model in which to study the contribution of perinatal estrogen actions on the differentiation of brain mechanisms controlling male-typical mating behavior. Males that are homozygous for a null mutation of the aromatase gene, *Cyp*19, (ArKO) are thought to be fetally deprived of estrogenic stimulation, because any maternal estrogen that might otherwise reach the brain would be bound with high affinity by α-feto protein (Savu et al., 1981), and the endogenous production of brain E via neural aromatization of T (Wozniak et al., 1992) would be absent due to the ArKO mutation (Bakker et al., 2004a). In an initial study (Honda et al., 1998), ArKO males that were gonadally intact showed significantly longer mount latencies and frequencies than WT control males in 30-min. tests. In a subsequent study (Matsumoto et al., 2003), fertility as well as the display of intromissive and ejaculatory behaviors was reduced, though not eliminated, in ArKO male mice. A similar deficiency in fertility among ArKO male mice was also reported by another group of investigators (Toda et al., 2001). Interestingly, this deficit in fertility was reversed in ArKO males that received neonatal injections of E, suggesting that the observed deficits in male sexual behavior and resultant fertility resulted from the lack of the perinatal, organizational actions of estrogens formed via neural aromatization as opposed to a deficiency in the activational actions of estrogens on the adult expression of sexual behavior. ArKO males, when tested while gonadally intact or after castration and treatment with T, did not prefer to approach (Y-maze tests) volatile body odors emitted from an estrous female as opposed to a stimulus male (Bakker et al., 2002). Again, as others had reported for gonadally intact males, deficits in mounting, intromission, and ejaculation were seen in these castrated, T-treated ArKO males. In a subsequent study (Bakker et al., 2004b), administration of E + DHT to gonadally intact ArKO male mice in adulthood stimulated the expression of all aspects of male sexual behavior above the level shown by intact ArKO males given no supplemental hormone treatments. This implies that some proportion of the deficit in male sexual behavior among ArKO males resulted from the absence of an activational (adult) synthesis and action of E. However, even after E + DHT treatment, ArKO males intromitted and ejaculated less frequently than WT controls. In addition, even after adult treatment with EB, gonadally intact ArKO males approached volatile body odors emitted from estrous females in Y-maze tests. These deficits in olfactory investigation as well as actual coital performance among ArKO males treated in adulthood with estrogen imply that estrogens, acting at some earlier (possibly perinatal) period in the subjects' lives, played an essential role in the process of male-typical psychosexual differentiation. Definitive proof of this hypothesis awaits a study to determine whether the perinatal administration of E to ArKO male mice will reverse their deficient olfactory and mating behavior, as assessed in adulthood after treatment with E.

4.3 Possible Interactions of AR and ERα in the Organization of Male Sexual Behavior

Although there are gaps in the database on the effects of AR, ER, and aromatase null mutations on the display of male-typical mating behavior in mice, the available results reviewed earlier are consistent with the previous suggestion (Baum et al., 1990a, 1990b; Tobet and Baum, 1987) that E, formed in the fetal male brain from circulating T, sensitizes the nervous system to the subsequent fetal and/or immediate postnatal and neonatal actions of T itself in completing the masculinization of neural circuits that control male-typical partner preference and mating behavior. Other than several reports (Vale et al., 1973; Manning and McGill, 1974; Gandelman and Kozak, 1988) that neonatal administration of TP to female mice enhanced their later capacity to show male-typical intromission- and ejaculation-like behaviors, there are no pharmacological experiments on mice that have systematically explored the effects of perinatal manipulation of AR- or ER-activation on the later expression of these sexual behaviors. Thus, the only evidence for this proposed sequential action of both E (acting via ERα) and T (acting via AR) comes from previous studies using ferrets. In ferrets, circulating T levels are consistently greater in males than in females over the last

quarter of the 41-day gestation (Krohmer and Baum, 1989), again within 2 h after birth (Erskine et al., 1988) and then intermittently over the first 3 postnatal weeks (Erskine and Baum, 1982). High levels of hypothalamic aromatase activity (Tobet et al., 1985; Krohmer and Baum, 1989; Weaver and Baum, 1991) as well as ERα (Tobet et al., 1993) and AR (Vito et al., 1985) are present in both sexes over this extended perinatal period. Although males have relatively high levels of circulating T, beginning as early as embryonic day 25 (E25) and extending to a few hours after birth, neither transplacental administration of TP to female ferrets over days E16–34 followed by a single injection of TP on postnatal day 3 (Baum, 1976) nor transplacental treatment of females with T over days E30–41 (Tobet and Baum, 1987) significantly augmented their capacity to display male-typical sexual behavior in adulthood. Instead, the available evidence (Baum et al., 1990b) suggests that sex steroid exposure over this period sensitizes the developing nervous system to a second phase of sex hormone action, which begins shortly after birth and extends to postnatal day 20. Recent studies on relative contributions of perinatal AR- and ER-activation in organizing male-typical coital capacity in mice have only pointed to an important role of each type of steroid in the control of this process. By contrast, the administration during specific perinatal periods of T, E, or of drugs that either block androgen receptors (Flutamide) or inhibit aromatase activity (1,4,6-androstatriene-3,17-dione; ATD) has allowed the specification of the sequential roles of ER and AR activation in the organization of neural mechanisms controlling ferrets' male-typical sexual behavior. Thus, depriving male ferrets of estrogens between days E30 and E41 via maternal ovariectomy and transplacental ATD treatment reduced their later ability to display male-typical mating behavior (Tobet and Baum, 1987), whereas treatment with the AR antagonist, Flutamide, had no such effect, even though it attenuated penile development. These findings imply that estrogenic metabolites of T play an important role in the initial perinatal masculinization of neural mechanisms controlling male sexual behavior. By contrast, during the second, neonatal period of steroidal masculinization of behavior it appears that T itself, acting via AR, plays a critical role. Thus T itself, when administered to female ferrets over postnatal days 0–15 was significantly more effective than treatment with either E or DHT in masculinizing male sexual behavior (Baum et al., 1982a). Further support for a neonatal role of T itself in this regard stems from the observation (Baum et al., 1983) that treating female ferrets over postnatal days 0–15 with either the aromatase inhibitor, ATD or the 5α reductase blocker, testosterone 17β−carboxylic acid, failed to disrupt the normal male-typical differentiation of sexual behavior capacity.

The duration of gestation in commonly studied rodents such as rats and mice is considerably shorter (22 and 19 days, respectively) than that of the ferret, a carnivore (41 days). The longer duration (∼36 days in ferrets versus ∼16 days in rats) of a critical period of development for neural tissues controlling male-typical brain and behavioral sexual differentiation has perhaps made it experimentally more feasible to identify separate, sequential periods of estrogen and androgen actions in the ferret than in rodent models. Estrogenic metabolites of T, formed perinatally, contribute to the capacity of male rats to ejaculate. Thus, neonatal administration of the aromatase blocker, ATD (Bakker et al., 1993b), or the anti-estrogen, MER-25 (Booth, 1977b) to male rats attenuated their later ability to achieve ejaculation after a series of mounts with intromission. Combined pre- and neonatal treatment with ATD also attenuated ejaculatory capacity, whereas prenatal ATD alone had no such treatment (Brand and Slob, 1991; Houtsmuller et al., 1994). These drug treatments had no detrimental effect on penile development in males. Thus, their disruptive effect on ejaculatory capacity cannot be attributed to a reduction in penile sensory functions during a mounting series. Castration of male rats within a day after birth, as opposed to 7–15 days postnatally, disrupted intromission and ejaculation without affecting mounting behavior (Beach et al., 1969). These behavioral effects were correlated with reduced penile development in neonatally castrated males. Likewise, disruptions in intromission and ejaculatory capacity were obtained in male rats after prenatal treatment with the antiandrogen, Flutamide (Clemens et al., 1978; Brand and Slob, 1991; Dominguez et al., 2002; Castro et al., 2003). These behavioral effects of prenatal Flutamide, like those of neonatal castration, were correlated with disruptions in normal AR-dependent penile development. A similar peripheral as opposed to central neural explanation, likely applies to the deficits in intromissive and ejaculatory capacity reported in androgen-insensitive tfm rats (Beach and Buehler, 1977; Olsen, 1979).

In contrast to the data implicating neonatal estrogen biosynthesis in the differentiation of neural mechanisms controlling intromissive and/or ejaculatory behavioral capacity, the evidence suggesting that

either ER or AR, activated either sequentially or over the same perinatal periods, is required for the development of male-typical mounting capacity is controversial. In female rats (Beach, 1942a; Emery and Sachs, 1975) as in female mice (Wersinger et al., 1997), surprisingly high levels of mounting behavior toward a stimulus female were observed after adult treatment with ovarian hormones, sometimes including intromission- and ejaculation-like behaviors. The presence of this capacity in female rats may reflect the fact that male and female rat pups have similar circulating levels of T over days E16, E17, E20, E21, and E22, with males having significantly higher levels only on days E18 and E19 (Weisz and Ward, 1980; Baum et al., 1991).

Although essentially all female rats will display mounting after ovariectomy and TP treatment in adulthood, the level of this behavior is typically significantly lower than the level displayed by male rats following adult castration and TP treatment (Whalen and Edwards, 1967; Dominguez et al., 2002; Amateau and McCarthy, 2004). There are conflicting reports on whether prenatal treatment of male rats with the aromatase inhibitor, ATD, reduces later mounting behavior. In one study (Gladue and Clemens, 1980a), prenatal ATD reduced males' later mounting capacity whereas in two other reports (Houtsmuller et al., 1994; Dominguez et al., 2002) no such effect of ATD was obtained in either male or female rats. Likewise, prenatal treatment with an AR blocker, Flutamide or cyproterone acetate (CA), had different effects on rats' mounting capacity in different studies. In some instances, prenatal Flutamide (Stewart et al., 1971; Clemens et al., 1978; Castro et al., 2003) or CA (Ward and Renz, 1972) treatment reduced later mounting capacity in both male and female rats, whereas in other studies (Brand et al., 1991; Dominguez et al., 2002) no such effect was obtained. Taken together, these results provide no conclusive evidence that fetal availability of T, or its estrogenic metabolites, contributes to the development of the mounting capacity that is seen in rats of both sexes. They also provide little evidence that the brief (days E18–19) sex difference in circulating T can account for the fact that male rats display higher levels of mounting behavior than females following treatment with T or E in adulthood.

In the rat, as in the ferret, males are exposed to significantly higher levels of T than females, beginning 2 h after birth (Corbier et al., 1978; Baum et al., 1988) and again over the first 10 postnatal days (Resko et al., 1968; Pang et al., 1979). Attempts to demonstrate that neonatal administration of TP to female rats enhances later mounting capacity have met with mixed outcomes. Thus in two studies (Hendricks, 1969; Sodersten, 1973b) neonatal TP treatment significantly augmented mounting capacity following ovariectomy and TP treatment later in life, whereas in other experiments (Whalen and Edwards, 1967; Pfaff and Sigmond, 1971) no such effect was found. Castration carried out on the day of birth (more than 4 h postpartum) failed to reduce the capacity of male rats to display mounting behavior after TP treatment later in life (Grady et al., 1965; Whalen and Edwards, 1967). Important, however, castration within minutes after birth caused a significant reduction, though not an elimination, of T-induced mounting behavior in male rats (Roffi et al., 1987). Immediate postnatal injection of T after castration reversed the disruptive effect of this treatment on later mounting potential, suggesting that the immediate postparturient rise in circulating T normally augments the sensitivity of neural mechanisms that control mounting to the activational effects of later T exposure.

Whereas there is general agreement that neonatal inhibition of E's availability or neural action disrupts later ejaculatory capacity in male rats (Booth, 1977b; Bakker et al., 1993a), there is less conclusive evidence that the action of E in the postnatal male rat brain contributes to the masculinization of mounting behavior capacity. Thus, there is a discrepancy in the outcomes of experiments assessing the ability of neonatal EB treatment to augment later mounting capacity in female or neonatally castrated male rats. No effects were found in two studies (Whalen and Edwards, 1967; Hendricks and Weltin, 1976), whereas an enhancement of later mounting capacity was induced by neonatal EB treatment in two other studies (Mullins and Levine, 1968; Sodersten and Hansen, 1978). Administration of the aromatase blocker, ATD, beginning 3–9 h after birth, in addition to dramatically reducing ejaculatory capacity in male rats, significantly reduced their mounting and intromission behavior later in life (Bakker et al., 1993a). In another study (Bakker et al., 1993b), however, the same ATD treatment slightly augmented the later display of mounting and intromissive behaviors in male rats that were tested late as opposed to early in the dark phase of the daily day/night cycle. Studies are needed to determine whether inhibiting the aromatization of the immediate postparturient T peak would disrupt later mounting potential as reliably as castration within minutes

after birth. The observation (Rhoda et al., 1984; Amateau et al., 2004) that levels of E in the hypothalamus and preoptic area were significantly higher in male than in female rats killed 1–2 h after birth points to a potential contribution in males of this steroid, formed via neural aromatization of the postparturient surge in T secretion, to the masculinization of brain mechanisms controlling mounting behavior.

4.4 Steroid Receptor Coactivators, GABA, and Prostaglandin-E2 as Possible Mediators of Sex Hormone-Dependent Behavioral Masculinization

Steroid hormones, including T and E, affect neural development and function by binding to specific intracellular ARs and ERs, respectively. In order for steroid–receptor complexes to interact effectively with DNA to promote gene transcription, an additional class of proteins referred to as nuclear receptor coactivators is thought to be required (Shibata et al., 1997). On the presumption that either ER or AR, or both receptors, normally contribute in male rats to behavioral masculinization during neonatal life, McCarthy and coworkers have carried out studies to explore the possible contribution of two such steroid coactivators to this process. In an initial study (Auger et al., 2000), antisense oligonucleotides to the steroid receptor coactivator-1 (SRC-1) mRNA were infused on the day of birth into the hypothalamus of either male or neonatally TP-treated female rats. This treatment dramatically augmented the ability of these groups of rats to display lordosis behavior after adult treatment with ovarian hormones, suggesting that the SRC-1 protein is essential for the normal defeminizing actions of E in male rats during neonatal life. By contrast, antisense to SRC-1 failed to reduce the incidence of later mounting behavior in these same subjects, suggesting that the neuroendocrine mechanism controlling behavioral defeminization and masculinization in male rats is fundamentally different. The cAMP response element-binding protein (CBP) may also function as a nuclear receptor coactivator by interacting with SRC-1, thereby enhancing steroid receptor action at hormone response elements on target DNA. The levels of CBP in the basomedial hypothalamus were significantly higher in male than female rats over the first 10 postnatal days (Auger et al., 2002). As with antisense to SRC-1, neonatal hypothalamic infusions of antisense to CBP into neonatally TP-treated female rats blocked the normal defeminizing action of this neonatal steroid treatment without reducing the capacity of these same females to display mounting behavior in adulthood after treatment with testosterone (Auger et al., 2002). Again, this divergence in the behavioral effects of neonatal antisense treatments to two steroid receptor coactivators reinforces the view that the neural mechanisms controlling these two types of behavior are different in many important ways (Goy, 1970), possibly including timing of their perinatal development.

Significantly higher levels of the neurotransmitter, γ-aminobutyric acid (GABA), were reported in the hypothalamus and limbic structures of male versus female rats killed over the first 5 postnatal days (Davis et al., 1999), raising the possibility that excitatory inputs from GABA neurons may mediate some of the effects of elevated ER- or AR-mediated neural signaling in the neonatal male rat brain contributing to the development of male-typical features of behavioral sexual differentiation (McCarthy et al., 1997; Perrot-Sinal et al., 2001). Indeed, neonatal intrahypothalamic infusion of antisense oligonucleotides to glutamic acid decarboxylase mRNA (the rate limiting enzyme controlling GABA synthesis) into female rats that had received neonatal injections of TP reduced their later display of intromission-like behavior in tests with estrous females (Davis et al., 2000). In another study (Amateau and McCarthy, 2004), prostaglandin-E2 (PGE2) was implicated in the estrogen-dependent signaling that has been hypothesized to contribute to the differentiation of masculine sexual behavior in male rats. Bilateral intracerebroventricular (icv) infusions of PGE2 made within 6 h after birth and again 24 h later significantly enhanced the capacity of female rats to display mounting and intromission-like behaviors in adult tests (after ovariectomy and T treatment) with estrous females. Males in which PGE2 synthesis was inhibited neonatally by s.c. injections of indomethacin, a potent cyclooxygenase-2 (COX-2) blocker, later showed significant reductions in mounting and intromission behaviors. This behavioral effect of indomethacin was correlated with a reduction in a marker for dendritic spine density in the preoptic area. Administering E on the day of birth and again on postnatal day 1 caused a significant rise in COX-2 mRNA levels in the preoptic area when female subjects were killed on postnatal day 3, suggesting that the higher levels of E present in male versus female hypothalamus shortly

after birth (Rhoda et al., 1984; Amateau et al., 2004) may stimulate PGE2 synthesis and male-typical aspects of preoptic area development. Finally, chronic perinatal exposure of developing male rats' pups to aspirin, a COX-2 inhibitor that was placed in their mothers' drinking water, led to significant reductions in mounting and intromission behaviors displayed later in two adult tests followed by a recovery of function in a third test. We need more research to determine whether in vivo inhibition of E biosynthesis by administering an aromatase inhibitor immediately after birth causes reductions in PGE2 synthesis that are correlated with deficits in masculine sexual behavior in adulthood. It is also important to show that these effects of neonatal aromatase inhibition are reversed by concomitant administration of either E or of PGE2.

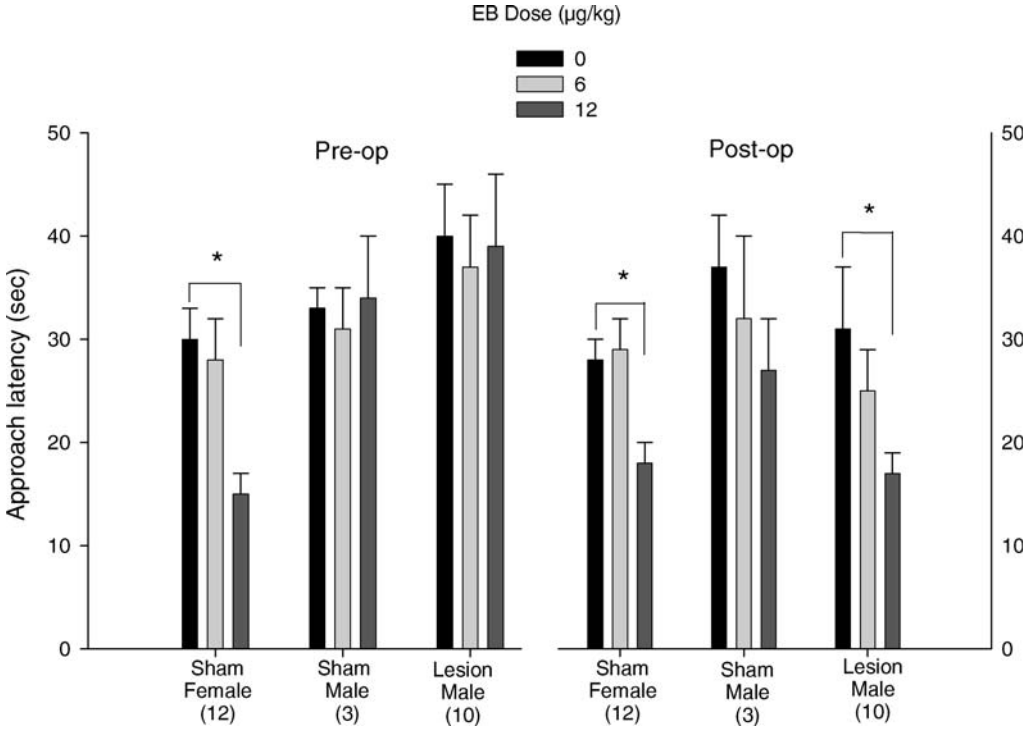
5 Relationship Between Sexually Dimorphic Hypothalamic Morphology and Male-Typical Sexual Behavior and Partner Preference

Gorski et al. (1978) first reported the existence of a sexually dimorphic nucleus (SDN) of the rat POA/AH. The SDN is 3–4 times larger in volume in male than in female rats. In light of the large literature (Hull et al., 2002) showing that destructive lesions of the medial POA/AH disrupt masculine sexual behavior, it was widely presumed that the behavioral deficits observed could be attributed to the destruction of the SDN. Indeed, Houtsmuller et al. (1994) reported that perinatal exposure to an aromatase inhibiting drug, ATD, reduced the volume of the SDN in male rats, and this reduction was correlated with subjects expressing less masculine mating behavior. Likewise, a strain (Noble) of male rats with significantly larger volumes of the SDN displayed significantly higher levels of mating, including ejaculation, than another strain (Wistar–Furth) with a smaller SDN (Lephart et al., 2001). These correlations not withstanding, bilateral destructive lesions restricted to the male rat SDN caused either no (Arendash and Gorski, 1983) or minimal (De Jonge et al., 1989) disruption of sexual behavior. In the latter study, disruptive effects of SDN lesions were most evident in male rats that lacked mating experience at the time the lesions were placed. There is also a sexually dimorphic male nucleus of the POA/AH in male ferrets, which is not present in females (Tobet et al., 1986). In contrast to the rat example, neonatal administration of TP to female ferrets augmented their later capacity to display male-typical mating behaviors without exerting any organizational effect on the morphology of the POA/AH (Cherry et al., 1991). Again, as in the male rat, bilateral lesions that were restricted to the male ferret's male nucleus of the POA/AH failed to disrupt male sexual behavior (Cherry and Baum, 1990). Lesions of the male gerbil's sexually dimorphic nucleus disrupted mating performance in gonadally intact subjects, although the deficits were abolished after castration and treatment with T (Commins and Yahr, 1984). Taken together, these various studies provide no consistent evidence that sexually dimorphic subdivisions of the medial POA/AH play an essential role in controlling the expression of male-typical mating behaviors in mammalian species.

Whereas the capacity to display *consummatory* components of masculine sexual behavior has not been reliably linked to the presence of a male-typical SDN, several lines of evidence have linked *appetitive* features of masculine sexual behavior, including males' preference to seek out a female as opposed to another male conspecific, to the function of sexually dimorphic portions of the POA/AH. An early linkage of this sort was obtained in ferrets (Cherry and Baum, 1990) in which discrete electrolytic lesions of the males' sexually dimorphic POA/AH caused them to show female-like patterns of approach behavior to stud males in L-maze tests. Following gonadectomy and adult treatment with increasing dosages of EB, female ferrets showed a dose-dependent reduction in approach latencies to the stimulus male, whereas male subjects approached this stimulus at a constant speed regardless of estrogen dosage (Baum et al., 1985). As shown in *Figure 1-3*, discrete bilateral lesions of the sexually dimorphic POA/AH caused castrated male ferrets, like control females, to show progressively shorter approach latencies to a stud male in response to increasing doses of EB (Cherry and Baum, 1990). Two subsequent studies using ferrets showed that either excitotoxic (Paredes and Baum, 1995) or electrolytic (Kindon et al., 1996) lesions centered in the males' sexually dimorphic POA/AH caused them to prefer to approach and interact with a stud male as opposed to a sexually receptive female when tested with these two types of stimuli in a T-maze. Again, castrated ferrets used in both of these studies received E at the time of testing. Likewise, as shown in *Figure 1-4*, castrated adult male rats that were treated with either T showed a robust preference to approach a stud male as opposed to

Figure 1-3

Descrete bilateral lesions of the sexually dimorphic male nucleus of the medial preoptic area/anterior hypothalamus (Lesion male) caused castrated adult male ferrets to show a female-typical profile of approach latencies in an L-shaped maze to a sexually active male ferret in response to s.c. injections of increasing doses of estradiol benzoate (EB). Approach latency results from both pre- and postoperative tests are shown for sham operated female (Fem), sham-operated male, and MN lesioned male ferrets. Data are expressed as mean +/−SEM; ns are given in parentheses. * Significant effect of EB dose by 1-way ANOVA. Adapted from Cherry and Baum (1990)

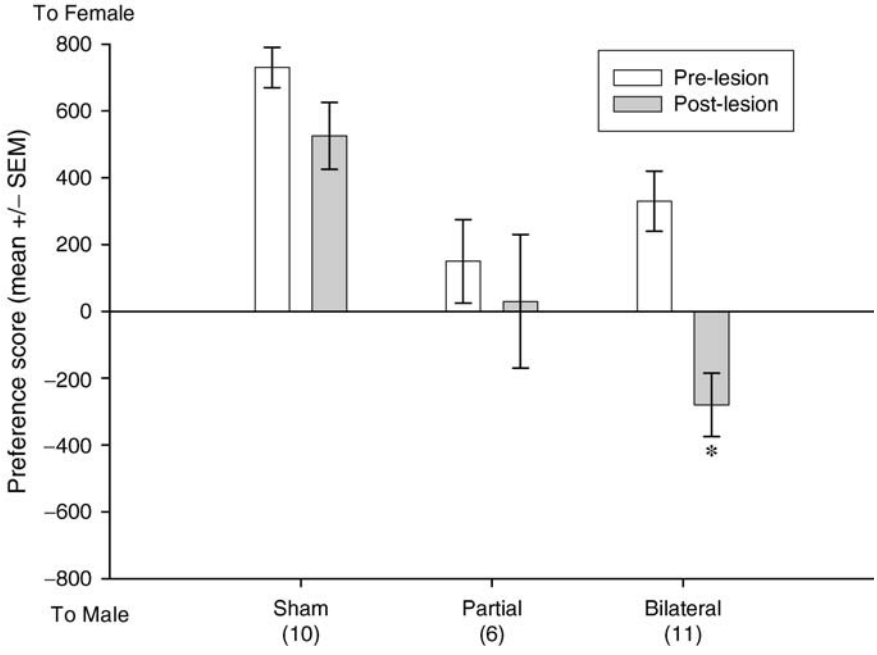


an estrous female following the placement of electrolytic lesions in the POA/AH (Paredes et al., 1998b). Sham-operated control males preferred to approach the estrous female. The placement of POA/AH lesions in female ferrets (Paredes and Baum, 1995) or in female rats (Paredes et al., 1998b) had no effect on their male-oriented partner preference. Taken together, these results suggest that a male-typical preference to approach female, as opposed to male conspecifics, depends on yet-to-be understood characteristics of the sexually dimorphic structures of the male's POA/AH.

Two additional lines of correlative evidence support the view that male-typical features (e.g., larger volume of the nucleus, larger cell bodies, larger dendritic arbor, high number of aromatase-expressing neurons (Tobet and Hanna, 1997) of the sexually dimorphic subdivision of the POA/AH) somehow contribute to the male-typical preference of male mammals to seek out female conspecifics, as opposed to other males, for the purpose of mating. The first of these examples stems from the early observation (Perkins et al., 1992) that ~8% of rams prefer to approach and mount other rams as opposed to ewes when given a choice between these alternatives. In sheep, as in rat and ferret, a sexually dimorphic group of cells exists in the POA/AH (ovine SDN), which is significantly larger in volume in males than in females (Roselli et al., 2004b). The volume of this ovine SDN was twice as great in female-oriented than in male-oriented rams (Roselli et al., 2004b), raising the question of whether there is a causal link between the size of the ram's sexually dimorphic POA/AH nucleus and the motivation to seek out an opposite-sex mating partner.

Figure 1-4

Bilateral lesions of the medial preoptic area/anterior hypothalamus (Bilateral) caused castrated, testosterone-treated male rats to switch their preference from a tethered estrous female (to female) to a tethered sexually active male (to male). Preference scores were calculated by subtracting the number of seconds that male subjects spent in a 3-compartment box with the tethered male from the time spent with the receptive female (negative numbers reflect time spent with the stimulus male). * Significant switch in male rats' partner preference following placement of a bilateral MPOA/AH lesion. Group Ns are given in parentheses. Adapted from Paredes et al. (1998b)



Three independent groups of investigators (Allen et al., 1989; LeVay, 1991; Byne et al., 2000) have published results showing that the volume of the third interstitial nucleus of the anterior hypothalamus (INAH3) is significantly greater in (presumptive) heterosexual men than women. In a widely publicized study (LeVay, 1991), it was reported that the volume of INAH3 was significantly greater in heterosexual than in homosexual men. The homosexual men whose brains were analyzed in this study had nearly all died of HIV/AIDS whereas the heterosexual subjects typically died of non-HIV related causes. This difference in cause of death led some critics to attribute the differences in INAH3 volume observed between homosexual versus heterosexual men to the presence of HIV infection in the homosexual sample as opposed to a difference in sexual orientation. A more recent study (Byne et al., 2001) suggested, however, that there was no effect of HIV infection on the dimensions of INAH3 in either heterosexual or homosexual male subjects. These investigators also reported only a nonsignificant trend for INAH3 volume to be greater in heterosexual as compared with homosexual men. Thus, the original report of LeVay (LeVay, 1991), although intriguing, still awaits full replication. Certainly, the recent report (Roselli et al., 2004b) of an analogous difference in the volume of the male sheep's sexually dimorphic POA/AH, depending on whether rams preferred to approach and mount other males over females, increases the importance of obtaining additional data on the dimensions of the human male's INAH3 as a function of sexual orientation.

There are no empirical data that establish whether fetal differences in T exposure cause the above-mentioned differences between men and women or between heterosexual and homosexual men in INAH3 volume. Nor is any information available about the respective roles of AR- or ER-mediation of any such

organizational effects of fetal T exposure in the human nervous system. By contrast, in both rat (Jacobson et al., 1981) and ferret (Park et al., 1997), experimental data have established that perinatal administration of T to females organizes male-typical size as well as phenotypic characteristics of sexually dimorphic structures in the MPOA/AH. Additional studies in both species have established that male-typical characteristics of POA/AH morphology depends on the perinatal neural aromatization of T, secreted by the testes, into E. Thus, neonatal treatment of male rats with the ER antagonist, tamoxifen, significantly reduced SDN volume (Dohler et al., 1984), and transplacental administration of the aromatase blocker, ATD, blocked the differentiation of the MN in the POA/AH of male ferrets (Tobet et al., 1986; Cherry et al., 1990). Subgroups of rams that preferred to mount females had significantly higher levels of aromatase activity (Resko et al., 1996) and aromatase mRNA (Roselli et al., 2004b) as well as estradiol receptor content (Perkins et al., 1995) in the sexually dimorphic portion of the POA/AH than did rams that preferred to mount other males. These correlative results raise the questions of whether variations in fetal estrogen signaling account for variations in the dimensions of the male-typical ovine SDN and whether these variations, in turn, control heterosexual versus homosexual partner orientation in rams (Roselli et al., 2004a). In the sheep model, as in other model systems in which the development and adult control of appetitive as well as consummatory components of masculine sexual behavior are studied, the future challenge is to understand how neuroendocrine signals organize the perinatal development and modulate the adult functions of male-typical circuits that mediate the sensory (olfactory, visual, auditory) inputs, which control these two kinds of behavior.

5 Unanswered Questions and Future Directions 76

Abstract: Steroid hormones regulate male sexual behavior, in part, by orchestrating the production and release of neurotransmitters in brain areas that control sexual motivation and copulatory performance. Major facilitative neurotransmitters are dopamine, glutamate, and, in some cases, norepinephrine. Serotonin, GABA, and opioid peptides provide primarily inhibitory influence, although low levels of some of these neurotransmitters, acting via specific receptor subtypes, may facilitate certain aspects of behavior. Other neuropeptides, including oxytocin, orexin/hypocretin, α-melanocyte stimulating hormone, gonadotropin releasing hormone, and galanin-like peptide may facilitate mating, whereas neuropeptide Y, prolactin, corticotropin releasing hormone, and angiotensin II may have inhibitory effects. Brain areas that are especially important for the control of male sexual behavior include the medial preoptic area, the medial amygdala, the paraventricular nucleus of the hypothalamus, the mesocorticolimbic dopamine tract, several midbrain and brainstem nuclei, and nuclei in the spinal cord that control the erectile and ejaculatory reflexes. Some dopaminergic and serotonergic receptor subtypes promote parasympathetically mediated erection, and other subtypes facilitate sympathetically mediated seminal emission and ejaculation.

List of Abbreviations: 5-HT, 5-hydroxytryptamine, serotonin; 5-HT_{1A}, 5-HT_{1B}, 5-HT_{2C}, Serotonin receptor subtypes; 5,7-DHT, 5,7-Dihydroxytryptamine, serotonin neurotoxin; α_1, α_2, Alpha noradrenergic receptors; α-MSH, Alpha-melanocyte stimulating hormone; AChE, Acetylcholinesterase; ACTH, Adrenocorticotropic hormone; ADP, Adenosine 5′-diphosphate; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, specific agonist for a type of glutamate receptor; AR, Androgen receptor; BL, Baseline; BS, Bulbospongiosus muscle of the penis; CCK, Cholecystokinin; cGMP, Cyclic guanosine monophosphate; CNQX, 6-cyano-7-nitroquinoxaline-2,3-dione, an AMPA/kainate receptor antagonist; CRH, Corticotropin releasing hormone; D_1, D_2, D_3, D_4, D_5, Dopamine receptor subtypes; D5KO, Mouse with deletion of the D_5 dopamine receptor; DA, Dopamine; EEG, Electroencephalogram; EMG, Electromyogram; eNOS, Endothelial nitric oxide synthase; ER, Estrogen receptor; ERα KO, Mouse with deletion of the ERα estrogen receptor; FSH, Follicle stimulating hormone; GABA, Gamma-aminobutyric acid; GAD, L-Glutamic acid decarboxylase; GALP, Galanin-like peptide; $G_{I/O}$, GTP binding protein that couples receptors to inhibition of adenylyl cyclase or other effects; GTP, Guanosine triphosphate; icv, Intracerebroventricular; IP_3, Inositol triphosphate; L5-S1, Fifth lumbar to first sacral vertebrae; L-DOPA, 3,4-dihydroxy-L-phenylalanine, precursor of dopamine; LHA, Lateral hypothalamic area; L-NAME, N-Nitro-L-arginine methyl ester; L-NMMA, N(G)-monomethyl L-arginine ; MC, melanocortin; MPOA, Medial preoptic area; NAc, Nucleus accumbens; NE, norepinephrine; NMDA, N-methyl-D-aspartic acid; nNOS, Neuronal nitric oxide synthase; NO, Nitric oxide; NOS, Nitric oxide synthase; NOS-ir, Nitric oxide synthase immunoreactivity; nPGi, Nucleus paragigantocellularis; NPY, Neuropeptide Y; ODQ, 1H-[1,2,4]Oxadiazole[4,3-a]quinoxalin-1-one, inhibitor of guanylyl cyclase; *p*CPA, *p*-chlorophenylalanine; PDE5, Phosphodiesterase 5; PGE_2, Prostaglandin E_2; PKA, Protein kinase A; PKG, Protein kinase G; POMC, Proopiomelanocortin; PVN, Paraventricular nucleus; SPFp, Subparafascicular nucleus, parvocellular division; SSRI, Selective serotonin reuptake inhibitor; tfm, Testicular feminization mutation; THP, Tetrahydrothienopyridine; TRH, Thyrotropin releasing hormone; VIP, Vasoactive intestinal peptide; VNX, Vomeronasal organ removal; VTA, Ventral tegmental area

1 Introduction

Sexual behavior and the courtship that precedes it are regulated by steroid hormones, which orchestrate the production and release of numerous neurotransmitters and neuropeptides that interact in specific brain areas to elicit the appropriately timed and coordinated behavioral response. In this chapter, we summarize recent contributions to our understanding of how neurotransmitters and neuropeptides in the central nervous system interact to regulate male sexual behavior. We begin with a brief description of copulatory behaviors of the most commonly studied species. Next, we consider the major neurotransmitters and neuropeptides that have been shown to influence male sexual behavior. For each, we describe the effects of systemically or intraventricularly administered drugs, followed by consideration of the role of each

neurotransmitter in specific brain areas. We conclude with a summary and a set of questions that may guide future research.

2 Patterns of Sexual Behavior of Male Mammals

2.1 Precopulatory Behaviors

Males advertise their fitness by using species-specific displays. They also assess the female's desirability and willingness to mate by investigating her face and anogenital region. Chemosensory, visual, and auditory stimuli may arouse him and signal the female's receptivity. A female may exhibit proceptive behaviors, such as hopping and darting, ending with an abrupt stop in front of the male. However, a female may reject the male's advances by running away, keeping her hindquarters and tail low, or kicking him.

2.2 Copulatory Behavior

2.2.1 Mounts

A receptive female typically remains immobile while the male clasps her flanks with his forepaws and initiates several shallow thrusts with his pelvis, while his penis is at least partially erect. The female may stand in a rigid lordosis posture, with her back flat or concave and her tail deflected to expose her vagina.

2.2.2 Intromissions

Intromission is the definitive event of copulation. If the male locates the female's vagina, he will perform a deeper, intravaginal thrust, followed by a rapid, springing dismount. The deep thrust and springing dismount are reliably associated with penile insertion (Pollak and Sachs, 1975) and are typically used as the measure of intromission in most rodents. Each intromission in rats lasts about half a second. In mice and some other species, the male thrusts repeatedly throughout the intromission (McGill, 1962), and in ungulates and canids, the male may ejaculate immediately after vaginal intromission (Bermant et al., 1969; Lott, 1981). Following an intromission, the male typically grooms his genitals.

In some species, increased numbers of intromissions preceding ejaculation may promote fertility by increasing the number of sperm in the ejaculate (Adler and Toner, 1986; Toner and Adler, 1986; Toner et al., 1987) or facilitating sperm transport in the female (Adler and Toner, 1986). Females of some species require a sufficient amount of vaginocervical stimulation to ovulate or to trigger a progestational state (reviewed in Dewsbury, 1990).

2.2.3 Ejaculation

Males of most mammalian species ejaculate only after receiving stimuli from multiple intromissions. Ejaculation in rats can be recognized behaviorally by a longer, deeper thrust followed by a slow dismount. Skeletal and striated perineal muscles usually contract rhythmically during ejaculation. Such muscle contractions are associated with orgasm in human males and females.

2.3 Postejaculatory Behavior and Satiety

Following ejaculation, males typically groom themselves and enter a period of sexual quiescence, which may last for as little as 30 s in Syrian hamsters or as long as hours or days in other species (Dewsbury, 1972); in

rats, it is usually 5–10 min. During the first 50–75% of this interval, the absolute refractory interval, the male will not copulate again, regardless of the amount of stimulation. Ultrasonic vocalizations may occur during this period, as well as a pattern of synchronized EEG waves, similar to those of sleep (Barfield and Geyer, 1975). During the remainder of the postejaculatory interval (the relative refractory period), the male may resume copulation with a novel female. Most male rats reach sexual satiety after 7–8 ejaculations and may not copulate again for 1–3 days. Recent data suggest that a reduction in androgen receptors in the medial preoptic area and related areas may give rise to satiety (Fernandez-Guasti and Rodriguez-Manzo, 2003).

2.4 Sexual Motivation versus Performance

Sometimes it is useful to distinguish between the motivation for sexual activity and the actual performance of the behavior. Appetitive behaviors are more variable than the relatively stereotypic consummatory behaviors and are thought to reflect an underlying motivational state. Sexual motivation may include sensory and motor processes that are sensitized by gonadal hormones, as well as more general activational processes that can energize other behaviors as well. It is best to use tests that are designed specifically to assess motivation and that do not confound possible changes in sensory, motor, or learning ability with motivation per se. Some of the tests that have been used for this purpose include the following: (1) the X (or cross) maze, in which a female is in a goal box at the end of one of four arms and a male or other goal objects occupy other goal boxes, or the other goal boxes remain empty; (2) the bilevel apparatus, in which a male changes levels apparently in search of a female, following a previous sexual encounter in the apparatus; (3) place-preference test, in which the male spends more time in an area in which he has previously copulated; (4) time spent near an estrous versus nonestrous female; and (5) lever pressing for access to a receptive female. However, several of these tests are subject to confounding of motor and motivational effects. It is difficult to design tests with no possible confounds, so it is helpful to test separately for drug effects on sensory or motor function.

2.5 Sexual Experience

Previous sexual experience confers increased sexual "efficiency." Experienced males require less time to initiate copulation and to ejaculate (Larsson, 1959; Dewsbury, 1969; Pfaus and Wilkins, 1995; Bialy et al., 2000). They are also less impaired by castration, various brain lesions, and exposure to a novel environment (Rosenblatt and Aronson, 1958; Lisk and Heimann, 1980; Arendash and Gorski, 1983; Meredith, 1986; Saito and Moltz, 1986; Kondo, 1992; Bialy and Beck, 1993; Claro et al., 1995; Pfaus and Wilkins, 1995; Bialy et al., 2000). Ejaculation activated more neurons (i.e., immunoreactive for Fos—the protein product of the immediate-early gene *c-fos*) in the medial preoptic area (MPOA) (Lumley and Hull, 1999) and in the shell of the nucleus accumbens (Lopez and Ettenberg, 2002a) in sexually experienced than in sexually naïve males. Therefore, increased sensitivity to sexual stimuli may be one mechanism that confers greater sexual efficiency and resistance to disruptions in experienced males.

2.6 Sexual Behavior Throughout the Lifespan: Puberty and Aging

The onset of copulatory ability is variable, with some male rats beginning to mount as early as 40 days of age, and the first ejaculations occurring between 48 and 75 days (reviewed in Meisel and Sachs, 1994). Prepubertal castration prevents the development of sexual behavior (Larsson, 1967), and exogenous testosterone or estrogens can hasten its onset (Baum, 1972; Södersten et al., 1985). However, the natural onset of copulatory behavior in male rats occurs several days before the pubertal rise in testosterone

(Södersten et al., 1977; Sachs and Meisel, 1979). Furthermore, the maturation or innervation of genital structures was not the decisive factor, as spinally transected male rats showed ex copula erections and penile anteroflexions 10 days before spinally intact animals (Sachs and Meisel, 1979).

Unlike rats, male hamsters begin to copulate only after the pubertal testosterone increase begins, although before it peaks (Romeo et al., 2002). Lack of testosterone during puberty resulted in impaired copulation after testosterone was replaced in adulthood, compared with castrates with testosterone replacement during puberty (Schultz et al., 2004). The odor of a receptive female activated Fos expression in the MPOA of male hamsters even before puberty (Romeo et al., 1998); however, increased dopamine (DA) activity in the MPOA (measured as increased DOPAC, a DA metabolite) in response to female odor occurred only after puberty (Schultz et al., 2003). Therefore, a hormonal factor is apparently required for this critical area to become fully responsive to the female's stimuli. Sisk and her colleagues have suggested that puberty is a second organizational period for gonadal hormones to alter neural processing in areas that regulate sexual behavior (Romeo et al., 2002; Sisk et al., 2003; Schultz et al., 2004).

The ability of aged males to copulate is also highly variable. Sexual behavior of aged male monkeys was not correlated with testosterone levels (Chambers and Phoenix, 1981; Chambers et al., 1981), nor did exogenous testosterone improve behavior in castrated or intact old monkeys, compared with young males (Phoenix and Chambers, 1986, 1988). In old male mice, testosterone levels, gonad weights, and spermatogenesis were lower than in young animals; however, some of the aged males could copulate and others could not, despite similar testosterone levels (Bronson and Desjardins, 1982). Neither decreased testosterone levels nor decreased nuclear androgen receptors (ARs) in the MPOA could account for the inability of old male rats to ejaculate (Chambers et al., 1991). However, a later study found that nuclear estrogen receptors (ERs) in the amygdala were lower in old than in young males, and that testosterone replacement did not restore ERs to the levels of young males (Roselli et al., 1993). The authors suggested that old males' ability to bind estradiol, derived from testosterone, may limit their androgen responsiveness.

2.7 Measures of Penile Function

2.7.1 In Copula Measures

The most direct way to study erectile function is to observe the penis during sexual behavior. Although this may be easy in some species, it is difficult in rodents, because erections are very brief and usually obscured from view. Erection, intromission, and ejaculation are usually inferred from the male's behavior. However, brain lesions or drug administration could affect ejaculation without obvious changes in behavior. Experimenters may inspect the female's vagina for sperm immediately after copulation or examine the cage floor for coagulated semen. However, males often eat their ejaculate while grooming their genitalia immediately after ejaculation (Orbach, 1961). Paradigms have been developed for monitoring genital reflexes ex copula. However, in copula and ex copula erections may differ in their physiological, CNS, neurochemical, or hormonal control (Sachs, 2000). Thus, one should be cautious when predicting the effects of a drug on copulation, based on ex copula tests. It is possible to measure physiological responses during copulation, using chronic implantation of electrodes in striated perineal muscles (Holmes et al., 1991) or telemetric measures of penile pressures (Giuliano et al., 1994). These methods are technically difficult, but do provide physiological measurements during normal sexual behavior.

2.7.2 Ex Copula Measures

2.7.2.1 Spontaneous Erections Various drugs, administered either systemically or into specific CNS sites, can increase the number of erections elicited outside of a sexual context. These drug-induced erections usually involve extension of the engorged glans beyond the sheath and are often accompanied by genital

grooming. The obvious advantages of this model are its ease and simplicity. However, it may not reliably predict the effects of a drug on copulatory performance.

2.7.2.2 Noncontact Erections Another model for studying erection is noncontact erection. Male rats show penile erections in response to volatile odors from an estrous female, even in the absence of physical contact (Sachs et al., 1994; Sachs, 1997; Kondo et al., 1999). This may be used as a model for psychogenic erections in humans. This response is produced by supraspinal mechanisms rather than spinal reflex pathways. Discrete brain lesions have resulted in differential effects on copulatory performance and erectile capability, as judged by noncontact erections (Liu et al., 1997).

2.7.2.3 Touch-Based Erections Although reflexive touch-based erections can be elicited in dogs (Hart, 1967; Beach, 1984), penile erection is inhibited by tactile stimulation of the penis in rats (Hart, 1968b). However, erections can be elicited in a male rat, restrained on his back, with the penile sheath retracted, exposing the glans penis. A series of erections typically ensue, usually accompanied by penile anteroflexions (previously called "flips"). Three gradations of glans erection can be observed—in the first, the penile body elongates and rises; in the second, the glans is engorged and slightly flared; and in the third, the glans flares into a cup. The cup is used during copulation to hold the ejaculated semen around the female's cervix, where it coagulates to form a copulatory plug. Without this plug, the semen can seep out of the vagina, greatly impairing fertility (Sachs, 1982). The sensory stimulus responsible for these erections may be the continuing pressure of the sheath around the base of the penis. Ex copula seminal emission occasionally occurs in this context.

2.7.2.4 Urethrogenital Reflex Sexual reflexes can be studied in anesthetized, spinally transected male and female rats, using urethral distension or stimulation of the dorsal nerve of the penis (McKenna et al., 1991). In male rats, the urethrogenital reflex comprises clonic contractions of the perineal muscles, rhythmic firing of the cavernous nerve, penile erections, and ejaculation. Therefore, the urethrogenital reflex is used as a model for both erection and ejaculatory reflexes.

3 Neurotransmitters and Neuromodulators

3.1 General Considerations

Steroid hormones regulate sexual behavior primarily through slow, genomically mediated processes. However, sexual behavior requires rapid processing of sensory input and motor output to produce intricate moment-to-moment interactions with a partner. Therefore, the slow hormonal effects must be translated into rapid neuronal responses. A major effect of hormones is to bias sensory inputs to favor sexually relevant stimuli and to prime central integrative areas and appropriate motor outputs to orchestrate integrated sexual responses. Major targets of steroid hormones are enzymes that synthesize (or catabolize) neurotransmitters or neuromodulators, mechanisms that regulate neurotransmitter release, neurotransmitter receptors, or second messenger systems. Drugs that influence one or more of these targets may be used to study the influence of a neurotransmitter on behavior. Because no drug is entirely specific for its major effect, it is important to block the effects of an agonist with a relevant antagonist or to administer a drug of a different class that targets the same receptor or enzyme.

There are advantages to systemic or intracerebroventricular (icv) drug administration. First, the brain areas in which a given neurotransmitter influences a behavior may not be known a priori. Second, a given neurotransmitter may act synergistically in several central and/or peripheral sites. Finally, drugs being developed for possible clinical use must be effective with systemic administration. However, drugs may also have competing effects at multiple sites. Therefore, studies employing both systemic and site-directed routes of administration should be used to fully explore a drug's effects on behavior.

3.2 Specific Neurotransmitters

3.2.1 Dopamine

3.2.1.1 Effects of Systemically or Intraventricularly Administered Drugs The catecholamines DA, norepinephrine (NE), and epinephrine are formed from the amino acid tyrosine; tyrosine hydroxylase, the rate-limiting enzyme, produces L-DOPA, which in turn is decarboxylated by aromatic amino acid decarboxylase to form DA. In noradrenergic neurons, dopamine β-hydroxylase converts DA to NE. In a few neurons, NE can be converted to epinephrine by phenylethanolamine *N*-methyl transferase. Two major groups of dopamine-containing cells are the A9 group in the substantia nigra of the midbrain and the A10 group in the adjacent ventral tegmental area (VTA). A9 axons ascend to the caudate-putamen (dorsal striatum) via the nigrostriatal tract, and A10 axons ascend via the mesocorticolimbic tract to the nucleus accumbens (ventral striatum), prefrontal cortex, and other limbic structures (reviewed in Fallon, 1986). There are several dopaminergic cell groups in the hypothalamus, including the A14 periventricular group, which lies along the third ventricle and sends axons laterally into the adjacent MPOA and anterior hypothalamus (reviewed in Moore and Lookingland, 1995).

As long ago as the late 1960s, DA was reported to facilitate sexual function. L-DOPA administered to Parkinsonian patients often increased libido and sexual potency (Barbeau, 1969; Bowers et al., 1971), and the classic DA agonist apomorphine has more recently been used to treat erectile dysfunction (Lal et al., 1984, 1987; O'Sullivan and Hughes, 1998). A sublingual form of apomorphine appears to be clinically effective, with fewer side effects (Dula et al., 2000; reviewed in Padma-Nathan and Giuliano, 2001; Giuliano and Allard, 2002).

In rodents, systemic administration of DA agonists facilitates male sexual behavior (reviewed in (Bitran and Hull, 1987; Melis and Argiolas, 1995; Giuliano and Allard, 2001). L-DOPA and/or apomorphine elicited copulation in sexually sluggish males and increased the numbers, while decreasing the latencies, of ejaculations. Apomorphine also elicited copulation in sexually satiated male rats (Mas et al., 1995b; Rodriguez-Manzo, 1999) and in socially stressed mice (Sugiura et al., 1997) and rats (Niikura et al., 2002). DA releasers decreased mount and intromission latencies in male rats that were sexually sluggish because of damage to the medial frontal cortex (Ågmo and Villalpando, 1995). Systemically administered apomorphine partially restored copulation in short-term (Malmnas, 1976) and long-term (Scaletta and Hull, 1990) castrated rats. Apomorphine also elicited copulation in mice lacking the gene for estrogen receptor alpha (ERα); such mice usually show little sexual behavior (Wersinger and Rissman, 2000). Therefore, stimulation of DA receptors appears to bypass the usual requirement for the organizational and activational effects of ERα, at least in some animals. Apomorphine also elicited ex copula penile erections in mice (Rampin et al., 2003). This effect was blocked by the DA antagonist haloperidol, which crosses the blood–brain barrier, but not by domperidone, which does not. In hamsters, apomorphine produced only slight decreases in ejaculation latency and postejaculatory interval; however, it also abolished long intromissions (a sign of approaching sexual satiety) in 60% of the animals (Arteaga et al., 2002). The effects of systemically administered dopamine agonists are typically dose-dependent; low doses facilitate, but high doses inhibit copulation, at least in part by eliciting stereotypic behaviors (Foreman and Hall, 1987).

Daily injections of amphetamine in sexually naïve male rats facilitated copulation on their first sexual behavior test (Fiorino and Phillips, 1999). Similar injections of amphetamine resulted in sensitization of locomotor responsiveness to amphetamine. Therefore, the (presumably dopaminergic) mechanisms that produce drug sensitization apparently "cross-sensitize" to a natural motivated behavior. Similar mechanisms may underlie the enhanced copulatory ability of sexually experienced animals and their resistance to various surgical and environmental insults.

The consistent facilitative effects of DA agonists suggest that DA antagonists, which block the effects of endogenous DA, would impair sexual behavior. As expected, copulation by both experienced (Ahlenius and Larsson, 1984a; Ågmo and Fernandez, 1989; Pfaus and Phillips, 1989; Ahlenius and Larsson, 1990) and inexperienced (Ågmo and Picker, 1990) male rats was impaired by systemically administered DA antagonists. These inhibitory effects ranged from failure to copulate to increased intromission and ejaculation

latencies. Touch-based erections were also decreased by haloperidol, which crosses the blood–brain barrier, but not by domperidone, which does not (Pehek et al., 1988a). Mild tail pinch can sometimes induce sexually sluggish males to copulate. The facilitative effects of tail pinch were blocked by both a DA and an opioid antagonist in sexually sluggish castrates maintained on a suboptimal testosterone regimen (Leyton and Stewart, 1996). Therefore, tail pinch may have activated copulation by increasing the activity of midbrain DA systems via an opioid mechanism. On subsequent days when tail pinch was no longer applied, the facilitation was still observed, suggesting that any temporary increases in motor activity did not explain the increased responsiveness.

A DA antagonist has also inhibited sexual motivation. Sexually naïve male rats received ten daily trials on which they ran down a runway to be near an estrous or a nonestrous female on different days (Lopez and Ettenberg, 2000). They then received either vehicle or one of three doses of haloperidol before being allowed to copulate to one ejaculation; the drug did not significantly affect any copulatory measure. Two days later, animals previously treated with vehicle ran faster after sexual experience than before and ran faster for the estrous than for the nonestrous female. Males that had received the low and moderate doses of haloperidol showed no change in running speed after the sexual experience and showed no preference for the estrous over the nonestrous female. Males that had received the highest dose ran more slowly after sexual experience than before and did not prefer the estrous female. They also showed more retreats as they approached the goalbox, suggesting that it was aversive. The drug effects on motivation do not appear to be confounded with motoric side effects. First, the runway test occurred 2 days after the drug was given, which should have allowed sufficient time for the drug to be metabolized before that test. Second, the drug did not significantly affect copulation on the experience day, and all males ejaculated. Thus, the experience-induced enhancement of sexual motivation was blocked by a systemically administered DA antagonist.

A similar experiment from the same lab provided additional support for dopaminergic influence on sexual motivation. Sexually naïve males were first exposed for 4 min to an estrous female, a nonestrous female, or an empty goal box, through a perforated barrier (Lopez and Ettenberg, 2001). They then received one of two doses of haloperidol or vehicle before traversing the runway. The drug did not affect run times to the nonestrous female or the empty goal box, suggesting that motoric ability was not impaired. However, the drug slowed run times to the estrous female, compared to vehicle-treated animals, and resulted in similar run times to all three targets.

Two additional experiments from that lab tested sexual motivation using conditioned olfactory stimuli (Lopez and Ettenberg, 2002b). Males had five copulatory experiences in the presence of either orange or almond odor and experienced the other odor when alone for a similar amount of time. After the 10 days of conditioning, all males had faster run times to the goal box scented with the odor that had been associated with copulation. An additional group of males was subjected to the same conditioning protocol, but received one of three doses of haloperidol or vehicle before the final runway test. As expected, animals receiving vehicle injections showed an increase in running speed to the odor associated with copulation and a decrease in running speed to the control odor. There were no differences in run times to the two odors in animals treated with the low and middle doses of haloperidol and no changes relative to their baselines. The highest dose of haloperidol slowed running to both odors, suggesting an impairment of motor ability. However, the selective inhibition of the conditioned preference by the two lower doses, without slowing running, compared with baseline, suggests that a DA antagonist can inhibit motivational processes independently of motor impairment. One study did report a lack of effect of dopaminergic drugs on a measure of sexual motivation in sexually inexperienced male rats (Ågmo, 2003). In that experiment, the DA agonists apomorphine and amphetamine did not affect the amount of time spent in front of a receptive female behind a barrier. In addition, only a high dose of the DA antagonist *cis*-flupenthixol, which also slowed motor behavior, decreased this measure. However, it is not clear that motoric effects explained the apparent decrease in motivation by the high dose, because, as the author noted, no more motor activity was required to stand in front of the estrous female than in front of the male.

Mice with a deletion of the gene for tyrosine hydroxylase only in dopamine-, and not in norepinephrine-containing neurons, required daily injections of L-DOPA in order to survive (Szczypka et al., 1998). After their daily L-DOPA injections, the DA-deficient males mounted estrous females, as well as other males

and nonestrous females. Following castration, they continued to mount receptive females for 21 days, whereas wild-type castrates mounted for only 7 days. In addition, DA-deficient castrates were more sensitive to both L-DOPA and testosterone than were wild-type castrates, in that lower doses of each were sufficient to restore copulation. The authors suggested that DA receptors might have been coupled to second messenger systems more efficiently in the DA-deficient animals.

DA receptors are divided into two families. The D_1 family consists of D_1 and D_5 receptors, whereas the D_2 family comprises D_2, D_3, and D_4 receptors. The D_1 family members stimulate adenylyl cyclase, whereas the D_2-like receptors inhibit adenylyl cyclase and influence certain ion channels and the phosphoinositide pathway. DA and apomorphine stimulate both D_1 and D_2 families; however, drugs that are relatively selective for members of one family have been used to analyze the roles of the two subtypes in various aspects of copulation.

There is evidence for a facilitative role of D_2-like receptors in the control of ejaculation. Ejaculation latencies and the numbers of intromissions preceding ejaculation were decreased by a D_3-selective agonist (7-OH-DPAT) and two D_2/D_3 agonists (SND 919 and B-HT 920); however, this effect was observed only in sexually active male rats, not in sexually inactive animals (Ferrari and Giuliani, 1995, 1996a; Giuliani and Ferrari, 1996). The pro-ejaculatory effects of 7-OH-DPAT (Ahlenius and Larsson, 1995) and of SND 919 (Ferrari and Giuliani, 1994) were blocked by a D_2/D_3 antagonist (eticlopride), confirming their receptor specificity. However, the muscarinic antagonist atropine also inhibited the effects of both a dopaminergic agonist and a muscarinic agonist (Zarrindast et al., 1994), suggesting that cholinergic muscarinic receptors may contribute to the pro-ejaculatory effects of D_2-like agonists. The D_1 agonist SKF 81292 facilitated copulatory ability in the DA-deficient mice mentioned earlier, but the D_2 agonist quinpirole inhibited their copulation by increasing stereotypic behavior (Szczypka et al., 1998). A different D_1 agonist, SKF 38393, also increased sexual motivation, measured as the time spent in a goal compartment with a receptive female (Beck et al., 2002). This effect reflected an increase in the number of copulatory behaviors while in the female's compartment. Neither the latency to run to the female nor the run duration was affected, suggesting that the effect on sexual motivation was independent of any motor confounds. The D_5 receptor is a member of the D_1-like receptor family. Mice with deletion of the D_5 receptor (D5KO) showed a place preference when ejaculation was paired with the experimental context, but not when intromissions alone were paired with the context (Kudwa et al., 2005). Wild-type (WT) males showed a preference for the context paired with either intromissions alone or ejaculation. Therefore, D_5 receptors may contribute to the rewarding aspects of intromission.

Some of the reported effects of D_1- and D_2-like agonists on ex copula genital reflexes appear to be contradictory. A presumed-selective D_2 agonist in one series of experiments elicited erections in a neutral arena, whereas a D_1 agonist inhibited those erections (Zarrindast et al., 1992). However, the D_2/D_3 antagonist eticlopride, administered with either cocaine or presumed-selective D_2 agonists, actually increased the number of drug-induced erections, suggesting that stimulation of D_2-like receptors inhibits, rather than stimulates, erections (Ferrari and Giuliani, 1996b). Cocaine increases extracellular levels of DA by inhibiting reuptake, which results in stimulation of both D_1- and D_2-like receptors. It seems likely that the presumed-selective D_2-like agonists also stimulated substantial activity at D_1 receptors. Stimulation of D_2-like receptors also inhibits touch-based erections in restrained male rats. Either systemic or intra-medial preoptic area administration of the D_2/D_3 agonist quinelorane decreased touch-based erections (Bitran et al., 1989). As is discussed later, intense stimulation of D_2-like receptors in the MPOA apparently shifts autonomic influence to favor sympathetically mediated seminal emission and ejaculation, and to inhibit parasympathetically mediated erection. However, the selective D_2/D_3 agonists 7-OH-DPAT and B-HT 920 evoked erections in sexually naïve male rats, tested in a neutral arena, and also elicited stretching, yawning, and sedation (Ferrari et al., 2002). Similarly, the D_4 agonist ABT-724 elicited erections in rats; its effects were blocked by the primarily D_2 agonist haloperidol and the primarily D_4 agonist clozapine, but not by domperidone, which does not cross the blood–brain barrier (Brioni et al., 2004). It is not clear whether these divergent findings resulted from different dose ranges or different test regimens (touch-based erections vs. drug-induced erections in a neutral arena).

The facilitative effects of D_1 stimulation appear to be evolutionarily conserved. A D_1 agonist (SKF 81297) systemically administered to two species of lizards (little striped whiptail lizards and

parthenogenetic desert grassland lizards) increased the proportion of animals that mated after gonadectomy and decreased mount latencies (Woolley et al., 2001). Conversely, a DA receptor antagonist inhibited courtship behavior in castrated, testosterone-implanted leopard geckos (reviewed in Woolley et al., 2004). Similarly, a D_1 agonist (SKF 38393) in quail increased both appetitive (the amount of time near a window through which a female could be seen) and copulatory behaviors (the numbers of mount attempts and of cloacal contact movements) (Balthazart et al., 1997). Conversely, the D_1 antagonist SCH 23390 decreased the numbers of approaches to the female's window and mount attempts. D_2-selective drugs yielded generally opposite results—the D_2 agonist quinpirole decreased both appetitive and copulatory behaviors, and the D_2 antagonist spiperone increased mount attempts but decreased approaches to the window. Somewhat earlier research from the same lab found that the classic DA agonist apomorphine inhibited both appetitive and copulatory behaviors, apparently by stimulating primarily D_2 receptors (Castagna et al., 1997). Intense stereotyped pecking elicited by the two higher doses of apomorphine could explain their inhibition of sexual behavior; however, the lowest dose also inhibited sexual behavior but did not significantly increase pecking. The indirect DA agonists nomifensine (which inhibits reuptake) and amfonelic acid (which primarily increases release) yielded mixed facilitative and inhibitory effects. Two recent articles from the same lab reported inhibition of sexual behavior by intraventricular injections of DA itself and suggested that the inhibitory effects were mediated by DA acting at α-2 noradrenergic receptors, rather than DA receptors (Cornil et al., 2004, 2005). However, the problem of cross-reactivity with α-2 receptors was probably avoided in the earlier studies, which used selective DA agonists and antagonists.

In summary, convergent data support the suggestion that systemically administered DA agonists facilitate multiple aspects of male sexual behavior in most species, including sexual motivation, genital reflexes, and copulatory behavior, and that DA antagonists produce the opposite pattern of results. DA agonists have restored sexual behavior in stressed or sexually satiated males, in castrates, in males with lesions of the prefrontal cortex, in males lacking ERα, and in DA-deficient males. DA agonists have also facilitated ex copula erections, although the relative importance of D_1 and D_2 families of receptors for ex copula erections is unclear. Conversely, DA antagonists have impaired both conditioned and unconditioned sexual motivation, often without confounding motor effects, have inhibited genital reflexes, and have decreased the incidence, rate, and efficiency of copulation. There is also conservation of D_1-like receptors' facilitative effects in reptiles, birds, and mammals.

A critical review recently suggested that DA has no role in sexual motivation because some of the studies reporting inhibitory effects of DA antagonists either measured approach to a female, which can confound motor and motivational factors, or studied sexually experienced males (Paredes and Ågmo, 2004). However, several of the studies that measured approach to a female specifically ruled out motor effects. Furthermore, the motivation of experienced males is nevertheless motivation and should be studied. DA antagonists have inhibited both the initial conditioning and the later expression of the enhanced motivation, without confounding motoric effects. Although no procedure has been devised to measure motivation selectively, without any possible sensory, learning, or motoric confounds, the preponderance of evidence supports the suggestion that DA contributes to sexual motivation, as well as to genital reflexes and copulatory performance.

3.2.1.2 Role of DA in Specific Brain Areas *Medial Preoptic Area.* The MPOA is a major integrative site for male sexual behavior. It has reciprocal connections with virtually all sensory modalities, allowing it to modify the processing of its sensory inputs (Simerly and Swanson, 1986). Both the MPOA and its afferent connections contain steroid receptors, which may bias inputs to favor sexually relevant stimuli. It has efferent connections to hypothalamic, midbrain, and brain stem areas that control autonomic or somatomotor patterns and motivational processes. Dopaminergic drugs microinjected into the MPOA influence copulation, genital reflexes, and sexual motivation. Dopamine innervation is from the periventricular system, whose cell bodies lie along the third ventricle and send widely branching axons laterally into the MPOA and anterior hypothalamus (reviewed in Moore and Lookingland, 1995).

Effects of drug microinjections into the MPOA. Microinjections of the classic D_1/D_2 agonist apomorphine into the MPOA facilitated copulation in intact male rats (Hull et al., 1986) and in long-term castrates (Scaletta and Hull, 1990), and increased the numbers of touch-based erections and seminal emissions

(Pehek et al., 1989a). Similarly, administration of the DA reuptake inhibitor bupropion into the MPOA by reverse dialysis increased both touch-based and noncontact erections (Adachi et al., 2003). Conversely, copulation was impaired by the D_1/D_2 antagonist *cis*-flupenthixol microinjected into the MPOA (Warner et al., 1991); *cis*-flupenthixol also decreased touch-based genital reflexes (Pehek et al., 1988b) and decreased the number of choices of a female in an X-maze, without affecting running speed or the number of no-choice trials (Warner et al., 1991). There was site specificity for the effects of both apomorphine and *cis*-flupenthixol, with microinjections anterior, dorsal, or lateral to the MPOA being ineffective. There was also behavioral specificity, with no effect of apomorphine or *cis*-flupenthixol on eating, drinking, locomotion, or rearing in the home cage, although flupenthixol slightly increased duration of inactivity (Warner et al., 1991). A different DA antagonist, haloperidol, increased intromission latency and decreased the number of ejaculations in a bilevel apparatus, although motoric slowing may have contributed to these deficits (Pfaus and Phillips, 1991). More recently, MPOA microinjections of apomorphine fully restored the ability to copulate in males whose sexual behavior was severely impaired by large excitotoxic lesions of the amygdala, which provides a major input to the MPOA (Dominguez et al., 2001). There were also trends toward apomorphine-induced increases in numbers of intromissions and ejaculations in sham animals. Therefore, a major consequence of amygdala lesions may be impaired DA activity in the MPOA.

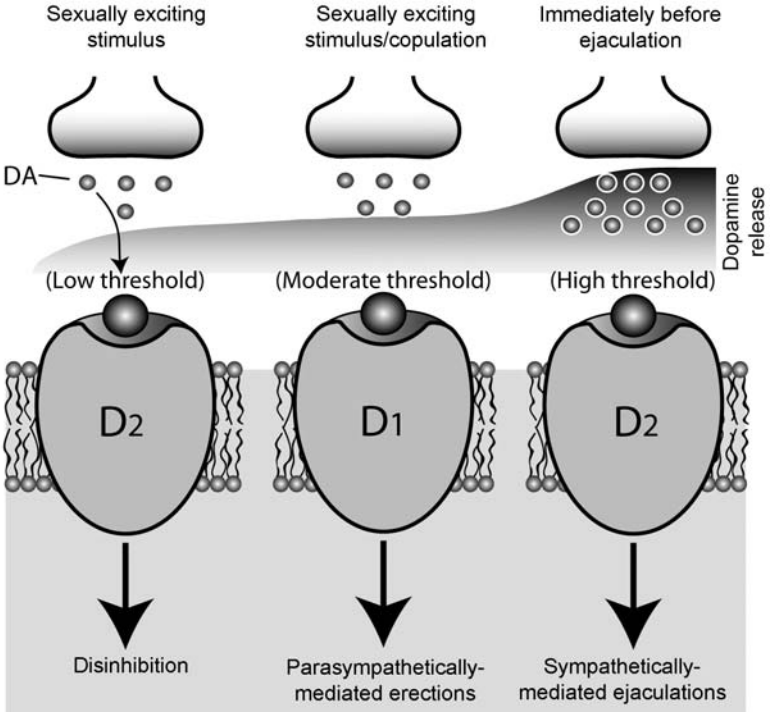
6-OHDA neurotoxic lesions of MPOA DA neurons impaired copulation only during the first 24 h after the lesion (Bazzett et al., 1992) or if a subthreshold dose of a DA synthesis inhibitor was administered before testing (Bitran et al., 1988a). The lesions produced only a 23% depletion of DA, probably because of the sparse DA transporters in the MPOA, which are needed to transport the toxin into the axon terminals. Therefore, increased DA synthesis occurred in the remaining neurons during the first 24 h postlesion and was able to restore copulation to normal. This effect was specific for DA, because the 6-OHDA was coadministered with an NE transporter inhibitor, desipramine, and NE levels were not affected.

As with systemic injections, MPOA microinjections of a D_1 agonist facilitated copulation and touch-based erections, whereas stimulation of D_2 receptors yielded biphasic effects (See *Figure 2-1*). A low dose of quinelorane, a D_2/D_3 agonist, decreased the latency to the first touch-based genital reflex, without affecting the numbers of erections, anteroflexions, or seminal emissions (Bazzett et al., 1991). Therefore, a small increase in dopaminergic stimulation may disinhibit reflexes via D_2-like receptors. However, a high dose of quinelorane, or of the D_1 antagonist SCH-23390, decreased the number of erections but increased the number of seminal emissions. Thus, intense stimulation of D_2-like receptors or antagonism of D_1-like receptors appears to increase sympathetic facilitation of seminal emission, while decreasing parasympathetic stimulation of erection. Conversely, the D_1 full agonist tetrahydrothienopyridine (THP) increased touch-based erections but inhibited seminal emission (Markowski et al., 1994). The D_1 partial agonist SKF 38393 was ineffective (unpublished observations). The suggestion that D_1 and D_2 receptors have opposing effects on autonomic function is supported by experiments using low and high doses of apomorphine, together with D_1 and D_2 antagonists. The low dose of apomorphine (1 μg) increased touch-based erections, but not seminal emissions; this effect was blocked by both D_1 (SCH-23390) and D_2 (raclopride) antagonists (Hull et al., 1992). These data suggest that both disinhibition by D_2 receptors and facilitation by D_1 receptors contributed to apomorphine's increase. Unexpectedly, a high dose (10 μg) of apomorphine did not increase erections significantly; however, coadministration of the high dose with a D_2 antagonist unmasked the facilitative effects mediated by D_1 receptors. The high dose of apomorphine did increase seminal emissions, and that effect was blocked by a high dose of the D_2 antagonist, but not by the D_1 antagonist.

The association of erections with D_1 receptor stimulation in the MPOA and of ejaculation with intense D_2 stimulation was supported in copulation tests. Microinjections of the D_1 agonist THP into the MPOA increased copulatory efficiency, resulting in more ejaculations in the 30-min test (Markowski et al., 1994). Conversely, microinjection of the D_1 antagonist SCH-23390 increased intromission latencies but decreased the threshold for ejaculation (Hull et al., 1989). It also decreased sexual motivation, measured as the choice of the female in an X-maze, without impairing motoric activity (Moses et al., 1995). A high dose of the D_2/D_3 agonist quinelorane in the MPOA also increased intromission latency and decreased ejaculation threshold (Hull et al., 1989; Moses et al., 1995). It did not affect the percentage of X-maze trials on which the male chose the female's goal box, but it did increase the latency to reach the female's goal box (Moses et al., 1995). However, this delay did not result from slowed motor function, but rather from apparent reluctance

Figure 2-1

Model showing possible effects of D_1 versus D_2 stimulation in the MPOA, as a result of a sexually exciting stimulus and/or sexual activity (reviewed in Dominguez and Hull, 2005). In this model, a low-threshold mechanism mediated by D_2 receptors disinhibits genital reflexes. A moderate threshold mechanism facilitates penile erections, via activation of D_1 receptors. A high threshold mechanism, activated by intense stimulation of D_2 receptors, facilitates seminal emissions and inhibits erections. These mechanisms may be activated successively by increasing levels or duration of DA activity (figure is from Dominguez and Hull, 2005, with permission)



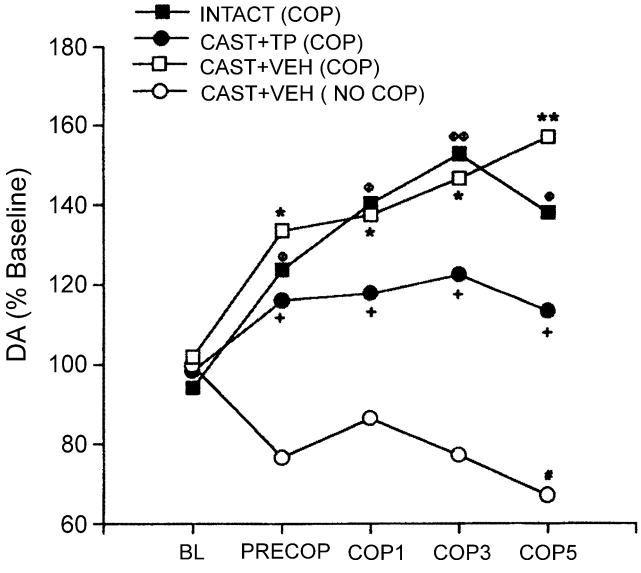
to cross the line in front of the female's compartment, beyond which the male would be placed into that compartment. In summary, D_1 and D_2 receptors in the MPOA appear to exert opposing effects on copulation and genital reflexes. Stimulation of D_1 receptors facilitates parasympathetically mediated erections and copulatory performance, whereas intense activation of D_2 receptors promotes sympathetically mediated ejaculation (See *Figure 2-1*).

Intra- and extracellular recordings in slice preparations from the MPOA of Japanese quail showed that bath applications of DA inhibited most cells (52–80%), but excited a few (10–24%). Neither D_1 nor D_2 antagonists blocked these effects; however, they were blocked by α_1 or α_2 antagonists, respectively (Cornil et al., 2002). However, DA was not being converted to NE to produce the effects, as dopamine-β-hydroxylase inhibitors did not block DA's effects. Therefore, in the quail MPOA DA affects neuronal activity via cross talk with NE receptors.

Chemical changes detected by microdialysis or from tissue punches. There is a close correlation between extracellular MPOA DA levels and sexual behavior in male rats. DA levels increased as soon as an estrous female was introduced across a perforated barrier; DA levels remained high or increased further, when the female was placed into the male's compartment and the animals were allowed to copulate (Hull et al., 1995; Sato et al., 1995) (See *Figure 2-2*). The recent presence of T is required for both the DA response to the

Figure 2-2

Levels of extracellular DA in the MPOA of male rats during baseline (BL), a 6-min precopulatory exposure to an estrous female (PRECOP), and three 6-min copulation samples (COP). Gonadally intact male rats showed an increase in extracellular DA during precopulatory exposure to an inaccessible estrous female, and all intact males copulated; males castrated 2 weeks before showed no DA release in response to the female, and none copulated. Values are expressed as mean ± SEM, *P < 0.05, compared to final baseline for intact males or for one-week vehicle-treated castrates that copulated; **P < 0.01, compared to final baseline for intact males or for one-week vehicle-treated castrates that copulated; +P < 0.05, compared to baseline for testosterone-treated castrates; #P < 0.05, compared to final baseline for vehicle-treated castrates that failed to copulate (figure is from Hull et al., 1995, with permission)



female and the ability to copulate. All gonadally intact males, as well as two-thirds of males castrated one week before the test, showed a precopulatory increase in DA and copulated when the female was placed with the male (Hull et al., 1995) (See *Figure 2-2*). The remaining third of the 1-week castrates, and all 2-week castrates failed to show the DA response to the female and failed to copulate. There was behavioral specificity, in that neither presentation of a male behind the barrier nor voluntary exercise in a running wheel increased DA levels (Hull et al., 1995); in addition, eating a palatable food did not increase levels of the DA metabolite DOPAC in an earlier study (Hull et al., 1993). There was also site specificity, in that no DA response to the female was observed in probes anterior or lateral to the MPOA. Because the increase in DA occurred before copulation began, it is evident that the increase was not caused by copulation, but was more likely associated with sexual motivation.

In the earlier studies described above, basal levels of extracellular DA were not measured; therefore, it was unclear whether castration also affected basal levels or only the response to a female. Subsequently, the no-net-flux technique was used to measure basal DA levels in castrates and in gonadally intact males (Du et al., 1998). In this technique, known amounts of DA are added to the dialysate; if there is more DA in the dialysate than in the brain, some of it will diffuse out of the dialysate into the brain, and the loss can be detected (Olson and Justice, 1993). Conversely, if there is less DA in the dialysate, or none, as in standard dialysis, DA will diffuse into the dialysate from the brain, and the gain can be detected. A regression line is drawn, and the point at which it crosses from loss to gain in the dialysate represents the basal extracellular DA level. In castrates, the basal extracellular DA levels were only about one-fourth those

of gonadally intact males (0.3 vs. 1.3 nM) (Du et al., 1998). Therefore, the deficit in extracellular DA in castrates was a general one, not only a lack of response to a female. However, systemic injections of amphetamine evoked greater DA release in castrates than in intact males, and tissue punches from castrates contained more DA than did those from intact males (Du et al., 1998). Therefore, DA synthesis and storage were at least as great in castrates as in intact males, but castrates were unable to release their abundant stores.

Further evidence of a correlation between DA release and the copulatory ability of castrates was provided by a study of restoration with 2-, 5-, or 10-day regimens of testosterone treatment (Putnam et al., 2001). None of the 2-day testosterone-treated castrates showed a DA response to the female, and none was able to copulate. Eight of nine 5-day testosterone-treated castrates showed a DA response and those eight were able to copulate, with five also able to ejaculate. All of the 10-day testosterone-treated castrates showed a precopulatory DA response, and all copulated. There were numerous correlations between DA levels and copulatory measures. Therefore, both postcastration loss of copulation and its restoration following testosterone replacement were closely correlated with female-elicited DA release in the MPOA.

Testosterone is primarily a prohormone, which is converted to either estradiol or dihydrotestosterone in target tissues. Its metabolites were differentially effective in restoring basal and female-stimulated DA release, as well as copulation, in long-term castrates (Putnam et al., 2003). Daily injections of estradiol restored high basal levels of DA, but not the increase in response to a female. All estradiol-treated males intromitted, but none showed a behavioral ejaculation pattern. Castrates treated with dihydrotestosterone or oil vehicle had very low basal DA levels and did not show a female-stimulated increase; no dihydrotestosterone- or oil-treated castrate copulated. Although dihydrotestosterone was ineffective by itself, when it was administered with estradiol, the combination restored basal and female-stimulated DA responses, as well as copulation.

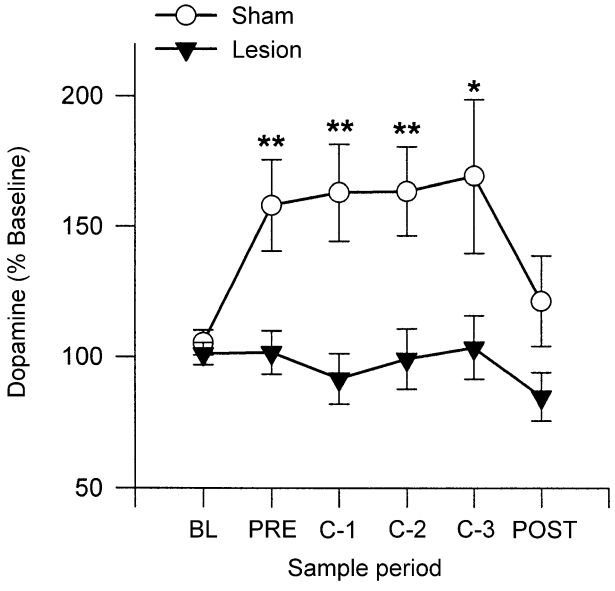
Although copulatory measures were positively correlated with extracellular DA levels, copulation was negatively associated with tissue (stored) DA levels (Putnam et al., 2005). Dihydrotestosterone- and oil-treated animals could synthesize and store DA, but had impaired release in basal conditions and in response to a female. An important factor regulating DA release in the MPOA is nitric oxide (NO). Both basal (Lorrain and Hull, 1993) and copulation-induced (Lorrain et al., 1996) DA release in the MPOA depended, in part, on NO. In addition, immunoreactivity for nitric oxide synthase (NOS-ir) in the medial preoptic nucleus is positively regulated by testosterone and estradiol (Hadeishi and Wood, 1996; Ceccatelli et al., 1996; Du and Hull, 1999; Scordalakes et al., 2002; Putnam et al., 2005) (but see Singh et al., 2000). A deficiency in NO may have led to the impaired DA release in the dihydrotestosterone- and oil-treated castrates described earlier. Those groups had less NOS-ir than did the three groups that were able to copulate (estradiol, estradiol+dihydrotestosterone, and testosterone) (Putnam et al., 2005). Therefore, testosterone may maintain both basal and female-stimulated DA release by upregulating NOS in the MPOA.

The major input that directly stimulates MPOA DA release in response to a female is from the medial amygdala, which in turn receives input from both the main olfactory and vomeronasal systems, as well as genitosensory information. Chemical stimulation of the medial amygdala increased DA release in the MPOA (Dominguez and Hull, 2001), and microinjection of the DA agonist apomorphine into the MPOA restored copulatory ability that had been severely impaired by amygdala lesions (Dominguez et al., 2001). Basal DA levels in the MPOA were normal in males with small radio-frequency lesions of the medial amygdala, but there was no DA increase in response to an estrous female or during copulation (Dominguez et al., 2001) (See *Figure 2-3*). In addition, males with lesions achieved only half the number of ejaculations in a 30-min test as did sham lesion animals. Therefore, as with estradiol treatment of castrates (Putnam et al., 2003), normal basal levels of MPOA DA were sufficient for suboptimal copulation. However, an increase in DA before and during copulation appears to contribute to copulatory ability. There are no DA-containing neurons in the medial amygdala of rats; therefore, amygdala efferents apparently synapse, directly or indirectly, on dopaminergic cell bodies or terminals in the MPOA.

The signal relayed by the amygdala to the MPOA apparently arises from the olfactory bulbs. Male hamsters with either sham bulbectomy or unilateral bulbectomy contralateral to the MPOA microdialysis site showed increases in extracellular DA in the MPOA when presented with an estrous female (Triemstra

Figure 2-3

Lesions of the MeA inhibit the release of DA in the MPOA resulting from exposure to an estrous female and copulation. Levels represent percent changes from baseline (BL) in response to precopulatory exposure to an estrous female (PRE), during copulation (C1–C3), and after the female was removed (POST). Extracellular levels of DA significantly increased during the precopulatory and copulatory stages of testing for animals with sham lesions but not for animals with MeA lesions. The baseline value used for computation was obtained by dividing the value of the last baseline by the mean of all three baselines. Values are expressed as mean ± SEM, *P < 0.05; **P < 0.01 (figure is from Dominguez et al., 2001, with permission)



et al., 2005). However, either bilateral or ipsilateral bulbectomy blocked the DA response and impaired copulatory behavior, similar to the results obtained by Dominguez et al. (2001). In another study of sexually mature male hamsters, pheromones from estrous females elicited an apparent increase in DA release, inferred from an increase in the DA metabolite DOPAC, in tissue punches from the MPOA, suggesting release of DA and subsequent uptake and metabolism (Schultz et al., 2003). Juveniles showed no such increase and were unable to copulate. Therefore, a maturational process rendered the processing of sensory stimuli effective in postpubertal males.

Immunocytochemistry. Copulation to one ejaculation elicited more Fos immunoreactivity (Fos-ir) in the medial preoptic nucleus of sexually experienced males than in naïve males, even though the experienced males had fewer intromissions before ejaculating (Lumley and Hull, 1999). The increased Fos-ir was inhibited by systemic injection of a D_1 antagonist in the naïve males, but not in experienced animals. This suggests that D_1 receptors may contribute to in the enhanced processing of sexual stimuli in the MPOA that results from sexual experience.

In summary, DA is released in the MPOA as soon as a male rat detects the presence of an estrous female, and it may increase further during copulation. Both basal and female-stimulated DA release depends on testosterone or estradiol, which in turn increases NOS. The signal that a female is present is conveyed by the medial amygdala. Normal basal levels of MPOA DA are sufficient for suboptimal copulation, but the increase in response to a female is associated with enhanced copulatory ability. Microinjection data show that stimulation of DA receptors in the MPOA facilitates several measures of sexual behavior, including sexual motivation, genital reflexes, and copulation.

Paraventricular Nucleus of the Hypothalamus. The paraventricular nucleus (PVN) is an important integrative site for autonomic and neuroendocrine functions. It consists of a parvocellular division,

which projects to several brain areas and the spinal cord, and a magnocellular division, which releases oxytocin and vasopressin from the posterior pituitary (reviewed in Swanson and Sawchenko, 1980). The parvocellular division receives input from the MPOA and from periventricular DA neurons.

Effects of drug microinjections into the PVN. Drug-induced erections were elicited by microinjection of the DA agonist apomorphine (Melis et al., 1987), the D_2 agonist quinpirole, or oxytocin (Argiolas et al., 1987) into the PVN; these effects were blocked by icv microinjections of an oxytocin antagonist (Melis et al., 1989). Microinjections of apomorphine (Pehek et al., 1989a) or the D_2/D_3 agonist quinelorane (Eaton et al., 1991) into the PVN also increased the numbers of touch-based erections and ex copula seminal emissions. Furthermore, PVN apomorphine increased intracavernous pressure in anesthetized rats; that increase was enhanced by systemic administration of the monoamine oxidase B inhibitor, selegiline (Allard et al., 2002), which would have decreased degradation of DA. In summary, stimulation of PVN D_2 receptors apparently increases oxytocin release, which then promotes drug-induced and noncontact erections (reviewed in Argiolas and Melis, 1995, 2004).

Chemical changes detected by microdialysis or voltammetry. Extracellular DA levels increased in the PVN during display of noncontact erections by male rats; PVN DA levels increased even more during copulation (Melis et al., 2003).

Mesocorticolimbic DA Tract. DA-containing cell bodies in the VTA give rise to axons of the mesocorticolimbic DA tract that innervate the nucleus accumbens (NAc), prefrontal cortex, and other forebrain regions (Domesick, 1988). This system is activated before and/or during a number of motivated behaviors, including eating, drinking, sexual activity, drug self-administration, and intracranial self-stimulation (Ikemoto and Panksepp, 1999; Kiyatkin, 2002). There is disagreement about whether this system is more important for reward (Wise and Bozarth, 1984), behavioral activation (Koob, 1992; Wilson et al., 1995; Salamone and Correa, 2002), "wanting" [as opposed to "liking" (Kelley and Berridge, 2002)], or incentive learning (Di Chiara, 1995; Spanagel and Weiss, 1999). However, it clearly is necessary for appetitive behaviors.

Effects of drug microinjections into the VTA or NAc. Stimulation of autoreceptors in the VTA with apomorphine delayed the onset and slowed the rate of copulation (Hull et al., 1990). Similar microinjections slowed running speed in all four arms of an X-maze and increased the number of trials on which the male did not leave the start area; however, the percentage of trials on which the male chose the female's goal box was not affected, nor were ex copula genital reflexes (Hull et al., 1991). Therefore, inhibiting DA activity in the mesocorticolimbic tract decreased behavioral activation but did not specifically affect sexual motivation or genital reflexes.

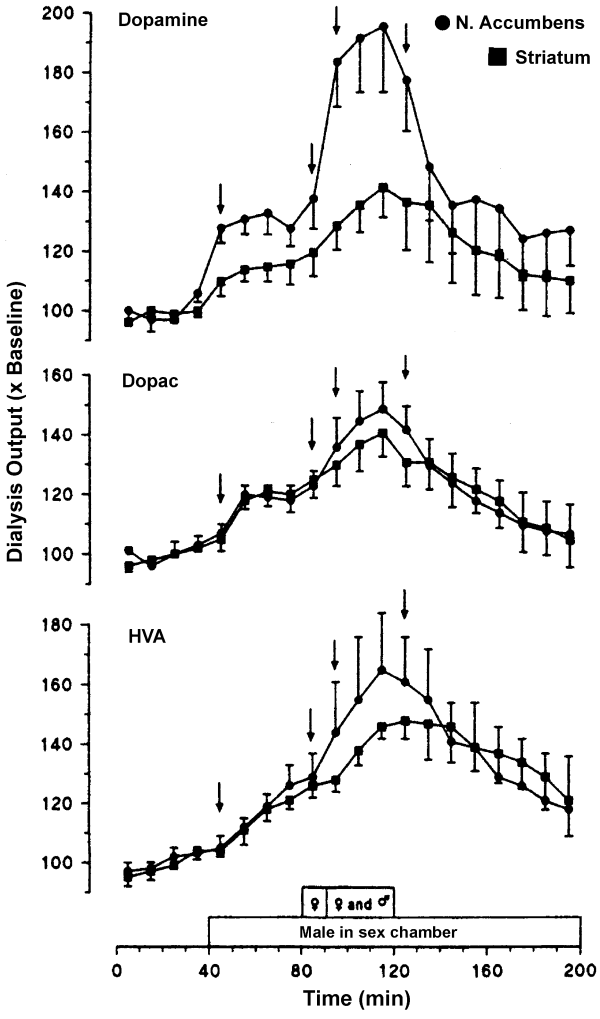
Microinjection of drugs into the NAc also primarily affected activity measures. The latency to begin copulating was speeded by amphetamine and delayed by *cis*-flupenthixol or by the DA neurotoxin 6-OHDA (reviewed in Everitt, 1990). Amphetamine in the NAc also increased responding for a secondary reinforcer that had previously been paired with copulation (Everitt, 1990). The D_2/D_3 agonist quinelorane increased the number of trials on which the male did not leave the start area but did not affect the percentage of trials on which he chose the female's goal box or his copulatory behavior when he reached the female (Moses et al., 1995). It is not clear whether quinelorane's effects were caused by stimulation of terminal autoreceptors or postsynaptic receptors. However, drug injections into either the VTA or the NAc have primarily affected motoric activation, with little influence specifically on sexual motivation or on copulatory measures.

Chemical changes detected by microdialysis or voltammetry. Exposure of male rats to the odor of an estrous, but not a nonestrous, female increased extracellular DA in the NAc (Pfaus et al., 1990; Louilot et al., 1991; Damsma et al., 1992; Wenkstern et al., 1993; Fumero et al., 1994). DA levels were also increased during copulation (Mas et al., 1990; Pleim et al., 1990; Wenkstern et al., 1993; Fumero et al., 1994) (See *Figure 2-4*). The DA response to the female's odor occurred on the male's first exposure to the odor (Wenkstern et al., 1993) and was lessened by systemic injections of the opioid antagonist naloxone, which may have blocked the disinhibition of DA neurons by endogenous opioids (Mitchell and Gratton, 1991). More recently, a neutral odor that had been paired with copulation enhanced the release of DA in the NAc of male rats (Gelez et al., 2005).

Finer temporal analysis, obtained with either in vivo voltammetry (Mas et al., 1990; Blackburn et al., 1992) or microdialysis with capillary chromatography (Lorrain et al., 1999), revealed that NAc DA rose with

Figure 2-4

Levels of extracellular DA, DOPAC, and HVA in the nucleus accumbens and striatum of sexually experienced male rats; microdialysis samples were collected during baseline when the male was in the sex chamber alone, during exposure to a female behind a barrier, during copulation, and after the female was removed from the chamber. Arrows indicate the first sample collected after the male was exposed to a new condition. Levels of DA increased in the presence of sexually exciting stimuli and rose sharply during copulation (figure is from Pfaus et al., 1990, with permission)

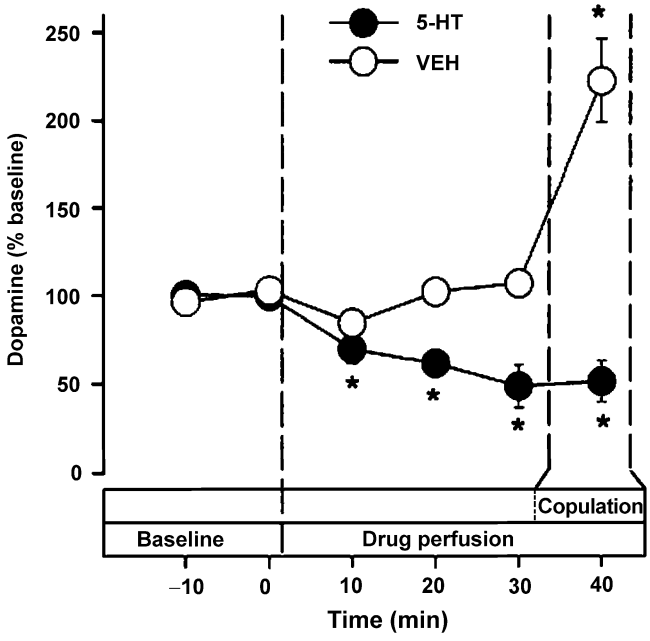


the initial presentation of the female, increased further during copulation, fell following each ejaculation, and increased again when copulation resumed. Reverse dialysis of serotonin (5-HT) into the lateral hypothalamic area (LHA) decreased basal levels of DA in the NAc and prevented the DA response to the female (Lorrain et al., 1999) (See *Figure 2-5*). Because 5-HT is increased in the LHA with ejaculation (Lorrain et al., 1997), one factor contributing to the postejaculatory interval of quiescence may be decreased NAc DA, because of 5-HT release in the LHA.

Sexually satiated male rats showed a small increase in extracellular DA in the NAc when they were presented with a novel estrous female behind a barrier; DA levels increased significantly when the barrier

Figure 2-5

Levels of extracellular DA in the nucleus accumbens of six male rats before and during 40 min of 5-HT perfusion into the anterior lateral hypothalamic area (LHA). Perfusion of 5-HT into the (LHA) decreased basal DA levels and inhibited the mating-induced DA release (*P < 0.05 relative to baseline) (figure is from Lorrain et al., 1999, with permission)



was removed and the animals copulated (Fiorino et al., 1997). In addition, sensitization to the motor-activating effects of amphetamine, after repeated systemic injections of amphetamine, also increased the NAc DA response to a female (Fiorino and Phillips, 1999). Therefore, there is evidence for cross-sensitization between a psychostimulant drug and a natural motivated behavior. However, prenatal stress decreased the number of male rats that were able to copulate, but did not affect the NAc DA response to an inaccessible female or DA levels during copulation (Wang et al., 1995).

Immunocytochemistry. Exposure of male quail to a receptive female for 60 min increased Fos-ir in tyrosine hydroxylase-containing neurons in the VTA, but not in the substantia nigra (Charlier et al., 2005). Therefore, dopaminergic neurons were activated in the VTA of male quail during copulation.

Nigrostriatal DA Tract. The nigrostriatal tract arises from cell bodies in the substantia nigra of the midbrain (A9 cell group) and innervates the dorsal striatum (caudate-putamen). Nigrostriatal activity enhances responsiveness to external stimuli (Robbins and Everitt, 1992).

Chemical changes detected by microdialysis or voltammetry. DA was released in the dorsal striatum only during copulation, in contrast to the DA release in the NAc and MPOA before, as well as during, copulation (Damsma et al., 1992) (See *Figure 2-4*). Therefore, nigrostriatal DA appears to be more important for motoric activation than for sexual motivation.

Spinal Cord. The spinal cord contains somatic and autonomic nuclei that control the striated and hemodynamic mediators of erection, ejaculation, and detumescence. They also provide the initial processing of sensory information from the genitals. Both descending axons from the brain and local reflex circuits regulate these processes (reviewed in Giuliano and Rampin, 2000).

Effects of intrathecal (around the spinal cord) drug administration. Intrathecal injections of the DA agonist apomorphine decreased the numbers of intromissions preceding ejaculation, suggesting that ejaculation was facilitated by stimulation of spinal cord DA receptors (Pehek et al., 1989b). However,

intrathecal apomorphine also increased interintromission interval, ejaculation latency, and postejaculatory interval. The highest dose of intrathecal apomorphine also decreased touch-based erections and anteroflexions but did not alter seminal emissions (Pehek et al., 1989b). These data contrast markedly with the effects of systemically administered apomorphine, which increased erections at low doses, inhibited erections at high doses, and facilitated seminal emissions at both low and high doses (Pehek et al., 1988a). In anesthetized rats, intrathecal apomorphine increased intracavernous pressure (Giuliano et al., 2001a). The explanation for these seemingly incongruent results is unclear.

Immunocytochemistry. DA-containing fibers and terminals are found in essentially all laminae throughout the spinal cord (Ridet et al., 1992; Holstege et al., 1996). D_2 receptors identified by immunohistochemistry and in situ hybridization are located in the parasympathetic area of the lumbosacral spinal cord and are abundant in the dorsomedial and dorsolateral motoneurons that innervate the bulbospongiosus and ischiocavernosus muscles of the penis (van Dijken et al., 1996).

3.2.2 Norepinephrine

Cell bodies of noradrenergic neurons in the CNS are primarily located in the locus coeruleus (A6) and in nuclei (A1–5,7) throughout the medulla and pons (reviewed in Kuhar et al., 1999). The locus coeruleus sends axons via the dorsal noradrenergic bundle to the cerebral cortex and hippocampus; the remaining cell groups project via the ventral noradrenergic bundle to the hypothalamus, amygdala, and septum. NE also serves as the major postganglionic neurotransmitter for the sympathetic nervous system. Noradrenergic receptors are divided into two classes. α_1 receptors activate phospholipase C to increase intracellular calcium; α_2 receptors inhibit adenylyl cyclase and are located on presynaptic terminals. β receptors are linked to stimulation of adenylyl cyclase.

3.2.2.1 Effects of Systemically or Intraventricularly Administered Drugs or Lesions of Cell Groups There are inconsistent results from experiments using noradrenergic drugs and lesions of NE pathways. Electrolytic lesions of the ascending dorsal noradrenergic bundle in the midbrain decreased postejaculatory intervals and increased the number of ejaculations (Clark, 1975, 1980). However, cytotoxic 6-OHDA lesions of the same area did not significantly affect copulation (Clark, 1980). Electrolytic lesions of the locus coeruleus or systemic injection of an NE synthesis inhibitor impaired copulation in one experiment (McIntosh and Barfield, 1984), but not in a more recent one (Fernandez-Guasti and Rodriguez-Manzo, 1997). However, locus coeruleus lesions blocked the facilitative effect of introduction of a new female to a sexually satiated male and decreased the facilitative effects of the 5-HT_{1A} agonist 8-OH-DPAT in both satiated and nonsatiated males (Fernandez-Guasti and Rodriguez-Manzo, 1997).

Presynaptic α_2 autoreceptors produce negative feedback on NE release. Systemic administration of the α_2 antagonist yohimbine increased mounts and intromissions by sexually sluggish males (Clark et al., 1984; Smith et al., 1987a), castrated males (Clark et al., 1985b), and males with an anesthetized penis (Clark et al., 1984), and also reversed sexual satiety (Rodriguez-Manzo and Fernandez-Guasti, 1994, 1995; Rodriguez-Manzo, 1999). However, yohimbine's reversal of satiety was inhibited by the DA antagonist haloperidol, suggesting that activation of DA receptors mediated that effect (Rodriguez-Manzo, 1999). The more selective α_2 antagonist delaquamine increased mounting by castrates and facilitated copulation in sexually naïve males (Tallentire et al., 1996). Copulation was also facilitated by two other α_2 antagonists, rauwalscine and phentolamine (Clark, 1995). In hamsters, too, yohimbine increased the numbers of ejaculations and of long intromissions (usually a sign of approaching satiety) (Arteaga et al., 2002). Therefore, blocking α_2 autoreceptors, and thereby increasing NE release, has enhanced sexual performance in both rats and hamsters. Conversely, the α_2 agonist clonidine inhibited both copulation and touch-based ex copula erections in rats (Clark et al., 1985b; Clark and Smith, 1990). However, copulation was inhibited by high doses of yohimbine (Sala et al., 1990), and the NE precursor dl-threodihydroxyphenylserine increased latencies to mount and intromit (Ågmo and Villalpando, 1995). Thus, increasing NE activity can either increase or decrease sexual behavior. The facilitative effects of moderate doses of yohimbine may be mediated by an increase in NE release, which would stimulate α_1 receptors; consistent with this suggestion,

the α_1 antagonists prazosin or methoxamine impaired copulation (Clark et al., 1985b, 1987). Yohimbine also facilitated erections in men with moderate erectile dysfunction; it was more effective in men with less severe dysfunction and higher levels of testosterone (Guay et al., 2002).

As the major postganglionic neurotransmitter of the sympathetic nervous system, NE inhibits erection. In contrast to its facilitative effects on copulation, yohimbine inhibited ex copula touch-based erections and seminal emissions (Smith et al., 1987b). However, touch-based erections were also inhibited by the α_2 agonist clonidine (Clark and Smith, 1990). Because penile reflexes were inhibited by both an agonist and an antagonist of α_2 receptors, it seems likely that low to moderate levels of NE facilitate erections, whereas high levels are inhibitory.

Most systemically administered drugs affect both central and peripheral receptors that regulate genital reflexes. However, guanethidine depletes peripheral, but not central, noradrenergic nerve terminals. A single injection of guanethidine increased the number of anteroflexions in restrained supine males; however, repeated treatments over 4 to 8 weeks decreased both touch-based erections and seminal emissions (Stefanick et al., 1985). Therefore, the sympathetic nervous system may provide some facilitation of erection, as demonstrated by Giuliano and colleagues (1997, 2000), in addition to its major roles in seminal emission and detumescence. The mixed excitatory and inhibitory influences of NE on genital reflexes may be relevant to human sexual function, as reviewed by Bancroft and Janssen (2000).

3.2.2.2 Role of NE in Specific Brain Areas *Medial Preoptic Area. Effects of drug microinjections into the MPOA.* NE microinjected into the MPOA facilitated both sexual arousal and copulatory performance; conversely, both the β-noradrenergic antagonist propranolol and the α antagonist phenoxybenzamine inhibited copulatory behavior (Mallick et al., 1996). The α_2 agonist clonidine, which would have stimulated autoreceptors and thereby decreased NE release, decreased the number of animals copulating and increased interintromission intervals and ejaculation latencies; however, intromissions preceding ejaculation were decreased (Clark, 1991). Furthermore, MPOA microinjections of the α_2 antagonist yohimbine (which would have disinhibited NE release) blocked the inhibitory effects of systemically injected clonidine (Clark, 1991). Therefore, copulation appears to be facilitated by stimulation of α_2 receptors in the MPOA.

Spinal Cord. Effects of intrathecal drug administration. Intrathecal injections of NE increased the frequency of pelvic thrusting during intromission, whereas similar administration of either the α_2 agonist clonidine or the β agonist isoproterenol decreased the frequency of thrusting (Hernandez et al., 1994). Clonidine's inhibitory effect may have resulted from stimulation of α_2 autoreceptors, which would have decreased NE release. These results are consistent with the findings noted earlier that α_1 receptors probably mediate NE's facilitation of copulation.

Penile detumescence is maintained by sympathetic noradrenergic nerves, which stimulate α_1 receptors on smooth muscle cells in the corpora cavernosa. This activates the inositol triphosphate (IP_3) second messenger cascade and increases intracellular calcium both from intracellular stores and through plasma membrane calcium channels. The increased calcium then activates a series of processes that result in smooth muscle contraction, decreased inflow of blood, and detumescence (Christ, 1995; Andersson and Stief, 1997). α_1 receptors may contribute to detumescence indirectly by increasing sensitivity of smooth muscle to calcium, via the Rho-kinase pathway (Somlyo and Somlyo, 2000). A Rho-kinase antagonist relaxed smooth muscle in strips of human or rabbit corpus cavernosum that had been contracted by the α receptor agonist phenylephrine (Rees et al., 2001). This antagonist also stimulated penile erection in rats (Chitaley et al., 2001). Therefore, Rho-kinase antagonists may provide a new type of treatment for erectile dysfunction.

Immunocytochemistry. Neurons and fibers containing immunoreactivity for α_{2a} and α_{2c} adrenoceptor subtypes were found in the intermediolateral cell column, the dorsal gray commissure, and the ventral horn of the T12-L2 and L5-S1 spinal cord. There were only immunoreactive fibers, not cell bodies, in the dorsal horn. Neurons in the autonomic nuclei that were retrogradely labeled from the penis were immunoreactive for α_{2a} and α_{2c} adrenoceptor subtypes and were closely apposed by α_{2a} and α_{2c} immunoreactive fibers (Yaîci et al., 2002). Therefore, pre- and postsynaptic α_2 adrenoceptors may provide an intraspinal modulation of the noradrenergic control of the autonomic outflow to the penis.

3.2.3 Serotonin

Serotonin (5-hydroxytryptamine, 5-HT) is synthesized from tryptophan, beginning with tryptophan hydroxylase, the rate-limiting enzyme, which produces 5-hydroxytryptophan, which is in turn converted to 5-HT by aromatic amino acid decarboxylase. There are nine groups of serotonergic neurons (B1–9) scattered throughout the midbrain, pons, and medulla. Serotonergic axons ascend and descend from these nuclei to nearly every part of the brain and spinal cord. However, some serotonergic cell bodies lie outside these nuclei, and the majority of neurons within the nuclei do not contain serotonin (Hillegaart, 1991; reviewed in Frazer and Hensler, 1999).

3.2.3.1 Effects of Systemically or Intraventricularly Administered Drugs or Lesions of Cell Groups Most serotonergic influences on sexual behavior are inhibitory. The use of selective serotonin reuptake inhibitor (SSRI) antidepressants often results in difficulty achieving orgasm or ejaculation and sometimes in decreased sexual interest as well (Seagraves, 1990; reviewed in Rosen et al., 1999). The time course of the inhibitory sexual effects is usually similar to that of the antidepressant effects. The physiological changes that mediate the sexual impairments are unclear, but they have been thought to include increased prolactin secretion, decreased NO production, anticholinergic effects (Rosen et al., 1999), or decreased sensitivity of the penis (Yilmaz et al., 1999). The ability of SSRIs to inhibit ejaculation has resulted in their use to treat premature ejaculation (Haensel et al., 1995; Kim and Seo, 1998; Waldinger et al., 1998; McMahon and Touma, 1999; Yilmaz et al., 1999); however, undesirable side effects have included anorgasmia and decreased sexual interest (McMahon and Touma, 1999).

In rats, too, chronic administration of the SSRI fluoxetine decreased both sexual motivation and the ability to ejaculate (Taylor et al., 1996; Vega Matuszcyk et al., 1998; Cantor et al., 1999; Frank et al., 2000). The inhibition of ejaculation was reversed by oxytocin injections, but sexual motivation, measured as level changes in a bilevel apparatus, was not improved by oxytocin (Cantor et al., 1999). Hamsters also showed ejaculatory impairment following chronic administration of a 5-HT reuptake inhibitor, clomipramine (Boscarino and Parfitt, 2002). A possible mechanism of the ejaculatory impairment may be a decrease in the pressure response of the seminal vesicle to splanchnic nerve stimulation (Hsieh et al., 1998). Most studies of acute, as opposed to chronic, administration of fluoxetine did not report inhibition of ejaculation (Vega Matuszcyk et al., 1998; Cantor et al., 1999; Mos et al., 1999). However, one study found that acute injections slowed copulation and that this slowing could be reversed by amantadine, which releases NE (Yells et al., 1995). Therefore, 5-HT and NE influences may interact in the regulation of ejaculation. Acute injections of fluoxetine have also inhibited one measure of sexual motivation (level changing in search of a female) but not the amount of time spent near a receptive female (Vega Matuszcyk et al., 1998). Injections of 5-hydroxytryptophan, the 5-HT precursor, also increased intromission and ejaculation latencies and increased the number of intromissions preceding ejaculation (Ahlenius and Larsson, 1991). Similarly, intrathecal (around the spinal cord) administration of 5-HT blocked the urethrogentital reflex, which was restored by systemic administration of the 5-HT antagonist methysergide (Marson and McKenna, 1992).

Conversely, copulation has been facilitated by drugs that deplete 5-HT (Salis and Dewsbury, 1971; Ahlenius et al., 1971; Mitler et al., 1972) and by lesions of the medial raphe nucleus, a major source of 5-HT in the brain; lesions of the dorsal raphe nucleus were ineffective (Albinsson et al., 1996; Kondo and Yamanouchi, 1997). Facilitation was found most often in animals that were initially noncopulators (Salis and Dewsbury, 1971; Ginton, 1976; Dallo, 1977), in castrates maintained on suboptimal testosterone replacement (Malmnas and Meyerson, 1971; Södersten et al., 1976, 1977; Larsson et al., 1978; Rodriguez et al., 1984), or in sexually naïve males (Rodriguez et al., 1984). In addition, 5-HT depletion caused by lesions of the median and pontine raphe nuclei increased ex copula genital reflexes (Monaghan et al., 1993), and neurotoxic destruction of 5-HT terminals in the brain and spinal cord disinhibited the urethrogenital reflex, a model of orgasm (Marson and McKenna, 1994a). Inhibition of 5-HT synthesis by *p*-chlorophenylalanine (*p*CPA) not only decreased the number of touch-based erections, but also decreased the latency to the first erection (Matsumoto et al., 1997). *p*CPA-treated males also had more noncontact erections in the presence of a female, but not when they were tested alone (Matsumoto et al., 1997). Therefore, 5-HT

appears to inhibit erections in response to a female, and to have mixed, but mostly inhibitory, effects on touch-based erections.

Although 5-HT's effects on sexual behavior are generally inhibitory, stimulation of the 5-HT_{1A} receptor subtype facilitates ejaculation. The classic 5-HT_{1A} agonist 8-OH-DPAT [8-hydroxy-2-(di-*n*-propylamino) tetralin] decreased both ejaculation latency and the number of intromissions preceding ejaculation (Ahlenius et al., 1981; Ahlenius and Larsson, 1984b; Ahlenius et al., 1989; Schnur et al., 1989; Rehman et al., 1999); indeed, some rats ejaculated on their first intromission (Ahlenius et al., 1989; Ahlenius and Larsson, 1991; Haensel and Slob, 1997). Another 5-HT_{1A} agonist, flesinoxan, also facilitated ejaculation, although no animals ejaculated on the first intromission (Haensel and Slob, 1997). The opposite influences of 8-OH-DPAT, compared to 5-HT itself, and the fact that some 5-HT_{1A} receptors are autoreceptors on serotonergic cell bodies and dendrites suggested that 8-OH-DPAT might facilitate sexual behavior by inhibiting 5-HT release. However, the effects of 8-OH-DPAT were not altered by lesions of serotonergic nuclei, suggesting that postsynaptic receptors mediated those effects (Fernandez-Guasti and Escalante, 1991). Furthermore, microinjections of 8-OH-DPAT into terminal fields (MPOA and NAc), where all 5-HT_{1A} receptors are postsynaptic, also facilitated sexual behavior (Fernandez-Guasti et al., 1992; Matuszewich et al., 1999). The facilitative effects of 8-OH-DPAT are seen only in sexually experienced animals with normal levels of testosterone. 8-OH-DPAT did not facilitate copulation in castrates with subnormal testosterone replacement, and in those with threshold testosterone levels, only sexually experienced males were able to copulate after 8-OH-DPAT administration (Rowland and Houtsmuller, 1998). The drug had a strong effect in males with high levels of testosterone.

One possible mechanism of 8-OH-DPAT's effects is increased noradrenergic activity in some brain area(s). The percentage of sexually satiated males that copulated on the following day was increased, not only by 8-OH-DPAT, but also by the α_2-adrenergic receptor antagonist yohimbine and the opioid antagonist naloxone (Rodriguez-Manzo and Fernandez-Guasti, 1994, 1995). In addition, neurotoxic lesions of noradrenergic neurons blocked the facilitation by 8-OH-DPAT and by naloxone, but not that of yohimbine, in satiated males (Rodriguez-Manzo and Fernandez-Guasti, 1995). Similar lesions in nonsatiated males decreased 8-OH-DPAT's effects (Fernandez-Guasti and Rodriguez-Manzo, 1997).

8-OH-DPAT's most common effect is facilitation of ejaculation, which is promoted by the sympathetic nervous system. Studies of ex copula reflexes are consistent with a prosympathetic, anti-parasympathetic influence. In male rats touch-based erections, cups, and anteroflexions were inhibited by 8-OH-DPAT, and the time and number of intromissions preceding ejaculation were decreased in copula (Rehman et al., 1999). In monkeys, a moderate dose of 8-OH-DPAT decreased erections in the presence of an inaccessible female (Pomerantz et al., 1993a) and facilitated ejaculation in copula, although a high dose delayed ejaculation (Pomerantz et al., 1993b). Therefore, stimulation of 5-HT_{1A} receptors may shift autonomic balance to favor ejaculation, in addition to facilitating copulation in previously noncopulating males. However, there is some species specificity in 8-OH-DPAT's effects. In male ferrets, low doses had no effect, and the doses that had facilitated ejaculation in male rats inhibited copulation in ferrets (Paredes et al., 1994). Furthermore, some of the effects of 8-OH-DPAT are mediated by D_2 receptors, rather than by 5-HT_{1A} receptors. Intraventricular delivery of 8-OH-DPAT induced rhythmic contractions of the bulbospongiosus (BS) muscles, which mediate the expulsion of semen (Clement et al., 2006). This effect was blocked by two D_2 receptor antagonists (raclopride and spiperone), but not by a 5-HT_{1A} receptor antagonist (WAY100635). Additional support for a major role of D_2 receptors came from the effectiveness of the D_2 agonist quinelorane in stimulating these contractions. A similar finding is described later, in which raclopride, coadministered with 8-OH-DPAT into the MPOA, partially blocked the effects of 8-OH-DPAT on copulation.

Stimulation of other 5-HT receptor subtypes generally inhibits copulation. In rats, ejaculation was inhibited by the 5-HT_{1B} agonist anpirtoline, whose effects were blocked by selective 5-HT_{1B} antagonists (Hillegaart and Ahlenius, 1998). Ejaculation latency was lengthened by coadministration of the SSRI citalopram and a 5-HT_{1A} antagonist, as expected, and that effect was blocked by a 5-HT_{1B} antagonist (Ahlenius and Larsson, 1999). A 5-HT_{1B} antagonist also blocked the increase in ejaculation latency that resulted from systemic administration of the 5-HT precursor 5-hydroxytryptophan (plus a peripheral decarboxylase inhibitor to restrict the increase in 5-HT to the CNS) (Ahlenius and Larsson, 1998). Several

serotonergic drugs produced less sexual impairment in 5-HT_{1B} knockout mice than in wild-type mice, consistent with an inhibitory effect of the 5-HT_{1B} receptor (Rodriguez-Manzo et al., 2002b). Therefore, 5-HT_{1A} and 5-HT_{1B} receptors appear to have opposite effects on ejaculation, with 5-HT_{1A} receptors facilitating, and 5-HT_{1B} receptors inhibiting, ejaculation.

However, in two studies of mice both the 5-HT_{1A} agonist 8-OH-DPAT and two 5-HT_{1B} agonists inhibited one or more components of sexual behavior. 8-OH-DPAT decreased the time spent near an estrous female (Popova and Amstislavskaya, 2002), as well as copulatory performance (Rodriguez-Manzo et al., 2002b). The 5-HT_{1B} agonist CGS-12066A also decreased the time spent near the estrous female (Popova and Amstislavskaya, 2002), and the 5-HT_{1B} agonist TFMPP inhibited copulation. These data suggest that both subtypes of 5-HT receptor impair sexual behavior. On the other hand, 5-HT_{1B} knockout mice required more stimulation to achieve ejaculation, suggesting that 5-HT_{1B} receptors may facilitate ejaculation; however, the knockout mice were less sensitive to the inhibitory effects of 5-hydroxytryptophan, the 5-HT precursor (Rodriguez-Manzo et al., 2002b). The authors suggested that compensatory mechanisms may have rendered the knockout mice less sensitive to the inhibitory effects of high levels of 5-HT.

Whereas stimulation of 5-HT_{1A} receptors facilitates ejaculation in male rats and may inhibit erection, 5-HT_{2C} agonists appear to produce the opposite pattern of effects. The 5-$HT_{2C/1D}$ agonist mCPP increased drug-induced and noncontact erections in male monkeys, but decreased the number of males that initiated copulation and that ejaculated (Pomerantz et al., 1993a). mCPP also increased erections in rats (Berendsen et al., 1990; Millan et al., 1997). When these studies were conducted mCPP was classified as a 5-$HT_{1C/1D}$ agonist. More recently the 5-HT_{1C} receptor was renamed the 5-HT_{2C} receptor (Hoyer et al., 1994). Therefore, we have changed the nomenclature from the original publication to be consistent with the current classification. mCPP also increased firing of the cavernous nerves to the penis and increased intracavernous pressure in anesthetized rats (Steers and de Groat, 1989) and produced drug-induced erections in awake rats (Berendsen et al., 1990). Erections in awake rats were also increased by a more selective 5-HT_{2C} agonist (RO60-0175) (Millan et al., 1997). Therefore, stimulation of 5-HT_{1A} receptors appears to promote sympathetically mediated ejaculation, whereas activation of 5-HT_{2C} receptors facilitates parasympathetic effects on erection, but may inhibit ejaculation.

A relatively nonselective 5-HT_2 agonist, DOI, has been reported to inhibit copulation (Foreman et al., 1989; Gonzalez et al., 1994; Klint and Larsson, 1995; Padoin and Lucion, 1995), and a 5-HT_2 antagonist facilitated copulation (Gonzalez et al., 1994). To summarize, 5-HT_{1B}, 5-HT_{2C}, and other 5-HT_2 agonists inhibit ejaculation and may impair copulation, although 5-HT_{2C} agonists may also facilitate erection. On the other hand, stimulation of 5-HT_{1A} receptors facilitates ejaculation and may inhibit erection.

3.2.3.2 Role of 5-HT in Specific Brain Areas *Medial Preoptic Area. Effects of drug microinjections into the MPOA.* In keeping with 5-HT's general inhibitory role in male sexual behavior, large doses of 5-HT microinjected into the MPOA impaired copulation (Fernandez-Guasti et al., 1992; Verma et al., 1989); similarly, a 5-HT_{1B} agonist delayed ejaculation (Fernandez-Guasti et al., 1992). Consistent with the facilitative effects of systemically administered 5-HT_{1A} agonists, 8-OH-DPAT microinjections into the MPOA facilitated ejaculation (Fernandez-Guasti and Escalante, 1991). Administration of 8-OH-DPAT by reverse dialysis into the MPOA also facilitated copulation (Matuszewich et al., 1999) and increased extracellular levels of both DA and 5-HT (Lorrain et al., 1998). 8-OH-DPAT's facilitative effects were partially blocked by the D_2 antagonist raclopride, but not by the 5-HT_{1A} antagonist pMPPI, suggesting that stimulation of D_2 receptors, as a result of the elevated DA levels, mediated much of the facilitation (Matuszewich et al., 1999).

Microdialysis. The 5-HT metabolite 5-hydroxyindole acetic acid (5-HIAA) was increased in dialysates from the POA of male rats after ejaculation (Fumero et al., 1994; Mas et al., 1995a); 5-HT itself was increased in tissue punches from the POA of males that had ejaculated (Mas et al., 1987). Mas and his colleagues suggested that 5-HT increases in the POA after ejaculation might contribute to postejaculatory quiescence. However, a more recent analysis of 5-HT itself concluded that 5-HT levels in the MPOA and, more laterally, in the POA were constant throughout copulation and the postejaculatory interval (Lorrain et al., 1997). However, there were increases of 5-HT in the anterior LHA at the time of ejaculation. The

increase in 5-HIAA that was observed by Fumero et al. (1994) and Mas et al. (1995a) may have reflected diffusion from the adjacent LHA. Therefore, it seems improbable that 5-HT in the MPOA contributes to postejaculatory quiescence.

Lateral Hypothalamic Area. Effects of drug microinjections into the lateral hypothalamic area (LHA). Microinjection into the anterior LHA of a SSRI delayed the onset of copulation and delayed ejaculation after the animals did begin to copulate (Lorrain et al., 1997). Thus, the impairment by SSRIs of sexual motivation and ejaculation (reviewed in Rosen et al., 1999) may be mediated, in part, by increased 5-HT in the LHA.

Changes detected by microdialysis. Extracellular 5-HT increased in the LHA when male rats ejaculated (Lorrain et al., 1997). Reverse dialysis of 5-HT into the LHA decreased basal DA levels in the NAc and prevented the DA increase usually seen during copulation (Lorrain et al., 1999) (See *Figure 2-5*). The inhibition of NAc DA release produced by 5-HT in the LHA may contribute to the decreased sexual motivation associated with clinical use of SSRI antidepressants (reviewed in Rosen et al., 1999).

Mesocorticolimbic Dopamine Tract. Microinjection of 5-HT into the NAc inhibited ejaculation (i.e., it increased the numbers of mounts, intromissions, and time preceding ejaculation); those same measures were decreased by the 5-HT_{1A} agonist 8-OH-DPAT (Hillegaart et al., 1991). Microinjection of these compounds into the dorsal striatum did not affect copulation. The authors suggested that 8-OH-DPAT's effects might have resulted from antagonism of 5-HT_2 receptors.

Paraventricular Nucleus. Axons from the PVN project to the nucleus paragigantocellularis (nPGi) (Bancila et al., 2002), which is a major source of inhibition of genital reflexes and copulation (see section on nPGi later). PVN axon terminals formed close appositions to serotonergic neurons in the nPGi that projected to the lumbosacral spinal cord and indirectly to the corpus cavernosum. Therefore, the PVN can provide control over inhibitory serotonergic projections to the spinal areas that control erection.

Nucleus Paragigantocellularis of the Medulla. There is tonic inhibitory control of the spinal mechanisms that control erection. Spinal transection in rats (Hart, 1968a; Sachs and Garinello, 1979; Sachs and Garinello, 1980), mice (Sachs, 1980), and dogs (Hart and Kitchell, 1966; Hart, 1967) increases the number or intensity of erections or urethrogenital reflexes or decreases the amount of stimulation required to elicit those responses. A major source of that inhibition is the nucleus paragigantocellularis (nPGi) of the medulla in the ventrolateral medulla. Neurons in the nPGi project directly to pudendal motor neurons, sympathetic and parasympathetic preganglionic neurons, and the interneuronal regions of the medial gray lumbosacral cord (Marson et al., 1992; Hermann et al., 2003).

Effects of drug microinjections into the nPGi. Administration of the serotonergic neurotoxin 5,7 dihydroxytryptamine into the PVN decreased the descending inhibition in UG reflex tests (Marson and McKenna, 1994a). Therefore, serotonergic input from the nPGi to the spinal cord tonically inhibits genital reflexes.

Immunocytochemistry. Approximately 78% of nPGi neurons that project to the ipsilateral lumbosacral spinal cord contain 5-HT (Marson and McKenna, 1992). These serotonergic neurons receive direct input from the PVN (Bancila et al., 2002).

Spinal Cord. Effects of intrathecally administered drugs. Typically, the urethrogenital reflex can be elicited only after transection of the spinal cord (McKenna et al., 1991), ablation of the nPGi (Marson and McKenna, 1990; Marson et al., 1992), or stimulation of the MPOA (Marson and McKenna, 1994b). However, the urethrogenital reflex could be elicited without any of these measures following either intraventricular or intrathecal administration of the 5-HT neurotoxin 5,7-DHT (Marson and McKenna, 1994a). Similarly, lesions of the median raphe nuclei, which, together with the nPGi, provide a major source of serotonergic axons to the spinal cord, significantly increased the numbers of touch-based anteroflexions (penile body erections) and cups (intense glans erections) (Monaghan et al., 1993). Conversely, application of 5-HT to the spinal cord suppressed the urethrogenital reflex in rats with transected spinal cords, and the 5-HT antagonist methysergide prevented 5-HT's effect (Marson and McKenna, 1992). Therefore, descending serotonergic input to the spinal cord appears to mediate much of the tonic inhibition of genital reflexes.

In copulation tests, intrathecal application of either 5-HT or thyrotropin releasing hormone (TRH) produced only slight increases in mount and intromission latencies. However, coadministration of 5-HT

and TRH markedly increased mount and intromission latencies (Hansen et al., 1983). Intrathecal administration of TRH alone inhibited touch-based penile reflexes, decreasing both the number of responders and the numbers of reflexes, and increasing reflex latencies (Holmes et al., 1997). TRH and 5-HT are colocalized in some neurons that descend from the medulla to the spinal cord (Hokfelt et al., 1986). Furthermore, methiothepin, a 5-HT antagonist, partially blocked some of TRH's inhibitory effects (Holmes et al., 2001). Therefore, either 5-HT or TRH alone may inhibit copulation and genital reflexes, but their effects may be enhanced by coadministration or endogenous corelease.

Intrathecal administration of the 5-HT_{1A} agonist 8-OH-DPAT facilitated copulation, producing decreased ejaculation latencies, intercopulatory intervals, and numbers of intromissions preceding ejaculation (Lee et al., 1990). In dramatic contrast, intrathecal injections of 8-OH-DPAT decreased the numbers of male rats that displayed touch-based erections and seminal emissions (Lee et al., 1990). The basis for the apparent discrepancy between in copula and ex copula measures is not clear.

Immunocytochemistry. Spinal 5-HT_{2C} receptors appear to facilitate erection. Consistent with a proerectile effect, 5-HT_{2C} receptor immunoreactivity was observed on motor neurons of the sacral parasympathetic nucleus, the dorsal gray commissure, and the motor neurons of the ventral horn (Bancila et al., 1999). In addition, 5-HT_{2C} receptor immunoreactivity was present in all neurons that were retrogradely labeled from the corpus cavernosum to the sacral parasympathetic nucleus and the dorsal gray commissure of L5-L6, as well as in ventral horn motoneurons retrogradely labeled from the ischiocavernosus and BS muscles of the penis. Therefore, the neurons that promote erection possess 5-HT_{2C} receptors.

3.2.4 Acetylcholine

Acetylcholine (ACh) is synthesized from choline and acetyl coenzyme A by choline acetyltransferase. There are eight major groups of cholinergic cell bodies (Ch 1–8) in the basal forebrain and brainstem (reviewed in Mesulam, 1995). ACh is also the neurotransmitter of peripheral motor nerves, preganglionic autonomic neurons, and postganglionic parasympathetic neurons. There are five types of muscarinic receptors, coupled to either $G_{q/11}$ or $G_{I/O}$ G-proteins (Alexander and Peters, 2000). They have either excitatory or inhibitory effects, depending on the tissue (Taylor and Brown, 1999). Nine subtypes of nicotinic receptors are excitatory, acting on sodium channels (Taylor and Brown, 1999; Alexander and Peters, 2000).

3.2.4.1 Effects of Systemically or Intraventricularly Administered Drugs or Lesions of Cell Groups Slowing the degradation of ACh (using the acetylcholinesterase antagonist physostigmine) or administration of the muscarinic agonist pilocarpine increased ejaculations in male rats; this effect was blocked by atropine, a muscarinic antagonist (Zarrindast et al., 1992). Pilocarpine also evoked ex copula erections in a neutral test cage (Maeda et al., 1990). The muscarinic agonist oxotremorine facilitated copulation in both sexually experienced and naïve castrates with testosterone replacement, but not in castrates without testosterone (Retana-Marquez and Velazquez-Moctezuma, 1997). A more recent study found that intraperitoneal administration of muscarine to spinally transected rats increased the numbers of penile reflexes, decreased their latencies, and increased their duration (Vargas et al., 2004). In addition, six of the nine animals ejaculated. The authors suggested that muscarinic receptors facilitate both erectile and ejaculatory functions mediated by the spinal cord. In summary, systemically administered muscarinic drugs appear to facilitate copulation and ex copula erections. However, because systemically administered cholinergic drugs affect striated muscles and autonomic targets, as well as central regulatory areas, it is difficult to determine whether their effects are centrally or peripherally mediated.

3.2.4.2 Role of ACh in Specific Brain Areas *Medial Preoptic Area. Effects of drug microinjections into the MPOA.* Microinjections of either the nonspecific ACh agonist carbachol or the muscarinic agonist oxotremorine facilitated ejaculation by decreasing the numbers of intromissions preceding ejaculation (Hull et al., 1988a). This facilitation was blocked by the muscarinic antagonist scopolamine, which also decreased the numbers of animals that copulated, when administered alone (Hull et al., 1988b).

Immunocytochemistry. Immunoreactivity for acetylcholinesterase (AChE), the degradative enzyme, was more dense in the sexually dimorphic area of male gerbils, compared with females (Commins and Yahr, 1984). AChE immunoreactivity decreased after castration and was restored by testosterone replacement, suggesting that ACh in the MPOA may contribute to hormonal regulation of male sexual behavior.

3.2.5 Glutamate

Glutamate is the major excitatory neurotransmitter in the CNS. However, relatively few studies have examined the role of glutamate in the regulation of male sexual behavior. Glutamate receptors are grouped into two distinct classes, the ionotropic and metabotropic receptors. The ionotropic receptors contain cation-specific ion channels and are further subdivided into AMPA (α-amino-3-hydroxy-5-methyl-4-isooxazole-propionic acid), kainate, and NMDA (N-methyl-D-aspartate) receptors. The metabotropic glutamate receptors, on the other hand, are coupled to GTP binding proteins (G-proteins) and modulate the production of intracellular messengers.

3.2.5.1 Effects of Systemically or Intraventricularly Administered Drugs or Lesions of Cell Groups Because of the ubiquity of glutamate in the nervous system and its ability to produce seizures and neurotoxicity, there have been no studies on the effects of systemically administered glutamatergic agonists on male sexual behavior. However, administration of the NMDA antagonist MK-801 impaired copulation in both naive and sexually experienced males and prevented the facilitation due to repeated noncopulatory exposures to a female (Powell et al., 2003).

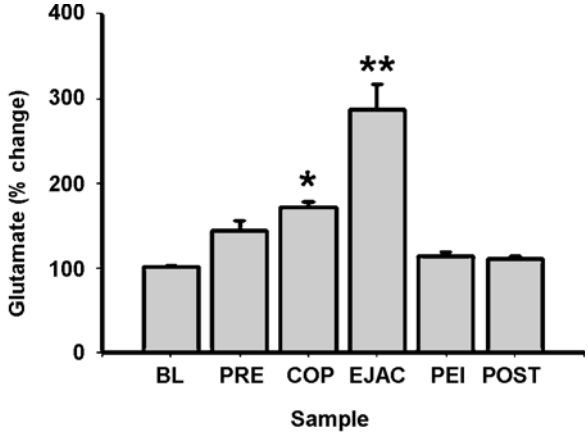
3.2.5.2 Role of Glutamate in Specific Brain Areas *Medial Preoptic Area. Effects of drug microinjections into the MPOA.* One brain region where increased glutamate appears to facilitate sexual behavior is the MPOA. Microinjections of glutamate into the MPOA of anesthetized rats increased erectile responses (Giuliano et al., 1996) and the urethrogenital reflex, a model of orgasm (Marson and McKenna, 1994b). Conversely, microinjections of the NMDA receptor antagonist MK-801 into the MPOA of both sexually naïve and experienced male rats decreased the numbers of mounts, intromissions, and ejaculations (Dominguez et al., 2003; Vigdorchik et al., 2003). MPOA microinjections of MK-801 in sexually naïve males before each of seven noncopulatory exposures to an estrous female prevented the facilitation of such exposures on a drug-free test on day 8 (Vigdorchik et al., 2003). Microinjections of MK-801 also inhibited 50-kHz ultrasonic vocalizations evoked in anticipation of a receptive female (Brudzynski and Pniak, 2002). Therefore, endogenous stimulation of NMDA receptors in the MPOA facilitates copulation in both naïve and experienced male rats, and is permissive for the sensitization to female stimuli induced by repeated exposures to a female.

Chemical changes detected by microdialysis. A recent microdialysis study found mating-induced increases in extracellular glutamate in the MPOA of male rats (Dominguez et al., 2006) (See *Figure 2-6*). Levels of glutamate increased to nearly 170% of baseline during mounts and intromissions, and nearly 300% during ejaculations. Glutamate levels decreased back to baseline in the first postejaculatory sample; the magnitude of this fall was highly correlated with the length of the postejaculatory interval of quiescence, suggesting that glutamate in the MPOA might also play a role in regulating the postejaculatory interval. In the same study, reverse dialysis of a cocktail of glutamate uptake inhibitors into the MPOA before and during mating increased extracellular glutamate (∼280% of BL), increased the number of ejaculations, decreased ejaculation latency, and decreased the postejaculatory latency to resume copulation (Dominguez et al., 2006).

Immunocytochemistry. It is not clear which mechanisms in the MPOA are altered by glutamate. However, glutamatergic stimulation of NMDA receptors appears to be important. Nearly 100% of cells in the MPOA containing mating-induced Fos-ir also contained NMDA receptors; additionally, mating increased phosphorylation of NMDA receptors, suggesting that NMDA receptors were indeed activated by mating (Dominguez et al., 2003). Finally, microinjections of the NMDA receptor antagonist MK-801 into the MPOA of male rats reduced the number of cells containing mating-induced Fos-ir (Dominguez and Coolen, 2004). Together, these studies indicate that glutamatergic stimulation in the MPOA facilitates male sexual behavior.

Figure 2-6

Mating increased extracellular glutamate in the MPOA of male rats. This increase was highest (~300% of baseline, BL) in samples collected when the animals ejaculated (EJAC); levels then dropped precipitously in samples collected during the postejaculatory interval (PEI). Levels returned to BL after mating, when the female was removed (POST). Values are expressed as mean ± SEM, *P < 0.05; **P < 0.001 (figure is from Dominguez et al., 2006, with permission)



Paraventricular Nucleus. Effects of drug microinjections into the PVN. Another region in the hypothalamus where glutamate might facilitate male sexual behavior is the PVN. Like in the MPOA, microinjections of glutamate agonists into the PVN facilitated erections, whereas antagonists inhibited this response. Specifically, microinjections of the glutamate agonist NMDA into the PVN increased erectile response; this effect was blocked by the NMDA antagonist MK-801 (dizocilpine) and by the NOS antagonist L-NAME (Melis et al., 1997). Therefore, glutamate, by opening calcium channels associated with NMDA receptors, may lead to calcium activation of calmodulin, which then activates NOS. Microinjections of MK-801 into the PVN also inhibited noncontact erections and copulation; an AMPA receptor antagonist (CNQX) had a similar effect, but to a lesser extent (Melis et al., 2004).

Chemical changes detected by microdialysis. Levels of extracellular glutamate and aspartic acid in the PVN increased during exposure to a receptive female and increased even further during copulation (Melis et al., 2004), suggesting that increased glutamate in the PVN may enhance male sexual behavior.

3.2.6 Gamma Amino Butyric Acid

Gamma amino butyric acid (GABA) is the major inhibitory neurotransmitter in the brain (reviewed in Paul, 1995). It is formed from glutamate by glutamic acid dehydroxylase (GAD). Stimulation of $GABA_A$ receptors opens chloride channels, thereby hyperpolarizing neurons. $GABA_B$ receptors inhibit several intracellular processes by acting through the $G_{i/o}$ G-protein.

3.2.6.1 Effects of Systemically Administered Drugs Systemically administered $GABA_A$ (Ågmo et al., 1997) and $GABA_B$ (Paredes and Ågmo, 1995) agonists impaired copulation without significant effects on motor activity. The $GABA_A$ agonist produced similar effects in rabbits (Paredes et al., 1998). However, a different $GABA_A$ agonist, as well as a GABA synthesis inhibitor and an inhibitor of GABA catabolism all impaired social and drinking behaviors, as well as sexual behavior, suggesting that these drugs had nonspecific effects on motivated behaviors (Paredes et al., 1997). Furthermore, some of the inhibitory effects on copulation may have resulted from decreased EMG activity in ischiocavernosus muscles during thrusting, (Paredes et al., 1993). The ischiocavernosus muscle is necessary for erection; therefore, the impairment of copulation

may have been due to a peripheral, rather than central effect. Furthermore, ex copula genital reflexes were inhibited by a $GABA_B$, but not a $GABA_A$, receptor agonist (Leipheimer and Sachs, 1988).

3.2.6.2 Role of GABA in Specific Brain Areas *Medial Preoptic Area. Effects of drug microinjections into the MPOA.* MPOA microinjections of the GABAergic drugs muscimol and ethanolamine-O-sulfate decreased the numbers of male rats that mounted, intromitted, or ejaculated; conversely, the $GABA_A$ antagonists bicuculline or 3-mercaptopropionic acid (3-MPA) dramatically shortened both ejaculation latencies and postejaculatory intervals and decreased the numbers of intromissions preceding ejaculation (Fernandez-Guasti et al., 1985, 1986). However, MPOA microinjections of the same two antagonists did not restore copulation in satiated males, suggesting that sexual satiety is governed by mechanisms separate from those that regulate the postejaculatory interval.

Paraventricular Nucleus. Microinjections of the $GABA_A$ agonist muscimol into the PVN inhibited erections elicited by apomorphine, oxytocin, or NMDA (Melis et al., 2000a). The $GABA_B$ agonist baclofen was ineffective.

Spinal Cord. Effects of intrathecally administered drugs. The $GABA_B$ agonist baclofen, intrathecally administered into the lumbosacral (L5-S1) spinal cord, decreased the numbers of touch-based erections and increased latency to the first glans erection (Bitran et al., 1988b). The highest dose completely blocked penile reflexes. However, none of the doses prevented males from copulating to ejaculation. In copula ejaculation shortly before the reflex test decreased latency to the first touch-based erection in saline controls and blocked the inhibitory effects of the two lower doses of baclofen, but not the highest dose. Therefore, different neural mechanisms appear to control copulation and ex copula reflexes. In contrast to the inhibitory effects of baclofen on ex copula reflexes, intrathecal administration of the $GABA_A$ agonist THIP produced only slight inhibitory effects at the highest dose. Therefore, ex copula reflexes are inhibited by spinal $GABA_B$, but not $GABA_A$, receptors.

Chemical changes detected by analysis of cerebrospinal fluid. Following ejaculation, the concentration of GABA in cerebrospinal fluid of male rats increased by more than 1,000%; aspartate and glutamate increased by about 200% (Quershi and Södersten, 1986). Although it is possible that such an increase in a major inhibitory neurotransmitter contributes to the absolute refractory interval, as noted earlier, ex copula reflexes can be elicited soon after an ejaculation. Therefore, any contribution of GABA to the PEI is probably mediated by brain, not spinal cord mechanisms.

3.2.7 Nitric Oxide

NO is a short-lived soluble gas that is produced by the enzyme NOS in the conversion of L-arginine to citrulline. NO acts both peripherally and centrally to promote vasodilation, erection, and other parasympathetic functions. Both neuronal (nNOS) and endothelial (eNOS) isoforms of NOS are present in central structures that regulate male sexual behavior, as well as in the corpus cavernosum of the penis and dorsal penile nerve. The major mediator of NO's effects is soluble guanylyl cyclase, which produces cGMP. The activity of cGMP is terminated by phosphodiesterase 5 (PDE 5).

3.2.7.1 Role of NO in Penile Erection nNOS in parasympathetic nerves produces NO, which directly promotes smooth muscle relaxation; it may also stimulate production of NO by eNOS in endothelial cells. The cascade of nNOS and eNOS activation can amplify the effects of neuronal stimulation. NO diffuses into smooth muscle in the corpus cavernosum and activates guanylyl cyclase, producing cGMP, which in turn activates protein kinase G (PKG) and, to a lesser extent, protein kinase A (PKA). These enzymes phosphorylate various proteins, including phospholamban, which normally inhibits the calcium pump that sequesters calcium into the sarcoplasmic reticulum (Horowitz et al., 1996). However, phosphorylation inhibits this inhibitory effect, resulting in greater sequestration and less intracellular calcium, resulting in muscle relaxation. PKG may also activate ion channels that extrude calcium from the cell, open potassium channels to hyperpolarize smooth muscle, and inhibit the IP3 contractile pathway (Andersson and Wagner, 1995; Miller et al., 1995; Bivalacqua et al., 1998, 2000). Because PDE 5 terminates the activity of cGMP, inhibitors of this enzyme prolong the effects of cGMP, thereby promoting erection.

Testosterone and dihydrotestosterone upregulate both nNOS and eNOS (Lugg et al., 1995; Zvara et al., 1995; Reilly et al., 1997; Marin et al., 1999; Baba et al., 2000). Castration decreased NOS in the penis and epididymis, but actually increased NOS in the seminal vesicles and prostate, an effect that was reversed by exogenous testosterone (Chamness et al., 1995). Furthermore, fertility in male rats was impaired by systemic administration of the NO precursor L-arginine, although sexual behavior was not affected (Ratnasooriya and Dharmasiri, 2001). Therefore, excessive NO in some portions of the reproductive tract may impair certain aspects of ejaculation or sperm motility.

3.2.7.2 Effects of Systemically Administered Drugs Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) inhibit PDE 5 and are used to treat erectile dysfunction (Goldstein et al., 1998; Christiansen et al., 2000; Giuliano et al., 2000; Meuleman et al., 2001; Porst et al., 2001). Sildenafil had no effect on erectile function in healthy men but did decrease the time between ejaculation and a subsequent erection (Aversa et al., 2000). In rats, too, sildenafil increased the number of ex copula erections, as well as genital grooming and homosexual mounting (Ferrari et al., 2002). Vardenafil administered to anesthetized rats was more effective than sildenafil in increasing intracavernous pressure (Giuliano et al., 2003).

Systemic administration of NOS inhibitors decreased the numbers of sexually experienced (Hull et al., 1994; Bialy et al., 1996) and inexperienced (Benelli et al., 1995) males that could ejaculate and increased the number of nonintromissive mounts. The numbers of noncontact erections (Melis and Argiolas, 1997) and touch-based erections (Hull et al., 1994) were decreased by NOS inhibitors, but the number of seminal emissions was increased (Hull et al., 1994). This pattern suggests a facilitation of parasympathetic activity and inhibition of sympathetic activity by NO. NOS inhibitors did not affect sexual motivation, measured as either percent choice of a female in an X-maze (Hull et al., 1994) or increased mount latency (Bialy et al., 1996). However, another study reported decreases in precoital activity and numbers of males that mounted (Ratnasooriya et al., 2000). In the latter study, the NOS inhibitor did not affect the numbers of spermatozoa, but did decrease the number of pregnancies and the number of implanted embryos per pregnancy. A possible explanation for the impaired fertility may be that NO must be injected by the sperm into the egg in order to release internal stores of calcium, which then trigger cell division (Kuo et al., 2000). nNOS "knockout" mice had normal erectile function, resulting from increased production of eNOS (Burnett et al., 1996). In fact, the knockout mice were able to ejaculate after fewer mounts and intromissions (Kriegsfeld et al., 1999), again suggesting that NO normally activates parasympathetic, and inhibits sympathetic, function. Therefore, NO may work to prevent "premature ejaculation."

Systemic administration of the precursor L-arginine or of NO donors has produced inconsistent results. L-arginine increased the number of sexually naïve male rats that were able to copulate and enhanced the performance of experienced males (Benelli et al., 1995). L-arginine also increased production of NO in the corpus cavernosum (Escrig et al., 1999). However, sodium nitroprusside, an NO donor, increased intracavernosal pressure in untreated castrates, but not in testosterone-replaced males (Reilly et al., 1997). In addition, L-arginine had only marginal facilitative effects on touch-based erections (Hull et al., 1994) and failed to increase intracavernosal pressure elicited by electrical stimulation in castrates, with or without testosterone replacement (Reilly et al., 1997). Therefore, most gonadally intact males may have sufficient NOS activity for normal copulation and may not benefit from exogenous precursor or NO donors.

3.2.7.3 Role of NO in Specific Brain Areas *Medial Preoptic Area. Effects of drug microinjections or reverse dialysis into the MPOA.* Reverse dialysis of the NO precursor, L-arginine, into the MPOA increased the rate of mounting, and the NOS inhibitor N(G)-monomethyl L-arginine (L-NMMA) decreased mount rate (Sato et al., 1998). L-NMMA microinjections decreased the number of sexually naïve males that copulated, although it did not affect experienced males; it also increased the number of ex copula seminal emissions (Moses and Hull, 1994, 1999). More recently, microinjections of the NOS inhibitor N(G)-nitro-L-arginine methyl ester (L-NAME) into the MPOA prevented copulation in sexually naïve males and decreased intromissions and ejaculations in experienced males (Lagoda et al., 2004). In addition, L-NAME microinjections in naïve males, before each of seven exposures to an inaccessible female, prevented the facilitation produced by such exposures, which was observed in saline-treated males, compared to nonexposed males (Lagoda et al., 2004).

The most common second messenger for NO is cGMP, although ADP-ribosylation and S-nitrosylation of intracellular proteins may mediate some of NO's effects. Reverse dialysis of a membrane-permeable cGMP analog, 8-bromo-cGMP, increased DA release in the MPOA, whereas an inhibitor of soluble guanylyl cyclase, ODQ, decreased DA levels (Sato and Hull, 2006). In addition, ODQ was able to block the increase elicited by an NO donor, sodium nitroprusside, whereas NOS inhibitor, L-NAME, was not able to block the increase produced by 8-bromo-cGMP, indicating that cGMP was "downstream" from NO. Finally, ODQ blocked the copulation-induced increase in DA and inhibited copulation, whereas 8-bromo-cGMP increased DA release and facilitated sexual behavior (Sato and Hull, 2006). In addition, production of cGMP was decreased in castrated male rats, as were NMDA-induced increases in plasma gonadotropin releasing hormone (GnRH) and in cGMP in MPOA slices (Pu et al., 1996). Therefore, the NO–>cGMP pathway in the MPOA is important for male sexual behavior and neuroendocrine function.

Activins are peptides that are primarily known for their stimulation of follicle stimulating hormone (FSH) in the anterior pituitary and in ovarian and testicular function (Gaddy-Kurten et al., 1995). However, they are also expressed in the brain. Adult activin receptor type II knockout mice have numerous copulatory deficits, including delayed and slowed copulation and fewer copulatory behaviors (Ma et al., 2005). The behavioral impairment was traced to deficient NOS activity in the MPOA, but not in the rest of the hypothalamus or the cortex. These animals had no defects in olfactory or motor functions and no penile malformations. This study provides additional support for the importance of MPOA NOS for male sexual behavior.

Immunocytochemistry. MPOA NOS is upregulated as a result of sexual experience. There was more nNOS-ir, as well as increased nNOS protein in Western blots from the MPOA of males that had copulated previously, whether or not they also copulated on the day they were euthanized (Dominguez et al., in press). The increased DA release occasioned by increased NO in experienced animals may account for at least some of their greater copulatory efficiency and resistance to impairments by stress, lesions, or castration.

MPOA NOS is also hormonally regulated. nNOS-ir in the MPN of male hamsters (Hadeishi and Wood, 1996) and rats (Du and Hull, 1999; Putnam et al., 2005) was decreased by castration. Testosterone replacement for 2, 5, or 10 days in castrated rats produced progressive increases in NOS-ir and improvement in copulation; greater NOS-ir density was correlated with shorter mount latencies (Sato et al., 2005). NOS-ir was restored by estradiol or testosterone replacement, but not by dihydrotestosterone, which cannot be aromatized to estradiol (Putnam et al., 2005). Estrogen receptor-α knockout mice (ERαKO) had less nNOS-ir in the MPN than did wild-type mice or mice that lacked AR because of the testicular feminization mutation (tfm) (Scordalakes et al., 2002). Therefore, aromatization of testosterone to estradiol, which would then bind to ERα, probably mediates the hormonal upregulation of NOS-ir. nNOS is colocalized with gonadal steroid receptors in mice (Scordalakes et al., 2002), rats (Sato et al., 2005), and hamsters (Hadeishi and Wood, 1996). In contrast to the decreases in NOS-ir in castrates in the studies mentioned here, there is one report of castration-induced increases in NOS-ir and activity and decreases produced by either testosterone or dihydrotesterone (Singh et al., 2000). The reason for this discrepancy is not clear, but may be a function of the more posterior location examined by Singh and colleagues or their use of an antibody that labeled very few cells. In summary, copulation is enhanced and GnRH release is increased by NO in the MPOA. Testosterone, probably via aromatization to estradiol and activation of ERα, increases NOS production in the MPN, although apparently not in more posterior areas.

3.2.7.3 Paraventricular Nucleus *Effects of Drugs Administered into the PVN.* Administration of the NOS inhibitor L-NAME into the PVN decreased the number of noncontact erections and impaired copulation in male rats (Melis et al., 1998). Reverse dialysis of a different NOS inhibitor, L-NMMA into the PVN decreased touch-based erections, and the NO precursor L-arginine increased erections; however, neither drug affected copulation (Sato et al., 1999). These authors pointed out that similar administration of L-NMMA into the MPOA did decrease the rate of mounting (Sato et al., 1998). Therefore, NO antagonists in the PVN have consistently inhibited noncontact and touch-based erections, but manipulations of NO have had inconsistent effects on copulation.

Chemical Changes Detected by Microdialysis. Increases in production of NO, inferred from increases in NO_2 and NO_3, were detected in PVN microdialysate during both copulation and noncontact erections

(Melis et al., 1998; Melis et al., 1999a). These increases were blocked by injections of hemoglobin (an NO scavenger) into the ventricle, but not by injections into the PVN; hemoglobin in the PVN also failed to inhibit noncontact erections (Melis et al., 1998). Therefore, NO may work intracellularly in the PVN, but it appears to have additional effects in other areas that regulate erections. Microinjections of morphine into the PVN inhibited both copulation and the copulation-induced increase in NO (Melis et al., 1999a). Reverse dialysis of L-arginine into the PVN increased both NO production and touch-based erections, and the NOS inhibitor L-NMMA had the opposite effects (Sato et al., 1999). Both noncontact erections and NO production were increased by microinjections of apomorphine or the D_2 agonist LY-171555, but not by the D_1 agonist SKF 38393 (Melis et al., 1996). The D_2 antagonist L-sulpiride, but not the D_1 antagonist SCH-23390, blocked the increase in NO production during exposure to the estrous female. However, the increase in erections was blocked by both antagonists, suggesting that both D_1 and D_2 receptors contribute to erectile function. On the other hand, a later study from the same lab reported no effect of PVN administration of either a D_1 or D_2 antagonist, or of an oxytocin antagonist, on noncontact erections or on the production of NO in the PVN, although both were reduced by an NMDA antagonist (Melis et al., 2000c). In addition, the NMDA microinjections that elicited erections (see earlier) also increased NO in the PVN (Melis et al., 1997).

NO production was prevented by microinjection of omega-conotoxin, a potent inhibitor of N-type voltage-activated calcium channels; omega-conotoxin also prevented apomorphine- and oxytocin-induced erections and (Succu et al., 1998). (Intracellular calcium is needed to activate NOS.) Administration of the NO donors sodium nitroprusside or hydroxylamine overcame the effects of the omega-conotoxin; apparently, the NO donors bypassed the need for activation of N-type channels that were indirectly activated by apomorphine and oxytocin. NMDA's facilitation of NO production and erections also was not blocked by omega-conotoxin, because NMDA stimulates ligand-activated calcium channels, not voltage-gated channels.

3.2.7.4 Spinal Cord Intrathecal administration of an NO donor, a cGMP analog, or the PDE 5 inhibitor sildenafil enhanced the increase in intracavernous pressure produced by electrical stimulation of the MPOA; this enhancement was reduced by the NOS inhibitor L-NAME (Sato et al., 2001). These treatments did not affect blood pressure or responses to cavernous nerve stimulation. Therefore, NO and cGMP in the spinal cord can increase erectile funtion.

3.2.8 Opioids

The three major classes of endogenous opioids are endorphins, enkephalins, and dynorphins (reviewed in Mains and Eipper, 1999). β-endorphin and several other neuroactive peptides are synthesized from proopiomelanocortin (POMC) in the hypothalamus and in the anterior and intermediate lobes of the pituitary. Met- and leu-enkephalin are produced from proenkephalin and are distributed throughout the central and peripheral nervous systems. Dynorphins, made from prodynorphin, include four major classes, dynorphins A and B and neoendorphins α and β, which also have a wide distribution. A more recently discovered peptide, orphanin FQ (also called nociceptin), binds to an "orphan" receptor that is structurally similar to other opioid receptors. Besides the orphanin FQ receptor, there are three major types of opioid receptors, μ (activated primarily by β-endorphin), δ (activated by enkephalins), and κ (activated by dynorphins) (Mains and Eipper, 1999). Neuropeptides, including opioids, are usually colocalized with classical transmitters and are released during high neural activity.

3.2.8.1 Effects of Systemically or Intraventricularly Administered Drugs Endogenous opioids and exogenous opiates affect male sexual behavior in a dose-dependent manner (reviewed in Hull et al., 2002). Opioids and opiates are generally thought to inhibit sexual behavior because of the facilitative effects of antagonists in sexually sluggish males (Gessa et al., 1979), sexually satiated males (Rodriguez-Manzo and Fernandez-Guasti, 1995), or sexually naïve males tested in a novel environment (Pfaus and Wilkins, 1995). The μ antagonist naloxone also facilitated copulatory behaviors in male quail, but did not affect anticipatory behaviors (Riters et al., 1999). However, the opiate antagonists naloxone and naltrexone have also produced inhibitory effects, including lengthened postejaculatory intervals (Sachs et al., 1981; van Furth and van Ree,

1994; Ågmo et al., 1994b) and decreased ability of mild tail pinch to activate copulation in castrated rats with subnormal testosterone replacement (Leyton and Stewart, 1996).

In addition to the reports of facilitation of copulation by opioid antagonists, opioid agonists have been found to inhibit sexual behavior. Either morphine or the κ agonists U-50,488 or bremazocine decreased the number of animals that copulated and inhibited the behavior of those that did copulate (Ågmo and Paredes, 1988; Leyton and Stewart, 1992; Ågmo et al., 1994b). However, the inhibitory effects of opioid antagonists on active copulators noted above suggest that at least a minimal amount of stimulation of opioid receptors can facilitate copulation, but an excess may impair it. Inhibition of genital reflexes may account for some of the inhibitory effects of systemically administered morphine. All doses of morphine inhibited touch-based erections and seminal emissions (Gomez-Marrero et al., 1988). However, touch-based erections were also inhibited by naloxone in those experiments, again suggesting that some opioid activity can facilitate sexual function. Naloxone also inhibited anticipatory level changing in a bilevel apparatus (van Furth and van Ree, 1994; van Furth et al., 1994; van Furth and van Ree, 1996), suggesting that sexual motivation is also facilitated by at least minimal endogenous opioid activity. Facilitation of sexual behavior by opioids may result from disinhibition of the mesolimbic DA system, as there are μ receptors on inhibitory GABAergic neurons in the VTA.

Stimulation of κ receptors also impairs sexual behavior. Dynorphins are the endogenous ligands of κ receptors, and they are upregulated after castration (Molineaux et al., 1986; Almeida et al., 1987). Systemic treatment with the κ agonist U-50,448 decreased the number of male rats that copulated and increased ejaculation latencies in the 12% of animals that remained competent (Leyton and Stewart, 1992). Selective κ receptor blockade by pretreatment with nor-binaltorphimine placed into the VTA, NAc, or MPOA, all partially restored decrements in copulation and female-directed investigative behavior induced by systemic U-50,448. Although the mechanism behind the MPOA effect is unclear, it seems likely that the behavioral impairments that follow κ receptor activation in VTA may be due to inhibition of DA neurons there (Margolis et al., 2003, 2005), particularly a subpopulation having projections to the prefrontal cortex (Margolis et al., 2006). Similarly, inasmuch as κ receptor signaling in the NAc is aversive (Carlezon et al., 2006), this would seem to offset natural reinforcers like sex.

Expression of the final class of endogenous opioid, the δ receptor ligand enkephalin, is downregulated in the ventromedial nucleus of the hypothalamus following castration and is restored by estradiol treatment (Hammer et al., 1993). An agonist at δ receptors had modest inhibitory effects on copulation (Ågmo and Paredes, 1988). Increasing endogenous enkephalins by intraventricular injections of an enkephalinase inhibitor decreased the time and number of intromissions preceding ejaculation, and increased mount and intromission latencies (Ågmo et al., 1994a).

In summary, low levels of opioid activity may increase genital reflexes and sexual motivation; however, excess opioid activity can impair sexual behavior, with some measures being more sensitive than others are to such interference. Because testosterone and estradiol downregulate opioids, it is tempting to speculate that opioid peptides may be one mediator of the impairments seen following castration.

3.2.8.2 Role of Opioids in Specific Brain Areas *Medial Preoptic Area. Effects of drug microinjections into the MPOA.* As with systemic manipulations, studies administering opiates or opioids into the MPOA support the proposal that low doses of agonists facilitate, and high doses inhibit copulation. The lowest doses of the μ agonist morphine and of the κ agonist dynorphin (1–13) decreased ejaculation latency and the numbers of intromissions preceding ejaculation, whereas animals treated with the highest dose of morphine failed to resume copulation after the second ejaculation (Band and Hull, 1990). The selective μ agonist morphiceptin increased mount and intromission latencies but had no effect on copulatory performance, touch-based erections, sexual motivation, or locomotion (Matuszewich et al., 1995). However, microinjection of β-endorphin into the MPOA delayed copulation and inhibited its performance without impairing grooming or drinking of sweetened solutions (Hughes et al., 1987; van Furth et al., 1995). In support of the importance of low levels of endogenous opioids, microinjections of naloxone into the MPOA prevented induction of sexual reinforcement (Ågmo and Gomez, 1993).

Immunocytochemistry. Endocytosis of μ opioid receptors in the MPOA was observed within 30 min after copulation; endocytosis was still apparent 6 h later (Coolen et al., 2004). Receptor internalization was

prevented by the opioid antagonist naloxone. Similar endocytosis was elicited by microinjections of a μ agonist, and copulation increased the number of Fos-ir in neurons that contained μ receptors. However, pretreatment with naloxone did not prevent the Fos response in μ receptor-containing neurons, suggesting that the Fos response was not a result of μ activation during mating.

Paraventricular Nucleus. Unilateral administration of morphine into the PVN before presentation of an inaccessible estrous female prevented noncontact erections as well as the increases in production of NO observed with control injections (Melis et al., 1999a).

Ventral Tegmental Area. GABAergic neurons in the VTA contain μ receptors; stimulation of these μ receptors disinhibits DA neurons of the mesocorticolimbic tract (Chiodo, 1988; Johnson and North, 1992). The opioid antagonist naloxone, microinjected into the VTA, decreased anticipatory level changing in a bilevel apparatus but did not affect sexual performance; β-endorphin microinjections had no effect (van Furth and van Ree, 1996). However, microinjections of low doses of morphine into the VTA, but not the substantia nigra, increased female-directed behavior and the proportions of animals displaying mounts, intromissions, and ejaculations (Mitchell and Stewart, 1990). Therefore, stimulation of opioid receptors in the VTA may disinhibit DA neurons there and increase behavioral activation.

Spinal Cord. Effects of Intrathecally Administered Drugs. Intrathecal infusions of naloxone decreased the number of intromissions preceding ejaculation, and intrathecal morphine had the opposite effect (Wiesenfeld-Hallin and Sodersten, 1984). These treatments did not affect other measures of copulation. The authors suggested that opioids influence the strength of the sensory signal from each intromission.

3.2.8.3 Effects of Sexual Experience or Hormones on Opioid Peptides or Precursor Leu- and met-enkephalins and opioid octapeptide were increased in tissue from the cortex, hypothalamus, and midbrain 24 h after copulation either to one ejaculation or to exhaustion, with no significant difference between the two groups (Rodriguez-Manzo et al., 2002a). Met-enkephalin and opioid octapeptide remained elevated in hypothalamic tissue even 48 h after ejaculation. In addition, sexually inactive males had higher enkephalin content in the hypothalamus than did sexually active males, consistent with an inhibitory effect of relatively high opioid levels.

Production of POMC, the precursor of β-endorphin and other neuroactive peptides, is under hormonal control in the mediobasal hypothalamus, which contains the arcuate nucleus, the major population of POMC-producing neurons in the forebrain. There is first a decrease in β-endorphin, measured with radioimmunoassy immediately following castration (Wardlaw and Blum, 1990), followed by a prolonged increase (Wardlaw, 1986). Either 5-α-dihydrotestosterone or estradiol was able to abolish postcastration increases in β-endorphin. These effects were replicated at the level of POMC message, with 4-week castrates showing elevated POMC mRNAs compared to testosterone replaced animals (Blum et al., 1989). Therefore, there is negative regulation of POMC by both estradiol and dihydrotestosterone. The mechanism underlying this effect must be indirect, as only a small portion of POMC neurons expresses ER or AR (Fodor and Delemarre-van de Waal, 2001).

3.2.9 α-Melanocyte Stimulating Hormone and Related Peptides

α-Melanocyte stimulating hormone (α-MSH) is derived from the precursor POMC and is secreted into the systemic circulation from the intermediate lobe of the pituitary. It and related melanocortin peptides are also expressed in numerous CNS and peripheral structures. In addition to α-MSH, these peptides include adrenocorticotropic hormone (ACTH) and β-lipotropin, which are released from the anterior pituitary; the opioid β-endorphin, discussed earlier; and other variants formed by posttranslational processing. They bind to G-protein-coupled receptors (MC-1 to MC-5), all of which activate adenylyl cyclase (reviewed in Giuliano, 2004).

3.2.9.1 Effects of Systemically or Intraventricularly Administered Drugs Intraventricularly administered α-MSH and ACTH were reported as early as the 1960s to increase erections in dogs, cats, rats, mice, and rabbits (reviewed in Argiolas, 1999; Giuliano, 2004). They have also decreased the numbers of mounts and intromissions preceding ejaculation and ejaculation latency. Injection of either α-MSH or ACTH into the

third ventricle elicited penile erections and stretching and yawning in rats; the stretching and yawning were blocked by an MC-4 receptor antagonist, but penile erection was not (Argiolas et al., 2000), suggesting that a different MC receptor mediated facilitation of erection (but see later). However, erections evoked by ACTH were inhibited by either intraventricular or systemic administration of the NOS anatagonist L-NAME, suggesting that the facilitative effects of intraventricular ACTH were mediated by increased central production of NO (Poggioli et al., 1995). Microinjections of ACTH (1–24) into the periventricular hypothalamus, including the PVN, elicited drug-induced erections (Argiolas et al., 2000). Similar injections into the POA, caudate nucleus, or hippocampus were ineffective.

There is currently a resurgence of interest in these peptides, and several synthetic peptides that are selective for subtypes of melanocortin (MC) receptors have been produced. Two of these synthetic peptides have increased erections and sexual interest in men—Melanotan-II, also called MT-II (Dorr et al., 1996; Wessels et al., 1998, 2000; Van der Ploeg et al., 2002) and PT-141 (Molinoff et al., 2003)—with nausea, yawning, stretching, and decreased appetite reported as side effects of MT-II. MT-II is a selective melanocortin-4 (MC-4) agonist that has also increased erections in rats; intrathecal administration was most effective, but intraventricular and intravenous injections also yielded positive effects (Wessels et al., 2003). The effects of MT-II were blocked by the MC-3/MC-4 receptor antagonist SHU 9119, confirming its receptor specificity. Direct intracavernosal injections were ineffective, suggesting that MC receptors in the spinal cord and brain mediated the proerectile activity. Intravenous injections of MT-II also increased cavernosal pressure in rabbits, and, as with rats, isolated cavernosal tissue was not responsive (Vemulapalli et al., 2001). The effects of MT-II were abolished by both SHU 9119 and the NOS inhibitor L-NAME, indicating that the proerectile effects of central MC-3/MC-4 receptors are mediated by release of NO. L-NAME also blocked the proerectile effects of intraventricular ACTH (Poggioli et al., 1995) and α-MSH (Mizusawa et al., 2002) in rats. In addition, MT-II facilitated copulation and augmented erections elicited by stimulation of the cavernous nerve in wild-type, but not MC-4 receptor knockout mice (Van der Ploeg et al., 2002). MC-4 receptors were expressed on nerve fibers and mechanoreceptors in both rat and human penis, but not in cavernosal smooth muscle; they were also expressd in rat spinal cord, brain stem, hypothalamus, and pelvic gangion (Van der Ploeg et al., 2002). Intranasal administration of the MC-4 agonist PT-141 also elicited erections in rats and in men with erectile dysfunction (Molinoff et al., 2003). Finally, a different, highly selective, MC-4 receptor agonist, THIQ, administered either systemically or intraventricularly, increased intracavernous pressure and elicited reflexive erections in rats; these effects were blocked by a synthetic MC-4-preferring antagonist, MBP10, as well as by the endogenous nonselective antagonist, agouti-related protein (Martin et al., 2002).

3.2.9.2 Effects of Hormones on α-MSH Measurements of hypothalamic α-MSH by radioimmunoassay show a testosterone-reversible decrease in the peptide 3 weeks following castration (Scimonelli and Celis, 1987). This is in contrast to the castration-induced increase in the precursor, POMC, as well as β-endorphin, as noted in the preceding section. In this way, castration reduced levels of a prosexual neuropeptide, even while increasing expression of its encoding gene. The simplest explanation that can reconcile these findings is that posttranslational processing of POMC may be differentially regulated with regard to its neuroactive cleavage products: In the absence of gonadal steroids, β-endorphin synthesis proceeds unimpeded and in a manner that is positively correlated with the abundance of POMC transcripts. Synthesis of α-MSH, on the other hand, appears to be inhibited and results in a much lower peptide-to-transcript ratio. This creates a circumstance in which castrates experience both an excess of the sexually inhibitory β-endorphin, and an insufficiency in the prosexual α-MSH.

In summary, α-MSH and ACTH, as well as the synthetic MC-3 and MC-4 receptor agonists, can promote erection by acting synergistically at nerve endings in the penis, the lower spinal cord, and several brain areas. Some of these effects are mediated by NO.

3.2.10 Oxytocin

The nonapeptide oxytocin is synthesized in the PVN and in the supraoptic nucleus. Magnocellular PVN neurons descend to the posterior pituitary, from which they release oxytocin into the circulation.

Parvocellular PVN neurons release oxytocin into numerous CNS structures. Circulating oxytocin stimulates smooth muscle and thereby facilitates seminal emission and, in humans, contributes to orgasm. In female mammals, it stimulates parturition and milk letdown. Plasma oxytocin was increased by copulation in naïve, but not sexually experienced male rats (Hillegaart et al., 1998). In the naïve males, plasma oxytocin was correlated with intensity of copulation.

3.2.10.1 Effects of Systemically or Intraventricularly Administered Drugs Systemically administered oxytocin reduced ejaculation latency and postejaculatory interval in male rats (Arletti et al., 1985). This facilitative effect extends to older (~20 months) rats that were "sexually sluggish" (Arletti et al., 1990). In these animals, oxytocin treatment reduced mount, intromission, and ejaculation latencies, as well as postejaculatory intervals. In addition, oxytocin increased the number of animals able to initiate additional bouts of copulation after the first ejaculation. Systemically administered oxytocin also restored copulation in male rats whose copulatory behavior had been impaired by chronic fluoxetine (Cantor et al., 1999). Facilitative effects of low doses of oxytocin have also been observed in dominant squirrel monkeys (Winslow and Insel, 1991). Conversely, intraventricular infusions of a peptide antagonist at oxytocin receptors dose-dependently impaired or abolished copulation in sexually experienced rats (Argiolas et al., 1988a). However, high doses of oxytocin have inhibited copulation in prairie voles (Mahalati et al., 1991) and rats (Stoneham et al., 1985; reviewed in Witt, 1995).

Intraventricular injections of oxytocin also increased spontaneous erections, and this increase was blocked by an oxytocin antagonist or an anticholinergic drug (atropine), but not by a DA antagonist (Argiolas et al., 1986, 1988b). The oxytocin antagonist also blocked erections elicited by the DA agonist apomorphine (Argiolas et al., 1988b), suggesting that DA is "upstream" of oxytocin in the control of drug-induced erections; ACh may, in turn, be "downstream" from oxytocin. In addition, an oxytocin antagonist, administered intraventricularly, inhibited noncontact erections, suggesting a role of oxytocin in the control of erections elicited by normal physiological stimuli, as well as drug-induced erections (Melis et al., 1999a). Finally, oxytocin injected systemically in 7-day-old neonatal rats elicited the rhythmic ejaculatory pattern characteristic of adult male rats (Carro-Juarez and Rodriguez-Manzo, 2005). The ejaculatory pattern matured over a period from postnatal day 2 until it was fully mature on day 28.

Presumptive evidence for the role of oxytocin in male sex behavior also comes from experiments in which levels of oxytocin in the CSF were seen to increase markedly following copulation (Hughes et al., 1987). Although the change in oxytocin level was significant by 5 min after ejaculation, it did not peak for another 15 min. This is likely due to the poor spatial and temporal resolution of the sampling method in which CSF was tapped rather than dialyzed.

3.2.10.2 Role of Oxytocin in Specific Brain Areas *Paraventricular Nucleus. Effects of drug microinjections into the PVN.* Microinjection of oxytocin into the PVN elicited drug-induced erections (Melis et al., 1989). However, an oxytocin antagonist administered into the PVN failed to inhibit those erections, although icv administration of the antagonist was effective (Melis et al., 1989). This suggests that axons from the PVN, terminating perhaps in the hippocampus (Melis et al., 1992), facilitate noncontact erections.

Immunocytochemistry. Fos-ir in the parvocellular PVN was increased by both intromission and ejaculation, with ejaculation inducing 2.5 times as many Fos-ir neurons (Witt and Insel, 1994). Ejaculation also elicited more Fos-ir in the magnocellular PVN than did intromission, although there were fewer labeled cells than in the parvocellular region. In half of the neurons, Fos was colocalized with oxytocin, even in noncopulating males. In fact, copulation did not alter the percentage of double-labeled cells, except in the most caudal portion of the PVN, where one-third of the lateral parvocellular neurons were double labeled after ejaculation, but no cells were double labeled in noncopulating animals. On the other hand, use of an antibody that is more selective for Fos, as opposed to Fos plus Fos-related antigens (Fras), revealed no double labeling of Fos and oxytocin following ejaculation in male rats (L. Coolen, personal communication). In gerbils, PVN Fos expression was not increased by exposure to an arena previously associated with copulation or by copulation itself (Heeb and Yahr, 1996). However, a more recent study found that copulation did increase double labeling for oxytocin and Fos-ir (Nishitani et al., 2004). Fos-ir was also increased in oxytocin-containing cells in sexually experienced males, but not in naïve males, following

exposure to an anesthetized female. Variability in Fos-ir in nonoxytocin cells may have contributed to a lack of statistical significance in the earlier studies that found no Fos increases.

Spinal Cord. Effects of intrathecally administered drugs. Lumbosacral, but not thoracolumbar, administration of oxytocin dose-dependently increased intracavernous pressure (Giuliano et al., 2001b). An oxytocin antagonist or pelvic nerve section blocked oxytocin's proerectile effects. Intrathecal administration of an NO inhibitor blocked the proerectile effects of intrathecally administered oxytocin, suggesting that the effects of oxytocin in the spinal cord are mediated by NO interneurons. Vasopressin, a nonapeptide that differs from oxytocin by only one amino acid, was ineffective, as was systemically administered oxytocin. Oxytocin's facilitative effects were not inhibited by blockade of striated muscle activation, suggesting that oxytocin's effects were mediated by the parasympathetic nervous system, rather than by striated penile muscles. Oxytocin release in the spinal cord also promotes seminal emission in rats. Excitotoxic lesions of the parvocellular PVN significantly reduced oxytocin content in the lower lumbar spinal cord and decreased the weight of seminal plugs following ejaculation, but did not affect measures of copulatory behavior (Ackerman et al., 1997). Together, these data provide compelling evidence for a role of oxytocin-containing axons from the PVN to the lumbosacral cord in both erection and seminal emission.

Expression of mRNA or immunocytochemistry for oxytocin. The PVN sends oxytocinergic axons to the thoracolumbar spinal cord, where they form dense clusters around sympathetic preganglionic neurons in the intermediolateral cell column (Swanson and McKellar, 1979; Millan et al., 1984). Oxytocinergic axons also make synaptic contacts on preganglionic neurons in the sacral parasympathetic nucleus (Swanson and McKellar, 1979; Schoenen et al., 1985; Tang et al., 1998) as well as the dorsal horn and the dorsal gray commissure (Véronneau-Longueville et al., 1999). These contacts provide a mechanism for oxytocin to regulate both parasympathetic facilitation of erections and sympathetic regulation of seminal emission and ejaculation.

Sexually impotent male rats had less expression of oxytocin mRNA in the PVN, and greater expression of mRNA for proenkephalin and prodynorphin, than did sexually competent males (Arletti et al., 1997). This finding fits well with the observation that morphine in the PVN inhibited NO production and copulation (Melis et al., 1999a). In addition, NOS is colocalized with oxytocin in the PVN (Yamada et al., 1996). Activation of these neurons facilitates ex copula erections and may contribute to copulation. The oxytocin is released in the hippocampus, where it promotes erections (Melis et al., 1992), and in the spinal cord, where it promotes both erection and seminal emission (Ackerman et al., 1997; Giuliano et al., 2001b).

3.2.11 Gonadotropin-Releasing Hormone

GnRH is a decapeptide that is produced in the mediobasal hypothalamus, lamina terminalis, and MPOA (Barry et al., 1985). It is released in the median eminence and carried via the hypophyseal portal system to the anterior pituitary, where it stimulates gonadotropin secretion. GnRH also acts as a neuromodulator in the MPOA and amygdala, as well as several other brain areas (Barry et al., 1985; Kostarczyk, 1986). Female pheromones elicit GnRH release in mice and hamsters (Meredith and Fernandez-Fewell, 1994; reviewed in Meredith, 1998; Westberry and Meredith, 2003).

3.2.11.1 Effects of Systemically or Intraventricularly Administered Drugs Experiments manipulating GnRH have provided inconsistent results. One study, by Moss and his colleagues, found that GnRH decreased the intromission and ejaculation latencies in castrated male rats that were maintained on a low dose of testosterone; GnRH was ineffective in gonadally intact males (Moss et al., 1975). However, Myers and Baum found that only intact males, but not testosterone-replaced castrates, were facilitated (Myers and Baum, 1980). In fact, the postejaculatory interval in testosterone-treated castrates was actually lengthened by GnRH. Phoenix and Chambers also found lengthened postejaculatory intervals in old rhesus monkeys after GnRH administration (Phoenix and Chambers, 1990). Ryan and Frankel found no effects of GnRH in male rats (Ryan and Frankel, 1978), but Dorsa and Smith reported increased mount

rates in male rats with anesthetized genitalia (Dorsa and Smith, 1980), and Boyd and Moore observed decreased intromission and ejaculation latencies in gray-tailed voles (Boyd and Moore, 1985). Intraventricular administration of GnRH promoted copulation in sexually naïve male hamsters whose vomeronasal organs had been removed (VNX) (Fernandez-Fewell and Meredith, 1995). VNX male hamsters are usually able to copulate only if they have had previous sexual experience; therefore, GnRH administration compensated for the lack of sexual experience. Intraventricular GnRH also increased female pheromone-induced Fos-ir in the MPOA of intact male hamsters and in sexually experienced VNX hamsters (Westberry and Meredith, 2003). GnRH increased pheromone-induced Fos-ir in the medial amygdala, but not the MPOA, of sexually naïve VNX males. GnRH improved sexual function in hypogonadal men with decreased LH release (Mortimer et al., 1974). However, it led to little (Benkert, 1975; Ehrensing et al., 1981) or no (Perras et al., 2001) improvement in men with erectile dysfunction.

Chronic administration of a synthetic GnRH agonist ([6-D-(2-napthyl)-alanine]GnRH) led to decreased testosterone levels and a disruption of copulation in gonadally intact male rats (Dorsa et al., 1981). This inhibitory effect probably occurred because continuous high doses of GnRH inhibit LH release and gonadal function; normally endogenous GnRH is released in a pulsatile fashion (Knobil, 1980; Crowley et al., 1985). Therefore, GnRH agonists have been suggested as potential antifertility drugs (Brodie and Crowley, 1984). However, they can also inhibit sexual behavior, probably because of the decrease in testosterone.

3.2.12 Galanin and Galanin-Like Peptide

Galanin is known primarily for its role in stimulating feeding. However, it has also produced apparently contradictory effects on sexual behavior.

3.2.12.1 Effects of Intraventricularly Administered Drugs Intraventricular microinjections of galanin decreased the numbers of mounts and intromissions in male rats (Poggioli et al., 1992). Those behaviors were increased by a galanin antagonist (galantide) (Benelli et al., 1994). However, intraventricular injections of a galanin antagonist in male ferrets decreased the time they spent near a receptive female, although it did not influence copulation (Park and Baum, 1999). It is not clear whether differences in site, species, dosage, or other factors account for these contradictory findings. Galanin-like peptide (GALP) is derived from a different gene but shares partial sequence homology with galanin. Intraventricular administration of GALP facilitated copulation in male rats, whereas similar injections of galanin inhibited the same measures that GALP had facilitated (Fraley et al., 2004). GALP stimulates GnRH secretion; however, even castrated males showed facilitative effects of GALP, suggesting that the behavioral effects were not mediated by increases in testosterone secretion.

1.3.2.12.2 Role of Galanin in Specific Brain Areas *Medial Preoptic Area.* In contrast to the apparently inhibitory effects of intraventricular galanin, microinjections of galanin into the MPOA of castrated, testosterone-replaced rats facilitated their mating behavior (Bloch et al., 1993). In addition, galanin neurons in the MPOA of male rats were activated selectively by ejaculation (Bakker et al., 2002).

Subparafascicular Nucleus of the Thalamus. The parvocellular portion of the subparafascicular nucleus of the thalamus (SPFp) comprises medial and lateral subdivisions. The medial subdivision contains numerous galanin-ir fibers (Veening and Coolen, 1998). Mating induces Fos in the medial subdivision, and galanin-ir fibers surround the Fos-positive nuclei. A major input to the medial SPFp is from laminae 7 and 10 of the lumbosacral spinal cord (Gréco et al., 1999; Truitt et al., 2003; Coolen et al., 2003), and the SPFp has bidirectional connections with forebrain areas that control sexual behavior (Coolen et al., 2003). Many of these connections also contained AR and mating-induced Fos (Gréco et al., 1998). Thus, galanin may be used to relay ejaculation-related somatosensory information to the SPFp, which relays it to forebrain areas related to ejaculation.

Spinal Cord. Neurons that project to the SPFp originate in segments L3 and L4 of the lumbar spinal cord (Wells and Coolen, 2001; Truitt and Coolen, 2002) and contain both galanin and CCK (Ju et al., 1987).

They are believed to relay somatosensory information from the genitals to the brain. Galanin- and CCK-containing neurons showed increased Fos-ir only in males that ejaculated, and not in those that only mounted or intromitted (except for a few Fos-ir neurons in one male that only intromitted) (Truitt and Coolen, 2002). In addition, ejaculatory ability of male rats was severely impaired by lesions of galanin-containing neurons in L3 and L4 (Truitt and Coolen, 2002). Therefore, these galanin-containing neurons are critical for eliciting ejaculation, not just relaying ejaculation-specific sensory information to the brain.

3.2.13 Orexin/Hypocretin

Orexin/hypocretin neurons are located in the perifornical lateral hypothalamus. This peptide is better known for its facilitation of feeding and prolonging wakefulness. However, recent studies suggest that it is important for several other functions, including male sexual behavior.

3.2.13.1 Role of Orexin/Hypocretin in Specific Brain Areas *Medial Preoptic Area.* Microinjection of orexin/hypocretin into the MPOA of male rats facilitated copulation, decreasing mount, intromission, and ejaculation latencies, while also increasing frequencies for these copulatory measures (Gulia et al., 2003).

Lateral Hypothalamus. Either exposure to a receptive female or copulation increased the number of orexin/hypocretin neurons that were Fos-ir, compared to exposure to another male or placement into an empty cage, respectively (Muschamp et al., 2004). Orexin/hypocretin is hormonally regulated. The number of orexin/hypocretin immunopositive cells near the perifornical lateral hypothalamus declined markedly at 28, but not 7 or 14 days following castration (Muschamp et al., 2004). Findings for the 28-day group were replicated using Western immunoblot, in which a ~20% decrease in hypothalamic orexin/hypocretin was seen, compared to sham-treated controls. It is unknown, however, which gonadal steroid mediates this effect. Whereas a small population (<5%) of orexin/hypocretin neurons in the dorsomedial hypothalamus coexpress ERα, the majority of cells express neither this receptor, nor nuclear AR, suggesting indirect hormonal regulation of orexin/hypocretin transcription (Muschamp, unpublished data).

Ventral Tegmental Area. Although orexin/hypocretin is likely to enhance sexual performance by its actions at the MPOA, its effects on sexual motivation may be exerted at the VTA, as orexin/hypocretin seems to influence natural reward (Harris et al., 2005; Thorpe et al., 2005). Intra-VTA orexin/hypocretin increased NAc DA efflux (Narita et al., 2006), and orexin/hypocretin peptides increased VTA DA neuron activity in vitro (Korotkova et al., 2003) and in vivo (Muschamp, unpublished data).

3.2.14 Other Peptides

3.2.14.1 Vasoactive Intestinal Peptide Vasoactive Intestinal Peptide (VIP) stimulates adenylyl cyclase in the corpus cavernosum, which contributes to smooth muscle relaxation and penile erection (reviewed in Aoki et al., 1994; Bivalacqua et al., 2000). VIP and ACh antagonists reduced erection elicited by pelvic nerve stimulation; however, administration of VIP and ACh together did not elicit a full erectile response (Suh et al., 1995). Therefore, although both VIP and ACh contribute to erection, they are not the principal mediators of that effect. VIP may also facilitate copulation. Systemically administered VIP reduced intromission latencies and interintromission intervals in castrated male rats that were maintained on suboptimal testosterone replacement; these effects were blocked by coadministration of a VIP antagonist (Gozes et al., 1989).

3.2.14.2 Prostaglandin E_2 Injection of prostaglandin E_2 (PGE_2) into the fourth ventricle of male rats decreased the postejaculatory interval (reviewed in Moltz, 1990; Blumberg, 1991). This treatment also increased basal forebrain temperature, measured in the MPOA. Similarly, microinjection of PGE_2 into the MPOA of castrates with subthreshold testosterone replacement activated copulation, with 40% of the treated males ejaculating within 30 min (Clemens and Gladue, 1977). MPOA temperature normally

increases during copulation and decreases following ejaculation (Blumberg and Moltz, 1987). It is not clear whether PGE_2 facilitates copulation directly, or by increasing brain temperature. Manipulations of PGE_2 during early development also influence masculinization of rats (Amateau and McCarthy, 2004; Todd et al., 2005).

3.2.14.3 Neuropeptide Y Neuropeptide Y (NPY) is distributed widely throughout the brain and is often colocalized with NE (Chronwall et al., 1985). Intraventricular administration of NPY stimulated feeding in male rats but inhibited copulation (Clark et al., 1985a; Poggioli et al., 1990). Conversely, intraventricular administration of an NPY antagonist facilitated copulation (Poggioli et al., 1994). However, systemic administration of NPY did not affect reflexive erections (Clark et al., 1985a).

3.2.14.4 Prolactin Numerous studies in the 1980s reported inhibitory effects of chronic prolactinemia, resulting from implantation of excess pituitary glands or prolactin-secreting tumors, from drugs that stimulate prolactin release, or by injection of prolactin itself (reviewed in Hull et al., 2002). Increased mount and ejaculation latencies and general slowing of copulation were the most commonly reported effects. However, not all studies found inhibitory effects of prolactin, and the mechanism by which chronic elevations of prolactin may impair sexual behavior is not clear.

3.2.14.5 Corticotropin-Releasing Hormone Corticotropin-Releasing Hormone (CRH) injected into the third ventricle increased latencies to mount, intromit, and ejaculate and increased the numbers of mounts and intromissions preceding ejaculation (Sirinathsinghji, 1987). These effects were attenuated by coadministration of the opioid antagonist naloxone. CRH can also inhibit GnRH release, perhaps by acting through endogenous opioids (Almeida et al., 1988). CRH promotes freezing and flight behaviors, suggesting that it facilitates a constellation of behaviors that are appropriate to stressful situations.

3.2.14.6 Cholecystokinin Cholecystokinin (CCK) has produced mixed effects on male sexual behavior. In one study, systemic administration of sulfated CCK decreased both the number of intromissions preceding ejaculation and ejaculation latency; the CCK antagonist proglumide reversed these effects (Pfaus and Phillips, 1987). However, other studies found that systemic (Linden et al., 1987; Bloch et al., 1988) or intraventricular (Bloch et al., 1988; Dornan and Malsbury, 1989) administration of CCK was without effect. However, the two main subtypes of CCK receptor (Altar, 1989) may have opposite effects (Dauge et al., 1989; Minabe et al., 1991). Therefore, lack of significant effects of CCK may result from opposing excitatory and inhibitory effects.

Microinjection of a cholecystokinin A (CCK_A) antagonist into the posteromedian portion of the NAc attenuated the facilitation that resulted from electrical stimulation of the VTA (Markowski and Hull, 1995). A similar result was observed with either a CCK_A or CCK_B antagonist microinjected into the anterolateral NAc (Markowski and Hull, 1995). In the posteromedian NAc, CCK is located in dopaminergic terminals, but it is in nondopaminergic terminals in the anterolateral portion (Hokfelt et al., 1980). Therefore, CCK in the NAc may potentiate the facilitative effects of mesocorticolimbic DA activity.

3.2.14.7 Angiotensin II Microinjections of angiotensin II into the third ventricle increased intromission latencies, numbers of intromissions preceding ejaculation, and postejaculatory intervals (Clark, 1989). The dose that produced the greatest inhibition of sexual behavior also increased drinking during the test. A more recent study also reported inhibitory effects of angiotensin II and those effects were blocked by an angiotensin I receptor antagonist administered in the drinking water (Keaton and Clark, 1998). However, it is not clear if the inhibition of sexual behavior was a direct effect or a result of increased thirst.

3.2.14.8 Hexarelin Analog Peptides Microinjections of hexarelin analog peptides into the PVN elicited erections, probably by stimulating receptors on oxytocin-containing cell bodies, which would increase Ca^{2+} influx and activate NOS (Melis et al., 2000b, 2001; reviewed in Argiolas and Melis, 2004).

4 Summary

Steroid hormones orchestrate the production and release of neurotransmitters in key CNS sites that control sexual motivation and copulatory performance. Dopamine, glutamate, and, in some cases, norepinephrine are the major facilitative neurotransmitters, and serotonin, GABA, and opioid peptides provide primarily inhibitory influence. However, activation of specific receptor subtypes may oppose the effects of other receptor subtypes that are activated by the same neurotransmitter. For example, some dopaminergic and serotonergic receptor subtypes promote parasympathetically mediated erection, and other subtypes facilitate sympathetically mediated seminal emission and ejaculation. The neuropeptides oxytocin, orexin/hypocretin, α-melanocyte-stimulating hormone, gonadotropin-releasing hormone, and galanin-like peptide may facilitate mating, whereas NPY, prolactin, corticotropin-releasing hormone and angiotensin II usually have inhibitory effects. The brain areas that are especially important for the control of male sexual behavior are the MPOA, the medial amygdala, the PVN of the hypothalamus, the mesocorticolimbic dopamine tract, several midbrain and brainstem nuclei, and nuclei in the spinal cord that control the erectile and ejaculatory reflexes.

5 Unanswered Questions and Future Directions

Answers to previous questions inevitably lead to new questions that can guide future research. Some of these questions include: Which neurotransmitters, and which receptors, mediate the behavioral effects in the various sensory, integrative, and motor control sites? Which neuropeptides are coreleased with classic neurotransmitters, in which brain areas, and under which conditions? Do alterations in neurotransmitter release primarily reflect changes in cell firing or influences on presynaptic terminals? Which (combinations of) neurotransmitters mediate long-term changes in sensitivity, as opposed to immediate responses to stimuli? Which ion channels or second messenger systems elicit the immediate and long-term effects of neurotransmitters in brain areas that respond to sexually relevant stimuli? What changes in neurotransmitter function or gene expression mediate the facilitative effects of sexual experience?

1 Introduction: Why Study Feminine Sexual Behavior in Rodents from Neuroendocrine and Molecular Neuroendocrine Perspectives?

Feminine sexual behavior in animals is studied by researchers in a variety of fields for an assortment of reasons. While some are interested in feminine sexual behavior from a strictly behavioral, comparative, or evolutionary perspective, others use it as a biologically significant behavior worthy of study to understand neuroendocrine, cellular, and molecular mechanisms. In this review, we will focus on the background and the research that have contributed to an understanding of the neuroendocrine, cellular, and molecular neuroendocrine underpinnings of this complex set of behaviors.

The neuroendocrine regulation of feminine sexual behaviors has long been used as a model to probe the cellular processes by which hormones act in the brain to result in changes in behavior. There are several reasons why this particular set of behavior lends itself particularly well to this analysis. Feminine sexual behavior has reflexive components that are readily studied and quantified. Motivational components are under hormonal regulation, as are sensory and motor aspects. Finally, the behaviors are influenced by an integration of hormonal and environmental factors. Because of the richness of the literature on the neuroendocrine and molecular neurobiology of feminine sexual behavior in rats, guinea pigs, and mice, most of the work to be discussed will focus on those species.

2 Description of Behaviors

A variety of terms have been used to describe the various components of feminine sexual behavior. Beach (1976) proposed that feminine sexual behavior comprises three basic types of behaviors: receptivity, proceptivity, and attractivity. Receptivity in rodents is defined as the reflexive postural responses by the female to sexual contact. In female rats, sexual receptivity, exemplified by lordosis, is accompanied by immobility, rear leg extension, dorsiflexion of the spine, elevation of the head, and tail deviation (Pfaff et al., 1973). Proceptive behaviors include a number of behaviors that indicate the female's willingness to mate and are usually followed by mounts by the male. These behaviors include, for example, ear-wiggling and darting and hopping. Attractivity, or the elements that make the female attractive to the male, comprises both behavioral and nonbehavioral aspects. These may include olfactory cues and visual displays.

More recently, Blaustein and Erskine (2002) suggested another set of categories of sexual behavior to highlight the active contribution of the female. These include copulatory, paracopulatory, and progestative behaviors. Copulatory behaviors are the behaviors that result in successful transfer of sperm from the male to the female. Although, like the term receptivity, this refers mainly to lordosis, this term emphasizes active participation by the female. Additional copulatory behaviors include those postural adjustments that occur during lordosis, and which are required to facilitate intromission by the male (Adler et al., 1977).

Paracopulatory behaviors are species-typical behaviors displayed by females, which presumably arouse the male and stimulate him to mount. In addition to Beach's term, proceptivity (Beach, 1976), these behaviors have been referred to as precopulatory (Madlafousek and Hlinak, 1977) or soliciting (Erskine, 1989) behaviors. Paracopulatory behaviors shown by estrous female rats include ear-wiggling (Beach, 1976; Madlafousek and Hlinak, 1977), presenting postures (Emery and Moss, 1984a, b), a rapid sequence of approach toward, orientation to, and withdrawal from a sexually active male (darting and hopping) (McClintock and Adler, 1978), and production of ultrasonic vocalizations (White and Barfield, 1989). The frequency and rate at which these paracopulatory behaviors are expressed are influenced by many factors, including hormone levels, the rate of copulation, and a variety of experimental conditions (Erskine, 1989).

The third component of feminine sexual behavior, progestative behaviors, includes those behaviors that increase the probability of occurrence of pregnancy (Blaustein and Erskine, 2002). These behaviors include primarily the female's pacing of sexual interactions, through approaches toward and withdrawals from the male (Bermant, 1961; Peirce and Nuttall, 1961; Krieger et al., 1976; Gilman and Hitt, 1978; Erskine, 1985). Also included are behaviors that regulate the frequency and timing of intromissions and ejaculations and include the female's selection of males that are ready to ejaculate (McClintock and Anisko, 1982) and the

female's postejaculatory interval, which enhances sperm transport by preventing removal of the copulatory plug (McClintock et al., 1982). These short-term behavioral adjustments in the timing of sexual interactions, in addition to adoption of a lordosis posture that allows for a sufficient level of vaginocervical stimulation (VCS) (Erskine et al., 2004), increase the probability of reproductive success.

3 Basic Neuroendocrinology of Feminine Sexual Behavior

Many behavioral tests have been used to assess the different aspects of sexual behaviors in female rodents. Each technique for assessing a particular aspect of sexual behavior fills in a different piece of the puzzle. Each technique has its advantages, and each has its disadvantages, which will be discussed, along with their neuroendocrine underpinnings.

3.1 Copulatory Behaviors

In many species, including rats and mice, lordosis in response to mounts by a sexually vigorous male is assessed as an index of copulatory (or receptive) behavior. Often, the lordosis quotient, the percentage of mounts that result in lordosis, is the only metric used. In rats, the lordosis rating, a rating on a 0–3 scale reflecting the intensity of the response, is often used as well (Hardy and Debold, 1971; Hardy and DeBold, 1972). In guinea pigs and hamsters, species with a sustained and obvious lordosis posture, lordosis duration is typically used, often in response to manual palpation (Young, 1969; Noble, 1973) (often with a soft brush in hamsters).

Although it took many decades and a multitude of experiments to fully understand the basic hormonal underpinnings of feminine sexual behavior in rats and guinea pigs, it is clear that during the estrous cycle, the sequential secretion of estradiol and progesterone from the ovaries results in a period of sexual behavior that is linked to the time of ovulation (Collins et al., 1938; Boling and Blandau, 1939; Powers, 1970; Barfield and Lisk, 1974) (*Figure 3-1*). After the period of sexual behavior (heat; behavioral estrus) terminates, sexual receptivity is not seen until the proestrous stage of the reproductive cycle returns, with the next episode of secretion of estradiol followed by progesterone. Many of the experiments on the neuroendocrinology of feminine sexual behavior were limited to assessing influences only on receptivity, so a bit of caution is warranted in generalizations to other aspects of sexual behavior.

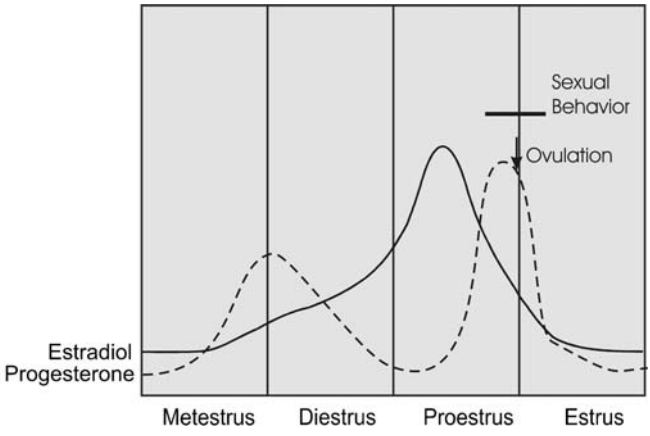
Removal of the ovaries causes an immediate decline in circulating ovarian hormones, and consequently cessation of the expression of feminine sexual behaviors (Dempsey et al., 1936; Boling and Blandau, 1939). Results of experiments in which rats or guinea pigs were ovariectomized at precise times during the estrous cycle demonstrate that the hormonal requirements for the induction of optimal sexual behavior include a sufficient period of estradiol priming followed by exposure to progesterone (Powers, 1970; Joslyn et al., 1971). Although far less work has been done in mice, it is clear that many of the same neuroendocrine principles apply to that species as well (Ring, 1944; Edwards, 1970; Thompson and Edwards, 1971; Mani et al., 1997; Rissman et al., 1997a, b), albeit with some notable differences, which will be discussed later (see *section 3.5*).

Estradiol and progesterone are both necessary and sufficient for optimal levels of sexual behaviors. Rats (Davidson et al., 1968), guinea pigs (Crowley et al., 1978), hamsters (Carter et al., 1976), and mice (Mani et al., 1997) respond to treatment with estradiol alone under some conditions. However, it is sequential treatment with estradiol and progesterone that typically results in expression of feminine sexual behavior that most resembles that seen in estrous-cycling rodents (Dempsey et al., 1936; Collins et al., 1938; Boling and Blandau, 1939; Beach, 1942; Edwards, 1970; Tennent et al., 1980). Increasing doses of estradiol used for priming allow lower levels of progesterone to be used to facilitate sexual behavior, and increasing doses of progesterone allow for lower priming doses of estradiol (Whalen, 1974).

Often after exposure to progesterone, rats (Powers and Moreines, 1976; Blaustein and Wade, 1977; Morin, 1977), hamsters (Carter et al., 1976), guinea pigs (Dempsey et al., 1936; Goy et al., 1966; Zucker, 1966, 1968), and mice (Edwards et al., 1968) become refractory to further stimulation of sexual behavior by either progesterone alone or, in some cases, estradiol and progesterone. Although progesterone desensitizes

Figure 3-1

Schematic diagram depicting the relationship between estradiol and progesterone during the estrous cycle of female rats. Although there are differences in the regulation of the estrous cycle among the species discussed in this review—guinea pigs, rats, hamsters, and mice—most of the elements of hormonal changes around the time of expression of sexual behaviors are similar. Note that the increase in progesterone around the time of metestrus/estrus is due to secretion from the corpus luteum, which is short-lived, unless the female rat becomes pregnant or pseudopregnant



response to itself in ovariectomized rodents receiving exogenous hormones, and it has generally been accepted that progesterone inhibits sexual behavior in guinea pigs under some circumstances (Goy et al., 1966; Feder et al., 1968), its role in termination of sexual behavior during the estrous cycle (Sodersten and Hansen, 1977; Hansen and Sodersten, 1978; Sodersten and Eneroth, 1981) and pregnancy (Baum et al., 1979; Blaustein and Feder, 1979a) of rats is unclear. As will be discussed later (see *section 4.2.6.2*), it has been suggested that it is not progesterone per se that is the proximate cause of heat termination. Rather, it is the secondary influence of progesterone and other factors on the regulation of neural progestin receptors (PRs) that seems to be critical to heat termination and the ensuing refractoriness to further stimulation by progesterone (also known as sequential inhibition).

Estradiol and progesterone are not the only sex hormones involved in regulation of sexual behaviors. In fact, dihydrotestosterone is inhibitory to the induction of sexual receptivity (Baum et al., 1974; Tobet and Baum, 1982; Blasberg et al., 1998), and it has been suggested as one of the factors that determines the duration of the period of sexual receptivity during the estrous cycle (Erskine, 1983).

The time course of estradiol and progesterone action on sexual behavior is of great interest, particularly inasmuch as it provides additional clues to the underlying cellular processes by which hormones act in the brain. Although estradiol priming of response to progesterone generally takes about a day (Green et al., 1970; Feder and Marrone, 1977), an intravenous injection of progesterone facilitates the expression of lordosis within an hour of injection (Meyerson, 1972; Kubli-Garfias and Whalen, 1977; McGinnis et al., 1981; Glaser et al., 1983). Therefore, it is clear that progesterone induces its neuronal changes associated with sexual behavior considerably more rapidly than estradiol, which suggests possible differences in the cellular mechanisms of each of the hormones.

3.2 Paracopulatory Behaviors

In some studies in rats and hamsters, paracopulatory behaviors, such as darting and hopping, ear-wiggling (Gerall et al., 1972; Pfaus et al., 2004), and ultrasound production (Barfield and Schoelch Krieger, 1977; McIntosh et al., 1977; Geyer and Barfield, 1978; Geyer et al., 1978; Floody et al., 1979), have also been

assessed. Sometimes, rejection behaviors, presumably indicative of aversive components of sexual interaction, are also quantified.

Paracopulatory behaviors are generally thought to be dependent on progesterone. Although estradiol alone induces paracopulatory (Fadem et al., 1979; Gorzalka and Moe, 1994), as well as copulatory (Boling and Blandau, 1939), behaviors in ovariectomized rats, in most cases, progesterone of adrenal origin has been shown to be necessary for the paracopulatory, but not the copulatory behaviors (Tennent et al., 1980; Gorzalka and Moe, 1994). However, with extremely high doses of estradiol, paracopulatory behaviors can be seen even in ovariectomized–adrenalectomized rats (Zemlan and Adler, 1977). It should be noted that on occasion, very high levels of paracopulatory behavior have been observed in ovariectomized–adrenalectomized rats, even with quite low doses of estradiol (SF Farrell and JD Blaustein, unpublished observations), suggesting that paracopulatory behaviors are not totally progesterone dependent. While lordosis can be observed within 1 h of progesterone treatment, maximum levels of paracopulatory behaviors are seen within about 2 h of treatment (Fadem et al., 1979; Glaser et al., 1983).

The importance of examining different aspects of sexual behavior is illustrated in a recent pharmacological experiment. Using this strategy, Pfaus and coworkers (2004) demonstrated a selective stimulatory effect of PT-141, a peptide analog of α melanocyte-stimulating hormone, which binds to melanocortin 2 receptors on the soliciting (paracopulatory) behaviors, but neither on lordosis (copulatory behavior) nor pacing (progestative) behavior. This type of finding suggests that lordosis, although critical for vaginal intromission and useful in some studies as a bioassay for particular cellular processes, cannot be used as a proxy for the full repertoire of sexual behaviors that allow the female to also initiate and pace the timing of sexual contact. Thus, limitations of individual behavioral tests highlight a need for a combination of behavioral tests required to elucidate the complexities of feminine sexual behavior.

3.3 Progestative Behaviors: Pacing

While indices of copulatory and paracopulatory behaviors are useful parameters, feminine sexual behavior is far more complex than these. Many studies of feminine sexual behavior have been performed in small arenas in which the male, not the female, is the principal controller of the rate of sexual stimulation. In contrast, in a natural or semi-natural condition, the solicitation behavior of the female activates the male pursuit and consequently the type and timing of mating stimulation (McClintock and Adler, 1978; McClintock and Anisko, 1982). Several methods are used to allow and assess the pacing of sexual interactions by the female. These include mating in bilevel chambers in which the female can move between the two levels to pace the rate of sexual interaction (Mendelson and Pfaus, 1989; Pfaus et al., 1999), an arena with a partition with a small hole through which the female, but not the male, can enter and exit (Erskine et al., 1989; Paredes and Alonso, 1997), or a bar-pressing situation in which the female must press a lever to gain access to the male (Bermant, 1961; Bermant and Westbrook, 1966; Matthews et al., 1997).

The role of estradiol and progesterone in pacing behavior has been studied. In general, nonreceptive rats do not pace (Brandling-Bennett et al., 1999). Although paracopulatory behaviors are dose dependent on progesterone, recent data suggest that pacing is unaffected by the dose of progesterone (Brandling-Bennett et al., 1999). However, it should be noted that in some situations, dose dependence of contact–return latencies on progesterone has been observed (Gilman and Hitt, 1978; Fadem et al., 1979). The reasons for the discrepancy in the role of progesterone are unclear, but it may relate to the specific procedures used.

In a direct comparison of paced mating during the estrous cycle and after injection of 10 μg estradiol benzoate followed by 500 μg progesterone in ovariectomized rats (Zipse et al., 2000), return latencies after mounts or intromissions, but not ejaculations, were considerably longer in the ovariectomized, hormone-replaced rats than in ovary-intact rats. Although this issue of timing of rate of copulation is of tremendous importance, at this time, there is virtually no understanding of the cellular mechanisms that underlie these acute, transient changes in the female's behavior.

It must be kept in mind that not all effects of steroid hormones on feminine sexual behavior are due to effects of the hormones in the brain. For example, the systemic administration of the estrogen antagonist, ICI-182,780, which does not seem to cross the blood-brain-barrier (Wade et al., 1993), was injected in rats

treated with estradiol + progesterone (Clark et al., 2003). While the antagonist was without effect on the expression of lordosis in response to mating stimulation by male rats, it lengthened the return latencies after intromission and ejaculations in a paced mating situation. Although the mechanism by which this occurs is not known, it is unlikely to be by an action on the brain. The possibility has been suggested that peripheral, nociceptive changes are involved (Clark et al., 2003).

3.4 Sexual Motivation

While assessment of naturally occurring paracopulatory behaviors, such as darting and hopping, and ear-wiggling, goes beyond mere recording of the lordosis response (Erskine, 1989), there is no evidence that these are indices of the female's motivation to mate. Because hormones influence the female's motivation to mate, techniques have been developed to assess this more complex aspect of feminine sexual behavior. These include, for example, tests of partner preference, the increasing barrier method, and tests of conditioned place preference.

Assessing sexual motivation often involves determining whether the female will seek proximity to a sexually active male (Meyerson and Lindstrom, 1973; Clark et al., 1981a; Edwards and Pfeifle, 1983). In addition, it can be determined if the female displays a partner preference for a sexually active male over another stimulus animal (Meyerson and Lindstrom, 1973; Edwards and Pfeifle, 1983). In this situation, females are placed in a three-compartment chamber in which two stimulus animals are positioned in different compartments, and the length of time the female spends with each animal is recorded. Preference for a sexually active male is interpreted as an increase in her sexual motivation. In general, rats in the proestrus/estrus stage of the estrous cycle, or rats injected with estradiol, testosterone, or estradiol + progesterone, are more likely to approach sexually active males (Meyerson and Lindstrom, 1973; Edwards and Pfeifle, 1983; De Jonge et al., 1986; Clark et al., 2004), demonstrating an influence of these hormones on the female's sexual motivation.

The female's motivation is influenced by the ability of the male to copulate with her. Females spend less time with males that are allowed to copulate with them than with males that are not allowed to mate. In tests with two sexually active and interactive stimulus males, ovariectomized rats treated with estradiol and progesterone avoid contact with the males, and spend more time in a neutral compartment. In addition, when given a choice between a castrated and an intact male, the females spend more time with the castrated male than with the intact male. However, females exposed to males in a situation that restricts their sexual interactions (for instance, by keeping the males in a wire cage or by using a vaginal mask to prevent intromissions) spend more time with sexually active males than with castrated, inactive males (Meyerson and Lindstrom, 1973; Broekman et al., 1988). These results suggest that females initially seek out contact with sexually active males, but that the mating stimulation they receive results in subsequent avoidance of this stimulation. This avoidance has also been observed in female rats, where intensive mounting accompanied by intromission and ejaculation by stimulus males during mating, not only reduces the probability and the intensity of lordosis response, but also enhances the rejection behaviors by the female (Hardy and Debold, 1971).

Stimulation by a male is reinforcing only when the females are allowed to pace the sexual interaction (Gilman and Westbrook, 1978), consistent with the idea that paced mating is a rewarding aspect of sexual behavior (Paredes and Vazquez, 1999; Martinez and Paredes, 2001). Finally, when a contact situation allows for pacing, lack of preference for a sexually active male is demonstrated in her pacing behavior, spending a lot of time away from the male (Clark et al., 2004). Therefore, the specific type of mating stimulation provided can have dramatic influences on the female's apparent motivational state, and the particular testing situation used must be kept in mind in interpretation of each experiment.

There are many inconsistencies in published reports of experiments, which have assessed motivation through the use of partner-preference tests (Oldenburger et al., 1992). Clark et al. (2004) recently published an informative paper that elaborates the inconsistencies in results of experiments that have used this technique. They point out the importance of allowing or not allowing contact with the male have on the

results of partner-preference tests. They argue for the importance of having a contact and no-contact test when assessing sexual motivation using partner-preference tests.

Sexual motivation can also be assessed by the increasing barrier method in which an electric grid is positioned between the starting cage and the goal cage containing a stimulus male (McDonald and Meyerson, 1973). The grid current is increased across trials, and the number of grid crossings and the maximum current exposure to gain contact with the male are measured as indices of motivation. In general, proestrous–estrous female rats and ovariectomized rats injected with estradiol are more willing to overcome the aversive stimulus and perform a higher number of grid crossings when approaching a sexually active male (Meyerson and Lindstrom, 1973), consistent with the idea that hormonal changes influence the female's motivation for sexual behavior.

Recently, conditioned place preference has been used extensively to assess the female's motivation for various aspects of the mating situation (Oldenburger et al., 1992). For example, it has been used to establish that estradiol− or estradiol + progesterone-treated female rats prefer a compartment, which has previously been associated with sexual interaction. They prefer, however, a compartment associated with a caged male to one in which copulation has been allowed. Similar to what was seen in partner-preference experiments, females develop a conditioned place preference for compartments in which they have been allowed to pace the mating, but not places where rate of copulation has been determined by the male (Martinez and Paredes, 2001). Furthermore, estradiol alone is not sufficient to induce the reward state that leads to a conditioned place preference; progesterone is necessary (Paredes and Alonso, 1997; Paredes and Vazquez, 1999; Gonzalez-Flores et al., 2004a).

3.5 Mice: A Different Pattern

The feminine sexual behavior of mice differs from rats, guinea pigs, and hamsters in a fundamental way. Although other species tend to respond to appropriate hormonal treatment at first exposure after ovariectomy, mice generally do not (Thompson and Edwards, 1971; Mani et al., 1996; Mani et al., 1997; Rissman et al., 1997a). In fact, mice often require numerous exposures to estradiol and progesterone before they express high levels of sexual receptivity, and as would be expected, this varies with strain of mouse (Thompson and Edwards, 1971) and housing conditions (Laroche et al., 2005). Interestingly, weekly hormone treatments are not effective without being accompanied by the experience of behavioral testing (Thompson and Edwards, 1971).

Most research on mice assesses sexual receptivity by way of the expression of lordosis in response to mounts by a sexually vigorous male. However, in one attempt to determine the presence of other behaviors using a semi-natural environment (Garey et al., 2002), a darting behavior was reported after mounting, that the authors suggested resembled a paracopulatory behavior. Likewise, after being mounted, the female was reported to dart to another part of the arena and then return, similar to pacing in rats.

4 Cellular Mechanisms of Hormone Action

As demonstrated by the preceding discussion, a good deal is known about the hormonal regulation of paracopulatory and progestational behaviors and on motivational aspects of sexual behaviors. However, the majority of research on cellular and molecular underpinnings of sexual behavior has been on the simplest, most reductionist measure of sexual receptivity, the lordosis response. Much of the discussion regarding cellular mechanisms of feminine sexual behavior will be focused on this behavior, but information about other aspects of sexual behavior will be added when known.

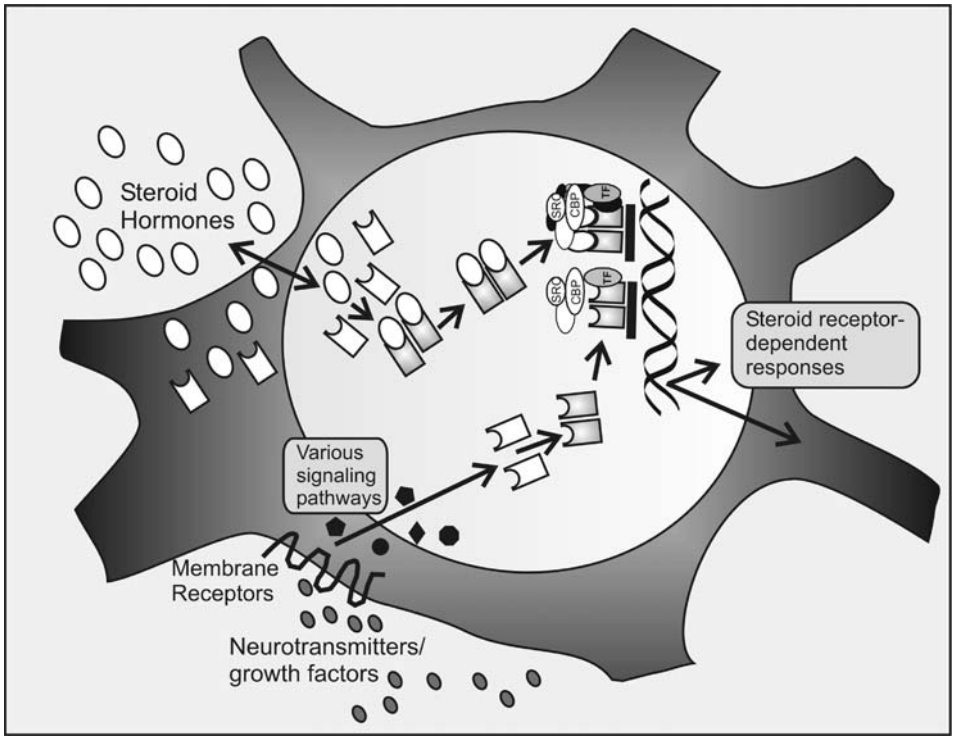
It was originally proposed (Gorski et al., 1968; Jensen et al., 1968) that steroid hormone receptors act by a two-step mechanism that involved steroid hormone binding to the receptor in the cytoplasm of cells, the receptor undergoing a conformational change, allowing it to be translocated to the cell nucleus. This model has morphed and become far more complex in the past four decades. The two-step model was modified in 1984 (King and Greene, 1984; Welshons et al., 1984), when it was reported that both unoccupied and

occupied estrogen receptors (ERs) are present almost exclusively in cell nuclei. It was suggested that the high concentration of unoccupied receptors typically found in the cytoplasm (usually in the cytosol—the high-speed supernatant after cell fractionation) was a procedural artifact. It should be noted that the presence of unoccupied receptor in cytoplasm remains somewhat controversial, seen in some situations (e.g., Blaustein, 1994), not others.

What started out as a very simple model of hormone binding to receptor protein and inducing changes in gene expression has become more elaborate over the years (*Figure 3-2*). A variety of protein–protein interactions is involved in steroid hormone regulation of the transcriptional machinery. This includes association with various heat shock proteins (Toft et al., 1987; Pratt and Toft, 1997; Gehring, 1998) and coregulators (McKenna et al., 1999; Tetel, 2000). Furthermore, much is now known about the nature of

Figure 3-2

Simplified, schematic representation of mechanism of action of steroid hormone receptors. Unoccupied receptors are present inactive complexes associated with heat shock proteins and chaperone proteins (not shown). In the classical, ligand-dependent pathway of activation of receptors by steroid hormones, binding of cognate hormone to receptors results in conformational change, dissociation of heat shock proteins, dimerization of the receptor, and binding to target DNA sequences (hormone response elements). The ligand-induced conformational change facilitates recruitment of cofactors and other basal TFs to the promoters of target genes, producing a transcriptionally active complex that can direct target gene transcription. Protein kinases and PPs present in the cell contribute to receptor activation by altering the phosphorylation of both receptor and coregulators (e.g., SRC-1 and cAMP-binding protein). Compounds such as neurotransmitters and growth factors can activate second messengers and protein kinase pathways in a rapid manner to activate receptors and/or coactivators in a ligand-independent pathway. In addition, although not depicted here, rapid effects of hormone and metabolites may involve direct actions on membrane receptor sites, GPCRs, ion channels, and second messenger systems



hormone response elements, often found in the promoter region of target genes. Coregulators (coactivators and corepressors) have been demonstrated to form a functional link between the activated steroid receptors and the transcriptional machinery for efficient transcriptional regulation. The modular arrangement of these complexes provides potential for different activators to assemble diverse configurations of regulatory complexes at the promoters of genes (McKenna et al., 1999; Glass and Rosenfeld, 2000; McKenna and OMalley, 2002). In vitro studies suggest that the relative expression levels of the coactivators and corepressors determine cell-specific, appropriate, and graded responses to steroid hormones (Lonard and O'Malley, 2005).

It also was originally believed that steroid receptors required hormone ligand for activation, which is of course how steroid receptors originally received their names. However, it is now well accepted that receptors can be activated by a variety of intracellular signaling pathways in the absence of hormone by a process called ligand-independent activation (Power et al., 1991a, b; Blaustein, 2004b). This will be discussed later in this chapter (*Section 7.1*).

4.1 Estrogen Receptors

Nearly 20 years after an estrogen-specific binding protein that met the criteria for a receptor was first documented (Gorski et al., 1968; Jensen et al., 1968), and its presence confirmed in the brain (Eisenfeld, 1969), the first ER gene, *ERα*, was cloned and sequenced (Greene et al., 1986). A second ER gene (*ERβ*) was discovered (Kuiper et al., 1996) 20 years later, and its protein was also found in the brain. ERβ shares a high level of sequence homology with ERα in some portions of the protein. Although both receptors bind to estradiol with similar binding affinity, they may differ in their affinity for other estrogens (Kuiper et al., 1997).

Depending on the ligand and the estrogen response elements present in cells, ERα and ERβ can have different transcriptional activities (Paech et al., 1997; Hyder et al., 1999; Zou et al., 1999). Furthermore, ERα and ERβ may heterodimerize or homodimerize, then bind to estrogen response elements, and have different transcriptional activities, depending on the particular dimer present (Pettersson et al., 1997, 1998; Tremblay et al., 1999). Using an in vitro genetic conjugation approach, it has been demonstrated that ERα not only functions as the dominant partner in the ERα/ERβ heterodimer in genomic signaling pathways dependent on estrogen response elements, but ERα homodimers also can mimic the transregulatory function of the heterodimer (Li et al., 2004). Because the responses of cells to estradiol depend on the presence and abundance of each ER subtype and the integrated effects of the homo- and heterodimers, an understanding of the distribution and the extent of cellular coexpression of ERα and ERβ in different neuroanatomical areas is essential.

4.1.1 Estrogen Receptor Distribution in Brain

Many of the studies on ER involvement in feminine sexual behavior were performed before the discovery of ERβ, with the reasonable assumption that there was one ER. Therefore, in earlier studies using in vitro receptor assays, which relied on binding of estradiol, the results obtained represented a complex, variable mixture of both receptors. On the other hand, in immunocytochemical studies, the original antibodies used were specific for ERα, so the results told only part of the story, albeit an important part, considering the critical role of ERα in feminine sexual behavior (Rissman et al., 1997a).

Although autoradiographic work and in vitro binding assays (Pfaff, 1968; Stumpf, 1968; Pfaff and Keiner, 1973; Warembourg, 1977; Rainbow et al., 1982c) demonstrated a high density of estradiol-concentrating cells in a variety of hypothalamic, limbic, and, to a lesser extent, midbrain structures, a full understanding of the role of ERs requires a comprehensive understanding of the location of each of the receptors. ERα and ERβ have distinct expression patterns through the brain, and each is present in abundance in a variety of brain regions (Simerly et al., 1990; Shughrue et al., 1997; Osterlund et al., 1998;

Shughrue et al., 1998a; Greco et al., 2001). In some cases, both are present in the same locations or individual neurons (Greco et al., 2001; Devidze et al., 2005), but not in others.

Although not localized exclusively to these regions, ERα mRNA or protein is expressed most densely throughout the bed nucleus of stria terminalis, in the posterodorsal part and cortical nucleus of the amygdala, medial and periventricular preoptic area, arcuate nucleus, ventromedial and periventricular hypothalamus, the ventral part of the lateral septum, and the midbrain central gray (Simerly et al., 1990; DonCarlos et al., 1991; Shughrue et al., 1997; Merchenthaler et al., 2004).

Abundant ERβ mRNA or protein has been reported in hypothalamic and limbic regions, which are known to contain high concentrations of ERα and PRs, as well as in other regions known to express little or no ERα or PRs. Although there is overlap of the areas expressing ERβ and ERα mRNA (Shughrue et al., 1996, 1997) and/or protein (Li et al., 1997; Shughrue and Merchenthaler, 2001; Merchenthaler et al., 2004), in the bed nucleus of stria terminalis, most amygdaloid nuclei, and medial and periventricular preoptic area, distribution of ERβ mRNA or protein extends to some regions containing no detectable or low levels of ERα (Shughrue and Merchenthaler, 2001; Merchenthaler et al., 2004). Some of the most striking differences in distribution between ERα and ERβ are found in the paraventricular and supraoptic nuclei, which are rich in ERβ mRNA with almost no detectable ERα mRNA (Shughrue et al., 1996, 1998a; Simonian and Herbison, 1997; Alves et al., 1998; Laflamme et al., 1998), as well as the dentate gyrus, isocortex, accessory olfactory nucleus, anterodorsal portion of the preoptic nucleus, and cerebellum. Most importantly, for a discussion of hormonal regulation of feminine sexual behavior, ERβ is abundant in the medial preoptic area, bed nucleus of stria terminalis, medial amygdala, ventromedial nucleus of the hypothalamus (VMN), midbrain central gray, and ventral tegmentum in rats (Shughrue and Merchenthaler, 2001; Merchenthaler et al., 2004), and it is present in all of these regions in mice as well (Mitra et al., 2003).

Since ERs can exist as homodimers or heterodimers, it is essential to know the coexpression patterns of the two receptors at the cellular level, not just at the level of whole brain areas. The highest proportion of cells coexpressing ERα and ERβ are within the principal nucleus of the stria terminalis, the posterodorsal medial amygdala, and the periventricular preoptic nucleus (Shughrue et al., 1998b; Greco et al., 2001). In the anteroventral periventricular area, 83% of the cells expressing ERα protein also coexpress ERβ mRNA. However, many cells containing only ERα or ERβ are also found in these regions. Because genes may be differentially regulated by the particular combinations of the ER dimers, changes in the intracellular coexpression may influence the moment-to-moment response of particular ER-dependent genes.

4.1.2 Role of Transcription Factor (Direct Genomic) Estrogen Receptors in Sexual Behavior

4.1.2.1 Interference with Estrogen Receptors The necessity of ERs for action of estradiol on sexual receptivity has been tested directly in two ways; using estrogen antagonists, which block the binding of estradiol to ERs, and in ER gene-disrupted mice (ERKOs, ER knockouts).

4.1.2.2 Estrogen Antagonists Receptor-blocking experiments demonstrated the necessity of the presence of unoccupied ERs and of accumulation of bound receptors in mediating the effects of estradiol on sexual behavior. Although the first estrogen antagonists used did not differentiate the two forms of ERs, treatment with a variety of antiestrogens that block the binding of estradiol to ERs, also blocks the effects of estradiol on the induction of sexual behavior (Landau, 1977; Roy and Wade, 1977; Walker and Feder, 1977a; Wade and Blaustein, 1978; Etgen, 1979; Vagell and McGinnis, 1996).

Antiestrogens can act as both estrogen antagonists and estrogen agonists, depending on the cell type and the context. For example, the antiestrogen tamoxifen and some other antiestrogens are antiestrogenic on breast tissue (Jordan, 1995), but estrogenic on bone metabolism (Jordan, 1999). Likewise, antiestrogens may block effects of estradiol on feminine sexual behavior (Roy and Wade, 1977), but have estrogenic effects on other behaviors [e.g., feeding; Roy and Wade (1976)] or neuronal endpoints. Furthermore, antiestrogens

can act both as antagonists or agonists on the same end-points, including feminine sexual behavior, depending on timing of administration and dose (Walker and Feder, 1977b; Wade and Blaustein, 1978; Wilcox and Feder, 1983; Etgen and Shamamian, 1986). While the data currently available deal with the effects of antiestrogens on ERs in general, it will be interesting to learn the effects of ERα- versus ERβ-specific antagonists and agonists on feminine sexual behavior.

4.1.2.3 Estrogen Receptor Gene-Disrupted Mice Because the two forms of ERs are made from independent genes, knockout strains of mice have been developed in which the gene for each (Lubahn et al., 1993; Krege et al., 1998) or both (Couse and Korach, 1999) of the receptors is disrupted. Targeted disruption of the *ERα* gene completely eliminates hormonal induction of feminine sexual behavior (Rissman et al., 1997a; Ogawa et al., 1998). However, disruption of the ERβ is without apparent effect in ovariectomized, hormone-injected mice (Kudwa and Rissman, 2003), but extends the period of behavioral estrus and enhances receptivity in estrous cycling mice (Ogawa et al., 1999). Double knockout mice (αβERKOs) with disruption of both ERs are not only infertile, but also show decreased levels of sexual receptivity confirming the critical role of ERα in copulatory behavior in mice (Kudwa and Rissman, 2003). Interestingly, an important role for ERβ in defeminization of the brain and behavior has recently been suggested (Kudwa et al, 2005).

While the knockout strains of mice provide powerful models for the study of the role of particular proteins in behavior, they suffer from all of the well-known shortcomings of this technique. The observed effects are a result of loss of receptors during early development, as well as absence during adulthood. In addition, some knockouts are not true null mutations. In fact, the first ERαKO mouse developed (Lubahn et al., 1993) had a residual ER fragment containing the AF2 region of the gene (Couse et al., 1997), and it has been shown that the transactivational activity can be as high as 75% of the full ERα in one cell type (Kos et al., 2002) and varies considerably by cell type. While this fragment does not allow for estradiol facilitation of feminine sexual behavior under typical hormonal priming conditions (Rissman et al., 1997a), under some conditions there is, in fact, a moderate amount of induction of neural PRs that could be mediated by this fragment (Moffatt et al., 1998; Kudwa and Rissman, 2003).

4.1.3 Necessity of Long-Term Retention of Estrogen Receptors

Is it necessary that estradiol remain bound to ERs in neurons for the full period of priming of sexual behavior, or is a short exposure sufficient? Although it was originally proposed that estradiol is needed only to trigger the early events necessary for subsequent response to progesterone (McEwen et al., 1975), later work showed that a small amount of estradiol remained bound to ERs in vivo a day after estradiol injection (Blaustein et al., 1979), the time at which animals express sexual behavior in response to progesterone treatment. Treatment with estrogen antagonists, long after estradiol injection, eliminates this remaining bound estradiol, inhibiting the expression of sexual behavior (Blaustein and Wade, 1977; Walker and Feder, 1979; Blaustein and Feder, 1979a). Therefore, it appears that estradiol must remain bound to activated ERs and interact with ER elements on particular genes around the time that sexual behavior is expressed. The reason for this undoubtedly relates to half-lives of transcripts and relevant proteins directed by the occupied ERs, but this area of research has not progressed to a point at which this type of question about molecular neuroendocrinology can be answered.

4.1.4 Involvement of Coregulators of Estrogen Receptors

Although a great deal of work has been done on the role of coregulators in modulation of transcriptional activity of ERs in vitro, very little has been done within the context of ER action in behavior. However, work in rats using antisense oligonucleotides to steroid receptor coactivator (SRC) mRNA reveals that SRC-1 and CBP (cAMP response element binding protein [CREB] binding protein) act together to modulate the induction of sexual receptivity by estradiol (Molenda et al., 2002), as well as progesterone (Molenda-

Fugueira et al., 2006). Likewise, others (Apostolakis et al., 2002) have shown the importance of SRC-1 and SRC-2 in the cellular action of estradiol in the induction of feminine sexual behavior in rats and mice.

4.1.5 Transcriptional Networks Involved in the Ventromedial Nucleus of the Hypothalamus

A novel approach has recently been used to characterize the network of genes involved in hormonal regulation of lordosis. Making the assumption that the ventrolateral aspect of the VMN is an essential component in the display of hormonally induced lordosis, individual neurons were probed for the expression of various mRNAs (Devidze et al., 2005). Real-time quantitative PCR was used to determine expression patterns for mRNAs for ERα, ERβ, oxytocin receptor, and four protein kinase C (PKC) isozymes. This type of experiment, of course, generates a tremendous amount of data. However, the most interesting results are obtained from analysis of patterns of expression of multiple transcripts. A marked sex difference was observed in the expression of four different PKC isozymes in cells expressing ERα, ERβ, and oxytocin receptors. However, there are some important limitations to this single-cell approach. Lesions of this particular neuroanatomical area do not always lead to severe deficits in estradiol plus progesterone-induced sexual behavior (*Section 5*), and of course, there is no way of determining if the neurons selected are actually involved in the particular behavior or physiological end-point of interest. Nevertheless, this novel approach promises to be a strong one in developing a catalog of the expression patterns associated with neurons in brain areas involved in feminine sexual behavior.

4.1.6 Regulation of Neural Estrogen Receptors by Ovarian Hormones

In general, estradiol downregulates ERα mRNA (Lauber et al., 1990; Simerly and Young, 1991), protein (Yuri and Kawata, 1991; Meredith et al., 1994; Osterlund et al., 1998), and [^{3}H]estradiol binding (Brown et al., 1996), but there are a number of discrepancies in the literature. Estradiol downregulates ERα mRNA levels in the arcuate nucleus and ventrolateral–VMN (Simerly and Young, 1991; Lauber et al., 1991). Greco et al. (2001) reported a decrease in ERα protein in the posterodorsal medial amygdala and paraventricular nucleus, but not the principal nucleus of bed nucleus of stria terminalis. However, estradiol treatment caused a decrease in ERα-ir in the guinea pig ventrolateral hypothalamus and the bed nucleus of stria terminalis, but not the periventricular preoptic area (DonCarlos et al., 1995). In related work in guinea pigs, estradiol downregulated ERα-ir in all brain areas studied, with the exception of the medial preoptic nucleus (Meredith et al., 1994). In recent work, it has been reported that estradiol increases ERα mRNA expression in some individual neurons of the ventrolateral–VMN (Devidze et al., 2005). Unfortunately, it is not known what accounts for these differences, but they could relate to specific physiological context or phenotypic differences in different cells.

Estradiol seems to either downregulate ERβ or have no effect, mainly based on the particular neuroanatomical area in which ERβ is assessed. One study reported a decrease in ERβ mRNA in the paraventricular nucleus, but not other areas (Patisaul et al., 1999), while another (Greco et al., 2001) reported a decrease in ERβ-ir in the periventricular preoptic area and the bed nucleus of stria terminalis, but not the paraventricular nucleus and posterodorsal medial amygdala. Shima et al. (2003) reported decreases in ERβ mRNA in a variety of areas including the amygdala, but not the medial preoptic area, ventromedial hypothalamus, or bed nucleus of stria terminalis. In contrast, a decrease in ERβ mRNA in the posterodorsal medial amygdala, but an increase in the arcuate nucleus, has been reported (Osterlund et al., 1998). In the recent study of mRNA within single cells in the ventrolateral aspect of the VMN discussed in the previous section, no change in ERβ mRNA expression was observed after estradiol treatment (Devidze et al., 2005) As with ERα, it is not known what accounts for these inconsistencies among studies. Nevertheless, it is reasonable to conclude that estradiol downregulates ERβ in some areas of the brain, and not others, and that the specifics depend on physiological and specific cellular context.

One situation in which the regulation of ERs by steroid hormones would be expected to be robust is after ovariectomy. Ovariectomy typically decreases the response of rats and guinea pigs to hormonal induction of sexual behavior (Beach and Orndoff, 1974; Clark et al., 1981b; Czaja et al., 1985; Delville and Blaustein, 1989). Long-term ovariectomy (Parsons et al., 1979; Clark et al., 1981b; Delville and Blaustein, 1989) results in a decrease in the concentration of estradiol-induced, hypothalamic PRs in rats, presumably secondary to diminished responsiveness to estradiol. Although typically no change in brain ERs has been reported after long-term ovariectomy (Parsons et al., 1979; Clark et al., 1981b), one study suggests that long-term ovariectomy results in an increase in ERα immunoreactivity (Liposits et al., 1990). Although this apparent increase in ERs after ovariectomy is consistent with the finding of downregulation of ER mRNA and proteins by acute estradiol (Simerly and Young, 1991; Meredith et al., 1994; DonCarlos et al., 1995), it does not explain the change in response to estradiol and progesterone, which typically results from ovariectomy. The fact that long-term ovariectomy, which decreases behavioral response to estradiol and progesterone, suppresses estradiol induction of PRs in the hypothalamus suggests a relationship of behavioral response to PR induction. The fact that ERs do not seem to be decreased by long-term ovariectomy suggests that regulation of response may occur at one of the many other steps involved in estradiol action or in subpopulations of ERα-containing neurons.

Although there have not been any studies to date that have investigated the effects of progesterone specifically on each form of ER, ligand-binding studies, which assess both ERα and ERβ, have typically found that progesterone downregulates ERs in hypothalamus (Smanik et al., 1983; Attardi, 1984; Blaustein and Brown, 1984).

Modulation of the concentration of steroid hormone receptors should be thought of as a means by which sensitivity to a particular class of hormone is modulated. Changes in the concentration of a particular receptor should result in changes in sensitivity to the hormone. Unfortunately, much of the immunocytochemical work that has been published has reported the number of cells, which immunostain positively for a particular receptor. However, "number of cells" can be influenced by sensitivity of the procedure used, and often tells us little about the concentration of protein in particular, relevant cells. While we are still a long way off from being able to assay concentrations of receptor protein in individual relevant cells, optical density measurements can provide indications of relative levels after particular treatments, as long as the quantitative aspects of the analysis are interpreted cautiously.

4.1.7 Another Neurally Active Form of Estradiol?

Finally, yet another twist in the ever-more complex story of ER action in the brain comes from reports that 17α-estradiol is an active estrogen in the brain (MacLusky et al., 2005; Toran-Allerand et al., 2005), while all along has been assumed that only the 17β-isomer was active. The mechanism by which the 17α-isomer exerts its effects is unclear, and it may involve a newly characterized receptor, ERX (Toran-Allerand et al., 2002, 2005) or a membrane receptor derived from the transcription-factor ER (Wade et al., 2001). Nevertheless, it is clear that 17α-estradiol induces functional changes in spatial memory and in synaptogenesis (MacLusky et al., 2005), and has neuroprotective effects in the brain (Green et al., 1997). It has also been suggested that 17α-estradiol is synthesized in the brain, as it is present even in ovariectomized–adrenalectomized rats (Toran-Allerand et al., 2005). Although potentially of great interest, earlier work failed to find an effect of this isomer on sexual receptivity (MacLusky et al., 1985).

4.2 Progestin Receptors

Although difficult to imagine considering the progress that has been made in the past three decades, early attempts to extend the intracellular receptor model of steroid hormone mechanisms to progesterone action in the brain were unsuccessful. There were numerous controversial and conflicting reports regarding the presence of neural PRs, based on in vitro binding techniques (Seiki and Hattori, 1973; Atger et al., 1974; Seiki et al., 1977) and in vivo unsaturable [^{3}H]progesterone uptake (Whalen and Luttge, 1971; Wade and

Feder, 1972; Luttge et al., 1974). While [^{3}H] progesterone or its metabolites were shown to concentrate in guinea pig brain in autoradiographic studies (Sar and Stumpf, 1973; Warembourg, 1978b), attempts to characterize the receptors biochemically were mostly unsuccessful (McEwen, 1976; Marrone and Feder, 1977). The development of R 5020 (promegestone), a synthetic progestin with a higher affinity for PRs than progesterone, was an important step in providing assays to identify and characterize neural PRs (Kato and Onouchi, 1977; Blaustein and Wade, 1978; Kato et al., 1978; MacLusky and McEwen, 1978; Moguilewsky and Raynaud, 1979b; Blaustein and Feder, 1979c).

4.2.1 Progestin Receptor Distribution in Brain

While estradiol priming dramatically increases the concentration of PRs (assayed by in vitro binding) in some neuroanatomical areas, including the hypothalamus and medial preoptic area of rats and guinea pigs (MacLusky and McEwen, 1978; Moguilewsky and Raynaud, 1979b; Blaustein and Feder, 1979c; Balthazart et al., 1980; Roselli and Snipes, 1983; Fraile et al., 1987) and the midbrain of guinea pigs (Blaustein and Feder, 1979c), PRs in other areas are mostly unaffected (MacLusky and McEwen, 1978, 1980). The punch microdissection technique provided slightly better spatial resolution than the grosser dissection done earlier (Parsons et al., 1982b; Thornton et al., 1986). With this technique, brain regions with the highest abundance of estradiol-induced PRs included the arcuate nucleus, the VMN, the periventricular preoptic area, the periventricular hypothalamus, the suprachiasmatic preoptic area, and the medial preoptic area, all areas that also have a high concentration of ERs (Rainbow et al., 1982c). Evidence obtained with the autoradiographic technique (Sar and Stumpf, 1973; Warembourg, 1978b) was consistent with the presence of PRs in the areas in which estradiol induces the highest level of PRs.

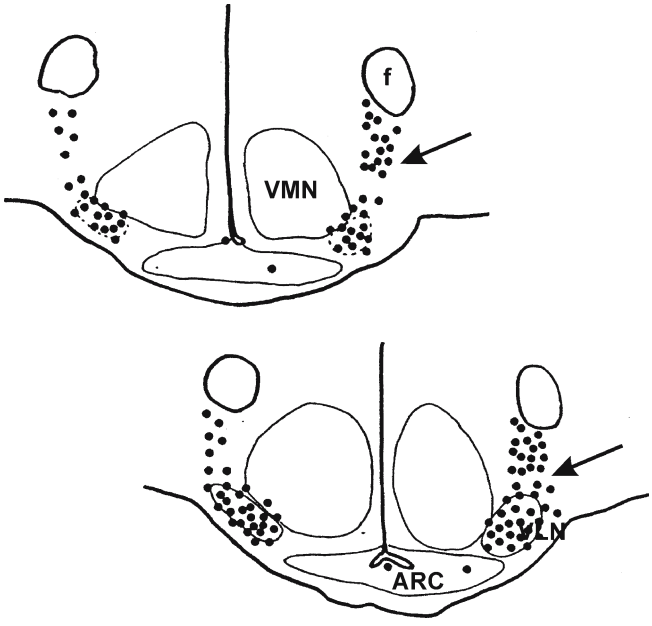
Despite the progress, a longstanding question that has remained unanswered is whether the PRs observed in many sites throughout the brain using in vitro binding assays represent a low level in all cells, or a few, scattered cells with an abundance of PRs (Blaustein and Olster, 1989). The development of a sensitive technique, immunocytochemistry (Warembourg et al., 1986; Blaustein et al., 1988; DonCarlos et al., 1989), provided much better anatomical resolution. Using this technique, the sites with the highest number of estradiol-induced PR-immunoreactivity (PRir) neurons in guinea pigs were found to be the bed nucleus of arcuate nucleus, periventricular preoptic region, medial preoptic nucleus, medial preoptic area, and the ventrolateral hypothalamic area. This technique also revealed PRir and ERir cells extending well beyond the Nissl-defined nuclei within the ventromedial/ventrolateral hypothalamus, a distribution that varies considerably from species to species (*Figure 3-3*). Areas with lower numbers of PRir cells include the bed nucleus of stria terminalis, paraventricular nucleus, and lateral hypothalamus. Even within most of the PR-rich areas, relatively few neurons are darkly stained. Although immunocytochemistry is not quantitative in a linear sense, this suggests that relatively few neurons have a high concentration of PRs. Consistent with the idea that most effects of progesterone require priming with estradiol, estradiol-induced PRir is found only in cells containing ERir (Blaustein and Turcotte, 1989; Warembourg et al., 1989).

The neuroanatomical sites containing high concentrations of PR-containing cells are in reasonable agreement in guinea pigs and rats with a few exceptions, including the following. In rats, many of the PRir cells lateral to the ventrolateral–VMN are located in a somewhat less dorsal position. PRs, assessed by either immunocytochemistry (Numan et al., 1999; Greco et al., 2001), autoradiography (Sar, 1988), or in situ hybridization histochemistry (Hagihara et al., 1992) are also seen in the parts of the amygdala in rats. In guinea pigs, PRir is only seen in the amygdala after colchicine treatment (Blaustein and Olster, 1993), which disrupts axonal transport.

Although there are PRs in the cerebral cortex and cerebellum, these PRs do not seem to be induced by estradiol. In fact, early immunocytochemical (Warembourg et al., 1986; Blaustein et al., 1988) and autoradiographic experiments (Warembourg, 1978a) failed to demonstrate any PR-containing neurons in these areas, suggesting that, while the PR concentration is sufficient to assay by in vitro binding techniques, the cellular concentration of PRs may be too low to be detected immunochemically with the procedures that were used. However, it should be noted that in many of the studies, antibody concentrations were

Figure 3-3

Reconstruction of the location of PRir cells at two levels of the ventrolateral hypothalamus in guinea pigs in which sexual behavior was induced by implantation of an estradiol cannula in the rostral region ventrolateral hypothalamus, followed by progesterone injection. The VLN of guinea pig is considered to be analogous to the VMNvl of rats. Note that the effective cannula placements induced PRir in regions clearly outside the Nissl-defined VMN and VLN (arrows). VMN = ventromedial nucleus of the hypothalamus, VLN = ventrolateral nucleus of the hypothalamus; f = fornix (from Delville and Blaustein, 1991)



titrated, so that only estradiol-induced PRs were visible (Blaustein et al., 1988). If this titration is not done, many more PRir cells are identified (Greco et al., 2001).

4.2.2 Progestin Receptors and Facilitation of Feminine Sexual Behavior

PRs are generally believed to be essential in mediating the effect of progesterone on facilitation of feminine sexual behavior ,although some exceptions have been reported (Frye and Vongher, 2001), presumably by an interaction of activated hormone–receptor complexes with the genome (Blaustein and Olster, 1989; Blaustein and Erskine, 2002). This hypothesis predicts that sensitivity to progesterone is determined by the concentration of unoccupied PRs available in specific neurons involved in progesterone-facilitated sexual behavior, and response is dependent on the presence of an adequate concentration of activated PRs after progesterone treatment in those cells. An increase in the concentration of PRs after estradiol priming increases the sensitivity of target cells for progesterone, presumably by increasing the concentration of receptors available to become activated in response to progesterone. Similarly, a decreased concentration of unoccupied PRs results in decreased sensitivity to progesterone. Although a number of studies also suggest nongenomic effects of progestins on feminine sexual behaviors (e.g., Debold and Frye, 1994), these are not inconsistent with a PR-mediated, genomic action as well.

Although estradiol has numerous effects in the brain, one of the ways in which estradiol prepares the brain for response to progesterone is by increasing the concentration of PRs in relevant neurons. Estradiol injection results in an increase in the concentration of PRs in the hypothalamus and preoptic area within

about a day in both guinea pigs (Blaustein and Feder, 1979c) and rats (Moguilewsky and Raynaud, 1979b; Parsons et al., 1980). The concentration of PRs first increases noticeably at about the same time as the first behavioral response to progesterone (Green et al., 1970; Feder and Marrone, 1977; Parsons et al., 1980). Behavioral response to progesterone is transient; response declines as the concentration of PRs in those areas declines. The timing of this decline is dependent upon the species, dose of estradiol, and mode of administration of the progesterone (Blaustein and Feder, 1979c; Parsons et al., 1980; Clark et al., 1982). Although most work has been done in ovariectomized animals in which hormone levels can be controlled, the concentration of hypothalamic unoccupied PRs in rats increases during proestrus, after peak estradiol levels and prior to, and presumably in preparation for, the preovulatory release of progesterone (McGinnis et al., 1981).

4.2.3 Interference with Progestin Receptors

4.2.3.1 Progestin Antagonists Treatment with progestin antagonists by system injection or by intracerebroventricular or intrahypothalamic administration inhibits the facilitation of sexual behavior by progesterone in rats, guinea pigs, and mice (Brown and Blaustein, 1984c; Etgen and Barfield, 1986; Richmond and Clemens, 1986; Mani et al., 1994a). In guinea pigs, RU486-induced inhibition of progesterone-facilitated, feminine sexual behavior was overcome by a high dose of progesterone, but not by cortisol (Brown and Blaustein, 1986), supporting the idea that inhibition was specific to PRs, and not due to antiglucorticoid (Moguilewsky and Philibert, 1984) or ERβ antagonist (Sathya et al., 2002) activity. Like estrogen antagonists that can have both antagonistic and agonistic effects, progestin antagonists have tissue-specific, agonist-like effects under particular conditions (Vegeto et al., 1992). One study suggested that the progesterone antagonist, RU486 (Pleim et al., 1990) can have progesterone-like effects on feminine sexual behavior under some conditions.

Recent in vitro studies on the structural and functional properties of PRs using isolated domains of the PRs have shed light on the mechanisms by which the RU486 acts as an agonist. By binding to the ligand-binding domain of the PR, RU486 induces conformational changes that not only prevent PR interactions with its coactivators, but also facilitate the interactions with and recruitment of corepressors, resulting in active repression of target gene expression (Allan et al., 1992; Jackson et al., 1997; Wagner et al., 1998a). The partial agonist property of RU486 is mediated exclusively through the PR-B isoform (discussed in *Section 4.2.4*) via its N-terminal domain (Meyer et al., 1990) and is dependent on the promoter context and the ratio of the coactivators and corepressors present in the cell. However, the regions of the PR-B domain and the actual mechanism by which RU486 functions as a partial agonist remain unknown.

4.2.3.2 Antisense Oligonucleotides Further evidence for the importance of PRs in the regulation of progesterone-facilitated sexual behavior comes from intraventricular (Mani et al., 1994c) or intrahypothalamic (Pollio et al., 1993; Ogawa et al., 1994) infusions of antisense oligonucleotides to PR mRNA, which inhibit PR synthesis. The results of these studies support the idea that facilitation of copulatory behavior, as well as paracopulatory behavior (Ogawa et al., 1994) by progesterone in rats, is mediated predominantly by genomic activation of neural PRs in the brain, including the ventromedial hypothalamic area (Pollio et al., 1993; Ogawa et al., 1994). Interestingly, the antisense oligonucleotides to PR mRNA decreased the levels of estadiol-induced cytosol PRs by half, a reduction sufficient to abolish lordosis response, suggesting the requirement of a threshold concentration of PRs for the facilitation of sexual behavior. A reduction in PR concentration would induce hyposensitivity and/or nonresponsiveness to progesterone, as noted later.

4.2.3.3 Progestin Receptor Gene Disruption A mutant strain of mouse with a targeted disruption of the PR gene, progesterone receptor knockouts (PRKOs) (Lydon et al., 1995), is completely unresponsive to the effect of progesterone in the facilitation of feminine sexual behavior (Mani et al., 1996 but *cf.* Frye and Vongher, 2001). In a parallel study of hypothalamic, unoccupied PRs in PRKO mice, a 70% reduction in estradiol-induced PRs was seen in the PRKO females, while heterozygous females had a 40% decrease in

estradiol-induced PRs, compared with wild-type controls. It cannot be determined if the binding in the PRKO represents a residual low level of high-affinity binding (i.e., PRs) or the low-affinity binder that binds [^{3}H]progestins in vitro. However, it is clear that the PRKOs at least have a greatly reduced level of estradiol-induced brain PRs. Additional experiments using mice with targeted disruption of each PR subtype will be discussed later (Section 4.2.4.).

4.2.3.4 Estrogen Antagonists and Agonists and Progestin Receptors As would be expected, work with estrogen antagonists is consistent with an obligatory role for estradiol-induced PRs in the facilitation of sexual behavior. In most cases, antiestrogen treatments that inhibit priming actions of estradiol on sexual behavior block induction of estradiol of PRs in the rat hypothalamus (Roy et al., 1979; Etgen and Shamamian, 1986). However, as was discussed earlier with respect to progesterone antagonists, estrogen antagonists (also referred to as selective ER modulators) also have estrogenic actions in some cases. Enclomiphene, an estrogen antagonist, substitutes for estradiol in its early priming effects on sexual behavior in guinea pigs, and it also results in an increase in the concentration of PRs in the hypothalamus (Wilcox and Feder, 1983). Likewise, the estrogen antagonist nafoxidine has estrogen antagonist effects in some situations, but agonist effects in others (Wade and Blaustein, 1978).

Interestingly, some xenoestrogens that have estrogen agonist properties can also act on other receptors. For example, the polychlorinated insecticide 1-(*o*-chlorophenyl)-1(*p*-chlorophenyl)-2,2,2-trichloroethane (*o,p*-DDT), has the estrogenic property of inducing behavioral response to progesterone in rats (Etgen, 1982). However, *o,p*-DDT also binds to PRs, suggesting that *o,p*-DDT can bind to ERs and induce PRs and then also bind to these PRs (Brown and Blaustein, 1984a).

4.2.4 Multiple Progestin Receptor Isoforms

The complexity of PR-mediated effects is augmented by the existence of two naturally occurring ligand-binding forms of the PR, PR-A and PR-B. Unlike the case with the two forms of ERs, the two PR isoforms are transcribed from the same gene and arise as the result of alternative initiation of translation from a single mRNA transcript (Conneely et al., 1989) or by alternative transcription from two distinct estrogen-inducible promoters on that gene (Kastner et al., 1990; Kraus et al., 1993). The production of these isoforms is conserved in a variety of vertebrate species, including rodents, primates, and humans (Lessey et al., 1983; Conneely et al., 1989; Duffy et al., 1997; Giangrande and McDonnell, 1999), rabbits being the only exception with only one form of PR (Loosfelt et al., 1984; Savouret et al., 1991). The isoforms differ only at the amino terminus, with PR-B containing an additional stretch of amino acids (128–165), known as the B-upstream sequence (BUS). The size variation in the isoforms is also reflected in their migratory profiles with the heavier form of the receptor (PR-B) typically migrating as a 110–120 kDa protein on Western immunoblots, and the smaller form (PR-A) typically migrating as an 80–95 kDa protein (e.g., Ilenchuk and Walters, 1987).

The BUS region of the PR also contains the transactivation function (AF-3) and is thought to be responsible for the divergent transactivational properties that have been reported for the isoforms, both in vitro and in vivo (Giangrande and McDonnell, 1999; Mulac-Jericevic and Conneely, 2004; Fernandez-Valdivia et al., 2005). The ability of PR-A and PR-B to form active homo- (A:A, B:B) or hetero-dimers (A:B) that bind DNA response elements, each with a distinct transactivational property (depending upon the absence or presence of the BUS domain) together with the differential coregulator recruitment, could expand the functional repertoire of progesterone responses and potentially dictate how a regulated expression of the two isoforms is critical for the spatial and the temporal responses to progesterone in vivo. Such a contribution by the distinct dimer ratios regulating progesterone effects is evident in vivo, where the ratios of the individual isoforms in reproductive tissues are known to change as a consequence of developmental (Kato et al., 1994; Beyer et al., 2002; Sakamoto et al., 2003; Aupperlee et al., 2005) and hormonal status (Mangal et al., 1997; Cheng et al., 2005). An imbalance of the native ratio of A to B form by the introduction of a PR-A transgene in mice results in developmental abnormalities of mammary glands, providing evidence that an aberration in the mechanisms regulating the differential expression of PR-A and PR-B can have major implications in physiology (Shyamala et al., 1998).

Although often ignored in work on the effects of progesterone in the central nervous system, these isoforms are of great importance. Experiments in vitro have suggested that some genes are preferentially activated by PR-B (Tora et al., 1988; Kastner et al., 1990; Vegeto et al., 1993), while some genes are equally responsive to PR-A and PR-B. In yet other cases, PR-A is an inhibitory regulator of PR-B (Vegeto et al., 1993). The isoforms also respond differently to progestin antagonists (Giangrande and McDonnell, 1999). While antagonist-bound PR-A remains inactive, antagonist-bound PR-B can function as a strongly active transcription factor (TF) by modulating intracellular phosphorylation pathways (Beck et al., 1993; Musgrove et al., 1993; Sartorius et al., 1994). Studies suggest differential subcellular localization of PR-A and PR-B in a mammalian cell line (Lim et al., 1999), with unoccupied PR-A being more nuclear in its localization than PR-B.

As with the finding of two forms of ERs, it is essential to keep in mind the presence of the two isoforms in interpretation of experiments on PRs. As progestins bind equally to both isoforms, and most antibodies are not selective for a particular isoform, nearly all experiments on PRs would have assayed a sum of both isoforms. However, a few studies have looked at the presence of PR-A and PR-B in the brain. Kato et al. (1993, 1994) first provided evidence for two distinct mRNA transcripts in the brain for PR-A and PR-B that seem to be regulated differentially. While PR mRNA transcripts are present throughout the brain, the PR-B form is differentially distributed, and is present in very high levels in cerebral cortex and in much lower levels in hypothalamus/preoptic area. In a more recent study (Camacho-Arroyo et al., 1998), both PR mRNA isoforms were induced and downregulated by estradiol and progesterone, in the hypothalamus. However, in the preoptic area, such a regulation was seen only for PR-B, not PR-A. In contrast, in the hippocampus, PR-A, but not PR-B, was induced by estradiol, and progesterone was without effect. Guerra-Araiza and coworkers (2000) also reported that during the estrous cycle, the PR-B isoform predominated in the hypothalamus, the preoptic area, and the frontal cerebral cortex, and the pattern of regulation differed among these areas. In contrast, no change was observed in the hippocampus. In monkey hypothalamus (Bethea and Widmann, 1998), the relative concentrations of the two isoforms are similar and do not appear to be differentially affected by hormonal treatments.

Interestingly, Guerra-Araiza et al. (2003) also examined the protein levels of the PR isoforms using western immunoblotting and found no downregulation of PR-B protein by progesterone in the preoptic area, contrary to their published findings on PR-B mRNA. This discrepancy between the mRNA and the protein levels could be due to the nature of antibodies used for protein detection by western immunoblotting. The available antibodies for PR bind to either PR-A and PR-B, or PR-B alone, and the extent of antigen–antibody reaction depends upon the epitope on the PR protein against which the antibodies are produced. Thus, reports of changes in isoform levels in neuronal tissue using western immunoblotting studies are antibody specific and need to be cautiously interpreted. Moreover, while the studies describe the spatiotemporal expression of one isoform over the other in the brain, the contribution of the individual isoforms in feminine sex behavior was not answered.

As mentioned earlier, recent in vivo studies using transgenic and knockout strains of mice demonstrate that normal tissue responses to progesterone are dependent upon appropriate levels of PR-A and PR-B (Shyamala et al., 1998; Mulac-Jericevic et al., 2000; Chou et al., 2003). The generation of PR isoform specific knockouts, PR-AKO and PR-BKO, has facilitated the analysis of spatiotemporal expression of the PR isoforms and their contributions to the reproductive actions of progesterone. The studies reveal that PR-A and PR-B isoforms modulate distinct, but partially overlapping, subset of reproductive functions of progesterone by regulation of diverse subsets of progesterone-responsive target genes in a cell- and tissue-specific manner (Mulac-Jericevic et al., 2000; Conneely et al., 2003; Mulac-Jericevic and Conneely, 2004; Fernandez-Valdivia et al., 2005). These knockouts have also elucidated the selective contribution of individual isoforms in progesterone-dependent and -independent facilitation of feminine sexual behavior. PR-AKO mice, containing the PR-B isoform alone, displayed significantly reduced levels of progesterone-facilitated lordosis response compared with their wild-type littermates. Interestingly, PR-BKO mice, containing the PR-A isoform alone, displayed higher levels of lordosis response than the PR-AKO mice, though not to the same level as their wild-type littermates. Western immunoblotting and normalization of the isoforms from the hypothalamus showed no evidence of upregulation of the detectable isoform upon ablation of the other. The studies demonstrate that the PR-A isoform plays a predominant role in mediating

Progesteron effects on feminine sexual behavior. The expression of the dominant PR-B isoform alone is insufficient to mediate progesterone-facilitated lordosis in mice. Furthermore, the observations also suggest that, while PR-A can mediate some of the effects of progesterone on lordosis, it is inadequate to mediate the full magnitude of the response, suggesting that the functional participation of both the isoforms, probably via heterodimerization of the two isoforms, contributes to the expression of the lordosis response.

4.2.5 Lack of Role of Progestin Receptors in Progesterone-Independent Sexual Behavior (Estrogen Heats)

Because estradiol binds to PRs in rats in vivo with an affinity 1% that of progesterone (MacLusky and McEwen, 1980; Parsons et al., 1984), it was suggested that induction of feminine sexual behavior in the absence of progesterone ("estrogen heats" or progesterone-independent sexual receptivity) might be referable to in vivo interaction of estradiol with intracellular PRs in addition to ERs. However, this idea has been ruled out by two major lines of evidence. First, a progesterone antagonist that blocks progesterone-facilitated sexual behavior does not block estradiol-induced or estradiol-facilitated sexual behavior (Blaustein et al., 1987). Second, estradiol induces lordosis, albeit at a lower level, in PRKO mice, mice without functional PRs, at the same level as in wild-type mice, demonstrating that the ability of PR-deficient mice to respond and exhibit lordosis is not compromised (Mani et al., 1996). As will be discussed in the section on the VMN (*Section 5*), the two modes of induction of sexual behavior are dissociable in other ways as well, so it should not be expected that they induce sexual behavior through a common mechanism.

4.2.6 Cellular Mechanisms Regulating Estrous Duration and the Refractory Period

4.2.6.1 Downregulation of PRs Leads to Estrous Termination The period of sexual receptivity typical for each species is rather tightly regulated. For example, in estrous-cycling guinea pigs, as after estradiol and progesterone treatments, sexual receptivity lasts about 8 h (Young, 1969). Similarly, rats remain sexually receptive for approximately 14 h (Blandau et al., 1941), but in ovariectomized rats, the duration is very dependent on hormonal treatment and the manner in which heat duration is defined (Pfaus et al., 2000). We suggested that this timing of sexual receptivity is referable to the regulation of occupied PRs in the neurons of the hypothalamus and the preoptic area (Blaustein and Feder, 1980). Injection of a behaviorally effective dose of progesterone in estradiol-primed guinea pigs and rats causes the rapid occupation (and presumably activation) of brain PRs, including in the hypothalamus and the preoptic area (Blaustein and Feder, 1980; McGinnis et al., 1981; Rainbow et al., 1982b). In rats, the preovulatory secretion of progesterone during the estrous cycle binds to hypothalamic PRs (Rainbow et al., 1982b). In guinea pigs, the transient presence of occupied PRs after progesterone injection returns to baseline levels by about 12 h after injection and correlates well with the expression of sexual behavior (Blaustein and Feder, 1980). This temporal concordance first suggested that the termination of sexual behavior is due to loss of intracellular occupied PRs in relevant neurons.

Physiological manipulations that extend the duration of the period of sexual behavior also increase the duration of occupied hypothalamic PRs, consistent with the hypothesis that the maintenance of sexual behavior is dependent upon occupied PRs. For example, a supplemental injection of estradiol in conjunction with a facilitating injection of progesterone in ovariectomized guinea pigs extends heat duration (Joslyn and Feder, 1971; Blaustein, 1982b), and prolongs the duration of occupied, hypothalamic PRs, presumably by increasing the concentration of PRs available to bind progesterone (Blaustein, 1982b). Similarly, supplemental progesterone treatment that prolongs the duration of occupied PRs (Brown and Blaustein, 1985) increases the duration of behavioral estrus.

Although a decrease in blood levels of progesterone and termination of behavioral estrus are often coincident, they are not inextricably linked (Feder et al., 1968; Blaustein and Feder, 1980). While supplemental progesterone administration elevates blood levels of progesterone and prolongs heat duration for 2–3 h in guinea pigs (Morin and Feder, 1973; Brown and Blaustein, 1985), heat nevertheless terminates even

in the presence of elevated progesterone levels. These treatments prolong the retention of occupied PRs for a short time (Brown and Blaustein, 1985). Failure to prolong retention of occupied PRs for longer durations, leading to the termination of behavioral estrus, may be due to the decline in PR concentration. Therefore, the loss of behavioral response can be caused by either a declining concentration of hypothalamic unoccupied PRs or the absence of a sufficient level of progesterone to interact with the threshold level of unoccupied receptors. The decline in the concentration of unoccupied PRs, in turn, can be caused by loss of estradiol priming with its resulting decline in the concentration of unoccupied PRs, previous exposure to progesterone with its resulting downregulation of PRs, or both. Considering the complexity of these interactions, it is not surprising that conflicting results concerning progesterone's role in estrous termination have been obtained, some results suggesting a role for progesterone (Barfield and Lisk, 1974; Powers and Moreines, 1976), and some suggesting no role (Hansen and Sodersten, 1978).

In an attempt to tease apart a possible active effect of progesterone on termination of behavioral estrus from the effects of declining estradiol levels, Wallen and Thornton (1979) induced sexual behavior in guinea pigs by daily injections of estradiol alone. When estradiol injections were stopped and the animals treated with progesterone or oil, sexual behavior did not terminate more rapidly in the progesterone-treated animals. The conclusion that termination of heat is not due to progesterone action may have relevance to the process of termination of sexual receptivity induced by estradiol alone. However, because estradiol-induced sexual behavior does not seem to be attributable to interaction with PRs (*Section 4.2.5*), this experiment does not shed light on progesterone-facilitated sexual receptivity.

Besides the concordance between the occupation of PRs and the maintenance of progesterone-facilitated sexual behavior, a causal relationship was shown by injection of the progestin antagonist, RU486, during the period of sexual behavior. The progestin antagonist causes the rapid displacement of hypothalamic, progesterone-occupied PRs, and it shortens the duration of behavioral estrus in guinea pigs (Brown and Blaustein, 1986) and rats (Brown et al., 1987). This loss of neural PRs appears to involve their degradation by the 26S proteosome, as treatment with a proteosome inhibitor prevents the degradation, while stabilizing the concentration of PRs in the hypothalamic and the preoptic areas (Gonzalez-Flores et al., 2004b)(*Section 4.2.6.2*).

Thus, by a variety of experimental paradigms in which estrous duration was either extended or abbreviated, the relationship between the retention of occupied neural PRs and the duration of behavioral estrus has been confirmed. Although the evidence suggests that the accumulation of occupied PRs is essential, the sequelae of PR action, whatever they may be, are essential as well. Thus, levels of other proteins, peptides, or neurotransmitters, endpoints of PR action, should also correlate well with facilitation of sexual behavior, heat duration, termination, and lack of further responsiveness.

4.2.6.2 Downregulation of Progestin Receptors and the Progesterone-Induced Refractory Period Following termination of behavioral estrus in guinea pigs (Goy et al., 1966) and in some circumstances in rats (Nadler, 1970; Blaustein and Wade, 1977; Gonzalez-Flores et al., 2004b), a refractory period occurs during which animals are not responsive to a second exposure to progesterone. Like heat termination, this seems to be due to downregulation of PRs by progesterone. First, during the refractory period, the concentration of hypothalamic PRs is depressed (Moguilewsky and Raynaud, 1979a; Blaustein and Feder, 1979b; Parsons et al., 1981; Gonzalez-Flores et al., 2004b), especially in the ventrolateral hypothalamus of guinea pigs (Blaustein and Turcotte, 1990), and progesterone treatment results in low levels of occupied PRs (Blaustein and Feder, 1980; Blaustein, 1982a). Second, hormonal treatments that influence responsiveness to progesterone also induce correlated changes in the concentration of PRs. Supplemental estradiol priming (Nadler, 1970; Joslyn and Feder, 1971; Blaustein and Wade, 1977; Shivers et al., 1980) offsets the progesterone-induced refractory period, so that animals regain responsiveness to the second progesterone injection. In guinea pigs, the supplemental estradiol injection also offsets the decrease in the concentration of unoccupied PRs, resulting in high levels of occupied PRs in response to progesterone (Blaustein, 1982b). Third, despite the presence of low PR levels, the refractory period can be overcome by a large dose of progesterone (Hansen and Sodersten, 1979; Blaustein, 1982b). This high dose increases progesterone-occupied, hypothalamic PRs, while a typical, behaviorally ineffective, lower dose does not (Blaustein, 1982a). Therefore, under a variety of conditions, there is a strong relationship between the level of

hypothalamic PRs, which become occupied after progesterone treatment, and the expression of lordosis in response to progesterone.

Heat termination and the progesterone-induced refractory period may both be due to a progesterone-induced decrease in the concentration of unoccupied PRs with consequent loss of occupied PRs (heat termination) or failure to accumulate an adequate concentration of occupied PRs in response to progesterone (refractory period). Indeed, pharmacological agents that prevent degradation of the PRs by inhibiting 26S proteosome activity within the hypothalamus and preoptic areas, not only stabilize the concentration of PRs, but they also prevent the progesterone-induced refractory period in female rats, confirming that the behavioral refractoriness is causally related to the downregulation of PRs (Gonzalez-Flores et al., 2004b).

The results of some pharmacological experiments support the hypothesis that the progesterone-induced refractory period is caused by desensitization specifically to progesterone, rather than by inhibition of action of estradiol. In rats that are refractory to progesterone, the serotonin antagonist, methysergide (Rodriguez-Sierra and Davis, 1977; Gilchrist and Blaustein, 1984), facilitates sexual behavior, even in progesterone-unresponsive rats. These earlier researches suggested that estradiol priming itself is unaffected by the intervening progesterone injection, and that animals seem to be specifically desensitized to progesterone, a finding consistent with a role for downregulation of PRs during the refractory period. However, in a more recent research (Gonzalez-Mariscal et al., 1993), in which the progestin, norgestrol, was used to induce "sequential inhibition," an opposite conclusion was arrived at. In this experiment, it was reported that animals became refractory to gonadotropin-releasing hormones, prostaglandin E_2 and cAMP, as well as progesterone. Gonzalez-Mariscal et al. first suggested that this cannot be explained by depletion of PRs, but by progestins having a depressive effect on the nervous system. On the other hand, in a subsequent experiment (Beyer et al., 1997), it was demonstrated that a progestin antagonist blocks the facilitation by each of these compounds, providing evidence that each may facilitate sexual receptivity by activation of PRs, a concept that will be discussed later in this chapter (*Section 9*) (Mani et al., 1994a, 1996).

The hypothesis that progesterone induces the refractory period by downregulation of PRs was challenged by the finding that when the protein synthesis inhibitor, anisomycin, was injected into rats around the time of the first progesterone injection, the response to the second progesterone injection appeared to be restored (Parsons and McEwen, 1981). However, although inhibition of protein synthesis rapidly inhibits ongoing sexual behaviors (Brown et al., 1987), it delays the termination of behavioral estrus, resulting in rats still being sexually receptive 24 h after the progesterone injection (Blaustein et al., 1982). Therefore, inhibition of protein synthesis can delay heat termination. Although the cellular basis for the delay is not known, it may be due to interference with the process of downregulation of PRs, perhaps by interference with the 26S proteosome. The suggestion that the process of downregulation of PRs results in heat termination and then persists in causing a refractory period may explain the difficulties in demonstrating a refractory period in rats. The ease of overcoming the refractory period with progesterone should be related to the ease of extending heat duration with progesterone. In fact, guinea pigs have a strong refractory period (Goy et al., 1966), they respond to supplemental progesterone with only a minor increase in heat duration (Morin and Feder, 1973; Brown and Blaustein, 1985), and they show dramatic downregulation of PRs with moderate doses of progesterone (Blaustein and Feder, 1979b). Conversely, in those rats in which the refractory period is only seen with very specific hormonal conditions like low estradiol and high progesterone (Blaustein and Wade, 1977), heat duration is readily extended by a variety of progesterone treatments (Hansen and Sodersten, 1978; Dudley et al., 1980; Brown and Blaustein, 1984b), and downregulation of PRs is far less extreme (Schwartz et al., 1979; Moguilewsky and Raynaud, 1979a; Parsons et al., 1981).

Questions have been raised about whether or not rats have a progesterone-induced refractory period during their estrous cycle. In fact, rats become hyposensitive to progesterone after termination of behavioral estrus during the estrous cycle as well as in the ovariectomized, hormonally treated model. A typical dose (0.5 mg) of progesterone is only effective in inducing sexual behavior during the proestrous stage of the estrous cycle (Sodersten and Hansen, 1979). The fact that in ovariectomized animals, a large dose of progesterone is effective immediately after heat termination (Hansen and Sodersten, 1979), but a low dose is not (Zucker, 1967; Powers and Zucker, 1969; Sodersten and Hansen, 1979) suggests that the animals are in fact hyposensitive to progesterone at the time of heat termination.

Another cellular event that may be related to estrous termination is the downregulation of ERs by progesterone under some conditions (Attardi, 1981; Smanik et al., 1983; Blaustein and Brown, 1984; Brown and MacLusky, 1994; Bethea et al., 1996). While this presumably decreases the effectiveness of estradiol, downregulation of ERs should then decrease the synthesis of PRs, which would then further contribute to the downregulation of PRs.

To summarize, the evidence suggests that termination of the period of sexual receptivity after progesterone treatment results from downregulation of PRs in relevant cells, and the ensuing period of hyposensitivity to progesterone is a consequence of this downregulation. Fewer PRs are available to bind progesterone, so animals tend to be hyposensitive to progesterone. Thus, the refractory period can be seen as a result of the cellular processes that lead to heat termination. Although this has not been studied yet, both may be referable to actions of the 26S proteosome on PRs.

4.3 Membrane Estrogen and Progestin Receptors (Nongenomic and Indirect Genomic)

Although the emphasis of this chapter is mostly on the genomic mechanisms involved in hormonal regulation of sexual behavior, the idea that membrane ERs and/or PRs are involved in mediating the effects of estradiol and progesterone on neuronal function (Watson and Gametchu, 1999; Kelly and Levin, 2001; Vasudevan et al., 2001; Ronnekleiv and Kelly, 2005) and sexual behavior (Debold and Frye, 1994) has received a great deal of support. There are at least two classes of membrane ERs—those made from the same genes that direct synthesis of the TF ERs (Levin, 1999; Razandi et al., 1999; Wade et al., 2001; Levin, 2002; Mhyre et al., 2006) and those potentially made from distinct genes (Ronnekleiv and Kelly, 2005).

In vitro, both the *ERα* and *ERβ* genes are capable of directing the synthesis of receptors that become associated with membranes, and are capable of signaling through the mitogen-activated protein kinase (MAPK), extracellular signal-regulated kinase (ERK) pathway by coupling, directly or indirectly, to G proteins (Driggers and Segars, 2002). Phosphatidyl inositol-3 kinase (Malyala et al., 2005) is also activated by estradiol binding to membrane ERs or other transmembrane G-protein coupled receptors (GPCRs). The activation of signaling pathways by estradiol appears to be tissue specific. Such regulation has been observed in activation of PKC by estradiol in the preoptic area, but not in the hypothalamus and the cortex of female rat brain slices (Ansonoff and Etgen, 1998). Activated signaling pathways influence not only the phosphorylation state of multiple nonER TFs [e.g., Fos, cAMP response element binding (CREB), activator protein-1 (AP-1)], but also the TF-ERs and their coactivators (Zhang and Trudeau, 2006).

Interestingly, membrane signaling also has an impact on the activation of nuclear ERs, resulting in recruitment of coactivator proteins and enhanced transcription of the receptors (Levin, 2005). In addition, a distinct class of GPCR, GPR30, has been shown to have the binding and the signaling characteristics of a membrane ER (Filardo and Thomas, 2005; Thomas et al., 2005). A novel GPCR for progesterone, totally unrelated to the nuclear PR, has been recently identified and demonstrated to play a role in progesterone-induced oocyte maturation in teleosts (Zhu et al., 2003a, b). Human PRs have been shown to mediate rapid progesterone effects via the activation of Src/Ras/Raf/MAPK signaling pathway by a direct interaction with the Src homology 3 domain of Src tyrosine kinases through a proline-rich (PXXPXR) motif located in the N-terminal domain of the PR (Boonyaratanakornkit et al., 2001).

The fact that some membrane receptors are derived from the same gene as the TF receptors has bearing on many of the earlier studies in which antagonists, antisense oligonucleotides, or targeted gene disruption were used to assess the involvement of steroid receptors acting as TFs. If the same ER and PR genes that direct synthesis of the receptors that act as TFs also direct synthesis of membrane receptors, then these manipulations could have influenced this type of membrane receptor as well as the targeted, TF receptors. Antiestrogens have been shown to block some of the rapid effects of estradiol on electrophysiological response (Lagrange et al., 1997). The possibility must be considered that the membrane receptor that is being blocked is a derivative product of the same *ERα* or *ERβ* genes that code for the TF receptors (Wade et al., 2001). ERα (Blaustein, 1992; Blaustein et al., 1992; Wagner et al., 1998b; Watson and Gametchu, 1999; Clarke et al., 2000; Milner et al., 2001) and PRs (Blaustein et al., 1988) have been found in extranuclear

locations, including distal dendrites, axon terminals, and synaptic densities in immunocytochemical studies (Blaustein et al., 1992; Blaustein, 1994). These findings are consistent with the idea that some extranuclear receptors are synthesized from the same *ERα* and/or *ERβ* genes.

Rats do not have to be exposed to estradiol continuously during the priming period in order to express sexual behavior. Two brief pulses of a very low dose of estradiol are more effective in inducing feminine sexual behavior in response to progesterone than a single large injection or continuous exposure (Sodersten et al., 1981; Parsons et al., 1982a; Clark and Roy, 1983; Wilcox et al., 1984). The behavioral effects of each pulse can be blocked by a protein synthesis inhibitor (Parsons and McEwen, 1981) or pentobarbital anesthesia (Roy et al., 1985). The particular proteins modulated in response to each injection may differ (Jones et al., 1986). Very little is known about the cellular basis for this understudied, enhanced response to pulsed exposure to estradiol. However, estradiol conjugated to bovine serum albumin (BSA), which makes the compound impermeable to cell membranes, can substitute for estradiol-17β in this two-pulse procedure (Kow et al., 2005). Interestingly, and at odds with previous work done in neuroblastoma cells (Vasudevan et al., 2001), the estradiol–BSA conjugate could also substitute for the second pulse of estradiol. The actions of the estradiol–BSA conjugate can be mimicked by compounds that activate either protein kinase A (PKA) or PKC, suggesting involvement of these two signaling pathways in the action of estradiol on feminine sexual behavior, as has been shown for the action of estradiol on neuronal electrophysiology (Kelly and Wagner, 1999). Although of great interest, experiments using BSA conjugates of steroid hormones must be interpreted very cautiously because of stability problems (Stevis et al., 1999) and because the position of the BSA on the steroid can have tremendous effects on function (Temple and Wray, 2005).

5 Neuroanatomy: Role of the Ventromedial Hypothalamus

In the vast majority of work on cellular and molecular underpinnings of feminine sexual behavior, one brain area, the VMN, and often specifically the ventrolateral aspect of this nucleus has been studied exclusively (VMNvl). This review is not focused on the neuroanatomical substrates of feminine sexual behavior, and the involvement of other important areas, including the preoptic area, midbrain central gray, and medial amygdala will not be discussed here [see reviews by Pfaff et al. (1994) and Blaustein and Erskine (2002) for more extensive discussion of other areas]. However, it is important to understand the reasons why a particular neuroanatomical area, the VMN, has been singled out as the most important area in studies of the cellular and molecular underpinnings and the limitations of the data in support of this idea.

Recent emphasis in this field has been on understanding the cellular and the molecular processes involved in hormonal regulation of sexual behaviors, with little emphasis on refining our understanding of the neuroanatomical substrates for these behaviors. It has become axiomatic that the VMN is the most critical site for hormonal regulation of feminine sexual behavior. In a recent review, the question was raised of whether there is strong evidence to support this idea (Blaustein and Erskine, 2002). Unfortunately, while this is not currently an area of intense investigation, we still do not have the full answers to some of the original questions. The issues to be considered concerning the possible critical role of the VMN will be summarized below.

1. In many cases, rather gross procedures were used that included, but were not limited to lesion of the VMNvl. As we have discussed earlier (Blaustein and Erskine, 2002), some of the earliest lesion studies implicated an area within the mediobasal hypothalamus in the regulation of feminine sexual behavior. In these studies, large hypothalamic lesions were often used, and in fact deficits in sexual behavior were seen. However, the fine points of many of these studies have been lost through the years. As is often cited, Goy and Phoenix (1963) did in fact report that lesions of the ventromedial hypothalamic area decreased lordosis in estradiol plus progesterone-treated, ovariectomized female guinea pigs. However, the lesions in that study included a wide variety of structures within the hypothalamic region, including the periventricular anterior nucleus, the anterior hypothalamic nucleus, and other areas. In referring to the four animals with the most severe deficit in behavior, the authors noted that "the common area of destruction for these brains may be described as lying with the lateral extensions of the arcuate nucleus

and ventrolateral portions of the ventromedial." The lesions from the four poorest responders appear to be in the area adjacent to the VMN, the precise region of highest density of ERir and PRir neurons in this area. The results support a role for the steroid–receptor-rich area in this region, so it is not accurate for this study to be cited in support of the involvement of the VMN specifically.

2. In many cases, in summaries of earlier work, the effects of estradiol have not been distinguished from those of estradiol and progesterone. The results of studies investigating the effects of lesions of the VMN on estradiol only versus estradiol + progesterone-induced sexual behaviors differ. In the work with most disparate results of the two treatments, Mathews and Edwards (1977a, b) reported that after some VMN lesions in ovariectomized rats, deficits were seen in estradiol-alone induced sexual behavior, but not in estradiol + progesterone-induced sexual behavior. This pattern of interference with estradiol-induced lordosis, but not estradiol + progesterone-induced, was also seen after sagittal knife cuts were made laterally to the VMN (Mathews and Edwards, 1977a) or anterior hypothalamus (Pfeifle et al., 1980). Although these data actually suggest a dissociation in the neuroanatomical substrates of estradiol-only versus estradiol + progesterone-facilitated sexual receptivity, other studies by Clark and coworkers (1981a) suggested that VMN lesions inhibit copulatory and progestative behaviors (pacing), induced by either estradiol alone or estradiol and progesterone. The possibility of slight differences in the extent of the lesions cannot be eliminated, especially because the lesions of the earlier researches were quite small, and the lesions made in much of the more recent researches have been larger. However, a later study found that VMN lesions inhibited time that estradiol + progesterone-injected females spent with a male, but did not inhibit their lordosis (Emery and Moss, 1984a). Nevertheless, these studies suggest that specific sites within the VMN itself, and perhaps its surrounding might be differentially involved in estradiol-induced versus estradiol + progesterone-induced sexual behavior. In related work, quite large VMN lesions resulted in near-total loss of estradiol and progesterone-induced lordosis, while lesions that spare 30–50% of the nucleus resulted in no decrement at all (Richmond and Clemens, 1988).

   To summarize, although not conclusive, the data suggest that the neuroanatomical sites mediating estradiol-induced sexual behavior may not be identical to estradiol + progesterone-induced sexual behavior. Therefore, caution must be exercised in extrapolating from the pharmacological induction of sexual behavior (estradiol only) to the more physiological means (estradiol + progesterone).

3. The VMN is not part of the actual reflex arc in estrogen only–induced lordosis (progesterone independent). Pfaff and Sakuma (1979) followed the time course of loss of sexual receptivity after VMN lesions in ovariectomized rats in which lordosis was induced by daily estradiol injections. Lordosis declined over the course of 36–60 h, suggesting that, while this area is critical to estradiol modulation of sexual receptivity, it is not likely to be a part of the actual reflex arc. In contrast, disruption of lordosis occurs within 15 min of lesion in hamsters treated with estradiol and progesterone (Gibson and Floody, 1998), suggesting that the VMN is part of the reflex arc in this particular situation. Besides the obvious species difference, an important difference between the two studies is that the latter was a study of progesterone-facilitated sexual behavior, and the former was a study of estradiol-induced sexual behavior. This illustrates the possibility that the neuroanatomical substrates by which sexual behavior is induced by either estradiol versus estradiol + progesterone are not necessarily identical.

   In a study in which pseudorabies virus (PRV) was used to label transneuronally the neurons innervating the lumbar epaxial muscles involved in the lordosis response (Daniels and Flanagan-Cato, 2000), many of the PRV-labeled neurons in the ventromedial hypothalamic area were outside of the core of the VMN. This study supports the suggestion that many of the relevant neurons involved in the lordosis reflex lie outside of the Nissl-defined VMN.

4. Hormone implant studies can only provide clues to the relevant sites. Many experiments zeroed in on the VMN as the most sensitive site of action for estradiol priming of sexual behavior in ovariectomized rats (Barfield and Chen, 1977; Davis and Barfield, 1979; Rubin and Barfield, 1980; Davis et al., 1982) and hamsters (Debold et al., 1982; Floody et al., 1987). While the results of many experiments point to the VMN as the most sensitive forebrain site for estradiol action, it must be noted that most other areas have not been as extensively studied as this nucleus. Results of experiments using localized implants of

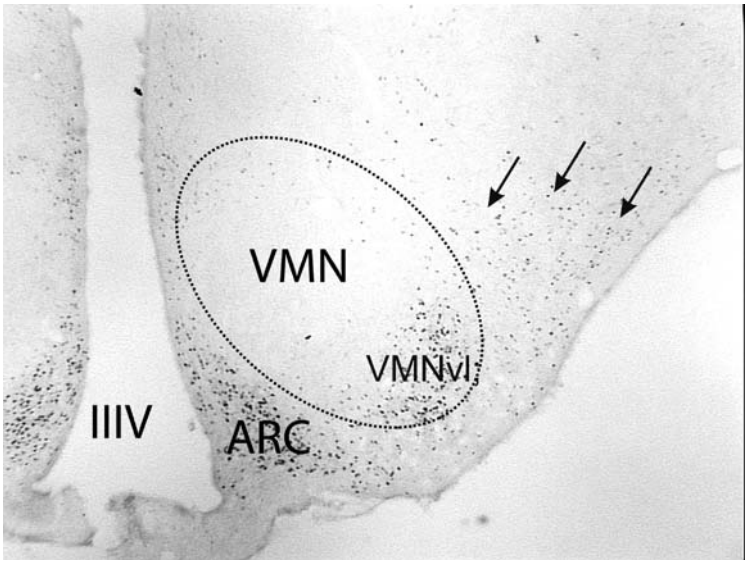
antiestrogens (Howard et al., 1984; Meisel et al., 1987), protein synthesis inhibitors (Rainbow et al., 1982a; Glaser and Barfield, 1984; Meisel and Pfaff, 1985), and transcription inhibitors (Yahr and Ulibarri, 1986) confirm that a site in or near the VMN is a critical site involved in regulation of sexual behavior by estradiol. However, it is critical to note that compounds implanted or infused into the brain do not remain precisely where they are placed, so the results should not be interpreted as having pin-point accuracy. Rather than concluding that the VMN itself is the active site, a more conservative interpretation is that the VMN and/or adjacent areas are involved in the regulation.

In related work in guinea pigs, small, dilute estradiol-containing cannulae were implanted directed at the ventrolateral hypothalamus, the region analogous to the VMNvl in rats (Delville and Blaustein, 1991). Guinea pigs were injected with progesterone, tested for lordosis responses, and brains immunostained for the expression of PRs. Due to the particular technique used, the presence of PRir is dependent upon exposure to estradiol, its presence in a cell served as a bioassay for spread of estradiol to other cells capable of expressing estradiol-induced PRir. Only cannulae located at the rostral and the ventral aspect of the ventrolateral hypothalamus induced behavioral response to progesterone, and the expression of estradiol-induced PRir in the rostral–ventral ventrolateral hypothalamus correlated with response to progesterone. Thus, stimulation of a population of ovarian steroid hormone-sensitive neurons within the ventrolateral hypothalamus by very low levels of estradiol may be sufficient to induce sexual behavior in response to progesterone in female guinea pigs. Many of the cells in which PRir is induced are located outside of the actual ventrolateral (or ventromedial) nucleus of the hypothalamus (*Figure 3-4*). This is in agreement with the suggestion that the defined nucleus itself may not be the critical site of action of estradiol and progesterone on feminine sexual behavior. Rather, receptor-containing cells in the adjacent area could be equally or more important.

In earlier work on the site of action of progesterone, the general area of the mediobasal hypothalamus was singled out as an important site for progesterone facilitation of sexual receptivity in rats (Powers, 1972) and guinea pigs (Morin and Feder, 1974), although many other areas have also been

Figure 3-4

Photomicrograph of ERα-ir in the rostral ventromedial hypothalamic area of an ovariectomized female rat showing that many of the ERα-ir cells are not in the actual ventromedial hypothalamic nucleus; rather they are in the surrounding (arrows point to general area). VMN = ventromedial nucleus of hypothalamus; VMNvl = ventrolateral aspect of ventromedial nucleus of the hypothalamus; arc = arcuate nucleus; IIIV = third ventricle



suggested (Ross et al., 1971; Ward et al., 1975; Luttge and Hughes, 1976; Yanase and Gorski, 1976; Franck and Ward, 1981; Rodriguez-Sierra and Komisaruk, 1982; Tennent et al., 1982). Later work using more refined intracranial implants of progesterone in rats (Rubin and Barfield, 1983) and hamsters (Debold and Malsbury, 1989) or a progesterone antagonist in rats (Etgen and Barfield, 1986) suggested that stimulation of the VMN is sufficient for facilitation of sexual behavior. These implant experiments are not inconsistent with the lesion experiments described earlier, which showed that estradiol + progesterone-induced sexual receptivity often remains even after VMN lesions, because the progesterone may diffuse to the adjacent area, where many steroid-responsive cells are found, and which may be a critical site of action.

As with the search for the site of facilitation of sexual receptivity, the work by Rubin and Barfield (1984) suggested that progesterone induces a refractory period in rats at the same site as it facilitates the expression of feminine sexual behavior—the VMN. This is consistent with our earlier reanalysis (Blaustein and Brown, 1985) of a report of Morin and Feder (1974), which suggested that progesterone implants in the mediobasal hypothalamus of guinea pigs at sites that cause facilitation of sexual behavior, also cause refractoriness to progesterone. Therefore, both the facilitation and the refractory period induced by progesterone can occur after implantation of progesterone in the same neuroanatomical site, perhaps in the same neurons. This interpretation is consistent with the PR model for the cellular mechanism of action of progesterone in feminine sexual behavior discussed earlier.

5. The constellation of sexual behaviors has seldom been studied after VMN lesions. Some apparent effects on lordosis may be secondary to motivational changes. VMN lesions inhibit pacing behaviors (Clark et al., 1981a). Similarly, although VMN lesions decrease contact with males when estradiol + progesterone-treated females are allowed to pace the contacts, they are often capable of displaying lordosis when mounted (Emery and Moss, 1984a). It was argued that the decrease in lordosis seen in other studies may be due to avoidance of mounting by the lesioned rats (Emery and Moss, 1984a). The possibility must be considered that this issue influenced the results of some lesion experiments, and is consistent with the earlier interpretation of La Vaque and Rodgers (1975), who studied the effects of lesions in gonadally intact female rats. While this discussion does not take away the importance of the VMN in feminine sexual behavior, it emphasizes the importance of distinguishing the effects of lordosis from other aspects of sexual behavior, and once again, of distinguishing estradiol-only induced sexual behavior and estradiol + progesterone-induced sexual behavior.

In spite of the limitations of these studies, there appears to be a number of conclusions that can be drawn about the role of the VMN:

1. The VMN and/or a nearby population of cells is involved in the action of estradiol on sexual receptivity.
2. Estradiol-induced sexual behavior is more adversely affected by small, VMN lesions than is sexual receptivity induced by estradiol and progesterone, suggesting that the VMN core may be less critical in the presence of progesterone.
3. Likewise, although the VMN may not be part of the actual reflex arc for estradiol-only induced sexual behavior, it may be part of the reflex arc for progesterone-facilitated sexual behavior.
4. Lesions of the VMN always reduce sexual behaviors, but they rarely eliminate them, perhaps because either the entire steroid receptor-containing region associated with the ventromedial hypothalamic area, or an as-yet-undefined subpopulation of cells within this region, is critical for hormonal regulation of sexual behavior.
5. Hormone implants in the area of the VMN are effective in inducing the expression of some aspects of sexual behavior.
6. The VMN is likely to be involved in motivational aspects of sexual behavior.

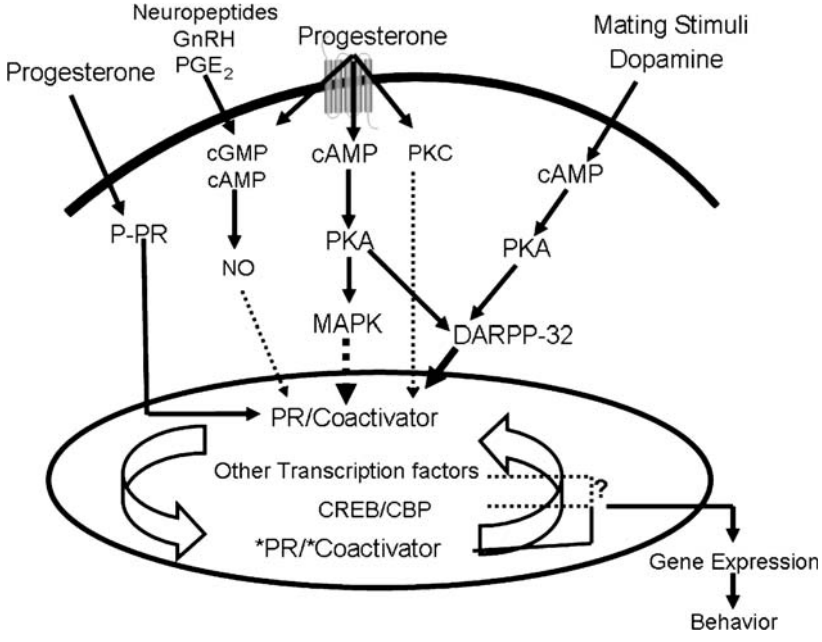
Therefore, studies of the cellular and molecular neuroendocrinology of this general area are warranted, but it could be argued that it is premature to investigate neurons within only the VMN to the exclusion of steroid-sensitive neurons in the adjacent areas that could be as—or more—important with the assumption that these are the neurons specifically involved in lordosis.

6 Intracellular Signaling Pathways Involved in Feminine Sexual Behavior

Regulation of feminine sexual behavior appears to involve more than steroid hormones acting via rapid nongenomic and slower genomic pathways (*Figure 3-5*). Diffusible molecules like nitric oxide (NO) have been shown to be involved in lordosis response in female rats. While NO has been demonstrated to be a mediator of gonadotropin releasing hormone (GnRH) release and of subsequent estrous behavior (Mani et al., 1994b), a role for NO in the facilitating effects mediated by α1-adrenoceptors (Chu and Etgen, 1999) and progestins on lordosis has also been reported (Gonzalez-Flores and Etgen, 2004). There are also reports

Figure 3-5

Crosstalk between signal transduction pathways operating in feminine sexual behavior. The schematic diagram presents several of the potential signal transduction pathways operating in the hypothalamus and preoptic areas. (1) Progesterone effects mediated by the "classical" genomic mechanism involving the intracellular receptors play a predominant role in signal transduction. Progesterone, binding to the classical intracellular PR, allosterically activates it to promote interactions with nuclear coactivators. (2) Progesterone effects mediated by the second messenger cAMP/cGMP, activates the PKA-mediated signaling, leading to the activation of MAP kinases and the phosphorylation of nuclear TFs, nuclear PRs, CREB, and/or its associated coactivator protein, CBP. (3) Progesterone, acting through the membrane via the cAMP/PKA/MAPK/DARPP-32 pathway, results in decreased dephosphorylation of PR and/or its associated coactivators. (4) Dopamine and mating stimuli (VCS) stimulate cAMP release and PKA activation. PKA-mediated pathway phosphorylates DARPP-32, which inhibits PP-1, leading to the activation of CREB/PR/coactivators. PRs are critical for this pathway denoting a crosstalk between dopamine and progesterone-initiated pathways. (5) Progesterone can also activate PKC pathway leading to the signal transmission to the nucleus and interaction with nuclear TFs. (6) Similarly, neuropeptides, GnRH and PGE_2, through various receptor-mediated mechanisms and/or second messengers (e.g., NO, cGMP, cAMP) transmit signals to the nuclear TFs to facilitate sexual behavior. The allosteric activation and the phosphorylation of various TFs work synergistically to promote progesterone receptor-mediated gene function. In addition, interactions between the signal pathways may serve as amplification mechanism and multiple upstream regulators converge on common effectors such as PRs/coactivators and/or CREB to regulate transcription of immediate early genes (*c-fos, c-jun, Egr*) and/or later genes to facilitate feminine sexual behavior



of NO involvement in melanocortin facilitation of lordosis in female rats (Nocetto et al., 2004). The involvement of NO in feminine sex behavior appears to be modulated by gonadal hormones, as correlated by the expression of nNOS in the estradiol-primed hypothalamic neurons (Rachman et al., 1998). NO regulation of sex behavior also appears to be species-specific, because estradiol-regulated nNOS increase has not been observed in avian species (Panzica et al., 2006).

A variety of compounds that activate several second and third messenger systems and stimulate protein kinases within the neurons also facilitate feminine sex behavior in estradiol-primed rats, adding another level of complexity to the mechanisms involved. These compounds include adenosine and guanosine nucleotides and their second messengers, cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) (Beyer et al., 1981; Limbird, 1981; Whalen and Lauber, 1986; Chu and Etgen, 1997) in addition to GnRH, prostaglandin E2, neurotransmitters, and neuropeptides [see Micevych and Sinchak (2006) in this volume]. Phosphodiesterase inhibitors that increase cAMP by interfering with the hydrolysis of cAMP, potentiate the effects of subthreshold doses of GnRH and progesterone in the facilitation of lordosis (Beyer and Gonzalez-Mariscal, 1986). Studies on the role of cGMP in lordosis response have identified a role for protein kinase G in the signaling cascade. Interestingly, PRs are also critical in this cGMP-mediated response suggesting the existence of crosstalk between the two (Chu and Etgen, 1997). Recent studies on progesterone-mediated signal transduction pathways also indicate rapid elevations in hypothalamic cAMP levels and PKA (cAMP-dependent PKA) activity by progesterone in estrogen-primed rats and mice. Inhibitors of PKA reduced progesterone-facilitated sexual behavior in estradiol benzoate (EB)-primed rats. This signaling cascade also includes a third messenger, dopamine and cAMP-regulated phosphoprotein-32 (DARPP-32), the absence of which renders both rats and mice incapable of expressing the progesterone-facilitated lordosis response (Mani et al., 2000). However, progesterone was ineffective in facilitating lordosis in the absence of PRs (Mani et al., 1994c, 1996). Thus, rapid membrane-initiated signaling cascades crosstalk with the genomic pathways involving intracellular PRs to enhance or bring about facilitation of sex behavior.

Two important factors to be borne in mind, when discussing the involvement of the multitude of signaling pathways and steroid hormones in feminine sex behavior, are that the pathways share signaling components and are not unidirectional. For example, involvement of MAPK pathway in progestin-facilitation of lordosis has been demonstrated in rats (Etgen and Acosta-Martinez, 2003; Gonzalez-Flores et al., 2004c). Not only does the MAPK-activated pathway facilitate the expression of lordosis, but it also subsequently promotes termination of behavioral estrous by targeting the PR for degradation by the 26S proteasome (Camacho-Arroyo et al., 2002; Gonzalez-Flores et al., 2004b). Furthermore, the MAPK pathway is also involved in δ opioid actions on lordosis (Acosta-Martinez et al., 2006). While the functional role of multiple signaling pathways can be explained by their ability to relay, amplify, and integrate signals from a variety of extracellular stimuli, it still remains unclear how the same MAPK pathway can both activate and inhibit the same behavioral endpoint. How does the neuron differentiate between the stimuli to activate as opposed to inhibit feminine sexual behavior?

Cellular signaling mechanisms that alter the levels of cAMP, PKA, MAPK, or calcium can increase phosphorylation of CREB (Ca^{2+}/CBP) or other TFs, for example, activating transcription factor-1 (ATF-1), enabling them to become transcriptional regulators (Armstrong and Montminy, 1993). Estrogen and progesterone are known to influence gene expression by activating signaling pathways involving PKA and PKC in rats (Petitti and Etgen, 1989, 1990; Kow et al., 1994). In several regions of the rat brain lacking the classical steroid receptors, estradiol causes a rapid increase in p–CREB immunostaining, with no concomitant increases in CREB protein or mRNA levels (Gu et al., 1996; Zhou et al., 1996). Progesterone, on the other hand, appears to have a bimodal effect on the phosphorylation of CREB, bringing about a rapid decrease followed by an increase (Gu et al., 1996). These rapid effects on CREB phosphorylation also appear to be nuclear receptor mediated; estrogen antagonists and progestin antagonists block the hormonal effects on CREB phosphorylation, again suggesting crosstalk between the distinct signaling pathways.

In addition, protein kinases also have effects on ion channels (Mermelstein et al., 1996; Rupprecht and Holsboer, 1999). Steroid hormones, growth factors, and neurotransmitters are known to activate intracellular cascades leading to increased p-CREB expression, binding of p-CREB to its coactivator, CBP, and inducing transcription of immediate early genes containing cAMP response element-sequences, as *c-fos* and

c-jun (Schule and Evans, 1991). These genes encode the TFs Fos and Jun that can form hetero- or homodimers and regulate downstream gene expression by acting on target AP-1 DNA recognition sequences near promoter elements. AP-1 elements can substitute for hormone response elements in the steroid hormone regulation of gene transcription (Kushner et al., 1994). Evidence from in vitro experiments indicates that ERs and PRs can also mediate transcription of genes controlled by an AP-1 enhancer element (Umayahara et al., 1994; Webb et al., 1995). Furthermore, it has also been demonstrated that the two distinct classes of TFs, steroid hormone receptors and AP-1 complexes, interact to modulate each other's activity (Shemshedini et al., 1991; Alkhalaf and Murphy, 1992). In addition, recent studies have also suggested that nuclear receptor coregulators may also integrate steroid hormone signaling through CBP (Torchia et al., 1997; Mahajan and Samuels, 2000; Xu et al., 2000a). Functional cooperation between MAPK cascade-mediated phosphorylation of coactivator SRC-1 and CBP has been demonstrated in the activation nuclear PRs in vitro (Rowan et al., 2000a). Thus, second messenger systems, including CaMK (calcium/calmodulin-dependent protein kinase) and PKC modulate gene expression via multiple TFs or transcription coactivators, providing an alternative pathway to the genome (Watters et al., 1997; Watters and Dorsa, 1998; Sweatt, 2004).

There is no doubt that multiple intra- and intercellular mechanisms coexist to ensure that the female is in behavioral estrus at the most appropriate time. However, several conundrums still exist. With all these kinases and coactivator proteins in the same cells, how does the cell/neuron keep the pathways distinct from one another? How do the neurons/cells distinguish different signals that use similar signaling molecules (e.g., MAPK)? How do these various mechanisms coexist, yet ensure that the neurons respond to the correct extracellular signals to control genomic and behavioral response? What mechanisms exist to prevent crosstalk between the pathways that could potentially have opposite behavioral endpoints?

7 Crosstalk Between Neurotransmitters and Steroid Hormone Receptors: Activation of Steroid Receptors by Afferent Input

7.1 Ligand-Independent Activation of PRs

During the first 25 years of studies of steroid receptors, it had been assumed that the steroid hormones were necessary for activation of the receptor for binding of receptors to their cognate ligands. However, we now know that steroid hormone receptors can be activated by a means other than steroid hormones, and a comprehensive understanding of feminine sexual behavior has to consider the potential roles of these other routes to activation. In 1991, Power et al. discovered that PRs and other steroid hormone receptors could be activated by dopamine and dopaminergic agonists in vitro (Power et al., 1991b). The process by which dopamine activates the receptors is via a second messenger signaling pathway rather than a direct effect of the agonist on the PR. This is referred to as ligand-independent activation or hormone-independent activation. The idea that steroid receptors can be activated indirectly via membrane-related events has now been supported by a wide variety of work (Blaustein, 2004b).

In the first test of this model on behavior, it was shown that the intracerebroventricular administration of a D_1-specific, dopamine agonist substitutes for progesterone in the facilitation of sexual behavior in estradiol-primed rats (Mani et al., 1994a). This finding confirmed and extended earlier work in which dopaminergic agonists were infused into the hypothalamus and preoptic area (Foreman and Moss, 1979). However, like facilitation of sexual behavior by progesterone, the facilitation of sexual behavior by dopaminergic agonists was blocked by progesterone antagonists or antisense oligonucleotides directed at the PR mRNA administered directly to the brain, as well as by a D_1-dopamine antagonist (Mani et al., 1994c). The inability of PRKO to exhibit D_1 agonist-facilitated sexual behavior, while their wild-type littermates responded to the agonist with lordosis (Mani et al., 1996), provides definitive evidence for the obligatory role of PRs as transcriptional mediators for dopamine-initiated pathways in sexual behavior. A similar relationship holds for sexual behavior facilitated by GnRH (Mani et al., 1995; Beyer et al., 1997), δ-opioid receptors (Acosta-Martinez et al., 2006), as well as prostaglandin E2 (Beyer et al., 1997); each can be blocked by treatment with a progesterone antagonist. Likewise, NO (Mani et al., 1994b), cAMP (Beyer

et al., 1997), cGMP (Chu et al., 1999), and MAPK (Acosta-Martinez et al., 2006) may each facilitate sexual behavior via activation of PRs. Thus, dopamine and other neurotransmitters may activate feminine sexual behavior by indirect activation of neural PRs.

7.2 A Mechanism for Ligand-Independent Activation

Protein phosphorylation that is common to the pathways and molecular mechanisms through which neurotransmitters and steroid hormones produce their biological effects is under investigation. The regulatory mechanisms governing a variety of cellular processes in target cells are not only dependent upon the state of intracellular phosphorylation of the receptor, but are also dependent on the dynamic balance between cellular protein kinases and protein phosphatases (PPs). This has been found to be the case with PRs, where the equilibrium between transcriptionally active and inactive forms of the receptor is under the regulation of kinases and phosphatases (Denner et al., 1990; Shenolikar and Nairn, 1991).

Modulation of protein kinases and PPs in phosphorylation and signal transduction mechanisms occurs in the mammalian brain, a tissue having an abundance of kinases and phosphatases (Nairn et al., 1985). Neuronal phosphoproteins, like neurotransmitters and cyclic nucleotides, are components of the signal transduction pathway in the nervous system (Shenolikar and Nairn, 1991; Watanabe et al., 2001; Svenningsson et al., 2004), and can be phosphorylated/dephosphorylated in response to extracellular stimuli; such dynamic covalent modification is evident in modulation of the activity of PP1 and PP2. Several studies have documented that dopamine signaling through the D_1 subclass of dopamine receptors increases the level of second messenger cAMP and activates cAMP-dependent PKA in the neostriatum. Increased PKA activity leads to the phosphorylation of the neuronal phosphoproteins, DARPP-32, and/or inhibitor-1 (I-1). The phosphoprotein I-1 is closely related structurally, enzymologically, and functionally to DARPP-32 (Shenolikar and Nairn, 1991). In its phosphorylated state, DARPP-32 and/or I-1, by inhibiting the activity of PP-1, increases the state of phosphorylation of many substrate proteins, leading to induction of physiological responses. Thus, the PR is one of the potential substrate proteins phosphorylated by DARPP-32. The involvement of DARPP-32 and/or I-1 as the downstream mediators in the dopamine–PR interactions was investigated in the facilitation of sexual behavior in female rats and mice.

Antisense oligonucleotides to DARPP-32 administered into the third cerebral ventricle inhibited D_1 agonist- and progesterone-facilitated sexual receptivity in estradiol-primed female rats (Mani et al., 2000). Sexual receptivity facilitated by either a D_1 agonist or by progesterone after estradiol priming was also inhibited in mice carrying a null mutation for DARPP-32 gene. However, I-1 null mutant mice exhibited no deleterious defects in D_1 agonist- and progesterone-facilitated lordosis response compared with their wild-type littermates, revealing that involvement of the DARPP-32 pathway was specific. Also, increased immunoreactive phospho-DARPP-32 cells in the PR-containing areas of the rat hypothalamus have been observed after genitosensory stimulation (Meredith et al., 1998).

Similar to dopamine effects in the neostriatum, the D_1 agonist, as well as progesterone, significantly increase hypothalamic cAMP levels and PKA activities and enhance the phosphorylation of DARPP-32 on threonine-34. Increases induced by a D_1 dopamine agonist are inhibited by the D_1 subclass dopamine antagonist, SCH 23390. This suggests that the increases are due to the effects of dopamine initiated at its membrane receptor. The progesterone-induced increase, however, was not inhibited by SCH 23390, suggesting that the increases observed are due to the direct effects of progesterone and not secondary to modulation of dopamine or dopamine receptors by progesterone (Mani et al., 2000). Rp-cAMPS, a compound that blocks the cAMP signal transduction cascade by inhibiting PKA, inhibited D_1 agonist, and progesterone facilitated sexual receptivity in estradiol-primed female rats. While these observations suggest that DARPP-32 activation is an obligatory step in PR regulation of sexual receptivity, the sequence of events leading to the activation of PR (from the DARPP-32 phosphorylation step) is complicated and remains to be completely defined. It is likely that the mechanisms include not only a direct decrease in dephosphorylation (activation) of PRs, but also enhanced phosphorylation of PR-associated coactivators leading to rapid efficient transcriptional activation (Font de and Brown, 2000; Rowan et al., 2000a, b).

Now that it is known that steroid hormone receptors can be activated by afferent input via neurotransmitters, we suggest that results of earlier experiments on facilitation of sexual behaviors by various drugs should be interpreted cautiously. The assumption is often made that the drugs are stimulating or antagonizing output of steroid hormone-sensitive systems. The existence of ligand-independent activation of steroid hormone receptors suggests that some of the drugs may act by altering the activation state of PRs as well as by more traditional mechanisms.

Studies on the regulation of GnRH during the rat and the mouse estrous cycles are consistent with the idea that activation of PRs may be an intermediate step in the mechanism by which some neurotransmitters and other factors regulate GnRH. Blockade of PRs or inhibition of PR synthesis blocks some of the effects of estradiol on GnRH regulation. It has been hypothesized that a neural consequence of estradiol action facilitates GnRH secretion via ligand-independent activation of PRs (Chappell et al., 1999; Chappell and Levine, 2000; Xu et al., 2000b).

In 1986, Whalen and Lauber proposed the novel hypothesis that many drugs that substitute for progesterone do so by elevating neuronal levels of cGMP. Furthermore, Beyer and his colleagues (1981) showed that drugs that increase cAMP may substitute for progesterone. Experiments discussed earlier are consistent with these ideas and suggest that some of the drugs that influence feminine sexual behavior do so by modulating second messenger systems and then by secondarily activating PRs (and perhaps other TFs).

The influence of afferent input on steroid receptors could be involved in the regulation of reproductive physiology. For example, VCS causes a variety of neuroendocrine changes in female rats, including the induction of pseudopregnancy (Gunnet and Freeman, 1983; Erskine, 1995; Erskine et al., 2004), increases in luteinizing hormone (LH) release (Moss et al., 1977), increases in lordosis intensity (Diakow, 1975), and subsequently termination of the period of sexual behavior (Blandau et al., 1941). Similarly, olfactory stimuli associated with mating have profound effects on reproductive physiology, and some of these could be mediated via afferent influences onto steroid-sensitive neurons.

8 Influence of Mating Stimulation on Long-Term and Short-Term Changes in Sexual Behavior and Influences on the Brain

It is generally accepted that fluctuations in hormone levels are the principal factors responsible for the changes in sexual responsiveness over the estrous cycle and in ovariectomized female rats. This is based on a long history of experiments demonstrating the effects of presence or absence of particular hormones on sexual behavior. Although it is well established that the hormonal changes underlying the onset of sexual behavior are an increase in estradiol followed by an increase in progesterone levels, this is not always the case. Many other factors associated with the mating situation result in both short- and long-term modulations of sexual behavior.

8.1 Short-Term Slowing of Sexual Response by Vaginocervical Stimulation: Pacing

During paced mating, the likelihood that a female will leave the compartment containing a male and the latency for her to return to the male's compartment after receipt of a copulatory stimulus is influenced by the specific type of stimulus that precedes the response. Withdrawals from the male occur more often, and the latency of the female's return to the male's cage is longer following an intromission or an ejaculation, than after a mount without intromissive stimulation (Bermant, 1961; Bermant and Westbrook, 1966; Erskine, 1985). Therefore, mounts, which include VCS, result in transient inhibition of sexual responsiveness or a short-term delay in the rate of copulation. Over the course of a test, the latency to return to the male's compartment (and consequently, the inter–intromission interval) increases as a function of the number of prior intromissions (Coopersmith et al., 1996). Therefore, allowing the female to pace sexual contacts with males causes a progressive decline in the rate at which females receive intromissions.

8.2 Short-Term and Long-Term Enhancement of Sexual Responding by Mating Stimuli

In contrast to the rapid and transient inhibitory influences of intromissive stimuli on pacing, in some cases, intromissive stimulation enhances the reflexive component of sexual behavior both in the short and the longer terms. As an example of the short-term change, while female rats that are sexually receptive respond to appropriate stimulation of the flanks and the perineum with the expression of the lordosis response, the presence of VCS by penile intromission results in a greater intensity of lordosis (Diakow, 1975). Similarly, VCS administered by a glass probe show an increased lordosis reflex in response to manual palpation of the flanks and the perineum (Komisaruk and Diakow, 1973). Ovariectomized rats, whether treated with subthreshold doses of estradiol or not, express enhanced lordosis to manual palpation immediately following experimenter-induced VCS (Komisaruk and Diakow, 1973). This acute facilitation of the lordosis response by VCS persists for at least 60 min (Rodriguez-Sierra et al., 1975). It should be noted that knife cuts parasagittal to the VMN that inhibit estradiol + progesterone-induced lordosis in response to a male, are without effect on cervical probing–induced lordosis (Pfeifle et al., 1980), potentially suggesting a different neural substrate for lordosis that is stimulated in this manner.

As an example of longer-term enhancement of sexual behavior, when ovariectomized rats are exposed to sexually active males for 15 min periods every 30 min (Foreman and Moss, 1977; Rajendren et al., 1990; Rajendren and Moss, 1993; Auger et al., 1997), the level of their sexual receptivity increases over time. In most earlier reports of mating enhancement of sexual receptivity, rats that had been ovariectomized, but not adrenalectomized, were used (Clemens et al., 1969; Hardy and Debold, 1973; Rajendren et al., 1990). Because adrenalectomy was reported to prevent this increase (Larsson et al., 1974), and because mere handling can substitute for mating (Hardy and Debold, 1973), the increase seen in those experiments was thought to be due to nonspecific causes, perhaps progesterone release from the adrenal (Feder and Ruf, 1969) in response to a minor stressor, rather than a specific response to afferent influences from the mating situation to the brain. It should be noted, however, that a small amount of enhancement had been seen in ovariectomized–adrenalectomized rats injected with large doses of estradiol (Zemlan and Adler, 1977).

In subsequent experiments in which the adrenal gland was removed as well, it was determined that repeated mating stimulation enhances sexual behavior in the absence of ovarian and adrenal secretions (Auger et al., 1997). In studies of the relative contribution of VCS as compared with flank and perineal stimulation provided by the male (Bennett et al., 2001), the first set of results published suggested that the mating enhancement is dependent in part upon VCS. Elimination of VCS (by placing tape over the vagina) blocked most of the enhancement. However, experimenter-induced VCS had only a very small influence on subsequent responding (Bennett et al., 2001). Nevertheless, on the basis of that work and work demonstrating the importance of intromissive stimuli/VCS on initiation of pregnancy and on abbreviation of estrus, a great deal of attention was paid to the cellular changes that accompanied intromissive/VCS specifically.

Surprisingly, a more recent study (Ghavami et al., 2005) suggests that VCS may not in fact be the proximate cause of mating enhancement in the repetitive mating situation. Mounts without intromissions were as effective in enhancing sexual behavior as mounts with intromission. Furthermore, this enhancement is not limited to lordosis; dramatic increases in paracopulatory behaviors are observed as well. While rats both receiving and not receiving intromissions show high levels of paracopulatory behaviors (ear-wiggling, darting, and hopping), those receiving intromissive stimuli predictably express higher levels of negative behaviors, such as rejection.

The conflicting results on the necessity of intromissive stimuli for enhancement of sexual behaviors in a repetitive mating situation are difficult to reconcile. There were, however, differences in procedures between the earlier and the later studies. For example, in the first study, ovariectomized–adrenalectomized rats were given salt replacement, but not corticosterone, while in the later study, the rats were implanted with a corticosterone pellet. It is not known at this time if there is an interaction with the presence of corticosterone replacement that could explain the differences. It should, however, be emphasized that there are complex interactions between adrenal hormones and ovarian hormones in the regulation of sexual responsiveness (DeCatanzaro and Gorzalka, 1979; DeCatanzaro et al., 1981; Gorzalka and Moe, 1994) and neuronal response to mating stimulation (Cameron and Erskine, 2003). In some neuroanatomical

areas, for example, ovariectomized–adrenalectomized rats show Fos expression in fewer cells in response to mounts without intromission than rats that are only ovariectomized, but expression in more cells in response to intromissions. Cameron and Erskine (2003) suggest that adrenal secretions may decrease sensitivity to low levels of mating stimulation. Regardless of the basis for the conflicting reports, it is now clear that mounting without intromission is a sufficient stimulus for enhancement of mating in estradiol-treated rats in ovariectomized–adrenalectomized rats in the absence of progesterone. This makes logical sense, because intromissive stimulation is rare in the early stages of this mating enhancement procedure, because at the start, rats are not expressing lordosis in response to mounts by the male.

Based on the finding that VCS is not necessary for mating enhancement of sexual receptivity, it can be predicted that the pelvic nerve does not mediate enhancement of sexual behaviors by mating stimulation. Rather it is likely to be mediated by the pudendal nerve, which innervates the perineal region, and whose sensory field is increased dramatically by ovarian hormone treatment (Komisaruk et al., 1972; Adler et al., 1977). In related work in rats at the proestrous stage of the estrous cycle, it has been shown that in some neuroanatomical areas, such as the preoptic area, medial amygdala, and bed nucleus of stria terminalis, mounts with and without intromissions are similar in their ability to induce Fos expression (Rowe and Erskine, 1993). In others, such as the VMNvl, paraventricular nucleus of the hypothalamus, and midbrain, mounts with or without intromissions had similar effects (Rowe and Erskine, 1993). A similar increase was seen after mounts without intromission in hormonally treated, ovariectomized rats in the central tegmental field and paraventricular nucleus of the hypothalamus (Polston and Erskine, 1995). While pelvic neurectomy blocked Fos expression in the preoptic area, medial amygdala, and bed nucleus of stria terminalis, it was without effect in the VMNvl, paraventricular nucleus of the hypothalamus, and midbrain (Rowe and Erskine, 1993).

Much of the earlier work in this field showing enhancement of sexual responding as a consequence of nonintromissive mating and even handling was dismissed as being due to nonspecific influences on the adrenal gland. The fact that enhancement of sexual behavior occurs even in rats without ovaries and adrenals suggests that adrenal involvement may not have been an adequate explanation for some of these results. In fact, in some cases, enhancement by repeated testing could be blocked by removal of the adrenals (Larsson et al., 1974). However, that is not the case for the results presented earlier. Most importantly, it is clear that there are numerous factors other than hormones that influence the moment-to-moment levels of sexual responding. As Hardy and Debold wrote (1973), "Thus, in spite of the clear dose–response relationship between level of hormone administration and degree of display of lordosis, variables other than hormonal dosage exert an important influence on the sexual behavior of the female rat." While these have been less well studied than the mechanisms mediating overall response to the hormones, because they can have a dramatic influence on fertilization, they are just as important as the more easily studied overall changes in lordosis quotients as a function of hormone dose.

8.3 Longer Latency Inhibition of Sexual Behavior by Mating Stimuli: Heat Abbreviation

The receipt of intromissions and ejaculations during mating has another longer latency influence on sexual behavior. Females that receive intromissive stimulation during mating express copulatory behaviors for a shorter length of time than do females who have not received VCS [rats (Boling and Blandau, 1939; Lodder and Zeilmaker, 1976; Reading and Blaustein, 1984; Erskine, 1985; Pfaus et al., 2000), guinea pigs (Goldfoot and Goy, 1970; Roy et al., 1993), and hamsters (Carter and Schein, 1971; Carter, 1972, 1973; Carter et al., 1976; Ramos and Debold, 1999)]. Estrous duration in unmated cycling female rats assessed the presence of lordosis in response to manual palpation as approximately 19 h, while the females' receipt of intromissive, but not mounts-without-intromissive, stimulation significantly reduced the length of estrus to 16 h (Lodder and Zeilmaker, 1976). In rats, pacing of sexual contacts increases the effectiveness of intromissive stimulation on reducing estrous duration (Erskine and Baum, 1982; Erskine, 1985; Coopersmith et al., 1996). Excessive intromissions reduce subsequent sexual receptivity (Hardy and DeBold, 1972), and experimenter-induced VCS resulted in some active rejection behaviors as well (Rodriguez-Sierra et al., 1975; Pfaus

et al., 2000). In some cases, some of the inhibitory effects of intromissions on subsequent sexual receptivity may be dependent upon trauma to the vagina, vulva, and cervix (VanderSchoot et al., 1992).

Although earlier studies defined the period of sexual receptivity as the time during which a female responds to mating stimulation with lordosis, another definition is that the period of sexual receptivity actually ends when the female either passively avoids the male in a pacing situation and/or demonstrates active rejection behaviors. For example, in a study of the effects of administration of 50 applications of VCS with a glass probe on subsequent sexual behavior, (Pfaus et al., 2000), rats displayed both passive (avoiding the male) and active rejection behavior toward the male, long before the levels of lordosis had declined.

8.4 Vaginocervical Stimulation Versus Perineal Stimulation

VCS, usually the result of penile intromission by the male, is an important component of the stimulation received by female rats during mating. VCS influences hormone-sensitive processes, including LH release (Moss et al., 1977) and the twice daily surges of prolactin that then result in pseudopregnancy (Gunnet and Freeman, 1983). In the short term, it prolongs lordosis responses (Diakow, 1975), and in the long term, it decreases lordosis responding, increases rejection (Hardy and DeBold, 1972; Pfaus et al., 2000), and causes abbreviation of the period of sexual receptivity (Blandau et al., 1941; Reading and Blaustein, 1984; Pfaus et al., 2000), especially when mating stimulation is paced by the female (Erskine et al., 1989).

The results of many experiments suggest that experimentally administered VCS in rats can sometimes mimic the effects of intromissions by a male rat on reproductive physiology and behavior. This finding is interesting, because the experimental probes that are used are typically smooth glass or plastic, and they provide pressure directly to the cervix with only mild distension pressure on the vaginal wall [and in some cases, electrical stimulation of the cervix has been used; e.g.,Gorospe and Freeman (1981)]. In contrast, the penis of rats is covered with keratinous spines, which likely cause much more intense stimulation of the vaginal wall than a smooth probe (Taylor et al., 1983; Sachs et al., 1984). Furthermore, it is not actually known if the penis contacts the cervix directly during an intromission. It is likely, however, that stimulation would result either from ejaculation or deposition of the seminal plug. Although it is unclear whether experimentally induced VCS provides the same crucial element of genitosensory stimulation provided by an intromission, experimenter-administered VCS causes longitudinal stretching of the vaginal wall, which causes sufficient vaginal stimulation to induce immobilization similar to that induced by an intromission (Komisaruk and Larsson, 1971). Therefore, experimentally administered VCS may induce some of the same physiological changes as intromission. It should be considered that experimenter-induced VCS may also be a better proxy for ejaculations than for intromissions, although it may have some common features of both.

The pelvic nerve mediates mating-induced heat abbreviation in rats, because pelvic neurectomy blocks the heat abbreviating effects of intromissions (Lodder and Zeilmaker, 1976). In contrast, in guinea pigs, transection of the pelvic, pudendal, and genitofemoral nerves (Slimp, 1977) is without effect. It has been argued that there is a nonneural route of travel for the information from the genitals to the brain in guinea pigs. However, because the vagus nerve also conveys sensory information from the vagina/cervix to the brain (Cueva-Rolon et al., 1996; Komisaruk et al., 1996), this neural route has to be considered as well before a neural connection is dismissed.

9 Mechanisms of Changes in Sexual Responsiveness: Mating Enhancement Requires Ligand-Independent Activation of Progestin Receptors

The mating enhancement of sexual receptivity seen in ovariectomized–adrenalectomized rats is dependent on PRs, because it is blocked by progesterone antagonists (Auger et al., 1997). Because mating-related stimuli induce release of dopamine, as well as other neurotransmitters (Vathy and Etgen, 1989; Mermelstein and Becker, 1995; Kohlert et al., 1997; Matuszewich et al., 2000; Paredes and Agmo, 2004) in the forebrain, we have suggested that the enhancement is referable to ligand-independent activation of PRs, perhaps

secondary to the release of dopamine or another neurotransmitter. This represents a physiological application of the pharmacological, ligand-independent activation of PRs by dopamine agonists discussed earlier.

Moss and collaborators (Moss et al., 1977; Foreman and Moss, 1979; Rajendren et al., 1990, 1991; Dudley et al., 1992; Rajendren and Moss, 1993) suggested an alternate pathway for at least some of the effects of mating on enhancement of sexual behavior. They suggested that an accessory olfactory system pathway, involving the vomeronasal organ, medial amygdala, and the VMN and release of GnRH, is involved in this potentiation. While the olfactory pathway may also be involved in the mechanism by which mating enhances sexual receptivity, the mechanism seems to be independent of the ligand-independent activation of PRs described earlier (Bennett et al., 2002).

We have proposed that heat abbreviation by intromissive stimuli may be a consequence of down-regulation of PRs induced by ligand-independent activation of PRs. This is, however, just a hypothesis at this time.

The question has arisen recently as to whether the facilitation of sexual behavior that has been attributed to ligand-independent activation of PRs is actually due to increases in neural progesterone synthesis. We now know that progesterone is synthesized in the brain (Jung-Testas et al., 1989; Baulieu et al., 1996; Guennoun et al., 1997), but little is known about the regulation of this synthesis. The fact that estradiol induces progesterone synthesis in the hypothalamus (Micevych et al., 2003; Sinchak et al., 2003) and that it increases mRNA for 3β-hydroxysteroid dehydrogenase (Soma et al., 2005), however, raises the possibility that some afferent influences on PRs could be attributable to increases in neuroprogesterone synthesis, and therefore ligand-dependent activation rather than ligand-independent activation. One report provided indirect evidence that this is not the case (Auger et al., 2000). Furthermore, we recently clamped progesterone synthesis with a steroid hormone synthesis inhibitor and found that this does not mitigate the effects of mating on activation of PRs. This suggests that an increase in neural progesterone synthesis is not the mechanism by which the social environment/mating stimulation activates PRs (Lawrence et al., 2005). Nevertheless, further study is essential to support or refute this alternate hypothesis. In addition, much more has to be learned about the factors involved in the regulation of neural progesterone synthesis.

10 Sites of Integration Between Information About Social Environment and Hormonal Milieu

In general, mating stimulation and/or experimenter-applied VCS induces Fos-ir expression in the medial preoptic area, ventromedial hypothalamic area, bed nucleus of stria terminalis, paraventricular nucleus, medial amygdala, accessory olfactory bulb, midbrain central grey, and central tegmental field (Dudley et al., 1992; Erskine, 1993; Pfaus et al., 1993; Rowe and Erskine, 1993; Tetel et al., 1993; Wersinger et al., 1993; Dudley and Moss, 1994). However, many of the cells that respond to mating-related stimulation also contain ERs (Tetel et al., 1994a; Calizo and Flanagan-Cato, 2003) and/or PRs (Auger et al., 1996), suggesting that they are part of the neuronal substrate for integration of hormonal signals with afferent input from the social environment. Extensive coexpression of Fos-ir with ERαir occurs in the medial preoptic area, bed nucleus of stria terminalis, posterodorsal medial amygdala, midbrain central gray (Tetel et al., 1994a), and ventromedial hypothalamic area (Tetel et al., 1994a; Calizo and Flanagan-Cato, 2003). Although other areas were not investigated, extensive coexpression of Fos-ir with PRir is seen in the medial preoptic area, ventromedial hypothalamic area, and the arcuate nucleus (Auger et al., 1996; Blaustein and Greco, 2002). Surprisingly, in the ventromedial hypothalamic area and bed nucleus of stria terminalis, hormonal priming with estradiol and progesterone decreases the number of Fos-ir cells after a moderate amount of VCS (Tetel et al., 1994b; Pfaus et al., 1996). In contrast, hormonal treatment increased Fos expression in other areas, including the medial preoptic area and posterodorsal medial amygdala (Pfaus et al., 1996).

In some, but not all, cells, VCS-induced Fos expression in estradiol-primed, ovariectomized rats, is dependent on PRs, suggesting that ligand-independent activation of PRs is an obligatory step in the induction of this immediate early gene (Auger et al., 1997; Blaustein and Greco, 2002). Although progestin antagonists block VCS-induced Fos expression in the medial preoptic area, medial bed nucleus of stria terminalis, and caudal ventromedial hypothalamic area, these were without effect in other areas, including

the medial amygdala, dorsomedial hypothalamus, and paraventricular nucleus. Interestingly, a progestin antagonist blocks VCS-induced Fos in the rostral medial preoptic area, but not the caudal (Blaustein and Greco, 2002). Collectively, the data support the interpretation that in cells expressing PRs, VCS induction of Fos expression requires functional PRs. The mechanism is likely to be ligand-independent activation of those PRs by the afferent input.

Olfactory stimuli are of great importance to reproduction and sexual behavior. However, unlike VCS-induced Fos expression (Auger et al., 1996), the neurons in which Fos is expressed after exposure to bedding soiled by male rats do not contain PRs (Bennett et al., 2002). Furthermore, unlike the case with VCS-induced Fos expression (Auger et al., 1997; Blaustein and Greco, 2002), injection of a progesterone antagonist does not block male odor-induced Fos expression. While olfactory stimulation, like genital stimulation, enhances sexual responding (Rajendren et al., 1990), it seems to do so by a mechanism that does not require PRs.

11 Integration of Approaches

The goal of much of the work in this field is to understand the regulation of feminine sexual behavior from genes to behavior and everything in between. The integration of studies directed at cellular, molecular, and organismic levels is an iterative process. It is important to attempt to complete the synthesis of behavior to genes, and, for example, to determine which genes are influenced by behaviorally relevant hormonal treatments in neurons that are likely to be involved in the behavior. However, as we study the mechanisms of, for example, copulatory behavior, we must keep in mind that the findings may or may not generalize to paracopulatory and/or progestative behaviors. We have to keep in mind that a particular mating situation may establish a reward state, and another may not. How does that difference in procedure alter the results and the conclusions of the experiments? We have to keep in mind that many experiments have looked at estradiol-only induced sexual behavior, and there are fundamental differences between this and estradiol- + progesterone-induced sexual behavior. If a particular study looked at the estradiol-only induced sexual behavior, does it generalize to progesterone facilitated? Is the neural substrate for both hormones one and the same?

A great deal of progress has been made at the molecular, cellular, and organismic levels. However, as we continue to fully integrate our understanding of the multiple levels, it is essential to remember that some of our assumptions may be false. We must constantly challenge the assumptions of the field (Blaustein, 2004a). Some of them are surely wrong. Just as we have learned over the past 30 years that the receptor does not always reside in the subcellular locations where we originally thought it did, and just as we have learned that steroid hormone receptors can be activated by multiple signaling routes besides steroid hormone ligand, we have to remain open minded to the possibility that the behavior is not modified in precisely the ways and the anatomical locations that we have always believed. We have to remain objective in assessing the possibility that the cells adjacent to the VMN are as important, or even more important than, the cells within the VMN. We also have to remain neutral in assessing the possibility that a reductionist approach that can help us understand some of the molecular aspects of complex behaviors may fall short without integrating what we learn about the complexities of regulation of the behaviors at the organismic level. Ultimately, an open mind to all levels of investigation will provide us the opportunity to develop a comprehensive understanding of how hormones regulate a set of behaviors, how the nervous system works to modify the expression of a behavior, and how the environment can influence both brain and behavior. Finally, there are numerous topics that could not be covered or covered in depth in this chapter.

Finally, it cannot be overemphasized that numerous relevant areas that contribute to the overall understanding of feminine sexual behavior were not covered in this chapter. Some of these include the influences of stress on sexual behaviors, the interactions of other hormones, such as glucocorticoids and thyroid hormones with sex steroid hormones and their receptors, the influence of metabolic changes on sexual behavior, and the relationships between the cellular mechanisms regulating sexual behavior with those regulating ovulation. Although this chapter has been quite selective in discussing work from just a few species, and by necessity interesting work on numerous other species has been ignored, the species covered

are those for which most information is available on cellular and molecular neuroendocrinology of feminine sexual behavior. The ultimate goal, which cannot be achieved in a review like this, is to integrate all of these issues at all levels, and in many species paying attention to all of the complexities of sexual behavior in a grand synthesis.

Acknowledgments

Work from the authors' laboratories was supported by the following grants from the National Institutes of Health: NS 19327 (JDB) and MH57442 and MH63954 (SKM). We are grateful to Dr Mary Erskine for her contributions to an earlier comprehensive review of feminine sexual behavior (Blaustein and Erskine, 2002), which provided some of the ideas discussed in this chapter.

Abstract: Female sexual receptivity is a vital component of reproduction. In many species, females allow sexual contact only during a period surrounding ovulation to maximize procreative success. In rats, the species most commonly studied, sexual receptivity can be determined by measuring the lordosis reflex. The lordosis reflex is elicited by appropriate hormonal priming: estradiol and progesterone in the intact female and stimulation of mechanoreceptors in the flank, perineum and area around the tail. Thus, lordosis is a global reflex that involves integration of information from a large number of brain areas to elicit this behavior. The critical sites for integration of hormonal with introceptive and extroceptive inputs are located in a circuit that spans the limbic system and hypothalamus. Using this highly reproducible and quantifiable behavior, lordosis, investigators have characterized the neurochemistry of neural circuits that control sexual receptivity. Since the hypothalamus and limbic systems are phylogenetically ancient parts of the brain, it is likely that information learned from rat model will be directly translatable to understand the neurochemistry of human sexual receptivity. A majority of studies have focused on hypothalamic regions to elucidate roles for a divergent population of neurotransmitters (i.e., acetylcholine, glutamate, dopamine, serotonin, norepinephrine, nitric oxide, prostaglandins) and neuropeptides (i.e., β-endorphin, enkephalin. α-MSH, ACTH, neuropeptide Y, oxytocin, galanin, vasopressin, TRH, leptin, PACAP and insulin growth factor-1) in the regulation of the lordosis as a measure of sexual receptivity. A striking discovery of this research is that central control of this lordosis involves a disproportionately large number of neuropeptides. This is reflected in this chapter, especially in terms of opioids. Opioids and opioid receptors are the best studied of the neuropeptides in terms of steroid regulation and behavioral actions. Although we have learned a great deal about the neurochemistry of lordosis, much work remains to be done before a synthetic overview emerges.

List of Abbreviations: 3β-HSD, 3β-hydroxysteroid dehydrogenase; 5-HT1-5, serotonin receptor 1–5; αDHP, 5α-dihydroprogesterone; ACTH, Adrenocorticotropin hormone; ADX, Adrenalectomized; AGT, aminoglutethimide; AP-5, 5-amino-phosphonoheptanoic acid; AP-7, 7-amino-phosphonoheptanoic acid; ARC, arcuate nucleus of the hypothalamus; AVP, arginine vasopressin; AVPV, anteroventral paraventricular nucleus; BSA, bovine serum albumin; BST, bed nucleus of the stria terminalis; cAMP, cyclic 3′,5′-adenosine monophosphate; CCK, Cholecystokinin; CCK-1, Cholecystokinin receptor 1; CCK-2, cholecystokinin receptor 2; CCK-A, cholecystokinin receptor A; CCK-B, cholecystokinin receptor B; cGMP, cyclic 3′,5′-guanosine monophosphate; ChAT, choline acetyltransferase; CRF, corticotrophin releasing factor; CTOP, H-D-Phe-*Cys*-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH_2; DA, Dopamine; DAMGO, H-Tyr-D-Ala-Gly-N-Met-Phe-glycinol-enkephalin; DOP, δ-opioid receptor; DPDPE, ([D-Pen2, D-Pen2]-enkephalin), a selective DOP agonist; EB, 17 β-estradiol benzoate; EOP, endogenous opioid peptides; EP 24-15, zinc metalloendopeptidase EC 34.24.15; ERα, estrogen receptor-α; ERβ, estrogen receptor-β; GABA, γ-amino butyric acid; GAD, glutamic acid decarboxylase; GALP, galanin-like peptide; GnRH, gonadotropin releasing hormone; GPCR, G protein coupled receptor; Icv, Intracerebroventricular; IGF-1, insulin-like growth factor-1; GluR, ionotropic glutamate receptor; KOP, κ-opioid receptor; LH, luteinizing hormone; LHRH/GnRH, luteinizing hormone releasing hormone/gonadotropin releasing hormone; L-NAME, *N*-Nitro-L-Arginine-Methyl-Ester, inhibitor of NOS; mAchR, muscarinic acetylcholine receptor; MC, Melanocortin; MC1-5, melanocortin receptor 1–5; MeApd, medial amygdaloid nucleus, posterodorsal part; MOP, μ-opioid receptor; MPN, medial preoptic nucleus; MSG, monosodium glutamate; MSH, melanocyte stimulating hormone; nAchR, nicotinic acetylcholine receptor; NK-1, neurokinin-1 receptor (substance P receptor); NMDA, *N*-methyl-D-aspartic-acid; NO, nitric oxide; NOP, nociceptin opioid receptor; NOS, nitric oxide synthase; NPY, neuropeptide Y; OFQ/N, orphanin FQ/nociception; OVX, ovariectomized/ovariectomy; OVX/ADX, ovariectomized and adrenalectomized; PAC1, pituitary adenylate cyclase 1 receptor; PACAP, pituitary adenylate cyclase-activating polypeptide; PAG, periaquaductal gray (also midbrain central gray-MCG); PGE2, prostaglandin E2; PKA, protein kinase A; POMC, proopiomelanocortin; PPT, β-preprotachykinin; PRKO, progesterone receptor knock out; V1a, vasopressin-1a receptor; VMH, ventromedial nucleus of the hypothalamus

1 Introduction

Once it was realized that the brain was involved in the regulation of sexual receptivity, it became clear that steroid hormones altered the activity of specific CNS circuits that regulated this behavior. Early studies showed that treatment with estradiol or estradiol + progesterone altered neuronal activity (Innes and Michal, 1970; Kubo et al., 1975; Bueno and Pfaff, 1976; Yamada and Nishida, 1978). The steroid environment imposes "states" on the brain. These states alter the activity of lordosis regulating circuits allowing them to respond to inputs with appropriate behavioral responses. These behavioral states are produced by steroid hormones that bathe the brain to coordinate the activity of inhibitory and facilitative lordosis circuits. Estradiol is obligatory for the expression of lordosis. However, its initial behavioral actions are to inhibit the expression of lordosis by activation of inhibitory circuits to allow for estradiol and progesterone to bring it "on line" with proper timing of the facilitative circuits. The discovery that the brain had a plentitude of neurotransmitters, and especially peptide neuromodulators, created an explosion of neurochemical examination of hypothalamic function in the 1980s. These led to studies aimed at determining the role of various extracellular messengers in the CNS control of sexual receptivity including nitric oxide (NO) and neurosteroids. Many of these studies infused a peptide or neurotransmitter into the III ventricle, and tested lordosis. Such studies were important because they relatively rapidly assessed which messengers needed further study. A number of groups chose to focus their attention on specific messengers or classes of messengers. These studies usually involved testing the actions of steroid hormones on messenger concentrations and receptors. For catecholamines, high pressure liquid chromatography was a major advance. For neuropeptides, the application of radioimmunoassay (RIA) to measure levels and various techniques to assess mRNA levels were a great boon. Soon there was an understanding about steroid-induced changes of neuropeptide levels, neuropeptide mRNA expression, and receptor mRNA expression with appropriate temporal and spatial resolution.

The plethora of transmitters/modulators and receptors associated with the regulation of sexual receptivity is highly redundant, yet every perturbation of the circuit had dramatic effects on the behavior. These outcomes were not always consistent with a highly redundant system. The question remains, why are there so many transmitters/modulators regulating sexual receptivity? Is there a hierarchical steroid activation of neurochemical circuits that regulate sexual receptivity or is there an accretion of actions with each transmitter/modulator contributing a proportionate part of the regulation leading to the full display of sexual receptivity? Another possibility is that the circuits have neurochemical nodes—constrictions through which information must flow to influence behavior. There is evidence that the medial amygdala, medial preoptic nucleus (MPN) and ventromedial nucleus of the hypothalamus (VMH) are discrete, morphologically identified nodes. Considerable data have been collected to support all these hypotheses, but a definitive answer has not emerged. Another important issue is the disparity between the pharmacological or acute molecular manipulations and the genetic manipulations. Often acute treatments dramatically amplify or block sexual receptivity. These and other questions should be kept in mind as this review is read. Sometimes the answers will be evident. In other cases the answers are currently not clear because the data are incomplete.

In this chapter, as appropriate, the methodology used to assess sexual receptivity in the rodent models will be discussed, since this often determines the outcome. The actions of estradiol and estradiol + progesterone in driving the behavior will be mentioned in addition to a review of extracellular CNS messengers implicated in the control of sexual receptivity.

2 Lordosis

Female sexual behavior has been divided into three components: attractivity, proceptivity, and receptivity [Beach, 1976; note the use of terms with slightly different emphasis by Blaustein and Mani (2006) in a chapter in this volume: copulatory, paracopulatory, and progestative, originally defined by Blaustein and Erskine, 2002]. In most laboratories, the female sexual behaviors that are studied are proceptivity and receptivity. Proceptive behaviors—designed to entice the male—are solicitation, hopping, darting,

and ear-wiggling. Beach defined sexual receptivity as a lordosis reflex. The stereotypic lordosis reflex is an arching of the back, elevation of the hindquarters, dorsoflexion of the tail, and extension of the neck (*Figure 4-1*). Beach proposed the lordosis quotient (number of lordosis divided by the number of mounts × 100) as a quantifiable measure of sexual receptivity (Beach, 1948; Beach and Leboeuf, 1967), and most studies have used this measure.

Figure 4-1

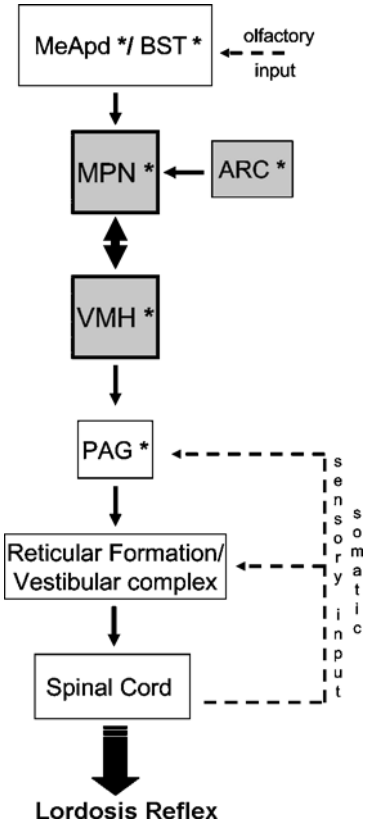
Photograph of two rats of the Long-Evans strain displaying sexual behavior. The male (*top*) has mounted the female (*bottom*) and achieved intromission (insertion of the penis into the vagina). In response to the mounting of the male, the female has assumed the stereotypical mating posture, the lordosis reflex, characterized by extension of the neck, arching of the back, elevation of the hindquarters, and dorsoflexion of the tail, which allows the male to intromit. The lordosis reflex in the female rat is dependent on the exposure of the neural circuits that regulate this behavior to ovarian hormones. Photograph by John T. Clark, Meharry Medical College, with permission

The lordosis reflex is elicited by appropriate hormonal priming: estradiol and progesterone in the intact female and stimulation of mechanoreceptors in the flank, perineum, and area around the tail. Under natural conditions this tactile stimulation is provided by a male. Although this is a global reflex requiring a large number of brain areas to elicit this behavior, the critical sites for integration of hormonal with introceptive and extroceptive inputs are located in a circuit that spans the limbic system and hypothalamus (see Micevych and Ulibarri, 1992 for review; *Figure 4-2*). Over the years, the underlying circuit that controls the lordosis reflex has been expanded to include the posterodorsal medial amygdala (MeApd), bed nucleus of the stria terminalis (BST), MPN, arcuate nucleus, and VMH. The VMH is considered to be the origin of the final common pathway from the integrative diencephalon to the periaquaductal grey (PAG), reticular formation, and vestibular nuclei. These regions provide descending projections to the spinal cord to activate medial lying dorsal horn motoneurons that innervate trunk and neck musculature producing the lordosis posture (reviewed in Pfaff et al., 1994).

Another method of testing sexual receptivity has been proposed as a more natural situation, and is termed "pacing" (Mendelson and Gorzalka, 1987; Pfaus et al., 1999); and references therein; also (Erskine,

Figure 4-2

Diagrammatic representation of the basic neural circuit regulating the lordosis reflex. Estradiol acts at several levels within the circuit (*) to allow sensory input from the accessory olfactory system and tactile stimulation from the perineum and flanks to elicit the sexual receptive behavior. The primary integration of sensory, hormonal, and metabolic states occurs in the hypothalamus (*shaded*). Secondary integration of reproductive relevant olfactory and hormonal information occurs in the MeApd and BST, and in the PAG, which receives ascending peripheral tactile stimulation from the spinal cord, hormonal information, and the positive output from the VMH. Descending information is relayed through the vestibular nuclei and the reticular formation before stimulating medial lamina IX motoneurons activating epaxial muscles resulting in lordosis



1987; Yang and Clemens, 1997). In the pacing model, females are allowed to approach the male or escape from him—thereby controlling the level of activity. Since this method has not been used to test most of the transmitters and modulators (but see Pfaus and Pfaff, 1992b) we will refer to it only when results with this paradigm conflict with results for the more traditional method of determining a lordosis quotient, the lordosis reflex.

3 Hormonal Modulation of Lordosis Reflex

Estradiol is essential for the display of the lordosis reflex. Estradiol actions in the brain increase the probability of reproductive behavior. Traditionally, estradiol actions that induce sexual receptivity have been thought to be mediated by nuclear receptors that alter the rate of transcription and translation.

Indeed, the induction of sexual receptivity was demonstrated to be dependent on protein synthesis in the brain (Ho et al., 1973; Rainbow et al., 1980a). More recently, both intracellular, nuclear receptors and membrane associated receptors have been implicated in the regulation of lordosis (Vasudevan et al., 2001). Regardless of whether genomic, nongenomic, or nongenomic to genomic signaling occurs, estrogen receptor-α (ERα) is generally considered mediate sexual receptivity relevant signaling (Rissman et al., 1997, 1999; Ogawa et al., 1998; reviewed in Rissman et al., 1999; Micevych et al., 2003b).

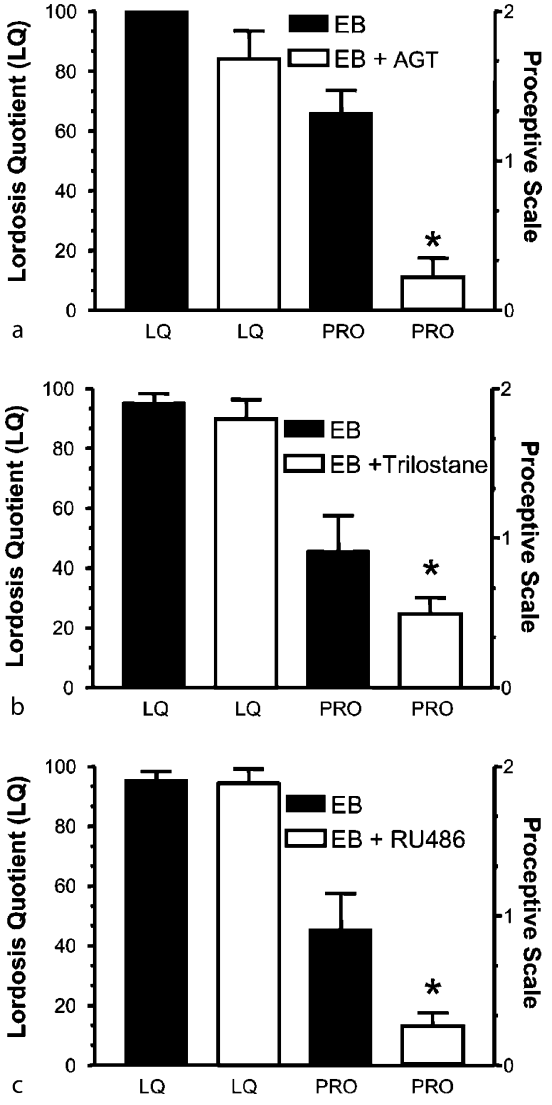
In gonadally intact rats, sexual receptivity is tightly regulated by the sequential release of estradiol and progesterone from the ovary. In ovariectomized (OVX) rats, sexual receptivity can be induced by either estradiol only or the sequential treatment with estradiol and progesterone. Although both steroid treatments induce sexual receptivity, several characteristics of the resulting behavior suggest that the mechanisms are different: (1) the dose of estradiol-only needed to induce sexual receptivity is higher than that needed when estradiol is supplemented with progesterone (Pfaff, 1970; reviewed in Clemens and Weaver, 1985); (2) repetitive estradiol treatment needed for maximal sexual receptivity results in a ramping increase of sexual receptivity as measured by lordosis quotient, whereas repeated estradiol + progesterone treatments produces a constant level of lordosis (Sodersten and Eneroth, 1981; Bloch et al., 1987); (3) progesterone receptors are not required for estradiol-only facilitation of lordosis (Mani et al., 1997) as evidenced by the fact that progesterone receptor antagonists do not disrupt estradiol-only induced sexual receptivity (Blaustein et al., 1987); (4) estradiol-only induced lordosis has a later onset and longer window of sexual receptivity compared with estradiol + progesterone (Quadagno et al., 1972; reviewed in Clemens and Weaver, 1985). In summary, progesterone subsequent to estradiol treatment transiently augments the estrogenic induction of the lordosis and eventually inhibits many of the estradiol-induced effects terminating the behavior and "resetting" the behavioral state of the female rat (Sodersten and Eneroth, 1981). In estradiol-only treated rats, the reversal of the behavioral state can be induced by the estradiol priming "wearing off" or induced by levels of vaginocervical stimulation that produces a pregnant or pseudopregnant state (Erskine et al., 2004).

Following estradiol treatment, sexual receptivity cannot be facilitated for almost a day Progesterone begins facilitating lordosis approximately 20 h after estradiol treatment, and this estradiol + progesterone induced sexual receptivity becomes maximal approximately 24 h after estradiol (Sinchak and Micevych, 2001b). In estradiol-only animals, the dose of estradiol required is higher when the receptivity is facilitated with subsequent progesterone. Either a single large dose of estradiol in a single bolus injection or smaller repeated injections are used to facilitate sexual receptivity. However, the onset of sexual receptivity is delayed approximately 48 h after initial treatment (Boling and Blandau, 1939).

The control of female reproduction requires coordination of sexual receptivity with production of a viable oocyte. The primary stimulus regulating reproductive behavior and ovulation is the increasing levels of estradiol that peak on proestrus. Interestingly, in the intact animal, the rise of ovarian progesterone is coincident with the luteinizing hormone (LH) surge and after the LH surge (Moss, 1974; Sodersten and Eneroth, 1981). In the intact female, both the behavior and LH surge appear dependent on the actions of progesterone (Brom and Schwartz, 1968; Ferin et al., 1969; Labhsetwar, 1970; Rao and Mahesh, 1986; Mahesh and Brann, 1998; Chappell and Levine, 2000). Moreover, progesterone that originates from the ovary and adrenal glands is not involved, since estradiol facilitates lordosis in OVX and adrenalectomized (OVX/ADX) rats (Bloch et al., 1987). One possible explanation is that estradiol induces progesterone synthesis in the hypothalamus that activates reproductive behavior as it has shown to trigger the LH surge (Micevych and Ulibarri, 1992; Micevych et al., 2003a). This locally produced neuroprogesterone would activate estradiol-induced progesterone receptors in the hypothalamus stimulating behavior before the levels of peripheral progesterone are significantly elevated. To directly test this hypothesis, OVX/ADX rats were treated with estradiol (10 μg 17 β-estradiol benzoate, EB) and then with free estradiol (50 μg 17 β-estradiol) 48 h after the first estradiol injection. This treatment induces both proceptive and receptive behaviors (Parsons et al., 1984; *Figure 4-3*). Treatment with a progesterone (and glucocorticoid) receptor antagonist, RU486, prevented proceptive behaviors, but not lordosis (*Figure 4-3a*; Mills et al., 2003). Similarly, blockade of steroidogenesis of neuroprogesterone with either aminoglutethamide (AGT; icv; *Figure 4-3b*) or trilostane blocked proceptivity but not sexual receptivity, i.e., lordosis (*Figure 4-3c*; Mills et al., 2003). These data indicate that neuroprogesterone may have a role in initiating proceptive

Figure 4-3

Effects of blocking the synthesis of progesterone and progesterone receptors in the CNS on sexual behavior. Blocking either progesterone synthesis (a and b) or activation of progesterone receptors (c) reduces expression of proceptive behaviors, but has no effect on expression of lordosis OVX/ADX rats treated weekly with 10 μg 17β-estradiol benzoate (EB) and then 4 h before the test with 50 μg 17β-estradiol. Animals were tested 53–56 h after the initial EB injection for sexual receptivity, as measured by lordosis quotient (LQ) and expression of proceptive behaviors (proceptivity scale). Treatments to block progesterone synthesis or progesterone receptors were delivered subcutaneously and started just before the EB treatment and on the following mornings before testing. Aminoglutethamide (AGT, 10 mg per treatment) blocks P450 side chain cleavage that converts cholesterol to pregnenolone (a); trilostane (TRI) blocks the enzyme 3β-hydrysteroid dehyrdrogenase (16.5 mg per treatment; 3β-HSD) which converts pregnenolone to progesterone (b). RU486 (5 mg per treatment) is a progesterone receptor antagonist (c). * = significantly less than control treatment within behavior group (Mills et al., 2003)



behaviors, but the lordosis reflex is not dependent on de novo synthesis of neuroprogesterone. The conclusion that can be drawn from these results is that neither progesterone nor progesterone receptors are needed to induce lordosis with estradiol alone, suggesting that estradiol activates a circuit that is distinct from the one activated by estradiol + progesterone as previously suggested [Mani et al., 1994a, c, 1997; see also Blaustein and Mani (2006) in this volume].

Progesterone has another important function vis-a-vis receptive behavior; it resets the lordosis regulating circuits in the brain. Sequential treatment of OVX animals with estradiol and progesterone facilitates lordosis and then terminates the behavior (Goy et al., 1966; Nadler, 1970; Feder and Marrone, 1977; Marrone et al., 1977; Morin, 1977; Schwartz et al., 1979). This relatively sharp cessation of lordosis is not seen in OVX animals made receptive by estradiol alone. Perhaps more importantly, females treated with 3–5 μg EB once in every 7–10 days have an increased lordosis quotient with each subsequent treatment until maximally receptive (Bloch et al., 1987; Butler et al., 2001). However, repeated treatments with 2 μg EB produce constant minimum levels of lordosis behavior (Sinchak and Micevych, 2001a), and subsequent progesterone treatment induces maximal receptivity. One intriguing idea is that progesterone induces "sequential inhibition" by promoting the degradation of estradiol-induced progesterone receptors (Blaustein and Mani, 2006). Interestingly, Gonzalez-Flores et al. (2004) recently demonstrated that blocking 26S-proteosome activity was associated with a lack of progesterone-induced sequential inhibition of lordosis reflex, and it prevented the loss of progesterone receptor immunoreactivity.

Studies over the past 40 years have suggested that sexual receptivity is not only complex in terms of the regions that are activated by ovarian steroids but is exceedingly more complicated in terms of the neurochemistry of this behavior. A cornucopia of extracellular signaling molecules has been identified and examined for their roles in modulating the lordosis reflex, or in some cases, pacing of sexually receptive behavior of the female.

Neuropeptides are disproportionately represented on the list of lordosis-promoting or lordosis-inhibiting molecules. The reasons for this are not entirely clear, but may reflect the large number of neuropeptides and their preferential distribution in the hypothalamus. Levels of most of these molecules are regulated by ovarian steroids. In many cases, the receptors for these molecules have also been characterized in terms of their response to estradiol and estradiol + progesterone.

4 Opioid Regulation of Lordosis

Arguably the best studied neurochemical mediators of lordosis are members of the family of endogenous opioid peptides (EOP). The EOP and their receptor systems are involved in all aspects of reproduction. EOP are distributed throughout limbic system and hypothalamic sites that regulate the lordosis reflex (*Figure 4-2*; Lee and Smith, 1980; Patterson et al., 1983; Smith et al., 1983; Law and Loh, 1999; Sinchak et al., 2006). These steroid receptive circuits are important not only for reproductive behavior in females, but also for integrative control of neuroendocrine regulation of reproduction by the hypothalamo-pituitary-gonadal axis. Opioid receptors are part of the superfamily of seven membrane pass, G protein-coupled receptors (Chen et al., 1993a, b; Reisine and Bell, 1993; Thompson et al., 1993; Mollereau et al., 1994; Wang et al., 1994a, b; Lachowicz et al., 1995; Dhawan et al., 1996), which include the classical opioid receptors μ-, δ-, and κ-opioid receptors (MOP, DOP, and KOP, respectively)—all blockable by the opioid receptor antagonist naloxone—and the opioid receptor-like receptor-1 (NOP, also known as ORL-1; Mollereau et al., 1994; Lachowicz et al., 1995). NOP shares a significant sequence homology with the other opioid receptors but is not antagonized by naloxone (Darland et al., 1998; reviewed in Meunier, 1997).

The early studies of opioid regulation of reproduction produced results that appeared incompatible with one another. The chronic use of heroin or morphine inhibited sexual behavior in female dogs, mice, monkeys, and chimpanzees, indicating that the global effect of opioid tone is inhibiting to reproductive behavior (Plant and Pierce, 1928; Tatum et al., 1929; Ko, 1934,1935; Seevers, 1936; Eddy and Reid, 1939; Spragg, 1940). However, further studies showed that chronic opioid administration did not preclude the dogs and rats from becoming pregnant and producing healthy young (Plant and Pierce, 1928; Myers and Flynn, 1931), indicating that estrous cyclicity and reproductive behavior were not eliminated, as previously

assumed. There were several factors in these early studies that made interpretation of the findings difficult. First, opioid treatment that produces tolerence state for opioids that may permit "normal" reproduction to occur, whereas acute treatments may have rapid transient effects on behavior. Second, agonists and antagonists used to investigate the role of opioids acted on multiple opioid receptor subtypes. Third, in the majority of these studies, drugs were given either peripherally or icv thereby activating multiple sites within the CNS. Fourth, the opioid receptors are promiscuous and will bind multiple opiates and opioids (Lee and Smith, 1980; Patterson et al., 1983; Smith et al., 1983; Law and Loh, 1999).

Despite these issues, the inhibition of sexual receptivity remained a consistent finding, especially following acute, global activation of opioid systems (reviewed in Pfaus and Gorzalka, 1987a). Yet with time, data suggested an additional, facilitatory role in sexual receptivity (Imura et al., 1985, 1986; Suda et al., 1986; Pfaus and Gorzalka, 1987b; Torii and Kubo, 1994; Torii et al., 1995, 1996, 1997, 1999). In this review, we will categorize opioid regulation of sexual receptivity by opioid receptor subtype.

4.1 MOP

The most well understood mechanism for MOP regulation of lordosis has been worked out in the MPN. MOP is expressed throughout the rostrocaudal extent of the medial preoptic area, especially in the dorsal aspect of the medial part of the MPN (Eckersell et al., 1998; Sinchak and Micevych, 2001a). In sexually receptive females, acute activation of MOP in the MPN inhibits lordosis (Wiesner and Moss, 1984; Sirinathsinghji, 1986; Pfaus and Pfaff, 1992b; Sinchak and Micevych, 2001a; Acosta-Martinez and Etgen, 2002a). Further, infusion of the general opioid receptor antagonist, naloxone, into the MPN of steroid primed nonreceptive females facilitated lordosis (Acosta-Martinez and Etgen, 2002a), indicating that steroid induction of sexual receptivity was blocked by MOP in the MPN.

Estradiol rapidly activates MOP in the MPN. This activation is coincident with the nonreceptive phase following initial estradiol exposure. The specific activation of MOP following estradiol treatment has been followed using the receptor internalization assay (Micevych et al., 1997; Eckersell et al., 1998; Mills et al., 2004; reviewed in Sinchak and Micevych, 2003). Estradiol, acting through ERα (within 30 min), rapidly induces activation of MOP in the MPN that lasts for at least 30 h before returning to basal levels by 48 h (Eckersell et al., 1998; Micevych et al., 2000, 2003b; Sinchak and Micevych, 2001a). This pattern of MOP activation in the MPN parallels the facilitation of lordosis in estradiol-only treated rats. Females treated with estradiol are not receptive at 30 h after treatment (Sinchak et al., 1997; Sinchak and Micevych, 2001a), but do exhibit lordosis approximately 48 h after estradiol treatment (reviewed in Clemens and Weaver, 1985), which coincides with the relief of MOP-mediated inhibition. Progesterone treatment 26 h after priming with physiological levels of estradiol facilitates lordosis 30 h after estradiol treatment and reverses estradiol-induced MOP internalization/activation (Sinchak and Micevych, 2001a). The steroid regulation of MOP activation in the MPN appears to be mediated by a multisynaptic circuit involving NPY and β-endorphin neurons in the arcuate nucleus, as discussed in the NPY section.

Further evidence that MOP in the MPN are relevant to the regulation of sexual receptivity in the intact rats is provided by the pattern of MOP activation during the estrus cycle (Sinchak and Micevych, 2003). MOR internalization/activation in the MPN is increased whereas sexual receptivity is low, on diestrus 1 and 2 when, estradiol is rising, and decreased when receptivity is elevated as on the afternoon and evening of proestrus after progesterone levels rise. After sexual receptivity is terminated, MOR internalization is again increased on the morning of estrus, suggesting that MOR in the MPN may also regulate the termination of sexual receptivity.

The activity of MOP in the MPN is important for integrating gonadal steroid information that regulates the timing of sexual receptivity—both the onset and termination. Antagonizing MOP in the MPN at the time of estradiol treatment prevents full progesterone facilitation of lordosis (Torii and Kubo, 1994; Torii et al., 1995, 1996, 1999). In mice that are MOP deficient, estradiol + progesterone do not fully induce the lordosis reflex or lordosis score (Sinchak et al., 2005). These behavioral studies indicate that the estradiol activates this lordosis inhibiting circuit early and that this MOP activity is important for estradiol actions on other lordosis facilitative circuits and the expression of maximal sexual receptivity. This MOP activation

may be one of the neural states that is induced by estradiol. This inhibitory tone over the lordosis circuit is maintained until either progesterone deactivates the MOP, which switches the state by allowing the coordination of circuits controlling the LH surge (ovulation) and sexual behaviors. If progesterone is not present, high levels of estradiol alter these neural circuits such that the female is eventually sexually receptive. Then copulatory behavior and/or olfactory cues from a male induce the LH surge and ovulation (Matt et al., 1987; Day et al., 1988).

The expression of MOP in the VMH remains controversial. A number of immunocytochemical and in situ studies have not demonstrated MOP in the VMH of rats or mice (Mansour et al., 1994a, b; Minami et al., 1994; Micevych et al., 1997; Eckersell et al., 1998), whereas others indicate that MOP may be expressed at very low levels (Bunzow et al., 1995; Loughlin et al., 1995; Acosta-Martinez and Etgen, 2002a). This controversy is born out in behavioral studies. Infusion of either morphine or the selective MOP agonist, H-Tyr-D-Ala-Gly-N-Met-Phe-glycinol-enkephalin (DAMGO), into the region of the VMH inhibited lordosis (Vathy et al., 1991; Acosta-Martinez and Etgen, 2002a). However, other studies indicate that the role of MOP in the VMH is either nonexistent or has little influence on lordosis (Sinchak et al., 1997; Acosta-Martinez and Etgen, 2002b; Sinchak and Micevych, 2003). One explanation is that site-specific injections aimed at the VMH may activate MOP in the arcuate nucleus, which affects the lordosis reflex through a multisynaptic mechanism that involves β-endorphin neurons or MOP that are located outside of the VMH (Bouret et al., 1999; reviewed below in NPY section).

The PAG receives projections from the VMH and is an important part of the motoric pathway for the facilitation of lordosis (Pfaff and Sakuma, 1979; Sakuma and Pfaff, 1979, 1980a, b , 1982; Sakuma and Akaishi, 1987; Dornan et al., 1990; Hennessey et al., 1990; Canteras et al., 1994; Daniels et al., 1999; Flanagan et al., 2006). The PAG expresses MOP, and site-specific injections of β-endorphin, an endogenous MOP ligand, inhibited lordosis. The inhibition was naloxone reversible (Sirinathsinghji, 1984, 1985). More recent studies using selective MOP ligands, endomorphin-1 and endomorphin-2, did not confirm the earlier studies (Acosta-Martinez and Etgen, 2002a). Although it is possible that β-endorphin may be acting through DOP (Law and Loh, 1999) in the PAG, the most parsimonious explanation is that the endomorphins were rapidly degraded before behavioral testing (Sinchak and Micevych, 2001a).

4.2 DOP

DOPs are also expressed throughout the limbic-hypothalamic lordosis regulating circuit. In the MPN, DOP binding has been reported (McLean et al., 1986; Eckersell and Micevych, 1997). The pattern of DOP immunoreactivity is diffuse and located on small fibers suggesting that DOP may be located on afferent fibers (Sinchak et al., 2004b). This is corroborated by a lack of DOP mRNA in the MPN (Desjardins et al., 1990; Mansour et al., 1994a, b). Interestingly, neither DOP binding levels nor patterns of immunoreactivity are sensitive to the steroid milieu (Acosta-Martinez and Etgen, 2002b; Sinchak et al., 2004b). Although, icv infusion of DOP agonists facilitate lordosis in estradiol primed female rats (Pfaus and Gorzalka, 1987b; Pfaus and Pfaff, 1992a; Acosta-Martinez and Etgen, 2002b), activation of DOP facilitates or inhibits lordosis depending on the site of activation. In the VMH, [D-Pen2, D-Pen2]-enkephalin (DPDPE), a selective DOP agonist moderately facilitates female sexual receptivity, whereas in the MPN DOP activation inhibits lordosis (Micevych et al., 2002; Acosta-Martinez and Etgen, 2002b; Sinchak and Micevych, 2003; Sinchak et al., 2004b).

Based on the presence of DOP binding and immunoreactivity in the MPN this is another region of where DOP may regulate lordosis. Infusion of DPDPE into the MPN-inhibited lordosis in sexually receptive animals and was blocked by pretreatment with naltrindole, a DOP antagonist (Sinchak et al., 2004b). This rapid inhibition of lordosis was similar to the activation of MOP in the MPN (Sinchak and Micevych, 2001a). Thus, both MOP and DOP in the MPN inhibit lordosis. In estradiol-primed female rats, infusion of naloxone, which antagonizes classical opioid receptors, into the MPN facilitates lordosis (Acosta-Martinez and Etgen, 2002a). Selective MOP antagonism did not facilitate lordosis in nonreceptive female rats primed with estradiol (Acosta-Martinez and Etgen, 2002a). Thus, the inactivation of both MOP and DOP in the medial preoptic area is required to facilitate lordosis (Sinchak et al.,2004b). The MPN contains the

endogenous ligands for both the DOP and the MOP, enkephalin and β-endorphin, which are capable of binding and activating both the receptors (Lee and Smith, 1980; Patterson et al., 1983; Smith et al., 1983; Law and Loh, 1999).

In the VMH, DPDPE moderately facilitates female sexual receptivity (Micevych et al., 2002; Acosta-Martinez and Etgen, 2002b; Sinchak and Micevych, 2003). Levels of sexual receptivity achieved by activation of DOP in the VMH are well below the sexual receptivity achieved by icv injection of DPDPE, suggesting that the VMH is not the only site at which DOP facilitates lordosis.

4.3 KOP

Endogenous KOP ligands (i.e., dynorphin 1–17 (dynorphin A), dynorphin B (rimorphin), leumorphin, a/β-neoendorphin) are produced from the endoproteolysis of prodynorphin (reviewed in Waldhoer et al., 2004). Although these KOP-activating peptides are marginally distributed in the limbic-hypothalamic lordosis regulating circuit, their role or that of KOP in the regulation of lordosis has received little attention. Intracerebroventricular infusion of dynorphin A has been reported to have either no effect or facilitate lordosis (Pfaus and Gorzalka, 1987b; Pfaus and Pfaff,1992a). Similarly, activation of KOP in the PAG was also ineffective in modulating the lordosis reflex (Sirinathsinghji, 1985). Based on these results there is consensus that KOP has a minor role, if any, in regulating sexual receptivity.

4.4 NOP

NOP and its endogenous ligand, orphanin FQ-nociceptin (OFQ/N, also known as nociceptin), comprise a more recently characterized endogenous opioid system (Mollereau et al., 1994; Wang et al., 1994a; Lachowicz et al., 1995; Brit J. Pharm, 2003; Neubig et al., 2003). The amino acid sequences for NOP and its endogenous ligand are highly homologous to KOP and dynorphin A, respectively (Fukuda et al., 1994; Mollereau et al., 1994; Wang et al., 1994a; Lachowicz et al., 1995; Meunier et al., 1995; Lee et al., 1997; Meunier, 1997; Reinscheid et al., 1998). Though it may be tempting to think that KOP actions on lordosis may be due to dynorphin A acting at NOP, NOP exhibits little affinity for endogenous ligands of MOP, DOP, or KOP (Pfaus and Pfaff, 1992a; Fukuda et al., 1994; Mollereau et al., 1994; Wang et al., 1994a, Lachowicz et al., 1995; Lee et al., 1997). Naloxone does not antagonize NOP, but does antagonize dynorphin A actions. The only known endogenous agonist for NOP is OFQ/N (Meunier et al., 1995; Dooley and Houghten, 1996; Reinscheid et al., 1996; Shimohigashi et al., 1996; Ardati et al., 1997; Butour et al., 1997; Guerrini et al., 1997; Meunier, 1997; Reinscheid et al., 1998), suggesting that dynorphin A is not the ligand for NOP.

In the female rat, NOP and OFQ/N are expressed in the limbic–hypothalamic lordosis regulating circuit: MeApd, BST, arcuate nucleus, and MPN (Neal et al., 1999a, b; Sinchak et al., 2006). In the VMH, only the NOP are expressed, but OFQ/N is transported to the nucleus in afferent fibers (Sinchak et al., 1997, 2006). Ovarian steroids regulate the mRNA expression of both OFQ/N and NOP mRNA expression and the functional coupling of NOP to its G protein that is temporally congruent with the facilitation of lordosis (Micevych and Quesada, unpublished observations; Sinchak et al., 2006).

Infusion of OFQ/N into the VMH facilitates lordosis in female rats primed with a physiological dose of estradiol (Micevych et al., 1996; Sinchak et al., 1997; Dewing et al., 2005; Sinchak et al., in press). The sequential exposure to estradiol and progesterone is important for increasing both the ligand and receptor expression and then activation of the OFQ/N in the VMH to facilitate lordosis. Estradiol priming increases the expression of NOP in the VMH, but does not induce NOP activation (Sinchak et al., 1997; Sinchak and Micevych, 2003; Dewing et al., 2005). Subsequent progesterone treatment that facilitates lordosis activates NOP, presumably by the release of endogenous OFQ/N (Sinchak and Micevych, 2003). Potential brain regions known to regulate lordosis that express OFQ/N mRNA and project to the VMH include the MeApd and the MPN. OFQ/N mRNA expression in these regions is upregulated by ovarian steroids (Sinchak et al., 2006).

As in the VMH, infusion of OFQ/N into the MPN facilitates the lordosis reflex of rats primed with physiological levels of estradiol (Sinchak et al., 2003; Dewing et al., 2005; Sinchak et al., in press). NOP activation is enhanced by ovarian steroid regulation of NOP expression and an increase in GPCR-G protein coupling in the MPN. In the medial part of the MPN, estradiol slightly increases NOP expression; however, estradiol and progesterone are needed to significantly increase NOP expression (Sinchak et al., 2006). This finding is consistent with results that the number of NOP binding sites in medial preoptic area, which contains the MPN, is increased by estradiol and progesterone treatment, but not by estradiol alone (Micevych and Quesada, Submitted). Further, estradiol and progesterone treatment increases the coupling of NOP to its G protein in the medial preoptic area. Thus, the upregulation and activation of the NOP system in the MPN by estradiol and progesterone is temporally associated with the onset of sexual receptivity. At this time, the relationship between the activation of NOP and the inactivation of MOP in the MPN needed for sexual receptivity is not clear. Further experiments are needed to understand these interactions.

The arcuate nucleus has recently emerged as a node for steroid regulation of lordosis (Mills et al., 2004). Recent studies suggest two mechanisms through which OFQ/N in the arcuate nucleus may facilitate sexual receptivity. First, OFQ/N that is released in the MPN may originate in the arcuate nucleus (Sinchak et al., 2003, 2004a). Second, OFQ/N hyperpolarizes β-endorphinergic neurons (Wagner et al., 1998), which are activated by estradiol to inhibit lordosis (Nguyen et al., 2006). Thus, progesterone facilitation of lordosis may be through inhibition of β-endorphin neurons that project to the MPN.

The estradiol–progesterone–EOP interaction appears to be designed to provide a timing mechanism that ensures reproductive success. Estradiol initiates a series of transcriptional events, especially the expression of progesterone receptors. Simultaneously, estradiol initiates a series of rapid actions that lead to an inhibition of the lordosis regulating circuits. Normally, the increasing levels of circulating progesterone block the MOR inhibition and activates facilitatory circuits among which is NOP release in the VMH and MPN to facilitate lordosis (Sinchak et al., 1997, 2003; Dewing et al., 2005; Sinchak et al., in press).

5 Neuropeptide Y

NPY infused icv robustly induces increased food intake and acutely inhibits the lordosis reflex in rodents (Clark et al., 1984, 1985; Stanley and Leibowitz, 1985; Kalra et al., 1988; Kulkosky et al., 1988; Corp et al., 2001; Mills et al., 2004). NPY, a member of the pancreatic polypeptide family, is highly conserved among the mammalian species (Tatemoto, 1982; Tatemoto et al., 1982; Adrian et al., 1983; Lundberg et al., 1984; Sabatino et al., 1987; Mercer et al., 1996). There are at least six known NPY receptor subtypes that have been characterized (Michel et al., 1998; Brit J. Pharmacol, 2003). Although there have been relatively few studies linking NPY and central regulation of lordosis, the similarity of NPY and *β*-endorphin inhibition of the lordosis reflex suggested that a study of these two neuropeptides may yield a more clear understanding of estradiol regulation of the limbic-hypothalamic lordosis regulating circuit. Moreover, it suggested that the arcuate nucleus may be an important, if overlooked node of estradiol and progesterone action. A series of studies have characterized NPY as an integral part of a neural circuit that involves the arcuate nucleus through which estradiol, by a multisynaptic circuit, rapidly induces and maintains the activation of MOP in the MPN that is ultimately important for ovarian steroid for the facilitation of lordosis (Eckersell et al., 1998; Sinchak and Micevych, 2001a; Mills et al., 2004; Sinchak et al., 2005).

Within the arcuate nucleus, NPY neurons express estrogen receptors, and estradiol regulates the expression of NPY (Sar et al., 1990; Baskin et al., 1995), indicating a direct mechanism for estradiol regulation of these arcuate nucleus neurons. Accordingly, estradiol induces the release of NPY that stimulates β-endorphin neurons by the NPY-Y1 receptor which project to the MPN to release β-endorphin and activate MOP (Mills et al., 2004). This is supported by observations that NPY-Y1 receptors in the arcuate nucleus and MOP in the MPN have a similar time course of estradiol-induced activation (Mills et al., 2004). Further, the estradiol-induced internalization of activated NPY-Y1 receptor and MOR is blocked by treatment with an NPY-Y1 receptor antagonist. Subsequent progesterone treatment that facilitates lordosis attenuates activation/internalization of NPY-Y1 in the arcuate nucleus and MOP in

the MPN (Sinchak and Micevych, 2001a; Mills et al., 2004). The progesterone inactivation of the MOP and NPY-Y1 receptors is reversed by NPY treatment, indicating that both the estradiol and the progesterone actions on MOR are mediated by the release of NPY in the arcuate nucleus (Mills et al., 2004). The acute NPY-induced (icv) inhibition of lordosis in estradiol + progesterone treated animals is reversed by pretreating with the MOP specific antagonist CTOP (Mills et al., 2004), indicating that the inhibitory action of NPY on lordosis is through the activation of MOP in the MPN (Mills et al., 2004). Thus, ovarian regulation of the MOP lordosis inhibitory circuit in the MPN is by the regulation of the accurate nucleus β-endorphin neuron activity by NPY.

6 Adrenocorticotropic Hormone/Melanocyte Stimulating Hormone

Proopiomelanocortin (POMC) is a precursor from which α-MSH (melanocyte stimulating hormone), *β*-MSH, *γ*-MSH, ACTH (adrenocorticotropic hormone), and *β*-endorphin are produced by posttranslational splicing (Uhler et al., 1983). The opioid product, *β*-endorphin, has been discussed separately. Both α-MSH and ACTH have implicated the regulation of sexual receptivity (Pfaus and Gorzalka, 1987a; Dornan and Malsbury, 1989; Gonzalez et al., 1999; Scimonelli et al., 2000; Pfaus et al., 2004). Melanocortin effects are mediated through a family of G protein-coupled seven membrane span receptors (reviewed in Catania et al., 2004 and Getting, 2006), which have a small second extracellular loop and short amino and carboxy terminal ends. To date 5 melanocortin (MC) receptors have been cloned and termed MC1 through MC5. These GPCRs are coupled to several intracellular signaling pathways including activation of adenylyl cyclase, and inositol triphosphate leading to increased cAMP levels and intracellular calcium levels, respectively (Wikberg et al., 2000).

The MC1 receptor is distributed in the skin where it mediates pigmentation and cutaneous neuroimmunomodulation. The MC2 receptor is distinguished from the other MC receptors because it binds ACTH, but not the other melanocortins (α-MSH, *β*-MSH, and *γ*-MSH). The MC3 receptor is mainly found in the brain (Roselli-Rehfuss et al., 1993), and the MC4 receptor is exclusively found in the brain (Mountjoy et al., 1994). The MC4 receptor subtype appears to mediate the effects of the melanocortins on eating behavior and body weight (Huszar et al., 1997). The MC5 receptor is also found in the brain and a wide range of peripheral tissues. This receptor has been implicated in regulating exocrine gland secretion (Chen et al., 1997).

ACTH and α-MSH act on similar MC receptors, α-MSH on most MC receptors and ACTH on MC2 (Chhajlani and Wikberg, 1992; Mountjoy et al., 1992; Chhajlani et al., 1993). α-MSH behaves like serotonin: facilitating lordosis reflex when animals are lowly receptive and inhibiting lordosis in highly receptive animals (Thody and Wilson, 1983; Raible and Gorzalka, 1986; Cragnolini et al., 2000). Both α-MSH, a pan-MC receptor agonist, and *γ*-MSH, a selective MC3 agonist, have shown to regulate lordosis in ovariectomized, estradiol primed rats after infusion into the VMH and the medial proptic area (Gonzalez et al., 1993, 1996; Cragnolini et al., 2000; Nocetto et al., 2004). Evidence has accumulated that the mechanism of this action is through the MC3 receptor that mediates stimulation of NO generation. Pretreatment of estradiol-primed rats with L-NAME, an inhibitor of nitric oxide synthase (NOS) completely abolished the stimulatory actions of both α-MSH and *γ*-MSH (Nocetto et al., 2004). On the other hand, PT-141, an analog of α-MSH that binds to the MC1 and MC2 receptors increased solicitation behaviors without altering lordosis reflex or pacing behavior (Pfaus et al., 2004), suggesting that the melanocortin action on sexual behavior may be differentiated according to the receptors activated. MC1 and MC2 receptors appear to be involved with regulation of proceptivity (anticipatory phase) and MC-3 regulates receptivity (consummatory phase).

7 Oxytocin

The classic neurohormone oxytocin is usually associated with the posterior pituitary and with a peripheral site of action. In the female, these actions are mainly on uterine smooth muscle (parturition) and milk ejection (lactation). Cells in the supraoptic nucleus and paraventricular nucleus of the hypothalamus

synthesize oxytocin and paraventricular oxytocinergic neurons have extensive CNS projections. Estradiol increases oxytocin levels (Jirikowski et al., 1988) and release (Caldwell et al., 1996a, b) in the medial preoptic area and medial basal hypothalamus. Estradiol also acts postsynaptically in the oxytocin system to increase oxytocin receptor expression (McCarthy, 1994a; Bale and Dorsa, 1995a, b; Bale et al., 1995a, b). The estradiol-induced increase in oxytocin receptor was shown to be due to a nongenomic to genomic signaling mechanism involving rapid activation of protein kinase C and protein kinase A (Bale and Dorsa, 1997, 1998; Bale et al., 2001).

A role of oxytocin in facilitating lordosis was demonstrated in the mid 1980s by Cort Pedersen and his colleagues (Caldwell et al., 1984, 1986). This action of oxytocin has been studied by other groups as well (Arletti and Bertolini, 1985; Gorzalka and Lester, 1987; Benelli et al., 1994; Bale et al., 2001), who established that oxytocin facilitates both estradiol and estradiol + progesterone induced lordosis reflex (Caldwell et al., 1984, 1986, 1992, 1994; Gorzalka and Lester, 1987; Schumacher et al., 1989; Schulze and Gorzalka, 1991). Oxytocin acts in both the medial preoptic area and the VMH to exert its effects by activating oxytocin receptors (Caldwell et al., 1990, 1994; Schumacher et al., 1990; Coirini et al., 1991; Johnson et al., 1991; Witt and Insel, 1991; McCarthy, 1994a; Pedersen and Boccia, 2002). Estradiol conjugated to bovine serum albumin (BSA), to prevent activation of intracellular ERs (Ke and Ramirez, 1990) along with oxytocin stimulated lordosis reflex after infusion into the medial preoptic area or the mediobasal hypothalamus (Caldwell and Moe, 1999). Additionally, estradiol induction of oxytocin mRNA levels is not as dramatic as estradiol effects on peptide content (Caldwell et al., 1989; Amico et al., 1995), and estradiol increases the affinity of oxytocin receptors (Caldwell et al., 1994), suggesting that estradiol's primary action on the lordosis regulating oxytocin system may be to rapidly influence oxytocin receptors. Further work is needed to demonstrate whether this is due to a change in the affinity of the oxytocin receptor for its G proteins in addition to altered affinity for oxytocin.

8 Vasopressin

Central administration of arginine vasopressin (AVP) has been shown to both facilitate and inhibit lordosis (Sodersten et al., 1983, 1985; Caldwell et al., 1986; Pedersen and Boccia, 2006). The inhibitory actions of AVP appear to be mediated through the V1a receptor subtype. Antagonism of the V1a receptor facilitates lordosis (Caldwell et al., 1990; Pedersen and Boccia, 2006) and appears to be acting in the medial preoptic area (Caldwell et al., 1990, 1994; Pedersen and Boccia, 2006). The inhibitory effect of AVP may be acting through reducing the activity of the oxytocin system (see oxytocin section), since pretreatment with a selective oxytocin receptor antagonist inhibits the facilitation induced by the selective V1a antagonist (Pedersen and Boccia, 2006). The inhibition of behavior by AVP was produced within 15 min, but the facilitation produced by the V1a antagonist had an onset that was much delayed, ranging from 90 min to 4 and 6 h (Caldwell et al., 1990; Pedersen and Boccia, 2006).

9 Cholecystokinin

Like most neuropeptides, CCK was implicated in the control of sexual receptivity in the 1980s (Pfaus et al., 1986; Bloch et al., 1988). These initial studies examined the effects of peripherally administered CCK on the lordosis reflex. CCK was shown to be both lorodosis-promoting and lordosis-inhibiting: facilitating lordosis in rats, which were slightly receptive and inhibiting lordosis in highly receptive rats (Bloch et al., 1987). Subsequent studies defined the distribution of CCK in the limbic-hypothalamic, lordosis-regulating circuit (Micevych et al., 1986, 1987, 1988a, b; see Micevych and Ulibarri, 1992 for review). The expression of CCK is sexually dimorphic (Micevych et al., 1987, 1988a) and regulated by estradiol in both males and females (Micevych et al., 1986, 1988b; Oro et al., 1988). Although there is a slight sexually dimorphic distribution in gonadectomized rats, the primary stimulus for CCK expression is the elevated level of estradiol and testosterone (which is metabolized to estradiol) at puberty (Micevych et al., 1994; Holland et al., 1996). It was determined that a physiologic dose of estradiol (2 μg estradiol benzoate) given every 4 days was more

effective at increasing CCK mRNA expression than bolus doses (50 μg EB) or continuously released estradiol from a 10-mm Silastic capsule (Micevych et al., 1996). This 2 μg dose of EB yields peak levels of circulating estradiol that mimic peak proestrous levels (Micevych et al., 1996; Asarian and Geary, 1999). In terms of lordosis, this estradiol treatment produces nonreceptive animals that can be reliably made maximally receptive with progesterone treatment (Sinchak and Micevych, 2001a). These estradiol + progesterone treated animals do not display a ramping of receptivity that was observed by Bloch et al. (1987) with estradiol only treatment (Bloch et al., 1987).

The facilitatory and inhibitory actions of peripherally administered CCK were explained on the basis of the distribution of CCK receptor subtypes. In the MPN, CCK-1 (also known as CCK-A) receptors mediate the facilitation of lordosis (Dornan et al., 1989; Holland et al., 1997). In the VMH, CCK-2 (also known as CCK-B) receptors mediate the inhibitory actions of CCK on lordosis (Bloch et al., 1989; Dornan et al., 1989). In addition, CCK binding in the VMH is modulated by estradiol and varies across the estrous cycle (Akesson et al., 1987). In the VMH, estradiol decreases the number of CCK binding, and this down-regulation is dependent on CCK innervation of the VMH (Schumacher et al., 1991). There are no CCK cell bodies in the VMH (Micevych et al., 1987) but there is a dense CCK terminal field (Fulwiler and Saper, 1985), suggesting that the decrease in receptors is secondary to the estradiol induced release of CCK. Such a rapid action of estradiol on CCK release from hypothalamic fragments was demonstrated in vitro (Micevych et al., 1988b). An hour of estradiol treatment dramatically augmented the potassium-evoked release of CCK. The time course of estradiol regulation of CCK binding levels in the VMH suggest that CCK is involved in the post-estradiol delay in response, 0–20 h after exogenous estradiol treatment of an OVX rat and diestrus in the estrous cycling rat, and in the cessation of lordosis following the period of receptivity. CCK receptor levels are low following estradiol, and return to basal levels by 48 h after estradiol treatment, and it is at this time that CCK is able to inhibit lordosis (Ulibarri and Micevych, 1993). Using microdialysis to measure extracellular levels of CCK in the medial preoptic area, in situ hybridization histochemistry for CCK mRNA and behavioral assessment of lordosis, Micevych and Sinchak (2001) demonstrated that the estradiol-induced synthesis of CCK precedes release, and that release remains basal for approximately 24 h after 2 μg EB treatment. During the time when CCK release is basal in the medial preoptic area, the rats do not respond to EB + progesterone treatment. When CCK release is elevated, the animals are receptive, suggesting a correlation between release of CCK in the medial preoptic area and receptivity. Support for this idea was evidenced by an antisense oligodeoxynuceotide study that demonstrated that blocking the expression of CCK-1 receptors in the medial preoptic area prevented the estradiol-induced lordosis reflex (Holland et al., 1997). When the treatments were stopped, and the animals were allowed to express CCK receptors, the rats previously treated with CCK-1 antisense deoxyoligonucleotide displayed full sexual receptivity.

The distributions of MOR and CCK largely overlap, suggesting that these two neuropeptides interact, except in the MPN (Micevych and Sinchak, 2001). MOR agonists inhibit the potassium-evoked release of CCK from hypothalamus (Micevych et al., 1982, 1985) and selective DOR agonists inhibit the estradiol-induced expression of CCK mRNA (Eckersell and Micevych, 1997), suggesting that activation of different EOP circuits regulate CCK expression or release. It is tempting to speculate that EOPs may regulate sexual receptivity by modulating the expression and release of CCK. Preliminary studies suggest that such an interaction may not be direct, since MOR protein and mRNA are not expressed in CCK-expressing neurons. A possible interaction may involve glutaminergic neurons based on the dependence of estradiol induced CCK expression on glutamate neurotransmission (unpublished observations).

10 Gonadotropin Releasing Hormone/Luteinizing Hormone Releasing Hormone

The distribution of GnRH cell bodies is scattered throughout the hypothalamus, depending on the species in question. In the rat and mouse, the majority of cell bodies is localized in the diagonal band of Broca and extends in a scattered band back into the medial preoptic area in an inverted "Y" when viewed in a horizontal plane (reviewed in Barry et al., 1985). GnRH was shown to facilitate lordosis in nonreceptive rats

treated with estrone (Pfaff, 1973; Pfaff and Keiner, 1973; Moss and McCann, 1973, 1975). GnRH was effective in the medial preoptic area and the arcuate nucleus but not the lateral hypothalamic area (Moss and Foreman, 1976). GnRH was also effective in other species (Alderete et al., 1980; Kendrick and Dixson, 1985; Mackay-Sim and Rose, 1986; Maney et al., 1997; Schiml and Rissman, 2000). Whereas GnRH increased the lordosis reflex, it did not increase sexual preference of estradiol-treated rats (Dudley and Moss, 1985) suggesting that only sexual receptivity is regulated by GnRH. In addition to hypothalamic sites, GnRH stimulates lordosis after injection into the PAG (Sakuma and Pfaff, 1980b; Riskind and Moss, 1983).

Reports questioning GnRH's efficacy may be explained by the fact that GnRH may need to be metabolized to an active fragment. As early as 1983, Dudley et al. (1983) reported that the lordosis-facilitating activity of GnRH was contained in the carboxy-terminal half of the decapeptide. However, the Ac-$GnRH_{6–10}$ has not been demonstrated in the brain (see Wu et al., 2006 and references therein). More recent work has demonstrated that the GnRH peptide is metabolized by the zinc metalloendopeptidase EC 3.4.24.15 (EP 24-15), which cleaves the decapeptide in half to produce $LHRH_{1–5}$ (Camargo et al., 1982; Krause et al., 1982). This enzyme has been shown to have a hypothalamic distribution and activity (Healy and Orlowski, 1992; Wu et al., 1997). In a study comparing GnRH and the $LHRH_{1–5}$ fragment, both peptides facilitated lordosis (Wu et al., 2006). Immunoneutralization of EP24-15 resulted in the inhibition of the LHRH-facilitated lordosis but did not inhibit $LHRH_{1–5}$ facilitated lordosis. The GnRH antagonist, antide, was capable of inhibiting GnRH facilitated lordosis, without affecting $LHRH_{1–5}$ facilitated lordosis, Suggesting that both GnRH and $LHRH_{1–5}$ affect sexual receptivity.

11 Substance P and other Tachykinins

Substance P is often associated with nociception, but its distribution in the limbic-hypothalamic lordosis regulating circuit suggests that this neuropeptide is also involved in the regulation of sexual receptivity. Substance P is a member of the tachykinin family of peptides. Mammalian tachykinins comprise a family of peptides now known to contain the products of three genes, *Tac1*, *Tac2*, and *Tac4* in mouse and rat (recently reviewed in Page, 2004; Patacchini et al., 2004; Pennefather et al., 2004). In addition to substance P, the family includes neurokinin A and its N-terminally extended analogs, neuropeptide K, and neuropeptide γ, all derived from the *Tac1* gene, neurokinin B from the *Tac2* gene, and the hemokinins and endokinins derived from the *Tac4* gene. In terms of specificity, substance P, and the mouse and rat hemokinins, endokinin A and B, are tachykinin neurokinin1 (NK1) receptor-preferring (Zhang et al., 2000; Kurtz et al., 2002; Page, 2004; Patacchini et al., 2004). Neurokinin A and its N-terminally extended analogs are tachykinin NK2 receptor-preferring, and neurokinin B is tachykinin NK3 receptor-preferring (Maggi, 1995; reviewed in Pennefather et al., 2004). Estradiol regulates NK1 receptor mRNA in vitro (Villablanca and Hanley, 1997).

Most studies have focused on substance P in the VMH and its descending projections. The expression of substance P gene, β-preprotachykinin (PPT, *Tac1*) is increased by estradiol treatment (Brown et al., 1990; Priest et al., 1995). The estradiol action was likely to be directly on PPT mRNA expressing cells, since 43% of the substance P immunoreactive cells were estradiol receptive in the ventrolateral part of the VMH (Akesson and Micevych, 1988). Interestingly, a constant level of estradiol replacement with an estradiol-filled Silastic capsule did not increase β-PPT mRNA levels (Romano et al., 1989), suggesting that a more natural pulsatile estradiol replacement may be needed to drive gene expression rather than a static replacement paradigm. Further support for this idea was provided by findings that the percentage of progesterone receptor/substance P immunoreactive cells in the ventrolateral nucleus of the hypothalamus of guinea pigs, an area analogous to the VMH in rats, was significantly higher in the estradiol pulse-treated compared with estradiol capsule-implanted animals (Olster and Blaustein, 1992). The estradiol pulse treatment was also more effective at inducing the display of lordosis reflex in guinea pigs.

Substance P injection into the PAG facilitates estradiol-induced lordosis behavior in OVX rats (Dornan et al., 1987). These authors blocked the action of endogenous substance P with antisera directed against the peptide attenuating sexual receptivity. Retrograde tract tracing from the dorsal PAG revealed cell bodies throughout the extent of the VMH with the majority of the substance P cells that project to the PAG localized in the caudal two-thirds of the VMH. Approximately 17% of the substance P-immunoreactive

cells of the ventrolateral part of the VMH projected to the dorsal PAG (Dornan et al., 1990). These results provide morphological evidence for a substance P projection from the VMH, where substance P expression is regulated by estradiol, to an area where substance P has been demonstrated to facilitate lordosis behavior.

More recently this idea of a lordosis-relevant substance P projection from the VMH to the PAG has been questioned. An analysis of pseudorabies virus-labeled neurons after injection into the lordosis-relevant, lumbar, epaxial muscles demonstrated that the vast majority of labeled neurons, both within and subjacent to the VMH, did not contain ERα (Daniels and Flanagan-Cato, 2000) the predominant form of ER in the VMH (Shughrue et al., 1997). Furthermore, these lordosis-relevant projection neurons and the population of ERα-containing neurons were largely segregated topographically. Consistent with these findings, previous studies have found estradiol binding within only a minority of the VMH projection neurons (Morrell and Pfaff, 1982; Akesson et al., 1994), whereas a significant population of substance P neurons are estradiol receptive. A significant population (28%), however, of neurons labeled with pseudorabies virus were shown to express NK1 receptors indicating that estradiol information from estradiol-receptive substance P neurons can influence VMH output neurons (Daniels et al., 2003) and suggest that the VMH is an important site for the substance P regulation of lordosis.

12 Corticotropin Releasing Factor

CRF has a CNS distribution that is more extensive than its role, regulating ACTH release, would suggest (Olschowka and Jacobowitz, 1983; Swanson et al., 1983). In the hypothalamus, the primary locus of CRF mRNA is the paraventricular nucleus (PVN); (Swanson et al., 1987; Matthews et al., 1991). Exogenous CRF powerfully inhibits the lordosis reflex in sexually receptive rats in the medial preoptic area and the PAG (Sirinathsinghji et al., 1983; Sirinathsinghji, 1985, 1986). This is consistent with the idea that severe stress negatively regulates the lordosis reflex, since the dose of CRF needed to inhibit lordosis also induced behaviors associated with stress. Note that not all stress is detrimental for reproduction. Psychosocial stress facilitates female sexual receptivity (Williams et al., 1992). Indeed, mild stress facilitates the expression of preproenkephalin (PPE) mRNA in the VMH (Sinchak et al., 2000), an event correlated with an enhanced lordosis reflex (Lauber et al., 1990). Consistent with this idea, estradiol and progesterone have been reported to reduce the negative actions of mild (restraint) stress on the lordosis reflex (White and Uphouse, 2004).

13 Galanin

Galanin is widely distributed throughout the limbic-hypothalamic, lordosis-regulating circuit (see Bedecs et al., 1995 for review) and the distribution of galanin-immunoreactive neurons is sexually dimorphic. Castrated males have more galanin cells in the MPN compared with OVX females (Bloch et al., 1993). Galanin immunoreactive neurons are estradiol receptive and galanin expression is increased by either estradiol or testosterone treatment (Bloch et al., 1992, 1993), suggesting that galanin may also mediate estradiol's actions on lordosis. Indeed, microinjections of galanin into the medial preoptic area facilitate female sexual receptivity in estradiol primed rats (Bloch et al., 1996, 1998).

More recently, a galanin-related peptide, galanin-like peptide (GALP) has been described. GALP is coded by a separate gene but has amino acid sequence homology with galanin (Ohtaki et al., 1999). Although, GALP stimulates male sexual behavior (Fraley et al., 2004), to date, this peptide has not been shown to modulate lordosis.

14 Serotonin

The initial observation that serotonin inhibits sexual receptivity (Meyerson, 1964) has been supported by over 40 years of intense research. In general, treatments that decrease monoamine concentrations increase the lordosis reflex and treatments that increase serotonin decrease lordosis. However, in the final analysis

there is little evidence that endogenous serotonin increases the lordosis reflex calling into question the physiological relevance of these observations (Luine and Paden, 1982; Luine et al., 1984; Frankfurt et al., 1985).

As with most transmitters/modulators, serotonin acts at several receptor subtypes that can have diametrically opposite actions. Vis-a-vis lordosis, the 5-HT1, 5-HT2, and 5-HT3 families have been well studied (see Uphouse, 2000 for review). The 5HT2 and 5-HT3 receptors appear to increase the lordosis reflex, and 5-HT1 and specifically the 5-$HT1_A$ receptors inhibit lordosis (Mendelson and Gorzalka, 1985; Hunter et al., 1985; Fernandez-Guasti et al., 1987; James et al., 1989; Uphouse et al., 1991, 1992; Aiello-Zaldivar et al., 1992; Hebert et al., 1995; Gonzalez et al., 1997; Wolf et al., 1998b, 1999; Jackson and Etgen, 2001; Uphouse and Wolf, 2004). Unlike other transmitters/modulators that have different actions on the lordosis reflex depending on the areas exposed, the 5-HT1 receptor is associated with the inhibition of lordosis in sites including the VMH, medial preoptic area, ventrolateral PAG, and medial raphe (Uphouse et al., 1992, 1993, 1996; Caldwell and Albers, 2002). The 5-HT1 is an autoreceptor located on the soma and dendrites of serotonin neurons that reduces neuronal activity and serotonin release (Sprouse and Aghajanian, 1987; Hjorth and Sharp, 1991; Adell et al., 1993; Hjorth et al., 1995). An interesting hypothesis is that the serotonergic system mediates the lordosis reflex in response to acute environmental cues (see Uphouse, 2000 for review). Under this scenario, the increase of serotonin following stress (Kirby et al., 1997; Maswood et al., 1998; Uphouse and Wolf, 2004) reduces lordosis through the 5-$HT1_A$ receptors; activation of 5-HT-$2_A/2_C$ may prevent disruption of the behavior in response to mild stress. Thus, dual activation of 5-$HT1_A$ and 5-$HT2_A/2_C$ enables a female to modify her behavior in response to environmental circumstances. Pharmacological activation of 5-HT1 or 5-HT2 receptors fits this schema (Hunter et al., 1985; Mendelson and Gorzalka, 1990; Gorzalka et al., 1997, 1998, 1999; Caldwell and Albers, 2002 see Mendelson, 1992 for review; but see Wolf et al., 1998a). However, manipulations of the endogenous serotonin system are not congruent with this hypothesis. The level of serotonin in the mediobasal hypothalamus declines near the time of sexual receptivity (Farmer et al., 1996; Maswood et al., 1999), suggesting that endogenous serotonin is tonically inhibitory but, estradiol, which stimulates lordosis, does not reduce ^{3}H-OH-DPAT binding (Clarke and Maayani, 1990; Mendelson and McEwen, 1991; Frankfurt et al., 1994; Gonzalez et al., 1997). Unlike the modest effects of estradiol on 5-$HT1_A$ receptors, 5-$HT2_A/2_C$ receptors are increased with estradiol treatment (Sumner and Fink, 1997; Sumner et al., 1999). Thus, a clear picture of the role of endogenous serotonin in the regulation of female sexual receptivity has not emerged.

15 Dopamine

The hypothalamus has a large number of DA neurons, rivaling the better known population in the substantia nigra. The best known DA populations are the tuberoinfudibular neurons located in the arcuate nucleus and the adjacent periventricular nucleus, the incertohypothalamic DA system clustered in the medial zona incerta, and a rostral AVPV group (Hokfelt et al., 1976; Zoli et al., 1993). Although this molecule and its receptors have been extensively studied in nigrostriatal neurons, its role in the regulation of female sexual receptivity remains complex and controversial. DA was implicated in regulating lordosis reflex in 1975 with the publication of the observation that apomorphine stimulated sexual receptivity (Hamburger-Bar and Rigter, 1975; Foreman and Moss, 1979). Studies from Gorski and Yanase (1981) to Fabre-Nys et al. (2003) conclude that there is a powerful interaction of DA with estradiol stimulation, such that DA facilitates lordosis reflex when administered at the beginning of estradiol priming and inhibits the behavior when given later. One attractive hypothesis for these results is that DA facilitates proceptive behaviors inhibiting receptivity at the same time (Everitt et al., 1974; Caggiula et al., 1979; Grierson et al., 1988; Wilson et al., 1991; Meisel et al., 1993; Mermelstein and Becker, 1995; Pfaus et al., 1995; Kohlert et al., 1997).

DA actions are mediated through a family of GPCR receptors, which is the subject of an excellent recent review (see Smythies, 2005). It is clear that the stimulatory actions of DA are mediated by the D1-like receptors, D1a and D1b (which are also known as D1 and D5) (Mani et al., 1996, 2001; Kudwa et al., 2005). The inhibition of lordosis behavior is mediated by D2-like receptors: D2, D3, D4 (Melis and Argiolas, 1995).

Several reports strongly suggest that DA mediates the hedonic aspects of sexual behavior (Fiorino and Phillips, 1999; Becker et al., 2001; Bradley and Meisel, 2001; Bradley et al., 2005). This action of DA is beyond the scope of the present review and involves the mesolimbic DA system and the nucleus accumbens (Fiorino and Phillips, 1999). The role of DA in activating progesterone receptors and sexual receptivity will be extensively discussed in the chapter by Blaustein and Mani in this volume (2006).

16 Norepinepherine

Norepinephrine is a biogenic amine that is synthesized from the amino acid tyrosine by three enzymes. The first, tyrosine hydroxylase, converts tyrosine to dihydroxyphenylalanine, which is then converted to DA by dihydroxyphenylalanine decarboxylase. Dopamine-β hydroxylase converts DA to norepinephrine, which is metabolized to epinephrine by phenylethanolamine *N*-methyl-transferase. Norepinephrine acts through the adrenergic family of receptors that are composed of two types of receptors, α and β-adrenoceptors. These two families are divided into a number of subtypes: α_{1a}-, α_{1b}-, α_2-, β_1-, β_2-, and β_3-adrenoceptors (Bylund et al., 1994; Alexander et al., 2004). The adrenergic receptors are members of the seven transmembrane GPCRs that are activated by either epinephrine or norepinephrine. The hypothalamus receives noradrenergic innervation from the ventral noradrenergic bundle (lateral tegmental tract) from the locus coeruleus.

Norepinephrine both inhibits and facilitates lordosis depending on the hormonal status of the female and the receptor subtype activated. Early studies demonstrated that drugs that decreased norepinephrine activity or transmission, through α-adrenergic receptors in general, facilitated lordosis in the estradiol-primed rats and those that increased norepinephrine transmission inhibited lordosis (Ahlenius et al., 1972a, b; Everitt et al., 1975; Herndon et al., 1978). Facilitation of lordosis is mediated by α_1-noradrenergic receptors, and inihibitory effects of norepinephrine appear to be through α_2-noradrenergice receptors. Systemic infusions of an α_2-adrenergic receptor agonist, clonidine, inhibited lordosis (Davis and Kohl, 1977). This effect appears to be localized to the medial preoptic area, since site-specific infusion of either epinephrine or clonidine (α_2-adrenergic receptor agonists) mimicked the effects of norepinephrine, whereas α_1- and β-adrenergic receptor agonists had no effect on lordosis (Caldwell and Clemens, 1986).

In contrast, a number of other studies indicate that endogenous norepinephrine is important for the facilitation of lordosis, but these effects are mediated through the α_1-adrenergic receptor. Bilateral lesions of the ventral noradrenergic bundle inhibited lordosis in cycling or estradiol + progesterone primed female rats, which was reversed by ventricular infusions of an α_1-adrenergic receptor agonist (Hansen et al., 1980, 1981; Davis et al., 1991). Although these lesions decreased norepinephrine concentrations in both the MPN and VMH, norepinephrine does not appear to act in either the MPN or VMH, since infusion of an α_1-adrenergic receptor agonist in either of these nuclei after ventral noradrenergic bundle did not restore lordosis (Davis et al., 1991). Furthermore, site-specific noradrenergic lesions of either the MPN or VMH did not affect lordosis in estradiol + progesterone treated rats (Davis et al., 1991). However, others indicate that the VMH is the site of action of norepinephrine for α_1-adrenergic receptor facilitation of lordosis (Fernandez-Guasti et al., 1985a, b; Etgen, 1990; Kow et al., 1992). Using more selective ligands, it was shown that the α_1-adrenergic receptors in the VMH facilitated the lordosis reflex (Etgen, 1990). Furthermore, α_{1b}-adrenergic receptor, which is upregulated by estradiol in the hypothalamus, is responsible for the noradrenergic facilitation (Petitti et al., 1992). The role of norepinephrine in the facilitation of lordosis is complex and involves the behavioral state of the animal. Although estradiol+ progesterone treatment that facilitates lordosis increases stimulus-evoked norepinephrine release in the VMH of anesthetized rats (Vathy and Etgen, 1988), norepinephrine release in the anterior region of the VMH was not increased in steroid-primed rats, unless she received an intromission from the stimulus male rat (Etgen and Morales, 2002). Moreover, norepinephrine levels in the VMH do not rise in steroid-primed females that are highly receptive with vaginal masks that block penile penetration (Etgen and Morales, 2002). These data indicate that basal norepinephrine release in the VMH is important for the facilitation of lordosis, and the increased release in response to vaginocervical stimulation of steroid primed female rats is a part of the steroid responsive pathway that conveys somatosensory, vaginocervical stimulatory information to be integrated in the hypothalamus that may be involved in the induction of pregnancy or psuedopregnant state (reviewed in

Flanagan et al., 1993; Pfaus et al., 1993; Tetel et al., 1993, 1994; Auger et al., 1996; Erskine and Hanrahan, 1997; Etgen and Morales, 2002; Erskine et al., 2004).

17 Acetylcholine

Acetylcholine is the endogenous neurotransmitter that is synthesized from choline and acetyl coenzyme A by a reaction that is catalyzed by choline acetyltransferase (ChAT). Acetylcholine acts through two types of receptors that are named for binding properties to muscarin (muscarinic: mAChR) and nicotine (nicotinic; nAChR; Alexander et al., 2004). The mAChR is a member of the G protein-coupled receptor family and has five distinct subtypes [M_1–M_5; (Caulfield and Birdsall, 1998)]. The nAChR is a member of the superfamily of "cys-loop" ligand-gated, ion channel receptors composed of five subunits that determine receptor properties including the channel open-time and desensitization (Karlin and Akabas, 1995; Itier and Bertrand, 2001; Quick and Lester, 2002; reviewed in Lindstrom, 2003).

Lindstrom and Meyerson (1967) initially demonstrated that activation of central cholinergic systems inhibited sexual receptivity in estradiol+ progesterone primed female rats. Subsequent studies demonstrated that the acute activation of cholinergic systems facilitates sexual receptivity in female rats and hamsters (Clemens et al., 1980, 1981; Dohanich and Clemens, 1981; Dohanich et al., 1990). Global antagonism or blocking choline reuptake of the muscarinic receptors inhibits lordosis in gonadally intact cycling rats or OVX, steroid-primed female rats (Clemens et al., 1980, 1981, 1989; Kaufman et al., 1988; Menard and Dohanich, 1989). Although early studies suggested that the medial preoptic area was important for muscarinic facilitation of lordosis (Clemens et al., 1980, 1981; Dohanich and Clemens, 1981), these weak effects were demonstrated to be due to the leakage of drugs into the ventricular system and interacting with cholinergic receptors elsewhere in the brain (Dohanich et al., 1984). Further evidence contradicting a role of mAChR in the medial preoptic area was a decrease in the receptor binding by estradiol (Dohanich et al., 1982). Based on mAChR distribution and estradiol regulation of mAChR binding (Rainbow et al., 1980b; Dohanich et al., 1982), ACh actions on lordosis were localized to the VMH and PAG (Dohanich and Clemens, 1981; Dohanich et al., 1984; Richmond and Clemens, 1986; Kaufman et al., 1988). The PAG has estradiol-regulated mAChR (Meyers and Clemens, 1985) and an intensive population of cholinergic neurons providing a local network that may act to augment VMH cholinergic effects on lordosis (Satoh et al., 1983).

The nature of the mAChR subtype facilitating lordosis has not been elucidated. Pharmacological manipulations, have ruled out the M1 mAChR subtype (Kow and Pfaff, 1985; Dohanich et al., 1991). The M3 receptor subtype, located in the hypothalamus in higher concentrations than other mAChR subtypes (Wall et al., 1991; Zubieta and Frey, 1993), appears to be at least partially responsible for the steroid facilitation of lordosis, but it does not account for the entire range of ACh actions in the VMH (Kow et al., 1995). The roles of the other mAChR subtypes present in the hypothalamus require further investigation (Ehlert and Tran, 1990; Vilaro et al., 1990).

Global activation of the nicotinic receptor system by nicotine produces moderate facilitation of lordosis in estradiol-primed females, which could be reversed by pretreatment with a nicotinic receptor antagonist (Fuxe et al., 1977; Weaver and Clemens, 1987). However, icv injection of mecamylamine, a nicotinic antagonist, did not affect lordosis in estradiol+ progesterone primed animals, indicating that nicotinic systems are not critically important for the acute regulation of sexual receptivity (Weaver and Clemens, 1987). Thus, the main effects that acetylcholine has on sexual receptivity are through the activation of muscarinic receptors in the VMH and PAG but the mAChR subtype has not been conclusively characterized.

18 Glutamate

In the CNS, the major excitatory transmitter is glutamate. Thus, it is not surprising that glutamate and its receptors are involved in the regulation of the lordosis reflex. Glutamate receptors are broadly divided into

ionotropic and metabotropic groups (Seeburg, 1993; Brann, 1995). Ionotropic glutamate receptors (GluR): are segregated based on their pharmacology into AMPA, kainate, and *N*-methyl-*D*-aspartic-acid (NMDA) type receptors, whose subunits are coded by six gene families (Dingledine et al., 1999). There are eight metabotropic glutamate receptors (mGluR; Baskys et al., 2005). The metabotropic glutamate receptors are a part of the GPCR superfamily. A further segregation is possible based on pharmacology, signal transduction, and sequence homology into group I: mGluR1 and mGluR5 and their splice variants; and group II: mGluR2 and mGluR3. The group III receptors are mGluR4, mGluR6, mGluR8 and their splice variants (Baskys et al., 2005). A role for glutamenergic transmission was proposed in 1980 by the results of Rodriguez-Sierra et al. (1980). These authors reported that neonatal administration of *L*-monosodium glutamate (MSG) prevented the estradiol+ progesterone induced lordosis reflex in the adult. Other workers have suggested that the glutamate effect is mediated through the release of GnRH (Hsu et al., 1993; Bailey et al., 2006). More recently, icv administration of a selective NMDA receptor agonist facilitated lordosis, and the antagonist 7-amino-phosphonoheptanoic acid (AP-7), blocked the effect (Gargiulo et al., 1992; Gargiulo and Donoso, 1995). As with a number of neuropeptides, site of action is important to understand glutamate's role in regulating lordosis. Microinjections of NMDA into the mediobasal hypothalamus significantly reduced lordosis in estradiol+ progesterone primed rats (McCarthy et al., 1991a). The NMDA antagonist 5-amino-phosphonoheptanoic acid (AP-5) attenuated lordosis following microinjection into the medial preoptic area. These results suggest that glutamate facilitates lordosis in the medial preoptic area and inhibits lordosis in the mediobasal hypothalamus, suggesting a complex microcircuitry regulating sexual receptivity in these regions. How glutamate interacts with other neurotransmitters or neuropeptides in these regions that control sexual receptivity is largely unknown. An understanding of chemical signaling regulating sexual receptivity will certainly need to include this information.

19 γ-Amino Butyric Acid

Whereas glutamate is the primary excitatory transmitter, GABA is the primary inhibitory transmitter in the CNS. Initially, GABA was thought to inhibit the lordosis reflex based on studies using systemic injections of GABA, or $GABA_A$, or $GABA_B$ agonists (Qureshi et al., 1988; Agmo et al., 1989). Like opioids, CCK and glutamate, eventually GABA was shown to have different actions in the medial preoptic area compared with the mediobasal hypothalamus and these effects are, as expected, opposite to those described for glutamate. Exogenous GABA inhibits lordosis in the medial preoptic area and facilitates lordosis in the mediobasal hypothalamus in estradiol or estradiol+ progesterone primed rats (McCarthy et al., 1990). Moreover, a good correlation exists between endogenous levels of GABA and sexual receptivity: elevated GABA levels in the hypothalamus and lower levels in the preoptic area are found in receptive females (McCarthy et al., 1991). Microinfusion of the $GABA_A$ antagonist, bicuculline, into the PAG of steroid-primed female rats resulted in a significant decrease in lordosis and proceptive behaviors and muscimol, a $GABA_A$ agonist, increased lordosis (McCarthy et al., 1991b; Frye and DeBold, 1992; Frye et al., 1993). That endogenous GABA is involved in regulating sexual receptivity was further evidenced by blocking the expression of the GABA synthetic enzymes glutamic acid decarboxylase, GAD 67 and GAD 65 (McCarthy, 1994b). These studies recapitulated the idea that increased GABA activity in the mediobasal hypothalamus and PAG facilitate lordosis behavior, since infusion of antisense oligodeoxynucleotide to GAD 67 significantly reduced lordosis for 24 h. The antisense oligodeoxynucleotide to GAD 65 reduced the behavior for 48 h. By 5 days following the antisense oligodeoxynucleotide treatments, the lordosis quotients had returned to normal.

20 Other Mediators

20.1 Prostaglandins

The role of prostaglandins in CNS regulation of female sexual receptivity is not clear. Implants of prostaglandin E2 (PGE2) into the medial preoptic area-anterior hypothalamic area facilitate sexual receptivity

in OVX, estradiol-primed rats (Hall and Luttge, 1977, 1978). Interestingly, PGE2 was also reported to induce lordosis in OVX rats without steroid priming (Rodriguez-Sierra and Komisaruk, 1978). In more recent studies, the actions of prostaglandins were shown to be dependent on activation of the progesterone receptor since the antiprogesterone receptor RU486 blocked the lordosis stimulating action (Beyer et al., 1997). In guinea pigs, however, prostaglandins E1 and F2α inhibited estradiol+progesterone induced receptivity (Irving et al., 1981), which appears to be a species difference (Marrone et al., 1979). More recently, the induction of lordosis with estradiol and progesterone metabolites (i.e., 5α-dihydroprogesterone (αDHP), allopregnanolone, epipregnanolone) was shown to be dependent on prostaglandin synthesis (Beyer et al., 1999).

20.2 Insulin-Like Growth Factor-1

IGF-1 is a protein related to insulin (Rinderknecht and Humbel, 1978) and an important mediator of growth hormone action (Daughaday and Rotwein, 1989; Jones and Clemmons, 1995). Although IGF-1 is predominantly produced in the liver, and can cross the blood–brain barrier, IGF-1 is also produced by cells in the brain (Bondy and Cheng, 2004; Kaur et al., 2006). IGF-1 has powerful effects on brain development and function (Lee et al., 1996; Fushimi and Shirabe, 2004; Xing et al., 2006; reviewed in Aberg et al., 2006). Estradiol regulates circulating (Zapf et al., 1995; Rempel and Clapper, 2002; Hilleson-Gayne and Clapper, 2005) and brain levels (Shingo and Kito, 2003; Mendez et al., 2005; Darnaudery et al., 2006) of IGF-1. Estradiol increases the expression of IGF-1, its cognate receptor and IGF-1 binding proteins (Dickson et al., 1986; Pons and Torres-Aleman, 1993; Wimalasena et al., 1993; Sahlin et al., 1994). It has been proposed that estradiol actions in the CNS may involve interactions with IGF-1 (Duenas et al., 1996; Garcia-Segura et al., 1996; Fernandez-Galaz et al., 1999; Quesada and Etgen, 2001, 2002; Quesada and Micevych, 2004).

Apropos of sexual receptivity, icv administration of IGF-1 facilitated the lordosis reflex without estradiol priming (Apostolakis et al., 2000). Acute blockade of IGF-1 receptors with a selective competitive, antagonist, JB-1 (Pietrzkowski et al., 1992), did not reduce lordosis, but treatment with JB-1 during estradiol priming attenuated lordosis quotient and lordosis score (a measure of the "quality of lordosis") (Quesada and Etgen, 2002). It was hypothesized that the estradiol-IGF-1 interaction modulates α_1-adrenergic signaling based on the results that IGF-1 potentiates α_1-adrenergic receptor signaling in hypothalamic slices from estradiol-primed females (Quesada and Etgen, 2001). Blockade of IGF-1 receptor during estradiol priming prevents this potentiation of receptor signaling and expression of α_{1B}-adrenergic receptors in the hypothalamus. Further evidence for this hypothesis is that the attenuation of estradiol-induced lordosis reflex with JB-1 was reversed by 8-bromo-cGMP, which stimulates an intracellular signaling cascade that facilitates lordosis (Chu and Etgen, 1997; Chu et al., 1999).

20.3 Leptin

A hormone produced by adipose tissue that has been implicated in the regulation of food intake and energy regulation and puberty facilitates the lordosis reflex in ad libitum fed hamsters and increased food-deprivation induced attenuation of lordosis (Campfield et al., 1996; Wade et al., 1997). On the other hand, leptin did not affect female sexual receptivity in either lean or obese Zucker (*fa/fa*) rats (Fox and Olster, 2000). However, these authors found a reduction in proceptive behaviors in both the lean and obese Zucker rats. In Syrian hamsters, that are made anestrus due to fasting, leptin restored estrous cyclicity (Schneider et al., 1998). This restoration was due to leptin stimulation of metabolic fuel oxidation. These data provide an important neurochemical link between sexual behavior and metabolic state.

20.4 Nitric Oxide

NO is a gaseous extracellular messenger that increases cGMP levels. In addition to an extensive distribution in peripheral tissues, NO is widely distributed in the brain (McCall and Vallance, 1992). NO is formed by

the conversion of arginine to citrulline by nitric oxide synthase (NOS). Estradiol which increases the expression of NOS in the hypothalamus and areas involved with lordosis, suggesting that estradiol promotes NO generation and cGMP accumulation (Okamura et al., 1994; Ceccatelli et al., 1996; Pu et al., 1998; Rachman et al., 1998). Additionally, progesterone alone was shown to increase guanylyl cyclase activity in peripheral tissues, suggesting an NO-mediated action (Vesely, 1979; Vesely and Hill, 1980). An interesting correlation: cGMP levels are highest in the afternoon of proestrus (Kimura et al., 1980). Thus, it was not surprising that manipulations that increase brain NO and cGMP levels facilitate lordosis behavior (Fernandez-Guasti et al., 1983; Chu and Etgen, 1997; Chu et al., 1999; Gonzalez-Flores et al., 2004).

It has been hypothesized that estradiol induced NO acts by the release of GnRH (LHRH) to facilitate the lordosis reflex (Mani et al., 1994b). Blocking NOS prevented estradiol+progesterone induced lordosis and this blockade was reversed by the treatment of the rats with GnRH. NO has also been reported to mediate the actions of a number of extracellular messengers on GnRH (LHRH) secretion including: glutamate (Mahachoklertwattana et al., 1994; Rettori et al., 1994), leptin (Yu et al., 1997), oxytocin (Rettori et al., 1997), and α1-adrenoceptors (Canteros et al., 1995, 1996; Kamat et al., 1995), suggesting a point of convergence of these lordosis-relevant circuits.

20.5 Thyroid Releasing Hormone

Thyroid releasing hormone has not been well studied; however reports indicate that this neuropeptide stimulates lordosis following injections into the PAG, and stimulates lumbosacral spinal motoneurons that may be involved in innervating epaxial musculature needed for the lordosis reflex (Ogawa et al., 1992; Kow and Pfaff, 1996).

20.6 Pituitary Adenylate Cyclase-Activating Polypeptide

PACAP is a member of the secretin/glucagon/vasoactive intestinal peptide (VIP) family that, as its name implies, increases the levels of cAMP (cyclic adenosine monophosphate; reviewed in Arimura and Shioda, 1995; and Sherwood et al., 2000). Localization of PACAP in the CNS and in the VMH (Ishihara et al., 1992; Jaworski and Proctor, 2000) suggested that this peptide may mediate steroid actions on the lordosis reflex. Indeed, the administration of PACAP into the VMH facilitated estradiol-induced lordosis (Apostolakis et al., 2004, 2005). These studies also demonstrated that these actions are mediated through PACAP activation of the selective PAC1 receptor (Arimura and Shioda, 1995). The facilitation of lordosis was dependent on estradiol-induced progesterone receptors and the cAMP/protein kinase A (PKA)/DARPP32 pathway (Apostolakis et al., 2005). Interestingly, PACAP did not rescue sexual receptivity in progesterone receptor knock out mice (PRKO; Apostolakis et al., 2004) suggesting that PACAP may be involved in modulating lordosis, but is not the final signaling molecule in this circuit.

21 Conclusions

As is evidenced by this review, much has been accomplished describing the action of a constellation of neurotransmitters and neuropeptides in regulating sexual receptivity. This has been paralleled by a tremendous progress in defining steroid action on the expression and release of endogenous extracellular messengers that regulate the lordosis reflex. One common theme that has emerged from these studies is that neurotransmitters and neuropeptides "substitute" for progesterone; however, what is usually meant by these statements is that neurochemicals facilitate estradiol-induced lordosis behavior. All too often, the other critical effects of progesterone, the termination of lordosis and the resetting of the lordosis regulating circuitry are ignored. In order to truly appreciate the action of progesterone, we need to develop an understanding of both limbs of progesterone action.

Although there is universal agreement that the lordosis reflex is dependent on estradiol action in the brain, less progress has been made in understanding which of the myriad of estradiol actions are critical for the expression of lordosis. In our opinion, this is due to the global nature of the estradiol action. Investigators have developed a catalog of estrogen actions on gene expression, transmitter and peptide release and intracellular signaling. Indeed, many of these studies have carefully demonstrated the temporal and spatial characteristics of estradiol action on the neurochemistry of lordosis regulating circuits.

Despite these gains, in some sense, we are still very far from an integrated view of the neurochemistry controlling the lordosis reflex. This review has concentrated on the neurochemical and pharmacological aspects of circuits that regulate sexual receptivity, and it is clear that the progress is substantial. These studies have provided an excellent underpinning for the next series of investigations. To date, studies have established a framework of neurochemical puzzle pieces and have begun to arrange the pieces into a neuroanatomical substrate providing a general picture of the circuits involved in regulating lordosis behavior. Within the broad picture, however, many parts of the puzzle are still not firmly in place.

Several guiding principles have emerged from the past work: (1) the lordosis regulating circuit is organized into nodes (the most prominent are the MPN, VMH, and PAG) that integrate hormonal, sensory, behavioral, and metabolic information; and (2) although all the nodes are exposed to estrogens at the same time, they are activated in-series to produce sexual receptive behavior that is coordinated with ovulation to maximize the potential for reproduction. For example, it is clear that the MPN is activated early by estradiol and is inhibitory to lordosis. The VMH appears to "come on-line" after the MPN and facilitates lordosis. The problems are within the nodes. What is the microcircuitry that dictates the output from the nodes? Are neurochemical circuits arranged in series, in parallel, or a mixture of the two relationships? Can inputs carrying information from different modalities substitute for others? For example, if the peripheral steroid signal is weak can metabolic and sensory information that food is plentiful and the days are long activate the circuit and elicit sexual receptivity? Or vice versa, despite strong hormonal input, in the face of imminent threats can unfavorable sensory input prevent the display of sexual receptivity. Indeed, there is evidence that this may happen. What is not known is how these circuits are organized to produce this effect. Working out microcircuitry underlying a global behavior such as the lordosis reflex is extremely difficult and is not easily approachable with standard tract tracing/immunohistochemical techniques. One method that may aid elucidation of microcircuitry relies on membrane receptor internalization. Agonist-induced receptor internalization is a universal receptor phenomenon, which can be used to identify activated neurons with neurochemical specificity. Indeed, receptor internalization has been used to begin to determine the neurochemical signature of estradiol and estradiol+progesterone stimulation in lordosis regulating circuits. As more reagents become available, this technique in combination with other techniques holds great promise for revealing microcircuitry within lordosis regulating nodes, and may possibly shed light on the basic problem of the difference between estradiol- only and estradiol+progesterone facilitated lordosis, which is another unresolved issue.

Another issue that must be resolved to elucidate CNS regulation of sexual receptivity is the relationship between neurochemical actions and the timing of sexual receptivity. Many of the studies reviewed here examined short-term effects of transmitters and peptides. Often this short-term regulation is only a part of the story, and may not even be predictive of the long-term consequences for regulation of lordosis. For example, opioid actions at the MOP acutely inhibit lordosis but removing MOP action prevents the full display of sexually receptive behavior, indicating that inhibition may be a necessary component of the circuitry regulating the lordosis reflex. Thus, to develop a comprehensive understanding of both the circuitry and the interaction of transmitters and peptides (microcircuitry) that regulate sexual receptivity requires further concerted effort to match the tremendous progress made to date.

Acknowledgments

The authors thank Ms. Amy Christensen for her help in the preparation of this chapter. We wish to acknowledge the support of NIH grants NS039495, DA13185, and HD042635 that funded some of the research present in this chapter.

5 Neuroendocrinology and Neurochemistry of Maternal Motivation and Behavior

J. S. Lonstein · J. I. Morrell

1 Introduction 197

2 Components of Maternal Care 198
2.1 Active Maternal Behaviors 198
2.2 Inactive Maternal Behaviors 199
2.3 Sensory Influences on Maternal Care 199

3 Peripheral Hormones Associated with the Onset and Maintenance of Maternal Behavior 200
3.1 Pregnancy and Parturition – the Optimal Endocrine Basis for Maternal Behavior and Maternal Motivation 200
3.1.1 Endocrine Sources During Pregnancy and Lactation 201
3.1.2 Endocrine Models for the Examination of Maternal Behavior 201
3.1.3 Minimum Endocrine and Physiological Elements Necessary for the Onset and Maintenance of Maternal Behavior 201
3.1.4 Postpartum Estrus and Consequences 202
3.2 Estrogen 202
3.2.1 Estrogens During Pregnancy and Postpartum 202
3.2.2 Estrogenic Influences on Maternal Behavior 203
3.3 Progesterone 203
3.3.1 Progesterone During Pregnancy and Postpartum 203
3.3.2 Progesterone Influences on Maternal Behavior 203
3.4 Prolactin 204
3.4.1 Prolactin and Related Hormones During Pregnancy and Postpartum 204
3.4.2 Prolactin Influences on Maternal Behavior 205
3.5 Other Participants in the Processes of Pregnancy, Parturition, and Lactation 205
3.6 The Brain as a Possible Source of Hormones that Regulate Maternal Behavior and its Neuroendocrine Processes 206

4 Neural Expression of Maternal Behavior 207
4.1 Fundamentals of the Traditional Maternal Behavior Circuit – the Preoptic Area 207
4.2 Other Components of the Maternal Behavior Circuit 208
4.2.1 Ventral Areas of the Bed Nucleus of the Stria Terminalis 208
4.2.2 Paraventricular Nucleus (PVN) 208
4.2.3 Habenula 208
4.2.4 Periaqueductal Gray (PAG) 209
4.2.5 Septum 209
4.3 Brain Regions that Inhibit Maternal Behavior in the Nonmaternal State 210
4.3.1 Amygdala 210
4.3.2 Anterior and Mediobasal Hypothalamus 210

4.4 Changes in Neural Hormone Receptor Expression Across Pregnancy and Lactation 211
4.4.1 Estrogen Receptors 211
4.4.2 Progestin Receptors 211
4.4.3 Prolactin Receptors 212
4.4.4 Oxytocin Receptors 212
4.4.5 Conclusions 213
4.5 Effects of Site-Specific Application of Hormones on Maternal Behavior 214
4.5.1 Estradiol 214
4.5.2 Progesterone 214
4.5.3 Prolactin 215
4.5.4 Oxytocin 215
4.5.5 Other Neuropeptides 215

5 Studies of Maternal Motivation 215

6 Neural Motivation Systems: Interfaces with Maternal Behavior Circuit and Effects of Hormones 222
6.1 Brief Description of Mesolimbic and Nigrostriatal Systems and their Anatomy/Neurochemistry 222
6.1.1 Additional Areas of Note for Maternal Motivation 223
6.1.2 Reward System Hierarchy 223
6.2 Role of Dopamine and the Nigrostriatal and Mesolimbic Systems on Maternal Behavior and Motivation 224
6.3 Changes in Dopamine Receptors Across Pregnancy and Lactation 226
6.4 Influences of Ovarian and Pituitary Hormones on Nigrostriatal Neurotransmission 227
6.5 Influences of Ovarian and Pituitary Hormones on Mesolimbic Neurotransmission 228

7 The Future – Functional Integration 229

Abstract: Successful reproduction requires transmission of traits from one generation to the next by ensuring that offspring carrying the genetic basis of these traits survive to reproductive age. Maternal caregiving is the most crucial behavioral pattern ensuring the survival of young in most mammals. Expression of maternal behavior requires complex interactions between internal and external sensory cues, numerous endocrine systems, and the brain. We herein summarize the components of maternal care, and the hormonal, sensory, and neural underpinnings of its expression, with the laboratory rat model as an exemplar. The impetus to act maternally is similar to other goal-directed behaviors, in that it requires an appropriate motivational state. We emphasize how endocrine systems during pregnancy, parturition, and lactation may interact with traditional neural motivation systems, including the mesolimbic and nigrosriatal dopamine systems, to facilitate the transition from indifference to infants to a state of irresistible nurturance toward them.

List of Abbreviations: 6-OHDA, 6 hydroxydopamine; AMYbl, basolateral nucleus of the amygdala; AVP, arginine vasopression; BNST, bed nucleus of the stria terminalis; CCK, cholecystokinin; CNS, central nervous system; $cPAG_l$, caudal lateral subregion of the periaqueductal gray; $cPAG_{vl}$, caudal ventrolateral subregion of the periaquaductal gray; D1, dopamine receptor subtype 1; D2, dopamine receptor subtype 2; D3, Dopamine receptor subtype 3; DA, dopamine; DAergic, dopaminergic ; DOPAC, dihydroxyphenylacetic acid; DHT, dihydrotestosterone; EB, estradiol benzoate; ER, estrogen receptor; ERα, estrogen receptor alpha; ERβ, estrogen receptor beta; Fos, protein product of the immediate early gene *c-fos*; FSH, follicle stimulating hormone; GABA, γ-aminobutyric acid; $GABA_A$, γ-aminobutyric acid receptor subtype A; h, hours; Hbc, habenular complex; H-O, hysterectomy-ovariectomy ; ICV, intracerebroventricular ; IR, immunoreactive; Lhb, lateral subdivision of the habenular complex; LH, luteinizing hormone; lPOA, lateral preoptic area; LS, lateral septum; MeA, medial nucleus of the amygdala; mPOA, medial preoptic area ; MRI, magnetic resonance imaging; mRNA, messenger ribonucleic acid; N, number of animals; NA, nucleus accumbens; OT, oxytocin; OTR, oxytocin receptor; PAG, periaqueductal gray; PFC, prefrontal cortex; POA, preoptic area; PR, progestin receptor; PRL, prolactin; PRL-R, prolactin receptor; PVN, paraventricular nucleus of the hypothalamus; s.c., subcutaneous; SEM, standard error of the mean; SN, substantia nigra; SNpc, substantia nigra pars compacta; T, testosterone; TH-ir, tyrosine hydroxylase immunoreactivity; V1a, vasopressin receptor 1^a; vBNST, ventral area of bed nucleus of the stria terminalis; VMN, ventromedial nucleus of the hypothalamus; VMH, ventromedial hypothalamus; VTA, ventral tegmental area

1 Introduction

One of the most dramatic changes in behavior by females of many mammalian species is the transition from a nonmaternal state existing before and during pregnancy, to a state of high maternal responsiveness that emerges after parturition. This transition from infant rejection to infant acceptance requires a complex milieu of hormones and other neurochemicals. The largest and most detailed literature on the biology underlying parental behavior has been generated using the laboratory rat model and has been reviewed many times with great completeness and care by Rosenblatt et al. (1979), Fahrbach and Pfaff (1982), Stern (1989), Numan (1988, 1994), Rosenblatt (1995), and most recently in an entire book devoted to the subject by Numan and Insel (2003). Our goals in this chapter are to highlight recent findings on the neural and hormonal regulation of maternal behavior in the rat. While we provide some context for these findings, we refer our readers to prior reviews of the extensive literature on this topic for additional details. We have attempted throughout to suggest future directions for the field and in particular, we examine the generally less investigated topic of maternal motivation.

Scientists examining maternal behavior often seek a reductionist, mechanistic model of each of the broad components of this behavior and their behavioral subroutines. Any behavioral subroutine is worth studying, but considering these subroutines within an ethologically relevant context is particularly powerful, because it allows a more complete understanding of how the brain supports a seamless behavioral sequence. This sequence emerges from a complex pattern of activity across neural structures with a particular neurochemistry. Most components of the circuit can be determined to be necessary or not,

sufficient or not. A component that is "not necessary" can nonetheless be normally used in the circuit, but redundant pathways may exist so that the behavior can continue to be displayed in the absence of a particular structure. Additionally, structures that are "not necessary" in one ethological context might, in fact, provide valuable flexibility so that normal behavior is maintained regardless of the demands of the environment.

We believe that the study of maternal behavior in the rat has two broad goals. First, maternal behavior can be considered a prototype complex behavior. We know it is important, because it is critical for the continuance of a very large number of vertebrate species. The assumption is that understanding the components of maternal behavior allows insight into how the integrated patterns of brain function ultimately yield other complex behaviors. Secondly, we propose that the information gathered in the rat will validly generalize to the fundamental neurobiological underpinnings of parental behavior in humans. Although obvious to most neuroscientists, we wish to emphasize that even human parenting behavior has its roots in central nervous system function, with cultural and "sentient" influences on parenting unique to humans layered on top of these fundamental biological roots. While most humans accept that our behavior is based in genetic and central nervous system (CNS) function, human maternal/parental behavior is often thought to function independently of these genetic and neural underpinning. That is, "true maternal behavior" is something of pure emotion and soul, and not definable by the cold light of science. We submit that, on the contrary, understanding the fundamental neuroanatomy and neurochemistry of this behavior is possible, and will ultimately be of great societal benefit.

2 Components of Maternal Care

Animal models of parental behavior define it operationally and in a species-specific framework. In rats, only the female cares for the pups and our operational definitions of parental behavior in the rat are referred to as maternal behavior. Operationally, defining complex behaviors in animal models is a typical approach to examining these behaviors. What is our definition of maternal behavior? The two aspects are (1) the outwardly visible behavioral components, or consummatory aspects, and (2) the motivation to perform maternal behavior, or the appetitive aspects. We define expression of the behavior by the retrieval, nest building, and pup care components that are detailed immediately below. We define the motivational components of maternal behavior in *Section 5* below through examining maternal motivation using measures typical of other behavioral and pharmacological examinations of motivation.

2.1 Active Maternal Behaviors

The consummatory aspects of maternal behavior in rodents encompass two general categories of behavior, active maternal behaviors and inactive maternal behaviors (see Stern, 1996; Lonstein and Fleming, 2001). Parturition behaviors are the first active maternal behaviors dams display toward pups and they begin with dams licking and pulling at the emerging fetuses to extract them from the vagina. Vigorous licking and gentle nibbling ensues, which removes pups from their amniotic sac, cleans them of amniotic fluid, and separates them from their umbilical cord and placenta (Hollaway et al., 1980). These oral behaviors by the dam not only help extract the neonates from their prenatal encumbrances, but also stimulate their respiration and general activity that leads to the first bout of nursing that may begin within minutes after completion of parturition (Hollaway et al., 1980). After parturition, one of the most recognizable and easily studied active maternal behaviors is the retrieval of displaced pups. In most cases, dams orient toward the pups and often sniff them (the appetitive response) prior to gently picking each one up with her mouth and transporting it (the consummatory response). Although retrieval of pups is very often studied in the laboratory, it may be rare in a natural setting unless the pups are older and more likely to wander from the nest, or if there is a disturbance to the nest site (Brewster and Leon, 1980).

Once pups are collected in a central location, such as the nest, dams spend a great deal of time actively hovering over the litter while performing other activities including self-grooming and licking the pups. Self-grooming during this time cannot be considered a maternal behavior because there is no known advantage for the offspring, although the mother's prepartum licking of her ventrum is important for her mammary gland development (Roth and Rosenblatt, 1968). In contrast, the frequent maternal licking of the offspring serves numerous purposes for the pups, not only cleaning them, but also stimulating excretion if licking is directed at their anogenital region. Maternal licking also activates them behaviorally, which facilitates their search for a nipple and subsequent suckling (Stern and Johnson, 1989). Licking the pups is also beneficial to the dam because the ingestion of pup's excreta provides her with additional water and electrolytes during this metabolically challenging period (Friedman et al., 1981).

Other active maternal behaviors differ from retrieval and licking because they are not directed toward the pups, but may still be necessary for their survival. Nest construction involves the dam using her mouth, snout, and paws to carry or push material to a central location and then shaping the material to form a structure with compact walls and a depression in the center. Nest construction is not exclusive to the lactating rat, but maternal nests are typically larger and more tightly constructed than those of nonmaternal animals. Construction of a nest is certainly important because it not only provides the locale where most mother–infant interactions occur, but is also important for thermoregulation of the dam and litter (e.g., Leon and Woodside, 1983).

Heightened aggression also emerges during lactation and is, of course, not directed toward offspring, but rather toward potentially threatening conspecifics. Maternal aggression serves to protect the dam's most valuable resources, the litter and nest site (Lonstein and Gammie, 2002). Increased foraging and food intake are also associated with lactation, and are necessary for the high metabolic demands of lactation (e.g., Fleming, 1976).

2.2 Inactive Maternal Behaviors

Interspersed with the display of these active maternal behaviors are prolonged periods of inactive nursing, when milk is transferred to the infants. When a sufficient number of pups suckle, dams undergo a transition from a highly active state to one of relative quiescence. During this quiescence, she will frequently assume a distinctive nursing posture, termed kyphosis (Stern, 1996), characterized by limb rigidity and an upward flexion of the spinal column. This posture provides sufficient room for pups to breathe, move, and suckle while underneath the dam. Kyphosis is not the only nursing posture that dams can assume. They can also lie prone on top of the litter with little limb support or nurse them while lying on their side in a supine position. Only during these periods of quiescent nursing does milk letdown occur (Voloschin and Tremezani, 1984), and during early lactation it is more likely to occur when dams are displaying kyphosis than other nursing postures (Lonstein et al., 1998).

2.3 Sensory Influences on Maternal Care

The sensory determinants of active and inactive maternal behaviors in rats are well understood and have been reviewed in detail previously (Stern, 1989, 1996; Numan, 1994). Dams normally use all sensory modalities to fine-tune their maternal responding, but do not require every type of sensory input to display maternal behavior. For example, eliminating the ability of dams to see and hear their pups does not abolish retrieval or any other maternal behavior (see Stern, 1989). How the sense of taste influences maternal behavior has not been examined in detail, but one could imagine that it might be involved in maternal licking of pups. Anesthetization of the tongue decreases maternal licking (Stern and Johnson, 1989), but because this procedure eliminates both taste and somatosensory inputs to the tongue, it is unclear if both lingual senses are important.

Olfactory input is critical for maternal behavior in mice (Gandelman et al., 1972), but its effects on maternal behavior in rats depend on their reproductive state. When virgin female rats have their olfactory bulbs or other areas of their olfactory system destroyed, maternal responding is facilitated, presumably because they no longer detect what is thought to be the repellant odors emanating from the neonates (Fleming and Rosenblatt, 1974a, b). The effects of postpartum olfactory bulbectomy on maternal behavior vary. If bulbectomy is performed during pregnancy, severe disruptions in maternal behavior may be observed following parturition in rats (Schwartz and Rowe, 1976; Kolunie and Stern, 1995), although some studies report virtually no effects (Fleming and Rosenblatt, 1974a; Numan and Numan, 1995; Walsh et al., 1996). If bulbectomy does impair maternal behavior, it might be particularly true in primiparous females without prior maternal experience or in previously cannibalistic females (Fleming and Rosenblatt, 1974a,b; Schwartz and Rowe, 1976; Kolunie and Stern, 1995). The relative importance of nonvolatile and volatile odors in maternal care has been carefully examined. Destruction of just the bed nucleus of the accessory olfactory tract, which primarily receives and transmits nonvolatile (pheromonal) information, facilitates maternal responding in virgin females and suggests that nonvolatile cues from pups inhibit the behavior (Del Cerro et al., 1991). Once dams are maternal, though, disruption of nonvolatile olfactory inputs by severing the vomeronasal organ has little effect on maternal behavior in rats (Jirik-Babb et al., 1984; Kolunie and Stern, 1995). Presumed reduction of volatile inputs with postpartum intranasal infusion of zinc sulfate also has little effect (Benuck and Rowe, 1975; Jirik-Babb et al., 1984; Kolunie and Stern, 1995). Therefore, it must be the case that either: (1) olfaction has little role in the postpartum maintenance of maternal behavior, (2) if it does, then volatile or nonvolatile olfactory input can singularly sustain normal maternal behavior, or (3) any olfactory bulbectomy effects on postpartum maternal behavior may be due to surgical or neurological factors other than disruption of olfactory inputs.

The sense of touch has been extensively studied for its role in maternal behaviors in rats (Stern, 1996), and in contrast to any other sensory modality, it is absolutely critical. Reduction or elimination of tactile inputs to the perioral region through anesthetization of the mystacial pads, or lesions of the infraorbital nerve subserving the mystacial pads and surrounding area, impairs or abolishes retrieval and licking of pups (Kenyon et al., 1983; Stern and Johnson, 1989). Analogously, quiescent nursing behavior is impaired or absent if somatosensory inputs to the dam's ventrum are reduced. This can be accomplished by anesthetizing her ventrum or removing her nipples. This can also be accomplished by manipulating the pups (by heating or cooling them, or anesthetizing them periorally or completely) so they cannot root for a nipple and/or suckle (Stern, 1996). In sum, maternal behavior is surely influenced by all sensory modalities, but any individual sensory modality other than somatosensation seems to be dispensable.

3 Peripheral Hormones Associated with the Onset and Maintenance of Maternal Behavior

3.1 Pregnancy and Parturition – the Optimal Endocrine Basis for Maternal Behavior and Maternal Motivation

The parturient rat immediately expresses complete maternal behavior at the moment her pups are born. While this immediate onset of the expression of maternal behavior is understood to require particular hormones, as discussed in detail below, once the hormonal induction of the expression of maternal behavior has occurred, the expression of maternal behavior does not require hormones. This rapid onset and complete behavioral expression at parturition are the basis to compare behavioral outcomes of other endocrine/behavioral models. Reductionist experiments using models with deliberately limited endocrine millieu typically demonstrate a slower onset of maternal behavior (1–4 days after presentation of foster pups), and may not produce all components of the behavior. Whether and to what extent hormones have a role in the onset or maintenance of maternal motivation has been examined much less than the hormonal basis of the expression of maternal behavior.

3.1.1 Endocrine Sources During Pregnancy and Lactation

Our greatest insights into hormonal regulation of maternal behavior have come from considering the hormones of pregnancy and the postpartum period. During this period the pituitary, ovary, and uterus are in unique endocrine states. Notable during pregnancy are the corpora lutea of pregnancy, the decidua (uterine mucosa) of the uterus, the placenta, and the fetus (Gibori et al., 1988; Talamantes and Ogren, 1988). Unique to the postpartum period are the postpartum estrus, the corpora lutea of lactation, the process of lactation, and the presence of the pups as endocrine/neuroendocrine stimuli (Tucker, 1988). If fertilization occurs during the postpartum estrus, the second pregnancy contemporaneous with lactation is another unique feature of this period.

3.1.2 Endocrine Models for the Examination of Maternal Behavior

Correlating hormone levels in the pregnant and parturient female with the expression of maternal behavior was an important initial model, often followed by studies eliminating the hormone sources. Such reductionist experiments to explore the causal links between hormones and behavior are limited by the endocrine and physiological demands of pregnancy, parturition, and lactation. That is, removal of glands may alter maternal behavior because of a disruption in these other processes. For example, the maintenance of pregnancy requires pituitary hormones during the first half of gestation and ovarian steroid hormone production throughout (Heap and Flint, 1986), and these glands cannot be removed without precipitating miscarriage. Similarly, the ovaries and pituitary are required for sustained lactation. Normal adrenal function greatly facilitates pregnancy, parturition, and lactation, but these can continue without adrenal hormones (Thoman and Levine, 1970; Thoman et al., 1970).

A very fruitful model for understanding the hormone dependency of the natural onset of maternal behavior after pregnancy is the hysterectomy–ovariectomy (H–O) model in which the uterus (including fetuses) and/or the ovaries are removed (Rosenblatt, 1995). Together with the use of foster pups provided by other parturient females, this model avoids the limitations of pregnancy and parturition. Nearly three decades of work with this model has uncovered the role of individual hormones or groups of hormone regimes, in the hormonally regulated onset of maternal behavior (Siegel and Rosenblatt, 1975a, b; Rosenblatt et al., 1979, 1998). For similar reasons, the H–O model has also been very useful in examining the neural basis of maternal behavior (Corodimas et al., 1992, 1993).

Virgin females and males, and even juvenile rats, can be stimulated to perform some maternal behaviors simply by continuously exposing them to pups. Pup-induced maternal behavior has historically been referred to as concaveation, or more commonly, pup-sensitized maternal behavior. This model has also been used to consider the hormonal basis of maternal behavior, as the onset of sensitized maternal behavior can be shortened by hormones (Rosenblatt, 1967; Rosenblatt and Ceus, 1998; Olazabal et al., 2002).

3.1.3 Minimum Endocrine and Physiological Elements Necessary for the Onset and Maintenance of Maternal Behavior

Very early studies established that the onset of maternal behavior in parturient females requires ovarian steroids (Terkel and Rosenblatt, 1972; Rosenblatt et al., 1979; Fahrbach and Pfaff, 1982). Less clear was the role of the pituitary, with some studies indicating that the pituitary was not necessary (Rosenblatt et al., 1979) and others indicating that pituitary prolactin was active in the rapid onset of maternal behavior (Moltz et al., 1970; Fahrbach and Pfaff, 1982; Numan and Insel, 2003). Prepartum adrenal hormones are also probably not absolutely necessary (Rosenblatt et al., 1979). Neither the pituitary, ovary, nor adrenal glands are required for the postpartum maintenance of the expression of maternal behavior once it is established, although subtle changes in maternal behavior may exist after their removal (Rosenblatt et al., 1979; Fahrbach and Pfaff, 1982; Numan 1988, 1994; Rees et al., 2004).

The H–O model revealed that as pregnancy progresses, the female will display maternal behavior more and more rapidly after the presentation of pups (Rosenblatt et al., 1979; Numan, 1988, 1994; Rosenblatt, 1995). While nulliparious or early pregnant females require as much as 6 days of exposure to pups before the expression of maternal behavior, females after 17–19th day of pregnancy are fully maternal within 1 day of pup exposure, depending on the additional hormone regime (Rosenblatt et al., 1998). Thus, the hormonal milieu of the progression of pregnancy is a critical basis for the onset of maternal behavior.

Early work has also ruled out parturition and lactation as requirements for maternal behavior. Removal of the fetuses and placenta at the later stages of pregnancy (by Caesarean procedures), leaving the uterus and ovary intact, demonstrated that the sensory processes of parturition are not required for the onset of maternal behavior (Moltz et al., 1966). Nor is the capacity to lactate necessary for the hormonal onset or the maintenance of maternal behavior, as neither galactophone transaction nor the more radical mammectomy (Moltz et al., 1967) decrease maternal behavior, although the patterns of mother–litter interactions are altered (Woodside and Popeski, 1999; Stern and Keer, 2002).

3.1.4 Postpartum Estrus and Consequences

The parturient female rat enters postpartum estrus approximately 6–12 h after the delivery of the last pup, and reaches a peak in lordosis responding at about 9 h after the last pup (Ying et al., 1973; Connor and Davis, 1980a). This behavioral peak is preceded by a peak in estradiol and is coincident with rising progesterone levels (Connor and Davis, 1980b). If mating does not occur or if the female does not become pregnant, the suckling stimulus inhibits further ovarian cycles. The larger the litter, the longer this period of inhibition, with a very large litter increasing the period up to 35 days (Van Der Shoot et al., 1978; Lindblom et al., 1985). Lactation is maintained by steroid hormones from the corpus luteum of the postpartum estrus and hormones from the pituitary.

Resumption of estrous cycles and sexual behavior occurs late in the postpartum period, with rising estradiol and falling progesterone and prolactin levels. This is around the time of weaning, which in the laboratory is postpartum day 21–28, but in the wild this can be later, because food supply and litter size also influence the timing of postpartum resumption of estrous cyclicity (Reisbick et al., 1975; Woodside et al., 2000).

If the female becomes pregnant at the postpartum estrus, there is a delay in the implantation of the embryos proportional to the number of suckling neonates in her newly born litter (Mantalenakis and Ketchel, 1966). This suckling-induced delay in implantation is caused by lack of FSH stimulation and the resultant low estradiol release, and is not related to prolactin release (Rosenblatt et al., 1979; Cummings and Laws, 1981). This reproductive state is probably common in feral rats and yet it is rarely used as a laboratory model. Thus in the wild, the corpora lutea of the estrous cycle or even pseudopregnancy is never formed and the corpora lutea of pregnancy is constantly present (Gibori et al., 1988).

3.2 Estrogen

3.2.1 Estrogens During Pregnancy and Postpartum

During pregnancy, circulating levels of estrogens are generally low and similar to diestrus until about day 16 when a gradual increase commences and continues until parturition (Shaikh, 1971; Garland et al., 1987). With the exception of a brief increase with the postpartum estrus, circulating estrogens are low during most of lactation, slowly rises across days 10–15, and rise more as weaning approaches (Smith and Neill, 1977; Taya and Greenwald, 1982).

The luteal cells of the corpora lutea of the ovary are the source of estradiol during pregnancy and lactation in the rat (Niswender et al., 1994). During the estrous cycle and pregnancy, this is the corpora lutea resultant from the initial ovulatory events that lead to pregnancy. During lactation this corpora lutea "of

pregnancy" regresses and the corpora lutea of the postpartum ovulation becomes functionally dominant (Taya and Greeenwald, 1982). During early pregnancy, the corpora lutea produces both the steroidogenic substrate for estrogen synthesis, and estradiol itself, while during the second half of pregnancy, the placenta becomes the source of the androgens that are the steroidogenic substrate for estradiol produced by the corpous luteum (Gibori et al., 1979; Gibori and Sridaran, 1981; Jones et al., 1987).

3.2.2 Estrogenic Influences on Maternal Behavior

One of the best understood hormonal requirements for the onset of maternal behavior is estradiol (Siegel and Rosentblatt, 1975a, b; Rosenblatt, 1995). During pregnancy, estradiol primes the female for the immediate onset of maternal behavior at parturition. The rapid onset of maternal behavior can be stimulated by either the first 10–13 days of pregnancy, or a treatment regime of estradiol for a similar period, followed by a single (triggering) dose of estradiol if progesterone is absent (Rosenblatt et al., 1979). While estradiol certainly affects the periphery, particularly the uterus and mammary glands, a key influence for the induction of behavior is on the components of the neural circuits that mediate maternal motivation and expression of maternal behavior (Rosenblatt et al., 1994). Regardless of the preparation used to demonstrate maternal behavior, estradiol always induces the onset of maternal behavior more rapidly (Rosenblatt et al., 1979).

An interesting corollary of the late pregnancy production of androgens by the placenta is that the circulating levels of androgens (T and DHT) rise from very low levels of 0.4–0.8 ng/ml early in pregnancy to a sustained and remarkable level of 2.8 ng/ml during the second half of pregnancy (Gibori et al., 1979). Circulating androgens in the cycling female range from 0.2 ng/ml to 0.4–0.5 ng/ml preceding the LH surge (Rush and Blake, 1982; Jones et al., 1987), and testosterone in the male rat is between 1.1 and 2.3 ng/ml (Keating and Tcholakian, 1979). In this context, the estrous cycle has much lower levels of androgens, and the peak values of the late pregnant female are remarkable. No studies have examined whether androgens during the second half of pregnancy in rats play any role in the hormonal onset of maternal behavior at parturition. Androgen levels similar to those in the rat are also observed in late pregnancy in the rabbit, where the hormone increases nest building (Gonzalez-Mariscal et al., 2003).

3.3 Progesterone

3.3.1 Progesterone During Pregnancy and Postpartum

During the estrous cycle, pregnancy, and lactation in rats, the corpora lutea of the ovary are also the source of progesterone (Niswender et al., 1994). This capacity is maintained by the luteotrophic action of prolactin and related hormones, the locally generated estradiol of the corpora lutea, and also by the luteinizing hormone (LH) (Gibori and Sridaran, 1981; Gibori et al., 1988). During most of pregnancy, beginning as early as day 5, progesterone levels are as high or up to tenfold higher than peak values during the estrous cycle. This is one of the most remarkable features of the endocrine milieu of the pregnant female. A sharp reduction in progesterone begins on day 19 of pregnancy, followed by a descent to very low levels at parturition (Grota and Eik-Nes, 1967; Sanyal, 1978; Garland et al., 1987; Rosenblatt et al., 1994). During lactation, progesterone levels rise rapidly during the first 5 days, peak at around day 10 to levels similar to proestrus, and then fall by day 21 to lower levels similar to diestrus (Smith et al., 1975; Smith and Neill, 1977; Taya and Greenwald, 1982).

3.3.2 Progesterone Influences on Maternal Behavior

While progesterone is critical for the maintenance of pregnancy, its withdrawal at the end of pregnancy is necessary for the hormonal onset of maternal behavior (Rosenblatt et al., 1979). Experiments with the H–O

model have shown that progesterone prevents the inappropriate display of maternal behavior during pregnancy, and that prepartum withdrawal of progesterone allows and facilitates the immediate onset of maternal behavior (Bridges et al., 1978; Siegel and Rosenblatt, 1978). In the absence of estradiol, neither progesterone alone nor withdrawal of progesterone stimulates maternal behavior (Doerr et al., 1981).

Although lactation can continue after ovariectomy, its normal maintenance requires progesterone. There is no evidence, however, that postpartum levels of progesterone influence the robust maternal behavior displayed during this period (Moltz et al., 1969b). The mechanism by which progesterone is alternatively inhibitory to maternal behavior during the prepartum period, and then permissive during the postpartum period, is not understood.

3.4 Prolactin

3.4.1 Prolactin and Related Hormones During Pregnancy and Postpartum

In the rat, prolactin and three functionally related hormones, decidual luteotrophin and placental lactogens I and II, are important during pregnancy (Robertson et al., 1982; Gibori et al., 1988; Tucker, 1988; Bridges, 1990, 1996). These hormones, along with LH, maintain steroidogenesis in the corpus luteum of pregnancy, and prepare the mammary glands for lactation (Smith et al., 1975; Freeman, 1988; Gibori et al. 1988; Niswender et al., 1994). In spite of structural differences, all these protein hormones bind to and exert their effects via the short or long form of the prolactin receptor (PRL-R). These receptors are expressed and differentially regulated in the corpus luteum, mammary gland, and brain (Gibori et al., 1988; Clarke and Linzer, 1993; Grattan, 2001; Bakowska and Morrell, 2003). Furthermore, all these hormones access the brain via an active receptor-transport mechanism in the choroid plexus (Walsh et al., 1987; Bridges et al., 1996).

The anterior pituitary is the source of prolactin, which is the functionally important hormone of this group during the estrous cycle and in the initial days of pregnancy (Freeman, 1988). Shortly after pregnancy begins, pituitary prolactin is secreted in a pattern of a two daily surges, with nocturnal and diurnal peaks (Taya and Sasamoto, 1981). Early in pregnancy, decidual luteotrophin is secreted by the decidua of the uterus, and by 6 days after insemination, pituitary prolactin is no longer required to maintain pregnancy (Gibori et al., 1988). However, the anterior pituitary continues to secrete prolactin for the first 12 days of pregnancy (Freeman, 1988). After midpregnancy, placental lactogens, first I and then II, become the predominant forms of this hormone group in circulation. During this period, decidual luteotrophin disappears and serum prolactin of pituitary origin is substantially lower than that in cycling females (Garland et al., 1987). Throughout the second half of pregnancy, placental lactogens inhibit prolactin secretion from the anterior pituitary through feedback on the brain. This inhibition ceases in the last few days of pregnancy and there is a prepartum surge of prolactin (Gibori et al., 1988; Tucker, 1988; Fliestra and Voogt, 1997).

After parturition, prolactin levels rise by day 4 of lactation and remain high until day 10, after which they decline abruptly and remain low until estrous cycling resumes. During the initial 10 days of lactation, prolactin levels are 2–3 times higher than the maximum of the estrous cycle (Smith et al., 1975; Taya and Sasamoto, 1981; Taya and Greenwald, 1982). During lactation, both prolactin and LH regulate production of progesterone from the corpus luteum (Taya and Greenwald, 1982), and prolactin has an important role in milk production of the mammary gland.

The importance of suckling for the release of prolactin can be most distinctly seen if a female rat is separated from and then reunited with her pups, upon which there is a rapid and sharp increase in circulating prolactin. The female housed constantly with her pups does not show the same stimulus-related secretion, but nonetheless, these lactating females do have generally high levels of prolactin in the first 10 days of lactation followed by a substantial decline (Taya and Sasamoto, 1981; Mattheij et al., 1985; Freeman, 1988). While lactation and suckling-induced prolactin release can be prolonged if younger pups are substituted for the natural pups approaching weaning, if litters are larger or if food is restricted, even under these conditions the period of lactation is finite (Mattheij et al., 1984; Tucker, 1988; Woodside et al., 2000).

The remarkable power of the pup as a sensory stimulus for prolactin release is seen even in the absence of the ability to nurse pups. Galactophore (milk duct) transection prevents suckling-induced milk delivery, but because the sensory capacity of the nipple is intact, both prolactin levels and anovulation are maintained in the postpartum period (Woodside and Popeski, 1999). There are also elevated circulating levels of prolactin in virgin females that have been induced into maternal responsiveness by pup exposure. If foster pups of naturally advancing age are offered to the maternal virgins, they have a prolactin pattern similar to the natural postpartum dam (Marinari and Moltz, 1978).

3.4.2 Prolactin Influences on Maternal Behavior

Prolactin was proposed in the early literature to be a facilitator in the hormonal onset of maternal behavior if estradiol was provided and progesterone withdrawn (Moltz et al., 1970; Numan and Insel, 2003). A surprisingly long period elapsed before Bridges and colleagues demonstrated that peripheral administration (via ectopic pituitary graphs) or a lengthy series of peripheral injections of prolactin will stimulate a fairly rapid onset of maternal behavior in inexperienced ovariectomized and hypophysectomized virgin females (Bridges et al., 1985). This was also contingent upon treatment with estradiol and progesterone. Using a similar steroid treatment, Bridges et al. (1990) demonstrated that an intracerebroventricular (ICV) infusion of prolactin will also stimulate the onset of maternal behavior.

Bakowska and Morrell have similar conclusions from a different model, a pregnant female H–O on day 16 of pregnancy (Bakowska, 1998; unpublished). This model was selected to consider the impact of the elevated levels of prolactin receptors (PRL-R) in the brain of late pregnancy females, compared with cycling virgin females. These females received only a single, very low dose of estradiol to maintain high levels of PRL-R, once the hormones of pregnancy were removed by the H–O procedure. This dose of estradiol does not support the initiation of maternal behavior in this H–O preparation (Rosenblatt et al., 1998) (*Figure 5-1*).

Prolactin substantially facilitated the onset of maternal behavior. All females infused with prolactin became maternal, while no more than 40% of females without prolactin were maternal after 5 days of pup exposure. This H–O model required less prolactin and less estradiol priming than in the virgin, suggesting that the hormones of pregnancy were facilitatory to the role of prolactin in the onset of maternal behavior, possibly by affecting the prolactin or PRL-R.

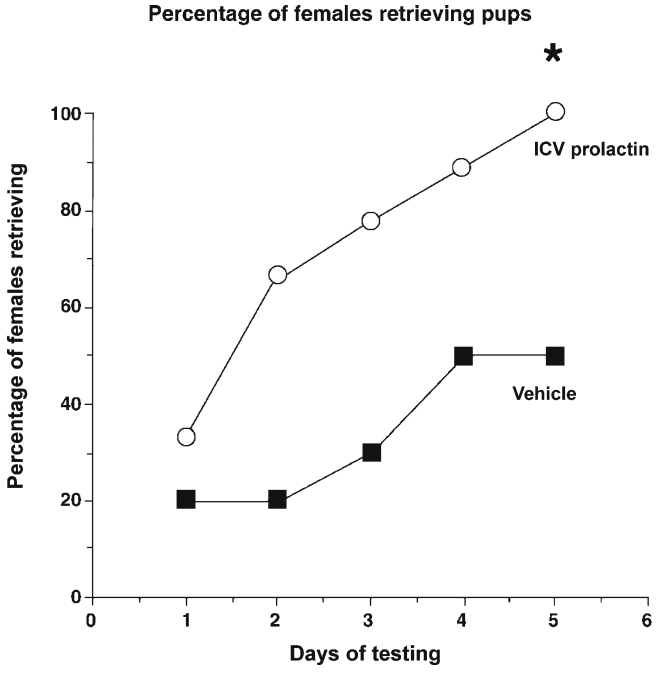
3.5 Other Participants in the Processes of Pregnancy, Parturition, and Lactation

As we develop a better understanding of the endocrine factors regulating physiological processes concurrent with maternal behavior, it is worthwhile to consider that some of these factors might also influence maternal behavior, or promote the co-ordination of maternal behavior with these physiological processes. Other unproven but possible candidates for such behavioral regulation are prostaglandins and relaxin (Sherwood et al., 1980; Sherwood, 1988). Relaxin is particularly intriguing. The rising level of relaxin in the latter part of pregnancy correlates with the onset of maternal behavior, and it has a close relationship with the secretion of oxytocin, which participates in the expression of maternal behavior. While the major source of relaxin is the corpus lutea of pregnancy, relaxin receptor expression in brain, relaxin synthesis by the brain, and activation of neurons by relaxin have also been demonstrated (Sherwood, 1988; Osheroff and Phillips, 1991; Gunnersen et al., 1995; Heine et al., 1997; McKinley et al., 1997). Relaxin may act in the brain to mediate increased water intake during the second half of pregnancy (Hornsby et al., 2001) and the timing of birth in rats (Summerlee et al., 1998).

Other yet unexplored endocrine links to maternal behavior may be found as our knowledge of pregnancy and lactation grows. For example, our understanding of the regulatory and synthetic capacity of the placenta is still emerging, and we now know that it has both serotonin receptors and transporters (Shearman et al., 1998), D2 dopamine receptors (Lee et al., 1999), glutamate transporters (Matthews et al.,

Figure 5-1

Females were hysterectomized and ovariectomized on day 16 of pregnancy, and administered one s.c. injection of estradiol (1.25 μg/kg). After five ICV infusions of 50 μg of prolactin (n = 16) or vechicle (n = 10) the animals were tested with foster pups for 5 days without any further infusions or injections. Foster pups were fed and cared for by their biological dams. Estradiol treatment as in Rosenblatt et al. (1998); prolactin regime as in Bridges et al. (1990). Cannula placement was verified postmortem. *P < 0.05. (Bakowska and Morrell, unpublished; Bakowska Doctoral Thesis, Rutgers University, 1997)



1998), leptin receptors (Smith and Waddell, 2002), and it produces grehlin (Gualillo et al., 2001) and nitric oxide synthase (Casado et al., 1997). In another example, the extinction of suckling-induced prolactin release in the later part of the lactational period can also be delayed by hysterectomy (Kanyicska et al., 1990), suggesting a potential role for the uterus during the postpartum period.

3.6 The Brain as a Possible Source of Hormones that Regulate Maternal Behavior and its Neuroendocrine Processes

The majority of work on the hormones that mediate or support maternal behavior has focused on peripheral sources of these hormones. In certain cases, however, the primary source of these hormones is the brain. For example, oxytocin facilitates maternal behavior when infused into the cerebral ventricles, or into some specific brain areas (see *Section 4*), but there is little evidence that oxytocin secreted into the periphery by the pituitary gland has any effect on maternal behavior. In this case, it is probable that oxytocin facilitates maternal behavior after release from neuronal endings within the brain, in a rich and well-described network of locations (Buijs et al., 1985; Russell et al., 2003). There is evidence that the brain also makes estrogens, prolactin and related compounds, opioids, and other substances that might have a role in mediating behavior (Schlinger and Arnold, 1983; Devito et al., 1992; Emanuele, 1992; Clapp et al., 1994; Gunnersen et al., 1995; Wagner and Morrell, 1996; Balthazart and Ball, 1998; Amateau et al., 2004).

It is interesting to note that these substances may have regulatory roles in maternal behavior that are more dependent on their central sources than we currently understand. It is possible that peripheral and central sources of these hormones work in concert to influence behavior and coordinate endocrine and physiological processes during pregnancy, parturition, and lactation. Grattan and his colleagues have suggested that prolactin may coordinate behavioral, neuroendocrine, and physiological processes during pregnancy and lactation (Grattan, 2001), and we propose that this may occur by the action of prolactin and related compounds of both brain and peripheral origin.

4 Neural Expression of Maternal Behavior

4.1 Fundamentals of the Traditional Maternal Behavior Circuit – the Preoptic Area

The most thoroughly investigated neural site necessary for the display of maternal behaviors in rats is the POA. Fisher (1956) provided the first evidence that the POA might be involved in maternal care and reported that maternal behaviors could be elicited in male rats when testosterone was infused in the POA. Later studies expanded upon these results to show that pre- or postpartum destruction of the POA severely disrupts maternal behaviors, particularly retrieval of pups and nest building (see Numan and Insel, 2003). The importance of the POA in maternal behaviors is not restricted to pregnant or parturient females, as POA lesions also impair the onset or maintenance of maternal responding in sensitized nulliparous female rats (Numan and Insel, 2003). Importantly these females do not have a general oral impairment and continue to carry food, eat, and drink. The POA projections necessary for maternal behaviors exit this structure dorsolaterally, and severing these projections also impairs retrieval and nest building (Terkel et al., 1979; Numan and Callahan, 1980; Numan et al., 1990). Interestingly, dams with severed dorsolateral POA connections will still approach and sniff pups as rapidly as nonlesioned controls (e.g., Terkel et al., 1979; Numan and Callahan, 1980), indicating that their motivation to seek out and investigate pups remains intact. These dorsolateral fibers likely come from many places in the brain to provide input to the mPOA necessary for maternal behaviors, but some important sources of afferents that likely reach the POA include the raphe nuclei, the ventral tegmental area (VTA), the locus coeruleus, the interpeduncular nucleus, and the nucleus of the solitary tract (Numan et al., 1990).

The effect of POA lesions on other maternal behaviors is somewhat unclear. In many cases, nursing the pups is disrupted or absent after destruction of the POA or its projections. However, this is not always the case (e.g., Terkel et al., 1979; Jacobson et al., 1980; Miceli et al., 1983; Numan, 1990; Numan et al., 1990). As noted by Stern and Johnson (1989), nursing is unlikely to occur if dams cannot gather enough pups in one place and receive sufficient suckling stimulation necessary to nurse. Therefore, deficits in nursing after POA lesions may in some cases be secondary to the deficit in retrieval. Licking of the pups is not often examined in these studies, but when quantified, it has ranged from little or no impairment after postpartum severing the lateral connections of the POA (Terkel et al., 1979) to a pronounced deficit after prepartum POA lesioning (Lee et al., 2000).

The POA is part of what is known as the POA/hypothalmic "locomotor" region, a diffuse area where electrical stimulation elicits locomotion in rats (Sinnamon, 1993). These cells are estrogen-sensitive (Takeo and Sakuma, 1995) and project to subthalamic areas and the pedunculopontine nucleus of the midbrain known to be involved in locomotor activity (Swanson et al., 1987). These are presumably the components of the POA projections necessary for the motor control of maternal behavior.

Lesioning the medial POA (mPOA) and lateral POA (lPOA) produce similar effects on maternal behaviors. It is thought that the mPOA is critical for the integration of hormonal and sensory information necessary for the onset and later display of maternal behaviors, but that its afferents synapse onto the lPOA before projecting to areas of the brain necessary for the motor performance of maternal behaviors (Numan et al., 1988). Because the POA is sensitive to a variety of gonadal and pituitary hormones (see *Section 5.4* below), receives olfactory inputs from the amygdala, and somatosensory information from the trigeminal

system (Li et al., 1997), it is perfectly situated to act as a hormone–sensory–motor integration site for the performance of maternal behaviors.

4.2 Other Components of the Maternal Behavior Circuit

In addition to the POA, numerous other neural sites have been examined for their role in maternal behaviors. Only those with a clear and indispensable role in a component of maternal care are presented below. Components of the nigrostriatal and mesolimbic systems involved in maternal care are discussed separately in *Section 6*.

4.2.1 Ventral Areas of the Bed Nucleus of the Stria Terminalis

Immediately adjacent to the POA is the bed nucleus of the stria terminalis (BNST), which among other functions is integral for the display of many social behaviors in animals because of its ability to relay information between the amygdala and the hypothalamus. As noted by Numan and Numan (1996), previous experimental manipulations of the POA often included ventral areas of the BNST (vBNST – generally corresponding to portions of the anterior dorsomedial, fusiform, and subcommissural nuclei; Swanson, 1998), and it was possible that the vBNST itself had a role in maternal care. Neurotoxic lesions of the vBNST affect maternal behavior as do POA lesions, including a disruption of retrieval and nest building, and a concomitant reduction in nursing, likely the result of the inability to collect the litter in one place (Numan and Numan, 1996). It is not known if the vBNST acts as a separate unit to influence active maternal behaviors or rather as part of a continuous population of neurons in this general area of the basomedial forebrain necessary for the display of maternal care (Numan and Numan, 1996).

4.2.2 Paraventricular Nucleus (PVN)

The PVN of the hypothalamus contains a large number of oxytocin- and vasopressin-synthesizing cells. In accordance with the facilitatory role of these neuropeptides on the onset of maternal behavior (Pedersen et al., 1982), prepartum electrolytic lesions of the PVN and surrounding hypothalamus induce cannibalism at parturition in some females, and also disrupt maternal retrieving, nest building, and nursing (Insel and Harbaugh, 1989). It is not yet known if cells in this structure, rather than fibers passing though it, are responsible for the disruption in the onset of maternal behavior. It is also difficult to determine whether lesioning of peptidergic or nonpeptidergic cells produces these effects. Postpartum electrolytic, radiofrequency, or neurotoxic lesions of the PVN, or knifecuts lateral to it, also impair retrieval and nest building (Numan and Corodimas, 1985; Olazabal and Ferreira, 1997), although not in all cases (Insel and Harbaugh, 1989; Consiglio and Lucion, 1996). Interestingly, PVN lesions apparently have no effect on the duration of nursing behavior (Numan and Corodimas, 1985; Insel and Harbaugh, 1989; Olazabal and Ferreira, 1997), but recent data have shown that central oxytocin (OT) antagonism in lactating rats reduced the dam's licking of pups and their display of kyphosis (Champagne et al., 2001; Pedersen and Boccia, 2003), suggesting that OT originating from the PVN may be more important for these behaviors than previously suggested.

4.2.3 Habenula

The habenular complex (Hbc) has a unique role in the regulation of maternal behavior in rats. Radiofrequency or excitotoxic lesions of the Hbc during midpregnancy produce effects on maternal behavior similar to POA lesions – disruption of retrieval, nest construction, and nursing (Corodimas et al., 1992, 1993; Matthews-Felton et al., 1995). In contrast, postpartum excitotoxic Hbc lesions have either little or

only transient effects on maternal behavior, indicating a particular importance of the Hbc for the onset of maternal behavior, but not its maintenance (Corodimas et al., 1993). It has been found that the lateral subdivision of the habenula (Lhb) is responsible for these effects (Corodimas et al., 1993; Matthews-Felton et al., 1995, Felton et al., 1998). While implants of estradiol into the Lhb are not sufficient to facilitate the onset of maternal behavior (Matthews-Felton et al., 1999), a population of neurons in the Lhb that express estradiol receptors suggests at least that some hormonal influence on either maternal behavior or postpartum estrus is possible (Wagner et al., 1998). However, Lhb lesions prior to exposure to pups also disrupt the acquisition of retrieval and nestbuilding in sensitized nulliparous females (Matthews-Felton et al., 1998). Therefore, the Lhb is in all models important for the onset of maternal behavior, but not necessarily related to the mechanisms by which hormones directly influence this onset. Because Lhb lesions produce effects similar to that of mPOA lesions, it is tempting to suggest that the Lhb effects are associated with impairments in mPOA inputs or outputs. Even though the Lhb does not project to or receive a projection from the mPOA directly, it does project to and from the lPOA, through which communication with the mPOA is possible (Wayner et al., 1983; Felton et al., 1999).

4.2.4 Periaqueductal Gray (PAG)

Studies of the neural control of retrieval and nest building in rats demonstrate a critical role of the mPOA, but as noted above, nursing behavior in these studies is not consistently affected by mPOA lesions. This suggests that neural sites other than the mPOA are more important for quiescent nursing. Nothing is known about what neural sites mediate the suckling-induced quiescence necessary for nursing, but the midbrain PAG is necessary for the postural component of kyphosis. Interactions with pups that include prolonged periods of suckling-induced kyphosis elicit expression of Fos, the protein product of the immediate-early gene *c-fos,* in a specific area of the PAG, the caudal lateral and ventrolateral regions ($cPAG_{l,vl}$) (Lonstein and Stern, 1997a, b). Electrolytic lesions of the $cPAG_{l,vl}$ impair the ability of dams to display kyphosis, but have little effect on any other maternal behavior. Lesioned dams do become quiescent and nurse, however, but do so in postures less effective in providing milk to young pups such as laying prone on top of the pups or nursing them in a supine position (Lonstein and Stern, 1997a; Lonstein et al., 1998). All of these effects are specific to the $cPAG_{l,vl}$ because lesions of the dorsolateral PAG do not impair kyphosis (Lonstein and Stern, 1998). Suckling appears to increase GABAergic input to the $cPAG_{l,vl}$ to elicit kyphosis, and infusion of the $GABA_A$ receptor antagonist bicuculline into the $cPAG_{l,vl}$ prevents the ability of suckling to produce this posture (Salzberg et al., 2002). There are dense reciprocal projections between the $cPAG_{l,vl}$ and the POA, some of which express Fos during the display of maternal behavior (Numan and Numan, 1997). These sites may reciprocally inhibit each other, such that kyphosis is inhibited at inappropriate times when dams need to perform active maternal behaviors, and active maternal behaviors are inhibited when dams are showing suckling-induced quiescence and kyphosis (Lonstein and Stern, 1997a).

4.2.5 Septum

Large lesions of the septum performed pre- or postpartum impair maternal care in parturient females, as well as in sensitized virgins. To what degree remains unclear. One study reports that LS lesions disrupt only the efficiency of retrieval, with dams picking up pups, but carrying them for prolonged periods of time and dropping them in locations other than the nest (Fleischer and Slotnick, 1978). In other cases, such lesions completely abolished maternal behavior (Flannelly et al., 1986; Novakova et al., 1993). It is difficult to interpret these results, partly because in some cases the lesions included parts of the ventral striatum, BNST, and/or the dorsal POA, which in itself could impair maternal care. As suggested by Numan and Insel (2003), cases of disorganized retrieval by septal-lesioned females may indicate that this structure is involved in behavioral inhibition and termination, and its integrity is necessary for the smooth transition between sub-components of each retrieval (e.g., picking up pups, transporting pups, dropping pups, searching for the next pup). Consistent with a role in the organization of maternal behaviors, cells of the

lateral septum express the immediate-early gene, c-fos, after the display of maternal behavior (Lonstein et al., 1998; Stack and Numan, 2000), and this neural activity requires a projection from the POA (Numan and Numan, 1997; Stack et al., 2002).

4.3 Brain Regions that Inhibit Maternal Behavior in the Nonmaternal State

4.3.1 Amygdala

As noted above (*Section 2*), olfaction is generally unnecessary for the postpartum display of maternal behavior in rats and inhibits the behavior in virgin females. The main and accessory olfactory bulbs densely project to the cortical and medial nuclei of the amygdala, which project heavily to the POA (Simerly and Swanson, 1986). If olfactory information accesses the POA via the amygdala to inhibit maternal responding in nulliparous females, it is possible that destroying the amygdala facilitates maternal behavior. This is exactly what occurs after electrolytic or excitotoxic lesions of the corticomedial amygdala, or of just the medial amygdala (MeA) (Fleming et al., 1980; Numan et al., 1993). Conversely, stimulation of the MeA delays the onset of maternal behavior (Morgan et al., 1999). Although MeA-lesioned females no longer avoid pups, they may not immediately act maternally toward them and still require 2–3 days of exposure to become fully maternal (Fleming et al., 1980), suggesting that inhibitory inputs also come from other neural sites. An interesting study by Sheehan et al. (2000) examined how the nonmaternal virgin female rat brain responds to pup stimuli, with the goal of finding areas that cause such stimuli to be aversive, and found that the MeA showed one of the greatest increases in Fos expression. However, postpartum and sensitized maternal rats also show high levels of Fos expression in the MeA (Fleming et al., 1994; Numan and Numan, 1994, 1995; Lonstein et al., 1998; Kalinichev et al., 2000), albeit at a somewhat lesser magnitude than nonmaternal virgin females (Sheehan et al., 2000).

4.3.2 Anterior and Mediobasal Hypothalamus

The amygdala may also inhibit maternal behavior by stimulating other areas of the brain that can inhibit maternal responding, and the mediobasal hypothalamus is one such site. Lesions of the mediobasal hypothalamus (the anterior hypothalamus, dorsomedial hypothalamus, or ventromedial hypothalamus [VMH]) facilitate maternal response in steroid-treated nulliparous female rats (Bridges et al., 1999; Sheehan et al., 2001). These lesions do not facilitate the behavior in females not given steroid hormones (Bridges et al., 1999) and the VMH must only then inhibit maternal response under certain hormonal conditions, such as pregnancy. In support, nonmaternal female rats show elevated Fos expression in the anterior hypothalamus and ventromedial nucleus in response to pups whereas maternal females do not (Sheehan et al., 2000). Other than the requirement for ovarian hormones to be present, little is known about the neurochemistry underlying the inhibition of maternal behavior by the mediobasal hypothalamus, with the exception that neuropeptide K infused into the VMH can inhibit the behavior (Sheehan and Numan, 1997). Evidence that these mediobasal hypothalamic areas receive an input from the MeA to inhibit maternal behavior is provided by the finding that MeA lesions reduce Fos expression in these sites of nonmaternal females after exposure to pups (Sheehan et al., 2001).

Areas of the brain associated with fear and anxiety, such as the PAG and septum, have also been suggested to be involved in the inhibition of maternal behavior (Numan and Insel, 2003). The novel stimuli eminating from pups are thought to be anxiety-generating in maternally inexperienced female rats and reduced neophobia of pups may be a prerequisite for females to act maternally (Fleming and Luebke, 1981; Hard and Hansen, 1985; Lonstein, 2005). Nonmaternal female rats do show high levels of Fos expression in the PAG and septum when exposed to neonates (Sheehan et al., 2000), but more work is needed to determine if these sites inhibit maternal care.

4.4 Changes in Neural Hormone Receptor Expression Across Pregnancy and Lactation

4.4.1 Estrogen Receptors

Estradiol is thought to be an important hormone for the onset of maternal responding and numerous studies have examined changes in ER expression in the rat brain across pregnancy and lactation. The pattern of these changes is site-specific, but probably not surprisingly, does not have a simple relationship to the onset of maternal behavior in the parturient rat. Estrogen receptor (ER) binding increases in the medial preoptic nucleus and MeA during pregnancy, and at the same time, decreases in other areas of the POA (Giordano et al., 1991). This pattern is most readily seen as preparing this region for the onset of maternal behavior. In contrast, a different pattern emerges in the VMN, where ER binding decreases during midpregnancy and rises again at the time of parturition (Giordano et al., 1991). This region is important for sexual behavior in the female, which is absent during pregnancy (Rosenblatt et al., 1998) but reemerges during the postpartum estrus. Changes in ER binding in the VMN support the idea that this area participates in the absence of sexual behavior during pregnancy and its reemergence after parturition.

Examining the number of neurons that express the mRNA (Wagner and Morrell, 1995) and immunoreactivity (Wagner and Morrell, 1996) of the estrogen receptor alpha isoform (ERα) has provided some insight into the transcriptional and translational regulation underlying the binding data. In general, changes in ERα mRNA expression in the mPOA are antecedent to the increases in binding, with peaks on day 8 of pregnancy, and then again on day 22 of pregnancy. The number of neurons in the mPOA expressing ERα immunoreactivity also increases on day 8 and day 16, accompanied by a shift in the expression per neuron such that more neurons express more protein on days 16–22 than before or after this period. Thus, increased estrogen binding in the mPOA is supported by increased mRNA and protein for the receptor. In the VMN, mRNA and immunoreactive protein are low during pregnancy, and increase just before parturition, consistent with the binding pattern. The patterns of neurons that express mRNA and immunoreactivity of ERα, and the amount per neuron, are the summation of both alterations in synthesis and degradation of the ER-α mRNA and protein. While they seem to generally support the binding patterns, additional levels of regulation are probably also involved, such that the stability of the mRNA and the immunoreactive protein may also change during these periods.

Expression of the more recently discovered beta isoform of ER also differs between virgin, pregnant, and lactating rats in sites relevant to maternal behavior. The number of cells in the POA expressing ERβ mRNA is lower in late-pregnant and lactating rats compared with proestrous virgins, although females at the end of pregnancy have very high ERβ expression per cell. Similarly, the number of ERβ-expressing cells is low in the MeA in lactating females, although they express more per cell (Greco et al., 2003). The functional relationships between ERα and ERβ are only now emerging, as are the functions of the ERβ (Matthews and Gustafsson, 2003).

4.4.2 Progestin Receptors

The only detailed study of nuclear progestin receptor (PR) expression during pregnancy and lactation in rats providing cellular resolution is by Numan and colleagues (1999). In both the POA and VMN, expression of PR-immunoreactivity is high in virgin females, but falls precipitously soon after insemination. PR levels then rise before parturition and fall during early lactation. A similar, but not statistically significant, pattern of change in PR expression was found in the vBNST and MeA. It is interesting that the low levels of PR after parturition are due to contact with pups, because their removal increases PR levels in these sites.

As noted above, progesterone has a dual effect on maternal behavior, first synergizing with estradiol during pregnancy to promote parental responding, but then having to be withdrawn for the behavior to emerge at parturition. How changes in the PR levels in sites involved in maternal behavior mediate the onset of the behavior is unknown and counterintuitive because the high sensitivity to progesterone afforded by high levels of PR in these sites just before parturition might be expected to inhibit maternal responding, not

promote it. One might also expect that recently inseminated females, which have very low PR expression, would be highly maternal, but this has not been demonstrated to be the case. Additional levels of regulation within a larger circuit must be interfacing with the PR system and is clearly an area for future attention.

4.4.3 Prolactin Receptors

The localization and concentration of prolactin receptors (PRL-R) in the brain have been examined numerous times in pregnant and lactating rats. PRL-R can be found in two forms Ouhtit et al., 1993, a long form that is regulated during pregnancy and lactation, and a short form that is not. In homogenates of the entire forebrain, mRNA for the long form increases during midpregnancy and is high through most of lactation (Sugiyama et al., 1994). In just the hypothalamus, the greatest long-form PRL-R mRNA expression is found in lactating dams (3–7 days postpartum), compared with late-pregnant or cycling females (Torner et al., 2002). In situ hybridization, which allows for cell-specific resolution, shows that mRNA for the long form of the PRL-R can be found in almost every site involved in maternal behavior. In the POA, PRL-R mRNA generally increases across pregnancy, peaks at parturition, and then falls as lactation progresses (Bakowska and Morrell, 1997; Pi and Grattan, 1999a; Mann and Bridges, 2001, 2002). PRL-R mRNA also rises in the dorsal and ventral BNST as pregnancy progresses (Bakowska and Morrell, 1997; Mann and Bridges, 2001, 2002), and lactating rats have greater long-form PRL-R mRNA in the VMH than diestrous virgins (Pi and Grattan, 1999b). The absence of changes in PRL-R expression in these brain regions has also been reported (Augustine et al., 2003). Other sites important for maternal behavior with numerous cells expressing mRNA for the long-form of the PRL-R include the MeA, lateral septum, anterior hypothalamus, and the ventrolateral PAG (Bakowska and Morrell, 1997), but it is not known if its expression changes across pregnancy and lactation in these sites. Presumably, when changes in PRL-R are found, they are due to changes in circulating hormones, as expression of PRL-R in the hypothalamus is reduced by ovariectomy, and restored by chronic estradiol or progesterone (Mustafa et al., 1995; Pi et al., 1999c, 2001, 2003). In some subdivisions of the POA and VMH, this PRL-R expression requires that dams have relatively recent contact with suckling pups (Sugiyama et al., 1996; Pi and Voogt, 2000, 2001). Exposure to neonatal pups may also alter PRL-R expression in the choroid plexus of virgin female rats (Sugiyama et al., 1994, 1996) and in the homogenized cerebrum of male rats (Sakaguchi et al., 1996).

Expression of mRNA for the short form can be found in many of the same sites (Bakowska and Morrell, 2003), but it is found in low abundance compared with the long form. In regions where both forms of the receptor are found, however, there is an additional level of complexity, as neurons with both forms exist. For example, in the paraventricular and supraoptic nuclei of the hypothalamus, nearly all the neurons have a low level of expression of the short form, while the distribution of neurons that express the long form of the receptor only substantially overlaps with oxytocin-producing neurons (Bakowska and Morrell, 1997, 2003). The differential regulatory roles of these two forms of the receptor in the brain are unknown. Two points are of interest. First, the activities of the short and long form are likely to interact in complex ways (Bole-Feysot et al., 1998), including the possibility that the short form inhibits the activity of the long form. Secondly, both forms may have a role in the regulation of neurogenesis during pregnancy (Shingo et al., 2003), which could be involved in changes in behaviors specific to the postpartum period.

Notably, in every study that includes analysis of the choroid plexus, this was the location of the largest amount of either mRNA for the long or the short form of the prolactin receptor or its immunoreactivity (Bakowska and Morrell, 1997, 2003). Every cell in the choroid plexus expresses high amounts of mRNA for both forms of the receptor. This appears to be the transcriptional evidence for the receptor-mediated mechanism for the transport of prolactin and prolactin-like substances from the peripheral blood into the brain (Walsh et al., 1987).

4.4.4 Oxytocin Receptors

Oxytocin is released most likely from within the brain, rather than from the pituitary, to facilitate maternal behavior in rats (Pedersen, 1997). Oxytocin receptor (OTR) expression can be found in many places of the

female rat brain involved in maternal behavior, and it changes across pregnancy and lactation in a manner that might modulate the onset and maintenance of maternal care. Discrepancies between studies using different methods to visualize OTR, however, make interpretation of these data somewhat difficult (see Young et al., 1997 for discussion). Insel (1986) first reported that OTR binding was greater in the dorsolateral BNST of lactating dams (1–6 days postpartum) than that in midpregnant females and in ovariectomized females treated with estradiol than in untreated females. Furthermore, binding was highest earlier in lactation than later (Insel, 1990). Differences between groups were not found in the VMH, and the figures reveal no noticeable differences in the BNST, septum, or POA (Insel, 1986). Additionally, significantly more OTR binding was found in the VMH on the day of parturition than in pregnancy or other times during lactation (Insel, 1990; Bale et al., 1995; Young et al., 1997). OTR mRNA shows a different pattern, with recently parturient females having greater expression in the VMH, lateral septum, and POA, but probably unexpectedly, not the BNST (Bale et al., 1995; Young et al., 1997). Consistent with this finding, analysis of OTR binding in the POA by Pedersen et al. (1994) showed increases during parturition compared with days 15–17 of pregnancy or postpartum days 5–7. OTR binding was also higher during parturition in the VTA (Pedersen et al., 1994).

The significance of changes in OTR expression in the dorsolateral BNST or VMH on the day of parturition is unknown. Day 4 postpartum lesions of the dorsolateral BNST have little effect on maternal behavior (Numan and Numan, 1997), although the very early postpartum increase in OTR expression here suggests that prepartum lesions of this area might effectively disrupt the onset of maternal behavior. Alternatively, changes in OTR expression on the day of parturition might be more closely related to the postpartum estrus or the onset of lactation rather than maternal behavior, as maternally sensitized females do not have increased OTR binding in either the BNST or VMH (Insel, 1990), and some BNST cells are responsive to suckling and are involved in milk letdown (Lambert et al., 1993).

OTR expression is sensitive to ovarian hormones, which may be responsible for the observed changes in OTR expression in parturient females. Estradiol is a potent stimulator of OTR expression in many areas, including the BNST, POA, LS, and VMH (Insel, 1986; Schumacher et al., 1989; Tribollet et al., 1990; Bale and Dorsa, 1995; Bale et al., 1995; Kremarik et al., 1995; Quinones-Jenab, 1997), and increases OTR affinity for OT in the POA (Caldwell et al., 1994). The addition of progesterone in some cases further enhances it (Schumacher et al., 1989; Coirini et al., 1991), but chronic progesterone can suppress basal and estradiol-induced OTR expression in some areas of the brain, including the VMH (Patchev et al., 1993; Bale et al., 1995).

As noted above, previous research had suggested little or no role for OT in maternal behavior after the behavior was established around the time of parturition, but this issue has recently been reexamined in detail. Francis et al. (2000) found that some lactating rats have greater OTR binding in the POA and dorsolateral BNST than other females, and that these differences were related to the higher levels of maternal licking these females received when they themselves were neonates. Furthermore, when such females are virgins, they more rapidly become maternally sensitized (Champagne et al., 2001). These differences in OTR expression appear to be related to differences between females in their postpartum maternal behavior because ventricular infusion of an OT antagonist reduces pup licking in dams with higher OTR expression (Champagne et al., 2001).

4.4.5 Conclusions

Region-specific changes in the expression of hormone receptors have complex relationships to the events of pregnancy and the onset of maternal behavior. One hypothesis is that these changes prepare the brain to rapidly induce and maintain maternal behavior because the correlations of these events and the behavioral outcomes are strong. However, this hypothesis must account mechanistically for the disjointed time course because some of the greatest changes in receptor measures occur well before the behavioral events. Causal linkages between changes in the expression of these receptors and the onset of maternal behavior will probably require examining both region- and temporal-specific regulation of expression using methods that are only now emerging in molecular biology. An understanding of how these region-specific changes in

receptors occur and are sustained is also needed. Estrogen and progestin receptors are regulated by circulating steroid hormone levels in several models (Parsons et al., 1982; DonCarlos et al., 1989; Lisciotto and Morrell, 1993; Morrell et al., 1995). The region-specific regulation of these receptors in the brain may involve additional regulation such as afferent signals by neurotransmitters as well as differences in transcriptional and translational regulation within each region.

The case of ER regulation across pregnancy exemplifies a theme that must be constantly revisited when examining the data describing changes in hormone levels, neuroendocrine factor levels, and receptor levels proposed to be functionally related to changes in maternal behavior or its physiological correlates. There are many well-known changes between the second half of pregnancy and the immediate postpartum period that may be regulating components of the neural circuit mediating maternal responsiveness. These correlations can only serve as the basis for a search for causality. It is also the case that there are less well-known changes in hormone regulation that may be associated with maternal care; for example, the work of Gibori and coworkers demonstrating that very high levels of androgens are circulating in the later part of pregnancy (Gibori et al., 1979). Also, consider that other processes, such as food intake, lactogenesis, and responsiveness to adrenal steroids, are altered during this time. All these changes have a temporal coincidence with the changes in the brain appearing to be necessary for the onset of maternal responsiveness. Proving some causal linkages and revealing their mechanisms are important future directions.

4.5 Effects of Site-Specific Application of Hormones on Maternal Behavior

4.5.1 Estradiol

Many sites in the female rat brain express ERs and may be targets for estradiol's facilitatory effects on maternal behavior. Numan et al. (1977) addressed this question by implanting crystalline estradiol benzoate (EB) into the POA of 16-day pregnant rats immediately after hysterectomy and ovariectomy. Two days later, the implants were removed and the females were exposed to neonates. Females with EB implants into the POA showed a significantly reduced onset of maternal behavior, from a median latency of 2 days after a subcutaneous injection of EB to an immediate onset of the behavior. Because undiluted steroid could spread considerably from the cannulation site, Fahrbach and Pfaff (1986) reexamined this question using POA implants of unconjugated estradiol diluted with cholesterol. They found that diluted estradiol implants shortened the latency of nulliparous ovariectomized females to retrieve pups, but had no facilitatory effects on the efficiency of retrieval or nest building. Similar effects of estradiol implants have been found in female rats hysterectomized and ovariectomized during late pregnancy (Felton et al., 1999) and in males (Rosenblatt and Ceus, 1998). Implantation of estradiol in other sites in the brain does not produce these facilitatory effects (Numan et al., 1977; Matthews-Felton et al., 1999).

Even though estradiol hastens the onset of maternal behavior when infused into the POA, antagonism of ERs in the POA via implants of the selective ER modulator tamoxifen at the end of pregnancy does not impair the onset of postpartum maternal behavior (Ahdieh et al., 1987). Nonetheless, tamoxifen implants into the POA somewhat reduced the percentage of females showing maternal care (by ~33%) if litters were delivered by caesarian section (Ahdieh et al., 1987), which suggests an interaction between estradiol and the experience of parturition to facilitate the onset of maternal behavior.

4.5.2 Progesterone

There has only been one study examining where progesterone might act in the brain to inhibit maternal behavior. Numan (1978) showed that H–O pregnant females given exogenous estradiol were almost immediately parental 48 h later, but not if also injected subcutaneously with progesterone. Unilateral or bilateral implants of progesterone into the POA, VMH, raphe nuclei, or the area of the ventromedial substantia nigra of similarly treated females did not inhibit maternal behavior. Numan (1978) suggested that either the site where progesterone is acting was not examined in the study, or that it acts on multiple sites simultaneously to produce its inhibitory effects. This remains a major area of inquiry within the field.

4.5.3 Prolactin

Infusion of ovine prolactin into the POA also facilitates maternal behavior, shortening the latency of steroid-primed females to act maternally from almost 6 days to approximately 1 day (Bridges et al., 1990). Infusion of neither growth hormone nor LH produces this effect (Bridges et al., 1997). Notably, the dose of ovine PRL infused into the POA is lower than the doses necessary to stimulate parental behavior when infused into the cerebral ventricles (Bridges et al., 1990), suggesting that the POA is particularly sensitive to the influence of PRL on maternal care. Bridges also demonstrated that rat placental lactogen I facilitates maternal responding when infused into the POA (Bridges et al., 1997), suggesting that the pituitary is not the only source of prolactogenic hormones that could be important for the onset of maternal behavior. Whether PRL or plactental lactogens act similarly on other areas of the brain is unknown.

4.5.4 Oxytocin

The POA is also a target for oxytocin's effects on maternal behavior. Infusion of oxytocin into the POA facilitates maternal responding (Fahrbach et al., 1985), whereas infusion of an oxytocin antagonist into the POA during parturition greatly delays or completely eliminates retrieval of pups, and delays the latency to crouch over pups (Pedersen et al., 1994). Similar to POA lesions, impairments in nursing behavior were found and may have been consequent to the impairments in retrieval. These behavioral impairments were also found after OT antagonist infusion into the VTA (Fahrbach et al., 1985; Pedersen et al., 1994). As with most other hormones and neuropeptides, other neural areas where oxytocin might produce its effects on maternal care have not been investigated.

4.5.5 Other Neuropeptides

Other neuropeptides have been infused into specific sites and their effects on maternal behavior examined. Infusion of a vasopressin V1a receptor antagonist into the POA during parturition in rats impairs maternal behavior, but not as effectively as an OT antagonist (Pedersen et al., 1994). Unlike the effects of an OT antagonist, V1a antagonism in the VTA has no effects (Pedersen et al., 1994). Administration of morphine into the POA also impairs the onset of maternal behavior in estradiol-primed nulliparious female rats, as well as ongoing maternal behavior in postpartum females (Rubin and Bridges, 1984). Because morphine in the POA also impairs the display of parent-like behavior in juvenile rats (Wellman et al., 1997), its role is not likely related to hormonal influences on the POA that promote parental care. The PAG is also sensitive to opioid effects on maternal responding, and unilateral infusion of the opioid receptor antagonist naloxone into the dorsolateral PAG reverses the impairing effects of acute systemic morphine on postpartum maternal behavior (Miranda-Paiva et al., 2003). The neuropeptide cholecystokinin (CCK) hastens the onset of maternal behavior in estrogen-primed nulliparous female rats when injected peripherally (Linden et al., 1989), but has also been reported to be ineffective after peripheral or ICV infusion (Mann et al., 1995). CCK can act as an opioid antagonist and when infused into the POA, it blocks the impairments in maternal behavior after POA injection of morphine (Mann et al., 1995). The tachykinin, neuropeptide K, delays the display of maternal behavior in pregnancy-terminated, estradiol-treated female rats when infused into VMH (Sheehan and Numan, 1997), which so far, is the only neurochemical known to act in the VMH to impede this behavior.

5 Studies of Maternal Motivation

Hormones acting on the brain surely affect both the appetitive and consummatory aspects of maternal care, but there has been relatively little study of maternal motivation in rodents. Of course, dams will only express the components of maternal care if motivation is sufficiently high, and therefore, motivation is an absolute prerequisite for the behavior. Early studies employed methods commonly used at the time to evaluate other

motivational states (e.g., hunger, thirst, libido) to evaluate the effectiveness of pups as an incentive for parturient female rats to learn mazes (Simmons, 1924) or cross electrified grids (Moss, 1924; Nissen, 1930) to gain access to neonates. As noted previously (Fahrbach and Pfaff, 1982), these studies were fraught with methodological problems that render it difficult to determine how maternal motivation compared with other motivating factors.

More recent studies also based on the premise that lactating rats will readily overcome adversity to retrieve offspring have examined retrieval of pups from unfamiliar and potentially anxiety-generating environments as a measure of maternal motivation. Lactating female rats and mice are more likely than virgins to retrieve pups from an unfamiliar straight alley or T-maze extension of their home cage (Gandelman et al., 1970; Bridges et al., 1972; Stern and Mackinnon, 1976). The fact that most maternally sensitized rats of both sexes will not retrieve pups from a T-maze (Bridges et al., 1972) is likely due to their hormonal milieu. Estradiol and progesterone are each anxiolytic in rats (e.g., Mora et al., 1996), and maternally sensitized female rats are as likely as parturient females to retrieve pups from a T-maze extension of the home cage only if administered estradiol benzoate before sensitization (Stern and Mackinnon, 1976).

Operant chambers requiring rodents to press a bar or make other behavioral responses to obtain a reward have been used extensively to evaluate the reinforcing properties of many types of stimuli, including infants. In the first such study (Wilsoncroft, 1969), recently parturient female rats learned to bar-press for access to a neonate, which was invariably retrieved to the subjects' nest box. Pups were apparently highly reinforcing and some dams would bar-press for hours, gaining access to and retrieving hundreds of pups within the 3-h test session. A study in a strain of nulliparous female mice that are spontaneously maternal provided somewhat similar results (Van Hemel, 1973). When compared with lactating mice, however, nulliparous maternal females were less motivated to bar-press for a pup reward (Hauser and Gandelman, 1985).

Circulating hormones are an important influence on females' motivation to bar-press for pups (Hauser and Gandelman, 1985). High levels of bar-pressing in female mice are observed only soon after parturition, suggesting that hormonal fluctuations occurring immediately before or at this time influence maternal motivation. However, hysterectomy and caesarian removal of pups just before parturition did not prevent high levels of operant response in the dams (Hauser and Gandelman, 1985). As noted above, hysterectomy and removal of fetuses during pregnancy produces hormonal changes mimicking those occurring at parturition (Rosenblatt and Siegel, 1975). If the ovaries and the uterus and fetuses are removed, mouse dams did not bar-press at high rates for infant reward (Hauser and Gandelman, 1985). Furthermore, the withdrawal of progesterone is not only necessary for the onset of maternal behavior in mice and rats (Bridges, 1996), but also the females' operant responding for pups, as daily injections of progesterone prevent bar-pressing for pups in pregnancy terminated females (Hauser and Gandelman, 1985). Hauser and Gandelman, (1985) also showed that the reinforcing quality of mouse pups decreases as they age, consistent with the decline in maternal behavior that occurs as lactation progresses and that older pups are less attractive to lactating females than younger ones (Reisbick et al., 1975; Stern and Mackinnon, 1978; Mayer and Rosenblatt, 1980).

Hormonal influences on maternal motivation in an operant paradigm have also been examined in common marmosets (*Callithrix jacchus*). Unlike mice, frequency of bar-pressing for the opportunity to view an artificial marmoset infant and hear infant cries increases not immediately before parturition, but rather during late pregnancy, and continues throughout early lactation. This is also presumably due to changes in ovarian hormones, because virgin marmosets treated with a regimen of estradiol and progesterone mimicking that of late pregnancy also bar-press at high rates for infant-related stimuli (Pryce et al., 1993).

More recently, an operant paradigm has been used to examine the effects of destroying various neural sites on maternal motivation (Lee et al., 2000). Such an examination could discern whether neural lesions impair maternal behavior by altering maternal motivation to be in contact with pups (i.e., the appetitive component) or by altering other factors necessary for the execution of maternal behaviors (i.e., the consummatory component). In multiparous female rats, lesions of the POA and basolateral amygdala (AMYbl) significantly reduced bar-pressing for pups, whereas lesions of the nucleus accumbens (NA) did not. However, all lesions disrupted the performance of maternal behavior when tested in the

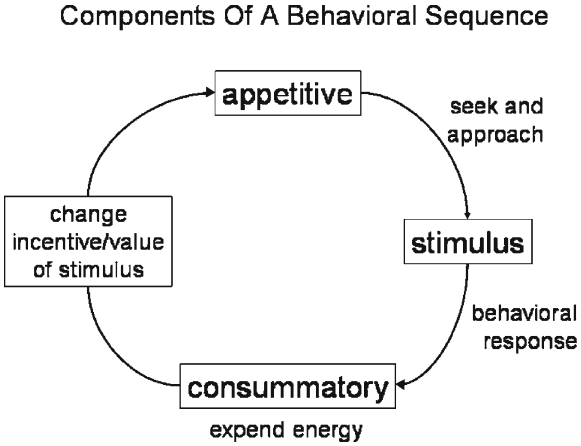
home cage. POA lesions also impaired bar-pressing for pups and home-cage maternal behavior in sensitized virgins. The reinforcing aspect of pups is apparently the contact that dams have with them after they are delivered through the reward bin, because even unlesioned dams will not bar-press for pups if they cannot thereafter make physical contact with them. In light of this, Lee et al. (2000) acknowledge that POA lesions may impair operant response for pups because they also impair the unconditioned maternal responses (retrieval, licking) that allow pups to be rewarding. Nonetheless, these results suggest that the neural sites mediating the reinforcing properties of pups differ in some ways than those necessary for expression of maternal behavior, with the POA and AMYbl necessary for both factors, but the NA unnecessary for maternal motivation.

Females' preference for locations or objects associated by residual sensory cues with pups also provides insight into the cues relevant for maternal motivation and responsiveness. Females with greater maternal motivation would be expected to show a higher preference for these pup-associated locations or objects. Not surprisingly, late-pregnant and parturient rats prefer a chamber containing bedding soiled by a lactating dam and her litter compared with a clean chamber (Bauer, 1983; Fleming et al., 1989). Virgin females do not show this preference, but a regimen of ovarian hormones that elicits maternal behavior in virgins also causes them to prefer the soiled bedding (Fleming et al., 1989). This paradigm shows that the chemosensory stimuli provided by pups are a sufficient representation of the motivating stimulus (pup) once the female enters late pregnancy, and that even before parturition she is motivationally prepared to respond to pups.

There are two common methods for determining the motivation or drive an animal has for an unconditioned stimulus, operant responding as described above, and place-preference conditioning. Place-preference conditioning is widely used in research on behavioral and neural processes involved in reward and reinforcement (Tzschentke, 1998). After a conditioning period when the rat learns to associate an unconditioned stimulus with a conditioned context (usually multiple neutral environmental cues in a chamber), preference for the conditioned cues is tested in the absence of the unconditioned stimulus. The environmental cues are neutral, that is not derived from the unconditioned stimulus. The time the rat spends in the chambers with the stimulus-associated cues is thought to indicate the motivation or desire for the stimulus. *Figure 5-2* allows us to consider some key differences in these two paradigms.

Figure 5-2

Schematic representation of the components of a behavioral sequence that can be identified in motivated, complex, naturally-occurring behaviors (B. Mattson, Doctoral Thesis, Rutgers University 2002). The two components discussed in the adjacent section are the motivational aspects and the expression of the behavior, with emphasis on their step-wise role in a complete behavioral sequence, particularly including consideration of the effect of achieving the stimulus on subsequence seeking of the stimulus



In the case of operant conditioning, the subject obtains and interacts with the stimulus, and so every operant response after the initial contact with the stimulus is one in which the incentive value of the stimulus is altered after interaction with the stimulus. While operant conditioning allows an examination of satiety, it is a paradigm in which motivation is likely altered by delivery of the unconditioned stimulus. Place-preference conditioning never provides the stimulus at any point during testing and so the entire test examines the initial appetitive state. The two methods have been fruitfully applied to explore motivation for pharmacological and natural rewards and data from both approaches together provides insight into issues of motivation.

The first use of a conditioned place-preference to study maternal motivation demonstrated that up to day 8 postpartum, lactating female rats preferred a pup-associated environmental context (Fleming et al., 1994). This response required that dams be deprived of pups for 23 h before testing, after which they were much more likely to show a preference for the pup-associated chamber than nondeprived dams, similar to the effects of deprivation on motivation for other types of rewards, such as food (Tzschentke, 1998). Morrell and colleagues further demonstrated that an equally strong preference for pup-associated environmental context occurred at both day 8 and 16 postpartum, using a similarly long pup deprivation period before conditioning with pups and before testing (*Figures 5-3* and *5-4*) (Wansaw et al., 2002, 2003a,b). One interpretation of these and the Fleming et al. (1994) data is that the need to nurse pups after such prolonged deprivation is reinforcing simply due to the relief from milk-engorged mammary glands provided by the pups. This would not be interpretable as a demonstration of maternal motivation per se.

Wansaw and Morrell are currently examining how these responses may be related to the different amounts of pup deprivation (Wansaw et al., 2002, 2003a,b). On day 8, postpartum females prefer pups over familiar neutral objects even if deprived of their pups for as little as 15 min or as long as 6 h before

Figure 5-3

Place preference of day 8 or day 16 postpartum dams conditioned and tested after 22 h of pup deprivation. Dams were conditioned to associate neutral context cues with either pups or pup-sized objects. The graph on the left represents the percentage of individuals in each group that met a very conservative quantitative criterion to be categorized as preferring one cue association or the other (Mattson et al., 2001). The graph on the right represents the proportion of the total test time of 60 min that the females spent in one of the three chambers – chamber associated with pups, a chamber associated with neutral pup sized objects, or a neutral empty chamber without conditioning. Both groups of dams showed a statistically significant effect of conditioning, and a preference for cues-associated with pups over those associated with objects ($P < 0.05$)

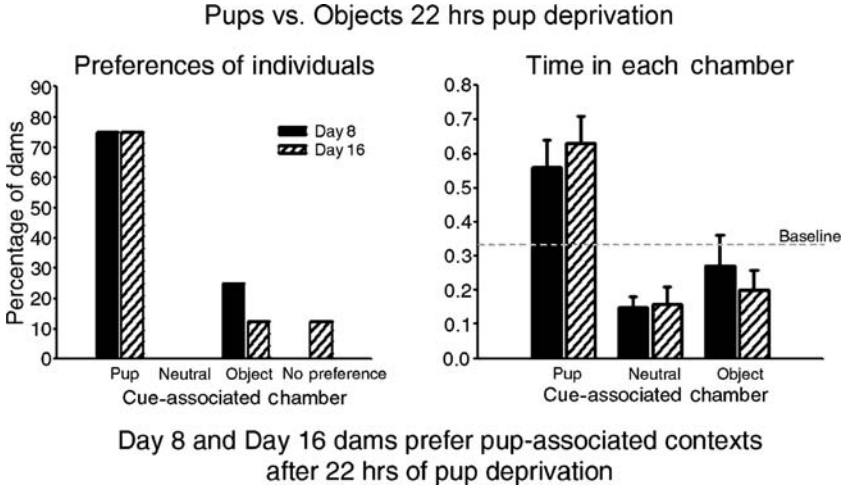


Figure 5-4

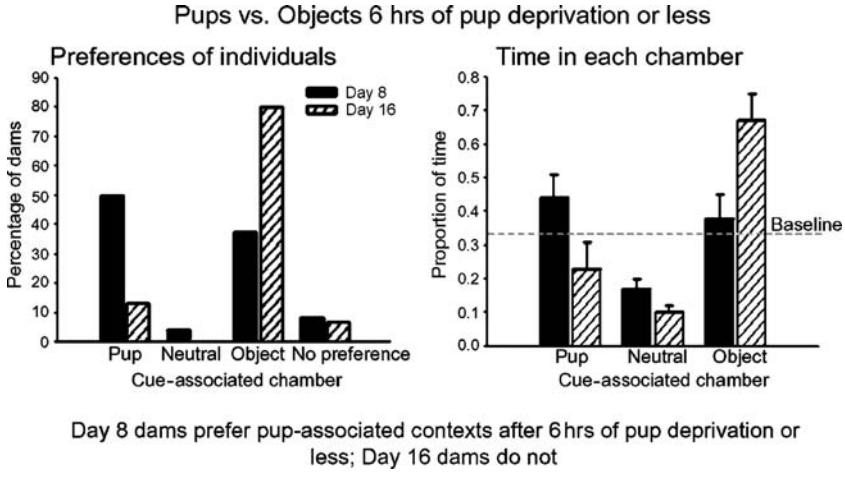
Place preference of day 8 or day 16 postpartum dams conditioned and tested after less than 6 h of pup deprivation. Separate groups of dams were deprived of their pups for either 15 min, 2 h or 6 h, and then were conditioned to associate neutral context cues with either pups or pup-sized objects. Both groups of dams showed a statistically significant effect of conditioning. On day 8, dams showed a statistically significant preference for a pup associated context, while on day 16, a preference for cues-associated with pups over those associated with objects emerged (P<0.05). Further details of graphs as in *Figure 5-3*



conditioning and testing. In contrast, by the later part of the postpartum period, similarly-treated females no longer preferred pups and instead exhibit a preference for neutral familiar objects. These data demonstrate that maternal motivation toward pups is waning as the postpartum period progresses. The experiments using very short pup deprivation times to reveal pup-associated place preference in the early but not the late postpartum period are interpretable as a demonstration of maternal motivation since the complication (confound) with any physiological need to nurse is avoided.

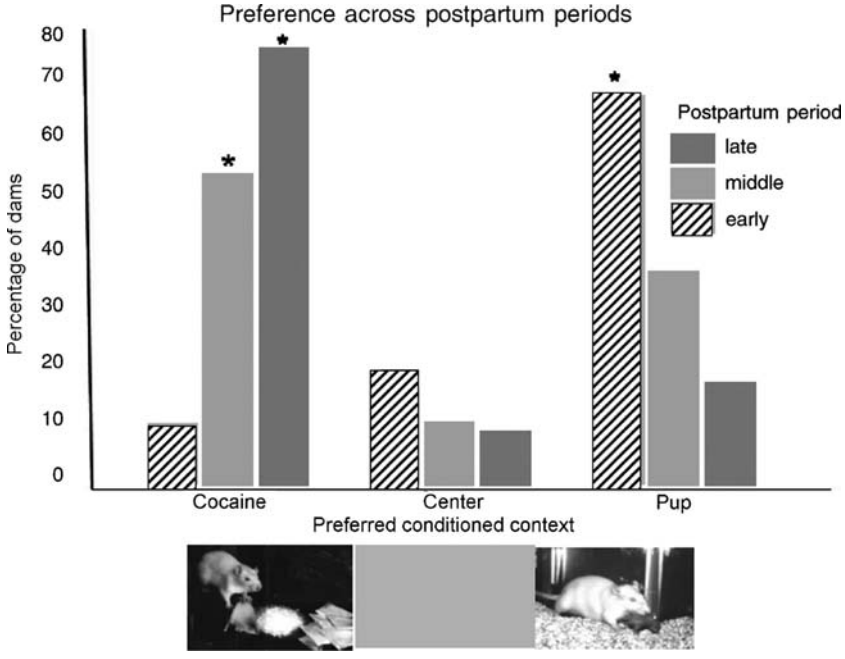
The reward salience of pups across the postpartum period has been further explored with a place-preference paradigm contrasting the response of cues associated with pups versus the highly rewarding neuroactive drug, cocaine (Mattson et al., 2001, 2003). Early in the postpartum period, the majority of the females preferred cues associated with pups over cues associated with cocaine (*Figure 5-5*). Later in the postpartum period, the preference for cues associated with cocaine becomes the dominant response. This paradigm highlights the strength of the pup stimulus as a reward and provides another illustration of the waning of maternal motivation in the late postpartum period.

Formation of an association between pups and pup associated context requires that dams received the full complement of sensory cues from pups while interacting with them. If dams receive only distal cues from pups are made anosmic, or have their ventrum or mystacial pads anesthetized just before the interaction with the litter during the conditioning phase, they do not form a conditioned place preference (Magnusson and Fleming, 1995). The hormones of pregnancy are likely important for conditioned place preference for pup-associated cues in postpartum dams, as virgin females given a regimen of estradiol and progesterone that induced maternal responding do show a place-preference for the pup-associated chamber (Fleming et al., 1994). The neurochemical underpinnings necessary to form the association between the pups and the environment, or at least necessary to display this preference, involves dopaminergic neurotransmission and can be disrupted by dopamine antagonism during the exposure phase even at doses that did not disrupt mother–litter interactions (Fleming et al., 1994).

Mattson et al. (2003) examined the expression of homecage maternal behavior in females that had been tested for their preference for cues associated with pups or cocaine. Regardless of their

Figure 5-5

Postpartum females were conditioned to associate pups with neutral cues in one chamber and on alternate days conditioned to associate the effects of a subcutaneous injection of cocaine with another set of neutral cues in a different chamber (Mattson et al., 2001, 2003). Summary graph comparing the percentage of females that preferred cues associated with pups, cocaine, or a neutral chamber. Three groups were conditioned: early postpartum conditioned days 4–7, tested day 8; mid postpartum conditioned days 6–9, tested day 10; late postpartum conditioned days 12–15 tested day 16. All groups demonstrated a statistically significant conditioning effect over baseline response to the conditioning apparatus. The majority of females in the early group preferred the chamber associated with pups, the mid group was bimodal with half the population choosing pup and half cocaine associated chambers, and most late postpartum dams chose the cocaine-associated chamber. The number of late and mid postpartum females that preferred the cocaine-associated chamber was significantly greater than the number of early postpartum females preferring the cocaine-associated chamber. Significantly more postpartum females preferred pup-associated cues compared to late-postpartum females ($P < 0.05$)

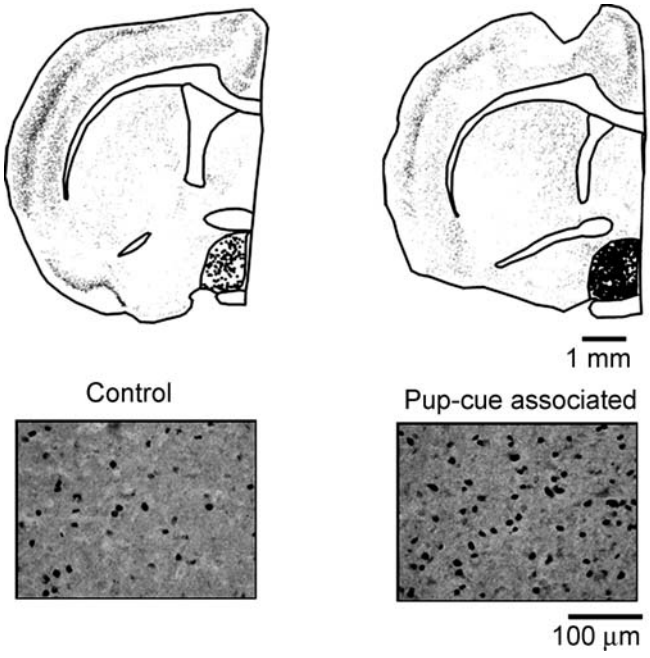


preference for cues associated with these two stimuli, all females were similarly strong in their expression of the consummatory aspects of maternal behavior. Thus, retrieving, nest building, maternal aggression, and nursing behaviors were identical in these groups of females, with different preferences for cues associated with pups or cocaine. The fact that robust and equal expression of maternal behavior could be detected in females that were also demonstrating different preferences suggests that the motivation to seek the pup stimulus (the appetitive component) can be regulated by processes that are, in part, dissociable from the processes underlying the expression of maternal behavior (consummatory components).

To explore the neural substrate that supports maternal motivation, Morrell and colleagues have examined the brains of the females after determining their preference for cues associated with pups, compared with controls using cFos immunoreactive protein as a marker for neural activity ❯ *Figures 5-6* and ❯ *5-7* demonstrate that the mPOA has a statistically significant increase in the number of cFos immunoreactive neurons when the dam is demonstrating a preference for cues associated with the pup,

Figure 5-6

Place-preference conditioning was used to determine the preference of day 10 postpartum maternal, lactating dams for a distinctive environment associated with pups. Control subjects received the same chamber exposure but no unconditioned stimuli. Animals were perfused after 2 h test exposure to the conditioning apparatus and brain sections prepared with cFos immunocytochemistry (Smith et al., 2003; Mattson and Morrell, 2005). Top – anatomically exact Neurolucida-generated illustration of a representative cross-section in the mPOA for each group. A single dot represents a c-Fos-IR neuron; larger dots represent the c-Fos-IR neurons in the medial preoptic area. Below – photomicrograph of a field in the same region. There was a much greater density of Fos-IR neurons in the mPOA of dams that preferred cues associated with pups (right photo and Neurolucida drawing) than that in control subjects (left photo and Neurolucida drawing)

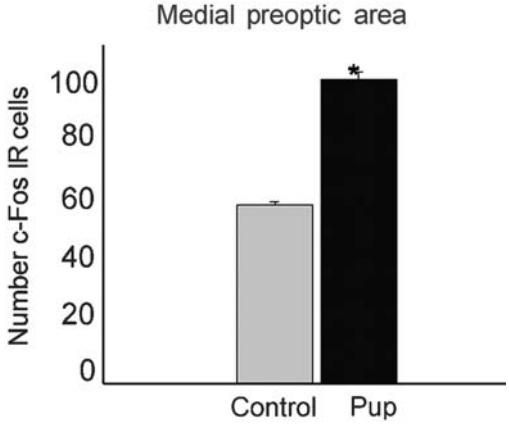


that is when the salience of the pup stimulus is high and that the dam is maternally motivated. Control areas as such as the pyriform cortex or the dorsal striatum showed no such differences, supporting the hypothesis that these neurons are engaged by the preference state of the female, and the salience of the pup-associated cues. Other brain regions including the prefrontal cortex (PFC), NA, and AMYbl also had the basolateral nucleus of the amygdala also had populations that were engaged with the preference for pup-associated cues. These data are the first to demonstrate an engagement of neurons in the mPOA for the purely appetitive components of maternal behavior, in the absence of the pup stimulus (Smith et al., 2003; Mattson and Morrell, 2005).

We know from a wealth of data that the mPOA is key to the expression of maternal behavior (Numan and Insel, 2003). The data presented above extend our understanding of the role of the mPOA in the motivational aspects of maternal behavior by demonstrating a neuronal activation in this region with a purely appetitive measure of motivational status. These data accord well with demonstration that the mPOA is involved in operant responding for delivery of pups (Lee et al., 1999). Thus, the mPOA may have a combined role in recognizing the pup as a highly salient reinforcer and in focusing the consummatory aspects of the behavior. How neuronal subsets within the mPOA carry out this dual function remains to be determined.

Figure 5-7

Histograms from each group represented in *Figure 5-6* showing the mean (±SEM) number of c-Fos-IR neurons, with one group preferring pup-associated cues and control. Asterisk indicates a significant difference from the control group, P < 0.05. The average number of Fos-immunoreactive neurons in the mPOA was 40% greater in pup-associated, cue-preferring dams (black bar; 92 SEM 2.25) than in controls (grey bar; 54 SEM1.04), and differences were statistically significant, P < 0.001



6 Neural Motivation Systems: Interfaces with Maternal Behavior Circuit and Effects of Hormones

The motivation to act maternally is presumed to be regulated by the same neural substrates underlying other types of motivation in rats. Here, we present a summary of this neural substrate and how components of this network are influenced by hormones in virgin rats, with the expectation that this information can be extrapolated to the conditions of pregnancy and lactation.

6.1 Brief Description of Mesolimbic and Nigrostriatal Systems and their Anatomy/Neurochemistry

The basal ganglia is comprised of striatal, pallidal, and associated mesencephalic structures (Heimer et al., 1995). The striatum has a dorsal and ventral subdivision, and the latter includes the NA which has two distinct subdivisions, with the core being more similar to the dorsal striatum, while the shell is more limbic-related (Zaborszky et al., 1985; Zahm and Brog, 1992; Pennartz et al., 1994; Groenewegen et al., 1996). Both striatal subdivisions receive glutaminergic afferents from cortex and thalamus, dopamineric afferents from the mescencephalon, and are constituted of GABAergic projection neurons. The pars compacta of the substantia nigra and the VTA contain DAergic neurons that give rise to the well-known nigrostriatal and mesocorticolimbic projections to the striatum, PFC, and other areas of the forebrain (Heimer et al., 1995). Major efferents targets of the dorsal striatum include the globus pallidus and substantia nigra pars reticulata, while major efferents targets of the ventral striatum include the ventral pallidum and the VTA (Heimer et al., 1995). Generally, the dorsal striatum and related structures are considered important for the programming and execution of voluntary movement, while the ventral striatum and related structures are considered more involved in reward-based responding or motivational processes (Groenewegen et al., 2003; Kelley, 2004). The dorsal structures of the system, however, also probably participate in certain aspects of reward-based responding (Voorn et al., 2004).

The mesolimbic DAergic projections to the NA, PFC, and amygdala are the best understood structures that mediate appetitive/motivational processes (Koob et al., 1987; Kalivas and Barnes, 1994; Wise, 1998;

Robbins and Everitt, 1999; Spanagel and Weiss, 1999). The NA is critical for the mediation of reward processes, containing separable neuronal populations responsive to pharmacological and natural rewards (Carelli et al., 2000; Neisewander et al., 2000; Carelli and Wondolowski, 2003), including pups (Fleming and Walsh, 1994; Lonstein et al., 1998; Stack et al., 2002). The functional repertoire of the medial PFC includes cognitive complexity and emotional tone, making it an excellent candidate to initiate the efferent activity related to motivated behavior (Isaac et al., 1989; Birrell and Brown, 2000; Franklin and Druhan, 2000a, b; Neisewander et al., 2000; Brown and Bowman, 2002). The literature suggesting that the PFC participates in the expression of maternal behavior is limited (Numan and Insel, 2003), although recent functional MRI work in humans shows increased responses in the anterior cingulate of mothers after hearing infant cries (Lorberbaum et al., 1999). Because the infralimbic, prelimbic, and cingulate cortex are engaged by natural as well as pharmacological stimuli (Schroeder et al., 1999; Mattson and Morrell, 2005), these regions may have a general reward response/recognition capacity.

Also important are afferent projections from the PFC, hippocampus, and amygdala *to* the NA. Both the GABAergic and glutametergic projections of these structures are of functional significance in reward processes (Pifl et al., 1993; Cornish et al., 1999; Kalivas and Nakamura, 1999; Li et al., 1999; Rosenkranz and Grace, 2001). These neural substrates are activated by many stimuli, including pharmacologic and natural rewards (Everitt and Wolf, 2002; Kelley and Berridge, 2002), and these diverse reward processes are thought to be mediated by specialized subcircuits or channels within and between these neural components (Pennartz et al., 1994; Ikemoto and Panksepp, 1999; Carelli et al., 2000; Carelli and Wondolowski, 2003).

The basolateral amygdala is well established to be involved in conditioned reward and reinforcement processes (Hiroi and White, 1991; Brown and Fibiger, 1993; Parkinson et al., 2001; Fuchs et al., 2004). Furthermore, it is engaged by both pharmacological and natural rewards, including pup stimuli (Brown et al., 1992; Schroeder et al., 1999; Neisewander et al., 2000; Mattson and Morrell, 2005).

6.1.1 Additional Areas of Note for Maternal Motivation

The mPOA is involved in the response to natural rewards in rats, including chocolate, sexual partners, and offspring (Balthazart et al., 1998; Hull et al., 1999; Schroeder et al., 1999; Lee et al., 2000; Smith et al., 2002; Numan and Insel, 2003; Mattson and Morrell, 2005). There is also a strong case that the mPOA has a remarkably analogous dual functional role for the appetitive and consummatory aspects of male sexual behavior and for maternal behavior (Balthazart et al., 1998; Hull et al., 1999; Numan and Insel, 2003). Known neuroanatomical connections of the mPOA connect it with components of the reward system discussed above and to the lesser understood motor regions of the mesencephalon, suggesting that it has sufficient network connections to support an integrated appetitive/consummatory function (Fahrbach et al., 1986; Simerly and Swanson, 1986, 1988–1989; Swanson, 1988–1989; Corodimas and Morrell, 1990; Saper, 2000).

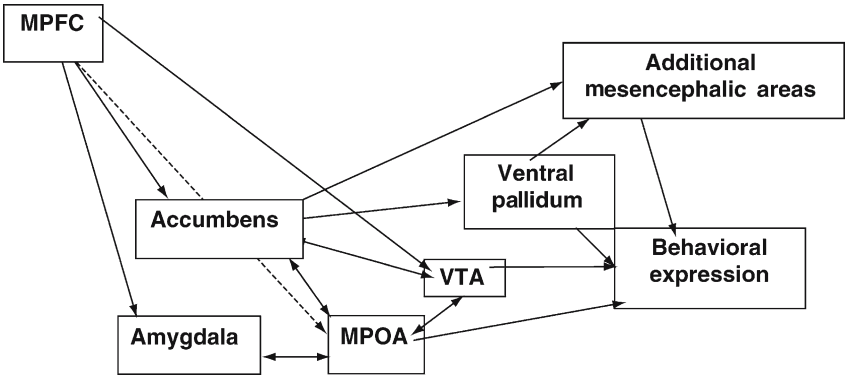
6.1.2 Reward System Hierarchy

Based on classical models of organization, the neural structures involved in motivation appear to be hierarchically organized (Groenewegen et al., 1996; Groenewegen and Uylings, 2000; Saper, 2000; Eichenbaum and Cohen, 2001). The associated figure presents one example of the possible efferent flow of activity through the neural components of such a neural circuit (*Figure 5-8*). This allows us to focus on the components of the system that are additional to the well studied mesolimbic DAergic projections, which are afferent to cortex and accumbens.

The sensory stimulation provided by natural rewards enters through particular and limited channels (sensory afferents), which vary depending upon the physical nature of the natural stimulus. In the case of the pup as natural stimulus, somatosensory and olfactory components are notable. This sensory information must reach the cortex, after thalamic or other (olfactory) processing, but it is also possible that such sensory information could enter this circuit at several additional points, for example, including the amygdala, POA, and the VTA, independent of thalamic processing. Responding to motivating stimuli

Figure 5-8

Schematic diagram of selected components of the neural circuit that mediates the expression of maternal behavior. Focus is on the efferent outflow of the system's components, presumably mediating the active expression of the behavioral sequences



must initially involve the PFC, which soon after receiving stimulus-specific sensory information and association memories via projections from other cortical areas including the sensory and parietal association areas, initiates a descending cascade. These corticofugal projections from the medial PFC to the NA, VTA, basolateral amygdala, and mPOA, are glutamatergic (Park et al., 2002; McFarland et al., 2003). The behavioral expression of motivation or reward response is then due to subsequent outflow of limbic and POA structures via the ventral pallidum and mesencephalic regions, and these efferents are either glutametergic or GABAergic. The consideration of reward based responses, in addition to the classically considered dopamine mediated responses, must include processes regulated by glutamate and GABA. These are generally less frequently examined in the context of maternal motivation or expression of maternal behavior and provide an important area for future focus.

6.2 Role of Dopamine and the Nigrostriatal and Mesolimbic Systems on Maternal Behavior and Motivation

Dopamine is the most thoroughly examined neurotransmitter with regard to maternal behavior in rodents. The general conclusion from this body of work is that increased DAergic neurotransmission in the nigrostriatal, and particularly mesolimbic, systems is necessary for active components of maternal behavior such as retrieval and licking the pups, whereas its inhibition is required for quiescent nursing. This has been gleaned after systemic injections of DAergic drugs. Injection of the mixed DA receptor antagonist haloperidol eliminates retrieval and licking of pups in most dams (Giordano et al., 1990; Stern and Taylor, 1991), and its effects can be reversed with concomitant treatment with the DA agonist apomorphine (Giordano et al., 1990). Notably, even though haloperidol-treated dams do not retrieve pups, they may readily approach and sniff them, and leave the nest for food (Giordano et al., 1990), indicating that these impairments are not due to generalized motor impairments. The fact that dams may still remain in contact with scattered pups and even nurse them (Giordano et al., 1990) provides evidence that the dams remain motivated to act maternally. Haloperidol-treated dams also become quiescent and begin to nurse sooner, and nurse for longer durations, which results in greater milk letdown and litter weight gains (Stern and Taylor, 1991). In fact, rats do not even need to be maternal or lactating for DA inhibition and pup stimulation to elicit kyphosis (Stern, 1991). The D1 and D2 receptors appear to be equally involved in mediating these effects and antagonists to either receptor produce these changes in maternal behaviors (Hansen et al., 1991b; Silva et al., 2001; Byrnes et al., 2002). These DA antagonist effects on maternal behaviors are not exclusive to rats, as haloperidol produces similar effects in

both sexes of the biparental prairie vole (Lonstein, 2002). Given all of these results, Numan and Insel (2003) noted that it is surprising that a lack of maternal care has not been even anecdotally reported in female mice with a selective deletion of dopamine receptors.

Although dams given DA antagonists still readily make contact with pups, these antagonists also produce deficits in maternal motivation that can be observed under some testing conditions. Muzzling of dams prevents their perioral contact with pups, but does not prevent them from attempting to make contact with pups with their snouts and paws (Stern and Johnson, 1989). Low doses of haloperidol that do not disrupt maternal retrieval or licking in unmuzzled dams reduce pushing and handling of pups in muzzled dams, suggesting that a basal level of DAergic neurotransmission is necessary for continued maternal motivation to contact inaccessible pups, and possibly accessible pups as well (Stern and Keer, 1999).

DA antagonists act centrally to produce their effects on maternal behavior and DA antagonists that act only peripherally have no effect (Stern and Taylor, 1991). This is in support of the early literature that showed various degrees of disrupted maternal care after chemical depletion of neural catecholmines with ventricular injection of 6-hydroxydopamine (6-OHDA) (Sorenson and Gordon, 1975; Rosenberg et al., 1977; Piccirillo et al., 1980) or lesions of the ascending catecholaminergic projections (Steele et al., 1979; Bridges et al., 1982). The first work examining a particular role for the nigrostriatal systems in maternal behavior was by Numan and Nagle (1983). Large, but not small, bilateral lesions of the substantia nigra and surrounding area disrupted all components of maternal behavior, but also were generally debilitating. A unilateral knifecut of the lateral projections of the POA combined with a lesion of the SN ipsilateral or contralateral to the knifecut produced similar effects, implying that projections between the POA and SN are necessary for maternal care. Maternal behavior in dams with knifecuts and lesions slowly recovered within a few days after surgery, however, concomitant with an improvement in lactational performance and overall health. Therefore, the nigrostriatal system is probably not absolutely necessary for the display of maternal behavior, and postsurgical compensatory mechanisms can supplant any functions that this system normally contributes.

Compared with the nigrostriatal system, the role of the mesolimbic system in maternal behavior has received much more attention. Large premating (Gaffori and LeMoal, 1979) or postpartum (Numan and Smith, 1984) radiofrequency or electrolytic lesions of the VTA and surrounding area severely disrupted all components of maternal care, but similar to dams that receive POA lesions, VTA-lesioned dams still approach and sniff the pups. Because dams with bilateral VTA lesions were often physically debilitated, Numan and Smith (1984) conducted further studies in which postpartum dams received a knifecut of the lateral connections of the mPOA or the lPOA, along with a unilateral VTA lesion on the ipsilateral or contralateral side. Maternal behavior was significantly impaired after all knifecuts, although dams with the mPOA knifecuts and contralateral VTA lesion were the most impaired. Nursing behavior was not more impaired than that produced from other knifecuts/lesions and POA–VTA projections appear to be more likely involved in active maternal behaviors than nursing. A role specifically for the DAergic projection of the VTA was provided by Hansen et al. (1991b) who demonstrated that postpartum 6-OHDA lesions of the VTA eliminate retrieval in most dams, but leave nest building and nursing intact (Hansen et al., 1991b). Preparturitional lesions completely abolished all maternal care, but dams were also physically debilitated (Hansen et al., 1991b). When lesions were made before mating, avoiding postpartum physical debilitation, there were no significant effects on retrieval, although it was severely impaired a few dams (Hansen et al., 1991b). The normal display in most dams may be due to compensation and recovery that might have occurred during the 8 weeks between surgery and parturition.

The role of the termination points of the mesolimbic DA system in maternal behavior has also been examined. Interactions with pups elicit Fos expression in the shell region of the NA (Lonstein et al., 1998; Stack et al., 2002) and this maximal Fos response requires integrity of the mPOA (Stack et al., 2002). Electrolytic lesions of the ventral striatum performed during midpregnancy have little effect on mother–litter interactions immediately after parturition (Lee et al., 1999), but NA-lesioned dams show impairments in all aspects of maternal behavior if tested repeatedly thereafter (Smith and Holland, 1975; Lee et al., 2000; Stack et al., 2001). These effects are probably due to DAergic neurotransmission in the NA because selective postpartum 6-OHDA lesions of the ventral striatum produce similar results

(Hansen et al., 1991a; Hansen, 1994). However, when 6-OHDA-lesioned dams were separated from the pups for 4–6 h prior to testing, retrieval was completely normal (Hansen, 1994), and increasing maternal motivation through separation from pups can apparently override the effects of impaired mesolimbic neurotransmission. It also indicates that sensory cues from pups increase DAergic activity in the ventral striatum in a manner that elicits maternal responses. Indeed, interactions with pups increase extracellular DA release in the NA (Hansen et al., 1993), particularly during bouts of pup licking (Champagne et al., 2004). Furthermore, DA release begins to rise *before* dams begin licking (Champagne et al., 2004) and DA release in the NA might be involved in the dam's transition from one maternal behavior to another. Importantly, 6-OHDA or electrolytic lesions of the dorsomedial striatum, which receives its primary projections from the SN, do not affect maternal behavior (Kirkby, 1967; Numan and Nagle, 1983; Hansen et al., 1991a).

Reducing DAergic neurotransmission in the ventral striatum by directly infusing the DA antagonist *cis*-flupenthixol impairs retrieval and enhances quiescent nursing (Keer and Stern, 1999), with infusions the NA shell producing the greatest effects (Keer and Stern, 1999). However, similar effects have also been found after infusions of the D2 receptor antagonist pimozide into the NA core (Silva et al., 2003). Pharmacological increases in DA receptor activity also impair maternal care. NA core infusion of the DA reuptake inhibitor cocaine reduces retrieval of pups from a runway extension of the home cage and impairs nest construction, with lesser effects found with NA shell infusions (Vernotica et al., 1999). These results are consistent with the inefficient retrieving of pups and reduced time spent in the nest by female mice with a deletion of the DA transporter, which chronically elevates extracellular DA (Spielewoy et al., 2000). Competing behaviors (burying, rearing, and self-grooming) were increased in these mice and thus the impairments may not be specific to maternal behavior. Systemic injection of the DA agonist apomorphine also impairs retrieval, concomitant with increased competing behaviors (Stern and Protomastro, 2000). Therefore, substantially decreased or increased DAergic neurotransmission in the NA and elsewhere is detrimental to active maternal behaviors such as retrieval.

Two recent studies examined intracellular DAergic activity in the striatum of maternal rats, with the aim of correlating changes in DAergic activity with maternal state, but were somewhat inconclusive. Olazabal et al. (2004) examined virgin females without exposure to pups, maternally-sensitized virgins, virgins that did not show maternal behavior after exposure to pups, and day 4 postpartum dams, to find that DAergic activity in the NA was similar between groups. They also found that DAergic activity in the NA was higher in adult rats than in juveniles, which may be associated with age-related differences in the propensity to spontaneously display maternal behavior. In another study, Lonstein et al. (2003) examined DAergic activity in tissue samples from the NA of virgin females or females that were sacrificed during early- and late-pregnancy, soon after parturition, or early and late-lactation, and found no differences between groups. However, in the dorsolateral striatum, DAergic activity was highest during late pregnancy and soon after parturition. Because this area of the striatum is electrophysiologically responsive to perioral stimulation (Mittler et al., 1994), changes in DAergic activity here might be involved in the onset of oral maternal behaviors emerging at parturition (Lonstein et al., 2003).

6.3 Changes in Dopamine Receptors Across Pregnancy and Lactation

There has been limited examination of neurotransmitter receptor or transporter expression across pregnancy and lactation, although naturally-occurring changes in the distribution or numbers of these proteins are likely involved in changes in maternal responsiveness. Dopamine receptors have been examined using in vitro autoradiography during early and late pregnancy, with reference to diestrous females and males (Bakowska and Morrell, 1995). Compared with males, late-pregnant females showed fewer D_1 and D_2 receptors in the striatum and NA. Late-pregnant females also showed fewer D_2 receptors in the olfactory tuberacle than females in either diestrus or early pregnancy. There were no differences in many other regions including the SN and VTA, or regions best understood to participate in the mediation of maternal behavior such as the mPOA and MeA. In general, the decreases in late pregnancy were 11–27% compared with other groups. The magnitude of these changes is less than typical after pharmacological intervention or

with pathology, but similar to the down-regulation of the receptors seen with other physiological events such as aging or estrogen treatment. During late pregnancy, voluntary activity decreases markedly, and grooming of the ventral body surface increases. Changes in the motivational state of the female and preparation for new motor patterns are also underway. Perhaps these region-specific cases of down-regulation are related to increased dopamine secretion that then participates in these preparatory events (Bakowska and Morrell, 1995).

6.4 Influences of Ovarian and Pituitary Hormones on Nigrostriatal Neurotransmission

DA neurotransmission within the nigrostriatal, and particularly mesolimbic, systems is strongly implicated in the control of maternal behavior and motivation. How ovarian and pituitary hormones alter DA neurotransmission across pregnancy and lactation in a manner that alters maternal responsiveness is generally unknown, but insight may be gained from the literature investigating hormone effects on these DA systems in nonpregnant and nonlactating rats.

Elevated levels of circulating estrogens established naturally or exogenously generally increase DA neurotransmission in the striatum (Becker and Ramirez, 1981; Crowley et al.,1978a; Tansey et al., 1983; Becker and Beer, 1986; Becker, 1990; Dluzen and Ramirez, 1990; Morissette et al., 1990b; Fernandez-Ruiz et al., 1991; McDermott, 1993; Pasqualini et al., 1995). Similarly, behavioral responses controlled by the nigrostriatal system, including amphetamine-, cocaine-, or electrical stimulation-induced locomotor behavior, are also potentiated by estrogens (e.g., Becker, 1990; Sell et al., 2000). Both the SN and striatum are sensitive to estrogens, and infusion into either site affects DA release in the striatum (Pasqualini et al., 1995), as well as postural and motor regulation in rats (Joyce and Van Hartesveldt, 1984; Roy et al., 1990). However, there are also many negative findings on estrogen's ability to increase nigrostriatal DA function (Gordon et al., 1977; Lofstrom, 1977; Tyler et al., 1979; Euvard et al., 1980; Dupont et al., 1981; Di Paolo et al., 1982a; Fields and Gordon, 1982; Kazandjian et al., 1988; Pasqualini et al., 1995; McDermott et al., 1997; Zsarnovszky et al., 2000) and one can conjecture that methodological differences in dose or length of estrogen treatment could explain the discrepancies.

Estrogenic effects on striatal DA neurotransmission likely result from changes that occur both presynaptically and postsynaptically. For example, physiological increases in circulating estradiol increase presynaptic DA release (Becker, 1990; Xiao and Becker, 1998; Xiao et al., 2003). Estradiol also increases the density of DA receptors in the striatum (Di Paolo et al., 1982a, 1988; Hruska and Pitman, 1982; Hurska and Nowak, 1988), although a decrease in expression or no changes have also been reported (Levesque et al., 1992; Lammers et al., 1999). The DA transporter, which allows DA reuptake from the synapse and termination of DA neurotransmission, also rapidly increases in number in the striatum and substantia nigra pars compacta (SNpc) after treatment with estradiol (Morissette et al., 1990; Morissette and Di Paolo, 1993; Bosse et al., 1997), or during proestrus (Morissette and Di Paolo, 1993; Bosse et al., 1997). It has also been reported that estrogens decrease DA transporter activity in the SNpc (Bosse et al., 1997) and striatum (Disshon et al., 1998; Rehavi et al., 1998).

Less is known about the effects of progesterone on the nigrostriatal system, but it appears to have dose- and time-specific effects. Low doses of progesterone reduce DA release from striatal tissue, whereas higher doses increase it (Becker et al., 1984; Dluzen and Ramirez, 1989a, b; Cabrera et al., 1993), and progesterone increases striatal DA release 2 and 12 h after injection, but reduces it 24 h later (Dluzen and Ramirez, 1984). Interestingly, pulsatile progesterone is more effective than continuous exposure in stimulating DA release (Dluzen and Ramirez, 1987), possibly relevant to different times of the reproductive cycle when the hormone can be either transiently released (as during estrous) or chronically released (as during pregnancy). It is unclear what the effects of progesterone are on striatal DA transporter activity (Morissette and Di Paolo, 1993; Rehavi et al., 1998).

The mechanism by which ovarian hormones influence the nigrostriatal DA system is unclear because this system does not appear to express nuclear ERs or estradiol-induced progestin receptors (e.g., Sar, 1988; Kritzer, 1997; Mufson et al., 1999; Creutz and Kritzer, 2002; Lonstein and Blaustein, 2004). Instead, ovarian hormones probably act rapidly, at least in part, via membrane-bound receptors on either DAergic cell

bodies in the mesencephalon and/or locally within the striatum to affect DA release (Chiodo and Caggiula, 1980; Dluzen and Ramirez, 1989a, b; Becker, 1990; Castner et al., 1993; Mermelstein et al., 1996; Ramirez and Zheng, 1996; Xiao and Becker, 1998; Xiao et al., 2003). Nonetheless, some long-term and presumably genomically-based effects of estradiol may also occur (e.g., Chiodo and Caggiula, 1980). It may do this by acting on non-DAergic neurons in the SN that do express ER. In fact, the nigrostriatal system contains a rich GABAergic network originating in the pars reticulata that inhibits DA release by acting directly on SNpc neurons, and by sending projections to the striatum where with local interneurons, it can influence DA release (e.g., Kilpatrick et al., 1980; Kubota et al., 1987; Reid et al., 1990; Tepper et al., 1995; Paladini et al., 1999; Rodriguez and Gonzalez-Hernandez, 1999). Estradiol reduces GABAergic activity in these systems (Gordon et al., 1977; Tyler et al., 1979; McGinnis et al., 1980; Nicoletti et al., 1982, 1985).

Pituitary hormones may also increase nigrostriatal DAergic activity and intracerebroventricular infusion of oxytocin or arginine-vasopressin (AVP) increase striatal DA release (Schulz et al., 1979), although it is unknown where they act to produce this effect. The effects of prolactin in this system have also been investigated, but are highly discrepant (Drago et al., 1981; Chen and Ramirez, 1982; Laping and Ramirez, 1988; Cebeira et al., 1991; Hernandez et al., 1994).

In sum, ovarian and pituitary hormones alter DAergic activity in the nigrostriatal system. Although some of the literature may be contradictory, estradiol seems particularly potent in increasing mesolimbic DA function. Along with contributory effects of progesterone, OT, and PRL, nigrostriatal DAergic activity is likely to be increased by the end of pregnancy when maternal behavior emerges (Lonstein et al., 2004).

6.5 Influences of Ovarian and Pituitary Hormones on Mesolimbic Neurotransmission

Unfortunately, the literature on the effects of hormones on mesolimbic DA neurotransmission in nonpregnant and nonlactating rat is frequently inconsistent and provides only limited insight for the field of maternal care. Cells of the NA do express ER, but not nearly as many as compared with ER-rich areas such as the medial preoptic nucleus (Pfaff and Keiner, 1973; Mufson et al., 1999). Furthermore, the VTA has not been reported to express ER at all, although the excitability of these cells is altered by estradiol (Sakamoto et al., 1993). Nevertheless, ovariectomy reduces DA content in the VTA (Russo et al., 2003) and potassium-stimulated DA release in NA is highest during diestrus when circulating hormones are low, and reuptake is enhanced during proestrus when they are high (Thompson and Moss, 1997). However, DA turnover in the NA has been reported to be highest (Shimizu and Bray, 1993) and extracellular DA the lowest, during proestrus (Shimizu and Bray, 1993). Virtually opposite results have also been reported (Fernandez-Ruiz et al., 1991; Kazandjian et al., 1988). Functionally, there is no influence of the stage of the estrous cycle on the ability of haloperidol to induce catalepsy (Kazandjian et al., 1988), but estrogen-treated female rats do sensitize to cocaine faster than those not given the hormone (Hu and Becker, 2003). While a single injection of estradiol has no effect on DAergic activity in any site measured (Lofstrom et al., 1977; Crowley et al., 1978b), a few days of treatment can either decrease DA turnover in the NA (Shimizu and Bray, 1993), increase DA synthesis in the NA (Hernandez et al., 1991), or have no effects (Gordon et al., 1977). In cases where estrogens reduce evoked DA release from the NA, it may slow clearance of the neurotransmitter from the synapse (Thompson and Moss, 1994; Thompson, 1999). A few days of estradiol also increases the number of cells expressing TH-ir in interfascicular region, but not paranigral region, of the VTA (Zsarnovszky et al., 2000). An even longer (2-week) regimen of estradiol reduces DA content in NA and VTA, but has no effects on turnover (Dupont et al., 1981), although this chronic regimen reduces DA content in the NA of hypophysectomized females (Di Paolo et al., 1982b), pointing to an influence of PRL. Note that very short-term effects of estradiol can also be found, with direct infusion into NA rapidly increasing DA release (Thompson and Moss, 1994). Similar to the nigrostriatal system, the GABAergic innervation of the VTA likely contributes to estradiol's effects on DAergic activity in the mesolimbic system (Gordon et al., 1977; McGinnis et al., 1980).

Chronic estradiol also influences DA receptor expression, having little effect on D1 and D2 receptor expression in either the VTA or NA, but possibly influencing the D3 receptor in the VTA (Lammers et al.,

1999; Zhou et al., 2002). D2/D3 receptor-mediated G-protein activation is reduced in VTA, but not the NA, after 1 week of EB treatment (Febo et al., 2003). The density or affinity of DA transporter sites in the NA is not modified by 2 weeks of EB treatment (Morissette and Di Paolo, 1993; Thompson et al., 2000), but is reduced in the NA shell after 3 weeks of estrogen treatment (Rehavi et al., 1998). Three months after ovariectomy, DA transporter binding is decreased in NA and its mRNA is increased in the VTA and these effects cannot be reversed with 2 weeks of estradiol treatment (Bosse et al., 1997).

There is little known about progesterone's effects on mesolimbic DA neurotransmission. DAergic cells of the VTA do not express nuclear progestin receptors (Sar, 1988; Lonstein and Blaustein, 2004), but may express PR mRNA (Curran-Rauhut and Pedersen, 2002), and there have been no reports of nuclear PR in the NA. Instead, membrane-bound progestin receptors may influence mesolimbic function. It is also likely that progesterone influences mesolimbic DA activity indirectly through non-DA cells that project to this system or by acting through its metabolites on the benzodiazepine binding site of the $GABA_A$ receptor (Frye, 2001). In any case, progesterone prevents estradiol's effects on DA turnover in NA (Shimizu and Bray, 1993), but it has also been reported to have no effects (Crowley et al., 1978b). Two weeks of progesterone is without apparent effect on the density of DA transporter sites in the NA (Morissette and Di Paolo, 1993), but 3 weeks of progesterone treatment reduced DA transporter binding in the NA (Rehavi et al., 1998).

Oxytocin binding sites are found in the NA (De Kloet et al., 1986), but apparently not the VTA. OT receptors are likely present in the VTA, though, because infusion of oxytocin here induces grooming (Kaltwasser and Crawley, 1987), though increased mesolimbic DA release (Drago et al., 1986; Stivers et al., 1988). Antagonism of OT in the VTA of parturient dams also inhibits maternal response (Pedersen et al., 1994), but there has apparently been no examination of mesolimbic DA release after OT infusion into the VTA or NA. Intracerebroventricular prolactin decreases DAergic activity and D1 receptor density in the limibic forebrain of male rats (Hernandez et al., 1994), and increases DOPAC output when infused into the NA, but not VTA (Chen and Ramirez, 1988). While cells expressing mRNA for either the long or short form were not found in the VTA (Bakowska and Morrell, 1997, 2003), fibers immunoreactive for the prolactin receptor are found in this region (Roky et al., 1996).

7 The Future – Functional Integration

It is clear that a substantial amount of information exists regarding the endocrinology, neuroendocrinology, neuroanatomy, and neurochemistry underlying the onset and maintenance of maternal behavior in rats. It is also clear that the volume of information dramatically decreases as one progresses from the endocrinology, to the neuroendocrinology, to the neurochemistry of this behavior. As noted above, future areas of focus that might be particularly fruitful to our understanding of maternal care might include a better comprehension of how progesterone both inhibits and facilitates the onset of maternal behavior, how the numerous areas of the brain involved in this behavior interact as a larger neural circuit, particularly to behavioral outflow, and how the many less-explored hormones secreted during pregnancy and parturition might influence maternal care and the coordination of its behavioral and physiological aspects. Significant focus on what hormones and neural sites are involved in maternal motivation, which is critical for the initiation and maintenance of the expression of the behavior, could be very fruitful. The literature detailing the effects of hormones on the nigrostriatal, and particularly the mesolimbic, DA systems points to these pathways as malleable substrates for hormone-induced changes in maternal motivation and behavior. The details of how pregnancy, parturition, and lactation modify these systems require examination.

Advances in our understanding of the hormonal and neurochemical basis of maternal behavior have been made with the use of relatively new genetic knockout technology. One of the earliest such models was the *fosB* gene knock out mouse, which has severe deficits in postpartum maternal behavior (Brown et al., 1996). Currently, many models with targeted disruption of specific genes can be found in the literature. These include knockout models of either form of the ER, the progestin receptor, the nitric oxide synthase gene, prolactin receptor genes, a variety of genes related to neurotransmitter systems, and genes that are

part of other transcription systems or imprinting processes (Brown et al., 1996; Gammie and Nelson, 1999; Ogawa et al., 1998; Kelly et al., 2001; Leckman and Herman, 2002; Schneider et al., 2003). Some of these gene disruptions interfere with the behavior or closely related functions (e.g., ER or prolactin receptor knockouts), while others facilitate it (e.g., progestin receptor knockout facilitates male parental behavior). At this stage in the development of the technology, all of these models completely inactivate the genes throughout the entire organism and during its entire development and adult life. Data gathered by these methods is rich and intriguing, but its interpretation is complex. As elegantly discussed by Rene Hen and his colleagues (Gingrich and Hen, 2000), in addition to simple loss of function, these models are also subject to a wide variety of plastic or compensatory changes leading to the altered functional state of the knockout animal. Advances in technology allowing for temporal- and region-specific knockout (referred to as conditional knockouts), or in the future, knockin models (Tonegawa et al., 2003; Champtiaux and Changeux, 2004), will be improved and valuable tools to explore the basis of maternal behavior.

Many studies have fruitfully used visualization of immediate-early genes or their products (e.g., *c-fos*) as a tool to survey the populations of neurons activated during maternal behavior (Numan and Insel, 2003). This approach, however, has little temporal resolution. Notable limits on progress in understanding maternal behavior can be seen in the field from the lack of understanding of the real time events and the coordinated and sequenced activity across neural components necessary for maternal behavior. Particularly useful would be a functional circuit analysis with electrophysiological approaches, with the goal of moving toward the more complex analysis currently underway in such structures as the hippocampus, amygdala, and isocortex (Pare and Collins, 2000; Buzsaki, 2004).

Functional imaging may also offer a means of simultaneously assessing the entire neural circuit mediating maternal behavior. The first paper dealing with stimulus responses of postpartum females using the tool of functional magnetic resonance imaging has examined the response of postpartum females to sucking by pups, or to the psychostimulant cocaine (Ferris et al., 2005). Relationships between outcomes using these different approaches in rats should provide fruitful links to data gathered from humans expressing parental behaviors and motivation. Expanding the use of these more recently-devised approaches may also help the field in our quest to adapt what we learn from maternal behavior and consider it as a broader model. That is, a prototypical complex behavior from which we may learn generalizable, fundamental concepts that will inform models of other complex behaviors.

Parental behavior directed toward offspring can uniquely help or materially harm the young and with life-long consequences. As researchers, struggling with the biological fundamentals of our models, we must not loose sight of the ideas that our understanding from the rodent model of maternal behavior may inform the human condition to benefit both parents and offspring during this critical period.

Acknowledgments

The authors would like to thank Dr. Jill B. Becker for helpful comments on some sections of this chapter.

Abstract: This chapter reviews current understanding and hypotheses in social behavior from molecular mechanisms of social feeding in *Caenorhabditis elegans* to social cognition in humans. The influential roles of steroids and neurohormones on the neural circuitry of social behavior are emphasized.

1 Introduction

Affiliation is the basis of all social units, from membership in a colony, troupe, or hive, to the selective attachments found in parent–offspring bonds, pair bonds, or other nonfamilial bonds. The complexity of the expression of affiliative behavior ranges broadly from aggregation behavior in *Caenorhabditis elegans* to the organization of human societies. The most basic definition of affiliation includes any prosocial behavior that brings two or more individuals into close proximity. Affiliation involves a complex set of processes including sensory detection of conspecifics, recognition of familiar individuals, and motivation to initiate proximity or contact. In addition, incompatible processes such as aversion or aggression must be suppressed. Here, we discuss the neuroendocrinological, molecular neurobiological, and neurochemical mechanisms underlying various components of affiliative behavior. We draw from studies on a variety of species to highlight unifying themes in the regulation of affiliative behavior.

2 A Brief Historical Context for the Study of Affiliation

Studies of the biological basis of affiliation began in the 1920s, with a focused interest on maternal behavior. Affiliation research dramatically increased throughout the 1990s (Levine et al., 1997), with a broadened emphasis on other forms of attachment in addition to the mother–infant bond, such as pair bonding and colony membership.

Historically, there have been two main approaches to investigating the mechanisms underlying affiliative behavior: behavioral endocrinology and functional neuroanatomy. Both approaches have been crucial in formulating our current understanding of the biological mechanisms of affiliation. Behavioral endocrinologists investigate the powerful relationship between changes in hormone concentrations and changes in behavior and manipulate hormone concentrations to determine cause and effect relationships. One of the earliest examples of this involved a study of prolactin-induced maternal behavior in birds and rats (Riddle, 1935a, b). In contrast, functional neuroanatomists investigate the role of different brain areas in the expression of behavior. A classic example of this approach is Michael Numan's (Numan et al., 1977) influential work demonstrating that knife cuts disrupting the medial preoptic area (MPOA) function block maternal behavior.

Within the past 30 years, these two approaches have merged to create a more unified field of Behavioral Neuroscience, which encompasses a wide range of topics including genetics, molecular and cell biology, neuroanatomy, and neuroendocrinology. Today, researchers in this area seek to understand the integration of hormonal states and neural circuits in regulating complex behaviors in variable genetic and environmental backgrounds. An example integrating these approaches involved injecting prolactin into the MPOA and observing increases in maternal behavior in steroid-primed rats (Bridges and Freemark, 1995). The advent of new experimental tools has allowed the behavioral neuroscientist to further explore the molecular neurobiology of affiliation. These tools include transgenic animals (knockouts), viral vector gene transfer, antisense, and microarray technology. With the rapid development of bioinformatics, behavioral neuroscience is branching out and seeking companionship in behavioral genetics (fruit fly, *C. elegans*, etc.) and neurogenomics. Interactions among researchers in these fields hold great promise for elucidating neurobiological mechanisms of affiliative behavior.

3 The Point of Social Behavior

A unifying theme across species that exhibit social behavior is that these species do so in response to stress (Wilson, 2000; Sokolowski, 2002). The simplest prosocial behavior is that of the single-celled prokaryotes like the bacterium *Myxococcus xanthus*, and the social amoeba, *Dictyostelium discoideum*. Both these species

aggregate in response to starvation stress to form fruiting bodies. In both cases, only some of the original cells go on to reproduce after this event, meaning that some cells sacrifice their genes for the "greater good" (species survival as opposed to individual survival, i.e., kin selection). Although there are cheaters in this scenario (Strassmann et al., 2000; Velicer et al., 2000), the cost of social cooperation might provide the benefit of increased fitness to genetically similar "cooperative" individuals. Regardless of an organism's awareness of it, prosocial behavior has a point: it is an evolutionary survival strategy.

While it may come across as a debatable model system for behavioral neuroscience, the single-celled organism – with no nerve cell, much less an entire nervous system – serves as an excellent reminder of the molecular nature of all behaviors. From the simplest "social" aggregation of single cells via sticky surface proteins (Rainey and Rainey, 2003) to the complex angst of the human teenager in the throes of love, all social behavior, no matter how complex, is a result of specific molecular interactions in the context of cells and systems.

4 Invertebrate Model Systems Informing the Molecular Biology of Social Behavior

4.1 The Roundworm

The roundworm, *C. elegans*, has become an informative model of the molecular neurobiology of social behavior. Its genes are easily manipulated and it has a very well-defined neuroanatomy, with precisely 302 neurons of known developmental origin and connectivity. It has become a model for studies of locomotion, sensory systems, survival, reproduction, learning and memory, and drug-related and most recently, social behaviors (Rankin, 2002).

4.1.1 Natural Variation in Social Behavior

In natural populations of *C. elegans*, individuals display one of these two responses to a food stimulus: solitary or social feeding. De Bono and Bargmann (1998) traced the variation in this behavior to a single gene that varies across strains of worms: *npr-1*. This gene encodes a G-protein coupled neuropeptide Y receptor-like protein (NPR-1). Interestingly, the mammalian homologue, the neuropeptide Y receptor, is also involved in feeding behavior. The variation in the *npr-1* gene across strains with different behavior is a single base-pair modification that results in a single amino acid change in the NPR-1 protein. The NPR-1 protein of all the solitary worm strains (five strains) contains a valine at amino acid number 215, whereas all the social worms (11 strains) have a phenylalanine at that position. This strong association of the genotype with the behavioral phenotype suggested that the genetic variation might actually cause the behavioral differences across strains. To test this idea, de Bono and Bargmann (1998) set out to manipulate the *npr-1* gene to see if genetic manipulation at this specific locus could cause a behavioral change. First, in social worms they changed the gene to code for a valine (solitary allele) instead of a phenylalanine (social allele). The behavior of these social worms was transformed into solitary-like behavior with this genetic change, demonstrating that these allelic differences between the strains significantly contribute to the strain-typical behavior. Furthermore, when the entire gene was removed in a solitary strain, the strain became social (de Bono and Bargmann, 1998). These results indicate that the normal role of NPR-1 (i.e., the solitary allele) is to inhibit aggregation behavior. The single amino acid change between solitary and social strains is thought to alter the efficiency of the biochemical interaction of NPR-1 with its appropriate G-proteins. In the solitary strains, with a valine at position 215, the interaction of NPR-1 with its G-proteins is very efficient. This efficient interaction serves to inhibit aggregation behavior. In the social strains, the efficacy is reduced and they have less inhibition of social behavior and are therefore more social.

4.1.2 Neural Circuitry of *C. elegans* Social Behavior

As mentioned above, *C. elegans* is a fantastic model system, because its neuroanatomy is known. Because of this, it is possible to deduce which neurons contribute to social behavior by identifying which neurons

contain the NPR-1 protein. NPR-1 is expressed in neurons in the head, ventral nerve chord, and preanal ganglion of *C. elegans*, as measured by an NPR-1-GFP fusion protein (de Bono and Bargmann, 1998). Three specific neurons, URX, AQR, and PQR, are particularly interesting, because they border the body cavity (the pseudocoelom) of the worm (Coates and de Bono, 2002). In *npr-1* mutant worms, which have a social feeding phenotype, selective restoration of functional NPR-1 to just these three neurons suppressed the social feeding phenotype. Selectively inhibiting these three pairs of neurons also results in the suppression of *npr-1* mutation-induced aggregation behavior. Thus, NPR-1 in these three neurons alone sufficiently antagonizes aggregation behavior. Likewise, without NPR-1, these three neurons promote aggregation behavior. Therefore, there must be proteins in these neurons whose activity results in increased cellular output to drive aggregation behavior. These three neurons express gene products that promote aggregation behavior: TAX-2 and TAX-4. These two genes encode two subunits of a cGMP-gated cation channel (Coates and de Bono, 2002). In these neurons, the activity of the TAX-2/TAX-4 cation channel increases aggregation behavior. This cation channel is inhibited by the activity of NPR-1. The authors hypothesize that these neurons, containing molecules that antagonize each other's actions, modulate the animal's response to a signal from the environment. One such signal may be oxygen.

C. elegans prefer a specific range of oxygen levels. Too little oxygen prevents proper cell functioning and too much oxygen results in oxidative stress and damage to the organism. Behaviorally, worms aggregate more in higher levels of oxygen, perhaps to reduce levels of oxygen in their microenvironment. The same three neurons described earlier also contain oxygen sensors that double as producers of cyclic GMP: GCY-35 and GCY-36 (Cheung et al., 2004; Gray et al., 2004). Therefore, in high levels of oxygen, GCY-35/GCY-36 binds oxygen and increases production of cGMP. These increased levels of cGMP stimulate the TAX-2/TAX-4 cGMP-gated ion channel in URX, AQR, and PQR neurons. The activity of these neurons increases aggregation behavior.

Taken together, these data suggest a model for converging genetic and environmental regulation of aggregating behavior (*Figure 6-1*). At the genetic level, variation at the *npr-1* locus contributes to the probability of aggregation: in solitary strains, the normal function of NPR-1 in URX, AQR, and PQR neurons is to inhibit the function of the TAX-2/TAX-4 cGMP-gated ion channel and thereby inhibit aggregation behavior. In contrast, this seemingly genetically determined behavior can be influenced by environmental conditions. When elevated oxygen levels cause more oxygen to bind to GCY-35 or GCY-36, more cGMP, which stimulates the activity of the cGMP-gated ion channel, is produced, thus promoting aggregation behavior. Coates and De Bono (2002) suggest that the interplay between these components (as well as other as yet unidentified components) contributes to the *probability* of social aggregating behavior. Just as we expect in vertebrates, the neurons of this invertebrate compute an output based on multiple converging inputs. This computation includes the integration of a genetic predisposition for a behavior with changing environmental conditions. Additionally, this is a very lucid example of how prosocial behavior reduces exposure to "stress," which in this case is oxygen free-radical toxicity.

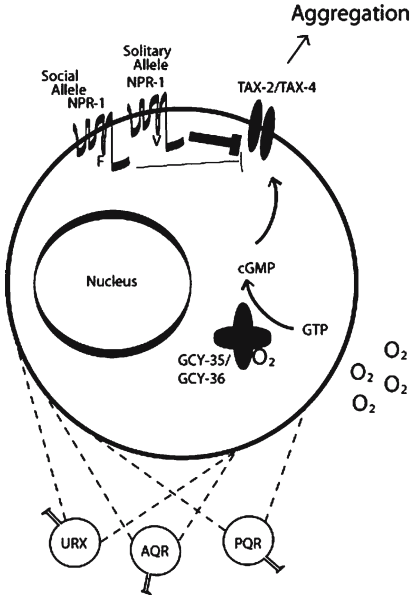
The fruit fly, *Drosophila melanogaster*, has also been used as a model to understand the molecular biology of social behaviors. Interestingly, the neuropeptide Y system regulates aggregation behavior in flies too. *Drosophila* larvae show an interesting social burrowing behavior. They aggregate and dig into the culture medium together, and prepare to pupate. Cooperative aggregation behavior is beneficial to the animals presumably because it allows for more effective burrowing into the substrate to be used for pupation. The onset of this behavior is correlated with dNPF expression levels (Wu et al., 2003), which is the ligand for the *Drosophila* neuropeptide Y receptor. Experimental downregulation of dNPF or its receptor causes aggregation in young larvae, while upregulation of either results in a prolonged solitary feeding stage, clearly demonstrating a role for dNPF in social feeding in *Drosophila* (Wu et al., 2003). It is interesting that this neuropeptide system is used in the regulation of social feeding behavior in both *C. elegans* and *Drosophila* (Sokolowski, 2003).

4.1.3 Chemodetection ("olfaction") is a Key Component of *C. elegans* Social Behavior

The "decision" to aggregate is an important one and should require high levels of regulation at various levels. The sensory detection of appropriate environmental stimuli is one such important level of

Figure 6-1

Genetic and environmental regulation of aggregation behavior in *C. elegans*. Social feeding in *C. elegans* involves the activity of many components. Genetic predisposition for social or solitary feeding and environmental influence of oxygen levels coverge in URX, AQR, and PQR neurons, where increased activity of the cGMP-gated TAX-2/TAX-4 ion channel promotes aggregation behavior. Environmentally, the activity of this channel can be enhanced by the soluble oxygen sensors GCY-35 and GCY-36 by oxygen-induced upregulation of cGMP production. In contrast, the activity of TAX-2/TAX-4 (and thus social feeding) can be inhibited by the activity of NPR-1. Genetic variants of NPR-1 differ in their ability to downregulate the TAX-2/TAX-4 ion channel, leading to heritable variation in social behavior. (F = phenylalanine, V = valine)



regulation. In addition to oxygen levels, *C. elegans* use food cues and social odor cues associated with population density to influence the probability of aggregation. In the laboratory, population density is directly correlated with levels of the constitutively secreted dauer pheromone on the plate of worms. This pheromone inhibits the expression of a gene called *daf-7* in ASI chemosensory neurons (Ren et al., 1996; Schackwitz et al., 1996). This gene encodes a TGFβ-like neuromodulator, which normally inhibits aggregation, among other things. When worms have a mutated *daf-7* gene, they aggregate. Environmental influences of population density and food availability on aggregation behavior are thought to be regulated in part by modulating expression levels of this *daf-7* gene in chemosensory neurons. High population density decreases *daf-7* expression and removes the inhibition of aggregation, while high food abundance increases *daf-7* expression and increases the inhibition of aggregation (de Bono, 2003).

In addition to the *daf-7* gene in ASI chemosensory neurons, there are other genes in other sensory neurons that participate in the regulation of aggregation behavior. Because *C. elegans* is such a well-defined experimental system, De Bono and colleagues (2002) were able to ask if discrete changes in sensory systems modulate aggregation behavior in social strains. Social behavior in social strains could be eliminated by selective laser ablation of two sensory neurons: ASH and ADL. In addition to neuronal lesions, social behavior was also eliminated by mutations in genes encoding cation channel subunits involved in chemosensation: *osm-9* and *ocr-2*. Social behavior was rescued in these mutants by selective expression of the *osm-9* or *ocr-2* genes in ASH and ADL neurons. Additionally, genes involved in olfaction, *odr-4* and *odr-8*, when mutated, disrupted the ability of *npr-1* mutants to aggregate in response to food. The product of *odr-8* is currently unknown. However, *odr-4* is exceptionally interesting because its gene product is thought to traffic odorant receptors to the distal cilia of ADL neurons. Therefore, a mutation in *odr-4* potentially disrupts the function of several other gene products in olfactory pathways. It is possible that

these receptors on these neurons detect noxious and odorant stimuli given off by the food (*C. elegans* eats *Escherichia coli*, which is occasionally toxic) and that this information is used to encourage the individuals to aggregate as a survival strategy (de Bono et al., 2002). These genetic studies clearly demonstrate the role of specific gene products in specific neurons for aggregation behavior to occur.

4.2 The Honeybee

4.2.1 Regulation of Division of Labor for Caregiving Behavior

The honeybee, *Apis mellifera*, is an asocial insect with a clear age-related division of labor among workers. Young adult bees take care of the young, and older adults bring food back to the hive. To begin to dissect the molecular players in this behavioral dichotomy, Ben-Shahar and coworkers (2002) drew a comparison of this behavioral dichotomy to the behavioral polymorphisms of sitter and rover flies. There are two foraging behavioral isoforms in adult *Drosophila*, sitter and rover (Sokolowski, 1980). Rovers wander much farther in search of food than do sitters. This behavioral variability maps to variation in a particular gene, *dg2* (also known as *for*), which codes for a protein kinase G (PKG) (Osborne et al., 1997). Sitter flies express lower levels of *dg2* mRNA, and lower PKG activity than do rover flies. Ben-Shahar and coworkers hypothesized that young sitter-like bees would have low PKG activity, and older rover-like bees would have higher PKG activity. The honeybee gene, *Amfor*, is orthologous to the *for* (*dg-2*) gene from flies described earlier. *Amfor* mRNA was indeed found to be upregulated in the adult foragers, and there was a fourfold increase in PKG activity in foragers relative to nurse bees (Ben-Shahar et al., 2002). To rule out whether this change in *Amfor* expression and PKG activity was just due to the confounding nature of age (foragers are older) or really related to the behavior, Ben-Shahar and coworkers (2002) set up a new hive containing only young nurse bees. This resulted in the generation of a few precocious foragers. These young adults, who would normally be caring for the brood, were now out foraging for food. As expected, these young foragers also showed changes in *Amfor* mRNA levels and PKG activity, demonstrating that the changes are related to the behavior and not due to age. Additionally, pharmacological upregulation of PKG activity resulted in the increased likelihood of precocious foraging in a dose-dependent manner. It seems that low levels of *Amfor* and related PKG activity are required for bees to remain as social caregivers. Parenting social behavior, presented here in honeybees, is likely the output of a system (the bee) computing important social inputs. In particular, the transition to foraging is heavily influenced by social signals, such as the number of foragers already in the colony, and by pheromones from the queen and the brood (Robinson, 2002).

4.2.2 Frontiers in "Sociogenomics"

An exciting postscript to the story above involves the use of microarrays to compare the gene expression profiles of forager versus nurse bees. Recently, Whitfield and coworkers (2003) used microarrays composed of bee brain expressed sequence tags (est) to determine the "molecular signature" of the changes in gene expression associated with the two behaviors. Not only did they confirm the upregulation of *Amfor* mRNA in the forager bee as described above, but they also observed changes in the expression of many other genes (Whitfield et al., 2003). Based on the differences in the gene expression profiles, they identified two distinct patterns of gene expression that were associated with either nurse or forager behavior. Because the transition to foraging involves many aspects of social behavior, like communicative dancing and detection of social stimuli, some of the changes in gene expression may be involved in pathways that mediate those behaviors. This kind of study opens the door for exciting revelations of the molecular machinery underlying the regulation of social behavior.

4.3 Conclusions from the Molecular Dissection of Social Behavior in Invertebrates

Some may argue against the value of a discussion of invertebrate social behavior in the context of social affiliation, but it is important to remember that because of the advanced molecular and genetic techniques

available in invertebrate models, these models provide very keen insight into the mechanisms underlying more complex affiliative behaviors in other animals. The important lessons learned from molecular genetic studies of social feeding in *C. elegans* and division of labor in the honeybee are fourfold.

First, natural variation in behavior (e.g., social versus solitary response to food; nurse versus forager division of labor) can be used to uncover molecular substrates of behavior. Social behavior is a rapidly evolving trait. Natural selection acts on genes and it is not surprising that heritable variation in social behavior can be traced to individual variation in single gene locus. It is important to keep in mind that *variation* in behavior can sometimes be traced to variation in a single gene. However, this does not mean that a behavior is a result of a single gene. This brings us to the next concept.

Second is the concept of locus heterogeneity. This means that the gene "locus" for a behavior is spread across the genome of the organism and is distributed across many genes rather than in one particular gene. In *C. elegans*, several different mutations resulted in the same behavioral phenotype. In the microarray study in honeybees, many gene products were associated with the nurses or foragers. In sum, there is no single gene for social behavior; rather, there are many genes whose products contribute to a highly regulated system.

Third, to engage in social behavior, individuals must be able to detect conspecifics. In the worm, social detection occurs through chemosensory cells containing gene products that respond to chemical social cues in the environment. In honeybees, individuals must gauge their potential role in the hive by taking in information about what other individuals are doing. This too requires detection, and perhaps discrimination, of conspecifics.

Finally, behavior is multisystemic in that the animal uses multiple sensory inputs, cellular memory, and state information to compute the appropriate behavior. Just as there is no single gene for a complex behavior, there is no single circuit. The behavior itself is composed of the probabilistic output of multiple systems, including motor systems and sensory feedback. Even in organisms as relatively simple as *C. elegans*, there are multiple pathways to influence social behavior. Each level of regulation contributes to the probability of occurrence of a particular behavior. The overall output of such a probabilistic system influences both the quantity and quality of behavior.

These important points apply not only to *C. elegans* and honeybees or just to invertebrates, but to all organisms. Although not quite as elegantly dissected as in invertebrates, we shall see more examples of these points in various vertebrates in the next sections.

5 Vertebrate Model Systems Informing the Neurobiology of Social Behavior

5.1 Rats and Mice

Most of what is known about affiliative behavior in rats and mice comes from a long history of studies of maternal behavior and social recognition memory in rats. Maternal behavior is a classic affiliative behavior because it brings a mother in close physical contact with her offspring. (A thorough presentation of maternal behavior can be found in the chapter by Lonstein and Morrell, in this volume.) Additionally, social recognition memory is a meaningful prerequisite to selective attachment behavior. Historically, mice were rarely studied for understanding social behavior; however, the transgenic mouse has changed that. Rats and mice are considered here together to illustrate important concepts in mammalian social behavior. In particular, we discuss the roles of gonadal hormones, and neurohormones like prolactin, oxytocin, and vasopressin.

5.1.1 Maternal Behavior

It is important to note that mice and rats display a not-so-subtle difference in their maternal behavioral phenotype. Female mice of some laboratory strains are spontaneously maternal, whereas adult female rats display an initial aversion to pups and overcome this through pregnancy and parturition, or long periods of repeated exposure to pups (Rosenblatt, 1967).

Originally, the main thrust of research on maternal behavior was to understand the role of pregnancy hormones in regulating the onset of maternal behavior. Estradiol, progesterone, and prolactin levels change during pregnancy. Specifically, 17β-estradiol and prolactin levels rise, while progesterone levels fall toward the end of pregnancy. In addition to preparing the uterus and mammary tissue, these changes appear to be important for initiating the appropriate events in the brain to prepare the animal for maternal behavior (Rosenblatt and Siegel, 1975; Bridges et al., 1977), although these hormones are not required for the maintenance of maternal behavior (Rosenblatt et al., 1988). This indicates that changes in the levels of these hormones somehow result in long-lasting changes in the brain structures that underlie these behaviors.

Which brain areas might be regulated by these circulating hormones? The MPOA has one of the highest concentrations of estradiol-binding sites in the brain (Pfaff and Keiner, 1973), and is therefore a likely target for the effects of pregnancy-induced changes in estradiol levels. Michael Numan's classic work, using lesion studies (knife lesions, radiofrequency lesions, neurochemical lesions, electrical lesions, etc), clearly identifies the MPOA as a critical brain structure in the onset and maintenance of maternal behavior (Numan, 1994). Implants of estradiol benzoate directly into the MPOA facilitate the onset of maternal behavior (Numan et al., 1977). Estrogen receptor-alpha knockout mice have poor maternal behavior (Ogawa et al., 1998), suggesting that this is likely to be the substrate with which estradiol interacts in the MPOA. The estrogen receptor alpha is a nuclear hormone receptor that, when bound to estrogens, interacts with regulatory regions of genes to change the transcriptional profile of the MPOA. Additionally, mice lacking the immediate early gene FosB have major defects in nurturing (Brown et al., 1996). It is likely that FosB contributes to the organization of transcriptional changes in the MPOA that must occur around the time of parturition for nurturing behavior (Lin et al., 1998). The hormone-induced changes in the MPOA may be either self-perpetuating or maintained by some other brain activity, potentially by activation of brain circuitry during interactions with offspring (Stern and Lonstein, 2001).

Estradiol-induced changes in the MPOA are not the only variable contributing to the onset of maternal behavior. Prolactin in the MPOA also facilitates maternal behavior, and prolactin receptor levels rise in the MPOA as parturition approaches (Bridges and Ronsheim, 1990; Bridges et al., 1990). Prolactin receptor knockout mice have pup retrieval and nesting deficits (Lucas et al., 1998). It is therefore apparent that the activities of the MPOA, by the actions of many gene products, affect maternal behavior.

The MPOA is heavily interconnected with many brain regions that are also involved in the regulation of maternal behavior. Sensory input from the main and accessory olfactory bulbs reaches the MPOA by way of the medial amygdala (MeA) and the bed nucleus of the stria terminalis (BST). Lesions of the vomeronasal organ in naive female rats can actually facilitate the onset of maternal behavior, suggesting that the accessory olfactory bulbs normally inhibit the onset of maternal behavior (Fleming et al., 1979). Lesions of the olfactory bulb and the bed nucleus of the accessory olfactory tract also facilitate maternal behavior in naive females (Del Cerro et al., 1991). Male rats are never naturally paternal and they have larger olfactory bulbs than females. Lesions of the olfactory bulb in males also permit parental behavior. These data fit with the idea that in naive rats, the olfactory bulb serves to inhibit parental care. Lesions of the olfactory nuclei, the amygdala, or the BST will result in the onset of parental behavior (Fleming et al., 1979, 1980; Del Cerro et al., 1991). It appears that the inhibitory nature of the olfactory pathway to the MPOA changes during pregnancy so that the odor of rat pups becomes attractive to lactating rats (Smotherman et al., 1974). Recently, it has been demonstrated that prolactin induces neurogenesis in the subventricular zone, which gives rise to new neurons in the olfactory bulb (Shingo et al., 2003). This could be a potential mechanism contributing to the pregnancy-induced onset of maternal behavior by affecting the olfactory processing of pup odor cues.

Oxytocin is a very important hormone during labor in mammals. Oxytocin promotes uterine contractions and regulates milk ejection. The source of oxytocin for these events is the magnocellular neurons in the paraventricular and supraoptic nuclei of the hypothalamus, which release their oxytocin content into the neurohypophysis, or posterior pituitary. Oxytocin is also produced in the parvocellular neurons of the hypothalamus. Hypothalamic neurons send projections to forebrain regions like the hippocampus, amygdala, striatum, hypothalamus, and to mid- and hindbrain nuclei, such as the locus coeruleus and nucleus of the tractus solitarius, as well as the spinal cord (Sofroniew, 1983). PVN lesions result in a near-complete loss of the brain oxytocinergic system (De Vries and Buijs, 1983) and a delay in the onset of maternal behavior in

naive animals (Insel and Harbaugh, 1989), but have no effect in animals that are already maternal (Numan and Corodimas, 1985).

Oxytocin from the PVN may act on oxytocin receptors (OTR) throughout the brain to promote maternal behavior. Oxytocin delivered into the ventricles in female rats enhances maternal behavior (Pedersen and Prange, 1979; Pedersen et al., 1982; Fahrbach et al., 1984) and reduces infanticidal behavior in female house mice (McCarthy, 1990). In contrast, OTR antagonists delivered to the ventricles delay the onset of maternal behavior in hormone-primed females (Fahrbach et al., 1985; van Leengoed et al., 1987). Finally, OTR antagonists injected directly into the MPOA and ventral tegmental area (VTA) inhibit maternal behavior (Pedersen et al., 1994). The above data indicate that oxytocin has a very clear role in maternal behavior. However, there has been some controversy surrounding the findings of the role of oxytocin in maternal behavior. Oxytocin does not always facilitate maternal behavior. It appears that the effects of manipulation of oxytocin systems are influenced by many factors such as the species or even the strain of the animal, housing conditions, and other experimental manipulations (Bolwerk and Swanson, 1984; Fahrbach et al., 1986). These kinds of contrasting data highlight the importance of other factors in determining how hormones can affect behavior and they also emphasize the complexity of biological systems.

The receptor for oxytocin (OTR) has been localized in the rat brain by mRNA in situ hybridization, immunocytochemisty, and receptor autoradiography (Brinton et al., 1984; van Leeuwen et al., 1985; Freund-Mercier et al., 1987, 1988a, b; Elands et al., 1988; Yoshimura et al., 1993; Adan et al., 1995). Oxytocin and OTR levels are regulated by estradiol and progesterone, followed by progesterone withdrawal in the hypothalamus and several areas throughout the brain (Bale and Dorsa, 1995; Amico et al., 1997). In particular, levels of OTR in the hypothalamus and MPOA are heavily influenced by estradiol. During pregnancy, when 17β-estradiol levels rise, there is an increase in the number of OTR in these brain areas (Young et al., 1997b). Treatment with estradiol also results in increased levels of OTR by estrogen receptor alpha (Breton and Zingg, 1997; Young et al., 1998). It seems that the hormones of pregnancy assist the brain in preparing to interpret a bolus of oxytocin that is released during pregnancy by increasing the ability to detect oxytocin.

Because OTRs are located in the olfactory bulb, amygdala, and BST, oxytocin might be acting on the aforementioned olfactory pathway to release the olfactory-mediated inhibition of the MPOA. Oxytocin delivered to the olfactory bulbs of parturient rats facilitates the onset of maternal behavior, whereas the application of an OTR antagonist inhibits the onset of maternal behavior (Yu et al., 1996a, b).

Curiously, oxytocin knockout mice have deficits in lactation, but initially appeared to have normal maternal behavior (Nishimori et al., 1996). However, with more sensitive and quantitative measures of maternal behavior, a deficit was detected in the oxytocin knockout mouse. These mice show a 22% reduction in the amount of pup licking in inexperienced females (Pedersen et al., 2004). In recent studies, the OTR knockout mouse has shown a maternal behavior deficit. Interestingly, naive receptor knockout mice show deficits in licking behavior similar to the oxytocin knockout, as well as deficits in other behaviors such as huddling with the pups [Takayanagi et al.(submitted); Olazabal et al., 2004]. Perhaps in mice, oxytocin promotes nurturing in both naive and experienced females and in rats, oxytocin is important in mediating the *switch* from pup avoidance to maternal behavior. In sum, the effect of oxytocin on maternal behavior in rats is quite dramatic, but less dramatic in laboratory strains of mice. Curiously however, the *peg3* knockout mouse, with a reduction in the numbers of oxytocin neurons in the PVN, exhibits almost no maternal behavior (nest building, pup retrieval, crouching) (Li et al., 1999). In wild-type animals, PEG3 is present in brain areas involved in maternal behavior such as the MPOA, BNST, PVN, and MeA. *Peg3* knockouts also have a lactation deficit. These data suggest that PEG3 activity may be upstream of oxytocin and many other gene products in the maternal behavior neural circuitry and that the activity of PEG3 may contribute to the organization of the behavior.

Individual differences in OTR levels have been associated with individual differences in maternal care (Francis et al., 2000; Champagne et al., 2001). In particular, rat dams that show high levels of licking and grooming of their pups have higher levels of OTR binding in the BST, the central amygdala, and the MPOA. Intriguingly, dams that show high levels of licking and grooming behavior rear female pups that grow up to have higher levels of OTR in the central nucleus of the amygdala and the BST (Francis et al., 2002).

It appears that good mothering results in good mothering in subsequent generations (Francis et al., 1999). Perhaps this is due in part to behavioral transmission of brain OTR levels.

It is clear that the MPOA is the site of converging action of multiple hormones (e.g., estradiol, prolactin, and oxytocin) and sensory input for maternal behavior. Once the MPOA has integrated that information, what does it do with it? The MPOA projects to numerous areas, most notably to reward circuitry such as the VTA. The VTA sends dopaminergic projections to ventral forebrain areas such as the nucleus accumbens (NAcc). Chemical lesions of dopaminergic projections of the VTA prevent the onset of maternal behavior (Hansen et al., 1991). It is thought that this circuitry underlies the motivational state or drive for maternal behavior (see Lonstein and Morrell's chapter for a detailed description).

This section on rodent maternal behavior was presented from the perspective of the mother, with no consideration for the behavior or the physiology of the pup. This was done only for clarity of discussion. In fact, pups do contribute to the mother–infant interactions in very proactive ways and many of the same hormones regulate pup behavior. For example, oxytocin knockout mouse pups show a deficit in separation-induced vocalization (Winslow et al., 2000), and pharmacological manipulation of central oxytocin systems alters isolation-induced calling in rat pups (Insel and Winslow, 1991). Recently, Moles and colleagues (2004) demonstrated that pups lacking the mu-opioid receptor gene do not cry in response to removal from their mother and show no preference for mother-associated cues. Perhaps normal pups have an activated endogenous opioid system during contact with the mother, but when removed from the mother, they suffer the equivalent of a painful opiate withdrawal (Nelson and Panksepp, 1998). The mu-opioid knockout mouse pup would not detect the rewarding state, nor the withdrawal state, and therefore would not cry in pain upon separation (Moles et al., 2004). Pup–mother interactions are critical for the success of the pups. In addition, it is very clear that a pup's early experience can dramatically affect behavioral phenotype later in life by epigenomic mechanisms (Francis et al., 1999; Weaver et al., 2004).

The main impact of the studies of maternal care on our understanding of social bonding has been to realize that steroid and neurohormones prime specific brain regions and organize behavioral efforts. Maternal behavior is very complex and involves many brain areas and gene products. There are many knockout lines of mice with maternal behavioral deficits, reminding us that there is not "a gene" for maternal behavior; rather there are many genes operating within a system that each contribute to the regulation of behavior. Other knockouts with maternal behavior deficits are reviewed in Leckman and Herman (2002).

5.1.2 Social Recognition in Mice and Rats

Social recognition is a prerequisite for more meaningful social encounters. Social recognition requires a complex set of processes: social approach and investigation, sensory processing, and learning and memory. Social recognition in rodents can be measured by allowing an animal to investigate a novel animal for a brief period followed by reexposure to the same or a novel stimulus animal. With each exposure, the investigator records the duration of anogenital and perioral sniffing by the test animal. With repeated presentations of the same stimulus animal, the duration of sniffing behavior by the test animal decreases. This decrease in the amount of investigation by the test animal is interpreted as social recognition. If the stimulus animal is novel, then the test animal reverts to a thorough anogenital/perioral investigation behavior. In this assay, social recognition memory was determined to be around 2 h or less for rats and mice, but can be prolonged or truncated with various behavioral and pharmacological manipulations.

For individuals to recognize each other, they must produce some unique identifying characteristic(s) that are stable over time. Rodents use olfaction as a primary sensory modality and therefore use unique odor cues to distinguish among individuals. There are two classes of polymorphic proteins found in urine that may provide a signal for individuality, or "odortype": the major urinary proteins (MUPs) and major histocompatability complex genes (MHC). The MUPs are highly polymorphic across individuals and stable over time, suggesting that they are good candidates for individual markers (Beynon and Hurst, 2003). In addition to MUPs, each individual has a set of highly variable MHC. These genes code for proteins that present both endogenous and exogenous protein fragments to the immune system (Germain, 1994). This

mechanism teaches the immune system to recognize "self" versus "not-self." MHC gene products are expressed throughout the body, and are present in both the urine and in olfactory sensory neurons (Brennan, 2004). The exact molecular mechanisms of how these MHC genes contribute to individual recognition are still unknown. Although MHC molecules are polymorphic, their molecular signature changes with experimental parameters, making them less than ideal candidates to represent the odortype of an individual (Beynon and Hurst, 2003). Behaviorally, the role of MHC genes is clear. Individuals tend to choose mates with less similar MHC genes and show increased cooperative and altruistic behavior toward individuals with more similar MHC genes (Potts et al., 1991; Manning et al., 1992; Yamazaki et al., 2000). These preferences appear to be learned and not innate, because cross-fostering of animals disrupts disassortative mating and preferences for cooperation with siblings and parents (Yamazaki et al., 1988; Penn and Potts, 1998). It seems that the MHC genes play a role in reducing inbreeding while increasing kin selection behaviors. Both MUPs and MHC genes will need to be studied further to gain a clearer picture of the mechanism of odortype diversity.

While the exact mechanism of odortype diversity and constancy is still unclear, it is clear that this information is processed in olfactory pathways in the brain. In rodents, much of the brain effort underlying social recognition memory involves the main and accessory olfactory bulbs and their projections. Social recognition memory mediated by these pathways is facilitated by the neurohormones oxytocin and vasopressin.

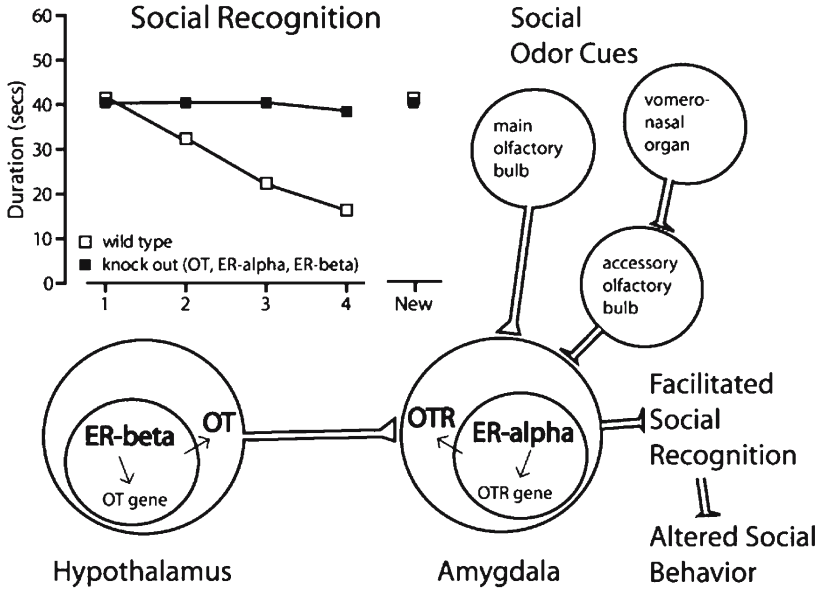
As described earlier, oxytocin plays a role in mother–infant interactions. Oxytocin also plays a role in social recognition. Oxytocin infused into the olfactory bulbs of rats minutes before behavioral testing prolongs the apparent duration of a social recognition response (Dluzen et al., 1998b), and this effect appears to be mediated through norepinephrine. 6-OHDA lesions of norepinephrine cells in the bulb prevent the prolonged social recognition response to oxytocin (Dluzen et al., 1998a), whereas stimulation of alpha-2 noradrenergic receptors with clonidine or blockade of norepinephrine reuptake by nisoxetine increases the social recognition response, even without oxytocin coadministration (Dluzen et al., 2000; Shang and Dluzen, 2001). Also, oxytocin treatment results in increased norepinephrine release as measured by microdialysis of the bulb (Dluzen et al., 2000). The emerging model is that oxytocin potentiates the release of norepinephrine in the olfactory bulb, and this increased norepinephrine stimulates alpha-2 noradrenergic receptors, which inhibit local inhibitory granule cells. This inhibition of granule cells *disinhibits* the output cells of the olfactory bulb to increase the social-recognition response. This model also applies to the mechanism underlying the Bruce effect, which is the phenomenon that female mice will resorb developing embryos when exposed to odors of a novel male. This phenomenon requires the discrimination of males and is blocked by 6-OHDA-induced lesions of noradrenergic inputs to the olfactory bulb (Rosser and Keverne, 1985).

Oxytocin appears to act in other brain areas in addition to the olfactory bulb to regulate social-recognition behavior. Oxytocin in the LS and MPOA of male rats can prolong social-recognition (Popik and van Ree, 1991, 1992). Male oxytocin knockout mice have an impaired ability to remember a mouse they just met in the kind of social recognition test described above (Ferguson et al., 2000). This deficit is reversed by infusion of oxytocin into the MeA before the learning trial, and in wild-type animals, the deficit is mimicked with an OTR antagonist into the MeA (Ferguson et al., 2001). The timing of treatment with oxytocin and the receptor antagonist indicates that oxytocin plays a role in the early stages of social recognition memory formation rather than in the subsequent expression of social recognition behavior. Similarly, estrogen receptor-alpha and -beta knockout mice also show social recognition deficits (Choleris et al., 2003). The female oxytocin knockout mouse has deficits in discriminating between healthy and parasitized male odors, but no impairment in tasks that require the discrimination of nonsocial odors (Kavaliers et al., 2003). Additionally, estrogen receptor-alpha and -beta knockout mice also have deficits in the ability to discriminate, remember, and avoid parasitized male odors (Kavaliers et al., 2004a). In a forced choice test, wild-type mice choose urine odors derived from other wild-type mice compared with urine odors from the oxytocin knockout and estrogen receptor-beta knockout mice (Kavaliers et al., 2004b). In contrast, the same wild-type mice chose odors from the estrogen receptor-alpha knockout mouse compared with wild type (Kavaliers et al., 2004b). This suggests that not only do these knockout animals have decreased social discrimination, but they also possibly produce different odor cues themselves.

Estradiol improves social memory in female rats (Hlinak, 1993), and oxytocin in the PVN and OTRs in the amygdala are regulated by estradiol through estrogen receptor-beta and -alpha, respectively (Young et al., 1998; Patisaul et al., 2003). Because all three knockouts (oxytocin, estrogen receptor-alpha, and -beta) have social-recognition deficits, Choleris and coworkers proposed a "four gene micronet" to synthesize the results from the knockout studies. The four genes encode oxytocin, OTR, estrogen receptor-alpha, and estrogen receptor-beta. In this "micronet" (*Figure 6-2*), social odor cues are detected by the main and accessory olfactory bulbs, which project to the OTR-dense amygdala. The amygdala receives oxytocinergic input from the hypothalamus. The amount of OTRs in the amygdala is determined in part by the circulating estrogens acting at the estrogen receptor-alpha. Likewise, the amount of oxytocin in the hypothalamus is determined in part by the circulating estrogens acting through the estrogen receptor-beta. In sum, the circulating estrogens may set the gain on a social recognition network by upregulating oxytocin and its receptor via estrogen receptors. In some yet undetermined way, the output of the amygdala contributes to social recognition behavior. While this is a simple model with just four genes in two brain areas, it is a decent framework to begin to understand the neural correlates of social recognition.

Figure 6-2

Social recognition is an important component of affiliative behavior. Social recognition can be examined by presenting a test animal with a series of novel and familiar stimulus animals. The test animal is first presented with a novel animal (trial 1) and spends roughly 80% of the 60-s trial investigating this novel individual. In the next three trials, the test animal is presented with the same stimulus animal. In these trials, the test subject spends less time investigating the stimulus animal. This decrease in investigation in trials 2, 3, and 4 represents social recognition. In a fifth trial, the test subject is presented with a novel stimulus animal and resumes full investigation. Knockout mice for oxytocin (OT), estrogen receptor-alpha (ER-alpha), and -beta (ER-beta) all have deficits in social recognition. This is a complex process and involves many gene products acting within a system. Choleris and colleagues have proposed a "four gene micronet," which includes the genes encoding OT, ER-alpha, ER-beta, and the oxytocin receptor (OTR), acting within the hypothalamus and amygdala. Social odor cues are processed in the main and accessory olfactory bulbs, which project to the amygdala, the output of which modulates social recognition. Oxytocinergic projections from the hypothalamus modulate the activity of the amygdala. The activity of this micronet is upregulated by circulating estrogens acting at ER-alpha and ER-beta to increase levels of OTR and OT, respectively. This figure was adapted from Choleris et al. (2004)



Vasopressin is a nine amino acid peptide hormone that is very closely related to oxytocin. Like oxytocin, vasopressin is also involved in social recognition. Central administration of vasopressin prolongs the duration of social recognition memory in rats (Le Moal et al., 1987). Vasopressin applied specifically to the LS also prolongs the social recognition response, while a vasopressin 1a receptor (V1aR) antagonist applied into the LS of rats inhibits social recognition (Dantzer et al., 1988; Popik and van Ree, 1991). The Brattleboro rat, which has a natural mutation in its vasopressin gene, has a social recognition deficit, and application of vasopressin directly into the LS of these rats restores social recognition (Engelmann and Landgraf, 1994). Downregulation of the V1aR in the dorsal LS of normal rats with an antisense oligonucleotide to V1aR inhibits social recognition behavior (Landgraf et al., 1995). Additionally, increasing V1aR density in the LS of normal rats by viral vector gene transfer of V1aR enhances the durability of social recognition memories (Landgraf et al., 2003). V1aR knockout mice also have a social recognition deficit (Bielsky et al., 2004a) and this deficit is corrected with replacement of the receptor by viral vector gene transfer into the LS (Bielsky et al., 2004b). The vasopressin 1b receptor (V1bR) also appears to be capable of influencing social recognition. The V1bR knockout also has a modest impairment in social recognition, although the overwhelming phenotype is a reduction in aggression (Wersinger et al., 2002). Before the social recognition processing occurs in the LS, however, the olfactory input is first processed in the olfactory bulbs. In fact, direct application of vasopressin to the olfactory bulbs prolongs the expression of the social recognition response (Dluzen et al., 1998b), and as with oxytocin, the treatment effect may depend on intact noradrenergic signaling in the olfactory bulb (Dluzen et al., 1998a).

It is clear from studies in rats and mice that both oxytocin and vasopressin play a role in social recognition behavior. These neuropeptides and their receptors can modulate this behavior in several brain areas, including the olfactory bulbs, the MeA, and the LS. It is not surprising that this complex behavior, which includes sensory processing, learning, and memory as well as motivation and motor activity, is influenced by such a broad network of brain areas and molecular mediators.

The need to develop rapid attachments to the caregiver is very strong in altricial species. In rodent pups, the ability to associate maternal care with the mother happens very quickly. Maternal licking and grooming of the anogenital region of the pup is a major aspect of rodent maternal care. Maternal licking can be experimentally simulated by stroking the pup with a paintbrush. Pups that have been stroked with a paintbrush and simultaneously exposed to an odor like peppermint will show a learned preference for peppermint odor (Sullivan et al., 1989). Therefore, maternal licking enhances olfactory learning in the pup. Rat pups have increased noradrenergic neurotransmission from the locus coeruleus into the olfactory bulb relative to adults (Sullivan et al., 2000; Sullivan, 2003). This increase in noradrenergic neurotransmission is present during a critical window of olfactory learning and coincides with increased olfactory stimulation representing the mother's odor in the olfactory bulb of the pup. This change in neural activity and modulation by ascending noradrenergic activity results in plasticity in the pup olfactory bulb and therefore learning of the mother's odor (Sullivan, 2003). This change in the bulb not only results in the learning of the mother's odor, but also a preference for her odor. In fact, this learning of and subsequent preference for an odor can be reproduced with exogenous application of norepinephrine into the bulb or stimulation of the locus coeruleus (Sullivan et al., 2000). Oxytocin and vasopressin may play a role in social recognition in pups as well. Normal rat pups learn to associate a nonsocial odor (such as lemon scent) with the odor of their mother and will subsequently show a preference for the lemon scent even in the absence of their mother. In contrast, preweanling vasopressin-deficient Brattleboro rats do not make the association of mother odor cues with a nonsocial odor, or at least they do not show a preference for the lemon scent after repeated mother-odor pairings (Nelson and Panksepp, 1998). Likewise, in normal preweanling rats, OTR antagonist administration i.c.v. before the learning trial inhibits the association of mother odor with a nonsocial odor (Nelson and Panksepp, 1996). Perhaps in rat pups, oxytocin and/or vasopressin potentiates the release of norepinephrine to modulate social memory as oxytocin does in adult rats (Dluzen et al., 2000). Therefore, an emerging model of social olfactory learning in the rodent pup includes increased noradrenergic drive to the olfactory bulb, which is potentiated by oxytocin and/or vasopressin released with social stimuli. This increased noradrenergic drive probably reduces the inhibitory tone on the olfactory bulb, allowing increased activity of the main output cells of the bulb. This increased excitation in the output cells of the bulb probably results in plasticity in both the bulb and its downstream projections. Individual

differences in developmental plasticity of the olfactory bulb may affect adult sociobehavioral phenotypes by differential tuning of the system to attend differently to social odors. There is a very similar norepinephrine mechanism acting in the olfactory bulb of the ewe when she learns her lamb odor, which we shall see later.

In rats and mice, it is very clear that appropriate social behavior requires an intact sensory modality (olfaction) for social recognition, a way to assess the valency of the olfactory input (as in the amygdala), and regulation of the motivation and reward circuitry (ventral forebrain). This circuitry is influenced by steroid and neuropeptide hormones, endogenous opioids, and classical neurotransmitters like norepinephrine. This is clearly a very simplified model as there are many other brain regions containing many hormones and gene products that contribute to the regulation of the many aspects of complex vertebrate affiliative behavior.

5.2 Maternal Bonding in Sheep

Sheep have become a very useful model of attachment and bonding, because like rats they also show strong maternal behavior after parturition. However, in contrast to rats and mice, sheep show *selective* maternal behavior. Maternal rats and mice take care of all infants, but the ewe cares only for her own lamb with which she bonds just after delivery. Many of the same molecular correlates for maternal behavior and social recognition in rats and mice have emerged in sheep.

The changes in hormones during pregnancy and the actual event of delivery are required for the onset of maternal behavior in ewes. Hormone priming with 17β-estradiol and progesterone followed by vaginocervical stimulation induces maternal behavior in virgin ewes (Keverne et al., 1983; Yeo and Keverne, 1986, Kendrick et al., 1991). Vaginocervical stimulation results in increased oxytocin release, measured in the CSF and in the brain (Kendrick et al., 1986; Kendrick et al., 1988a, b). Additionally, oxytocin levels rise in the MPOA, BST, and olfactory bulbs during parturition (Kendrick et al., 1988b, 1992b). The ascending sensory input from the vagina appears to be important for the release of oxytocin in the brain because peridural-anesthetized females require exogenous application of oxytocin to exhibit appropriate maternal behavior (Levy et al., 1992). Therefore, the effects of vaginocervical stimulation can be replicated by intracranial delivery of oxytocin. In fact, as in rats, maternal behavior can be induced by oxytocin infusion into the ventricles in steroid-primed ewes (Kendrick et al., 1987).

As in rats, estradiol and progesterone levels change throughout pregnancy and at parturition, and they alter gene expression in the brain. These changes in gene expression prepare the brain to interpret signals at parturition (such as the flood of oxytocin) to promote/allow the onset of maternal behavior. 17β-estradiol and progesterone have been shown to increase levels of oxytocin, opioids, corticotrophin-releasing hormone, OTR, and prolactin receptors (Schumacher et al., 1992, 1993; Broad et al., 1993a, b, 1995, 1999). These gene expression changes probably also act to increase the salience of lamb-related stimuli for long-term maintenance of maternal behavior. In summary, there are very clear similarities in neural mechanisms of maternal behavior across rats, mice, and sheep.

As described above, sheep come with an added feature in that they also display selective attachment. Ewes become maternal immediately after delivery; however, within a few hours they become selectively maternal and will only accept their own lamb to nurse. This behavior is thought to be mediated in part by reorganization of the olfactory bulb (Kendrick et al., 1992a). Nulliparous ewes find odors associated with a placenta repulsive (Levy et al., 1983). However, with parturition, ewes find these odors extremely attractive. Some important changes must happen in the ewe's brain to change the perception of a stimulus from repulsive to attractive, and to learn that the attractive quality belongs to her lamb but not to others.

One site of learning in the brain for this dramatic behavioral switch appears to be the olfactory bulb. Vaginocervical stimulation like parturition results in changes in various neurotransmitters in the sheep olfactory bulb. Oxytocin, noradrenaline, acetylcholine, glutamate, and GABA levels rise following parturition or vaginocervical stimulation (Kendrick et al., 1988a, b; Keverne et al., 1993; Levy et al., 1993). Oxytocin appears to modulate the release of the other neurotransmitters, suggesting that the release of oxytocin *organizes* the changes in the olfactory bulb after parturition or vaginocervical stimulation

(Levy et al., 1995). The cells in the olfactory bulb become very highly tuned to detect lamb odors and specifically to discriminate among lambs. After giving birth, the output of the olfactory bulb changes in response to lamb odors. Mitral cells are the output cells of the olfactory bulb. The number of mitral cells that respond to lamb odors increases greatly after parturition, and these increases in activity are associated with increased cholinergic and noradrenergic neurotransmitter release (Kendrick et al., 1992a). The majority of these mitral cells respond to any lamb odor, while a subset of the mitral cells respond strongly and selectively to the specific lamb's odors. Associated with this selective responding is an increase in the number of mitral cell to granule cell synapses and an increase in glutamate and GABA signaling in response to one's own lamb (Kendrick et al., 1992a). Granule cells are inhibitory interneurons that form dendrodendritic synapses with the mitral cells. It seems that the selective increase in glutamate signaling is due to nitric oxide acting as a retrograde messenger within the olfactory bulb. Specifically, glutamate binds to NMDA receptors on both mitral and granule cells and this stimulates nitric oxide synthase. This enzyme catalyzes the production of nitric oxide, which diffuses throughout the bulb. Within the mitral cells, the increased nitric oxide levels then increase glutamate signaling via a cGMP-dependent mechanism (Kendrick et al., 1997b). Inhibitors of the nitric oxide synthase enzyme inhibit olfactory learning as do lesions of more upstream components of this process such as noradrenergic projections to the bulbs or application of beta-noradrenergic antagonists (*Figure 6-3*; Kendrick et al., 1997a).

To summarize, in sheep, sensory information about vaginocervical stimulation ascends through the spinal cord, stimulating A1, A2, and A6 hindbrain noradrenergic cell groups. These cells project to the PVN that has been primed with the hormones of pregnancy to rapidly release large amounts of oxytocin into the posterior pituitary and throughout the brain. Several OTR-expressing areas [MPOA, VTA, BNST, MeA, and olfactory bulb (Broad et al., 1999)] respond to the increased levels of oxytocin and permit or promote maternal behavior. In particular, changes in the olfactory bulb represent the associative learning of the specific odor of the lamb with the events surrounding birth. These changes result in long-lasting memory of and selective attachment to the lamb.

5.3 Pair Bonding in Voles

5.3.1 Monogamous Behavior

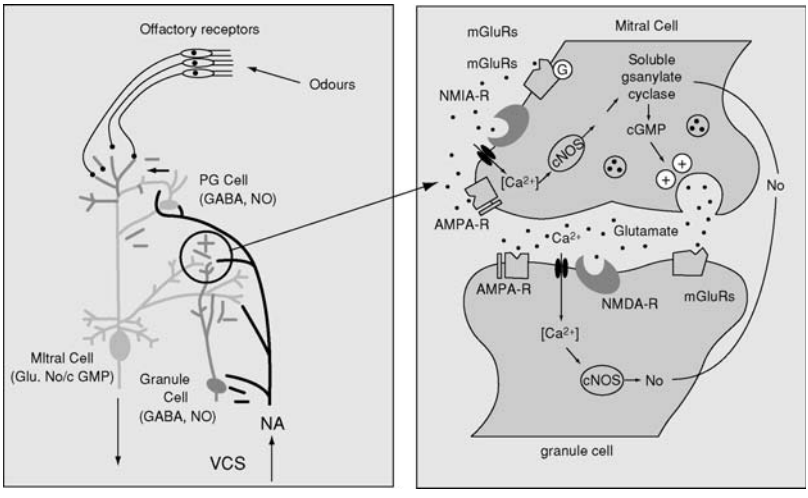
Voles are a diverse genus of rodents and vole species display a wide array of social behaviors, from asocial to prosocial and promiscuous to monogamous (Carter et al., 1995a). Comparative analyses of vole species with divergent social structures have been used to unveil the neural mechanisms of social behavior. Studies of voles for their species diversity in social behaviors began in the field (Getz et al., 1981). In the 1980s voles were brought into the lab and comparative analyses of the brains were begun to gain insight into the underlying neural mechanisms of the species-typical behavior (Getz et al., 1981). Monogamy is defined here as a long-term selective association with a partner (Carter et al., 1995a). Prairie voles form lasting attachments with a partner throughout breeding and nonbreeding seasons, and males contribute to care of the young. Additionally, prairie voles show selective aggression toward novel conspecifics after becoming sexually experienced (Winslow et al., 1993; Insel et al., 1995). This definition of monogamy does not preclude sexual promiscuity.

In the field, monogamy is observed when animals are routinely trapped together and share nest sites. In the laboratory, monogamy is assessed by measuring several social behaviors: partner preference, biparental care of offspring, and selective aggression toward unfamiliar intruders. Monogamous-typical behaviors include high levels of affiliation with juveniles, high levels of paternal care, high levels of selective aggression toward a novel conspecific after sexual experience, and a persistent preference for a familiar partner animal (Carter et al., 1995a). Also, pups of monogamous prairie voles, but not promiscuous montane voles, show a robust stress response to maternal separation with increased vocalization and increased serum corticosterone levels (Shapiro and Insel, 1990).

In addition to the work on selective bonding in sheep, much of the laboratory work that has been done to understand the molecular neurobiology of selective social attachment has used the prairie vole pair bond

Figure 6-3

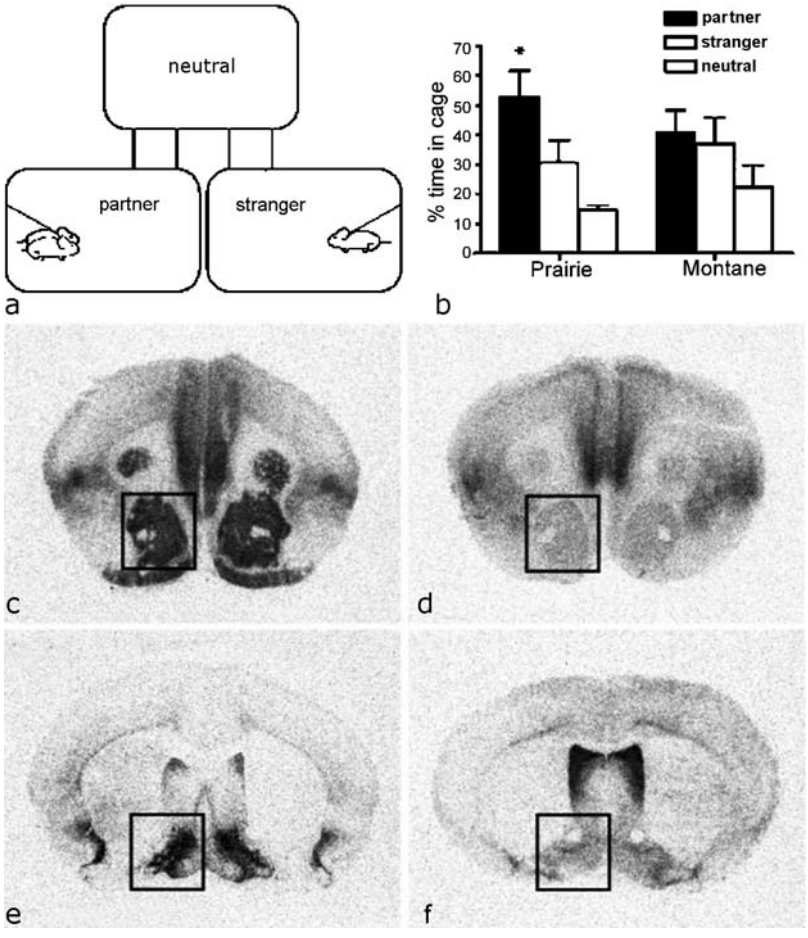
The sheep olfactory bulb undergoes changes at parturition to learn the odor of the lamb. Odors are detected by olfactory receptor neurons and this information is transferred to the mitral cells of the olfactory bulb. These cells make dendro-dendritic contacts with several other cell types. In particular, the mitral to granule cell synapses appear to be the major site of plasticity in the bulb. Immediately after birth, glutamate levels rise throughout the bulb due to the increased inhibition of inhibitory neurons in the bulb. Glutamate release from the mitral cell stimulates the postsynaptic granule cell to produce the retrograde messenger, nitric oxide (NO). This NO diffuses back to the presynaptic mitral cell and further potentiates the release of glutamate and strengthens the synapse. This plasticity is most robust at mitral-granule cell synapses that have received stimulation from the olfactory bulb (i.e., neurons whose activity represents the odor of the lamb). This figure is taken from Kendrick and coworkers (1997), with permission. The contribution of oxytocin, which serves to facilitate olfactory memory formation in the bulb by potentiating the release of neurotransmitters is not shown here. The sub-cellular location of the OTR is currently unknown



as a model. To establish a pair bond in the lab, sexually naive animals are paired for a cohabitation period (24 h of cohabitation with mating will produce reliable partner preferences in at least 80% of the animals). After 24 h of cohabitation, the animals are tested in a 3-h "partner-preference test." The testing chamber consists of three cages connected by Plexiglas tubes (*Figure 6-4a*). The test subject has access to all three cages. The test subject's "partner" (from the cohabitation period) is tethered in one of the cages; a "stranger" animal is tethered in a second cage; and the third cage is considered "neutral" (it does not contain any animal). Both males and females can be tested in this apparatus. A "pair bond" or "partner preference" is operationally defined by the amount of time the test animal spends with the partner compared with the time it spends with the stranger. The animals are considered "pair bonded" when the test animal spends twice as much time with the partner than with a stranger. Monogamous animals like prairie and pine voles show pair-bond formation by this definition with prolonged cohabitation, which is facilitated by mating. In contrast, promiscuous meadow and montane voles do not show a preference for either animal and actually spend more time alone in the neutral cage than monogamous voles (*Figure 6-4b*), although meadow voles have been observed to form pair bonds in certain circumstances (Parker, 2001). Parameters of the cohabitation period can be altered to increase or decrease the frequency of pair-bond formation in a given sample of prairie voles. For both males and females, increased cohabitation lengths can increase the frequency of pair-bond formation, even in the absence of mating. Decreasing the length of cohabitation and preventing mating during the cohabitation period reduce the frequency of pair-bond formation. It is important to note that the specific conditions ensuring robust partner-preference formation do vary from laboratory to laboratory, indicating that there are high levels of environmental regulation of social bonding.

Figure 6-4

The pair-bonding component of monogamous social behavior is tested in the laboratory using the partner-preference test. (a) A three-chambered apparatus is used for this test. The partner is tethered in one cage, while a stranger is tethered in another cage. The test animal has access to these two stimulus animals and a neutral cage via Plexiglas tubes. The amount of time spent in side-by-side contact with either the stranger or the partner can be quantified. Additionally, the amount of time the animal spends in each of the three cages can also be quantified. Prairie voles, but not montane voles, spend significantly more time in the cage with their partner than with the stranger (b; adapted from Insel et al., 1995). These species differences in behavior are correlated with species differences in oxytocin receptor (OTR) and vasopressin 1a receptor (V1aR) distribution in the reward areas of the brain. Specifically, prairie voles (c) have more OTR than montane voles (d) in the nucleus accumbens. Additionally, prairie voles (e) have more V1aR than montane voles (f) in the VP



5.3.2 Oxytocin

As just described, in both male and female prairie voles, copulation and cohabitation are involved in the natural development of pair bonds and subsequent selective aggression toward strange intruders (Carter et al., 1988; Winslow et al., 1993). What occurs in the brains of prairie voles as two individuals spend time together and/or mate? As described previously, oxytocin plays a very important role in other social

behaviors such as social recognition, maternal behavior, and maternal–infant bonding. Oxytocin injection into the brain increases social contact in female prairie voles (Witt et al., 1990), male rats (Witt et al., 1992), and male squirrel monkeys (Winslow and Insel, 1992). Because of the abundance of data demonstrating an important role for oxytocin in other prosocial behaviors, oxytocin was hypothesized to play an important role in social bonding in voles. Indeed, central infusion of oxytocin facilitates partner-preference formation in female prairie voles, and OTR antagonists inhibit partner-preference formation even if the females have not mated with their partner (Williams et al., 1994; Insel and Hulihan, 1995). Injections of oxytocin facilitate partner-preference formation in ovariectomized female prairie voles (Williams et al., 1992a, 1994), demonstrating that oxytocin is sufficient and that gonadal hormones are not necessary.

Where in the female brain does oxytocin exert its effects on partner-preference behavior? There are drastic species differences in OTR-distribution patterns across monogamous and nonmonogamous vole species (Insel and Shapiro, 1992). Some regions of the brain like the caudate and the NAcc have large numbers of receptors in monogamous species compared with nonmonogamous species (*Figure 6-4c, d*). It has been hypothesized that the species differences in receptor-distribution patterns are responsible for the species differences in response to central administration of oxytocin. OTR antagonists applied directly to the NAcc or prelimbic cortex of female prairie voles inhibit partner-preference formation (Young et al., 2001). The mechanism by which species differences in OTR are generated is still unclear, although the observed species differences are most likely not posttranslational (Young et al., 1996). It is possible that the species differences in the regulatory regions of OTR genes guide the neuroanatomical distributions of the receptor (Young et al., 1996).

5.3.3 Vasopressin

In male prairie voles, it is the related neurohormone, vasopressin, that seems to play a larger role in the regulation of pair-bond formation and other aspects of monogamy like paternal care. Vasopressin is involved in many social behaviors in males including flank marking and aggression in hamsters (Albers and Bamshad, 1998) and social recognition in rats and mice (Bielsky and Young, 2004). Vasopressin-distribution patterns are highly conserved across species (Wang et al., 1996). Several brain areas contain either vasopressinergic cells (cells expressing vasopressin mRNA and vasopressin immunoreactivity) and/or vasopressin immunoreactive fibers (Bamshad et al., 1993; Wang et al., 1994a, 1996; Wang, 1995; Lim et al., 2004a). Vasopressin immunoreactive and mRNA-containing cells are found in the hypothalamus (suprachiasmatic nucleus, SCN; paraventricular nucleus, PVN; supraoptic nucleus, SON), the BST, and the MeA. Vasopressin immunoreactive fibers appear in the lateral septum (LS), ventral pallidum (VP), lateral habenular nucleus (LH), MPOA, BST, PVN, and MeA. Vasopressin expression levels in extrahypothalamic areas of the brain are sexually dimorphic, with males showing higher numbers of vasopressin-expressing cells in BST and more fibers in the LS and lateral habenula (Bamshad et al., 1993; Wang et al., 1994, 1996). Vasopressin levels are regulated by gonadal steroids (Wang and De Vries, 1993), which may coordinate the behavior of the animal with reproductive capacity (Carter et al., 1995a). Specifically, when sexually naive males are castrated, the levels of vasopressin immunoreactivity are reduced in cells and fibers of brain areas thought to be involved in paternal care: cells of the BST and MeA, and fibers within the LS, which receives input from BST and MeA (Wang and De Vries, 1993). Vasopressin levels in hypothalamic regions of the brain (PVN, SCN, SON) are not altered by castration (Wang and De Vries, 1993). Infusion of vasopressin into the LS of castrated males increases pup-directed behaviors and antagonist treatment decreases pup-directed behaviors (Wang et al., 1994a). Vasopressin immunoreactivity is altered in male prairie voles after cohabitation and mating and pup exposure (Bamshad et al., 1993, 1994). Vasopressin immunoreactivity decreases in the LS with sexual experience and the onset of parental care, while vasopressin mRNA levels increase in the BST (Bamshad et al., 1994; Wang et al., 1994b). The BST projects to the LS, so the changes in vasopressin are probably a result of vasopressin release in the LS and a compensatory increase in vasopressin production. The changes in vasopressin levels with the onset of paternal care could be a result of the ingestion of hypertonic urine during anogenital licking and grooming of the pups (Bamshad et al., 1993; Wang et al., 1994a). In contrast to the findings presented above, castrated sexually naive prairie voles, with

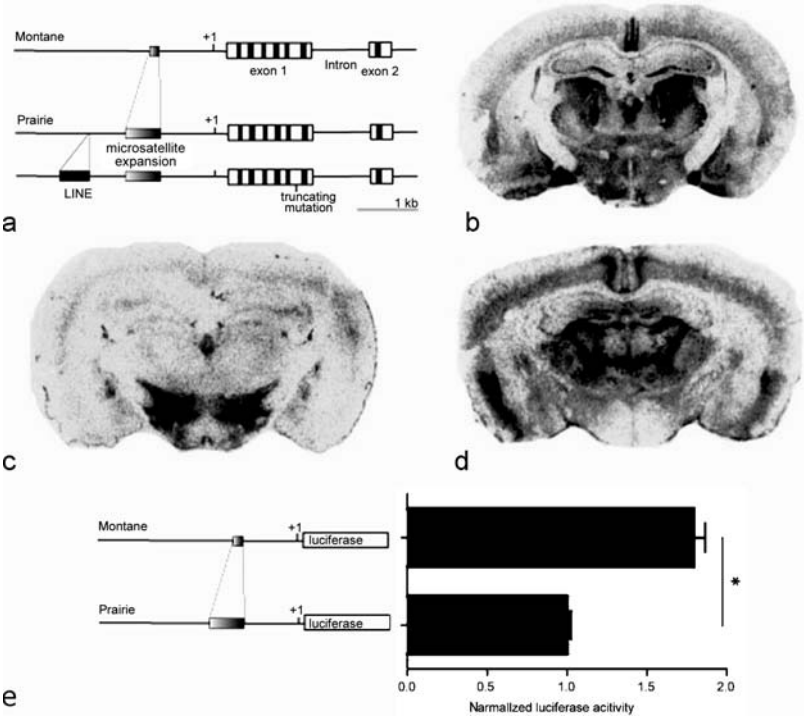
no vasopressin immunoreactivity in the LS, show only mild deficits in spontaneous paternal behavior (Lonstein and De Vries, 1999). This indicates that vasopressin may not be required for the expression of paternal care, although it does not preclude a role for its influence.

As mentioned above, pair-bond formation relies on prolonged cohabitation with a partner facilitated by concomitant mating. Vasopressin is thought to be released in the brain during the cohabitation due to both mating and social contact. Injections of vasopressin directly into the brain facilitate partner-preference formation (without mating) and receptor antagonists block partner-preference formation in male prairie voles (Winslow et al., 1993). Considering that vasopressin distribution is so highly conserved across species, it is interesting that it has such dramatic differences in behavioral effects when injected into the brain (Young et al., 1997a). The brain-distribution pattern for the vasopressin 1a receptor (V1aR) is not conserved even across closely related species like prairie and montane voles (*Figure 6-4e, f*) . Like the OTR, species differences in V1aR-distribution patterns have been hypothesized to contribute to the species differences in social structure (Insel et al., 1994; Young et al., 1997a). In particular, the V1aR levels are higher in the VP, the central nucleus of the amygdala, cingulate cortex, and the laterodorsal thalamus in monogamous prairie voles than in promiscuous montane voles (Insel et al., 1994). Within the prairie vole species, there do not appear to be any sex differences in the distribution patterns of V1aR (Insel et al., 1994; Phelps and Young, 2003; Lim et al., 2004a). To test the idea that species-specific V1aR-distribution patterns have important behavioral consequences, site-specific modulation of V1aR has been used. For example, V1a receptor blockers prevent partner-preference formation when applied directly to the VP at doses that are ineffective when delivered into the lateral ventricles (Lim and Young, 2004). A viral vector containing the prairie vole *v1ar* with a neuron-specific enolase promoter has been used to alter V1aR levels in specific brain regions. With such a tool, it is possible to test the hypotheses about the molecular and neural substrates of pair bonding. Increasing V1aR in the VP of monogamous prairie voles using this V1aR-expressing virus facilitates partner-preference formation (Pitkow et al., 2001) in the absence of mating.

Clearly, the species differences in V1aR-distribution patterns have important consequences for behavior. The differences could be due to differences in receptor pharmacology across the two species or the differences in gene regulation. It appears that the latter is the case. The two species are highly homologous in the coding region for the *v1ar* gene (Young et al., 1999) and consequently there are no differences in the receptor pharmacology across the two species (Insel et al., 1994). Additionally, the species differences in receptor binding levels are apparent at the perinatal period, indicating that environmental effects on regulation are less likely than genetic effects (Wang et al., 1997). Furthermore, the species differences in distribution are not only apparent at the level of receptor binding, but also at the mRNA level, suggesting species differences in gene regulation rather than in posttranslational processing (Young et al., 1997a). In the regulatory region of the *v1ar* gene, there is a striking species difference at about 660-bp upstream of the transcription start site (*Figure 6-5a*). In monogamous prairie and pine voles, there is a 500-bp repetitive expansion at this locus, which is only about 50-bp long in the promiscuous meadow and montane voles (Young et al., 1999). It is possible that this microsatellite modifies gene expression patterns by changing the promoter structure of the *v1ar* gene across monogamous and promiscuous species (Young et al., 1999; Hammock and Young, 2002). A transgenic mouse for the prairie vole *v1ar* gene, including this microsatellite, has a receptor-distribution pattern that is more like that of a prairie vole than like a wild-type mouse (*Figure 6-5b, c, d*), suggesting that sequences in the prairie vole *v1ar* gene contribute to species-specific distribution patterns (Young et al., 1999; Hammock and Young, 2002). In cell culture, this prairie-vole-specific microsatellite modulates gene expression. Specifically, deleting the microsatellite results in an increase in the activity of a reporter gene in some, but not all, of the cell lines that were tested (Hammock and Young, 2004). This indicates that the microsatellite acts in a cell-type-dependent manner to regulate gene expression. We would expect that such a regulatory mechanism is also functioning in the brain, because not all brain areas show species differences in receptor-binding levels. In addition, when the prairie vole microsatellite was replaced with the montane vole microsatellite, the short montane vole microsatellite also increased reporter gene activity relative to the long prairie microsatellite (*Figure 6-5e*), demonstrating that species differences in microsatellite length affect gene regulation (Hammock and Young, 2004). It is plausible that the species differences in gene structure lead to changes in gene expression patterns, which ultimately have behavioral consequences.

Figure 6-5

Species differences in V1aR distribution patterns are associated with a functional microsatellite polymorphism in the 5′ regulatory region of the *v1ar* gene. The *v1ar* gene in montane and prairie voles is highly homologous in coding regions (a; hatched boxes), but not in the 5′ regulatory region. Specifically, there is an expanded repetitive microsatellite in the prairie vole *v1ar* 5′ region but not in the montane vole *v1ar* gene (shaded box). Additionally, the *v1ar* gene appears to have undergone a gene duplication event for this locus and therefore this species has two copies of the *v1ar* gene. One copy, however, contains a mutation in the coding region that would result in a truncated form of the receptor. In support of the role of the microsatellite in the regulatory control of the distribution of V1aR, transgenic mice (d) for the prairie vole *v1ar* gene (including the microsatellite) have V1aR distribution patterns that resemble prairie voles (b) more than wild-type mice (c). In vitro, species-specific lengths of the microsatellite modify gene expression (e), demonstrating that it is possible that this rapidly evolving sequence can regulate gene expression in the brain. (Figures adapted from Young et al., 1999 and Hammock and Young, 2004)



5.3.4 Neural Circuitry of Pair Bonding

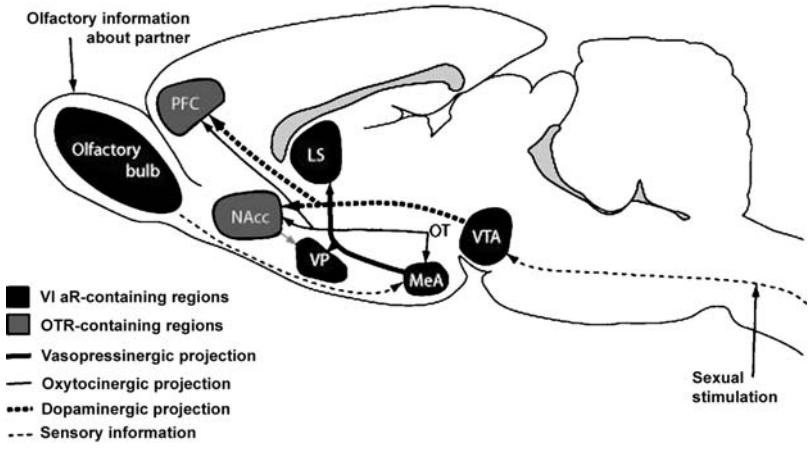
If the main difference in the brain contributing to the observed species differences in pair-bond formation in male voles were the amount of V1aR in the VP, then one would predict that changes in V1aR levels in the VP would modulate behavior. Lim and colleagues (2004) tested this idea by injecting promiscuous meadow voles with a V1aR-expressing viral vector directly into the VP. After injection and recovery, the animals were tested for their ability to form pair bonds in the partner-preference test. All the meadow voles that were tested had been transformed by the addition of V1aR in the VP: they all preferred to be in side-by-side contact with their partner. It was very intriguing to see that changes in the levels of one protein in the brain can dramatically alter species-typical behavior.

Because both the NAcc and VP are key relay nuclei in the brain circuits involved in reward, it has been hypothesized that both oxytocin and vasopressin may be facilitating affiliation and social attachment in

monogamous species by modulating these reward pathways (Young et al., 2001; Young and Wang, 2004; Lim et al., 2004b). The NAcc plays a major role in the regulation of pair-bond formation in female prairie voles. After mating, dopamine turnover increases in the NAcc (Gingrich et al., 2000). Dopamine D2 receptor antagonists in the NAcc block partner-preference formation and agonists facilitate female partner-preference formation (Gingrich et al., 2000). Concurrent activation of D2 dopamine receptors and OTRs in the NAcc is necessary for partner-preference formation in female prairie voles (Liu and Wang, 2003). Additionally, dopamine in the NAcc is necessary for partner-preference formation in the male prairie vole. Similar to female prairie voles, in male prairie voles dopamine turnover increases in the NAcc with mating (Aragona et al., 2003a). Dopamine D2 antagonists in the NAcc in males block partner-preference formation while D2 receptor agonists facilitate partner-preference formation (Aragona et al., 2003a). The VP and the NAcc are heavily interconnected. Perhaps the activation of OTR in the NAcc of females and V1aR in the VP of males, along with concurrent activation of dopamine receptors in the reward circuitry in both males and females, provides sex-specific, but parallel mechanisms for pair-bond formation in this species (*Figure 6-6*; (Lim et al., 2004a, b)).

Figure 6-6

Proposed neural circuitry of pair-bond formation in male and female prairie voles. The olfactory signature of a particular individual is combined with sex-induced activity of the reward circuitry. Presumably, future exposure to that individual could continue to activate endogenous reward pathways even in the absence of mating. Individuals therefore associate specific individuals with reward and then prefer that particular individual for their acquired rewarding properties. (Adapted from Lim et al., 2004)



It appears that the species-specific distribution of V1aR and OTR in this reward circuitry is a defining difference in pair-bonding behavior between monogamous and promiscuous vole species. In the meadow vole experiment by Lim and colleagues described earlier, the effect of V1aR application to the VP was reversed when those same animals were treated with D2 receptor antagonists. This demonstrates that in these meadow voles, the DA reward circuitry was playing a critical role in the formation of the pair bonds. Therefore, it does seem likely that the addition of the V1aR in the VP, by changes in the 5′ regulatory region of the *v1ar* gene, was permissive for the natural selection of monogamous behavior in the evolutionary history of prairie voles.

It is easy to see how a mechanism based in reward circuitry could allow for the formation of pair bonds. However, if the concurrent activation of D2 receptors and OTR or V1aR in the reward circuitry is part of the mechanism for pair-bond formation, and animals engage in extrapair copulations, what prevents the formation of pair bonds with all individuals? What stabilizes the monogamous social structure, as it is known that even socially monogamous animals like prairie voles do engage in extrapair copulations?

It appears that dopamine D1 receptors in the NAcc may play a role. D1 receptor activation actually inhibits pair-bond formation. In the transition from "not bonded" to "pair bonded," D1 receptor levels rise in the NAcc. It is possible that simple increases in the levels of the D1 receptor antagonize the future development of multiple pair bonds (Aragona et al., 2003b).

For voles to be able to form enduring social bonds, several events have to take place. The animals must first be able to detect each other and discriminate among individuals to make the association with the partner and "reward." The ability to detect each other and discriminate among individuals starts with chemosensory detection by the olfactory bulb. Lesions of the main and accessory olfactory bulb inhibit partner-preference formation in female prairie voles (Williams et al., 1992b; Curtis et al., 2001). In male prairie voles, lesions of the olfactory bulb result in decreased social behavior (Kirkpatrick et al., 1994). With an intact olfactory system, the social information probably passes through to the amygdala, where saliency may be ascribed (Meredith and Westberry, 2004). Social exposure to a male and subsequent parturition in females alter neurogenesis in the amygdala and subventricular zone, which sends new neurons to the olfactory bulb (Fowler et al., 2002). This neurogenesis may influence social recognition by increasing the discriminatory capacity of the olfactory bulb–amygdala social discrimination pathway. Perhaps in voles, as in mice (Shingo et al., 2003), this neurogenesis is a result of elevated prolactin levels associated with mating and pregnancy. The duration of "social memory" of prairie voles is between 1 and 2 weeks (Carter et al., 1995a), whereas the social memory of rats and mice is less than 2 h (Dantzer et al., 1987). However, when group-housed, mice display drastic improvements (days) in the duration of social memory (Kogan et al., 2000). Interestingly, while there are clear data that suggest a role for vasopressin and oxytocin in social recognition memory in rats and mice, the role of these neurohormones in the requisite social recognition component of pair-bonding behavior in voles is not known. Due to the prolonged duration of social memory in monogamous voles, there are perhaps additional neural mechanisms underlying social recognition memory compared with rats and mice.

5.3.5 Bonding and Stress

There is evidence suggesting that adrenal hormones and the hypothalamic-pituitary-adrenal (HPA) or "stress" axis play a role in the social behavior of voles. Presentation of a novel intruder to a sexually experienced vole, but not a naive animal results in an increase in serum corticosterone, and the removal of a mate results in an increase in corticosterone levels, while the subsequent reunion with a mate decreases corticosterone levels (Carter et al., 1995a, b). The direction of change in stress hormone levels indicates that familiarity among prairie voles buffers the activity of the HPA axis.

Prairie voles are sexually dimorphic in their response to stress and stress hormones. Stress antagonizes partner-preference formation in females and promotes partner-preference formation in males. A forced swim stressor inhibits partner-preference formation in females and facilitates partner-preference formation in males (De Vries et al., 1996). Adrenalectomy (and therefore elimination of corticosterone) inhibits partner preference in males (De Vries et al., 1996); however, the same treatment facilitates partner preference in females (De Vries et al., 1995). Furthermore, intraperitoneal injections of 20 to 200 μg corticosterone facilitates partner-preference formation in male prairie voles after just 6 h of cohabitation with a female (De Vries et al., 1996). When very low doses of corticotropin releasing factor (CRF) are injected directly into the brain, male partner-preference formation is facilitated with just 3 h of cohabitation (De Vries et al., 2002). On the basis of previous findings with species differences in behavioral response to oxytocin and vasopressin, one would hypothesize that brain distribution patterns of receptors for CRF would also vary across behavioral phenotypes. Specifically, we would predict that CRF receptor-distribution patterns might vary at least across sex within the prairie vole species and possibly across vole species with divergent social structures. These hypotheses are currently being investigated.

Interestingly, both maternal behavior and pair bonding involve modifications to olfactory centers in the brain and are heavily influenced by the reward circuitry, although by different mechanisms. Additionally, it is possible that both maternal behavior and pair bonding benefit the animal by reducing lifetime exposure to stress hormones via an oxytocinergic mechanism (De Vries et al., 2003). Other hormones,

neuropeptides, receptors, and brain areas, in addition to those described here, are likely to be important for social bonding.

5.4 Nonhuman Primates

5.4.1 Stress Reactivity and Social Behavior

Much of the work on the physical correlates of affiliation in nonhuman primates has been on the effects of social interaction on the activity of the HPA-axis. Like prairie voles, monogamous titi monkeys form strong partner preferences and display increased aggression toward novel strangers (Mendoza and Mason, 1997). Upon separation, males and females show behavioral and endocrine signs of distress. Specifically, titi monkeys show an increased cortisol response to separation (Mendoza and Mason, 1986). This cortisol response is similar to that seen in prairie voles when pair-bonded individuals are separated from each other. Interestingly, infants of titi monkeys show higher cortisol response when separated from their father than from their mother (Hoffman et al., 1995). Additionally, pairs of titi monkeys have reduced cortisol response to novelty than do individuals (Hennessy et al., 1995), suggesting that the presence of the mate serves as a buffer to stress.

In contrast, squirrel monkeys are not monogamous and do not have different cortisol responses to novelty when tested alone or with a cagemate (Hennessy et al., 1995). Even though they do not form adult heterosexual monogamy-like attachments, squirrel monkeys do show maternal–infant bonds and adult friendships. Social separation in mother–infant pairs or like-sex adult friendships results in increased cortisol production in squirrel monkeys (Lyons et al., 1995). Even though these monkeys have reduced adrenocorticotropic hormone (ACTH) concentrations, the adrenal cortex appears to be more sensitive to ACTH and this results in increased serum cortisol levels following a social separation (Levine et al., 1997).

Interestingly, levels of the brain stress neurohormone, CRF were observed to be correlated with social and emotional reactivity behavioral traits in two species of macaques (Rosenblum et al., 2002). Bonnet macaques are gregarious animals with relatively low stress reactivity, which spend a lot of time in social huddles composed of both relatives and nonkin alike. In contrast, pigtail macaques are emotionally volatile and tend to spend more time in isolation, and when they do interact with others it is usually only with their kin. The highly social, temperamentally stable bonnet macaques had low levels of CRF in their spinal fluid compared with the high levels seen in the asocial, volatile pigtail macaques. Furthermore, the social bonnet macaques had high levels of oxytocin in their spinal fluid compared with the asocial pigtail macaques. Across individual members of each species, the levels of oxytocin were modestly positively correlated with CRF in the bonnet macaques and strongly negatively correlated in the pigtail macaques. The strong correlations between these two neurohormones within individuals suggest some underlying shared mechanism. The mechanisms underlying the observed biobehavioral correlation across these two macaque species are currently unknown. It is certainly intriguing that oxytocin has again emerged as a correlate of social bonding.

5.4.1 Endocrine and Socioenvironmental Influences on Social Behavior

In promiscuous matrilineal rhesus monkeys, female–female grooming maintains normal female troupe relationships, except during the periovulatory period. During ovulation and related mating, females appear to either increase aggressive or submissive behaviors toward other females based on social rank. In contrast, affiliative grooming behavior by a female toward a male occurs only during this periovulatory portion of the female's cycle, when estradiol levels peak. In this matrilineal society, unsolicited mating by a male could be disastrous for the male. It is thought that the transient increase in female–male social grooming helps to maintain a short-term relationship to indicate to the male that mounting behavior is appropriate (Wallen and Tannenbaum, 1997). If a rise in estradiol levels permits the inclusion of males in the matrilineal social structure, then groups composed of females with no chance of increased estradiol levels

(i.e., ovariectomized females) should be less likely to include males in their group. Interestingly, a group of adult ovariectomized females did not integrate a group of young male rhesus monkeys even after 2.5 years of cohousing. However, when those females were given periovulatory doses of estradiol, they immediately integrated the males into the colony, as assessed by grooming of the males. This integration of males into the female group lasted long after the hormone treatment ended, but only for the males who mated with the females (Tannenbaum and Wallen, 1997). Perhaps in rhesus monkeys, as in rats, mice and sheep, estradiol exerts its effects on social behavior by regulating prosocial brain oxytocin systems. Estradiol might also influence oxytocin systems important for maternal care. In pigtail macaques, individual differences in late pregnancy estradiol/progesterone ratios were highly positively correlated with the frequency of infant contact (Maestripieri and Zehr, 1998). In addition, ovariectomized females engaged in infant contact less often than ovariectomized females receiving estradiol replacement or intact females (Maestripieri and Zehr, 1998). As in rats, these differences in maternal behavior probably have effects on subsequent adult phenotypes of their offspring. As an extreme example of variation in maternal care, rhesus monkeys that were reared in a nursery instead of by their mother, showed reduced social reciprocity and increased agonistic behavior as adults. These changes were associated with reduced levels of oxytocin in the cerebrospinal fluid (Winslow et al., 2003).

5.4.2 Prolactin and Paternal Care in Monogamous Primates

In several New World primate species, males contribute to the care of the offspring. The male assists by carrying the infants and sharing his food with his young. A large body of research on monogamous biparental birds and rodents demonstrates that in males, prolactin levels contribute to or are associated with paternal care (Schradin and Anzenberger, 1999; Ziegler, 2000). Interestingly, in monogamous biparental monkeys, plasma prolactin levels in males correlate with levels of paternal care, suggesting that prolactin may play a role in primate paternal care as well (Schradin et al., 2003). Signals from pregnant females and/or contact with offspring may increase plasma prolactin levels to further promote parenting behavior in males (Ziegler, 2000). Prolactin may influence paternal care in human males as well. In pregnant couples, men had increased plasma prolactin levels toward the end of their partner's pregnancy and there was a positive relationship between plasma prolactin levels and couvade (pregnancy-like) symptoms in the men (Storey et al., 2000). While there is mounting evidence that prolactin is involved in paternal care in biparental species, the mechanisms are unknown (Schradin and Anzenberger, 1999).

5.5 Humans

Our understanding of the molecular neurobiology, neurochemistry, and neuroendocrinology of social behavior in humans is very limited. Studies in humans are limited to genetics, blood and CSF measures, relatively low-resolution neuroimaging, and postmortem analyses. As we gather information from experimentally tractable model systems such as maternal–infant bonding in rodents and sheep and pair bonding in voles, we can begin to piece together hypotheses about what mechanisms the human brain might use to achieve complex social behavior.

5.5.1 Oxytocin and Vasopressin

In studies of other organisms, it is clear that oxytocin and vasopressin systems are involved in social behavior. Studies in humans suggest that these same molecules may play a role in our own social behavior. For example, oxytocin is released in women during childbirth and subsequent lactation and nipple stimulation (Sogolow, 1966; Christensson et al., 1989), which is temporally appropriate for it to serve a role in mother–infant bonding. Vasopressin levels in serum are elevated in men during sexual arousal (Murphy et al., 1987), and oxytocin levels in serum are elevated in both males and females at orgasm

(Carmichael et al., 1987; Murphy et al., 1987). These changes in neurohormone levels occur at the appropriate time to permit vasopressin and oxytocin to play a role in social bond formation in humans in a similar manner to their roles in monogamous voles.

A recent study used intranasal application of oxytocin via a nasal spray to assess a role for oxytocin in social behavior. Four groups of men were tested in a social stress paradigm (they had to give an unprepared speech and do mental arithmetic in front of strangers). One group received a placebo nasal spray, the next group received nasal spray containing oxytocin, the third group received placebo but were accompanied by their best friend, and the fourth group received oxytocin and were also accompanied by their best friend. After giving the speech, subjects in all four groups donated serum for measurement of cortisol. The group without extra oxytocin or their best friend reported the most stress while in the stress task and had the highest levels of cortisol. In contrast, the participants who received oxytocin and had their best friend had the lowest self-report of stress and the lowest cortisol measures. The two groups with either oxytocin or their best friend, but not both, had intermediate levels of stress and cortisol levels. This experiment effectively demonstrates the role of both a social buffer on stress (the presence of the best friend) and the role of oxytocin in stress buffering (Heinrichs et al., 2003).

Social contact in rodents produces endocrine changes that are consistent with increased parasympathetic activity conducive to stress reduction (Uvnas-Moberg, 1997). In humans, social contact such as a Swedish massage results in modest increases in serum oxytocin (Turner et al., 1999, see also Wikstrom et al., 2003). Such increased levels of oxytocin could mediate the calming effects of social contact and perhaps facilitate social memory. Additionally, cultural traditions that employ some sort of touch during social introductions such as the western handshake or cheek-to-cheek touch may be involved in reducing stress associated with introduction of novel individuals and/or facilitate social recognition memory. If so, it is plausible that this stress reduction and/or facilitation of social memory may occur through oxytocin or vasopressin mechanisms.

In support of the idea that oxytocin and vasopressin are involved in human social behavior, children with autism have lower serum levels of oxytocin (Modahl et al., 1998) and higher oxytocin prohormone/oxytocin ratios (Green et al., 2001), suggesting deficits in oxytocin metabolism. In the prairie vole, it has been demonstrated that a 5′ regulatory microsatellite in the vasopressin 1a receptor gene modifies expression levels of the gene and can potentially direct regional expression (Hammock and Young, 2004), which has important behavioral consequences (Lim et al., 2004c). In the human vasopressin 1a receptor gene, there is also a polymorphic microsatellite that could potentially contribute to gene expression differences across individuals (Thibonnier, 2000), and also potentially have behavioral consequences (Hammock and Young, 2002). There are two reports indicating that particular alleles of this 5′ regulatory microsatellite may be associated with autism (Kim et al., 2002; Wassink et al., 2004).

5.5.2 Brain Imaging

Some of the neural correlates of human social behavior have been identified in imaging studies. Imaging technology, such as MRI, fMRI, and PET, allows visualization and hypothesis testing of the human "social brain." These techniques can measure structural changes in the brain in patients with social deficits in comparison with healthy controls. Additionally, changes in activity in the brain associated with performance in sociobehavioral tasks can also be observed.

Abnormal social behavior in humans helps to provide insight into how the normal brain functions. There are various disease states in humans that result in impaired social behavior; these include Rett's syndrome, Asperger's syndrome, schizophrenia, and autism as mentioned above. Rett's syndrome occurs primarily in females and is caused by a mutation in the MecP2 gene (Amir et al., 1999). The causes of the remaining disorders are still unknown. It is possible that because these disorders are so heterogeneous there are multiple contributing factors across or even within individuals. One emerging mechanism of social behavior dysfunction, at least in schizophrenia and autism, is that of defects in visual processing of faces. Social behavior in rodents and sheep is very olfactory-driven, as that is the main sensory modality used to discriminate individuals. In contrast, humans are a visual species, and we use visual information about faces

to aid in distinguishing among individuals. The cognitive processing required to discriminate individuals appears to be mediated in part by the fusiform gyrus in the temporal lobe (Kanwisher et al., 1997; Gauthier et al., 2000). Autistic patients have an increased volume of this brain area (Frith, 2003), while schizophrenics have a decrease in volume in this brain area (Onitsuka et al., 2003) compared with healthy controls. In functional imaging studies, autistic patients show a lack of activation of this brain area when presented with face stimuli (Schultz et al., 2000). Perhaps these differences in size of this area result in (or from) the visual processing deficit in these disorders.

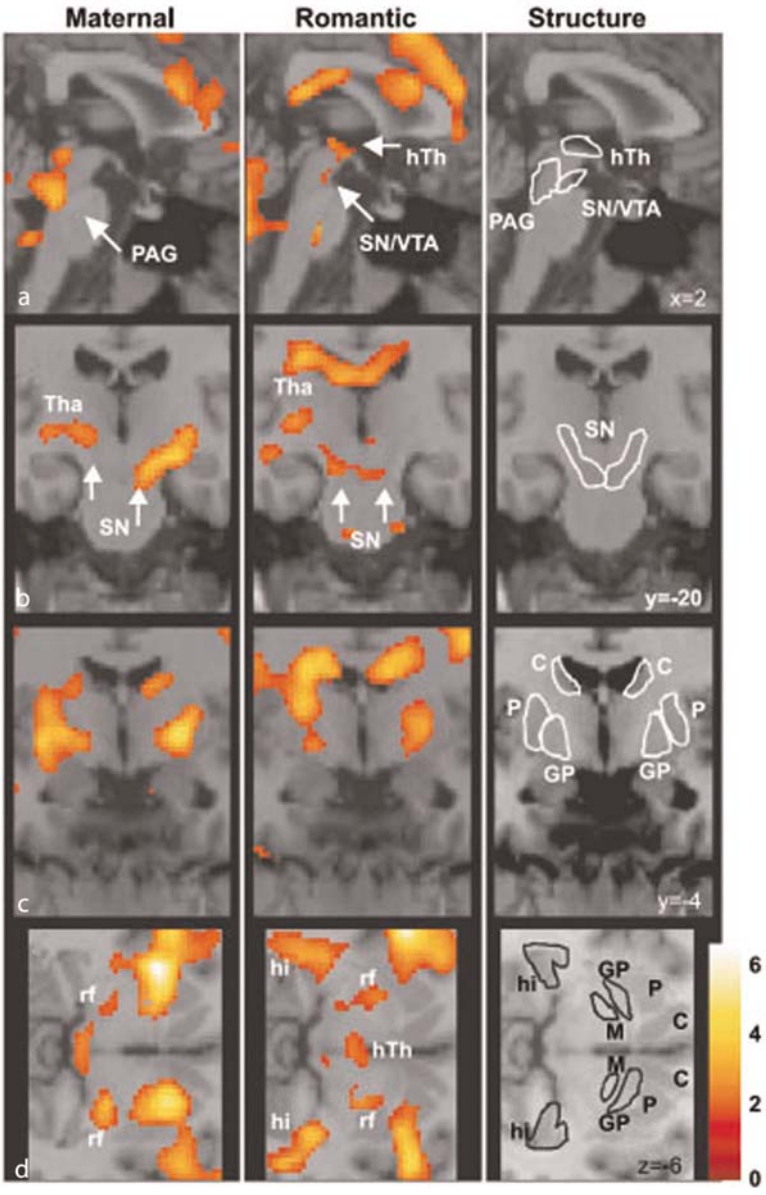
Which brain areas are activated while attributing "sociality" to abstract objects, and are these areas part of the human "social behavior circuit"? To answer this question, Castelli and coworkers used a PET study in which subjects viewed abstract objects that were behaving "socially" or "mechanically" or "randomly" (Castelli et al., 2002). Interestingly, regions that have been implicated across vertebrate species as playing a role in social behavior were significantly more activated when the abstract objects were behaving "socially." These areas include the lateral fusiform gyrus, the superior temporal sulcus, the ventromedial prefrontal cortex, and the amygdala.

There are some interesting structural changes associated with deficits in social behavior in humans. A single individual, patient S.M., with Urbach-Wiethe disease, which produces bilateral amygdaloid damage, was reported in 1994 to be unable to recognize the facial emotion that represents fear (Adolphs et al., 1994). With further characterization, this deficit was detected as specific to recognition of the facial expression of fear and not in understanding the idea of fear (Adolphs et al., 1995). In a follow-up study, several other individuals with bilateral damage to the amygdala tended to rate pictures of unfamiliar faces as "more trustworthy" and "approachable" than normal subjects who would give negative ratings to the same faces (Adolphs et al., 1998). These results are interesting because the results from nonhuman primate studies suggest that the amygdala serves as a filter, or gate, regulating the saliency of social information, with most emphasis on fear-eliciting social stimuli (Amaral, 2003). In a human imaging study, the amygdala was robustly activated when parents heard the sounds of infants crying compared with nonparents (Seifritz et al., 2003). Amygdaloid abnormalities have been implicated in autism, but the results are equivocal (Palmen and Van Engeland, 2004; Palmen et al., 2004). Most recently, the deficit in patient S.M. has been attributed to a lack of attention to the eyes when looking at pictures of faces. When she was reminded to look at the eyes, she easily recognized the facial expression of fear (Adolphs et al., 2005).

In other animals, it is clear that social attachment requires utilization of the brain circuitry underlying motivation and reward, such as the MPOA, the VTA, and the ventral striatum. Neuroimaging studies in humans have recently provided evidence that brain activity in these brain regions may also play a role in human bonding. Using healthy adults as volunteers, Bartels and Zeki showed brain activation in ventral forebrain and midbrain reward circuitry when males and females looked at pictures of their partners (Bartels and Zeki, 2000). In this study, increased brain activity was observed in the anterior cingulate cortex, the medial insula, and the ventral forebrain, including the caudate and putamen, the hypothalamus, and the midbrain substantia nigra/VTA. In particular, the activation of reward areas such as the substantia nigra/VTA point to convergent mechanisms of social bonding in mammals. During this task, several brain areas were less active including the posterior cingulate gyrus and the amygdala. In a follow-up study Bartels and Zeki compared the neural correlates of maternal and romantic "love" (Bartels and Zeki, 2004). Again using healthy volunteers, they first had mothers look at photos of their children and separate photos of other kids matched for age and familiarity. When looking at the pictures of their own children, the mothers had significantly increased brain activation in the anterior cingulate cortex, middle insula, striatum, periaqueductal gray, and substantia nigra. Additionally, the amygdala was less activated when looking at pictures of their own versus other children. This deactivation of the amygdala occurs in both maternal and romantic love. This fits with the idea that the role of the output of the amygdala is to signal "fear" to other brain areas: it would be contradictory to activate fear circuitry when looking at one's child or partner. Additionally, when Bartels and Zeki compared the activations in both maternal and romantic "love," they observed consistent activations in brain regions that were previously reported to contain OTRs and vasopressin receptors, such as the substantia nigra/VTA (Loup et al., 1989, 1991). This suggests that the oxytocin/vasopressin systems observed in the reward pathways in monogamous voles may play a similar role in social bonding in humans (*Figure 6-7*).

Figure 6-7

There are both common and distinct neural correlates in humans underlying maternal love and romantic attachment. Images here show neural activation in the brain in the ''maternal'' condition (mothers looking at their own versus a familiar but unrelated child) and in the ''romantic'' condition (women viewing pictures of a loved partner versus three friends). All the labeled areas in this figure have been previously reported to contain vasopressin receptors or oxytocin receptors. Some of the brain areas that show altered activity in these conditions overlap with such brain areas. (a) sagittal, (b–c) coronal, (d) transverse. Abbreviations: C, caudate nucleus; GP, glubus pallidus; hi, hippocampus; hTh, hypothalamus; P, putamen; PAG, periaqueductal (central) gray; M, nucleus of Meynert; rf, retrorubal fields/intralaminar/subthalamic nuclei; SN, substantia nigra; Tha, lateral thalamus; VTA, ventral tegmental area. (This figure was taken from Bartels and Zeki 2004, with permission)



If similar mechanisms of pair bonding occur in humans as in voles, then mating should involve the activation of the reward circuitry. Holstege and colleagues (2003) measured changes in blood flow during ejaculation using PET imaging. Heterosexual adult males were placed in the PET scanner and stimulated by their partners. Among other brain areas with increased blood flow, the VTA showed increased blood flow during ejaculation, which is similar to brain activation during a heroin rush (Holstege et al., 2003).

5.5.3 Pain and Social Cognition

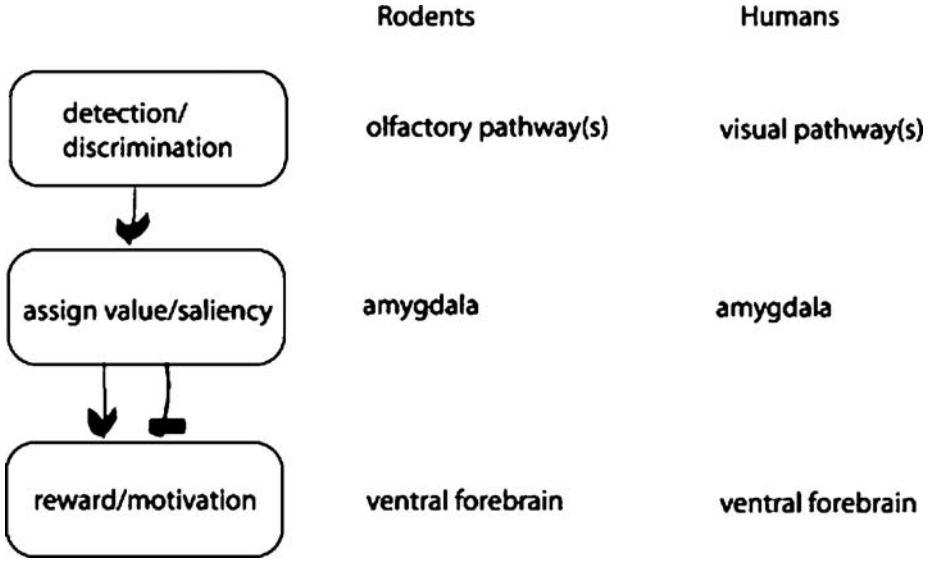
Because social behavior is so important to the survival of prosocial species, it is important for an individual to perceive changes in social context. Activation of pain systems may be one way to motivate an individual to avoid or rectify certain social situations that have negative implications (Panksepp, 2003). An individual with an activated pain system should try to remedy the situation to reduce the perceived pain. Social behavior may have evolved to use pain-perception mechanisms to regulate behavior. Eisenberger and coworkers recently demonstrated that perceived social exclusion is associated with changes in brain activity involved in the perception of physical pain, such as the anterior cingulate cortex and the right ventral prefrontal cortex. Using fMRI, they had subjects engage in a virtual reality ball tossing game, where the ball was tossed back and forth from the subject and two other "players." The other "players" were actually part of a preprogrammed computer game. Part of the way through the ball tossing game, the subject in the scanner was excluded from the game. After the scan, the subjects reported that they had felt excluded and they were distressed. This measure of distress was significantly correlated with activation in the anterior cingulate cortex, which in turn was strongly negatively correlated with activity in the ventral prefrontal cortex (Eisenberger et al., 2003). These brain areas have been shown to be involved in the perception of physical pain. Interestingly, lesions of the anterior cingulate in female hamsters result in a decrease in pup retrieval behaviors, and the same lesions in squirrel monkeys result in a decrease in isolation calls. The anterior cingulate is activated in human mothers listening to infant cries (Murphy et al., 1981; MacLean and Newman, 1988; Lorberbaum et al., 1999). Perhaps across species, activation of the anterior cingulate results from cries of the infant or feelings of social isolation, which may be perceived as physically painful and could produce a motivational state to remedy the situation.

5.5.4 Foundations

While we still know relatively little about the neurochemical, neuroendocrine, and molecular neurobiological mechanisms of human affiliation, studies in simpler model systems have yielded promising insights. *Figure 6-8* briefly summarizes human social behavior from a systems perspective. As in rodents, we must detect and discriminate among individuals. Visual pathways primarily serve this process, whereas in rodents these processes are primarily olfactory. Next, the identification of specific individuals must be accompanied by a signal of valency. We tend to have strong positive or negative feelings about others and current data suggest that the amygdala plays some role in this process. Before the initiation of prosocial behavior, we must be motivated to act, and our levels of motivation are influenced by the activity of the ventral forebrain reward circuitry. Our genes and hormonal milieu permit the development of such a system as well as act within the system to produce behavior. Likewise, the environment in which humans develop is critical for the development of appropriate social behavior. Early experience serves to tune the genetically and hormonally wired system and influence our choices. Extreme social deprivation early in life has profound effects on adult social behavior. For example, children reared in extremely deprived environments (e.g., the infamous orphanages of Romania) often display autistic-like behavior in addition to dramatic deficits in growth (Carlson and Earls, 1997). Other studies have indicated that social touch in humans is important for infant growth. Massage of premature infants can result in rapid increases in weight gain and reduction in hospital stays (Field, 2002). These studies indicate that early experience with social interaction in humans

Figure 6-8

Affiliative behavior requires detection and discrimination of social stimuli through highly developed sensory systems. In humans, visual processing of faces is an important component of social recognition, while in rodents, social recognition is primarily an olfactory process. The affective value of the social stimulus may be assessed or ascribed in the amygdala. After such information processing, motivational and reward systems must be engaged to prompt the animal to act. This is a very simplified view in an attempt to summarize common themes that have emerged from vertebrate models of affiliation



has important consequences not only for the appropriate development of social cognition, but also for the basic mechanisms of growth and survival. These data underscore the importance of basic science research into the underlying mechanisms of social behavior in animals, because it pertains to both the psychological and physical well-being of our own exceedingly social species.

6 Conclusions

Social behavior is highly variable across species. This fact allows for informative comparative studies. An ongoing comparative approach of natural variation has revealed mechanisms of social behavior at the genetic, molecular, cellular, and systems levels of understanding. Social behavior is multisystemic. Proper social behavior requires integration of internal states with environmental stimuli. In vertebrate species, adrenal and gonadal hormones serve to organize behavior, as do central neurotransmitter systems such as prolactin, oxytocin, and vasopressin. Similar humoral mechanisms function in invertebrates as well. Studies in invertebrates have certainly aided our understanding of social behavior. We can apply the mechanistic principles obtained from simpler systems to generate hypotheses and guide our understanding of the biological substrates of more complex social behavior.

There are numerous remaining questions from these cross-species studies of social behavior. Of course, many of the species-specific circuit and molecular details remain to be elucidated. There are currently more questions than answers, especially of our own species. However, the once seemingly impossible task of elucidating mechanisms of complex social behavior is now a tractable topic of investigation with appropriate model systems and new techniques.

Abstract: The molecular events through which social experiences shape future aggressive acts are beginning to be deciphered. The brain serotonin system is by far the major focus of neurobiological inquiries into the mechanisms mediating certain types of aggressive behavior. Its significant role in impulsive, hostile, antisocial and intensely violent outbursts has been supported by several findings including: deficient levels of 5-HT and its acid metabolite; polymorphisms in the genes coding for its metabolic enzymes; mutations in the genes for some of its receptor and transporter molecules; and altered responses to pharmacological challenges of 5-HT agonists. The reciprocal interactions of serotonin with other amines, acids, peptides and steroids provide further evidence that this indolamine mediates impulsive aggressive behavior. Afferent and efferent projections from dopamine and norepinephrine cells to serotonin cells as well as serotonergic presynaptic modulation of catecholaminergic transmission are the basis for serotonin's impact on sensory, integrative motivational and motor facets of aggressive acts. Similarly, serotonin influences the actions of oxytocin and vasopressin as well as corticotrophin releasing factor and opioid peptides in their ultimate effect on aggressive behavior. New tools are required to determine how experience-dependent phasic changes ("state") in serotonergic terminals in prefrontal cortex, ventral striatum, central and basolateral amygdala, tegmental area and raphé nuclei are superimposed on the serotonin tone in violence-prone individuals ("trait"). Among the urgent research needs are the development of laboratory model systems that capture the transition from the species-typical patterns of dominance or territorial aggression to escalated forms of aggression, since the latter is of primary clinical relevance. The emerging neurobiological research areas focus on: the allosteric modulation of the $GABA_A$ receptor and its subunit composition as a site for the escalation of aggressive behavior; the triggering of aggressive acts by glutamate action, presumably via NMDA receptors, in the lateral hypothalamic area; the predisposing role of specific polymorphisms in enzymes and transporter molecules that are critical for the inactivation of monoamines; and the dissociation between catecholaminergic activities in anticipation of intense aggressive encounters vs. the recovery from such interactions. Important targets for intervention are the long-term neuroadaptive changes in DA, opioid peptides and glutamate in the VTA as they are engendered by repeated aggressive experiences, both in the perpetrator and in the victim of aggression.

1 Opening Vignettes: Lessons from Lobsters and Birds

Integrating and evaluating the current research on the neurobiological mechanisms of aggressive and violent behavior will develop an agenda for urgent research needs. Although the WHO "World report on violence and health" (2002) ignores this topic entirely, understanding the molecular events through which social experiences shape future aggressive acts may bridge the rift between the social and biological science approaches to aggressive behavior—a problem for the public health and the criminal justice systems.

Understanding the chemical characteristics of neural circuits that mediate different kinds of aggressive behavior began in the 1960s by focusing on the prominent role of brain serotonin, and this effort continues even today. The initial findings correlated low levels of this indolamine in the brainstem of isolated mice with their propensity to fight (Giacalone et al., 1968). A decade later, this observation was complemented by the measurements of low levels of the major serotonin metabolite 5-hydroxyindolacetic acid (5-HIAA) in the cerebrospinal fluid of violence-prone marine soldiers (Brown et al., 1979). This finding is often, but not always, replicated in various species, including humans; and it is the basis for linking the serotonin deficiency to individuals prone to engage in the cluster of impulsive, antisocial, hostile, intense violent outbursts relative to instrumental, calculating aggressive acts (Stoff and Vitiello, 1996; Vitiello and Stoff, 1997).

The anatomy of the serotonin cell bodies in the midline raphe region with their efferents and afferents are remarkably similar throughout phylogeny (Parent et al., 1984). Fundamental insights for serotonin into aggressive behavior emerged from measurements in crustaceans that confronted each other. These studies showed that serotonin could exert multiple roles—one role at the neuromuscular junction and another in the central nerve cord (Livingstone et al., 1980; Edwards and Kravitz, 1997; Kravitz and Huber, 2003). Contrary to the serotonin deficiency in many aggressive vertebrates, lobster or crayfish that assume an aggressive stance, threaten, and attack an opponent, are characterized by high levels of serotonin in the

central cord. Injections of serotonin and indirect serotonergic agonists into a lobster at rest trigger aggressive displays (Kravitz and Huber, 2003), and these receptor subtype–specific serotonin effects in crayfish depend on the individual's prior experience as subordinate or dominant (Yeh et al., 1996). The studies in invertebrates led to the proposal that serotonin in the ventral cord exerts a gain-setting role in the neural circuit, which integrates aggression-provoking sensory information with signals that initiate the motor acts for aggressive displays (Kravitz, 1988). This integrative function of serotonin at the neural level of crustaceans is instructive, and may serve as model for conceptualizing how serotonin in corticomesolimbic circuits operate in the mammalian nervous system, albeit in a functionally opposite manner.

Linking the direct measurement of neurotransmitters such as serotonin and its metabolites with behavioral events remains a traditional approach to the study of the neurochemistry of aggression, but is clearly limited by the *correlational* nature of the evidence. A considerably more cogent strategy is based on the endocrine research paradigm that was introduced by Arnold Berthold (1849). When the glandular source of the endogenous candidate substance was removed (i.e., the roosters were castrated), aggressive displays declined. Upon replacement of the glandular material, aggressive behavior recovered (Berthold, 1849). The depletion and repletion effects for testosterone have been replicated in animal species ranging from lizards, snakes, and fish to birds, for whom testosterone is obligatory in order to engage in aggressive behavior (Crews and Moore, 1986; Wingfield et al., 1987). By contrast, in mammalian species, experience can *modulate* the obligatory role of androgens on aggressive behavior, sometimes attenuating the effects of castration (Christie and Barfield, 1979; DeBold and Miczek, 1981). The endocrine research paradigm of depletion and repletion has become a model for studying the canonical neurotransmitters, such as the monoamines, and their role in aggressive behavior (e.g., Kantak et al., 1981). More recently, this logic has been applied with molecular biology tools to the study of aggression. Once aggressive behavior is established, the expression of a gene of interest can be suppressed with the so-called knock-down techniques and subsequently reexpressed with the tetracycline-gene regulation system (Chen et al., 1997).

Pharmacological interventions offer a further important approach to the neurobiological study of aggressive behavior. Drugs that selectively modulate discrete elements of a neurochemical system can reveal a neurotransmitter's specific function in the initiation, execution, and termination of aggressive behavior. For example, the simple functional label of serotonergic inhibition of aggression has yielded to a more intricate perspective, which is prompted by the knowledge of an array of receptor subtypes and transporter molecules for serotonin and discrete anatomical 5-HT pathways (Hoyer et al., 2002). Activation of the 5-HT_{1A} and 5-HT_{1B} receptor subtypes, for example, produces divergent effects in various behavioral and physiological activities such as movements, alimentary behavior, and sexual libido, and it is possible to extrapolate such opposing roles also to aggressive behavior (Jenck et al., 1989; Dulawa et al., 2000; Olivier, 2004; Faccidomo et al., 2005).

2 Behavioral Foundations

Aggression encompasses a range of diverse behavior patterns, each with unique distal and proximal antecedents and various functions. Aggression is by no means unitary in its origins, motivations, expressions, or functions, implying diverse neurobiological mechanisms. From a clinical perspective, it has been useful to distinguish between kinds of aggression, such as the impulsive–reactive–hostile–affective, as opposed to the controlled–proactive–instrumental–predatory subtype of human aggression (Vitiello and Stoff, 1997). Behavioral biologists focus on types of aggressive behavior that have evolved as social and reproductive adaptations. In socially cohesive species, such as primates and rats, males establish and maintain dominance hierarchies, whereas dispersed species, such as mice, mark, patrol, and defend territories with the overarching objective of securing the resources to reproduce successfully and transmit genes. Similarly, females suppress the reproductive activities of rivals and defend their offspring (Huntingford and Turner, 1987). Experimental models of aggressive behavior that escalate the intensity and frequency beyond the species-typical norms are particularly relevant to understanding the types of human aggression that are of clinical concern.

2.1 Species-Typical Aggressive Behavior: Fighting as an Adaptation

2.1.1 Dominance Aggression

In socially organized and cohesive species, dominance hierarchies are established and maintained by aggressive acts, postures, and displays that result in submissive, defensive, and evasive responses by lower-ranking individuals. Facial grimaces, body postures, and mounting are prominently displayed by both old world and new world primates that are occasionally used in neurochemical studies of aggressive behavior (Mehlman et al., 1994; Higley et al., 1996; Fairbanks et al., 1999; Bennett et al., 2002). Intense, frequent, and potentially injurious aggression characterizes the early phase of forming a dominance hierarchy in rhesus monkeys (Bernstein et al., 1974; Bernstein, 1981) and in rats (Steiniger, 1950), particularly in the presence of females. Later on, dominance is maintained by threat displays. These displays are part of an elaborate repertoire of acts and postures that have evolved in each species to communicate social signals and to engage in aggressive confrontations, often referred to as agonistic behavior (Scott and Fredericson, 1951). This behavioral repertoire of aggressive acts, postural, and facial displays, develops during rough-and-tumble play fighting in the prepubertal period (Pellis and Pellis, 1987). In many established groups of primates, dominance is determined early in life by the social rank of the mother (Walters and Seyfarth, 1986). In contrast to the prevailing ethological thesis that dominance aggression consists chiefly of ritualized displays (Eibl-Eibesfeldt, 1961; Lorenz, 1966; Goodall, 1986), rare, but memorable instances of injurious aggression have been documented in chimpanzees that track down neighboring groups for the purpose of deadly attacks (Nishida et al., 1985; Wrangham, 1999).

The functional significance of dominance aggression is expressed in its operational definition of gaining ready access to essential resources such as preferred foods, protected sleeping places, and high-status mates. From a sociobiological perspective, the transmission of genetic information into the next generation is the essential definition of dominance (Wilson, 1974). Yet, the significance of lethal raiding parties in hominids remains a challenging topic, as it focuses on relatively rare behavioral events that are associated with intense autonomic excitement as well as careful planning and coordination.

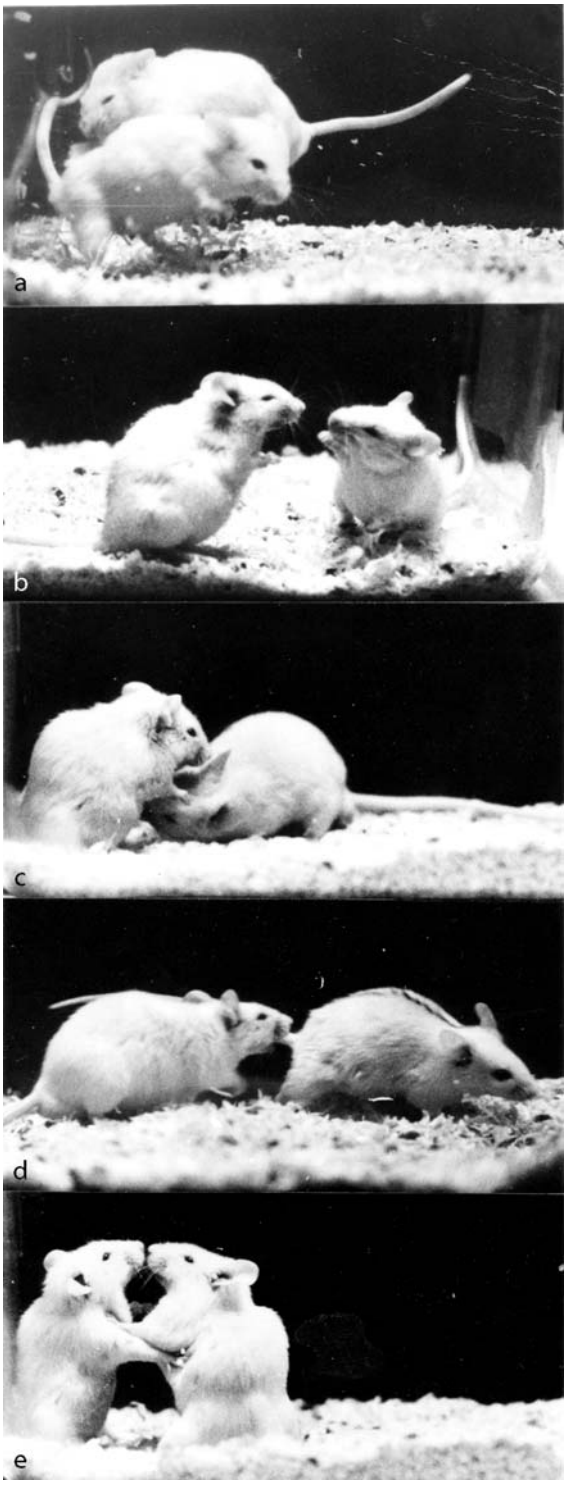
2.1.2 Territorial Aggression

Much neurochemical work on aggressive behavior is performed in murine species that are characterized by territorial aggression (Garattini et al., 1967; Henley et al., 1973; Saudou et al., 1994b). Adult breeding male mice patrol, mark, and defend their territory that becomes the site of the deme (breeding unit, "Grossfamilie") when they attract fertile females and exclude other breeding males (Eibl-Eibesfeldt, 1950; Crowcroft and Rowe, 1963; Reimer and Petras, 1967; Cairns and Nakelski, 1971; Poole and Morgan, 1976). The term territorial aggression is applied to the behavior of a male in control of an "exclusive territory" or of one male who dominates others ("dominance territory"). Even under laboratory conditions, nearly all offspring are sired by dominant males, whereas subordinate males are rarely seen mating and are the targets of frequent attacks in this pugnacious species (Mackintosh, 1970). A breeding male resident mouse attacks an adult male who intrudes into the territory rapidly, vehemently, and frequently. Under controlled laboratory conditions, this type of confrontation is referred to as *resident–intruder aggression* (Crawley et al., 1975; Miczek and O'Donnell, 1978) (*Figure 7-1*).

Figure 7-1

Mouse agonistic behavior. Behaviors of resident and intruder mice engaged in an aggressive confrontation: (a) the resident leaps and bites the intruder as the intruder attempts to escape; (b) the resident (*right*) threatens as the intruder (*left*) holds a defensive upright posture; (c) the resident investigates the intruder's anogenital region; (d) the resident pursues the fleeing intruder; (e) both resident and intruder engage in a mutual upright defensive posture. Copyright 1978 by Springer-Verlag. Reprinted with permission from Miczek and O'Donnell (1978)

Figure 7-1 (continued)



Laboratory mice are housed most often in groups, preventing the formation of demes, and under these conditions territorial aggression is seen only in some proportion of outbred mice. Most inbred mice, particularly those used as background strains for transgenic mice, exhibit rarely species-normative social and aggressive behavior (Silver, 1995; Parmigiani et al., 1999; Miczek et al., 2001). Social experiences during development are required for most male *Mus musculus* to engage in aggressive behavior during adulthood (Cairns and Nakelski, 1971). In addition to the aggressive confrontations with territorial intruders, outbred laboratory mice such as Swiss mice that are housed in large same-sex groups often develop despotic relationships, with one mouse dominating all other mice (Uhrich, 1938; Poole and Morgan, 1973; Brain, 1975).

2.1.3 Female Aggression

Rivalries among breeding females and protection of the offspring from harm are the key determinants of aggressive behavior in females of most mammalian species (Hurst, 1987). In the presence of dominant females, the endocrine cyclicity and fecundity of low-ranking females are suppressed, as illustrated in several primate species such as marmosets and baboons (Smuts, 1986). Harassing attacks by dominant females interrupt opportunistic matings by low-ranking females. The neurobiological mechanisms for these types of female–female rivalry in the context of mate choice have not been studied so far.

Nearly all neurobiological research on aggressive behavior in females has focused on postpartum or maternal aggression in rodents (Lonstein and Gammie, 2002). In fact, female mice, rats, voles, and hamsters fight more near their nest site, possibly a parallel to the male territorial defense. Exposure to pups can promote aggression in females, even in virgins, given the appropriate endocrine conditions. In most rodents, aggressive behavior becomes more frequent, shortly before gestation, reaches a peak during the first week postpartum, and declines thereafter (Noirot et al., 1975; Erskine et al., 1980; Mann and Svare, 1982). The behavioral repertoire for maternal aggression shares many similarities with male aggression, but importantly includes frequent bites directed at the snout and the face of both male and female opponents that are defensive in character (Haney et al., 1989).

Even when not lactating and without maternal experience, female rodents and primates can exhibit substantial amount of aggressive behavior, and females compete for reproductive opportunities (Smuts, 1986; Palanza et al., 2005). In mice and rats, even ovariectomized females that are housed with a male will attack intruders (DeBold and Miczek, 1981; Zitzman et al., 2004). The degree to which the neurobiological basis of aggressive behavior by nonlactating and maternal females overlap, remains to be studied.

2.2 Escalated Aggressive Behavior: Models for Disorders

Aggressive behavior in animals becomes increasingly relevant to clinical concerns in humans when it exceeds the species-typical pattern (Miczek et al., 2004a; de Almeida et al., 2005). The ethical dilemma of investigating escalated forms of aggressive behavior is the necessity of allowing potentially harmful and injurious behavior to proceed, and at the same time, attempting to follow the principle of harm avoidance as much as possible (Miczek, 2001). Aside from illegal breeding practices in fowl, dogs, and cattle, mice have been bred for aggressive behavior under controlled laboratory conditions (Lagerspetz, 1964). These genetic selection studies are particularly relevant for questions addressing individual differences in aggressive trait characteristics. In addition, provoking an individual with frustrative experiences or with social instigations examines the resilience and the vulnerability to engage in aggressive behavior.

2.2.1 Bred for Aggression

Domestication of feral animals amply demonstrates the success with selective breeding for nonaggressive behavioral characteristics (Blanchard et al., 1998; Koolhaas et al., 1999). Conversely, neurobiological studies

have taken advantage of genetic selection for aggressive behavioral phenotypes, by comparing lines of rodents and canine species that express high levels of aggressive behavior relative to low levels (Weerts et al., 1992; Gariepy et al., 1998; Van Der Vegt et al., 2001; Badino et al., 2004).

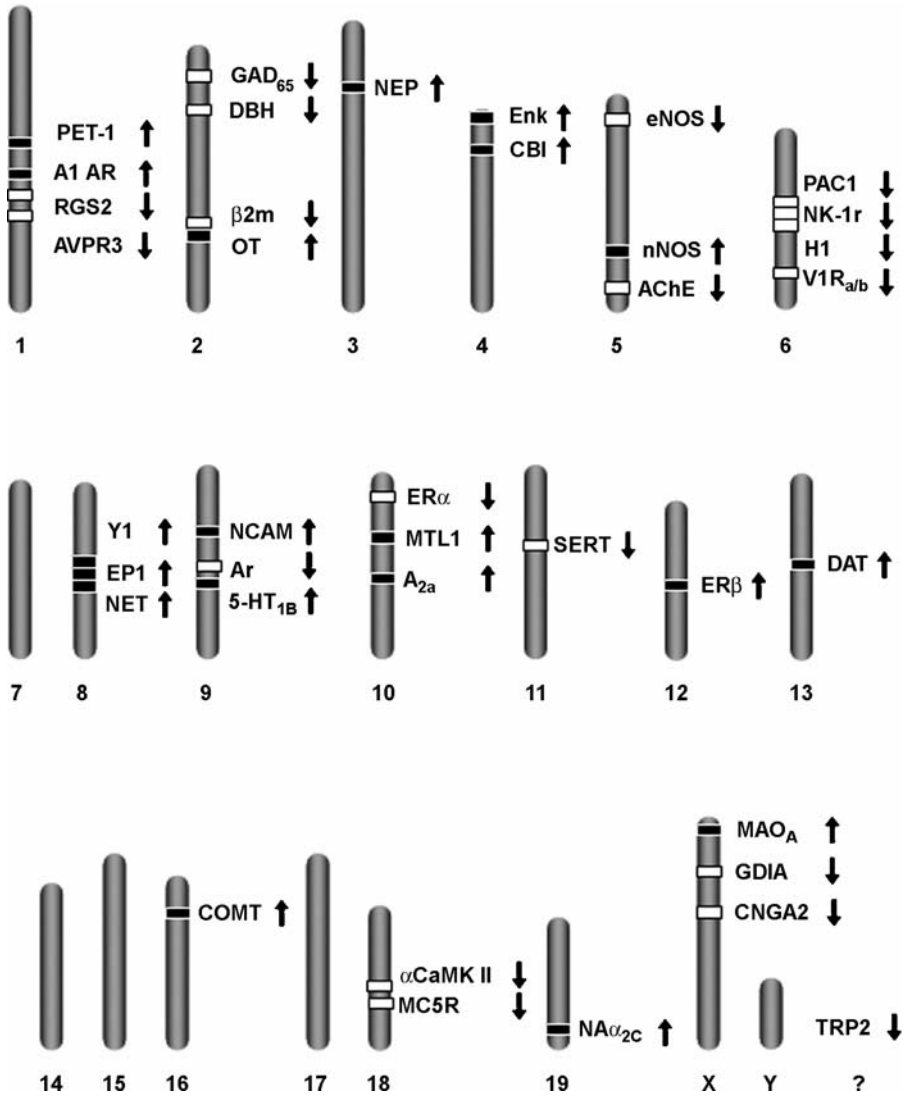
Systematic efforts in selective breeding for aggression in mice have demonstrated that lines of highly aggressive and nonaggressive males diverge promptly and stabilize at high and low levels after ca. 15 generations ("top–down genetics") (Lagerspetz, 1964; van Oortmerssen and Bakker, 1981; Sandnabba, 1986). Individual differences in aggressive behavior have been characterized in strains or breeds of animals that show extreme expressions of the behavior, and this strategy has been exploited in the study of various neurochemical markers in postmortem assays of neural tissue.

An alternative approach focuses on a single candidate gene for the pathogenesis of escalated aggressive behavior ("bottom–up genetics"), and it has become feasible by techniques that enable the deletion or overexpression of a specific gene. This approach has pointed to the influence of several genes on most chromosomes, ranging from the 5-HT_{1B} receptors, nNOS, MAO_A, preproenkephalin, adenosine A_{2a} receptor, neural cell adhesion molecule, estrogen receptor beta, and adrenergic alpha2 receptor to oxytocin (Miczek et al., 2001). Concordant with the polygenic influences on aggressive behavior, mouse mutants have demonstrated that several gene products are important in the development of escalated aggressive behavior (*Figure 7-2*).

The genetics of aggressive behavior may be advanced by the recently sequenced DNA of the fruit fly (*Drosophila melanogaster*) and by the detailed analysis of its aggressive behavior (Chen et al., 2002). The techniques for generating genetic mutants in fruit flies are fully established, and it should be possible to identify all the relevant genes that are critical for escalated aggressive behavior in Drosophila.

Figure 7-2

Gene deletions and mouse aggression. Gene deletions affecting aggressive phenotypes in mice. This figure portrays representations of 21 chromosomes (*vertical bars*) and the approximate location of genes (*filled and open horizontal bars*) that have been knocked out in mice and engendered heightened- (*filled bars, upward arrow*) or suppressed- (*open bars, downward arrow*) levels of aggression. The proteins targeted by the gene deletion are indicated in abbreviated text. Deletions that have not affected aggressive behavior are not shown. Abbreviations and references: 5-HT_{1B}, serotonin receptor 1B (Saudou et al., 1994b); A1AR, adenosine receptor A1 (Saudou et al., 1994a); A_{2a}, adenosine receptor 2A (Ledent et al., 1997); AchE, acetylcholinesterase (Duysen et al., 2002); αCaMK II, alpha-calcium-calmodulin kinase II (Chen et al., 1994); Ar, aromatase (Matsumoto et al., 2003); AVPR3, arginine vasopressin 1B receptor (Wersinger et al., 2002); β2m, beta2-microglobulin (Loconto et al., 2003); CB1, cannabinoid receptor 1 (Martin et al., 2002); CNGA2, cyclic nucleotide gated channel alpha 2 (Mandiyan et al., 2005);COMT, catechol-*O*-methyltransferase (Gogos et al., 1998); DAT, dopamine transporter (Rodriguiz et al., 2004); DBH, dopamine beta hydroxylase (Marino et al., 2005); eNOS, endothelial nitric oxide synthase (Demas et al., 1999); ENK, enkephalin (Konig et al., 1996); EP1, prostaglandin E receptor 1 (Matsuoka et al., 2005); ERα, estrogen receptor alpha (Ogawa et al., 1998); ERβ, estrogen receptor beta (Ogawa et al., 1999); GAD_{65}, glutamic acid decarboxylase (65 amino acids) (Stork et al., 2000); GDIA, guanosine diphosphate (GDP) dissociation inhibitor 1 (D'Adamo et al., 2002); H1, histamine receptor 1 (Yanai et al., 1998); MAO_A, monoamine oxidase A (Cases et al., 1995); MC5R, melanocortin-5 receptor (Morgan and Cone, 2006); MTL1, nuclear receptor subfamily 2, group E, member 1 (aka ''FIERCE'') (Young et al., 2002a); Naα_{2C}, adrenergic alpha receptor 2C (Sallinen et al., 1998); NCAM, neural cell adhesion molecule (Stork et al., 1997); NEP, neutral endopeptidase (Fischer et al., 2000); NET, norepinephrine transporter (Haller et al., 2002); NK-1r, neurokinin receptor 1 (De Felipe et al., 1998); nNOS, neuronal nitric oxide synthase (Nelson et al., 1995); OT, oxytocin (Winslow et al., 2000); PAC1, adenylate cyclase activating polypeptide 1 receptor 1 (Nicot et al., 2004); PET-1, ETS (E26 transformation specific) domain transcription factor (Hendricks et al., 2003); RGS2, regulator of G protein signaling (Oliveira-dos-Santos et al., 2000); SERT, serotonin transporter (Holmes et al., 2002); Trp2, transient receptor potential family 2 (Stowers et al., 2002); $V1R_{a/b}$, a cluster of vomeronasal receptor genes located on chromosome six, $V1ra_{1–9}$ and $V1rb_{1–4, 7–9}$ (Del Punta et al., 2002);Y1, neuropeptide Y receptor 1 (Karl et al., 2004). As of March, 2006



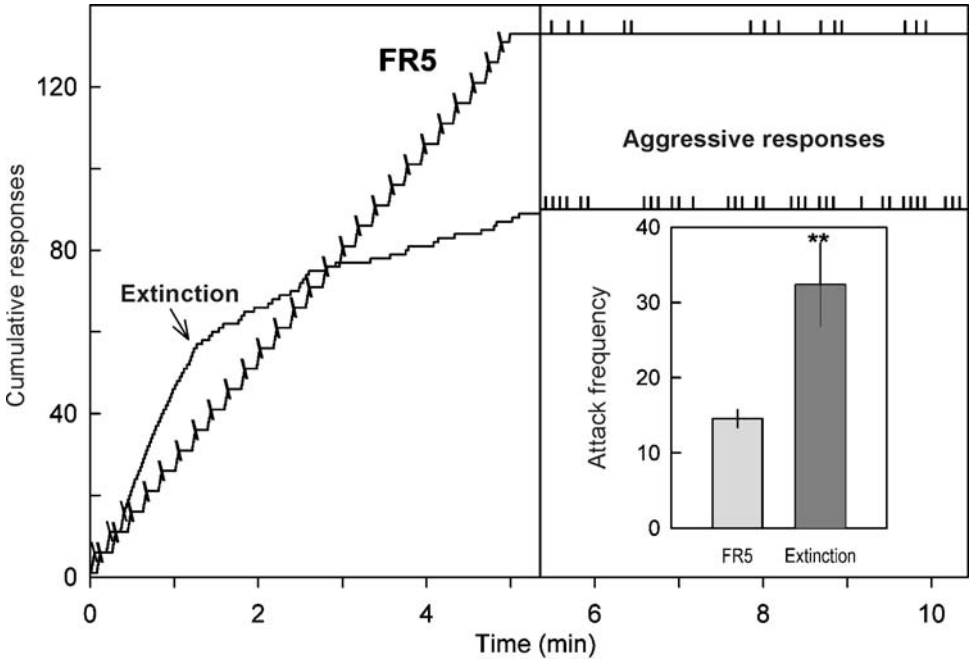
2.2.2 Frustration Aggression

By far, one of the generally most effective ways to escalate aggressive behavior is the exposure to frustrative experiences (Dollard et al., 1939). When a scheduled reward is suddenly omitted, the probability of heightened aggressive behavior increases greatly in various animal species, including humans. Violent youths characteristically show a low-frustration threshold (Calkins and Johnson, 1998; Nock and Kazdin, 2002). Several experimental protocols in avian species, rodents, and primates have captured this phenomenon (Azrin et al., 1966; Cherek and Heistad, 1971). The basic principle of omitting a scheduled reward as a trigger for escalated aggressive behavior can be readily implemented in laboratory mice (Fish et al., 1999; de Almeida and Miczek, 2002) (*Figure 7-3*).

In spite of the ubiquitous nature of frustration-escalated aggressive behavior, neurobiological studies have been limited to pharmacological manipulations involving therapeutic agents and drugs of abuse

Figure 7-3

"Frustration-induced" aggression in a resident male mouse after omission of scheduled reinforcement. (*Left panel*) During a 5 min session, the mouse responds on a fixed ratio 5 schedule of positive reinforcement for the delivery of a sucrose solution (indicated by a slash) and then confronts an intruder. On extinction sessions, only three reinforcers are available. (*Right panel*) Aggressive responses (indicated by vertical deflections in the time line) are heightened after extinction. (*Inset*) The mean frequency of attack bites (±SEM, vertical lines) in the reinforced (FR5, light gray bar) and extinguished (dark gray bar) conditions, **denotes $p < 0.01$. Copyright 2002 by Springer-Verlag. Reprinted with permission from Miczek et al. (2002)



(Cherek and Pietras, 2003). So far, the neural mechanisms through which a frustrative experience triggers aggressive outbursts remain to be delineated; similarly, the trait characteristics of resilience to frustration experience or, operationally, resistance to extinction, have not been characterized in terms of neurobiological mechanisms.

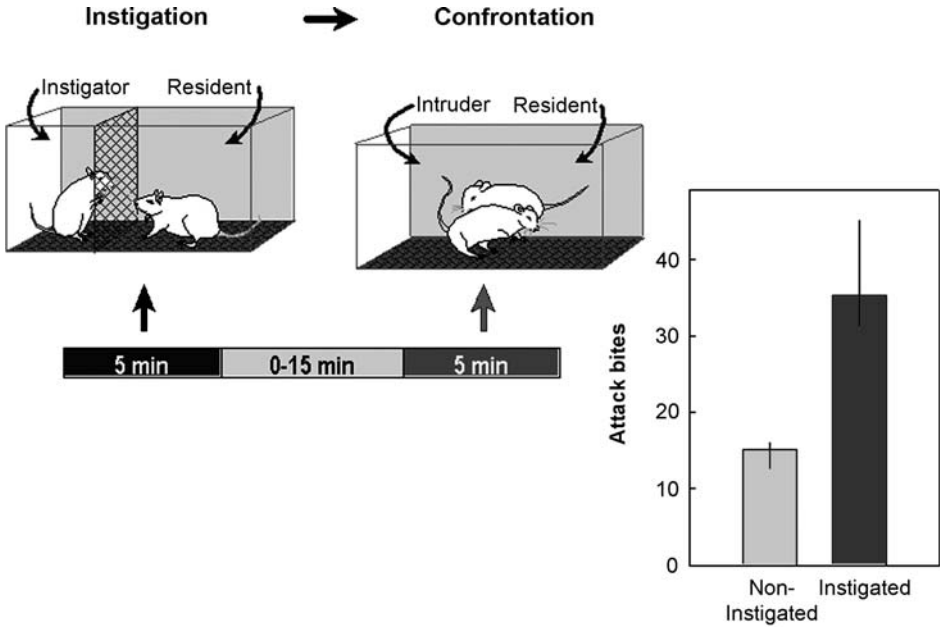
2.2.3 Instigation or Social Provocation

Closely related to the escalated aggression resulting from frustrative experiences are the provocations by a potential opponent. In experimental laboratory preparations with research animals, a resident male fish, mouse, rat, or hamster is exposed to a breeding male, which is placed into the resident's home cage and protected by a screen for a brief period (Heiligenberg, 1974; Potegal and Tenbrink, 1984; Kudryavtseva, 1991; Potegal, 1991; Fish et al., 1999). The presence of a breeding male provokes the resident into intense and frequent aggressive behavior, when given the opportunity. This provocation is hypothesized to induce specifically "aggressive arousal" or "attack readiness," presumably due to the olfactory, visual, and auditory cues emanating from the intruder.

So far, escalated aggression due to social instigation has begun to be characterized in terms of GABAergic and serotonergic activity (Fish et al., 1999; de Almeida and Miczek, 2002), and the neurochemical basis for the postulated aggressive arousal remains to be identified (*Figure 7-4*).

Figure 7-4

Social instigation of aggression. Heightened aggression by social instigation. For 5 min, a resident male mouse is exposed to an intruder male that is protected by a screen through which olfactory and visual cues are still available. After an interval, the resident attacks an unprotected intruder with greater frequency. Bars represent the median attack bites and vertical lines represent the interquartile range after control (light gray) and instigated (dark gray) conditions



As discussed earlier, aggression is behaviorally rich and functionally complex. An equally rich and complex neurochemistry underlies its expression. Situations and stimuli that provoke specific forms of aggression activate shared and unique neural mechanisms to coordinate how an individual initiates, performs, responds to, and recovers from these acts. In some instances, such as maternal aggression, these neural mechanisms are well characterized and distinguished from those involved in other forms of aggression. In others, such as escalated aggression, the distinctive features are currently being advanced. Across all forms of aggression, a prominent role exists for the neurotransmitter 5-HT, and this is highlighted in the following sections. However, 5-HT depends upon its interaction with amino acids, other monoamines, neuropeptides, and steroids (Miczek et al., 2002).

3 Neurotransmitters and Aggression

3.1 Excitatory and Inhibitory Amino Acids: A Delicate Balance

Most synaptic transmission in the CNS relies on excitatory and inhibitory amino acids, and their role in the mechanisms mediating aggressive behavior has been delineated with increasing success. Based on their cellular mode of action, the earliest hypothesis simply extrapolated the excitatory effects of glutamate and the inhibitory effects of GABA to the level of aggressive behavior (Mandel et al., 1979). This approach was elaborated by the "limbic dyscontrol" hypothesis of aggression, which portrays the expression of aggressive outbursts as a result of an imbalance between glutamate excitation and GABA inhibition (Monroe, 1978).

Clinically, the imbalance between excitatory and inhibitory neurotransmission is evident in patients with temporal lobe epilepsy, who engage in explosive aggressive acts or "interictal rage" (Mirsky and Harman, 1974; Bear and Fedio, 1977; Monroe, 1978; Weiger and Bear, 1988; Siegel and Mirsky, 1994). However, it is not known if the seizures themselves are the causal mechanisms for the aggressive behavior (Fenwick, 1989; Marsh and Krauss, 2000). Animal models of seizure disorders, such as in cats or rats exposed to repeated intermittent stimulation with electric pulses in the amygdala or hippocampus (i.e., kindling) or administration with a neurotoxin like trimethyltin, also provide evidence for increased emotional reactivity and defensive aggressive responses (Pinel et al., 1977; Adamec, 1990; Kalynchuk et al., 1992). The enhanced neural activation due to repetitive stimulation seems to exaggerate the responses to already threatening stimuli, rather than causing indiscriminate or stereotypical aggressive behavior. Thus, under conditions of heightened excitation, an animal may engage in defensive biting or attack, an otherwise mild stimulus.

Support for the glutamate–GABA imbalance hypothesis derives from the initial measurements of higher levels of glutamate and lower levels of GABA in whole brain, hypothalamus, amygdala, frontal cortex, and olfactory bulbs of aggressive relative to nonaggressive animals (Agrawal et al., 1967; Early and Leonard, 1980; Simler et al., 1982; Clement et al., 1987; Munoz-Blanco and Porras, 1987). Moreover, pharmacologically decreasing glutamate or increasing GABA levels inhibits various kinds of aggressive behavior (Puglisi-Allegra, 1980; Puglisi-Allegra et al., 1981; Lumley et al., 2004). Similar antiaggressive effects occur in rats and mice that are treated with direct agonists to $GABA_A$ receptors such as muscimol (Haug et al., 1980; Puglisi-Allegra, 1980; Mandel et al., 1981; Molina et al., 1986). Clinically, anticonvulsant medications, such as valproate, carbemazepine, and phenytoin, restore the balance between glutamate and GABA, and these compounds are also efficacious antiaggressive treatments (Barratt, 1993; Pabis and Stanislav, 1996; Lindenmayer and Kotsaftis, 2000; Stanford et al., 2001).

However, there are some notable exceptions to the imbalance hypothesis. Deleting the gene that codes for the GAD_{65} isoform of the synthetic enzyme for GABA, reduces brain levels of GABA and decreases aggression (Stork et al., 2000), and higher levels of GAD_{65} are found in the brains of hamsters induced to high levels of aggression by prior exposure to cocaine (Ricci et al., 2005). These findings demonstrate that there are instances when GABA may facilitate, rather than inhibit, aggressive behavior.

3.1.1 Critical Neuroanatomy

Preclinical studies have begun to identify the neural sites of action for glutamate and GABA within the pathways that regulate aggression. Although several brain regions are known to critically modulate aggressive and defensive behavior (Chi and Flynn, 1971), a region of the hypothalamus, referred to as the hypothalamic attack area (HAA), is thought to be of particular importance for the control of offensive attack behavior (Siegel et al., 1999) (*Figure 7-5*).

Electrical stimulation of the HAA elicits promptly the complete coordinated pattern of offensive attacks toward a conspecific in rats and cats, provided an opponent is present. More medial periventricular regions, extending from the septal area to the medial hypothalamus and periaqueductal gray area, have been identified to control the expression of defensive behavior (Bandler et al., 1985; Siegel et al., 1999). The HAA is not localized to a conventional anatomical nucleus, but consists of a zone that extends from the anterior hypothalamus (AH) through the lateral and parts of the ventromedial hypothalamus (Hrabovszky et al., 2005). Its neurons appear to be predominantly glutamatergic, because they express more mRNA for the type 2 vesicular glutamate transporter rather than for the enzyme glutamic acid decarboxylase $(GAD)_{67}$ (Hrabovszky et al., 2005). This cytochemical difference suggests the presence of excitatory efferents from the HAA that may be inhibited by local GABAergic interneurons (Gregg and Siegel, 2001). Further support for tonic inhibition of offensive aggressive acts by hypothalamic GABAergic interneurons derives from the effects of microinjection of GABA antagonists or, alternatively, glutamate agonists into the HAA (Hrabovszky et al., 2005) and/or GABA antagonists (Adams et al., 1993; Roeling et al., 1993).

In addition to its excitatory role in the HAA and in the amygdaloid and hippocampal seizure foci, glutamate is a key transmitter in the neural processing of olfactory cues that provoke or inhibit aggression. The projections from the olfactory bulb, via the lateral olfactory tract to the amygdala, are glutamatergic

Figure 7-5

Hypothalamic attack area. Three-dimensional portrayal of hypothalamic areas that elicit offensive aggressive behavior when electrically stimulated. The hypothalamic attack area is shown in red (or dark gray) and consists of portions of the anterior hypothalamus, ventromedial hypothalamus, the subfornical hypothalamus, and an area between the ventromedial hypothalamus and the medial forebrain bundle. For orientation, the ventrolateral hypothalamus (VMH), paraventricular nucleus (PVN), fornix (F) and third ventricle (IIIV) are also illustrated (PVN) and rostral to caudal and medial to lateral coordinants are given relative to bregma and midline. and are essential for the display of sexual, maternal, and aggressive behavior (Gandelman et al., 1971; Denenberg et al., 1973; Larsson, 1975; Kendrick et al., 1997). Considerable evidence documents glutamatergic projections from the medial prefrontal cortex to the amygdala (Gerfen and Wilson, 1996; Rosenkranz and Grace, 2002), and this pathway is activated by various types of stressors (McFarland et al., 2004). Within the mPFC of maternal sheep, glutamate activity increases following exposure to novel stimuli that prompt the display of aggressive behavior (Broad et al., 2002b), and it would be useful to directly measure glutamate in the initiation and the termination of aggressive confrontations.

There is some support for the early hypothesis that aggressive behaviors are influenced by the balance between the excitatory actions of glutamate and the inhibitory actions of GABA. However, this attractively simple hypothetical framework needs now to accommodate the diverse range of receptor subtypes that are the targets for these ubiquitous transmitters. Stimulation, blockade, and modulation of some of the glutamate and GABA receptor subtypes, particularly $GABA_A$ receptors, have begun to reveal very significant roles in different kinds of aggressive behavior.

3.1.2 Glutamate Receptors

Most pharmacological studies on glutamate and aggression have relied on rather nonspecific agents that primarily target the NMDA receptors and do not differentiate between receptor subtypes (Broad et al., 2002a). Meanwhile, it is clear that ionotropic (iGluR) and metabotropic (mGluR) receptors mediate the

neurochemical and behavioral effects of glutamate. The NMDA, AMPA, and kainate glutamate receptors are ligand-gated ion channels that permit the flow of Na^+ and Ca^{2+} and typically depolarize the membrane. Additionally, the group I (mGluR1 and mGluR5) and group II (mGluR2 and mGluR3) receptors increase the activity of phospholipase C (PLC), whereas the group III (mGluR4, mGluR6–8) decreases the activity of adenylate cyclase. The emergence of novel and more selective drugs for each of these receptor subtypes holds promise for elucidating their specific aggression-modulating effects (Kew and Kemp, 2005).

3.1.2.1 NMDA Receptors Classic antagonists of the NMDA receptors, including phencyclidine (PCP) and dizocilpine (MK-801) that block the ion channel in the receptor, have inconsistent effects on aggressive behavior that are accompanied by motor side-effects including incoordination. In some individuals, in certain test conditions (as discussed later), these compounds increase aggressive behavior (Rewerski et al., 1971; Krsiak, 1974; Burkhalter and Balster, 1979; Musty and Consroe, 1982; Wilmot et al., 1987; McAllister, 1990), while in others, they are suppressive and sedative (Tyler and Miczek, 1982; Miczek and Haney, 1994; Lang et al., 1995; Belozertseva and Bespalov, 1999). Behaviorally nonspecific effects of these high-affinity antagonists are not surprising, given their dissociative and hallucinogenic effects. The more recently developed low-affinity channel blockers, such as memantine and MRZ 2/579, or partial agonists to the glycine binding site on the receptor, such as HA-966 (Kew and Kemp, 2005), appear to have fewer adverse side effects (Rogawski, 2000; Kemp and McKernan, 2002), and could be useful pharmacotherapeutic options for aggressive disorders due to their primary action on escalated, rather than on basal excitation. Neither memantine nor the related compound MRZ 2/579 altered basal levels of aggression or the latency to attack (Belozertseva and Bespalov, 1999; Minkeviciene et al., 2004), but they specifically reduced the intense aggression that followed withdrawal from morphine (Sukhotina and Bespalov, 2000).

Two key determinants for the disparate effects of NMDA receptor manipulations across studies on aggression are the individual's prior history with aggressive behavior and the intensity of the encounter. NMDA receptor antagonists render inexperienced animals that fight at low rates more aggressive, while experienced, intensely aggressive animals become calmer—an example of the law of initial value (Wilder, 1958). This pattern raises the interesting possibility that repeated aggressive experiences alter the regulation of NMDA receptor expression along the neural pathway that regulates the behavior. As aggression becomes more likely and more intense, the role of glutamate becomes more significant.

Changes in glutamate neurotransmission and signaling have long been identified as significant targets for repeated exposures to salient stimuli, and such changes are strongly related to learning and memory and adaptation to stressors (Holscher, 1997; Braunewell and Manahan-Vaughan, 2001). Following aggressive experience, there are also changes in glutamate (Broad et al., 2002b), and this effect needs to be further characterized. Changes in the NMDA receptor system occur in repeatedly defeated rats and mice, as evidenced by the prevention of the sensitized responses to psychomotor stimulants by protective treatments with NMDA receptor antagonists (Covington and Miczek, 2002; Yap et al., 2005). Exposure to repeated anabolic steroids, which can facilitate aggressive behaviors in rats (e.g., McGinnis, 2004), decreases the expression of mRNA for the NR2A subunits in the hypothalamus and hippocampus, as well as the NR2B subunit in the hypothalamus (LeGreves et al., 1997), but in lizards (*Anolis carolinensis*) these proteins upregulate following establishment of dominant-subordinate status (Summers et al., 2005). These changes in the NR2B receptor due to aggressive experiences should prompt direct manipulations with subunit-selective antagonists, such as ifenprodil, in an effort to alter the long-term consequences of aggressive experience. It can be hypothesized that the most important role of NMDA receptors in aggression is to determine whether an individual will attack or submit in future encounters.

3.1.2.2 AMPA and Kainate Receptors Regarding aggressive behaviors, AMPA and kainate receptors have been studied much less than the NMDA receptors. This has been due, in part, to the lack of selective pharmacological agents for these receptors. Genetic studies have so far identified subunits of the AMPA receptor as important for aggressive behavior. A QTL study by Brodkin et al. (2002) identified the AMPA3 subunit gene as a candidate related to attack behavior, whereas mice without the gene for the AMPA2 subunit show very little offensive attacks (Vekovischeva et al., 2004). At this early stage, it is evident that

certain AMPA receptor subtypes can significantly modulate aggressive behavior. It is likely that other AMPA subunits contribute to the neural mechanisms of aggression.

3.1.3 $GABA_A$ Receptors

Direct stimulation and positive modulation of $GABA_A$ receptors have a range of effects on aggressive behavior, from inhibition to escalation (Miczek et al., 2003). These receptors are composed of five transmembrane proteins, encoded by at least 17 separate genes, forming a Cl^- channel that when opened typically promotes the inward flow of Cl^- to hyperpolarize the surrounding membrane (Mohler et al., 1995). Their sensitivity is determined in part by the combination of individual proteins to the receptor complex, comprising alpha, beta, gamma, and delta subunits in mammalian brain neurons (review refs Mehta and Ticku, 1999). Drugs such as benzodiazepines, barbiturates, alcohol, and certain neurosteroids allosterically modulate the $GABA_A$ receptor to potentiate the actions of GABA and to increase Cl^- flow.

3.1.3.1 Positive Allosteric Modulation These positive modulators are used clinically to reduce anxiety, seizures, muscle tension, and sleep disorders (Shader and Greenblatt, 1993). Alcohol has many of these same behavioral effects, and though this ubiquitous agent affects a variety of ionotropic receptors, its positive modulation of the $GABA_A$ receptor complex is particularly important for these acute effects (Liljequist and Engel, 1982; Vanover et al., 1999a, b). When used clinically, the rapid administration of $GABA_A$ receptor positive modulators at substantial doses effectively reduces aggressive outbursts (Dietch and Jennings, 1988). However, early astute clinical observations noted patients who become more aggressive, particularly after benzodiazepine treatments (DiMascio, 1973). In laboratory animals, heightened aggression can occur not only after benzodiazepines, but also after the neurosteroid allopregnanolone or the synthetic steroid alphaxalone (Fish et al., 2001). These reactions have been considered "paradoxical," because they contradict the primarily calming effects of these drugs.

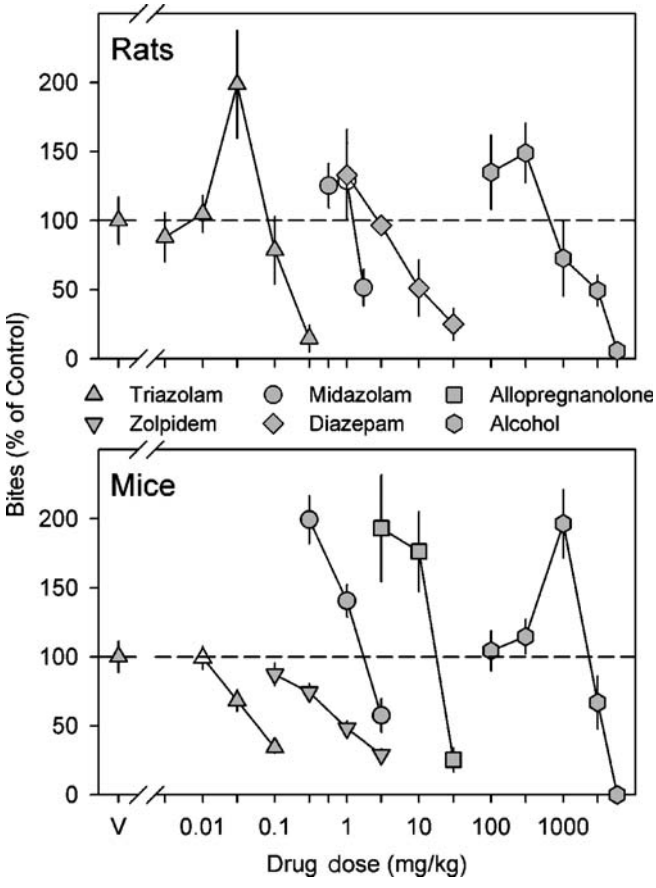
Several factors interact to determine how benzodiazepines affect aggressive behavior. These include the drug itself, the dose, the context of administration, and the individual's history (Gardos et al., 1968; Bond et al., 1995). In humans, increased aggression has been reported after treatment with the benzodiazepines diazepam, chlordiazepoxide, lorazepam, flunitrazepam, and alprazolam (DiMascio et al., 1969; Brown, 1978; Bond et al., 1995; Weisman et al., 1998; Daderman and Lidberg, 1999), particularly if these individuals have a history of previous violent behavior. Chlordiazepoxide, diazepam, and midazolam have all been shown to increase dominance, territorial, and maternal aggressive behavior in mice, rats, pigs, and monkeys (Cole and Wolf, 1970; Miczek, 1974; Arnone and Dantzer, 1980; Miczek and O'Donnell, 1980b; Rodgers and Waters, 1985; Mos and Olivier, 1989; Weerts and Miczek, 1996; Ferrari et al., 1997; Gourley et al., 2005). This pro-aggressive effect is reversible by antagonists at the benzodiazepine binding site on the $GABA_A$ receptor complex, indicating that this site is critical for heightened aggression (e.g., Olivier et al., 1991), and the search for the relevant subunit composition of the $GABA_A$ receptor for the aggression-modulating effects has begun (Gourley et al., 2005). However, regardless of an individual's past violent behavior, other benzodiazepines, such as oxazepam, clorazepate, and zolpidem, either reduce aggressive behavior or have no effect at all (DiMascio, 1973; Bond and Lader, 1988; Pabis and Stanislav, 1996; Weisman et al., 1998; Martin-Lopez and Navarro, 2002; de Almeida et al., 2004). One hypothesis for these differential effects of benzodiazepines suggests that compounds with higher intrinsic activity at the $GABA_A$ receptor are more likely to reduce aggressive behavior (Ducic et al., 1993; Gourley et al., 2005).

Another important determinant of the pro-aggressive effects is the dose of the $GABA_A$ positive modulator. All $GABA_A$ receptor positive modulators that heighten aggression do so at low to moderate doses and are sedative at higher doses, which at least partially accounts for their antiaggressive effects. It is very likely that doses along the ascending limb of the bidirectional dose–effect curve recruit different mechanisms than those along the descending limb (*Figure 7-6*).

Context and prior experiences with aggressive behavior are two further determinants of the effects on aggression that result from stimulation of $GABA_A$ receptors. When benzodiazepines are given to individuals without an identified pathology or are used in a clinical setting, they typically decrease aggressive and

Figure 7-6

$GABA_A$ positive allosteric modulators and aggression. Biphasic effects of $GABA_A$ receptor positive modulators on aggression in rats (*top panel*) and mice (*bottom panel*). Low doses of alcohol (*filled hexagons*), the benzodiazepines diazepam (*filled diamonds*, rats only) and midazolam (*filled circles*) and the neurosteroid allopregnanolone (*filled triangles,* mice only) increase the mean (±SEM, *vertical lines*) number of attack bites, expressed as a percentage of vehicle control, while higher doses decrease this measure of aggression. Triazolam (*filled upward triangles*) increases attack bites in rats but not mice. No increase in aggression was seen after treatment with zolpidem, the α_1 receptor selective agonist, (*filled downward triangles*, mice only). The *dotted line* represents the baseline at 100%



hostile behavior (Cherek et al., 1990; Cherek et al., 1991; Dorevitch et al., 1999; Pietras et al., 2005). However, the same compounds can increase aggression when given to or used by individuals who are prone to violence (DiMascio et al., 1969; Brown, 1978; Daderman and Lidberg, 1999). For example, flunitrazepam can be used to calm violent patients in emergency rooms, but when used repeatedly in recreational settings, the same compound has been associated with sexual and aggressive assaults (Daderman and Lidberg, 1999; Dorevitch et al., 1999). The importance of experience and context to $GABA_A$ positive modulator effects on aggression is also evident in mice. Chlordiazepoxide increased aggressive behavior in those animals with previous aggressive experience but decreased aggressive behaviors of mice without previous aggressive experience (Rodgers and Waters, 1985; Ferrari et al., 1997). Similarly, allopregnanolone increased aggression when given to resident male mice with repeated aggressive experiences (Fish et al., 2001), but decreased

aggression when given to socially isolated male mice without a history of aggression (Guidotti et al., 2001; Pinna et al., 2003). Moreover, chlordiazepoxide and midazolam exert larger aggression-heightening effects when they are tested under conditions that engender low, rather than high, levels of aggressive behavior (Miczek and O'Donnell, 1980a, b; Fish et al., 2005). The molecular basis for these powerful effects of experience with aggressive behavior apparently includes changes in the expression of $GABA_A$ receptors and in particular some of the yet to be determined subunits.

An individual's prior exposure to drugs may also affect its response to positive modulators of the $GABA_A$ receptor. Alcohol's effect on aggression varies substantially across individuals; a small percentage becomes consistently more aggressive while moderately intoxicated, but most are not affected (e.g., Miczek et al., 1998a). However, mice that have received prior daily alcohol, but not morphine, administrations may "sensitize" to the aggression-heightening effects of alcohol and allopregnanolone (Fish et al., 2002; Miczek et al., 2004b). The ongoing challenge is to understand how an individual's prior history and current level of aggression modify the $GABA_A$ receptor complexes that are necessary for these actions of $GABA_A$-positive modulators.

Such divergent effects of $GABA_A$ receptor positive modulators may be the result of alterations in the subunit composition of the $GABA_A$ receptor complex. The receptor's subunit composition has been proven important for the binding of a drug as well as for particular drug effects. For example, in order for a benzodiazepine to bind, the $GABA_A$ receptor must contain a γ_2 and an α_1, α_2, α_3, or α_5 subunit (Pritchett et al., 1989; Rudolph et al., 1999). The sedative effects of benzodiazepines appear to result from actions at the α_1, rather than the α_2 and α_3 subunits, and the latter appear necessary for antianxiety effects (Low et al., 2000; Rudolph et al., 2001; Rowlett et al., 2005). The functional importance of the α_1 subunit protein has begun to be investigated for its role in aggressive behavior, primarily due to the availability of α_1-preferring agonists, such as zolpidem, and antagonists such as β-CCt and 3-PBC (Cox et al., 1995; Huang et al., 2000). Antagonist effects suggest that the α_1 subunit is important in the aggression-heightening effects of midazolam and alcohol (de Almeida et al., 2004; Gourley et al., 2005). Furthermore, these data suggest a structural dissociation between the anxiety-attenuating and aggression-heightening effects of $GABA_A$ receptor positive modulators.

3.2 Monoamines: Anticipation, Permission, Execution, and Pattern

The canonical amines, norepinephrine (NE), dopamine (DA), and serotonin, are the traditional targets for pharmacotherapeutic interventions of pathological aggression during the past decades. Next to the androgens, they have been studied most extensively for their role in the neurobiology of different kinds of aggressive behavior. The early emphasis on catecholamines in the "fight–flight" syndrome (Cannon, 1929) has shifted to recognizing the importance of serotonin, and this indolamine has emerged as a major research focus. Molecular neurobiological techniques have greatly advanced the study of serotonin and identified several components in the life cycle and receptor subtype diversity of this system that are related to aggression. Although a role for brain serotonin is repeatedly demonstrated for certain types of hostile–impulsive–violent behavior, the precise mechanism through which 5-HT controls these types of aggression is yet to be convincingly demonstrated. One complication to demonstrating mechanisms is the broad distribution of 5-HT throughout the brain and the diversity of the receptor subtypes.

3.2.1 Norepinephrine

Confrontations between individuals are characterized by a high degree of arousal and likewise, increased central and peripheral NE activity. Fighting is one of many behavioral events associated with noradrenergic activation, and this finding has been confirmed in various animal species and contexts (Welch and Welch, 1965; Bell and Hepper, 1987; Summers and Greenberg, 1994; Sgoifo et al., 1996; Gerra et al., 1997). Elevations in the activity of noradrenergic cell bodies in the locus coeruleus and in cortical NE occur when events are important and command an individual's attention; they are not specific to agonistic interactions. In fact, merely observing a fight is sufficient to elevate NE levels in the cortex of mice (Hendley

et al., 1973). Perhaps because of the importance of NE to general arousal, a consistent relationship between aggressive behavior and NE is yet to be established. Nonetheless, treatments using β-blockers, such as propranolol, can be highly effective for reducing aggressive outbursts (Elliott, 1977; Yudofsky et al., 1981; Sorgi et al., 1986; Ratey and Gordon, 1993).

3.2.1.1 Levels The correlations between aggressive behavior and levels of NE or its metabolite 3-methoxy-4-hydroxyphenylethylene glycol (MHPG) in the brain or CSF are not as strong or as replicable across studies as those for 5-HT. Some have found positive correlations (Brown et al., 1979; Higley et al., 1992; Traskman-Bendz et al., 1992; Placidi et al., 2001; Kaplan et al., 2002; van der Vegt et al., 2003), while others find inverse (Bernard, 1975; Linnoila et al., 1983) or no correlations (Brown et al., 1982; Reisner et al., 1996; Höglund et al., 2000; Kim et al., 2000). The positive correlations are suggestive for a link between brain NE and aggressive behavior, but genetic manipulations in NE levels offer stronger support.

So far, three genetic manipulations of the NE system have resulted in altered levels of NE and altered aggressive behavior. The effects of deleting the enzyme catechol-*O*-methyltransferase (COMT) are discussed later in the dopamine section, because this mutation does not alter NE levels. Elevations in NE levels have occurred in mice lacking the gene for the norepinephrine transporter (NET) or for the catabolic enzyme monoamine oxidase A (MAO-A) (Cases et al., 1995; Haller et al., 2002). Mice from the 129SvJ × C57BL/6J strain exhibit few retaliatory attacks toward a larger, aggressive resident mouse (Haller et al., 2002). However, those that are missing the NET are more likely to attack the aggressor during the first, but not later, encounters. In agreement with the findings of heightened aggression in male members of a Dutch family with a point mutation in the *MAO-A* gene (Brunner et al., 1993), C3H/HeJ mice without this gene attack intruders faster than do C3H wild-type mice and have significantly more wounding when living in a cage with other males (Cases et al., 1995). Deletion of MAO-A also alters 5-HT levels, so the importance of NE relative to 5-HT to the aggressive phenotype is debatable. NE remains elevated in the MAO-A KO mice throughout adulthood, whereas 5-HT deficiencies are largest during early development, suggesting a more likely acute contribution of NE (Cases et al., 1995; Shih et al., 1999a). Genetically reducing NE in 129/SvEV × C57Bl6/J mice by knocking out the gene coding for dopamine β-hydroxylase produces nonaggressive mice (Marino et al., 2005). Interestingly, the effects of these gene manipulations of the NE system seem to be most significant on the initiation of attack.

Antidepressant treatments that increase extracellular NE by inhibiting the NET or MAO-A have been studied extensively for their effects on aggressive behavior. Under different testing conditions, the aggressive behavior of mice, rats, cats, and monkeys is altered by tricyclics like desipramine, imipramine, and amitriptyline, but there is a significant amount of variability across studies (for review see Miczek et al., 1994a). Many studies have found inhibitory effects on aggressive behavior (e.g., Cook and Wiedley, 1960; Krsiak, 1979; Tobe et al., 1981; Yoshimura, 1984), but there are also examples when low doses of desipramine and imipramine can increase aggressive behavior, such as when isolated mice confront each other (Matsumoto et al., 1991; Cai et al., 1993; Cutler et al., 1997) or when rats respond defensively after receiving footshock (Allikmets and Lapin, 1967; Burov, 1975). NE microinjections into the medial hypothalamic area, which regulates "affective defense" in cats, facilitated this behavioral display (Barrett et al., 1987; Barrett et al., 1990). Conversely, decreasing levels of NE can attenuate offensive aggressive patterns (Crawley and Contrera, 1976) and facilitate some forms of defensive aggression (Thoa et al., 1972).

3.2.1.2 α and β Receptors The actions of NE on aggressive behavior depend upon which receptor is targeted, although limited receptor selectivity of agonists and antagonists prompt cautionary interpretation of these findings (Bell and Hepper, 1987; Haller et al., 1998). The antiaggressive effect of β blockers in human and nonhuman subjects suggests that NE facilitates intensely arousing, hostile aggressive behavior via action at this receptor. However, this calming effect may be accompanied by significant slowing of motor activity, as evident by the sedative effects of β receptor blockade (Hegstrand and Eichelman, 1983; Matsumoto et al., 1991; Bell and Hobson, 1993; Gao and Cutler, 1993). In addition, propranolol, pindolol, and similar β blockers bind to 5-HT_{1A} receptors and antagonize the antiaggressive effects of 8-OH-DPAT (Sanchez et al., 1996). Modulation of 5-HT neurotransmission could be a further mechanism through which β blockers affect aggression.

Both agonists and antagonists at α_2 noradrenergic receptors produce antiaggressive effects, but these effects on aggressive behavior are embedded in very different behavioral and physiological effects of these compounds (Haller and Kruk, 2003)—a constellation of effects that is also apparent with agonists and antagonists at D2 DA receptors. Aggressive mice treated with α_2 receptor antagonists, such as yohimbine, respond with increased defensive, rather than offensive, behaviors (Kemble et al., 1991; Haller et al., 1996b), which may reflect the anxiogenic effects of these compounds (Charney et al., 1983). In rats, there are biphasic effects of α_2 receptor antagonists; low doses increase and high doses decrease aggression, even when the rats are highly aggressive (Haller, 1995). Modulation of aggressive behavior in mice after gene deletion and over-expression provides additional evidence for an inhibitory role of the α_2 receptor subtype. Isolated mice lacking the gene for the α_{2c} receptor attacked an intruder faster than the wild-type mice, whereas mice over-expressing this receptor had the opposite behavioral phenotype (Sallinen et al., 1998). The major effect of this receptor was on the initiation of the attack, because once the fight began, the mice attacked equally.

It is evident that noradrenergic activation is a necessary prerequisite for and consequence of aggressive behavior. One key function of cortical NE is its role in attention to salient events, and aggressive confrontations certainly fulfill this definition. Other functions of locus coeruleus activation during stressful and anxiogenic experiences appear pertinent for the increased defensive reactions after NE agonist treatment. NE can regulate aggressive behavior by acting upon aggression-facilitating β receptors or aggression-inhibiting α adrenoreceptors. However, basal NE levels do not consistently differentiate individuals with a history of past aggression, from those with a history of nonaggressive behavior. This suggests that the largest effects of NE may occur at the time a fight is initiated, possibly by determining whether an individual will fight or flee. Previous experience with victory or defeat is likely to be an important factor in this outcome, as locus coeruleus activation is heavily influenced by past social experiences (Kollack-Walker et al., 1997).

3.2.2 Dopamine

Three sources of information implicate dopaminergic synaptic activity in the neurobiological mechanisms of aggressive behavior, particularly escalated forms of aggression, in both animals and humans. First, studies of the neural mechanisms via which neuroleptic drugs achieve their pharmacotherapeutic effects in violent patients, point to the DA D2 receptor family as a target for effective antiaggressive interventions (Itil and Wadud, 1975; Humble and Berk, 2003). Second, investigations of preclinical model systems, mainly in rodents and cats, highlight the obligatory role of intact DA activity as a prerequisite for initiating and executing aggressive and defensive behavior (Miczek et al., 1994b; Miczek et al., 2002). Thirdly, intense violence has been linked to illicit drugs, but this link refers primarily to trafficking and the violent drug trade (e.g., National Drug Intelligence Center. 2005), and is only very indirectly related to the action of cocaine and amphetamines on brain DA. Careful examination of the data does not support a direct causative link between these drugs and violence in people (Parker and Auerhahn, 1998; Hoaken and Stewart, 2003). Controlled laboratory studies, in which graded doses of amphetamines are administered to human volunteers, have found moderately disruptive effects on aggressive behavior (Cherek et al., 1986; Beezley et al., 1987; Cherek and Steinberg, 1987). These data from experimental studies contrast with the clinical case studies of a select group of addicts, who take large amounts of amphetamines or its congeners and are documented to engage in heinous violent acts (Ellinwood Jr, 1971).

3.2.2.1 Amphetamines and Apomorphine Diverse findings in various animal species and contexts prompt a careful examination of the exact experimental details and behavioral measures when developing an emerging role for brain DA systems in aggressive and defensive behavior. Low doses of indirect and nonselective agonists of DA, such as amphetamines or apomorphine, can increase aggressive behavior of isolated mice or provoked rats, whereas higher doses of amphetamine increase defensive reactions to electric shock pulses or to attacks by an aggressive opponent (Senault, 1968, 1971; Crowley, 1972; Hasselager et al., 1972; Miczek, 1974; Puech et al., 1974; Miczek and O'Donnell, 1978; Ray et al., 1983;

Miczek and Haney, 1994). The hyper-defensive behavior in amphetamine-treated animals may be due to the general stimulus reactivity rather than a specific effect on defense. Ever since the introduction of amphetamines, the effects of enhancing performance in fatigued individuals have been exploited, and this phenomenon can be reproduced under controlled laboratory conditions during extended fights in mice (Winslow and Miczek, 1983). In monkeys and mice with extensive experience in aggressive confrontations, amphetamines disrupt the intricate pattern of aggressive and social interactions (Hodge and Butcher, 1975; Miczek and O'Donnell, 1978; Miczek and Yoshimura, 1982; Field and Pellis, 1994). Finally, chronic treatment with such drugs may have different effects than acute or subchronic exposure (Sokolov et al., 2004). These pharmacological data suggest a role of DA in neurobiological mechanisms of aggressive behavior at multiple levels—to enhance low-level aggressive tendencies, to disorganize species-typical ritualized aggressive displays, to intensify stereotypical aggressive acts, and to prolong aggressive activities. These changes in frequency, duration, intensity, and patterning of aggressive behavior as a result of dopaminergic stimulation parallel those seen on many other motivated behaviors such as feeding, drinking, sexual behavior, or drug taking.

3.2.2.2 Antipsychotics Treatment with antipsychotic drugs that function as DA receptor antagonists continue to be commonly used to reduce aggressive outbursts in schizophrenic patients (Citrome and Volavka, 1997a, b). In addition, such pharmacotherapies can be effective in the treatment of impulsive aggression in conditions like borderline personality disorder (Friedel, 2004). Initially, the usually employed treatments were classic antipsychotic drugs like haloperidol, which are primarily DA D2 antagonists. However, more recently, the atypical neuroleptics that have pronounced effects on other neurotransmitter receptors have been found to be effective at reducing aggressive outbursts with a superior profile of side effects. For example, risperidone, olanzapine, and clozapine have all been reported to be more effective than haloperidol in reducing aggressive behavior in schizophrenic patients (Volavka et al., 2004; Bitter et al., 2005). These atypical antipsychotics drugs are now being used in various psychiatric conditions for reducing aggression and agitation (Bhana et al., 2001; Kennedy et al., 2001; Aman et al., 2004; Ballard and Waite, 2006). In clinical practice, the atypical antipsychotic drugs that are increasingly used for control of aggressiveness are less specific for DA receptors. These so-called atypical compounds have additional effects on neurotransmitter receptors other than DA, including those for serotonin. In addition, one of the populations in which atypical antipsychotics have been reported to be effective are children and adolescents (Findling et al., 2005; Patel et al., 2005). Using an entirely different approach to manipulating DA activity, children and adolescents receive indirect DA agonists (i.e., amphetamine, methylphenidate) to reduce aggressive outbursts associated with ADHD and some other conditions (Connor and Steingard, 1996; Connor et al., 2002; Hazell and Stuart, 2003).

3.2.2.3 Genetic Association and Manipulation Links between polymorphisms in the dopamine transporter (*DAT1*) gene and increased aggressive behavior have been reported for several patients groups (Young et al., 2002b; Chen et al., 2005). In addition, differences in striatal *DAT* distribution or heterogeneity have been reported when comparing violent and nonviolent alcoholics (Tiihonen et al., 1995; Kuikka et al., 1998). Disruption of the *DAT1* gene in mice also leads to an increase in aggressive behavior toward conspecifics (Rodriguiz et al., 2004). This pattern of results could be interpreted to suggest that increased DA in synapses contributes to the escalation of aggression.

The role of catecholamines like DA are implicated in aggressive traits by research on the two primary catabolic enzymes involved in the clearance of catecholamines, COMT and MAO-A. Genetic disruption of either COMT or *MAO-A* genes using the gene deletion ("knock-out") methodology has been found to increase aggressive behavior in male mice (Cases et al., 1995; Gogos et al., 1998). These findings are particularly interesting, because a proclivity to increased aggressive behavior has been reported in patients with a point mutation that reduces MAO-A activity (Brunner et al., 1993). Furthermore, a specific polymorphism in the gene for COMT is also associated with increased aggressive behavior and violence in schizophrenic men (Strous et al., 1997; Lachman and Papolos, 1998; Kotler et al., 1999). However, these enzymes are involved in the degradation of multiple neurotransmitters and thus do not specifically implicate DA in the behavioral outcomes. Furthermore, interpretation of differences in behavior associated

with genetic mutations or disruptions must take into account that the individual's development may have been altered in such a way that there are other physiological differences that are a consequence of compensations to altered levels of neurotransmitters during development. Nonetheless, this association of increased aggressive behavior in mice and men with reduced COMT or MAO-A is intriguing and needs to be delineated in terms of anatomical and developmental specificity.

3.2.2.4 D1, D2, and D3 Receptors Preclinical studies using various experimental protocols in animal species have afforded the opportunity to manipulate and measure DA and its receptor systems to assess their role in aggressive behavior. In rodents, drugs that act either as DA D1 or as DA D2 antagonists reduce male aggressive behavior (Janssen et al., 1960; Rolinski, 1975; Krsiak et al., 1981; Olivier and van Dalen, 1982; McMillen et al., 1989; Tidey and Miczek, 1992a; Aguilar et al., 1994; Miczek et al., 1994b; Rodriguez-Arias et al., 1998, 1999b; Bondar and Kudryavtseva, 2005). However, the pharmacological characterization of the DA D1 and DA D2 receptors in terms of their role in aggressive behavior presents a pattern that requires careful and detailed analysis. Both DA D1 and DA D2 agonists and antagonists can decrease aggressive behavior, but the antiaggressive effects of these compounds are embedded in distinctively different profiles of effects. While particularly the DA D2 antagonists slow motor routines and reduce locomotor activity (Fowler and Liou, 1998), the antiaggressive effects appear to be part of the sedative effects of these drugs. By contrast, DA D2 agonists disrupt and fragment the behavioral sequences required for species-typical aggressive behavior. When animals are undergoing withdrawal from opiates, their sensitivity to DA D2 agonists greatly increases (Gianutsos and Lal, 1978). The aggression-heightening effects of indirect and direct DA agonists are readily seen in opiate-withdrawing mice (Kantak and Miczek, 1988; Tidey and Miczek, 1992b). A promising novel target among the DA receptor subtypes is the DA D3 receptor; agonists such as 7-OH-DPAT or PD128907 reduce aggressive behavior without concurrent sedative effects (Gendreau et al., 2000), but the DA D3 antagonist U-99194A also exerts similar antiaggressive effects (Rodriguez-Arias et al., 1999a). As more selectively acting compounds become available and more types of aggressive behavior are studied, the respective role of DA D1, D2, and D3 receptors in reducing aggression will be more adequately characterized.

3.2.2.5 Dopamine Levels The actions of specific DA receptor agonists and antagonists depend on the ongoing up or downregulation of receptors, processes that are regulated by impulse flow in DA pathways that is engendered by aggressive behavior itself. Early postmortem tissue assays pointed already to increased DA levels in the frontal cortex and ventral striatum after the display of aggressive and defensive behavior in mice or rats (Mos and Van Valkenburg, 1979; Haney et al., 1990; Puglisi-Allegra and Cabib, 1990). In the meantime, in vivo microdialysis has provided real-time measurements of DA in corticolimbic structures as aggressive behavior is initiated, executed, terminated, and undergoes recovery. Rises in extracellular DA, presumably reflecting release, in nucleus accumbens and prefrontal cortex are evident in both the offensively aggressive rat and in the defensive–submissive opponent (Tidey and Miczek, 1996; Miczek et al., 1999; Van Erp and Miczek, 2000) (*Figure 7-7*).

With increasing temporal resolution, it may become possible to identify a more precise synchrony between the increase in DA and specific aggressive or defensive acts. The DA release in nucleus accumbens is particularly noteworthy in rats that are targets of threats and react defensively, suggesting a role for accumbal DA that is separate from the often-reiterated interpretation of a reward signal.

After repeated aggressive episodes in regular intervals, neuroadaptive changes in accumbal DA become evident. In anticipation of the very next aggressive confrontation, the extracellular DA in nucleus accumbens rises even before the specific time of the fight, and the heightened DA persists, even in the absence of the accustomed confrontation (Ferrari et al., 2003) (*Figure 7-8*).

These findings suggest that the release of monoamines can be conditioned to prepare the individual for action in a salient event. Heightened corticolimbic DA appears to characterize the individual who is reacting to an aggressive confrontation as well as anticipating such an event, and these different roles may become dissociated with more precise anatomical and temporal analyses.

Figure 7-7

Dopamine and serotonin during aggression. Measurements of extracellular dopamine and serotonin via in vivo microdialysis in resident male rats before, during, and after a confrontation with an intruder. (a) In the nucleus accumbens (*top panel*), dopamine levels (gray circles) rise and remain elevated after the confrontation, while serotonin levels (black diamonds) do not significantly change. (b) In the prefrontal cortex (*bottom panel*), dopamine levels rise after the confrontation, while serotonin decline and remain lower after the confrontation. Samples were collected every 10 min and levels are expressed as mean (±SEM, vertical lines) percent of baseline. Baseline was measured for 50 min before the fight. The vertical light gray bar indicates the occurrence of the 10-min fight. * and ** represent significance from baseline (dashed line) at the $p < 0.05$ and $p < 0.01$ levels, respectively. 3.3 Serotonin: Inhibitory Control versus Impulse

Brain 5-hydroxytryptamine (5-HT, serotonin) has been the focus of neurobiological research on aggression and violence more than any other neurotransmitter. Ever since the discovery of this indolamine in the

mammalian brain (Twarog et al., 1953), a tropotrophic action was proposed as its all-encompassing function (Brodie and Shore, 1957), including also its calming effects on aggression.

3.3.1 CSF Metabolite

The initial evidence relied on postmortem assays of brainstem tissue from previously isolated Swiss albino mice. These animals became aggressive when confronting other isolated mice and also showed lower concentrations of 5-HT and 5-HIAA in the lower portion of the brain, including the brainstem (Giacalone et al., 1968). The first neurochemical data from humans were derived from marine soldiers who were dismissed from the service on account of their life history of repeated aggressive behavior and who had reduced CSF levels of 5-HIAA (negative correlation between CSF 5-HIAA and life history of aggression of $r = -0.78$) (Brown et al., 1979). The inverse correlation between CSF 5-HIAA and trait measures of impulsive aggression has been confirmed subsequently often, particularly in psychopathic deviants (Brown et al., 1982), in impulsive violent offenders (Linnoila et al., 1983), in type II alcoholic violent arsonists (Virkkunen et al., 1987, 1989, 1994), and in behaviorally disruptive youngsters (Kruesi et al., 1990). On the other hand, in several studies, this inverse correlation was not seen, possibly due to the intensity and nature of the aggressive behavior (Gardner et al., 1990; Castellanos et al., 1994; Moller et al., 1996; Coccaro et al., 1997a). In nonhuman primate studies, a similar discrepancy remains unresolved. Significant inverse correlations between CSF 5-HIAA and an individual's prior history of impulsive aggressive behavior are evident in samples of rhesus and pigtail macaques and vervet monkeys (Higley et al., 1992; Westergaard et al., 1999; Manuck et al., 2003; Fairbanks et al., 2004), but not in talapoin monkeys and squirrel monkeys (Yodyingyuad et al., 1985; Miczek and Donat, 1989). The significance of CSF 5-HIAA measures is compromised by the considerable uncertainty as to their precise anatomical origin. CSF samples, whether obtained from the lumbar region or the foramen magnum, reflect the activity of several brain regions, particularly those close to the ventricles, and 5-HT exerts different functions in these cell groups than in circuits that are more distant from the ventricles. Nonetheless, it has been proposed that lumbar samples of CSF 5-HIAA correspond to serotonergic activity in the prefrontal cortex (Doudet et al., 1995), a structure that is significant for behavioral inhibition and impulsive behavior (Raine et al., 1998; Best et al., 2002).

3.3.2 Pharmaco-Challenge

A second approach to define a serotonergic marker in aggressive individuals relies on challenging brain serotonin, either with an agonist such as D,L-fenfluramine or buspirone, or alternatively, a brief exposure

Figure 7-8

Anticipatory changes in nucleus accumbens serotonin and dopamine and heart rate in male rats. The *filled circles* represent the mean (±SEM, vertical lines) measurements from rats that fought an intruder at a specific time (vertical gray bar) everyday over the initial 10 days. The open circles represent measurements from rats without the history of daily aggression and that were entrained to the onset of the dark cycle. Measurements were taken on the 11th day, when no aggressive confrontation occurred. In the *top panel*, dopamine levels (expressed as a percent of baseline) rise in the 10 min before- and in the *middle panel* serotonin levels (expressed as a percent of baseline) decline after the regularly scheduled aggression test. No such changes occur in rats without the prior history of aggression. In the *bottom panel*, the peak heart rate is higher in the rats anticipating the aggression test (*thick lines*) than in those anticipating the light change (*thin lines*). The dark portion of the light–dark cycle is indicated in the horizontal black bar. The *denotes significance ($p < 0.05$) from the light entrained group. to tryptophan-depleted diet. Initial studies in patients with personality and mood disorders, and also in patients with a history of suicide attempts, demonstrated a blunted plasma prolactin response to a D,L-fenfluramine challenge, relative to patients without those disorders (Coccaro et al., 1997a, b, 1989). This finding has been replicated in violent abstinent alcoholics (Moss et al., 1990; Handelsman et al., 1996), sociopathic violent offenders (O'Keane et al., 1992), personality-disordered patients, and nonpatients (New et al., 1997; Manuck et al., 1998). But, similar to the CSF 5-HIAA studies, there are also notable failures to

replicate with blunted prolactin responses to fenfluramine that comprise studies in children and adolescents with attention-deficit and disruptive behavioral problems (Halperin et al., 1994; Pine et al., 1997) and in cocaine addicts (Fishbein et al., 1989; Handelsman et al., 1998). At present, at least two serotonin receptor subtypes, 5-HT_{1A} and 5-HT_{2C}, have been proposed as the eventual sites of action, through which indirect or partial serotonin agonists produce the blunted prolactin response in aggressive individuals (Cherek and Lane, 1999; Cherek et al., 1999). Presumably, such an action occurs through either raphé projections to PVN neurons that release oxytocin or vasopressin (VA) which affect prolactin, or via raphé projections to GABAergic neurons in the mediobasal hypothalamus which then inhibit the DA neurons (Mirkes and Bethea, 2001; Emiliano and Fudge, 2004). It will be important to link this mechanism of action with the characteristic corticolimbic activity of impulsive aggressive individuals.

When the essential aromatic acid precursor L-tryptophan is omitted acutely from the diet in humans, an immediate depletion of plasma tryptophan and presumably brain serotonin results (Delgado et al., 1990). In nonpatient research volunteers, acute tryptophan depletion resulted in increased aggressive responding in experimental situations that provoke the subjects by a fictitious opponent and that allow the subject to inflict harm by administering an electrical shock or to take monetary rewards away (Cleare and Bond, 1995; Pihl et al., 1995; Moeller et al., 1996). Conversely, under similar conditions, buspirone and eltoprazine, drugs with partial agonist actions at 5-HT_{1A} receptors, decrease aggressive responding in the point subtraction aggression paradigm (Cherek et al., 1995, 1999). Earlier studies in laboratory mice had provided evidence that tryptophan-free diet resulted in increased aggressive behavior (Kantak et al., 1980), and dietary tryptophan supplements decreased murine aggressive behavior (Lasley and Thurmond, 1985). Overall, these studies on changes in serotonin via dietary manipulations support the serotonin deficiency hypothesis of increased aggressive behavior.

3.3.3 In vivo Microdialysis

Considerably more detailed insights into the dynamic serotonin fluctuations associated with aggressive behavior begin to emerge with in vivo microdialysis sampling. Instead of relying on a single sample of CSF, a peripheral marker, or an endocrine response to a single pharmaco-challenge, in vivo microdialysis offers the opportunity to monitor 5-HT activity in a specific brain region while the experimental animal rests, initiates, executes and terminates aggressive acts and postures, and recovers from an aggressive confrontation. It is noteworthy that during the initiation phase of an aggressive encounter, cortical 5-HT of a resident rat confronting an intruder remains unchanged, whereas a decline in 5-HT in prefrontal cortex, but not in nucleus accumbens, is measured during the actual performance of aggressive behavior and during the termination and recovery (Van Erp and Miczek, 2000). These 5-HT changes in the termination phase of aggressive behavior can be dissociated from the vigorous motor activity that characterizes fighting. Resident rats that have confronted an intruder regularly at a specific time of the day, show a decrease in 5-HT in nucleus accumbens on a day when the fight was omitted (Ferrari et al., 2003). These data suggest that the anticipation of a fight and its termination is sufficient to lower 5-HT in the nucleus accumbens. It will be essential to develop in vivo methodologies that provide higher temporal resolution, so that aggressive acts and samples of serotonergic activity can be better synchronized.

3.3.4 5-HT Receptors

The identification of the genetic basis and molecular features of several receptor families for 5-HT and the 5-HT transporter (SERT) has emerged as the most significant accomplishment during the past decade (Hoyer et al., 2002). This information prompts questions as to the functional significance of these receptors, including their role in modulating aggressive behavior. So far, only the first two families of serotonin receptors, belonging to the G-protein coupled superfamily, have been studied with regard to their role in aggressive behavior.

3.3.4.1 Serotonin$_1$ Family The 5-HT$_1$ family comprises 5-HT$_{1A}$, 5-HT$_{1B}$, and 5-HT$_{1D}$ receptors (Barnes and Sharp, 1999; Hoyer et al., 2002), and it has been implicated in the modulation of various behaviors ranging from sex, feeding, drug self-administration, sleep, anxiety, depression, and also aggression (Olivier et al., 1995; Lee and Simansky, 1997; Ahlenius and Larsson, 1998; Hillegaart and Ahlenius, 1998; Parsons et al., 1998; Sari, 2004). A high concentration of 5-HT$_{1A}$ receptors is located in the raphé nuclei and provides negative feedback via somatodendritic synapses (Zifa and Fillion, 1992). A second population of 5-HT$_{1A}$ receptors is found as postsynaptic heteroreceptors in the terminal regions of serotonergic projections. Two major populations of 5-HT$_{1B}$ receptors can be distinguished; one serves as presynaptic autoreceptors on axon terminals and a second one as postsynaptic heteroreceptors in nonserotonergic neurons in terminal areas (Zifa and Fillion, 1992). There are also 5-HT$_{1B}$ receptors found in the raphé nuclei acting as autoreceptors (Hoyer et al., 1985, 1986; Sari et al., 1999; Sari, 2004). Application of 5-HT$_{1A}$ agonists onto midbrain raphé tissue slices decreases the firing rate of these 5-HT neurons (Sinton and Fallon, 1988a, b; Sprouse and Aghajanian, 1988; Sprouse, 1991). In contrast, 5-HT$_{1B}$ agonists have either no effect or potentiate the firing rate of raphé neurons (Sprouse and Aghajanian, 1987; Evrard et al., 1999). The contrasting effects of 5-HT$_{1A}$ and 5-HT$_{1B}$ agonists on raphé electrophysiology may reflect activation of somatodendritic versus heteroreceptors.

Behaviorally, systemic administration of 5-HT$_1$ agonists dose dependently decreases species-typical levels of aggression in mice and rats (Olivier and Mos, 1986, 1992; Muehlenkamp et al., 1995; Sanchez and Meier, 1997; Miczek et al., 1998b; de Boer et al., 1999; Fish et al., 1999; de Boer et al., 2000; McKenzie-Quirk et al., 2005). In the dose range that produces effective reductions in aggressive behavior, most of these ligands also sedate, slow motor routines, or can induce stereotyped movements, indicating a behaviorally nonspecific effect of these drugs on aggressive behavior (Miczek et al., 1998b; de Boer and Koolhaas, 2005; McKenzie-Quirk et al., 2005). Alnespirone, S15535, and some other compounds in development that act presumably on subpopulations of 5-HT$_{1A}$ receptors differ from the prototypic 8-OH-DPAT in that they reduce specifically aggressive behavior in feral rats (de Boer et al., 1999, 2000; de Boer and Koolhaas, 2005). The reversal by WAY 100635 points to the 5-HT$_{1A}$ receptor as the site of action for the antiaggressive effects of these compounds. Genetic studies, however, generate evidence that is difficult to reconcile with the pharmacological data. Mutant mice without the gene for the 5-HT$_{1A}$ receptor protein actually exhibit less aggressive behavior (Zhuang et al., 1999). In mice that have been selectively bred for attacking rapidly, the mRNA for 5-HT$_{1A}$ receptors and the binding to this receptor are significantly higher in the hippocampus and prefrontal cortex (Korte et al., 1996). When challenged with the 5-HT$_{1A}$ receptor agonist alnespirone, short attack latency mice and feral aggressive rats were significantly more sensitive to the hypothermic effects, suggesting a heightened, rather than a deficient, 5-HT$_{1A}$ receptor activity in highly aggressive individuals (Van Der Vegt et al., 2001).

The distinctive feature of 5-HT$_{1B}$ receptor agonists is that, in most situations, they appear to specifically reduce aggressive behavior without sedation (Olivier et al., 1990; Fish et al., 1999; de Almeida et al., 2001; de Almeida and Miczek, 2002; de Boer and Koolhaas, 2005) (*Figure 7-9*).

Ligands such as CP-94,253 and CP-93,129, that selectively bind to the 5-HT$_{1B}$ receptor subtype (Macor et al., 1990; Koe et al., 1992), proved to be promising pharmacological tools with antiaggressive effects in mice and rats. Microinjections of CP-94,253 into the ventral orbitofrontal cortex effectively reduced aggressive behavior in mice (de Almeida et al., 2006).

The precise mechanisms and sites of action for the antiaggressive effects by 5-HT$_{1A}$ and 5-HT$_{1B}$ receptor agonists remain unclear. Microdialysis measurements indicate that systemic administration of 5-HT$_{1A}$ agonists decreases extracellular levels of 5-HT in the striatum, hippocampus, frontal cortex, nucleus accumbens, and medial septum, although the magnitude of the decrease varies between brain regions (Hjörth and Sharp, 1991; Kreiss and Lucki, 1994; Gobert et al., 1998; Dekeyne et al., 2000). Similarly, systemic administration of 5-HT$_{1B}$ receptor agonists decreases extracellular levels of 5-HT in the striatum, hippocampus, and prefrontal cortex (Knobelman et al., 2000a, b; Johnson et al., 2001; De Groote et al., 2003). These data would point to an inhibition of 5-HT release by 5-HT$_{1A}$ and 5-HT$_{1B}$ receptor agonists, presumably via stimulation of somatodendritic receptors at raphé neurons (Blier et al., 1998; Adell et al., 2002). The decrease in extracellular levels of corticolimbic 5-HT on the one hand, and

the antiaggressive effects on the other, represent a significant challenge to the serotonin deficiency hypothesis of aggression.

A second mechanism for the antiaggressive effects of 5-HT_{1A} and 5-HT_{1B} receptor agonists focuses on the postsynaptic heteroreceptors (Olivier and Van Oorschot, 2005). For example, when presynaptic 5-HT neurons are destroyed by the neurotoxin 5,7-DHT, the antiaggressive effects of 8-OH-DPAT, eltoprazine, and zolmitriptan remain unaffected, suggesting a postsynaptic site of action (Sijbesma et al., 1991; de Almeida et al., 2001). If in fact, low-5-HT levels are inversely related to intense, impulsive aggressive behavior, then differential sensitivity due to presynaptic gating via 5-HT_{1B} receptors would be predicted. Yet, 5-HT_{1B} receptor agonists reduce aggressive behavior independent from the basal level; species-typical normative as well as escalated types of aggressive behavior due to social instigation or consumption of low alcohol doses is effectively reduced by 5-HT_{1B} receptor agonists (Mos et al., 1992; Fish et al., 1999; de Almeida and Miczek, 2002). These observations can be interpreted in support of a postsynaptic site of action for the antiaggressive effects of 5-HT_{1B} receptor agonists.

So far, the contribution of gene deletion studies of the 5-HT_{1A} and 5-HT_{1B} receptors has been obscured by the influence of the background strain of mice in which null mutations were implemented. It is difficult to interpret the level of aggressive behavior in mice in which the gene for the 5-HT_{1B} receptor was deleted, when in fact the level of aggressive behavior in the wild-type 129 strain mice is species-atypically absent, possibly influenced by abnormalities in brain structures (Saudou et al., 1994b; Bouwknecht et al., 2001; Wahlsten et al., 2001). Moreover, pharmacological antagonists of 5-HT_{1B} receptors do not alter different types of aggressive behavior, which has been interpreted to reflect the low serotonergic tone at this receptor (Olivier and Van Oorschot, 2005).

Some data begin to emerge that link allelic variation in the polymorphic gene for the 5-HT_{1B} receptor to type II antisocial alcoholism (Lappalainen et al., 1998), repeated suicidal behavior (New et al., 2001), and attention deficits and behavior disorders in children. There is no differentiation between pre- and postsynaptic 5-HT_{1B} receptors in terms of allele frequency, and the functional significance of these polymorphisms remains to be determined.

3.3.4.2 Serotonin$_2$ Family The 5-HT_2 receptor family became relevant to the neurobiology of aggression, with the development of neuroleptics that achieve their effects via antagonism of 5-HT_{2A} receptors. These compounds proved effective in the clinical management of aggressive behavior in children, adolescents, middle-aged, and elderly patients with diagnoses ranging from schizophrenia, dementia, depression, and posttraumatic stress disorder (Czobor et al., 1995; Buckley et al., 1997; De Deyn et al., 1999; Keck Jr et al., 2000; Buitelaar et al., 2001; Zarcone et al., 2001; McCracken et al., 2002; Swanson et al., 2004; Bitter et al., 2005; Kratochvil et al., 2005; LeBlanc et al., 2005; Nolan et al., 2005; Volavka et al., 2005). As discussed with neuroleptic drugs acting on DA D2 receptors, the lack of behavioral specificity of 5-HT_{2A} agonists in reducing aggressive behavior is a critical issue. Preclinical studies in isolated male mice highlight that the antiaggressive effects of risperidone and similarly acting drugs can be achieved at doses that also inhibit motor activity (Rodriguez-Arias et al., 1998), and similar results are seen with ketanserin in MAO-A-deficient mice (Shih et al., 1999b).

Microinjections of DOI, a substituted phenylisopropylamine that acts as an agonist at both 5-HT_{2A} and HT_{2C} receptors, into the periaqueductal gray of cats enhance the defensive hissing that was evoked by hypothalamic stimulation (Shaikh et al., 1997). This effect is most likely related to the anxiety-like behavior that results from activation of these receptors (Lucki and Wieland, 1990; Nogueira and Graeff, 1995). In experimental models of murine aggression, agonists at 5-HT_{2A} and 5-HT_{2C} receptors decrease aggressive behavior concurrently with other motor activities (Sanchez et al., 1993; Bonson et al., 1994; de Almeida and Lucion, 1994; Baxter et al., 1995; Muehlenkamp et al., 1995; Olivier et al., 1995). A more satisfactory characterization of 5-HT_2 receptor subtypes regarding their role in aggressive behavior will have to await the development of more specific molecular tools for targeting these receptors.

3.3.4.3 Serotonin Transporter In support of the 5-HT deficiency hypothesis, restoring levels of 5-HT represents an effective means to calm and sedate aggressive individuals. Indeed, drugs that block the reuptake mechanism for 5-HT, the 5-HT transporter (SERT), reduce aggressive outbursts, particularly when

administered over extended periods of time (Fava and Rosenbaum, 1993; Knutson et al., 1998; Swann, 2003; New et al., 2004). Although there are occasional reports of increased aggressivity and suicidal tendencies among those receiving selective serotonin reuptake inhibitors (SSRIs) (Troisi et al., 1995; Spigset, 1999), these compounds are beneficial for most patients, as documented by large meta-analyses of the accumulated clinical studies (Heiligenstein et al., 1993; Walsh and Dinan, 2001). The reports of increased aggressive behavior should not be dismissed, however, because they reveal the existence of individual differences in the response to SSRIs. These differences may be related to the etiology of the aggressive behavior (i.e., whether it is associated with symptoms of an underlying disorder such as depression or with a personality disorder such as an antisocial personality) or to the individual's genotype and unique expression profile of the SERT. As modification of 5-HT levels continues to be a focus of pharmacotherapies, understanding the nature of these individual differences may lead to more precisely targeted and safer treatments.

The importance of the SERT to aggressive behavior is also evident in studies on animal aggression. Acutely, SSRIs reduce aggression in species as diverse as lobsters, dogs, monkeys, hamsters, and mice (Olivier et al., 1989; Ferris and Delville, 1994; Dodman et al., 1996; Huber et al., 1997; Pinna et al., 2003; Sanchez et al., 2003). The few long-term studies that have administered SSRIs repeatedly point to important treatment conditions and prevailing levels of aggressive behavior as critical determinants of outcome. Laboratory rats that typically do not engage in fighting have been shown to become moderately more aggressive after long-term SSRIs (Mitchell, 2005). However, in mice, consuming alcohol and fighting at high levels of repeated citalopram administration reduces aggression (Caldwell and Miczek, 2005); similar findings characterize prairie voles (Villalba et al., 1997). Apparently concordant with the 5-HT deficiency hypothesis, the antiaggressive effects of SSRIs can be interpreted to result from the elevations in extracellular 5-HT, but this interpretation does not differentiate between the acute and the chronic effects. It is also possible that the effects of SSRIs increase the $GABA_A$ receptor positive modulator allopregnanolone (Pinna et al., 2003). This mechanism is interesting, because allopregnanolone can inhibit or activate aggression, depending on the individual's prior experience (see GABA section), and could contribute to the occasional increases in aggression during the clinical use of SSRIs.

The genes coding for the SERT have also been related to aggressive behavior, as demonstrated by studies in mutant mice ("knockout") and associations with polymorphisms. Creation of mice in which the *SERT* gene was deleted results in a long-lasting reduction of aggressive behavior, increased 5-HT synthesis, and reduced 5-HT stores (Holmes et al., 2002; Kim et al., 2005). SERT KO mice also show elevated anxiety-like behavior (Holmes et al., 2003a, b), which may also contribute to the reduced aggressive behavior. A further hypothesis postulates that the altered aggressive behavior results from long-lasting developmental consequences of *SERT* gene deletion. 5-HT is essential for neural development (Lauder, 1993; Azmitia, 1999), and sustained 5-HT elevations during early life following repeated exposure to an SSRI generate a more anxious-like phenotype into adulthood (Ansorge et al., 2004). Whether the altered aggressive phenotype is the result of ongoing or past changes in 5-HT neurotransmission remains an unresolved but urgent issue.

Human and nonhuman primate studies have focused on polymorphisms in the *SERT* gene that confer variation in SERT expression and 5-HT uptake. The 5-HT transporter linked polymorphic region (5-HTTLPR) has been associated with several behavioral and personality traits related to aggression and other affective disorders (Lesch et al., 1996; Lesch, 2005), but there is controversy regarding the particular allelic variation. Many studies find a stronger association between the short allele, which renders lower expression of the transporter, and affective disturbances (e.g., Lesch et al., 1996; Hallikainen et al., 1999; Gorwood et al., 2000; Greenberg et al., 2000; Haberstick et al., 2006). However, the long allele has also been associated with aggressive feelings and prior aggressive acts (Twitchell et al., 2001; Zalsman et al., 2001), not only in children but also alcoholics (Parsian and Cloninger, 2001) and patients with dementia (Sukonick et al., 2001; Sweet et al., 2001). The apparent disagreement between these findings does not discount the importance of this association between the 5-HTTLPR and aggression. The contribution of the 5-HTTLPR to the variability in aggressive personality traits is relatively small and subject to obligatory interactions between this gene, other genes, and the environmental triggers (Bouchard, 1994; Lesch and Mossner, 1998). Nonetheless, a thorough understanding of how SERT expression influences aggressive behavior and extracellular concentrations of 5-HT in specific brain regions could prompt a revision of the 5-HT deficiency hypothesis.

3.4 Dynamic Interactions: Reciprocal Neurochemistry Coordinates Behavior

One persistent puzzle with brain serotonin is how so very little of this amine can affect so very much. The consistent link of brain 5-HT to aggressive behavior, although often seemingly contradictory, is based on action of this indolamine at distinctively different levels of the neuroaxis modulating sensory, motivational, and performance aspects of aggression. The 5-HT system is anatomically organized to both directly and indirectly affect several facets of aggression. First, serotonergic projections arising from the dorsal, median, and linear raphé nuclei are widely distributed throughout the mid- and forebrain. The areas most heavily influenced by 5-HT include the striatum, hippocampus, hypothalamus, thalamus, amygdala, septum, frontal cortex, substantia nigra, ventral tegmental area, locus coeruleus, and the periaqueductal gray area. By acting directly within these pathways, 5-HT can influence aggression in several ways, from the perception of triggering stimuli, which involves the olfactory bulb, the amygdala, and frontal cortex, to the intricately patterned motor output necessary for aggressive acts and postures, which involves the substantia nigra, striatum, thalamus, motor cortex, and the descending motor neurons. When these regions are interconnected, 5-HT may further affect their functions by altering the activity of projection neurons. Serotonergic activity in the prefrontal cortical terminals is of particular relevance in the initiation and termination of aggressive acts as part of the inhibitory control of behavior. To illustrate the diversity in 5-HT's neural control over aggression behavior, the following section focuses on 5-HT's interactions with other neurochemical systems in the brainstem, hypothalamus, and cortex (*Figure 7-10*).

3.4.1 Mesolimbic Dopamine

Serotonergic neurons from the dorsal raphé (DR) nucleus project directly to the VTA and substantia nigra (Herve et al., 1987; Corvaja et al., 1993; Gervais and Rouillard 2000). Serotonergic 5-HT_{1A} and 5-HT_{2A} receptors can also be found in the VTA and substantia nigra (Wright et al., 1995), and colocalization of 5-HT_{2A} receptors on TH positive neurons has been described (Doherty and Pickel, 2000). Pharmacological methods have demonstrated that this serotonergic input can effectively modulate mesencephalic DA activity, which in turn alters telencephalic DA release (Schmidt and Fadayel, 1995; Pehek et al., 2001; Nocjar et al., 2002). This neuroanatomical and neuropharmacological evidence suggests a basis for serotonergic modulation of DA-mediated motivational and motoric processes of aggressive behavior.

In the ventral striatum, the nucleus accumbens septi is an area that is critical for the motivation of many goal-directed behaviors (Robbins and Everitt, 1996; Wise, 2005), including aggressive behavior (Miczek et al., 1994b) and impulsive choices (Cardinal et al., 2001). Serotonergic, dopaminergic, and noradrenergic projections overlap in the nucleus accumbens in both rats and humans (Gaspar et al., 1985; Delfs et al., 1998; Tong et al., 2006). The demonstration of increases in accumbal DA in advance of the regularly scheduled aggressive confrontations provides evidence of a potentially important role of this amine in the anticipation, preparation, and prediction for a salient event (Ferrari et al., 2003). The anatomical data indicate how this catecholaminergic activity in aggressive individuals is modulated by serotonergic input.

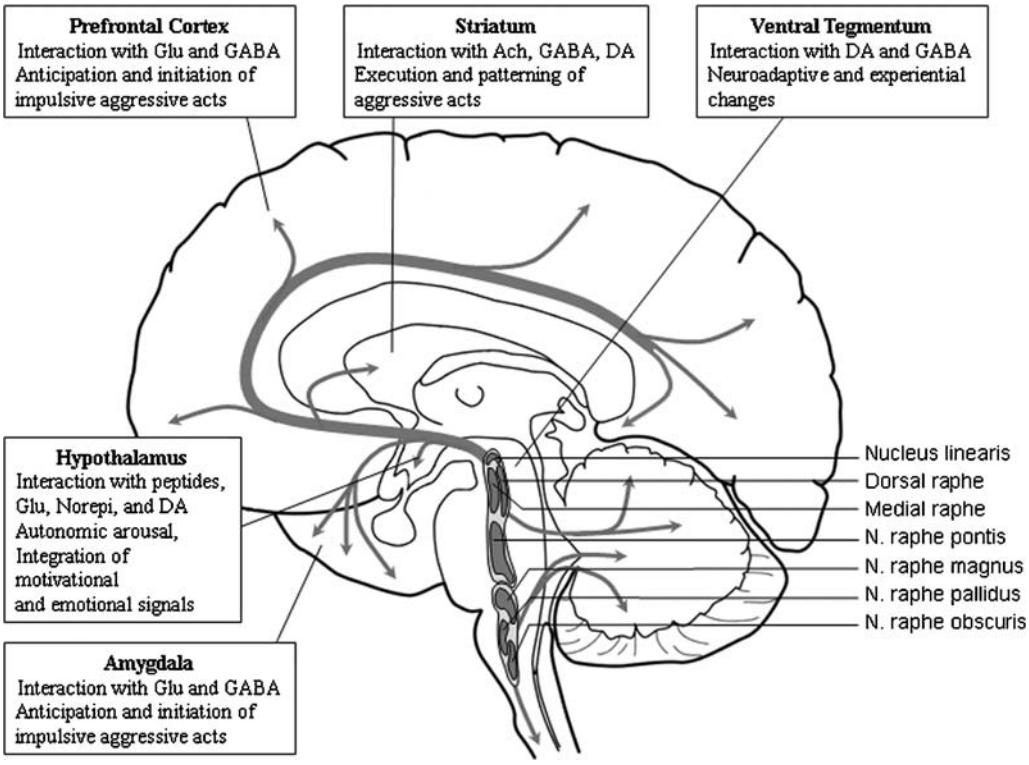
3.4.2 Hypothalamic Vasopressin

Neuroanatomical and neurophysiolgical studies established hypothalamic regions to be essential for the performance of attack behavior, identifying HAAs in rats and cats (Flynn, 1967; Halasz et al., 2002). 5-HT neurons project into this area and regulate the release and action of VP, a neuropeptide associated with high levels of aggression in several animal species (Compaan et al., 1992; Winslow et al., 1993; Ferris, 1996; Haller et al., 1996a; Ferris et al., 1997; Bester-Meredith and Marler, 2001), through actions at 5-HT_{1A} and 5-HT_{1B} receptors (Ferris et al., 1997, 1999). A reduction in VP levels in the AH may also contribute to the antiaggressive effects of fluoxetine (Altemus et al., 1992; Ferris, 1996).

A possible interaction between 5-HT and VP on aggression is an opposing influence on the same neuron. VP and 5-HT innervation are proximally oriented in the AH (Ferris et al., 1997). If 5-HT and VP

Figure 7-10

Serotonin interactions and facets of aggression. Serotonergic innervation of brain structures involved in various aspects of aggressive behavior. The brain in sagittal view is presented schematically with raphé nuclei shown in dark gray oblong shapes and major ascending and descending serotonergic projections shown in black arrow paths. Regions that are prominently involved in aggression are highlighted in text boxes. Each text box indicates neurochemicals with which serotonin interacts and suggests a functional outcome of these interactions. For simplicity, several projection regions are not highlighted, such as the hippocampus, thalamus, septum, and nucleus accumbens



affect the same neuron, it is likely to be glutamatergic, given the high expression of vesicular glutamate transzrter in the HAA (Hrabovszky et al., 2005) and the importance of glutamate stimulation of attack (Siegel et al., 1999). A second and not exclusive interaction is that 5-HT affects the soma of VP neurons at other locations, such as the medial supraoptic nucleus and nucleus circularis to alter release (Ferris et al., 1997). The change in VP levels after fluoxetine may be anatomically specific to the AH, because fluoxetine has been shown to increase peripheral VP levels (Gibbs and Vale, 1983). Moreover, administration of 5-HT_1 and 5-HT_2 agonists did not affect VP mRNA levels in the SON (Jorgensen et al., 2003), though this does not preclude an effect on release.

3.4.3 Cortical Glutamate and GABA

A further region where 5-HT can act to regulate aggressive behavior is the PFC, particularly the medial PFC. In human studies, this brain area is consistently recognized as being important to several psychiatric diseases with aggressive symptoms, as well as being involved in impulsive and aggressive behaviors (Raine et al., 1998, 2000; Best et al., 2002). The PFC coordinates behavioral and autonomic responses to complex environmental

stimuli, and has been implicated in sensory motor gating, attention and cognitive processes, motivation, motor control, as well as the hormonal and cardiovascular responses to stressors (Verberne and Owens, 1998). All of these processes are involved in various components of aggressive behavior, such as the motivation to fight, the initiation and maintenance of fighting, and the termination and recovery from fighting.

Anatomically, the PFC is well situated for these diverse functions and to influence aggressive behavior. It projects to motivational and motor regions such as the dorsal and the ventral striatum, ventral tegmental area, and spinal cord, sensory regions such as the mediodorsal thalamus, and affective regions including the basolateral amygdala, lateral hypothalamus, septum, PAG, DR, and nucleus of the tractus solitarius (Verberne and Owens, 1998; Carr and Sesack, 2000; Grace and Rosenkranz, 2002; Gabbott et al., 2005). Several of these regions directly influence aggressive behavior (Siegel et al., 1999).

In the PFC, 5-HT modulates the release of other neurotransmitters, particularly GABA and glutamate. The 5-HT projection to the PFC incorporates several receptors, including the SERT, 5-HT_{1A}, 5-HT_{1B}, and 5-HT_2 receptors. 5-HT can act at presynaptic heteroreceptors or postsynaptic receptors to alter cellular activity and extracellular GABA and glutamate concentrations, particularly in cortical layer V, and lead to further changes in any of the PFC projection regions. The PFC's inhibition of activity and 5-HT release in the DR (Celada et al., 2001) or the activity of the BLA (Rosenkranz and Grace, 2002) are two examples of how 5-HT's initial actions in the PFC can stretch throughout the neural circuitry regulating aggression.

The effect of 5-HT on GABA and glutamate concentrations is differentially regulated by 5-HT_{1A} and 5-HT_2 receptors. Stimulation of 5-HT_2 receptors increases levels of GABA and glutamate by depolarizing GABA interneurons and by acting at the terminals of glutamatergic afferents from the thalamus (Marek and Aghajanian, 1998; Lambe et al., 2000) in layer V of the cortex (Lambe et al., 2000). 5-HT_{1A} receptors are located postsynaptically on pyramidal and GABA interneurons and can be colocalized with 5-HT_{2A} receptors (Amargos-Bosch et al., 2004; Santana et al., 2004). Stimulation of 5-HT_{1A} receptors in the PFC hyperpolarizes neurons and can reduce glutamate and 5-HT release in this region (Calcagno et al., 2006).

3.4.4 Dorsal and Median Raphé Auto- and Heteroregulation

The dorsal and median raphé nuclei are important sites in which 5-HT and other neurochemicals can interact to control aggressive behavior. It is in this region that the activity of 5-HT can be modulated by several distal projection neurons as well as local interneurons and its own release through somatodendritic autoreceptors. 5-HT can be influenced by the catecholamines through NE fibers from the locus coeruleus and DA from the SN and VTA. The function of NE is to increase 5-HT cell firing (Baraban and Aghajanian, 1980) and release, when measured in the raphé (Adell and Artigas, 1999) or PFC (Linner et al., 2004). This effect most likely involves the α1 receptor (Svensson et al., 1975), because the antagonist prazosin inhibits NE-stimulated release (Adell and Artigas, 1999). α2 receptors in the DR and MR appear to have the opposite effect by inhibiting 5-HT release (Clement et al., 1992), and antagonists to these receptors facilitate 5-HT release (de Boer et al., 1996). However, the actions of DA on the DR 5-HT activity are less clearly defined (Adell et al., 2002). GABA can decrease 5-HT through neurons projecting from the PAG and hypothalamus as well as local interneurons (Tao et al., 1996; Abellan et al., 2000b; Tao and Auerbach, 2002). This inhibition is caused by $GABA_A$ receptors located on 5-HT cell bodies (Gao et al., 1993), rather than $GABA_B$ receptors that stimulate 5-HT activity (Abellan et al., 2000a). An opposing excitation can arise from the mPFC through NMDA, AMPA, and kainate receptors (Tao and Auerbach, 2000). Changes in 5-HT may represent a common path through which these neurotransmitters can influence aggression. The ultimate expression of a neurotransmitter's effect on aggression may depend upon its actions at 5-HT cells in the raphé. Modulation of 5-HT may also be a mechanism through which genetic manipulations affect aggression.

3.4.5 Indirect Alterations by Gene Manipulation

Serotonergic function has been indirectly altered in several knockout mice that have unusual aggressive phenotypes, such as the MAO-A, NAα2C, NCAM, H1 receptor, α-CaMKII, Pet-1, and nNOS knockouts

(Miczek et al., 2001). For example, the high levels of aggressive behavior by mutant mice lacking the gene for the neuronal isoform of nitric oxide synthase ($nNOS^{-/-}$) occur with impaired 5-HT turnover and reduced sensitivity of 5-HT_{1A} and 5-HT_{1B} receptor-mediated feedback control (Chiavegatto et al., 2001; Chiavegatto and Nelson, 2003). The lack of nNOS apparently causes dysfunctions in 5-HT metabolism in cortex, hypothalamus, midbrain, and cerebellum, while the endothelial isoform of NOS appears to facilitate 5-HT turnover. NO may modulate the receptor function for the 5-HT_{1A} and 5-HT_{1B} subtypes in these areas, rendering them less effective for mediating antiaggressive effects.

4 Conclusions

Aggressive behavior is the expression of several neurochemical interactions, each of which regulates the display of different behavioral elements. There is a consistently demonstrated significant role of 5-HT synthesis, release, and interaction with receptor and uptake sites, particularly in the affective dimension of impulsive, hostile, reactive, and violent behavior. The instrumental dimension, which requires proactive calculation, planning, premeditation, and memory, is based on a considerably more distributed neural circuitry. The mesocorticolimbic DA system in interaction with 5-HT, excitatory and inhibitory amino acids, monoamines, and peptides is critical for the rewarding aspects of aggressive behavior and may form the basis of recidivist acts of aggression.

A research strategy on aggressive behavior needs to pursue 5-HT as a potential target for pharmacotherapies and/or a mechanism underlying aggressive phenotypes. Given the limited available tools, stimulation of 5-HT_{1A} and 5-HT_{1B} receptors are promising targets for effective antiaggressive treatments, with the latter showing considerably more behavioral specificity than stimulation or blockade of other 5-HT receptor subtypes. We discuss evidence that emphasizes the reciprocal interactions between 5-HT, monoamines, and peptides.

It will be useful to learn how 5-HT interacts with DA, opioid peptides, and glutamate in the VTA for the long-term neuroadaptive changes that are engendered by repeated aggressive experiences. The interactions between 5-HT, glutamate, and GABA in the prefrontal cortex need to be defined systematically to understand their roles in the initiation and the inhibition of impulsive aggressive acts. In addition to the cortical influences on limbic and hypothalamic regions with significance for aggressive behavior, amygdaloid modulation of these subcortical areas requires neurochemical analysis that is related to aggressive outcomes. The promising information on CRF, GABA, and glutamate in these amygdaloid connections with hypothalamic and brainstem structures in situations of intense emotional behavior (Davis and Whalen, 2001; Pare et al., 2004) should prompt a close examination of these candidate mechanisms in escalated types of aggressive behavior.

The research agenda for molecular neurochemical studies needs to define the cascade of events that convey vulnerability and resilience to aggressive behavior. Early life experiences during critical developmental periods trigger gene expression that appears relevant to adult aggressive behavior, and the recent studies on early childhood maltreatment and adult changes in 5-HT metabolism represent promising examples of this interaction (Caspi et al., 2002). Individuals displaying hypoarousal and low glucocorticoid activation may be particularly prone to engage in intensely violent acts (Raine, 1996; Haller and Kruk, 2006). Further advances in in vivo methodologies will create the opportunity to study momentary neurochemical changes that match the time scale of the sudden behavioral outbursts more adequately than the current microdialysis approach. For example, it will be important to learn to which degree dopaminergic signals in the prefrontal cortex correspond to uncontrollable aggressive impulses devoid of serotonergic inhibition. Moreover, rapid measurements could resolve the issue of cause and consequence. Are altered 5-HT release and impulse flow necessary to alter aggressive behavior, or are they consequences of altered aggressive behavior? These need not be mutually exclusive possibilities but the distinction may be important for diagnosis and treatment, as well as for understanding mechanism. Additionally, molecular neurochemical studies may identify novel components of the 5-HT system that specifically regulate the threshold to trigger aggressive behavior but do not disrupt 5-HT's coordination of ongoing neural activity.

Abstract: An import role for gonadal steroid hormones, particularly testosterone, in mediating aggressive behavior is well-established across vertebrate taxa. Due to the emphasis placed on testosterone much less is know regarding the potential role of other steroid and peptide hormones in the regulation of aggression. The idea that any single hormone mediates aggression, however, is overly simplistic. In fact, research over the last two decades or more have has suggested that aggression in a complex behavior that is regulated by a wide range of hormones in addition to testosterone. This chapter reviews several novel neuroendocrine mechanisms that have been recently identified as being implicated in the regulation of aggressive behavior. Specific focus is placed on studies conducted in rodents, birds and primates, as the majority of research in this area has focused on these groups of animals.

1 Introduction

► "It is the habit of every aggressor to claim that it is acting on the defensive" (Jawaharlal Nehru)

Among the wide array of social behaviors displayed by organisms, undoubtedly one of the most important and well studied is aggression. Aggression is a highly complex behavior displayed by virtually all living organisms, and serves a wide range of adaptive functions. The possibility for aggressive behavior exists whenever the interests of two or more individuals are in conflict, typically involving limited resources (e.g., food, territories, and mates). In nature, social interactions dictate which animals gain access to a limited resource and which ones do not. In many cases, a submissive posture displayed by one animal avoids the necessity of physical aggression. Additionally, animals may engage in threat displays or ritualized combat in which dominance is determined in the absence of physical harm. If such displays are ineffective, however, physical aggression can result. In some cases a material goal for aggression cannot be identified, and animals appear to fight over dominance status (cf. Mason, 1993). Aggression is an essential part of the socialization process, as mothers and other adults use aggression to modify inappropriate behavior in developing animals.

Despite its importance, aggression is a notoriously nebulous concept that has been defined and categorized in a multitude of ways over the years. Aggression has traditionally been defined as overt behavior with the intention of inflicting physical damage upon another individual or "goal entity" (Moyer, 1971). One of the most commonly employed classifications of aggression was described by Moyer (1971), who divided aggression into specific subtypes based on differences in social conditions in which the behavior was elicited. Among these forms of aggression were predatory aggression, intermale aggression, fear-induced aggression, irritable aggression, maternal aggression, territorial defense, and instrumental aggression. One of the primary tenets of Moyer's classification system was that, although these different forms of aggression share behavioral features, the environmental factors eliciting these responses and the biological substrates underlying their manifestation differ markedly. More recently, a simplified classification of aggression has been suggested (Blanchard and Blanchard, 1988) in which

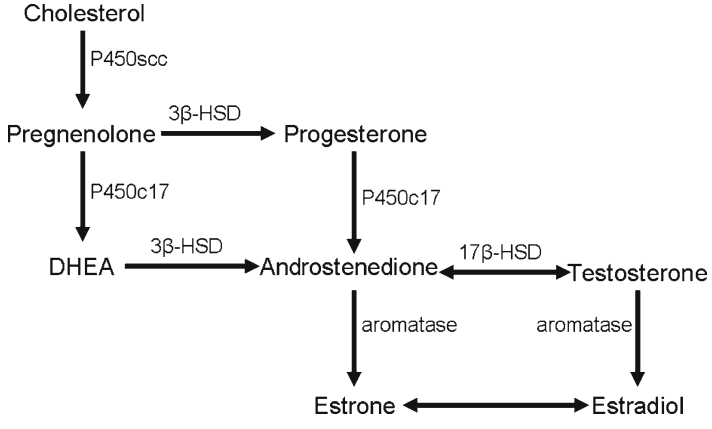
aggression is divided into *offensive* and *defensive* aggression. Offensive aggression refers to behaviors used in attack, whereas defensive behaviors do not involve an active approach to the opponent; rather, they serve as a defense against an attack. This latter classification system provides a useful framework with which to identify and describe aggressive behavior across many species.

Aggressive behavior has received extensive study under a wide range of environmental settings and experimental conditions; the experimental models used, the types of aggression measured, and the species tested, however, can vary considerably from study to study. Thus, it is often difficult to compare results across a range of studies. Although a relatively large number of experimental paradigms have been developed to test aggression (e.g., electric shock or brain lesion-induced aggression, conditioned aggression), one of the most prevalent models of assessing offensive aggression in rodents has been the resident–intruder model. This test is intended to simulate rodent territorial aggression and involves introducing a group-housed, nonexperimental "intruder" (typically younger and smaller than the experimental animal) into the home cage of an experimental animal, and the amount and duration of aggressive behavior (e.g., chases, attacks, bites) are subsequently recorded in a timed test. Another less-commonly employed but useful model is aggression in a neutral arena, which involves placing two animals in a novel "neutral" cage and recording the amount of aggression directed toward each animal. In addition, this latter model has the added benefit of assessing the formation of dominance relationships among animals because "territories" have not been established at the time of testing. Finally, it is important to consider the time of testing (i.e., day versus night), as most rodents are nocturnal and display significantly more behavior during night; many primates in contrast are diurnal. Thus, behavioral testing is more appropriately assessed during the day.

Much of the early research on the neuroendocrine mechanisms of aggression focused on the role of gonadal steroid hormones, and predominantly testosterone (T), as the primary factor regulating aggression (*Figure 8-1*). In fact, most behaviorally oriented textbooks discuss the role of T in aggression almost exclusively, with much less emphasis placed on the role of other factors (e.g., neuropeptides, neurotransmitters) in mediating this behavior. One of the goals of this chapter is to suggest that the idea that a single hormone or neurotransmitter mediates aggression is overly simplistic. For example, recent evidence indicates that T can be converted to 17β-estradiol within the brain and that estrogens may mediate aggressive behavior, at least in some species and contexts (Soma et al., 2000a, b). Alternatively, the so-called

Figure 8-1

Simplified diagram of sex steroid synthesis. *Steroids*: PREG = pregnenolone; PROG = progesterone; DHEA = dehydroepiandrosterone; AE = androstenedione; T = testosterone; E_1 = estrone; E_2 = 17β-estradiol. *Enzymes*: *P450scc* = Cytochrome P450 side chain cleavage; *P450c17* = Cytochrome P450 17α-hydroxylase/C17,20 lyase; *3β-HSD* = 3β-hydroxysteroid dehydrogenase/isomerase; *17β-HSD* = 17β-hydroxysteroid dehydrogenase; *Aromatase* = Cytochrome P450 aromatase



"weak" androgens such as dehydroepiandrosterone (DHEA) may be produced in extragonadal tissue (e.g., adrenals) or *de novo* within the brain. In fact, it has been suggested that both adrenal and neurally derived androgens, the latter called neurosteroids (Baulieu, 1991), may play an important role in regulating aggressive responses (Simon, 2002). Collectively, these important findings have helped elucidate several possible pathways by which androgens can act on the brain, either directly or indirectly, to affect aggression (*Figure 8-2*).

In addition to androgens, a wide range of neuroendocrine factors have now been established as playing a major role in aggressive behaviors. We will review important classical findings, as well as more recent discoveries for some of the key factors; however, an encyclopedic review of all the neuroendocrine factors regulating aggression is beyond the scope of this chapter. For a more in-depth discussion of specific neuroendocrine factors and their effects on aggression, we refer the reader to some excellent recent reviews (Ferris and Delville, 1994; Albers and Bamshad, 1998; Ferguson et al., 2002; Chiavegatto and Nelson, 2003).

Another important goal of this chapter is to present a comparative approach to the study of aggression. Historically, much of the early work on the physiology of aggression placed considerable emphasis on rodent models (e.g., Edwards et al., 1969; Brain and Poole, 1974). In fact, much of this research has focused on highly domesticated species (e.g., inbred strains of rats and mice). Although these models have provided important insights into the mechanisms of aggression, and continue to do so (especially in the light of recent advances in molecular and genetic techniques), recent evidence suggests that specific mechanisms mediating aggression can differ markedly across taxa (reviewed in Wingfield et al., 1997). Thus, an important aim of this chapter is to integrate research findings from several different taxa with the goal of elucidating common themes and noteworthy differences, with respect to the neuroendocrine regulation of aggression. With this goal in mind, we have chosen to focus on three groups of animals – rodents, birds, and primates—where considerable data from both laboratory and field settings are available. The application of a comparative approach to the study of aggression will allow for the development of a more comprehensive understanding of the factors mediating social behavior.

2 Neuroendocrine Regulation of Aggression in Rodents

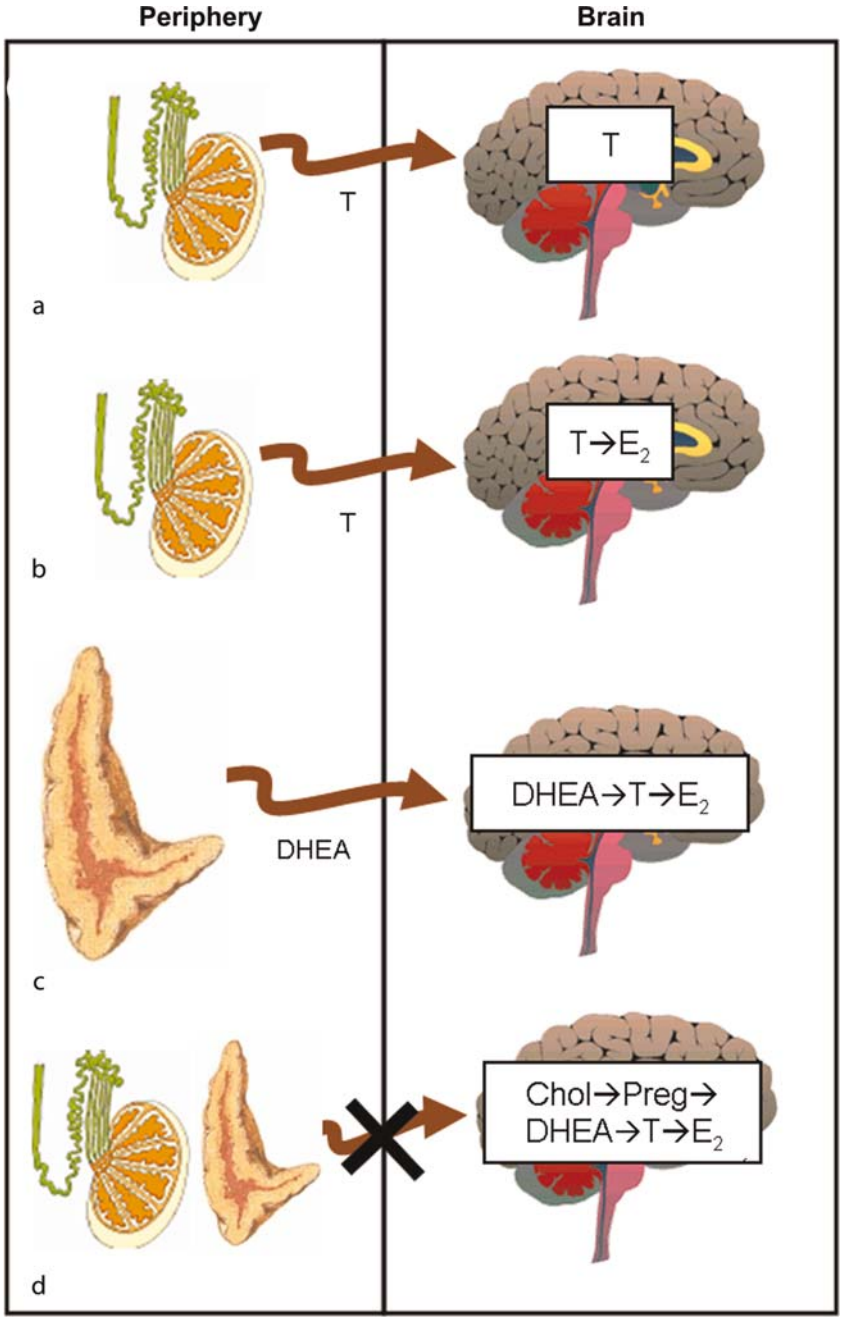
Much of the early work on the neuroendocrine regulation of aggression focused on the role of gonadal steroids in mediating intermale aggression and a majority of this work was conducted using laboratory-bred strains of rats and mice. Although space constraints do not permit an exhaustive discussion of this literature, a review of the major findings in this area will serve as a foundation for interpreting more recent findings, as well as exploring alternative physiological mechanisms regulating aggression in rodents.

2.1 Androgens: Organizational Versus Activational Effects

The link between T and aggression in rodents was first reported by Uhrich, who demonstrated that castration of postpubertal male rats decreased aggression, and that T replacement substantially reversed this effect (Uhrich, 1938). Since this initial finding, literally thousands of papers have been published examining the relationship between androgens and aggression (Beeman, 1947; Bevan et al., 1958, 1960; Yen et al., 1962; Sigg et al., 1969; Suchowsky et al., 1969; Brain and Haug, 1992). An important distinction must be made, however, between *organizational* and *activational* effects of androgens on aggression. Ever since the initial findings of Young and colleagues studying the effects of steroids on reproductive behaviors in guinea pigs, a well-established tenet of behavioral endocrinology is that steroid hormones can exert differential effects on physiology and behavior, depending on the time course of exposure during development (Phoenix et al., 1959). For example, for some behavioral responses (e.g., reproduction), androgens are required during a critical or "sensitive" period of perinatal development to permanently organize the neuroendocrine substrates required for adequate display of appropriate responses during adulthood. In many cases, the presence of androgens during adulthood is also required to activate the appropriate responses.

Figure 8-2

Steroid hormones can reach the brain to affect aggression via several possible mechanisms. (a) Gonadal testosterone can act directly on the brain; (b) gonadal T can be converted locally to estradiol; (c) adrenal DHEA can be converted locally to T or E_2; (d) neurosteroids can be produced locally in the absence of gonadal and adrenal steroid production



A large number of studies have demonstrated both organizational and activational effects of androgens on aggression in rodents. For example, castration of male mice on the day of birth eliminates aggression during adulthood, despite the presence or absence of exogenous androgens at the time of testing (Bronson and Desjardins, 1969). However, treatment of castrated pups with exogenous T immediately following surgery will result in normal levels of male aggression in adult animals, provided that androgens are given at the time of behavioral testing. Interestingly, the level of aggression displayed by adult female mice can be increased to that seen in male mice by treatment with exogenous androgens early during development, again provided that injections of hormone are also administered at the time of testing, consistent with an organizational effect of androgens on aggression (Edwards, 1968; Bronson and Desjardins, 1970). Male-like aggression in females treated with T prepubertally is not seen if T is not administered in adulthood, suggesting that activation of aggression is androgen-dependent.

The sensitive period for the organizational effects of androgens appears to be relatively long, although exogenous treatment with T is most effective when administered close to the time of birth in mice. For example, a single injection of T in castrated mice is sufficient to organize adult aggression, but this treatment is more effective on Day 0 than on Day 10 after birth (Edwards, 1969; Bronson and Desjardins, 1970). Furthermore, single injections of T become ineffective between 12–24 days of postnatal age, although more prolonged treatment (e.g., 20 days) can effectively organize adult aggression as late as 30 days postnatal (Edwards, 1970).

The widely accepted relationship between the presence of the testes (and normal circulating T concentrations) and aggression, however, is based primarily on studies of male–male aggression in a limited number of highly domesticated species such as laboratory rats (*Rattus norvegicus*) and house mice (*Mus musculus*) typically maintained in 12:12 light—dark (LD) cycles and tested during the light phase. In these species, removal of the gonads results in substantial decreases in circulating T and subsequently, reduced aggression (e.g., Edwards, 1969, 1970). When males of several nondomesticated species are examined, however, exceptions to the relationship of low circulating T concentrations and reduced aggression begin to emerge (Mathewson, 1961; Tiefer, 1970; Whitsett, 1975; Caldwell et al., 1984; Demas et al., 1999; Wiley and Goldizen, 2003; Gottreich et al., 2001). For example, several species of animals, including Mongolian gerbils (*Meriones unguiculatus*), prairie voles (*Microtus ochrogaster*), Syrian hamsters (*Mesocricetus auratus*), blind mole rats (*Spalax Ehrenberg*), saddle-back tamarins (*Saguinus fuscicollis*), European starlings (*Sturnus vulgaris*), and red-sided garter snakes (*Thamnophis sirtalis*) do not display decreased aggression after castration (Davis, 1957; Mathewson, 1961; Tiefer, 1970; Christianson et al., 1972; Epple, 1978; Dewsbury, 1991; Demas et al., 1999b). However, even in laboratory species, T does not stimulate aggression under all conditions. For example, in rats, T appears to be most effective in stimulating aggression during competitive experiences, but not during other social encounters (Albert et al., 1992).

2.2 Androgens and Seasonal Aggression

Several studies have examined the role of T in aggression *indirectly* by manipulation of the photoperiod. Many nontropical rodent species are seasonal breeders, maintaining reproductive function during summer and curtailing breeding during the winter. Ambient day length (photoperiod) is the proximal environmental cue used by individuals within these species to coordinate their reproduction to the appropriate season (Goldman, 2001). For example, reproductive function (and high levels of circulating T) is maintained during long "summer-like" days (e.g., >12.5 h of light/day) whereas reproductive regression, including virtual collapse of the gonads and marked decreases in T occur during the short "winter-like" days (i.e., <12.5 h of light/day) (Goldman, 2001). Interestingly, in male Syrian hamsters maintaining animals in short days actually *increases* resident–intruder aggression compared with long-day hamsters (Garrett and Campbell, 1980). Specifically, adult male Syrian hamsters housed in short days for nine weeks display approximately twice the amount of aggression in a resident–intruder test compared with long-day controls when tested 4 h before dark, despite gonadal regression (Garrett and Campbell, 1980). After prolonged maintenance in short days (>15 weeks) hamsters typically undergo spontaneous gonadal recrudescence

(i.e., increased testicular mass and circulating T), despite continued maintenance in short days. The short-day increases in aggressive behavior largely disappear in animals undergoing spontaneous recrudescence, returning to long-day levels of aggression by 21 weeks (Garrett and Campbell, 1980). More recently, short-day increases in aggression in male Syrian hamsters have been confirmed (Jasnow et al., 2002; Caldwell and Albers, 2004). For example, Syrian hamsters housed in short days (LD 10:14) for 10 weeks displayed a significantly greater number of attacks and a longer duration of attacks than did long-day hamsters when tested using a resident–intruder test (Jasnow et al., 2002). Furthermore, timed daily melatonin injections mimicking short-day patterns of the hormone in long-day, pineal-intact animals will produce short-day-like increases in aggression. Because these injections occurred for only 10 days, the gonadal mass and circulating levels of T are unaffected, supporting the idea that photoperiodic changes in aggression are not mediated by changes in gonadal steroids in this species (Jasnow et al., 2002). In contrast, these results suggest that levels of aggressive behavior are mediated by changes in the pattern of melatonin secretion.

Photoperiodic changes in aggression have been demonstrated in females of at least one species, Syrian hamsters (Fleming et al., 1988; Badura and Nunez, 1989). Female hamsters were housed in long (LD 14:10) or short days (LD 6:18) for 12 weeks and then both offensive and defensive aggression were tested (Fleming et al., 1988). Female hamsters maintained in short days displayed significantly less defensive aggression compared to long-day animals and thus had a higher ratio of offensive to defensive aggression than long-day animals (Fleming et al., 1988).

In virtually all mammals, photoperiodic responses are mediated by changes in the pineal indolamine melatonin. Melatonin is secreted in abundance during darkness, whereas daylight inhibits pineal melatonin secretion (Goldman, 2001). Thus, changes in ambient day length result in changes in the pattern of secretion of melatonin. In this manner, it is the precise pattern of melatonin secretion, and not the amount of hormone per se, that provides the biochemical "code" for day length (Goldman, 2001).

Pinealectomy, which eliminates melatonin secretion and renders animals physiologically "blind" to day length, prevents the short-day increase in aggression in female Syrian hamsters, whereas treatment of long-day hamsters with exogenous short-day-like melatonin increases aggression in female Syrian hamsters (Fleming et al., 1988). Ovariectomy, in contrast, has no effect of aggression. This finding suggests that photoperiodic changes in aggression are independent of changes in gonadal steroids in female Syrian hamsters (Fleming et al., 1988). A subsequent study in female Syrian hamsters confirmed these findings and provided further support for a role of pineal melatonin in mediating photoperiod changes in aggression. Specifically, a higher percentage of female hamsters housed in short days (LD 6:18) showed aggressive behavior compared with long day housed (LD 16:8) hamsters (Badura and Nunez, 1989). Consistent with previous findings, short-day aggression was attenuated by pinealectomy, but treatment with exogenous estradiol (E_2) (alone or in combination with progesterone) had no effect on aggression. These results support the hypothesis that photoperiodic changes in aggression are mediated by pineal melatonin, but independent of gonadal steroids, at least in female Syrian hamsters.

In Syrian hamsters, unlike most rodent species, females are more aggressive than males (Marques and Valenstein, 1977; Ciacco et al., 1979). Few studies have examined the role of photoperiod on male aggression in rodents displaying typical male-dominant aggression. Unlike Syrian hamsters, male Siberian hamsters (*Phodopus sungorus*) display significantly more aggression than females. It has recently been demonstrated that short-day male Siberian hamsters are significantly more aggressive than long-day animals (Jasnow et al., 2000; Jasnow et al., 2002), consistent with previous studies in Syrian hamsters. Specifically, male Siberian hamsters housed in short days (LD 8:16) for 10 weeks display a greater number of attacks during a resident–intruder test and have a lower latency to initial attack, relative to long-day (LD 16:8) animals. As previously reported for many rodent species, prolonged maintenance on short days (i.e., 20 weeks) resulted in spontaneous reproductive recrudescence in which the gonads, and thus T, returned to normal long-day levels (Jasnow et al., 2000). Interestingly, gonadally recrudesced hamsters displayed less aggression than gonadally regressed animals even though both groups experienced the same photoperiod and melatonin signal; levels of aggression in recrudesced hamsters were generally indistinguishable from long-day hamsters (Jasnow et al., 2000). These results support previous findings in male Syrian hamsters (Garrett and Campbell, 1980). When short-day Siberian hamsters were implanted with Silastic capsules

containing T (to achieve long-day-like levels), aggression actually *decreased* compared with short-day control animals (Jasnow et al., 2000), suggesting that short-day increases in aggression may be *inversely* related to serum T concentrations.

Despite growing evidence that short-day increases in aggression are independent of (or inversely related to) circulating levels of T, much less is known about the precise neuroendocrine mechanisms underlying seasonal aggression in rodents. As previously described, several studies have implicated changes in the pineal hormone melatonin in mediating short-day aggression. More recent research in male Siberian hamsters (Demas et al., 2004) confirms previous findings that treatment of long-day animals with short-day-like levels of melatonin mimics photoperiodic changes in aggression; long-day hamsters given daily timed injections of melatonin 2 h before lights-out to mimic short-day levels of the hormone displayed elevated aggression in a resident–intruder test compared with control animals. As with previous studies, these results were not likely due to changes in gonadal steroids, as serum T was unaffected by this injection protocol.

The effects of melatonin on aggression in rodents may be due to direct actions of this hormone on neural substrates mediating aggression (e.g., hypothalamus, limbic system). Alternatively, melatonin-induced aggression may be indirectly due to changes in hypothalamo–pituitary–adrenal (HPA) activity, as adrenal hormones have been implicated in aggressive behavior (Haller and Kruk, 2003). In support of the latter hypothesis, changes in both the size and function of the adrenal gland are associated with changes in aggression (Paterson and Vickers, 1981). In addition, male house mice housed in a LD 12:12 photoperiod and treated with melatonin display increased territorial aggression but decreased adrenal masses compared to saline-treated animals (Paterson and Vickers, 1981). The increases in aggression displayed by melatonin-treated animals, however, can be blocked by adrenalectomy (Paterson and Vickers, 1981). Experimental reductions in both adrenomedullary catecholamines, as well as adrenocortical glucocorticoids, are associated with decreased aggression in rodents (Patterson and Vickers, 1981; Haller and Kruk, 2003) and reductions in glucocorticoids via pharmacological blockade of adrenocorticotropic hormone (ACTH) release can attenuate melatonin-induced increases in aggression in mice (Patterson and Vickers, 1981). Thus, exogenous melatonin, despite reducing adrenal mass, appears to increase aggression by stimulating adrenocortical steroid release. These results are particularly intriguing given that house mice have traditionally been assumed to be photoperiodically nonresponsive (Nelson, 1990).

More recently, research has implicated changes in adrenocortical hormones in mediating melatonin- and possibly short-day-induced aggression in Siberian hamsters. As described previously, long-day hamsters treated with short-day-like levels of melatonin displayed increased aggression, comparable to levels seen in short-day animals (Demas et al., 2004). Interestingly, melatonin-induced aggression could be blocked by bilateral adrenalectomy, consistent with previous results in house mice (Paterson and Vickers, 1981). Adrenal demedullation, which eliminates adrenal catechloamines (i.e., epinephrine) but leaves adrenocortical steroid release (i.e., cortisol, DHEA) intact, had no effect on melatonin-induced aggression (Demas et al., 2004). Collectively, these results support the hypothesis that the effects of exogenous melatonin on aggression are mediated by the effects of this hormone on adrenocortical steroids. However, it is currently not known which class of steroid hormones may mediate this effect, as adrenal androgens (e.g., DHEA) and glucocorticoids (e.g., cortisol) have both been implicated in aggression in rodents (Schlegel et al., 1985; Haller and Kruk, 2003). In laboratory rats and mice, corticosterone (CORT) is the predominant adrenal glucocorticoid, and these species secrete little to no adrenal DHEA. In contrast, in hamsters, as in humans, cortisol is the primary adrenal glucocorticoid, and both hamsters and humans secrete measurable amounts of DHEA and its sulfated form, DHEA-S (Pieper et al., 2000; Mellon and Vaudry, 2001).

Recent evidence in avian species suggests that aggression in the nonbreeding season (i.e., winter) may be mediated by changes in DHEA (Soma et al., 2000; see Section 4). Although similar evidence suggesting a role for DHEA in mediating photoperiodic changes in aggression in rodents is lacking, studies in mice suggest that exogenous melatonin can stimulate DHEA production from cultured adrenal glands (Haus et al., 1996). Behavior was not examined in this study; however, these results are consistent with the hypothesis that short-day increases in melatonin may increase adrenal production of DHEA and thus affect aggression.

Several field studies published to date support the laboratory data discussed above suggesting differential dependence on gonadal steroids in animals during breeding season versus when they are not breeding. Specifically, male rat-like hamsters (*Cricetus triton*) in the field display elevated aggression during the winter nonbreeding season, despite low levels of plasma T (Zhang et al., 2001). Seasonal changes in aggression appear independent of seasonal changes in circulating T in wild wood rats (*Neotoma fuscipes*) (Caldwell et al., 1984). Pronounced seasonal changes in aggression are seen in male wood rats, with high levels during midbreeding season and low levels during the nonbreeding season. Despite differences in circulating T levels at these two time points, castration has no affect on aggression, suggesting an independence of seasonal aggression from circulating levels of T (Caldwell et al., 1984). More recently, seasonal changes in aggressive encounters have been examined in free-living arctic ground squirrels (Buck and Barnes, 2003). The effects of challenges by conspecific males on circulating T levels varied seasonally, with challenges by male intruders eliciting significant increases in circulating T during the spring breeding season, but similar challenges failed to trigger increase in androgen at the end of the summer after the breeding season. These results suggest that androgens play a more important role during the breeding season than during the nonbreeding season (i.e., late summer). Collectively, these studies fail to support the simple notion that all forms of aggression are mediated by circulating T by providing salient examples of T-*independent* aggression, at least with respect to circulating levels of the hormone. Unlike other forms of aggression, however, very little is known regarding the neuroendocrine mechanisms underlying seasonal changes in aggression in mammals.

2.3 Estrogens and Aggression

The specific role of estrogens in the regulation of aggression is complicated by the fact that both estrogens and androgens (if aromatized to estrogens) can act on estrogen receptors (ER) within the brain. Thus, many of the effects of androgens on aggression traditionally ascribed to actions via androgen receptors (AR) may in fact be due to activation of ER following aromatization. In addition, unlike the AR, two isoforms of ER, ERα, and ERβ, have been identified, and these receptors can exert differential effects on rodent aggression (Nomura et al., 2002). Much of the experimental evidence implicating ER in the regulation of intermale aggression has been determined using genetic knockout (KO) techniques in inbred male mice. For example, initial studies using ERKO mice that lack functional ERα demonstrated that intermale aggression was markedly reduced and male-typical offensive attacks were rarely displayed by ERKO mice (Ogawa et al., 1997). Moreover, both castrated wild-type (WT) and ERKO mice displayed comparably low levels of aggression; T replacement increased aggression in castrated WT males, but had no effect on ERKO aggression (Ogawa et al, 1998).

Unlike studies using ERKO mice, male mice that lack functional ERβ (BERKO) display relatively normal or even slightly elevated levels of aggressive behavior compared with WT males (Ogawa et al., 1999). Male aromatase KO mice that lack a functional aromatase enzyme necessary for the conversion of androgens to estrogens also display marked reductions in aggression (Matsumoto et al., 2003). This finding, coupled with the data from ERKO studies, suggests that the effects of androgens on intermale aggression may be due, at least in part, to conversion of these hormones to estrogens and the subsequent action of estrogens on ER within the brain. Furthermore, these results support the idea that ERα is the active form of ER for regulating neuroendocrine effects on aggression (Ogawa, 2003), although more research is needed. These results suggest that ERβ may provide a "brake" on aggression.

2.4 Glucocorticoids and the Development of Aggression

Although many pre-pubertal rodents display some form of "play aggression" prior to the development of fully functioning testes (Delville et al., 2003), fighting among males typically begins at the onset of puberty. Postpubertal aggression is mediated by the surge in circulating steroids that can "activate" aggressive behavior. Much of the work in this area has been performed in Syrian hamsters. For example, repeated

social stress in male Syrian hamsters inhibits aggression and increases submissive behaviors in adulthood. Acute social defeat in adult male Syrian hamsters increases subsequent submissive behavior and produces a complete loss of normal territorial aggression (Huhman et al., 2003). This change in agonistic behavior, however, appears mediated by the CNS and not by glucocorticoid feedback (Cooper and Huhman, 2003). Interestingly, recent evidence suggests that social stress during puberty enhances offensive aggression, most likely via the actions of glucocorticoids on the organization of aggression in this species (although a potential role for the adrenal androgen DHEA has not been examined to date). Syrian hamsters initiate aggression on approximately postnatal Day 20, engaging in considerable flank marking (a stereotyped form of communicative behavior employing odors) and play fighting (Goldman and Swanson, 1975; Ferris et al., 1996). Play fighting occurs as soon as coordinated movement is possible, and juvenile hamsters engage in more attacks during agonistic behavior than adult hamsters (Pellis and Pellis, 1998; Wommack et al., 2003). The number of attacks increases over development, reaching peak levels at approximately postnatal Day 35, and subsequently decreases until stable levels are reached at ∼45 days postnatal (reviewed in Delville, 2003).

It is important to note that the development of aggression in Syrian hamsters occurs when juvenile hamsters are attempting to establish independence from other territorial males and thus, are potentially exposed to social stressors from their dominant conspecifics (Delville, 2003). Recent research has examined the role of the stress response, and particularly the activation of the HPA axis and subsequent release of glucocorticoids, in the development of agonistic behavior in juvenile Syrian hamsters (Delville et al., 1998; Wommack et al., 2003). Specifically, juvenile hamsters were placed daily in the home cages of an aggressive adult hamster for short periods from weaning to midpuberty, whereas control animals were moved to an empty cage. Initially, both groups of animals displayed significantly increased levels of circulating cortisol. By two weeks, however, only hamsters exposed to males maintained elevated cortisol levels. Unlike previous studies in rats (Blanchard et al., 1995), chronic social stress did not result in altered body mass or lower circulating T concentrations. Social stress did not affect the frequency of attacks against a smaller intruder during early puberty (Wommack et al., 2003); however, at midpuberty, socially stressed hamsters displayed significantly more attacks than control animals (Wommack et al., 2003). Socially subjugated animals also performed adult-like attacks at an earlier developmental age, while decreasing the amount of play-fighting (Wommack et al., 2003). More recent data provide support for the idea that social stress during development may enhance offensive aggression in Syrian hamsters. Specifically, hamsters were exposed to social subjugation or isolation (control) from postnatal day 28 until midpuberty (Wommack et al., 2004). Hamsters were then assessed under basal conditions or after social defeat during early puberty, midpuberty or early adulthood. Socially stressed animals had lower post-defeat cortisol levels than control males during midpuberty, as well as complete inhibition of olfactory investigation of aggressive adults (Wommack et al., 2004). Collectively, these results suggest an important role for social stress, and subsequent HPA activation, in the development of age-appropriate levels of aggression.

2.5 Neurosteroids and Aggression

The concept of "neurosteroids" was first introduced by Baulieu to describe the high levels of the androgen DHEA, and its sulfated form DHEA-S, seen in rat brain even after castration and adrenalectomy (Baulieu, 1981; Corpechot et al., 1981). It is now established that DHEA, among other steroid hormones [e.g., allopregnanolone (ALLO)], can be synthesized *de novo* within the central nervous system and can act locally on specific neural substrates to regulate behavior (Simon, 2002). For example, a recent study has demonstrated that intermale aggression is associated with changes in brain neurosteroid synthesis (Pinna et al., 2005). Specifically, administration of testosterone propionate (TP) to male mice decreased brain ALLO content by ∼40% and was correlated with increased aggression. Increasing brain ALLO levels pharmacologically attenuated aggressive behavior in these mice. It remains unclear, however, how neurosteroids might be synthesized in adult rodent brain, given that some of the relevant synthetic enzymes (e.g., P450c17) are apparently nondetectable in the brains of many rodents (Mellon and Vaudry, 2001).

DHEA has also been implicated in the regulation of aggression in rodents. For example, DHEA has been shown to be a potent inhibitor of female-typical aggression (Bayart et al., 1986; Haug et al., 1989, 1992; Young et al., 1996; Perché et al., 2000). Attack behavior in ovariectomized females, intact females, or castrated male mice toward lactating females can be significantly reduced following treatment with exogenous DHEA (Bayart et al., 1989; Brain and Haug, 1992). Because this effect requires prolonged (~15 days) DHEA treatment, it has been suggested that the results are consistent with a genomic mechanism of action (Lu et al., 2003). More recently, it has been shown that prenatal T treatment enhances DHEA-induced inhibition of aggression in female offspring (Perché et al., 2001). It is important to note, however, that this testing paradigm (i.e., aggression toward a lactating intruder) is less commonly employed than more traditional models of aggression (e.g., intermale aggression); thus, the role of DHEA in mediating other forms of aggression has received very little experimental attention. One recent finding, however, suggests that increases in aggressive behavior can be induced by a single injection of DHEA-S immediately prior to behavioral testing in mice tested in a neutral arena (Nicolas et al., 2001). Furthermore, treatment with COUMATE, a drug that inhibits the steroid sulfatase enzyme involved in converting DHEA-S to DHEA, also increased aggression in male mice (Nicolas et al., 2001). Despite these intriguing results, more studies are needed to fully elucidate the role of DHEA and DHEA-S in intermale aggression.

The effects of DHEA on aggression have led to an attempt at determining the physiological mechanisms underlying this behavioral response, with much of the work focused on the interaction of this steroid with gamma aminobuteric acid (GABA) neurotransmission (reviewed in Simon, 2002). It has been demonstrated that DHEA alters brain levels of pregnenolone sulfate (PREG-S), a neurosteroid that inhibits GABAergic actions via the $GABA_A$ receptor. Specifically, DHEA-induced changes in GABA activity appear responsible for the effects of DHEA on aggression. These results are consistent with previous findings demonstrating an inhibitory effect of GABA on aggression (Miczek et al., 1994, 1997). Although the precise mechanisms of action are still unknown, DHEA can modulate the actions of both GABA and glutamatergic NMDA receptors (Labrie, 1998; Mellon and Vaudry, 2001). Alternatively, DHEA may act by further conversion in the brain to T and E_2 via 3β-HSD and the aromatase enzyme (Soma et al., 2004).

More recent findings suggest that an additional mechanism for the effects of DHEA on aggression may exist (Simon, 2002). Although is has long been assumed that DHEA is incapable of directly interacting with androgen receptors (AR), recent data suggest that DHEA upregulates AR in mouse brains (Lu et al., 2003). For example, because intact and gonadectomized, T-treated males do not display aggression toward females and prolonged treatment with DHEA is necessary to elicit antiaggressive effects, it has been speculated that androgens such as DHEA play an inhibitory role, presumably through a genomic action by binding directly on AR and altering AR transcription and translation (Simon, 2002). For example, it has recently been demonstrated that DHEA can compete for recombinant AR binding, up-regulate neural AR protein levels in mouse brains and immortalized GT1-7 hypothalamic cells, and induce transcription through AR in CV-1 cells, suggesting direct actions of DHEA on AR (Simon, 2002). Although this idea is intriguing, the affinity of DHEA for AR is low relative to T, so high local levels of DHEA would be necessary for this mechanism to be plausible.

2.6 Arginine Vasopressin and Dominant/Subordinate Relationships

Arginine vasopressin (AVP) when released as a neurohormone from the posterior pituitary is involved in the control of several important homeostatic functions, including the regulation of cardiovascular responses and fluid balance. However, there are also neural circuits in the brain that contain AVP and that have important effects on social behavior, including aggression (Ferris and Delville, 1994; Albers and Bamshad, 1998; Albers et al., 2002). One of the first demonstrations of a role for AVP in agonistic behavior occurred accidentally when it was found that injections of AVP into the anterior hypothalamus (AH) elicited flank marking in Syrian hamsters (Ferris et al., 1984). Since this initial discovery, a number of studies have implicated AVP in the regulation of aggressive behavior and dominance status (Ferris and Delville, 1994; Albers and Bamshad, 1998, Albers et al., 2002). For example, AVP released within the medial preoptic area (MPOA)-AH appears to be critical for the communication of dominance status by flank

marking in Syrian hamsters (Ferris et al., 1986). AVP antagonists injected into dominant hamsters inhibit the high levels of flank marking observed when these hamsters are placed with their subordinate partners. In response to this inhibition of flank marking in the dominant hamsters, subordinate hamsters significantly increase their levels of flank marking. Injections of AVP into the MPOA-AH of subordinate hamsters can also increase flank marking. Although injections of AVP and AVP antagonists can significantly modulate flank marking in both dominant and subordinate hamsters, these injections do not appear to modify the basic dominant/subordinate relationship (Ferris et al., 1986).

Studies on both Syrian hamsters and laboratory rats also suggest a role for AVP in the regulation of offensive aggression, most typically studied using the resident–intruder model. For example, injections of an AVP receptor antagonist into the AH trigger a dose-dependent decrease in offensive aggression of a resident male hamster toward an intruder (Potegal and Ferris, 1990). Similar results were found when animals were tested using a neutral arena. Injection of AVP into the AH increases aggression; however, the concentration of AVP administered must be below the levels that induce flank marking (Ferris et al., 1997; Caldwell and Albers, 2004). In addition, it appears that AVP enhances aggression only in hamsters that have been exposed to social conditions that increase their potential for aggression (see Caldwell and Albers, 2004). There is also evidence that AVP injected into the ventrolateral hypothalamus can facilitate offensive aggression (Ferris and Delville, 1994).

Aggressive behavior plays a critical role in the establishment of dominant/subordinate relationships in rodents. For example, when two male rodents that have not experienced one another previously are placed in a neutral arena, an initial period of high aggression is followed by a decrease in aggression once one male has established dominance. Injection of a specific AVP V_{1a} receptor antagonist into hamsters that have not previously interacted prevents the formation of a dominant/subordinate relationship (reviewed in Albers and Bamshad, 1998), suggesting that the period of aggression or flank marking is necessary for the establishment of social hierarchies. In contrast, injections of either AVP or AVP antagonists in hamsters with established hierarchies can affect the amount of flank marking displayed by both dominant and submissive hamsters. For example, injection of AVP into the MPOA-AH of subordinate hamsters increases flank marking in the presence of the dominant animal. Conversely, injections of an AVP antagonist into a dominant hamster reduces flank marking, despite the presence of the subordinate hamster (reviewed in Albers and Bamshad, 1998). The development of stable dominant/subordinate relationships appears to result in marked changes in the AVP system within the CNS. For example, subordinate hamsters in stable dominance relationships have reduced levels of AVP-ir and fewer AVP-ir fibers in the AH, but not in other brain regions, relative to dominant animals (reviewed in Albers and Bamshad, 1998). Lastly, knock-out mice that lack the V_{1b} AVP receptor display a marked reduction in aggression (Wersinger et al., 2002).

In addition to mediating aggression in adult animals, AVP has been implicated in the *development* of aggression in several rodent species. For example, adult sexually naïve male prairie voles (*Microtus ochrogaster*) are typically not aggressive; however, significant aggression is seen toward strange males within 24 h of mating. Furthermore, icv injections of AVP can induce intermale aggression in sexually naïve prairie voles, mimicking the effects of social experience (Stribley and Carter, 1999). Recently, it has been shown that developmental exposure of sexually naïve male prairie voles to AVP can elicit long-lasting changes in social behavior, with sexual naïve males exhibiting levels of aggression comparable to that displayed by male postmating, suggesting an important role for early AVP in the development of aggression in this species (Stribley and Carter, 1999). The monogamous California mouse (*Peromyscus californicus*) is typically more aggressive than its polygynous relative, the white-footed mouse (*Peromyscus leucopus*). Cross-fostering pups from these two species can reverse the species-specific bias toward aggression, with California mouse pups becoming less aggressive in a resident–intruder test and white-footed mouse pups becoming more aggressive in a neutral arena test (Bester-Meredith and Marler, 2001). Interestingly, the decrease in aggression seen in California mice was associated with decreases in AVP-immunoreactive in the bed nucleus of the stria teminalis (BnST), supraoptic nucleus, and medial amygdala (Bester-Meredith and Marler, 2001). In Syrian hamsters, repeated androgenic steroid treatment during adolescence increases hypothalamic V_{1a} AVP receptor staining and facilitates offensive aggression (DeLeon et al., 2002). Collectively, these studies suggest that in addition to regulating adult aggression, AVP plays an important role in the development of agonistic behavior in a range of rodent species.

3 Neuroendocrine Regulation of Aggression in Birds

Studies in birds have contributed greatly to our current understanding of the neuroendocrine regulation of aggression (Harding and Follett, 1979; Wingfield et al., 1987; Konishi et al., 1989; Schlinger and Callard, 1990; Goodson et al., 2005). Indeed, the first study of hormones and aggressive behavior was conducted in birds, as described below. More recently, field studies of wild songbirds, such as sparrows, have been invaluable for revealing hormone–behavior relationships across species, seasons, and habitats, as well as the molecular mechanisms underlying territorial aggression. Free-living animals are often more aggressive and have higher circulating T levels than captive animals (Wingfield, 1984a, b; Schwabl and Kriner, 1991; Smulders et al., 2000). In addition, testing conditions in the laboratory can have large, unexpected effects on behavior, particularly when animals are forced to interact in small spaces without the opportunity to flee. For these reasons, field studies can be an important complement to laboratory experiments. Such approaches in birds have produced novel insights into the social regulation of T levels, the expression of aggression during the nonbreeding season, the "costs" of elevated T levels, and species-specific effects of hormones (Goodson et al., 2005).

3.1 Aggressive Behavior

Our knowledge of the natural history, ethology, social systems, and seasonal reproductive patterns of birds is by far greater than for other classes of vertebrates. There are approximately 9,000 species of birds, living in habitats as diverse as deserts, arctic tundra, and tropical rainforest (DeVoogd et al., 1993; Brenowitz, 1997). A total of 5,300 species belong to the order Passeriformes ("perching birds"), which is composed of the oscine suborder ("true songbirds," 4,000 species) and the suboscine suborder (1,300 species; e.g., antbirds, flycatchers). There is a rich diversity of social systems from colonial to strictly territorial species, permitting comparative studies of aggression and the underlying physiological mechanisms (Soma and Wingfield, 1999; Goodson et al., 2005). In addition, many birds are terrestrial and diurnal, making their natural behavior relatively easy to observe in the field. Moreover, some species are highly territorial and show little spatial movement, facilitating long-term behavioral studies of individual animals.

For example, the ethologist Nice (1943) carried out groundbreaking studies of song sparrows (*Melospiza melodia*), a common North American songbird, by marking animals with unique combinations of color bands and conducting detailed behavioral observations, sometimes following individuals for several years. Nice (1943) provides descriptions of territorial aggression, including postures and vocalizations. For example, song sparrows use songs, specific threat postures, feather "puffing," wing "waving," and actual physical contact during territorial conflicts. Such encounters can go on for hours or days. Nice (1943) also described seasonal patterns of territorial behavior and the development of such behaviors in juveniles. Moreover, she was able to incorporate these behavioral observations into the larger context, including weather and population ecology. This foundation provides significant advantages when studying the hormonal and neural mechanisms underlying aggressive behavior in song sparrows (see later). Similar data are available for many other species, including European robins (*Erithacus rubecula*), European starlings (*Sturnus vulgaris*), and red-winged blackbirds (*Agealius phoenecius*), in which the neuroendocrinology of aggression has been investigated (Beletsky et al., 1990; Kriner and Schwabl, 1991; Schwabl and Kriner, 1991; Pinxten et al., 2002).

3.2 The Role of Testicular Hormones: Berthold's Capons

The study of hormones and aggression, and of hormones in general, can be traced back to the work of Berthold (1849). Berthold removed the testes of immature male chickens (the castrated animals are called capons) and found a decrease in some secondary sex characteristics and male-typical behaviors. Specifically, capons did not crow, did not try to mate with females, and did not fight aggressively with other males. Importantly, transplantation of testes into castrated animals restored male sexual and aggressive behavior. When a single autotransplanted testis was replaced after all original vascular and neural connections to the

testis were cut, these animals showed normal male aggressive behavior. Further, when a single heterotransplanted testis was replaced, these animals also showed typical male fighting. Additionally, when the testis from one heterotransplanted bird was removed, the animal behaved as a capon. Upon dissection, Berthold found that the transplanted testes in the abdomen had established new vascular connections. From these results, Berthold concluded that the testes release a substance into the blood that affects behavior and the body in general. Thus, from its beginning, the study of hormones and aggression was focused on gonadal secretions, primarily T. This conceptual framework has greatly influenced subsequent studies up to the present day. It is clear that T secreted by the testes is important for the expression of aggressive behavior. However, an *exclusive* focus on the testes and circulating levels of T is too simplistic and can often be misleading.

In seasonally breeding avian species, the gonads grow (recrudesce) markedly prior to the breeding season and regress following the termination of breeding. In parallel, circulating sex steroids fluctuate, generally with high levels during the breeding season and basal levels during other times of the annual cycle (e.g., molt, nonbreeding season) (Farner and Wingfield, 1980; Wingfield and Farner, 1993). In many species, territorial behavior shows a similar seasonal pattern: animals are territorial in spring, but gregarious and form flocks in autumn and winter (Wingfield et al., 1997, 2001). Note, however, that there are exceptions to this general pattern, and such exceptions can yield novel insights into the neuroendocrinology of aggression (see Section 3.6 and also Section 2.2).

3.3 Field Endocrinology and the Challenge Hypothesis

Ethologists generally focus on the behavior of free-living birds, whereas early behavioral endocrinologists focused on domesticated species, such as chickens. These two fields were combined in a series of elegant studies of wild songbirds by Wingfield and colleagues (Wingfield et al., 1987, 1990). Previous laboratory studies had demonstrated that long day lengths stimulate testis growth and increase plasma T levels in birds, but field studies were important for identifying the role of social interactions. In field studies, the temporal pattern of T titers differed from lab studies, and the absolute values of T concentrations were higher in wild-caught animals (Wingfield, 1984a, b). These two discrepancies suggested that environmental information in addition to day length was critical for T secretion.

As mentioned previously, song sparrows are common North American songbirds. In a migratory population, plasma T levels are very high in free-living males when they first arrive in early spring and are aggressively establishing breeding territories (Wingfield, 1984a, b). After pairing with females, plasma T levels in males decline, even though day lengths are increasing at this time. These data raised the hypothesis that aggressive male–male interactions stimulate T secretion, which may be important during periods of intense fighting or challenge. This hypothesis was tested experimentally in both the field and laboratory. In the field, wild territorial males were given either long-term subcutaneous T implants or empty implants in spring (Wingfield, 1984a, b). T-treated males were more aggressive, as measured by simulated territorial intrusions (STI) using taped song playback. Hormone levels were measured in the untreated *neighbors* of implanted animals. The immediate neighbors of T-treated males had higher circulating T levels than the immediate neighbors of control subjects. The hormone levels of distant neighbors were not affected. These results suggest that cues from aggressive males can stimulate T secretion (Wingfield, 1984a, b). In a separate field experiment, free-living males were exposed to a simulated territorial intrusion (STI) using both song playback and a live caged decoy for up to 120 min (Wingfield, 1985). The combined visual and auditory cues provoked a robust aggressive response. In addition, plasma T levels were significantly higher in males exposed to STIs than in controls. Further field experiments demonstrated that rapid changes in plasma T can occur within only 10 min of STI exposure (Wingfield and Wada, 1989).

In one laboratory study, the timecourse and specificity of STI response were investigated (Wingfield and Wada, 1989). Breeding male song sparrows were captured in the field and brought into captivity. After interaction with a novel male conspecific, plasma T titers were elevated. Interaction with a control stimulus (i.e., heterospecific male) had no effect. Lab experiments also assessed the relative importance of auditory

and visual cues using taped song playback only or a devocalized male only. Exposure to the devocalized male significantly increased plasma T, whereas there was only a trend for the song playback to do so (Wingfield and Wada, 1989).

These results and studies in many other bird species led to the formulation of the "challenge hypothesis" (Wingfield et al., 1990). This hypothesis states that plasma T levels and aggression are positively correlated during periods of social instability, or challenge, such as establishment of territorial boundaries or attempts at territory takeover. During such periods, aggressive interactions are more frequent, leading to high T concentrations. In contrast, during times of social stability, status or boundaries are maintained by social inertia, and plasma T levels are lower. Under such stable conditions, aggression and plasma T may not be correlated. This idea has been extremely influential and has been examined in a variety of birds, fish, lizards, rodents, and primates.

It may be advantageous to limit high circulating T levels to periods of instability during the breeding season because high T levels incur "costs" (Ketterson et al., 1992; Ketterson and Nolan, 1999). For example, systemic T treatment can increase the metabolic rate (Wikelski et al., 1999) and decrease body mass and fat stores in birds (Wingfield, 1984a, b; Ketterson et al., 1991). In addition, T treatment suppresses the immune function in some, but not all, species of birds (Casto et al., 2001; Owen-Ashley et al., 2004). These costs of high circulating T are likely to be most evident in the field, where food is not typically available ab libitum and parasites are often present. Moreover, several field studies have shown that T treatment can reduce male parental care (Hegner and Wingfield, 1987; Ketterson et al., 1992). In many bird species, biparental care is important, or even obligatory, for offspring survival. In such species, there should be strong evolutionary selection for low T levels during the parental phase of the breeding season (Van Roo, 2004). The relative importance of the costs of T will likely change across different stages of the life history cycle (e.g., breeding versus nonbreeding season) and across different habitats (e.g., temperate zone versus tropics) (Levin and Wingfield, 1992; Goymann et al., 2004).

3.4 Possible Neural Sites of Action of Testosterone

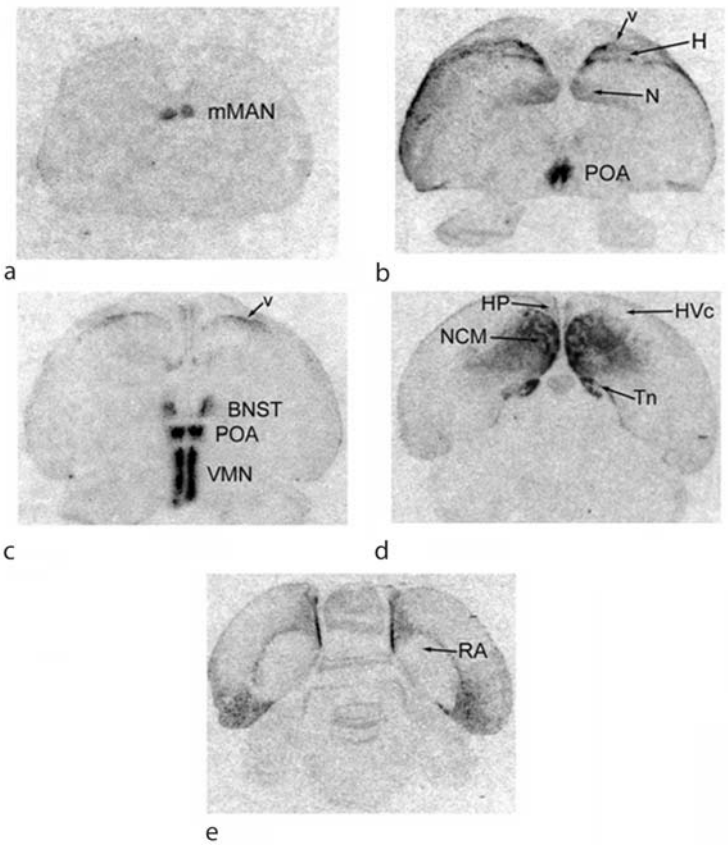
Where does T act in the avian brain to modulate aggression? In an important early study, Barfield et al. (1978) used steroid autoradiography and injected radiolabeled T into adult (3–4 months old) male chickens. The subjects were castrated at 5 weeks of age to remove gonadal T that would compete with radiolabeled T for receptors (Barfield et al., 1978). This method does not distinguish between direct uptake of T and uptake after local metabolism of T to 5α-DHT, E_2 or other steroids. Other caveats are that castration can affect the expression of hormone receptors, and castration will not reduce the competition of possible nongonadal androgens with radiolabeled T for receptors. Nevertheless, the results demonstrated that radioactivity accumulated in the POA (*Figure 8-3*), several regions of the hypothalamus, nucleus taeniae (Tn, homologous to the mammalian medial amygdala), lateral septum, and midbrain (including the central gray) (Barfield et al., 1978). This pattern was similar to that of other vertebrates and coincided with regions known to be important for reproduction. Several of these interconnected regions are considered part of a general "social behavior network" in vertebrates (Wood, 1997; Goodson et al., 2005).

More recent studies have examined the localization of androgen (AR) and ER in the avian brain using immunocytochemistry and in situ hybridization (Gahr et al., 1993; Soma et al., 1999; Fusani et al., 2000; Kim et al., 2004). In addition to the steroid autoradiography results, recent studies demonstrate that there is robust expression of AR and ERα in the BnST, a region involved in regulating aggression (Saldanha and Coomaralingam, 2005). There is less information regarding the expression of ERβ in the avian brain, but ERβ mRNA is present in the avian amygdala and POA (Bernard et al., 1999). Currently, there is no clear evidence for membrane AR or ER in avian brain, and this is a key topic for future research.

It is important to note that songbirds, unlike nonsongbird species such as chickens, have additional sites of abundant AR and ER expression in the song control system, which controls the production of birdsong in aggressive and sexual contexts (Arnold et al., 1976; Brenowitz et al., 1997; Schlinger, 1997; Tramontin and Brenowitz, 2000). The song control system is a circuit comprising interconnected, discrete regions that

Figure 8-3

Rostral (a) to caudal (e) distribution of brain aromatase mRNA from autoradiographic film from a wild male song sparrow in spring. (a) Expression in the medial magnocellular nucleus of the anterior nidopallium (mMAN). (b) Expression in the hyperpallium (H) near the ventricles (v), the nidopallium (N), and preoptic area (POA). (c) Expression in the bed nucleus of the stria terminalis (BNST), POA, and ventromedial nulceus (VMN). (d) Expression in caudomedial nidopallium (NCM), nucleus taeniae of the amygdala (Tn), and hippocampus (HP). A few cells in caudomedial HVC expressed aromatase. (e) Expression in the caudal nidopallium, but not in the robust nucleus of the arcopallium (RA)



controls the muscles of the syrinx (the vocal production organ in birds) (Nottebohm et al., 1976; Brenowitz et al., 1997). Several telencephalic song nuclei, such as HVC, robust nucleus of the arcopallium (RA), and Area X of the striatum, contain AR (Arnold et al., 1976; Harding et al., 1984; Soma et al., 1999; Kim et al., 2004) (*Figure 8-3*). HVC also contains ERα (Walters and Harding, 1988; Gahr et al., 1993; Perlman and Arnold, 2003; Saldanha and Coomaralingam, 2005). No song nuclei are known to express ERβ (Bernard et al., 1999).

In addition to localizing hormone receptors, a complementary approach is to assess the effects of local, intracerebral hormone implants in castrated animals. Small TP implants into the POA-AH do not activate aggression in chickens, but are effective in ring doves (Barfield, 1971; Phillips and Barfield, 1977). TP implants near Tn or the lateral septum do not increase agonistic behavior in chickens or ring doves (Barfield, 1971). It remains possible, however, that *multiple* sites must be activated by T to elicit aggression. Administration of hormone receptor antagonists locally in intact animals can be used to test this idea.

3.5 Brain Aromatase and Aggression

In many cases, the effects of plasma T are mediated by local metabolism within the brain. For example, T can be metabolized to 17β−E_2 by the enzyme P450 aromatase or to 5α-DHT by 5α-reductase (Schlinger and Callard, 1987; Fusani et al., 2000; Balthazart et al., 2003). Importantly, aromatase is expressed at high levels in the avian brain, facilitating its measurement in birds relative to mammals. 5β-reductase metabolizes T to 5β-DHT, an apparently inactive steroid, and brain 5β-reductase is present at very high levels in birds, but not rats and mice (Schlinger and Callard, 1987).

A series of laboratory studies with breeding Japanese quail (*Coturnix coturnix japponica*) illustrates the key role of brain aromatase in the expression of male aggressive behavior (Schlinger and Callard, 1990). To assess aggressive behavior, males were allowed to view a stimulus bird (i.e., nonaggressive female) through a glass partition (Schlinger and Callard, 1989). The number of pecks directed toward the glass partition and locomotor activity were recorded for 2 min. Males were killed either 90 s or 24 h after behavioral tests to measure aromatase, 5α-reductase, and 5β-reductase activities in several brain regions. Enzyme activities were assessed by measuring the metabolism of radiolabeled androgen (androstenedione, AE) by tissue homogenates in vitro. Aggressive behavior was positively correlated with aromatase activity in the hypothalamus but not in other brain regions (Schlinger and Callard, 1989; Schlinger and Arnold, 1992). Aggressive behavior was not correlated with 5α- or 5β-reductase or circulating T or estrogen levels. In a separate study, aggression was correlated with nuclear ("occupied") ER in the hypothalamic-POA (Schlinger and Callard, 1989). Moreover, in breeding males, experimental treatment with an aromatase inhibitor or ER antagonist decreased aggression, but a 5α-reductase inhibitor and AR antagonist had no effect (Schlinger and Callard, 1990). Taken together, these data argue that T affects aggression in quail via the aromatase pathway. In addition, there is evidence for a negative correlation between aggression and 5β-reductase activity in quail (Delville et al., 1984).

Generally similar results were obtained in studies of zebra finches (*Taeniopygia guttata*) and red-winged blackbirds. Captive reproductively active male zebra finches were castrated and treated with AE (androstenedione; an aromatizable androgen), AE + an aromatase inhibitor (ATD), or AE + ATD + E_2 (Walters and Harding, 1988). Although levels of aggression in this social species were generally low, only the AE and AE + ATD + E_2 groups displayed aggression, suggesting that the aromatase inhibitor reduced aggression (Walters and Harding, 1988). In captive breeding male red-winged blackbirds, castration greatly reduced aggression. Treatment of castrated animals with aromatizable androgens (T or AE) or E_2 + 5α-DHT in combination restored aggression (Harding et al., 1988). Treatments with E_2 alone or 5α-DHT alone were not effective, suggesting that the presence of both metabolites was necessary for the full expression of aggression (Harding et al., 1988). In a separate study of captive red-winged blackbirds, treatment with an AR antagonist (flutamide) decreased dominance and aggression, but not singing (Searcy and Wingfield, 1980). In a field experiment, blackbirds treated with flutamide and an aromatase inhibitor in combination lost parts of their territories (Beletsky et al., 1990). These data suggest that both estrogenic and androgenic metabolites of T are important for aggression in some avian species.

Field studies have examined seasonal changes in brain aromatase and/or 5α- and 5β-reductase in wild birds. In pied flycatchers (*Ficedula hypoleuca*) in Sweden, during early summer, males switch from defending a territory to helping with parental care. At the same time, plasma T levels decrease, and aromatase activity and immunoreactive cells in the diencephalon decline (Foidart et al., 1998). In another study of this species, aggression was measured using a simulated territorial intrusion, or STI; males were captured immediately afterwards; and brain tissue was collected (Silverin et al., 2004). Aromatase activity was measured by the release of tritiated water during aromatization of [1β-^{3}H]-AE, which is a sensitive technique but one that does not assess 5α- or 5β-reductase. Aggression was not correlated with plasma T or 5α-DHT. Aggression was, however, positively correlated with aromatase activity in the POA-anterior diencephalon, but not in the posterior diencephalon or telencephalon (Silverin et al., 2004). Specific telencephalic regions were not examined (e.g., Tn, BnST, lateral septum). It is possible that the STI rapidly upregulates aromatase activity, and this is a topic for future studies.

In Lapland longspurs (*Calcarius lapponicus*) in arctic Alaska, during the brief breeding season, males rapidly court females, then aggressively guard mates, and finally switch to parental care. Aggression is only

robustly expressed during the mate-guarding phase. In this species, plasma T is correlated with singing behavior but not territorial aggression, and T treatment increases song but not aggression (Hunt et al., 1995, 1997). Aromatase, 5α-, and 5β-reductase activities were measured in seven brain regions during all three phases of the breeding season (Soma et al., 1999). Aromatase activity in the anterior diencephalon generally matched temporal changes in aggressive behavior. Changes in 5β-reductase did not explain the pattern of aggressive behavior (Soma et al., 1999). Taken together, these data suggest a significant role of aromatase in the anterior diencephalon/POA in the control of aggressive behavior. In addition, studies in song sparrows suggest the presence of aromatase in Tn and perhaps BnST is involved in nonbreeding territoriality (see Section 3.6).

3.6 Territorial Aggression During the Nonbreeding Season: Beyond Berthold

During the autumn and winter, many birds are in nonbreeding condition, which is generally characterized by regressed gonads and secondary sex characteristics (e.g., cloacal protuberance, wattles) and basal plasma sex steroid levels. Typically, nonbreeding birds abandon exclusive territories in favor of flocks. Some species, however, aggressively defend territories during the nonbreeding season, even if plasma T is basal at this time (Wingfield et al., 1997; Soma and Wingfield, 1999). The physiological regulation of breeding territoriality has been the focus of numerous studies (Wingfield et al., 1987), but the proximate mechanisms underlying nonbreeding territoriality have been enigmatic.

Winter territoriality may be dissociated from plasma T because of the costs of circulating T. In seasonally breeding birds, sex steroids in the general circulation may have particularly high costs during the nonbreeding season. The nonbreeding season may last the majority of the year and can be a difficult time because of low ambient temperatures and reduced food supply (Soma and Wingfield, 1999). Moreover, diurnal birds do not forage during the long nights of winter. Many costs of T during the nonbreeding season may be energetic in nature. For example, T treatment can increase the basal metabolic rate (Wikelski et al., 1999). T treatment also decreases fat stores (Owen-Ashley et al., 2004), which are important for surviving snow and ice storms. T treatment stimulates secondary sex characteristics (Soma et al., 2002), which require energy to grow and maintain. Other costs of T are not directly related to energetic constraints. Importantly, T can suppress the immune system of birds (Casto et al., 2001); T also inhibits molt (Schleussner and Gwinner, 1989). Finally, T treatment may stimulate reproductive behavior, which is inappropriate during the winter (Logan and Carlin, 1991). These various effects may explain why T treatment of wild birds reduces overwinter survival in some species (Dufty, 1989; Moss et al., 1994; Ketterson et al., 1996).

In Washington State, song sparrows (*Melospiza melodia morphna*) are sedentary. Males are territorial during the spring (breeding season), when plasma T is high (Wingfield and Hahn, 1994; Wingfield and Soma, 2002). After breeding, the animals molt their feathers (August–September), and during the molt, plasma T levels are basal, gonads are regressed, and aggression is greatly reduced. Following completion of the molt, there is a resurgence of territorial aggression in the autumn (nonbreeding season). Males in autumn and spring respond similarly during the STI, but autumn birds are less "persistent" after the intrusion has ended. After the decoy is removed, territorial behavior is extinguished more rapidly in autumn (Wingfield, 1994). The social context of territoriality also changes seasonally. Spring territories are defended by a breeding pair, but autumn territories can be defended by individuals, pairs, or larger groups (Wingfield and Monk, 1992; Wingfield, 1994). Plasma T is nondetectable during the autumn, and the testes and cloacal protuberance are fully regressed (Wingfield and Hahn, 1994; Soma and Wingfield, 1999). While agonistic interactions between males increase plasma T in spring (Section 3.3; Wingfield and Hahn, 1994), they do not affect circulating T in autumn (Wingfield and Hahn, 1994; Soma and Wingfield, 2001). Plasma 17β-E_2, 5α-DHT, AE, and estrone concentrations are also basal in males during the nonbreeding season (Soma and Wingfield, 1999). Moreover, castration does not decrease aggressive behavior in autumn (Wingfield, 1994). Thus, aggression may be independent of T in autumn.

The hypothesis that nonbreeding season aggression is independent of T was tested in three field experiments by treating wild song sparrows with pharmacological inhibitors of aromatase, with or without

an AR antagonist. A combined treatment of an aromatase inhibitor (ATD) and AR antagonist (flutamide) decreases nonbreeding aggression in free-living males after 30 days, but not after just 7 days (Soma et al., 1999). Fadrozole, a more potent and specific aromatase inhibitor than ATD, strongly decreases nonbreeding aggression within 10 days. The effects of fadrozole are rescued by E_2 replacement (Soma et al., 2000). Moreover, fadrozole did not affect body condition or plasma CORT levels, indicating that the animals were not affected in a nonspecific manner (Soma et al., 2000). Additional studies suggest that fadrozole can reduce some aspects of autumnal aggression within only 24 h (Soma et al., 2000). These data indicate that sex steroids, particularly estrogens, are important for the expression of aggressive behavior in the nonbreeding season, even though plasma sex steroids are nondetectable and castration has no effect.

In addition, studies have also examined regional and seasonal differences in song sparrow brain aromatase using biochemical and molecular techniques. In situ hybridization reveals that aromatase mRNA is highly expressed in the POA, ventromedial nucleus of the hypothalamus, Tn (avian medial amygdala), BnST, caudomedial nidopallium (NCM, implicated in song perception), and medial magnocellular nucleus of the anterior nidopallium (MMAN, a song nucleus) (Soma et al., 2003). In addition, brain regions were dissected and androgen-metabolizing enzyme activities were measured in several brain regions during spring, molt, and autumn. Aromatase activity in the ventromedial telencephalon (includes Tn) is specifically reduced during molt, matching seasonal changes in aggression (Soma et al., 2003). Aromatase activity in the diencephalon, however, is high only during spring. 5β-reductase is not elevated during molt and thus cannot explain the low aggression during molt. These results suggest that changes in aromatase activity may regulate seasonal changes in aggression in birds.

Despite the evidence implicating aromatization of androgens, the precise source of androgen substrate for brain aromatase in the nonbreeding season remains unknown, because plasma levels of aromatizable androgens (e.g., T and AE) are basal at this time. One endocrine candidate, DHEA, is considered an "inert" androgen precursor and does not bind to AR or ER with high affinity (Kroboth et al., 1999). DHEA, however, can be converted into active sex steroids within tissues that express the appropriate enzymes (Labrie et al., 2001). Interestingly, plasma levels of DHEA are detectable and elevated (several-fold higher than plasma T) in nonbreeding song sparrows (Soma and Wingfield, 2001). Circulating DHEA may originate from the adrenals or regressed testes in autumn (Soma and Wingfield, 2001). As described for rodents, another, as yet untested, possibility is that the brain synthesizes DHEA de novo from cholesterol in the autumn. Across the annual cycle, circulating DHEA levels are specifically reduced during the molt, the one life-history stage when song sparrows show reduced aggressiveness (Soma and Wingfield, 2001). In a separate experiment, treatment of wild nonbreeding males with high physiological levels of DHEA increased territorial singing behavior (but not other territorial behaviors) and the size of the song-control nucleus HVC (Soma et al., 2002). DHEA treatment did not, however, stimulate the growth of a peripheral secondary sex characteristic (cloacal protuberance). More recent results suggest that DHEA treatment, unlike T, does not inhibit the immune system of nonbreeding song sparrows (Owen-Ashley et al., 2004).

Next, DHEA metabolism was examined in song sparrow and zebra finch brain. The in vitro assay measures the conversion of tritiated DHEA to AE and estrogens by the sequential activities of 3β-HSD and aromatase (Soma et al., 2002; Soma, 2004; Soma et al., 2004). The song sparrow brain can indeed convert DHEA to androgens and estrogens, with the highest levels of 3β-HSD activity in the diencephalon and telencephalon (K. Soma, D. Wacker, J. Wingfield, B. Schlinger, unpublished results). Interestingly, seasonal studies demonstrate that neural DHEA metabolism is highest in the nonbreeding season (unpublished results). These data support the novel hypothesis that in nonbreeding song sparrows, adrenal and/or gonadal DHEA synthesis is coupled with neural DHEA metabolism to supply sex steroids to brain circuits controlling aggression. This mechanism would reduce the exposure of peripheral tissues to T, which is deleterious in winter. Thus, nonbreeding song sparrows may circumvent many costs of circulating T. These studies on song sparrows provide a broad picture of hormone–behavior relationships in this species, integrating field studies of behavior, endocrinology, and ecological constraints with biochemical and molecular mechanisms (Wingfield and Soma, 2002).

Similar results have been obtained in field and laboratory studies of tropical birds. Several avian species that breed in the tropics defend territories year-round and have very low levels of circulating sex steroids throughout the year (Levin and Wingfield, 1992; Goymann et al., 2004). One example is the spotted antbird

(*Hylophylax n. naevioides*) in Panama. In this species, both sexes sing and aggressively defend territories year-round in the rainforest (Wikelski et al., 2000). Wild spotted antbirds have basal plasma T and E_2 levels, even during the breeding season, except for transient increases during territorial encounters (Wikelski et al., 1999). In a laboratory experiment, a combined treatment of aromatase inhibitor and AR antagonist decreased male aggressive vocalizations (songs and "snarls") in the breeding season, even though plasma T was basal (Hau et al., 2000). In the nonbreeding season, both sexes show high levels of aggression, primarily to intruders of the same sex (Hau et al., 2004). Both males and females have regressed gonads and low levels of plasma sex steroids in the nonbreeding season (Hau et al., 2004). However, plasma levels of DHEA are elevated in both sexes during the nonbreeding season, and in males, plasma DHEA levels are positively correlated with aggressive vocalizations and/or the duration of territorial intrusions (Hau et al., 2004). These data suggest that DHEA regulates aggressive behavior, particularly vocal behavior, in both males and females of this species. In tropical species facing a large number of parasites, the immune function may be particularly important (Martin et al., 2004), thus favoring the evolution of endocrine mechanisms which avoid the immunosuppressive effects of circulating T.

Taken together, such studies suggest that nonbreeding aggression is not regulated by gonadal T in some species. Instead, circulating DHEA, from the adrenal glands or regressed gonads, may be converted to active androgens and estrogens locally within the brain. It is also possible that DHEA and/or sex steroids are synthesized de novo from cholesterol by the brain (Corpechot et al., 1981). These alternate mechanisms have important consequences for interpreting data on peripheral levels of T and the effects of castration.

Such mechanisms are likely to be of general importance in birds and other vertebrates. Winter territoriality is not uncommon among birds. For example, excellent field studies have documented nonbreeding territories in mockingbirds (Logan and Wingfield, 1990), willow tits (Silverin et al., 1984), European robins (Kriner and Schwabl, 1991; Schwabl, 1992), and European stonechats (Gwinner et al., 1994), to name just a few cases. In these species, robust territorial aggression is expressed despite basal circulating T levels during the autumn and winter. In European robins, an AR antagonist (flutamide) decreases aggression in spring but not in winter (Schwabl and Kriner, 1991). In European stonechats, a combined treatment of flutamide and an aromatase inhibitor (ATD) for 7 days does not decrease aggression in winter (Canoine and Gwinner, 2002). It would be useful to examine the effects of a more potent aromatase inhibitor, such as fadrozole, in this species. Red grouse in Scotland also defend territories in autumn, but in this species, there is a small peak in plasma T during autumn (Mougeot et al., 2005). Thus, the regulation of territorial behavior outside the breeding season is not identical in all species. In addition, birds that do not defend a winter territory may nonetheless display aggressive behavior within dominance hierarchies in winter flocks, for example, European starlings and dark-eyed juncos (Ketterson, 1979; Pinxten et al., 2000; Pinxten et al., 2002; Pinxten et al., 2003). The endocrine mechanisms regulating dominance in flocks are largely unknown.

3.7 Testosterone and Aggression in Juvenile Birds

Several interesting studies have documented the presence of steroids in egg yolk and consequences for behavioral development. For example, in an important study, it was demonstrated that yolk has significant quantities of AE, 5α-DHT, and T in the eggs of captive canaries (*Serinus canaria*) (Schwabl, 1993). In addition, the concentration of T depended on the order in which the eggs were laid. The T content increased with laying order (i.e., the first egg in a clutch had the lowest T levels). Moreover, the social rank of siblings was correlated with the T content in the yolk. These and other data suggest that steroid exposure in ovo can affect subsequent behavior (Whittingham and Schwabl, 2002). Manipulation of steroids in yolk is easier than manipulations of pregnant mammals, making birds excellent animal models for studying the organizational effects of steroids.

In addition to maternal steroids from yolk, young chicks can synthesize steroids independently. For example, black-headed gull (*Larus ridibundus*) chicks defend territories from conspecifics and transiently increase plasma T levels (Ros et al., 2002). An extreme form of aggression in juvenile birds is siblicide. Lethal attacks against siblings have been reported in several avian species. For example, in a

seabird such as the Nazca booby (*Sula nebouxii*), each clutch has 2 eggs that hatch 4–7 days apart (Ferree et al., 2004). If both eggs hatch, the first chick attacks the second chick and aggressively pushes it out of the nest. The second chick then dies of starvation or predation. A recent study indicates that plasma T levels are generally basal in chicks (~0.04 ng/ml), but transiently elevated during aggressive interactions with siblings (up to 0.15 ng/ml) (Ferree et al., 2004). This was true for both first and second chicks. However, even these peaks of plasma T are far lower than typical levels in many breeding adult birds. Plasma DHEA levels were much higher (0.5–4.0 ng/ml) but did not differ among groups. In general, little is known regarding the control of aggression in developing birds, and this remains an excellent topic for future studies.

3.8 Corticosterone and Aggression

In birds, the predominant circulating glucocorticoid is CORT. In song sparrows, aggressive interactions do not appear to increase plasma CORT levels (Wingfield, 1985). However, treatment of wild males with exogenous CORT during the breeding season affected territorial aggression (Wingfield and Silverin, 1986). After 18–24 h of treatment, the majority of CORT-treated males failed to respond to an STI, and the ones that responded did so weakly (Wingfield and Silverin, 1986). Surprisingly, CORT treatment did not affect luteinizing hormone (LH) levels and only decreased plasma T levels slightly.

A similar study was conducted on tree sparrows (*Spizella arborea*) breeding in arctic Alaska (Astheimer et al., 2000). Interestingly, CORT treatment had no effect on aggressive behavior or reproductive hormones in tree sparrows. It is possible that ecological constraints, such as a short breeding season, reduce the sensitivity of neural circuits to CORT, allowing animals to successfully breed in spite of environmental stressors. This could be achieved, for example, by modulating corticosterone binding globulin (CBG) or glucocorticoid receptor levels (Wingfield and Sapolsky, 2003).

3.9 Arginine Vasotocin and Aggression

Arginine vasotocin (AVT) is a neuropeptide homologous to AVP in mammals. Classically, AVT/AVP neurons in the hypothalamus have been shown to play an important role in water balance. More recently, AVT/AVP neurons in the extended amygdala (medial amygdala and BnST) have been implicated in the regulation of social behavior (Goodson and Bass, 2001). These neurons project to many regions, including the lateral septum, nucleus accumbens, and periaqueductal gray (Goodson and Bass, 2001). In particular, the lateral septum receives AVT input from the BnST and contains high levels of AVT/AVP receptors.

In songbirds, a series of studies by Goodson and colleagues have examined the behavioral effects of septal AVT infusions in different species. Interestingly, intraseptal AVT administration had opposite effects in species with different social systems. In a colonial species, the zebra finch, AVT infusions facilitated aggressive behavior (Goodson and Adkins-Regan, 1999). In contrast, in territorial species, the violet-eared waxbill (*Uraeginthus granatina*) and field sparrow (*Spizella pusilla*), AVT infusions inhibited overt physical aggression (Goodson, 1998a, b). Zebra finches and violet-eared waxbills are both estrildid finches and share critical features of breeding ecology, except for social organization. Thus, this species comparison is less likely to be confounded by phylogeny or other ecological variables.

Song sparrows have also been a useful model system for understanding the role of AVT in territorial aggression. In one experiment, immediate early gene (ZENK) responses were assessed following STI and/or nonsocial stress (restraint) in breeding male song sparrows under semi-natural conditions. Exposure to STI and/or restraint significantly increased ZENK protein in the lateral septum, whereas the medial BnST showed a highly selective response to STI. Interestingly, infusion of an AVT/AVP antagonist (Manning compound, specific to V_1 receptors) into the lateral ventricle abolished these ZENK responses, and influenced ZENK-ir in the medial BnST only after STI, but not after restraint (Goodson and Evans, 2004). These data suggest that AVT acts within the BnST to specifically modulate neural responses to social stimuli. In a second experiment, the role of DHEA in nonbreeding song sparrows was examined. Captive male song sparrows were exposed to an STI and then perfused 90 min later. Plasma DHEA levels were

negatively correlated with immediate early gene expression in medial BnST (J. Goodson, K. Soma, unpublished results). In addition, plasma DHEA levels were *positively* correlated with AVT cell counts in the medial BnST, which may indicate decreased transport and release of AVT (unpublished results). Although speculative, one possible interpretation of these data is that DHEA acts within the medial BnST to decrease the transport and release of AVT in the lateral septum. Because intraseptal AVT inhibits aggressive behavior in territorial species, DHEA would be reducing a "brake" on aggression.

4 Neuroendocrine Regulation of Aggression in Primates

Aggression has been a central topic of primate research for decades. A great deal of research indicates the importance of environmental and social influences on the development and expression of primate aggressive behavior. Dominance is certainly the most well-known social influence on aggression, and dominance hierarchies are considered a major organizing principle in many primate societies. Knowing an animal's dominance rank provides valuable information about that individual's aggressive tendencies. In primates, high-ranking males are more likely to initiate and win aggressive encounters, but they are not necessarily the most aggressive animals in the group (Bernstein et al., 1983). Furthermore, unlike in rodents, in primates individual aggressive power does not necessarily correlate with dominance rank. For instance, the best fighters do not inevitably achieve the highest dominance rank because alliances are critical for acquiring and maintaining high dominance rank (Chapais, 1992). Young primates must learn the proper settings for expressing aggression and the social skills required for recruiting allies. In sum, achieving high dominance rank in primate species probably depends as much on inhibiting aggression as it does on expressing aggression.

Although the study of the hormonal mechanisms of aggression has some experimental attention, much less is known than in the case of rodents. Most recent studies on the neuroendocrine regulation of primate aggression have used fecal or urinary assays to measure androgens. Although the advent of these assays has stimulated new research questions in primate socioendocrinology, their limitations need to be recognized. The different steroids and steroid metabolites present in urine and feces are species-specific, and the levels that are excreted frequently represent a fraction of plasma concentrations. The extended time tag for fecal excretion probably favors the use of fecal samples, and to a lesser extent urinary samples, for assaying hormonal baselines; however, this characteristic makes fecal steroids a less-sensitive measure of hormonal responses to a single behavioral event. Also, most immunoassay kits used to detect steroids were developed for use with human serum or plasma, and may not have been tested for cross-reactivity with metabolites that may be present in urine or fecal samples. High cross-reactivity between excreted metabolites can limit conclusions regarding the origin of a steroid and its mechanism of action. In addition, plasma, urinary, and fecal assays are not recommended for investigating a steroid's mechanism of action due to the importance of local metabolism. Although most primate studies report little cross-reactivity between steroids and related metabolites, some studies have reported considerable cross-reactivity. For instance, 46% cross-reactivity between T and DHT was reported in a study using urine samples in chimpanzees (*Pan troglodytes*) (Muller and Wrangham, 2004), which makes conclusions regarding specific hormone–behavior relationships difficult. Finally, most research on the neuroendocrinology of primate aggression has been conducted with Old World monkeys such as macaques, baboons, and vervets. Apes, prosimians, and New World monkeys share some characteristics with Old World monkeys, but unfortunately much less is known about the neuroendocrine mechanisms regulating aggression in these primates. Thus, our review is biased toward Old World monkeys, although we include examples from other primate taxa, including humans, when possible.

4.1 Androgens and Aggression

In general, high rates of aggression tend to be positively correlated with elevated androgen concentrations in nonhuman primates. This correlation is observed in seasonal changes in androgens and rates of aggression, sex differences in aggression, and increased aggression at puberty. Many primates are seasonal breeders and these species have provided much of the information available on correlations between androgens and

aggression. Seasonality in testicular activity, with circulating T levels peaking during the mating season, has been reported in many primate species, including squirrel monkeys (*Saimiri sciureus*: Wiebe et al., 1988), Hanuman langurs (*Presbytis entellus*: Lohiya et al., 1998), ringtailed lemurs (*Lemur catta*: Cavigelli and Pereira, 2000), mandrills (*Mandrillus sphinx*: Setchell and Dixon, 2001), and several species of macaques (*Macaca mulatta*: Gordon et al., 1976; *M. radiata*: Glick, 1979; *M. fuscata*: Barrett et al., 2002). Both environmental and social cues may elicit the onset of increased T production. Some studies have shown that environmental cues, such as photoperiod, are sufficient to produce seasonal fluctuations in T secretion (Rostal et al., 1986; Perret, 1992; Herndon et al., 1996). In contrast, other studies have found that exposure to females is necessary to maintain a seasonal pattern of T secretion (Gordon et al., 1978; Schiml et al., 1996), and that exposure to sexually active females outside the mating season can elicit increases in T (Ruiz de Elvira et al., 1982). Several studies have shown that rates of aggression in males tend to parallel the rise in T during the mating season (Gordon et al., 1976; Rostal et al., 1986; Cavigelli and Pereira, 2000). In addition, seasonal changes in T have been associated with aggression in females. In ringtailed lemurs, aggressive conflicts between females were found to increase during the mating season and correspond to a seasonal increase in fecal androgen concentrations (von Engelhardt et al., 2000). However, in this study individual rates of aggression did not correlate with androgen levels. It is interesting to note that T fluctuations do not always peak during the mating season. For instance, male muriqui monkeys (*Brachyteles arachnoides*) do not compete aggressively for mates, and fecal T concentrations do not increase during the mating season (Strier et al., 1999).

Although exceptions exist, the majority of research suggests that androgens do not necessarily increase aggression in nonhuman primates. For instance, in Japanese macaques seasonal increases in serum T and 5α-DHT levels were found to precede seasonal increases in aggression by 1–2 months, which was interpreted to mean that neither hormone affects aggression in a simple causal way (Rostal et al., 1986). Also, pharmacologically elevating T does not reliably increase rates of aggression. In rhesus monkeys, twice-weekly injections of human chorionic gonadotropin stimulated T production but had no consistent effect on rates of aggression (Gordon et al., 1979). Rather, increased circulating T levels were associated with an intensification of existing behavior, which did not disrupt group stability. On the other hand, Rejeski et al. (1990) showed evidence of a causal link between anabolic steroids and aggression in male long-tailed macaques (*M. fascicularis*). They found that injection of TP increased aggression in dominants, although it also increased submission in subordinates. When male marmosets (*Callithrix jacchus*) were castrated as neonates and tested as adults, they were found to display high rates of aggression with female partners and low rates with male partners (Dixson, 1993a). This pattern of aggression is opposite to that expressed by intact male marmosets. Further, the effects of neonatal castration on aggressive behavior were reversed by TP treatment in adulthood (Dixson, 1993b). Finally, several studies have found that castration of adult males has little effect on their aggressive behavior, suggesting that T is not required to maintain aggression in adults (Wilson and Vessey, 1968; Epple, 1978; Dixson, 1993c).

A common finding is that winning increases T, while losing decreases T. Among macaque males, animals that lost social conflicts showed a reduction in plasma T, especially if the defeat resulted in a fall in dominance rank (Rose et al., 1972; Bernstein et al., 1979). Similarly, on days when vervet (*Cercopithecus aethiops*) males fought, plasma T levels were higher in the winners than in the losers (Steklis et al., 1985). Also, several studies have shown that during periods of group formation plasma T concentrations increase in future dominants and decline in future subordinates, but that plasma T levels prior to group formation do not predict dominance rank (Rose et al., 1975; Mendoza et al., 1979; Keverne et al., 1982). In sum, these studies suggest that changes in T may be a consequence, rather than a cause, of aggression. In humans, physical aggression among males also seems unrelated to plasma T concentrations. Rather, T appears associated with the achievement and maintenance of high social status (Mazur and Booth, 1998). For instance, winning at tennis (Booth et al., 1989), chess (Mazur et al., 1992), or soccer (Neave and Wolfson, 2003) has been associated with transient increases in circulating T. Similarly, the rise in T during puberty has been related to nonaggressive symptoms of conduct disorder in boys with deviant peers, whereas it has been related to leadership in boys without deviant peers (Rowe et al., 2004).

Correlations between androgens and dominance rank appear to be mediated by the relationship between rank and aggression. This was demonstrated by the pioneering work of Sapolsky (1983; reviewed

in 1993) on olive baboons (*Papio anubis*). This work demonstrated that during periods of instability in the dominance hierarchy, dominant males were more aggressive and had greater plasma T concentrations than subordinates; in contrast, no correlations existed during stable periods. Since then, numerous studies have found that during stable periods, individual differences in rates of aggression and dominance rank do not correlate with T concentrations (e.g., Eaton and Resko, 1974; Steklis et al., 1986; Nieuwenhuijsen et al., 1987; van Schaik et al., 1991), whereas such correlations have been found during periods with unstable hierarchies or other social challenges (e.g., Wicklings and Dixson, 1992; Brockman et al., 1998). In chimpanzees, however, dominance rank has been correlated with afternoon (but not morning) urinary T concentrations during a period with a stable dominance hierarchy (Muller and Wrangham, 2004). A similar correlation has been found in chimpanzees by measuring fecal T during stable conditions (Muehlenbein et al., 2004). As the authors suggested, these correlations may be due to high-ranking males being more aggressive than low-ranking males regardless of hierarchy stability.

4.2 The Challenge Hypothesis

Recent studies on the neuroendocrinology of primate aggression have addressed the challenge hypothesis, which states that T levels are related to the degree of reproductive competition rather than mating activity (Wingfield et al., 1990; section 3.3). As in birds, T levels in primates appear more closely associated with competition than with reproduction. In primates, T facilitates spermatogenesis and sexual behavior but has little effect above minimum threshold levels (Weinbauer et al., 1988; Michael and Zumpe, 1993). In contrast, high rates of aggression have been associated with maximal plasma T levels (Rose et al., 1971). A similar relationship has been found between rates of aggression and T levels measured in CSF (Higley et al., 1996c). Only mild forms of aggression, however, correlate with increased T, whereas severe aggression (i.e., contact aggression such as biting) occurs throughout the year and tends to be independent of plasma and CSF T levels (Rose et al., 1978; Bernstein, 1983; Higley et al., 1996c). In Japanese macaques fecal T was found to correlate with noncontact aggression during the mating season, but no correlation was found with contact aggression (Barrett et al., 2002). Also, correlations between aggression and T levels predominately occur in competitive situations such as rank instability (Sapolsky, 1983; Higley et al., 1996c; Brockman et al., 2001) and mate competition (Cavigelli and Pereira, 2000; Barrett et al., 2002; Muller and Wrangham, 2004). Interspecies comparisons are also consistent with the challenge hypothesis. In multimale groups, where male reproductive competition is expected to be more frequent, breeding season concentrations of serum T are higher than those in unimale groups, where male challenges over mates occur more sporadically (Whitten, 2000).

Some primate studies have found mixed support for the challenge hypothesis, while others have suggested it needs a slight modification when applied to primates. In capuchin monkeys (*Cebus apella*), which show little direct mate competition among males, fecal T concentrations increased during a period of synchronized female sexual activity, but rates of male aggression did not correspond to the peak in T (Lynch et al., 2002). In male redfronted lemurs (*Eulemur fulvus*), fecal T concentrations tracked the increase in aggression observed during the mating season, but the highest T levels were recorded during the birth season (Ostner et al., 2002). These studies demonstrate that T levels can show a mating season peak without overt reproductive competition, and that T levels can be associated with social challenges outside a reproductive context. The risk of infanticide in some primate species may produce more predictable challenges, and may require males to elevate T and be prepared to aggressively defend infants against intruders during relatively well-defined periods of high risk (Ostner et al., 2002; Whitten et al., 2004). As previously mentioned, male chimpanzees respond to competition for estrous females with elevated urinary T (Muller and Wrangham, 2004), although urinary and fecal T concentrations remain positively correlated with dominance rank during periods of relative social stability (Muller and Wrangham, 2004; Muehlenbein et al., 2004). The fission–fusion society of chimpanzees, in which individuals regularly form small subgroups for foraging but occasionally join together in larger groups, creates unpredictable social challenges for males, and thus may require dominant males to maintain relatively high levels of circulating T to remain ready for potential confrontations with other males (Muller and Wrangham, 2004;

Muehlenbein et al., 2004). In addition, Muehlenbein et al. (2004) suggested that male chimpanzees may selectively lower T levels during infection to prevent the immunosuppressive effects of high circulating T.

4.3 Estrogens and Aggression

Although estrogens contribute to the expression of aggression in nonhuman primates, the available research is mixed. Some studies suggest that E_2 facilitates aggression in females; other studies suggest that estrogens inhibit aggression, and still others have found no effect. In rhesus macaques, females were found to display increased rates of noncontact forms of aggression (e.g., threats) during the middle of the menstrual cycle, when E2 peaks (Walker et al., 1983). Similarly, in ovariectomized rhesus, E_2 replacement has been shown to increase rates of noncontact aggression compared with nonhormone treated ovariectomized controls (Michael and Zumpe, 1993). In contrast, in long-tailed macaques ovariectomy without hormone replacement was shown to increase aggression, including biting, compared to sham-operated controls (Stavisky et al., 1999). A similar effect on aggression has been reported in a prosimian primate, the greater galago (*Galago crassicaudatus*). In this case, ovariectomy increased aggression and E_2 replacement decreased it (Dixson, 1978). Finally, a study on long-tailed macaques found no effect of ovariectomy on rates of aggression (Shively et al., 1986).

Clearly, the effect of estrogens on aggression in female nonhuman primates is equivocal. One possible reason for the variable results is the variety of social conditions used for behavioral testing such as male–female pairs, small same-sex groups, or large mixed-sex colonies. These different social conditions may also influence the type of aggressive behavior displayed such as contact and noncontact forms of aggression. Further, it should be noted that the reduction in E_2 produced by ovariectomy does not affect only aggression, but it can also decrease affiliation (Shively et al., 1986; Stavisky et al., 1999). Interestingly, recent data suggest that aggression in males may also be modulated by an estrogen-dependent pathway. In male long-tailed macaques, diets high in isoflavones, which are partial agonists of ERβ, have been associated with increased rates of aggression (Simon et al., 2004). Although aromatase inhibitors have been shown to decrease sexual behavior in male macaques (Zumpe et al., 1996), their effect of aggression has not been investigated. Indeed, the local metabolism of T into E_2 is an excellent area for future primate research.

Some studies also suggest that progesterone increases aggression in nonhuman primates. In vervet monkeys (*Cercopithecus aethiops*), aggression was shown to peak during the late luteal phase of the menstrual cycle, when progesterone levels are high (Rapkin et al., 1995). Also, medroxyprogesterone acetate (MPA), a synthetic progestin, has been shown to increase rates of aggression in female macaques (Linn and Steklis, 1990; Pazol et al., 2004). However, which steroid receptor mediates the effect of MPA is unclear.

4.4 Adrenal DHEA

Studies from rodents and birds suggest that androgens such as DHEA may regulate aggression in situations where aggression seems otherwise T-independent. Some studies in primates also suggest that aggressive behavior can be unrelated to fecal T levels (Lynch et al., 2002; Ostner et al., 2002). Although primate adrenal glands are known to secrete high levels of DHEA and DHEA-S (Rehman and Carr, 2004), the role of adrenal androgens in primate aggression is largely unknown. In some primate studies, measures of androgens may be confounded by adrenal DHEA and DHEA-S, causing difficulty in interpretation. For instance, Mohle et al. (2002) showed that in macaques metabolites of T and DHEA may cross-react with T antibodies in urine and fecal assays (Mohle et al., 2002). Thus, when a correlation is found between aggression and fecal or urinary androgens, it may be difficult to conclude with certainty the origin of the steroid. In addition, a lack of a correlation between aggression and excreted T does not necessarily mean that aggression is androgen-independent, as other androgens such as DHEA may regulate behavior.

One study has assessed circulating DHEA-S levels in a population of wild baboons (Sapolsky et al., 1993). They found that DHEA-S concentrations were high in both male and female baboons and showed

marked age-related decreases in both sexes; however, circulating levels of DHEA-S were not compared with aggression. Adrenal androgens appear to play a role in human aggression, as indicated by studies on conduct disorder, which is a term used to describe a collection of symptoms including aggression to people or animals, destruction of property, theft, and serious violations of rules. Prepubertal boys with conduct disorder were found to have higher levels of plasma DHEA-S, but not T, than normal control boys (van Goozen et al., 1998). Also, DHEA-S concentrations were correlated with the intensity of aggression as rated by parents and teachers. In another study, plasma DHEA-S concentrations were found to be higher in boys with conduct disorder than in boys with attention-deficit/hyperactivity disorder (ADHD) or normal controls (van Goozen et al., 2000). These studies suggest that adrenal androgens play an important role in the onset of aggression in adolescent boys. Adrenal androgens may also contribute to the regulation of aggression in human females. Adolescent and adult females with congenital adrenal hyperplasia, who were exposed to high levels of adrenal androgens in the prenatal and early postnatal periods, were found to have greater self-reported aggression ratings than were control females (Berenbaum and Resnick, 1997).

5 Conclusions

In rodents, birds, and primates, rates of aggression in males are often associated with circulating levels of T. This relationship has been extensively demonstrated in rodents, predominantly rats and mice, in which castration has been shown to reduce aggression and exogenous T treatment restores aggressive behavior (Edwards, 1969, 1970; Barfield, 1971). In birds, a positive correlation between plasma T and rates of aggression has been repeatedly documented during periods of social challenge, and particularly during mate competition (Wingfield et al., 1987). Likewise, recent data from primates has largely supported the challenge hypothesis (Cavigelli and Pereira, 2000; Barrett et al., 2002; Muller and Wrangham, 2004). These findings in primates build on previous work demonstrating a positive relationship between aggression and circulating T during periods of social instability (Sapolsky, 1983). It is important to remember, however, that in many cases, aggression is independent or even inversely related to circulating levels of T.

Seasonal aggression provides a valuable paradigm with which to study the neuroendocrine mechanisms of aggression. In many species (e.g., song sparrows, Siberian and Syrian hamsters, capuchin monkeys), high rates of aggression in males occur outside the period of high plasma T levels (Garrett and Campbell, 1980; Soma et al., 2000; Lynch et al., 2002, respectively). The neuroendocrine mechanisms regulating aggression under these conditions are poorly understood, but recent data provide some interesting possibilities. In birds, the metabolism of T to E_2 may mediate aggression during the mating season. During the nonmating season when circulating T is basal, steroid metabolism may still mediate aggression, albeit via a different endocrine mechanism (Soma et al., 2000). Despite low levels of circulating T, the androgen precursor DHEA remains elevated in blood, and conversion of DHEA to E_2 within the brain appears to play an important role in nonbreeding season aggression in some species (Soma et al., 2000; Soma and Wingfield, 2001).

In rodents, the aromatization of androgens also appears to regulate, at least in part, intermale aggression. Although seasonal changes in rodent aggression are less well-studied than in birds, recent data suggest that melatonin may mediate the increased aggression observed in hamsters during winter-like photoperiods (Jasnow et al., 2002; Demas et al., 2004). It seems likely that melatonin might regulate aggression under these conditions by affecting adrenal steroids such as cortisol and DHEA (Haus et al., 1996).

In nonhuman primates, little is known about the regulation of aggression when plasma T levels are low. In prepubertal boys, plasma DHEA-S levels have been associated with conduct disorder, and in particular with the aggressive symptoms of conduct disorder (van Goozen et al., 1998). Human and nonhuman primates secrete relatively high levels of DHEA and DHEA-S from the adrenal glands, but the role of DHEA in mediating nonhuman primate aggression has received little attention and is an exciting area for future research. An exclusive focus on T levels limits our understanding of the neuroendocrine regulation of aggression and strengthens the mistaken perception that aggression is simply a function of T. The idea that circulating T is not always associated with physical aggression, and instead is more often associated with

competition in specific situations, has been extended to humans (see Mazur and Booth, 1998). It seems likely that continued research on the role of steroid hormones in the regulation of aggression in animals will improve our understanding of aggression and violence in humans.

In addition to steroid hormones, a large number of peptides and neurotransmitters have been implicated in the regulation of aggression, including the neuropeptides oxytocin and vasopressin, as well as serotonin and nitric oxide among other factors. A brief discussion of only some of these factors could be presented here. It is important to keep in mind that, although each of these factors is typically studied in isolation, no single factor can sufficiently explain the wide range of aggressive behavior displayed by humans and nonhuman animals. Rather, a comprehensive examination of the multiple factors that regulate aggression and how these factors interact is needed to provide a complete understanding of the neuroendocrine regulation of aggression.

Acknowledgments

The authors would like to thank Dr. James Goodson, Dr. Michaela Hau, Melissa Scotti, and Amy Newman for helpful comments on the manuscript. This work was supported in part by NIH award NS10596, an HHMI Capstone award (G.E.D), NIH F32 award MH072085 (M.A.C), NIH award MH062641, and the STC program of the NSF (H.E.A) and NSERC, Canadian Institutes of Health Research, Michael Smith Foundation for Health Research, and Canada Foundation for Innovation (K.K.S).

9 Molecular Neurobiology of Bird Song

D. F. Clayton

1 Introduction: Why This—A Molecular Neurobiology of Bird Song? 375
1.1 Reason #1: The Song-Control System 375
1.1.1 A Note on Nomenclature 376
1.2 Reason #2: Rich Opportunities to Study Song Learning 376
1.3 Reason #3: Circuit Formation, Brain, Sex, and Neurogenesis 378
1.4 Reason #4: Social and Environmental Integration 378
1.5 Reason #5: Perspectives on Evolution and Diversity 379
1.6 Major Questions for Songbird Molecular Neurobiology 379

2 Molecular Characteristics of the Song System 379
2.1 Molecular Anatomy 379
2.2 Functional Anatomy Revealed by Gene Activation 382
2.2.1 *ZENK* and Other Immediate Early Genes 382
2.2.2 IEG Activation by the Sound of Song 383
2.2.3 IEG Activation in Other Contexts 383
2.2.4 IEG Activation in the Songbird Hippocampus 384

3 Learning Mechanisms 385
3.1 Song-Recognition Learning 385
3.1.1 Field Observations 385
3.1.2 Laboratory Studies of Song-Recognition Learning 386
3.1.3 Role of Gene Regulation in Song-Recognition Learning 387
3.1.4 Other Molecular Mechanisms in Song-Recognition Learning 389
3.2 Song-Production Learning 391
3.2.1 Boundary of the Sensitive Period 392
3.2.2 Sensorimotor Learning 392
3.2.3 Do Songbirds Dream Song? 393
3.2.4 Song Crystallization 394
3.2.5 Gene Expression Across the Critical Period 395
3.3 Critical Issues for the Molecular Biology of Song Learning 395

4 Song Pathway Development: Sex Differences, Sex Hormones, and Neuronal Replacement .. 396
4.1 Sex Differences in Song-Control System 396
4.2 Sex Hormone Production in the Brain 396
4.3 Regulation of Neuronal Birth, Death, and Replacement 397

5 Social and Environmental Integration 398
5.1 Influence of Social Factors on Song-System Molecular Biology 398
5.2 Seasonal and Photoperiod Effects 398
5.3 Linking Environment to Genome 399
5.3.1 Dopamine and Other Catecholamines 399
5.3.2 Adrenocorticoids 399

5.3.3 Gonadal Steroids 399
5.3.4 Endocannabinoids 399

6 Diversity and Evolution 400
6.1 Aromatase and Estrogen Receptor 400
6.2 *ZENK* Expression 402
6.3 FoxP2 402
6.4 Beyond the Song 402

7 Critical Issues for the Future 402
7.1 Gene Network Analysis 403
7.2 Targeted Gene Manipulation 404
7.3 Conclusion 404

Abstract: Songbirds (oscines of Order Passeriformes) are emerging as a major focus of research in neurobiology. This review considers five broad research topics that are proving amenable to molecular biological analysis in songbirds: (1) molecular anatomy of a functioning neural system (the song system); (2) regulation of learning and memory formation; (3) brain circuit development, including roles for sex steroids and ongoing neurogenesis; (4) integration of social and environmental signals; (5) species diversity and evolution. Results from ~400 references are considered, illustrating the enormous breadth and vitality of bird song molecular neurobiology.

List of Abbreviations: AFP, anterior forebrain pathway; BAC, bacterial artificial chromosome; BDNF, brain-derived neurotrophic factor; BOS, bird's own song; CMM, caudomedial mesopallium; CREB, cyclic AMP response element binding protein; ERK, extracellular signal-regulated kinase; EST, expressed sequence tag; FOXP2, forkhead box P2; HVC, (proper name for nidopallial song nucleus previously misnamed Hyperstriatum Ventrale pars caudalis and commonly referred to as High Vocal Center, see Reiner et al., 2004b); IEG, immediate early gene; IGF-II, Insulin-related growth factor II; LMAN, lateral magnocelluar nucleus of the anterior nidopallium; LTD, long-term depression; LTP, long-term potentiation; NCM, caudomedial nidopallium; NMDA, N-methyl-D-aspartic acid; RA, robust nucleus of the arcopallium; SNAg, song system nuclear antigen; ZRALDH, zebra finch retinaldehyde dehydrogenase

1 Introduction: Why This—A Molecular Neurobiology of Bird Song?

Songbirds have fascinated humans probably since history began, and are still worshiped as gods by the aborigines of Australia (Zann, 1996). However, only in the last few decades songbirds have become common subjects of formal scientific investigation. Interest in songbirds is now skyrocketing. The annual rate of new publications is now approaching 400 per year (PubMed), up tenfold from a decade ago. More than 10 million dollars in research grants from the NIH and more than 50 major labs around the world are involved in work that contributes to songbird neurobiology. Songbird research (Dingemanse et al., 2004) was the focus of a recent editorial in the New York Times (Editorial, 2005). An opinion piece in Nat Rev Neurosci (Jarvis et al., 2005) on a seemingly arcane topic—a revised nomenclature for avian neuroanatomy deriving primarily from songbird work—was treated as a major news story in the popular press. In October, 2005, the National Human Genome Research Institute targeted a songbird, the zebra finch, for whole-genome sequencing (http://www.genome.gov/11007951).

Why this sudden interest? And why should we advance a molecular neurobiology of songbirds? Birds do have a natural appeal, and they have contributed to many areas of scientific research (Konishi et al., 1989). In the last 20 years, the questions and tools of molecular biology have increasingly been brought to bear on songbird research, as in every other area of biology. But beyond these general factors are five specific reasons why the "molecular neurobiology of bird song" is emerging as a discrete field of scientific study.

1.1 Reason #1: The Song-Control System

Songbirds communicate through learned vocalizations, an ability shared only by humans and a small number of other species (Doupe and Kuhl, 1999; Jarvis, 2004). The neural system that controls vocal learning and production in songbirds lies within the basic framework of sensory, motor, and modulatory pathways conserved in all vertebrates (Reiner et al., 2004b; Jarvis et al., 2005). Yet it also sits apart, comprising a set of unique, interconnected "song nuclei" that can often be seen by the naked eye in the unstained brain and are readily highlighted by distinctive patterns of gene expression (*Section 2*). The motor components of the system appear to be dedicated to a single function: learning and production of species-specific vocalizations. The ready ability to identify the functional components of the system, to manipulate them, and to study their function in a seemingly simple yet "higher" integrative behavior has established the song system as a superb model for fundamental neuroscience.

Definition of the song-control system began in 1976, with this simple declaration: "We have traced central nervous pathways controlling bird song in the canary using a combination of behavioral and

anatomical techniques" (Nottebohm et al., 1976). In that report, a large superficial nucleus in the forebrain [proper name for nucleus commonly known as High Vocal Center] was identified by a lesion as essential for singing behavior. Two other connected nuclei (RA, Area X) were identified by degenerating fibers following the lesion (*Figure 9-1a*) .

In the years since Nottebohm's seminal 1976 publication, any illusions that the song-control system could be defined by merely three nuclei have been dashed by the steady identification of other interconnected, functionally related components (*Figure 9-1b*). Although the system as we now understand it appears complex, it can be broken down into three functional subsystems, as indicated by shadings and dashed lines in *Figure 9-1b*. Elements associated primarily with motor control are shown in gray. On the left edge of the figure two of the nuclei identified in (Nottebohm et al., 1976) HVC and RA can be found. They constitute the essential telencephalic output pathway for motor control of singing. HVC sends a major projection to RA, and in this review we shall refer frequently to the HVC–RA pathway.

HVC also sends a separate projection to a striatal nucleus, Area X. This forms the beginning of the second subsystem, known as the "anterior forebrain pathway" (AFP). The AFP, which is indicated in the figure by the dashed line, proceeds through a striatal > thalamic > cortical loop and ultimately converges again onto the motor output pathway at RA via a projection from nucleus LMAN. The AFP is more clearly involved in learning how to sing than in song performance, as we shall see later.

The third subsystem to consider in song communication is the auditory forebrain, which forms the primary representations of song patterns heard. The auditory forebrain has a complex internal organization that is still being sorted out. Auditory afferents from the thalamus enter the forebrain primarily at an area known as Field L2a, but molecular analyses have focused mainly on two reciprocally connected stations further upstream, representing the caudomedial portions of nidopallium and mesopallium, respectively. In this review, we shall refer to these areas, considered functionally analogous to secondary auditory cortex, by their anatomical abbreviations NCM and CMM.

1.1.1 A Note on Nomenclature

In 2002, a consortium of avian brain scientists began working on new nomenclature to resolve explicit conflicts between mammalian and avian designations, while preserving as much as possible the familiar acronyms for major avian brain centers like the song-control nuclei. The results of their deliberations were published (Reiner et al., 2004b) and have been generally adopted in the songbird research community. In this article, we shall exclusively adhere to the new nomenclature and shall generally rely on acronyms, where those are preserved between the old and the new. The interested or confused reader should consult the following for more guidance: Perkel (2004); Reiner et al. (2004a, b); Jarvis et al. (2005).

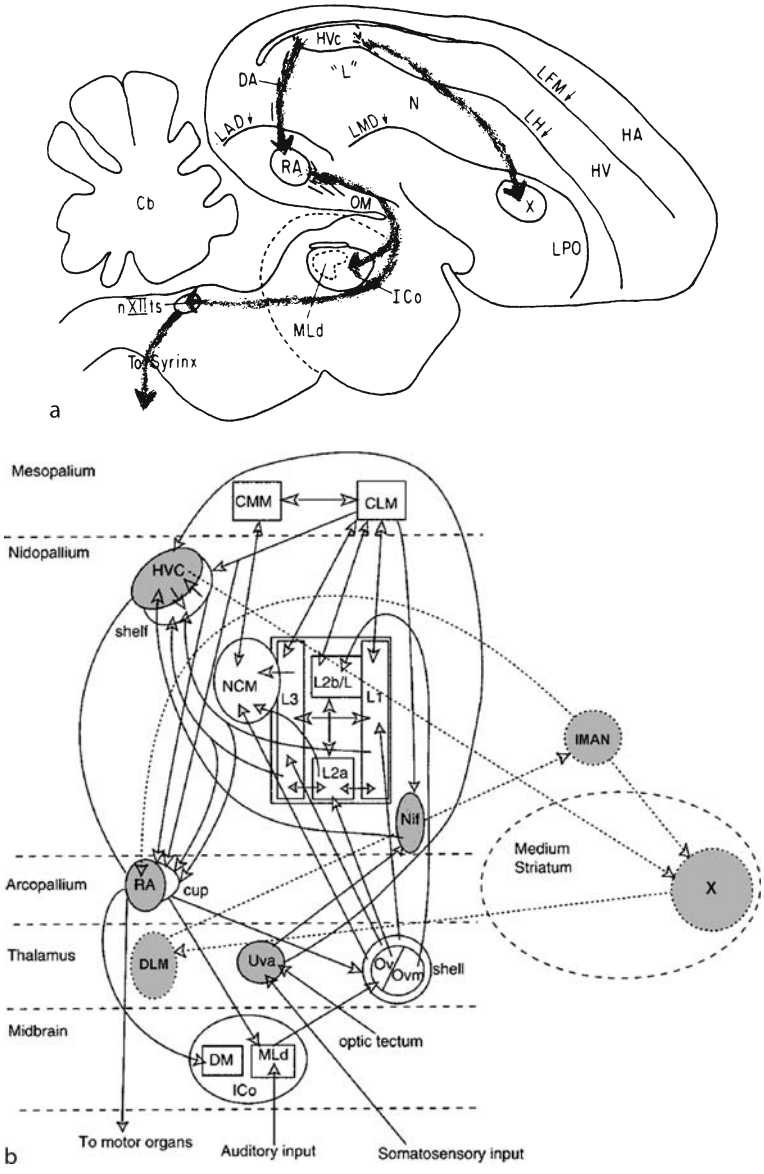
1.2 Reason #2: Rich Opportunities to Study Song Learning

Song learning is central to the social life of a songbird, and in more ways than one. In fact, the term encompasses multiple discrete situations, processes, and phases. Most common is *song-recognition learning*. Birds of both sexes and all ages learn to recognize songs and discriminate individuals on the basis of those songs. Song recognition is used in territoriality (in some species) and probably colony organization (in others); in courtship; in maintenance of pair bonds; and perhaps in other social situations (Zann, 1996). Song-recognition learning can occur quickly, within a day at most and probably within minutes. Behavioral assays have been developed to demonstrate this learning, and molecular correlates of song-recognition learning have been well established (*Section 3.1*).

A more specialized aspect is *song-production learning*, or learning to sing. In many species, only males actually learn to sing, even though both sexes produce vocalizations. Song-production learning itself can be broken into two separate phases (Thorpe, 1958; Konishi, 1965; Nottebohm, 1968; Immelmann, 1969; Marler and Peters, 1977; Marler and Waser, 1977; Marler, 1997). First is a "sensitive period" during which an initial auditory memory is formed of the song of a tutor, typically the bird's father. This is followed by a "sensorimotor" period during which the bird attempts to replicate the model song on his own through a

Figure 9-1

Two views of the song system. a: From the original description of elements in the central nervous system responsible for control of song production (Nottebohm et al., 1976). Reprinted with permission. b: After a recent review of elements now associated with song perception and performance (Theunissen et al., 2004). Brain regions in this panel are identified using the new revised nomenclature (Reiner et al., 2004b). Areas in gray represent components of the primary motor control pathway, the output of which proceeds from RA "to motor organs" (via the nucleus of the 12th tracheosyringeal nerve, as shown in Panel a). Unfilled areas represent areas associated primarily with auditory processing. The dotted lines (with arrowheads) connect the nuclei of the Anterior Forebrain Pathway (AFP)



process of trial and error. These two periods may be separated in time by months as in the case of the swamp sparrow (Marler and Peters, 1982) or nightingale (Geberzahn and Hultsch, 2003), or they may closely overlap as in the case of the zebra finch (Section 3.2). In many species, including the zebra finch, this entire process occurs only once during a restricted period in juvenile development; with sexual maturity the song "crystallizes" and is retained with little change throughout the rest of the bird's life (Price, 1979; Marler and Peters, 1987).

As models for analysis of learning, both song recognition and song production share several advantages. Both are forms of natural learning; they occur spontaneously and are deeply important to the individual's social life, survival, and reproduction. The primary sensory stimuli – songs – can be easily manipulated (e.g., through sound recording, editing, and playback). The learned responses are easily recorded and quantified.

1.3 Reason #3: Circuit Formation, Brain, Sex, and Neurogenesis

The song-control system, especially of the zebra finch, has emerged as an exceptional model for the study of a range of fundamental issues in developmental neurobiology. There are several reasons for this. The heart of the circuit, the projection from HVC to RA, develops long after the rest of the brain is anatomically mature, making it easy to study against a relatively stable developmental background (Konishi and Akutagawa, 1985; Konishi and Akutagawa, 1988; Mooney and Rao, 1994). The HVC–RA pathway is never even completed in the female zebra finch, reflecting the sharp sex difference in singing behavior in this species and setting the stage for fundamental analysis of the signals and mechanisms associated with regulated circuit formation (Holloway and Clayton, 2001). There are also major differences between the sexes in the volume of the song-control nuclei (Wade and Arnold, 2004).

The song-control nuclei are very responsive to sex steroids (Ball and Balthazart, this volume). Almost half the cells in HVC and LMAN of adult males contain androgen receptor proteins, which are also present in RA (Arnold and Saltiel, 1979; Arnold, 1980; Nordeen et al., 1986; Bottjer, 1987; Nordeen et al., 1987a; Balthazart et al., 1992; Nastiuk and Clayton, 1995). Both projections from HVC (to RA and Area X) include a substantial proportion of androgen-binding neurons (Sohrabji et al., 1989; see also Gahr et al., 1996; Gahr and Metzdorf, 1997; Bernard et al., 1999; Gahr and Metzdorf, 1999; Metzdorf et al., 1999; Maney et al., 2001; Perlman et al., 2003; Kim et al., 2004). HVC also contains estrogen receptors in neurons that project to Area X but not in those projecting to RA (Nordeen et al., 1987b; Gahr et al., 1993; Johnson and Bottjer, 1995; Gahr, 1996; Jacobs et al., 1996; Gahr and Metzdorf, 1997; Bernard et al., 1999; Gahr and Metzdorf, 1999; Metzdorf et al., 1999; Perlman and Arnold, 2003). In females, exposure to estrogen in the first weeks of life increases the size of the song nuclei, stimulates the formation of synapses between HVC and RA, and instills the capacity for song production (Gurney and Konishi, 1980; Simpson and Vicario, 1991b; Simpson and Vicario, 1991a).

Study of how the song nuclei develop and can change has already led to two unexpected discoveries that have potentially wide ramifications. First was the discovery that new neurons are continually being born in the adult avian brain (Goldman et al., 1992). This came at a time when the dogma was that neurogenesis was limited to early development in the vertebrate, and it reawakened interest in the neurogenic potential of other animals, including humans (Nottebohm, 2004). Second was the discovery that "gonadal" (sex) steroid synthesis can occur within the brain itself (Section 4).

1.4 Reason #4: Social and Environmental Integration

With their abundant presence in nature, diversity of niches, and many different adaptations and social structures, songbirds are a natural focus for research in behavioral ecology and environmental influences on brain and behavior. Singing is associated with reproduction, and so not surprisingly, there are profound effects of season and photoperiod on form and function in the song system (Schwabl, 1996; Bernard and Ball, 1997; Kirn and Schwabl, 1997; Smith et al., 1997; Brenowitz et al., 1998; Gulledge and Deviche, 1998; Whaling et al., 1998; Tramontin et al., 1999; Reeves et al., 2003; Singh et al., 2003; Bhardwaj and Anushi, 2004; Perfito et al., 2004). These themes are reviewed in detail elsewhere (Ball et al., 2004; Ball and Balthazart, this volume) and discussed briefly later in this article (Section 5).

1.5 Reason #5: Perspectives on Evolution and Diversity

Almost half of the more than 9,000 avian species now on Earth are songbirds, oscines of the order Passeriformes (Barker et al., 2004). This extraordinary diversification began ~65 million years ago, after divergence from nonsongbirds such as the chicken, quail, and pigeon. Thus, even the most distantly related oscines are closer to one another in evolution than, for example, many mammals. This has two consequences for the molecular neurobiologist. First, it offers an incredible range of species, habitats, and adaptation to study. Second, the relatively high relatedness may facilitate ultimate comparative genomic analyses aimed at identifying key genetic events associated with species differences; for example, in singing behavior and learning ability.

For the moment, this research potential is largely untapped. Roughly half of all song-related publications listed in PubMed focus on a single species, the zebra finch (Williams, 2004). There are several good reasons why the zebra finch has come to be favored, especially for laboratory research. Unlike the large majority of oscines, zebra finches breed well in captivity (given a warm and humid environment), and have long been a favorite of bird fanciers. Unlike seasonal species like the domesticated canary, the zebra finch breeds year-round and is comparatively insensitive to potentially confounding photoperiod effects. It has a relatively short generation time, reaching sexual maturity 3–4 months after hatching. It is relatively small (~10 g) and easy to rear. The bulk of the research reviewed here focuses on zebra finch studies.

1.6 Major Questions for Songbird Molecular Neurobiology

Each of the points above defines a focal point for research into associated molecular mechanisms. The rest of this review focuses on these five questions:

1. What molecular properties (e.g., specific gene expression) characterize the song-control system and contribute to its unique organization?
2. What molecular events accompany or determine the observable learning events (song recognition, sensory template formation, sensorimotor learning, song crystallization)?
3. What molecular events determine sex-specific developmental decisions, including the relative production and survival of new neurons?
4. What molecular processes allow external factors (social context, photoperiod) to modulate song learning and singing behavior?
5. What molecular (genetic) variations underlie species differences?

2 Molecular Characteristics of the Song System

2.1 Molecular Anatomy

The song system is unique to songbirds and anatomically distinct – are there also unique or distinguishing molecular properties? The songbird brain probably expresses at least 30,000 different gene products (Clayton and Huecas, 1990), and a definitive answer to the question awaits a thorough characterization of at least a modest fraction of these (until early 2004, sequences for only ~35 had appeared in Genbank). With the rapid development of new technologies in genomics and proteomics and their application to songbird research (reviewed in Clayton, 2004b), that day may not be so far in the future.

For now, however, we must focus on the much smaller set of gene products that have already been described in some part or all of the song system [*Table 9-1*; for additional summary information and discussion, see also Clayton (1997, 2004a)]. A review of these references suggests that each song nucleus generally tends to express the gene products that are characteristic of the surrounding brain region in which it sits. No single marker has yet been found that is expressed in all song nuclei and only in song nuclei. Nevertheless, each song nucleus can be frequently distinguished from the surrounding brain by higher or lower expression of specific gene products.

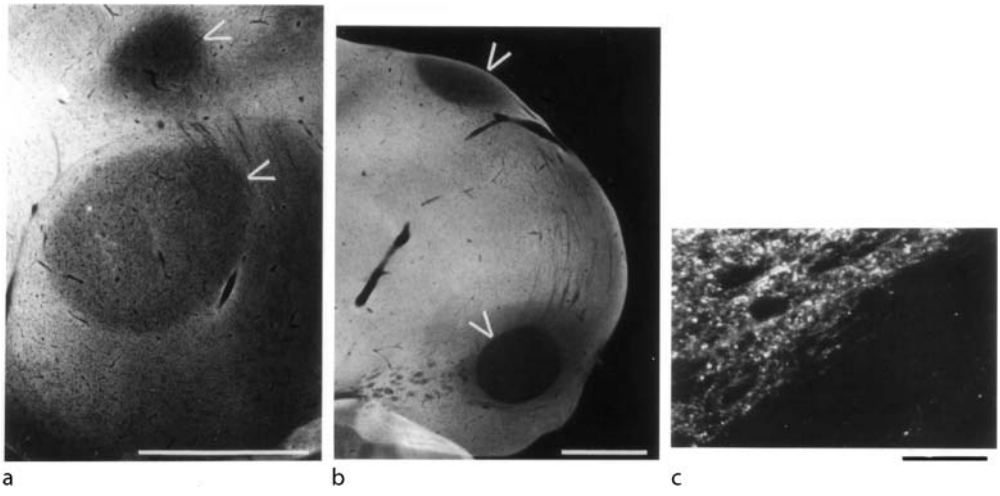
Unknown Function	
SNAg	Akutagawa and Konishi, 2001

To illustrate, consider the example in *Figure 9-2*. This shows the level of expression in four song nuclei of a protein initially called synelfin in the songbird (George et al., 1995). Synelfin is recognized as the ortholog of alpha-synuclein, a presynaptic protein associated with neurodegenerative disease in humans (George, 2001). Synelfin is a striking marker of these four nuclei by its relative *absence* compared with the surrounding brain. This absence is not constitutive as synelfin mRNA is transiently expressed in juvenile LMAN, with the accumulation of the protein in axonal terminals in RA up to the age of ~45 days (Jin and Clayton, 1997b). In sparrows, more subtle changes in gene expression also occur in Area X in response to testosterone treatment (Hartman et al., 2001). The protein is believed to have some role in presynaptic plasticity, but the functional significance of its early expression and then virtual removal from the song system remains to be established.

A complementary example is seen in the expression of the gene encoding retinaldehyde dehydrogenase (zRalDH), which is responsible for the synthesis of retinoic acid (Denisenko-Nehrbass et al., 2000). Very high expression was observed rather specifically in the HVC neurons that project to Area X. Developmental expression was observed in RA, peaking at day 38 and declining by day 60. Pharmacological interference with retinoid synthesis in HVC beginning at day 30–35 disrupted normal song crystallization (Denisenko-Nehrbass et al., 2000).

Figure 9-2

Synelfin (alpha-synuclein) immunoreactivity demarcates song nuclei (from George et al., 1995). Panels show immunostaining of parasagittal canary brain sections using monoclonal antibody H3-C, revealed by immunofluorescence (where light indicates presence and dark indicates absence of the synelfin protein). a: Song nuclei LMAN (*upper arrow*) and Area X (*lower arrow*) are revealed by relative absence of immunoreactive synelfin. b: Song nuclei HVC (*upper arrow*) and RA (*lower arrow*) are revealed by relative absence of immunoreactive synelfin; note also the evident fibers (decreased staining) extending from HVC to RA. c: Higher power view of the boundary between interior of RA (*lower right half*) and the surrounding arcopallium (*upper left half*), as revealed by synelfin immunoreactivity. In all panels, dorsal is up and rostral is to the left. Bar = 1 mm (panel a), 1 mm (panel b) and 20 μm (panel c). Reprinted with permission



A third example is provided by a monoclonal antibody epitope referred to as song system nuclear antigen (SNAg) . It reacts rather specifically with some of the neuronal cell nuclei in several of the song nuclei, but apparently only in the zebra finch and other members of the Estrilidine family of songbirds. Its expression increases between days 20 and 40 and only in males or in females masculinized by early estrogen treatment (Akutagawa and Konishi, 2001). The antigen has not been identified.

These three examples show that molecules that show striking differential expression in the song system can be readily identified. However, as in most of the examples found so far, each pattern is distinct. Synelfin/alpha-synuclein is selectively absent from song nuclei, except early in the critical period. SNAg is selectively present in a different subset of song nuclei, but only in males and perhaps only in one family of songbirds. ZRalDH is selectively present in another subset of song nuclei (especially HVC) and developmentally regulated in RA. The example of zRalDH in particular illustrates the power of an experimental approach that uses differential gene expression within the song system to identify regulated molecules; follows with the characterization of the predicted proteins; and finally employs localized pharmacological interference to move from molecular anatomy to physiological function.

2.2 Functional Anatomy Revealed by Gene Activation

2.2.1 *ZENK* and Other Immediate Early Genes

Most of the gene products listed in ❯ *Table 9-1* display relatively stable patterns of expression in the adult brain. Notable exceptions to this are found in the list of transcription factors. Three of the genes in this category (*c-fos, c-jun, zenk*) are well-established examples of "immediate early genes" (IEGs). IEGs show rapid changes in transcription in response to cell stimulation and activity (Lanahan and Worley, 1998).

A pulse of IEG expression has been likened to a "genomic action potential," and may be a means by which neurons integrate information over periods of minutes to hours and modulate long-term information storage (Clayton, 2000). Links between IEG expression and song memory formation are considered further in *Section 3* (see also Ribeiro and Mello, 2000). Apart from their functional role in memory formation, IEGs have proven very useful in identifying sites in the brain that are physiologically active during specific behaviors or in response to specific sensory stimuli (Mello, 2002). In songbirds, this was first demonstrated in studies of the gene known as *zenk* (Mello et al., 1992), an acronym for *zif-268, egr-1, ngfi-a, krox-24*—all different names assigned to the same gene in mammals (Milbrandt, 1987; Christy et al., 1988; Lemaire et al., 1988; Sukhatme et al., 1988).

2.2.2 IEG Activation by the Sound of Song

The sound of birdsong triggers a sharp pulse of *zenk* expression in various parts of the auditory system of songbirds (Mello et al., 1992; Mello and Clayton, 1994). This can be observed in awake, unrestrained birds, even outdoors in natural populations (Jarvis et al., 1997). Changes in gene expression can be easily measured in histological sections of brain tissue, using in situ hybridization (to measure the mRNA) or immunocytochemistry (to measure the protein). In unstimulated birds, few cells in the auditory forebrain show much evidence of *zenk* mRNA, but the fraction of *zenk*-expressing cells increases to 30–90% after the bird hears a complex conspecific song stimulus (Mello et al., 1992). From the results of double-label analyses, the population of responding cells includes both GABAergic and non-GABAergic neurons (Pinaud et al., 2004). The mRNA peaks in cells about 30 min after the onset of stimulus (Mello and Clayton, 1994; Mello et al., 1995) and the protein follows, peaking after 1–2 h (Mello and Ribeiro, 1998). As little as a single presentation of a 2-s song will elicit a detectable *zenk* response, developing on this same slow timecourse (Kruse et al., 2000).

Zenk gene induction by song was among the first demonstrations of gene activation in the brain driven by a natural behavioral stimulus, and the discovery prompted a significant shift in thinking and research about song representation systems in the songbird brain. Before this, the focus of song perceptual research had been almost exclusively on the distinctive song-control nuclei that are now appreciated more for their role in male song production. Mello et al. (1992) showed that the sound of song playbacks had no detectable effect on the *zenk* expression within the song-control nuclei. Instead, the responsive regions defined an interconnected network distinct from but communicating with the classical song-control nuclei (*Figure 9-3*). The most intense responses were observed in NCM and CMM, and these areas have become the focus of ongoing research into the mechanisms of song learning (*Section 3*).

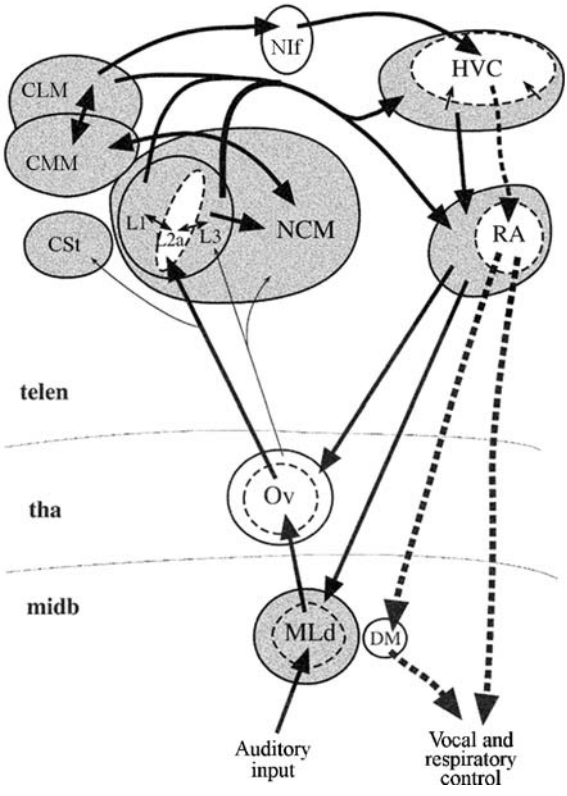
Within NCM and CMM, variations have been observed in the regional density of *zenk*-expressing cells depending on the stimulus, and these observations may give clues to the internal functional organization of the auditory representation system. For example, in canaries, distinct bands of cells show relative preferences for different frequencies and acoustic features in natural vocalizations (Ribeiro et al., 1998). In female starlings, the ventral portion of NCM specifically shows heightened responsiveness to long male songs, which the birds also prefer by behavioral criteria (Gentner et al., 2001). However, it would be premature to draw broad generalizations about the functional organization of NCM/CMM based on the present results, as different patterns have been observed in different species and with various stimuli. For example, in a study of chickadees, the dorsal portion of NCM and not the ventral portion showed greater response specificity (Phillmore et al., 2003). In house finches (Hernandez and MacDougall-Shackleton, 2004) and white-crowned sparrows (Maney et al., 2003), CMM showed more specificity than did NCM for conspecific song over heterospecific song. In female zebra finches, the opposite result was observed, with conspecific specificity more evident in NCM than in CMM (Bailey and Wade, 2003).

2.2.3 IEG Activation in Other Contexts

Activation of IEGs has also been used to identify and map patterns of brain activation associated with other behavioral or perceptual contexts, including song production and sexual imprinting. The act of singing

Figure 9-3

Sites of *zenk* response to song stimulation (after Mello et al., 2004). Gray areas represent regions where the *zenk* gene is induced in response to conspecific song presentation; thick solid arrows represent auditory pathways and broken arrows represent connections of the motor pathway for song production. Thin solid arrows represent minor or to-be-confirmed projections. Abbreviations: CMM and CLM, medial and lateral portions of the caudomedial mesopallium; DM, dorsomedial nucleus of the intercollicular complex; L1, L2a, L2b, and L3, subdivisions of field L; midb, midbrain; MLd, nucleus mesencephalicus lateralis, pars dorsalis; NCM, caudomedial nidopallium; NIf, nucleus interfacialis; Ov, nucleus ovoidalis; CSt, caudal striatum; RA, nucleus robustus arcopaliallis; telen, telencephalon, tha, thalamus



induces IEG expression in the primary song-control nuclei, including HVC, RA, LMAN, and Area X (Jarvis and Nottebohm, 1997; Kimpo and Doupe, 1997; Jin and Clayton, 1997a). Of great interest, the pattern of expression varies with developmental and contextual factors, which again may provide clues about the internal functional organization of the system. Within RA, the *zenk* response varies with developmental age in the zebra finch, becoming more restricted with the progress of the juvenile song-learning period (Jin and Clayton, 1997a). In adults, the response is much more widespread throughout the song system when the bird is singing an undirected song instead of presenting a song to a female (Jarvis et al., 1998). The significance of these last two examples is not known, but in both cases one notes a correlation of broader *zenk* activation with periods of more acute song rehearsal.

2.2.4 IEG Activation in the Songbird Hippocampus

In other studies, *zenk* and *c-fos* have been used to measure lateralized patterns of activation in the hippocampus and the visual system associated with sexual imprinting and courtship in zebra finches

(Sadananda and Bischof, 2002; Lieshoff et al., 2004; Sadananda and Bischof, 2004) and also in the hippocampus associated with food-hoarding behavior in the chickadee (Smulders and DeVoogd, 2000). Interestingly, IEG responses to song stimulation have generally not been observed in the hippocampus, with two exceptions: the experiments of Bailey and Wade on female zebra finches (Bailey et al., 2002; Bailey and Wade, 2003) and in one experiment by Kruse et al. in which the song was specifically paired with a novel visual stimulus (Kruse et al., 2004). Taken together, these few observations suggest that IEG responses in the songbird hippocampus may involve or require some multimodal or visual associations, even if an auditory stimulus is the immediate trigger.

3 Learning Mechanisms

What molecular events accompany or determine observable events in song learning? As introduced earlier (Section 8.1.2), there are at least two forms of song learning to study, song recognition and song production. Fascination with the cultural passage of song from generation to generation motivated early studies of songbird learning (Thorpe, 1958; Immelmann, 1959; Marler, 1976). A distinctive advantage in the study of song-production learning is the ability to observe a clear behavioral endpoint—the song produced by the adult bird. A disadvantage (for the molecular biologist) is the slow timecourse of its development. In the zebra finch, it can take as much as two months from the time of tutor exposure before the final song has crystallized. At the molecular level, this may mean that molecular differences associated with the learning process itself will be hard to isolate. The result, a crystallized song performance, may be the accretion of many small, transient learning events; each daily rehearsal may mark a separate short pulse of synaptic plasticity and reinforcement.

Another challenge for mechanistic analysis of song-production learning is the entanglement of multiple stages and processes. Consider this example: a young bird is exposed to two different tutors early in juvenile life. When he reaches adulthood, the song he produces is more like one tutor than the other, but a perfect copy of neither. What mechanisms led to this result? It could be that he established a more accurate and lasting auditory memory of the tutor he copied more thoroughly. It could be that the auditory memories were equivalent, but other factors led him to reproduce one over the other—maybe he simply liked one tutor better. Why was his song copy imperfect? Maybe some elements of the tutor's song were simply too hard for him to copy, or maybe the influence of the second tutor or other distractions biased his earliest attempts and the variations quickly became engrained with rehearsal. In other words, song-production learning is an integration of multiple processes—sensory template formation, motor learning, feedback-mediated sensory-motor integration, selective attention—which may be distributed in multiple neuroanatomical loci and play themselves out slowly over weeks and months.

Song-recognition learning occurs on a much quicker timescale, and may be a more tractable problem for molecular and biochemical analysis. Even so, if behavioral measures are used to score learning, again there are confounding results (Cahill et al., 2001). Song responses may be affected not just by learning and familiarity, but also by complex factors such as motivation and attentional state. The discovery of sharp changes in gene expression in the auditory system of songbirds hearing song playbacks (*Section 2.2.2*) ignited interest in recognition learning partly because it opened the door to direct observation of neurophysiological "learning," at least for the moment bypassing some of the ambiguities of behavioral analysis. Of course, the ultimate goal is to link behavior and neurophysiological function. Below we begin with a review of the behavioral and molecular biology of song recognition, and then return to the more complex topic of song production learning.

3.1 Song-Recognition Learning

3.1.1 Field Observations

Songbirds use song (and more broadly, vocal communication) for many purposes. At least among the species most commonly studied, there is clear evidence that songbirds learn to recognize and discriminate

between individual birds by the songs they sing. Females recognize the song of their mates (Miller, 1979a; Lind et al., 1996) and fathers (Miller, 1979b) and respond more to strangers' songs if they sound more like their fathers' (O'Loghlen and Beecher, 1999). Male song sparrows, a territorial species, not only recognize their neighbors but come to know their individual repertoires and display their knowledge in a form of countersinging called "repertoire matching." The countersinging bird responds with a different song from the one presented, but one that is also contained in the repertoire shared between the two individuals (Beecher et al., 1996; Beecher et al., 2000). Birds also learn to associate a particular song with a particular context, and modify their territorial responses to the song if the context of its presentation changes (Brooks and Falls, 1975; Falls, 1982; Stoddard, 1996).

Zebra finches are an interesting case because they are colonial, and there is no known territorial function for song in zebra finches. Yet, as Zann summarizes in his thorough review (Zann, 1996), song is used by zebra finches on a daily basis to recognize mates, kin, and potentially other members of the colony. Mate recognition is important for maintenance of the male–female pair bond, especially during the looser bonding period necessary for egg incubation and brooding. Fledglings recognize their parents by their vocalizations, and preferentially associate with their siblings (Burley et al., 1990). Although the evidence is anecdotal, there is reason to think that song may be used to maintain the dynamic organization of foraging groups, within which preferential mate/kin associations are locally maintained. In addition, song may be used to learn about new arrivals in the colony (a daily occurrence in the wild, due to emigration and "extended local excursions"). Theoretically, the structure of a song may convey not only the identity of the singer, but also socially relevant information such as the singer's age and geographic origin. Individual nests within a socially cohesive colony can lie as far away as a kilometer from the center, and yet the birds commute throughout the colony and congregate and assort daily, for flock foraging and other social activities (Zann, 1996).

3.1.2 Laboratory Studies of Song-Recognition Learning

Two threads run through the literature on song-recognition learning. One emphasizes the effects of early juvenile experience on later preferences; the other emphasizes day-to-day learning in adulthood. In both cases, it is worth keeping in mind that a bird's behavioral response to a song (a "preference" or "recognition") may depend greatly on the context in which the song is heard, including the hormonal status of the listener. A bird may apply different criteria depending on whether the song is a stimulus for mating, affiliation, or competition.

For studying juvenile preference learning, a common approach has been to focus on females, who respond to preferred songs with sexual displays that are easy to quantify (in this case, the preference index is specifically related to mating). Female zebra finches will perform more sexual displays for songs they were tutored on early in life, even preferring songs of another subspecies if that is what they were trained on (Clayton, 1990). Riebel (2000) tested whether early exposure to a tape-recorded song was sufficient for inducing a stable preference in female zebra finches, using an operant task in which pecking of response keys led to song playback. Tutored females repeatedly preferred the song they were tutored on. In a related study (Riebel et al., 2002), both males and females showed clear and equivalent preferences for their father's song in an operant training assay (in which song playback itself was the reward for key pecking). The amount of variability was as great between siblings as between nest groups, suggesting that song preferences developed independent of inherited factors or quality of father's song. It is notable that song recognition in the zebra finch does not show a strong sex bias despite the essentially absolute sex difference in song-production ability in this species. Interestingly, although effects of early experience on song preferences have been demonstrated in some other species [e.g., canaries (Nagle and Kreutzer, 1997) and white-crowned sparrows (Casey and Baker, 1992; Macdougall-Shackleton et al., 2001)], not all species show evidence of early preference learning. Examples where preferences (e.g., for local dialects) appear to be independent of early experience include the house finch (Hernandez and MacDougall-Shackleton, 2004), the swamp sparrow (Balaban, 1988), and chaffinch (Riebel and Slater, 1998).

In addition to preferences based on juvenile experience, adult zebra finches continue to form new memories and associations based on the songs they hear later in life. In response to operant conditioning, naïve adult zebra finches learn to perform a song discrimination task over a period of 1–8 days (Cynx and Nottebohm, 1992). However, once the birds learn the task (i.e., to respond to the right song to get a food reward), they can learn to discriminate songs within just a few hours (Shy et al., 1986; Weary, 1989; Beecher et al., 1994; Jarvis et al., 1995; Braaten, 2000; Benney and Braaten, 2000). Thus, adult zebra finches apparently have the capacity to form memories and associations linked to specific songs they hear within a single day.

The observation of rapid induction and stimulus-specific habituation of gene responses to song playbacks also implies the formation of stable song-specific memories in a matter of hours (*Section 3.1.2*). A simple "listening" assay was developed as a way to measure behavioral correlates of genomic habituation, without introducing any explicit reinforcement or operant training requirement (Stripling et al., 2003). Zebra finches show visible evidence of attending to a song playback, when song playback first begins. They perch in one place, stop vocalizing, and orient toward the speaker from which the song is coming. The first time a song is played, this "listening behavior" may be sustained for 10–20 min or even longer. After the bird has been exposed to a series of playbacks of the same song, however, subsequent presentations of the same song elicit a much shorter listening response. The term "habituation" has been used to describe the shortening of the listening response after a test song has been repeated. The development of behavioral habituation correlates with habituation of IEG responses to the song, as considered in the next section.

3.1.3 Role of Gene Regulation in Song-Recognition Learning

Thus song-recognition learning has been observed on two different time scales: across juvenile development, and in the course of a single day in adult life. IEG responses have been implicated in both, but in contrasting ways. Put simply, experiments on learned preferences emphasize the use of IEG activation as an indicator of past learning completed. Experiments on adult song habituation emphasize IEG expression as a measure of new learning in progress. The goal of this section is to synthesize the diverse observations (*Table 9-2*) into a coherent mechanistic account of the function of IEG activities associated with learning and memory.

Workers focused on early preference learning have tended to regard the adult IEG response as an analog or correlate of song preference—which is to say, past learning or "memory strength" [e.g., Bolhuis et al., 2000; Bolhuis et al., 2001; see also Ball and Balthazart (2001), for a variant of this idea, emphasizing the relationship to "sign" stimuli]. The "memory strength" interpretation rests on two assumptions: (1) that prior learning leads to increased activity in the system that represents the learned object or association; (2) that the amount of IEG expression is proportional to the amount of that representational activity. Neither of these points is particularly well established on its own. Indeed, some evidence in other systems indicates that learning leads to a more efficient representation that requires less metabolic activity (Chialvo and Bak, 1999), and there are a number of examples where IEG expression clearly diverges from cellular metabolic or synaptic activity (Clayton, 2000).

Nevertheless, the "memory strength" argument has been propelled by observations such as those of Bolhuis and colleagues, who found a correlation between the magnitude of gene response to tutor song playbacks and the fractional representation of tutor song elements in an adult zebra finch's own song (Bolhuis et al., 2000; Bolhuis et al., 2001; Terpstra et al., 2004). When the bird's own song (BOS) was used as the stimulus, there was no significant correlation between the magnitude of each bird's response and the similarity of the BOS to the original tutor song. Thus, the birds who copied the tutor song most closely showed selectively greater IEG responses to the tutor song than did the other birds.

Bolhuis et al. concluded that tutor song is better represented in the birds with the higher responses, and the magnitude of the response reflects this degree of representation. An equally plausible possibility not considered is that the birds who originally copied the tutor song did so better because they liked it (or the

Kruse et al., 2004	zebra finch			enhancing	

The table shows how reports of IEG responses to song stimuli have emphasized two different functional interpretations. Some reports have emphasized relationships to innate or learned preferences ("learning completed"). Others have emphasized the recent novelty of the stimulus and the context in which it is experienced ("learning in progress"). See text for further discussion and reconciliation of these interpretations.

tutor) more, and this relative preference is reflected in greater "strength of activation" to that stimulus in adulthood. In other words, some birds invest the tutor's song with greater significance, and this may be the true proximal correlate of IEG response magnitude.

Workers focused on acquisition of new song memories in adulthood have regarded the IEG response as an indicator of active, current learning ("learning state"). This interpretation, which is developed in detail elsewhere (Clayton, 2000), is rooted in a major tenet of learning and memory research, that a wave of new gene expression is necessary to consolidate labile short-term memories into stable long-term memories (McGaugh, 2000; Kandel, 2001; Sweatt, 2003). In this view, induction of IEGs by song stimulation is an essential part of the brain's mechanism for storing new information—either memories of the song itself, or new associations *about* that song and the context in which it was heard.

An immediate impetus for extending this view to songbird research is the phenomenon of song habituation (*Figure 9-4*). When one song is played repeatedly over several hours or days, *zenk* mRNA levels in NCM/CMM return to the baseline measured in unstimulated controls, and subsequent presentations of that song no longer elicit any increase in *zenk*. However, a new round of *zenk* expression occurs when the bird is presented with a different song (Mello et al., 1995). This result was extended by Kruse et al. (2004) to show that the habituated song can reinduce a *zenk* response if the context of its presentation is changed (position in space, association with novel visual elements). This suggests that IEG expression is driven not so much by the novelty of the song itself as it is by the novelty of the context in which the song is heard. The study of Jarvis et al. (1995) also attempted to place the *zenk* response in the context of associational learning and generated a similar observation: a *zenk* response to habituated song can be restored by pairing the habituated song with an aversive shock, even though shock alone has no detectable effect on *zenk* levels in NCM/CMM.

Electrophysiological responses in NCM (measured as spike frequency) also undergo changes described as "habituation" when a song is repeated (Chew et al., 1995, 1996; Stripling et al., 1997). The habituation is highly selective for the repeated song. It takes approximately one half hour from stimulus onset before spike habituation is stable (Stripling et al., 1997), and the habituation is not sustained if protein synthesis inhibitors are injected at the recording site (Chew et al., 1995). Taken together, these observations are consistent with a requirement for new protein synthesis (IEG expression) in the consolidation of synaptic change in NCM/CMM. Importantly, these changes may underlie formation of memories or associations *about* the song, and not necessarily *of* the song's acoustic pattern (Jarvis et al., 1995; Kruse et al., 2004).

How then to reconcile these two interpretations, "memory strength" versus "learning state?" If IEG induction is all about the formation of new memories, why does it appear to be so clearly correlated with past learning and behavioral preference (*Table 9-2*)? Subtly, the two perspectives can be resolved by recognizing that preferred stimuli are also the ones that will trigger the most attention and provide the most salient motivation for new learning and associations. The magnitude of the IEG response intrinsically integrates past experience, current context, and any innate perceptual filtering. The outcome of this integration can be thought of as an indicator of *significance*. Significance is highest if perceptual filtering indicates that the stimulus is conspecific (Mello et al., 1992); if the stimulus has been associated with significant others (such as Father or Tutor) earlier in life (Bolhuis et al., 2001); and if the stimulus is immediately associated with a strongly aversive (Jarvis et al., 1995) or an unexpectedly novel context (Kruse et al., 2004). Thus, both interpretations capture part of the dynamic reality: IEG expression has a function in new memory formation, but its appearance is also correlated with old memory strength because old memories are the scaffolding upon which new learning is constructed.

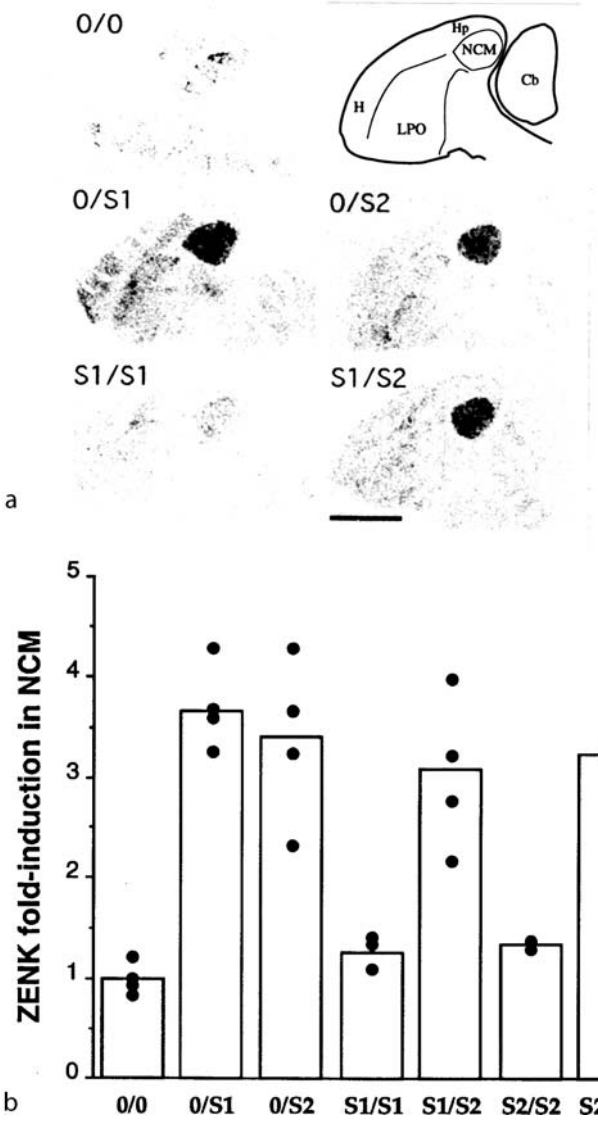
3.1.4 Other Molecular Mechanisms in Song-Recognition Learning

If IEG expression is part of the mechanism underlying song-recognition learning, how does it carry out this function? In answer to this fascinating question, at this point one can offer only broad hypothetical models (Clayton, 2000) and a few specific observations. The most familiar IEGs, including *zenk*, encode DNA-binding transcription factors (Lanahan and Worley, 1998). These are presumed to have their effects by activating or repressing other genes, and indeed a number of potential target genes under apparent regulation by the *zenk* protein have been identified, including genes that encode synaptic proteins [see Knapska and Kaczmarek (2004) for a recent review]. However, not all IEGs are transcription factors, and some may have immediate effects on neuronal form and growth. For example, the gene for the growth factor BDNF responds as an IEG and is induced in HVC by singing activity (Li et al., 2000). Understanding how IEG activity might affect memory formation requires information about two points that for the moment lie out of reach: a functional "proteomic" analysis of all the regulated proteins and how they interact (e.g., O'Donovan et al., 1999); and more insight into the precise synaptic structure of song representations and associations within the song system.

What are the proximal cellular signals that determine whether a given pattern of activity induces an IEG response? Regulation of common IEGs (and specifically *zenk*) in other systems has been extensively

Figure 9-4

Song-specific habituation of the *zenk* response in NCM/CMM (reprinted with permission from Mello et al., 1995). Zebra finches were presented with a repeated song stimulus for a 2.5 h training period, immediately followed by a second test stimulus for another 30 min. The combined training-test protocol for each experimental group is indicated (first stimulus/second stimulus). S1 and S2 represent the specific songs of two different individuals from another aviary, and 0 represents silence. a: Representative in situ hybridization autoradiograms of parasagittal brain sections (200 μm from midline). The diagram on the upper right indicates the visible structures: Cb, cerebellum; H, hyperpallium; Hp, hippocampus; LPO, lobus parolfactorius (now referred to as medial striatum); NCM, caudomedial nidopallium (also including a portion of CMM, caudomedial mesopallium, not labeled). Scale bar, 3 mm. b: Quantitative analysis of *zenk* hybridization signal in NCM. Each dot represents *zenk* mRNA abundance in NCM in one animal, and the bars represent means for each experimental group



reviewed elsewhere (Lanahan and Worley, 1998; Davis et al., 2003; Knapska and Kaczmarek, 2004). The proximal cause of *zenk* gene transcription in the rodent brain appears to be the phosphorylation of constitutively expressed transcription factor proteins, which bind to specific recognition sites in the gene's promoter; the critical transcription factors include Elk-1 and CREB. Elk-1 and CREB phosphorylations are caused by ERK (MAP Kinase), and a complex network of signaling pathways couples the stimulation of various cell-surface receptors (e.g., for neurotransmitters) to functional activation of ERK.

In songbirds, a critical role for ERK in *zenk* gene expression has also been demonstrated recently (Cheng and Clayton, 2004). Song presentations resulted in a very rapid pulse of ERK activation measured by immunoblotting using an antibody specific for the activated form of the protein. Pharmacological inhibition of ERK activation in NCM/CMM blocked the *zenk* response to song. Interestingly, the activation of ERK was transient, reaching a sharp peak in less than 2 min from song onset. ERK activation also showed stimulus-specific habituation, analogous to that described earlier for both *zenk* expression and electrophysiological spike rate. Other evidence suggests that ERK activation by song depends on stimulation of the noradrenaline/α_1-receptor (Ribeiro and Mello, 2000; Cheng, 2003). These results suggest that the *zenk* gene response to a song can be influenced by diffuse neuromodulator systems, thus defining a pathway by which information about context and significance might be integrated with the primary song representations generated in the activity of neurons in NCM/CMM (Clayton, 2000).

Evidence for CREB activation following song stimulation has also been presented, but the evidence is difficult to interpret (Sakaguchi et al., 1999). The authors reported that conspecific song presentation selectively induced an increase in pCREB in adult male zebra finches after 30 min of stimulation. Surprisingly, this effect was reported for HVC and not NCM/CMM. The authors did not offer any comment or show any data on CREB or pCREB in NCM/CMM, but the absence of evident labeling in the shelf and nidopallium surrounding HVC in the photomicrographs suggests a lack of any effect. In HVC, they localized CREB to the cells that project to Area X, but did not observe any increase in pCREB in Area X itself. Nor did they observe any increase in pCREB in HVC associated with singing activity. These results thus contradict expectations on a number of fronts. There is scant evidence that zebra finches retain significant sensory plasticity related to song production in adulthood (see › *Section 3.2.4*). The sound of song has not been shown to induce other plasticity-associated activities in HVC (e.g., *zenk*, *c-jun*, *c-fos*, phospho-ERK). Conversely, singing (but not listening) has been shown to induce *zenk* and *c-fos* in the HVC of adult singers, which may be interpreted in the context of ongoing engrainment of motor patterns (Lombardino and Nottebohm, 2000). Given the small group sizes ($n = 3–5$) and the unspecified criteria for judging cells as immunopositive, replication of this intriguing observation seems especially important.

Another rather surprising enzyme activity has been observed in NCM/CMM following novel song presentation: song presentation has been observed to trigger an increase in caspase-3 enzyme activity, specifically in or near post-synaptic densities (Huesmann and Clayton, 2002; Huesmann and Clayton, submitted). The activity peaks about 10 min after song onset; it shows song-specific habituation much as observed for *zenk*, ERK, and electrophysiological spike rate; and pharmacological inhibition of it appears to block *zenk* habituation. Caspase-3 activation is commonly thought of as the terminal step in the commitment of cells to apoptotic death, but there is no evidence that song presentation triggers apoptosis. The phenomenon is currently under investigation as a potential mechanism for learning-related synaptic modification.

3.2 Song-Production Learning

A male zebra finch's song performance is refined through practice over a critical period spanning the second and third months of life after hatching, and auditory feedback throughout is required for normal song development. He begins to practice singing at (30–40 days of age and develops a stable song pattern by 65 days (Arnold, 1975; Bottjer et al., 1984). During this time, he continues to be receptive to influences from additional tutors (Slater et al., 1991), but once adulthood is reached (approximately day 90), his song is fully crystallized and normally will not change significantly for the rest of his life (Arnold, 1975; Price, 1979).

A deep understanding of song-production learning will require knowledge of how specific song patterns are represented in the neurophysiological activity of the song system. It seems very likely that there are

multiple representations (e.g., tutor song, maps for sensorimotor matching, crystallized motor performance), perhaps distributed and woven throughout the system and interacting differently as the animal passes through different states of arousal and maturation. The greatest progress has been made in working out the respective roles of spike activity in HVC and RA in sequencing the elements of a mature vocal performance (Margoliash, 1997; Fee et al., 2004; Rose et al., 2004; Leonardo and Fee, 2005). Mechanisms for representing an auditory song memory are much less clear. Until recently, research was heavily focused on examination of auditory responses in HVC and the AFP in anesthetized birds. Neurons that responded selectively to playback of the BOS were identified. Methods for analyzing responses in awake birds have improved; however, the interpretation of BOS responses in the motor system has become cloudy (Dave et al., 1998; Hessler and Doupe, 1999a; Konishi, 2004; Leonardo, 2004), and more researchers are turning their attention to examination of the auditory regions such as NCM/CMM (for further considerations of song selectivity, see Theunissen et al., 2004).

Regarding the learning process itself, neurobiologists have been compelled by two major questions about song development: how is the system structured so that vocal performance will gradually evolve to match a template acquired from early auditory experience? And what determines the developmental boundaries of the learning process? There are reasonable ideas about how these feats might be accomplished (e.g., Adret, 2004; Bottjer, 2004; Brainard, 2004; Deregnaucourt et al., 2004; Doupe et al., 2004; Mooney, 2004), but there is little conclusive evidence about the critical molecular processes or control mechanisms. Rather, the field has seen an accumulation of bits of evidence for various factors or processes, each of which may have at least a contributing role in some aspect of song learning.

3.2.1 Boundary of the Sensitive Period

A young male zebra finch will sing the song of his father if exposed to him only until day 35, the approximate age of independence from his parents (Böhner, 1990; Funabiki and Konishi, 2003). Thus, a complete and intact sensory memory must already be formed by then. However, a young bird is still sensitive or receptive to further experience until ∼day 65. If raised in the presence of his father but then isolated at day 35 and exposed sequentially to other tutors, he will copy elements of new tutor songs he hears before ∼day 65 (Eales, 1985; Slater et al., 1991). This suggests that juvenile finches have the capacity to update or overwrite their initial song models during the period between days 35 and 65 (Slater et al., 1991). In general, social interactions are clearly very significant in determining whether or not a bird will copy a particular song (Clayton, 1987a, b).

Receptivity to new song models may be extended into adulthood under conditions of social isolation. Birds raised by females only, in isolation from their father or other potential adult tutors, will still copy large amounts of the father's song if first exposed to him as late as day 65 (Eales, 1987). In a more extreme case, birds raised by their mother alone and then kept in sound-proof chambers until day 120 developed very abnormal and variable songs that contained an unusually large number of elements, suggesting that crystallization had not occurred. When later exposed to a tutor (beginning at day 120) they showed some learning from the tutor (Slater et al., 1993). Similar results were obtained in another study, which also found that birds would copy elements of tutor songs presented in adulthood after they had been maintained in visual and social (but not necessarily auditory) isolation from other birds (Morrison and Nottebohm, 1993). It is not known whether conditions of extreme social impoverishment such as these show their effects by modulating normal development (i.e., "extend the critical period") or whether they force adaptations that may have no direct relationship to the mechanisms that constrain learning under normal circumstances.

3.2.2 Sensorimotor Learning

The process by which a young male zebra finch gradually refines his own stereotyped vocal performance requires auditory feedback, physical completion of the primary control pathway (HVC–RA), and an intact

AFP. Active song-like vocalizations around the 30th day after hatching correspond to the arrival in RA of axonal fibers from HVC (Konishi and Akutagawa, 1985; Mooney and Rao, 1994; Holloway and Clayton, 2001). Microstimulation of HVC and RA can elicit vocalizations (Vu et al., 1994; Vicario and Simpson, 1995), and electrophysiological analyses have correlated spike activity of individual RA neurons with specific elements of a bird's song (Yu and Margoliash, 1996). HVC neurons appear to fire sequentially in short bursts to form an explicit representation of the temporal organization of the song (Hahnloser et al., 2002). Thus, the primary excitatory drive for song production is provided by inputs from HVC, and much of the mystery of song-production learning may be transposed into questions of mechanism for adjusting or maintaining specific HVC–RA synaptic relationships.

An intact AFP is also required for normal song development (Bottjer et al., 1984; Scharff and Nottebohm, 1991), and its precise functional role is a subject of intense current investigation (Adret, 2004; Bottjer, 2004; Brainard, 2004; Deregnaucourt et al., 2004; Doupe et al., 2004; Mooney, 2004; Kao et al., 2005). The AFP can be considered a specialization within the general "cortical > striatal > thalamic > cortical" organization of processing in the vertebrate brain, important for skill and sequence learning (reviewed in Perkel, 2004). The AFP converges onto the HVC–RA pathways via an NMDA-receptor-mediated projection from LMAN onto RA neurons; these terminals are present and functional by day 25, before the arrival in RA of terminals from HVC (Mooney, 1992). Abarbanel et al. (2004) constructed a biophysical model based on observed timing delays in inputs from AFP versus HVC onto RA, and concluded that subtle variations in these timing relationships could readily shift the balance between synaptic potentiation and depression via NMDA receptors in RA.

Two examples of developmentally restricted, spike timing-dependent synaptic plasticity in the AFP have been reported (based on observations made in anesthetized animals or brain slices). Boettiger and Doupe (2001) observed NMDA-receptor-dependent long-term potentiation (LTP) of synapses from recurrent collaterals in LMAN, and long-term depression (LTD) of out-of-phase thalamic afferents. Both of these phenomena could be elicited at day 20 but not at day 60, thus corresponding to the early sensory period for song-model acquisition. This suggests the possibility that tutor song exposure might refine a representation in LMAN, which may then be used as the template for a subsequent error correction phase of sensorimotor learning. Working even further up the AFP, Ding and Perkel (2004) observed NMDA- and dopamine D1-receptor-dependent LTP in Area X, but only after day 47. This might provide a mechanism for refining, reinforcing, or maintaining the bird's own vocal performance.

A recent investigation examined the effects of microstimulation of LMAN on song performance in adult zebra finches, where the stimulus was applied only during a specific song syllable by use of a computer-controlled system for syllable detection and stimulus generation (Kao et al., 2005). Intriguingly, this resulted in acute changes in the amplitude and fundamental frequency of the song element being performed concurrently (or more precisely, within 35–70 ms of microstimulation). This suggests that activity in the AFP may contribute directly to song performance, even in adult birds. Consistent with this, a correlation was measured between variability in the multiunit firing pattern of LMAN (higher in undirected than directed song) and variability of the fundamental frequency of concurrent song elements (also higher when undirected than when directed). The authors point out that the effect of AFP activity could be instructive (by directly influencing the structure of specific song elements), and yet also supportive of a selection-based learning mechanism, in which variability in AFP activity generates variability in song performance—a necessary prerequisite for trial-and-error learning. For the molecular neurobiologist, it is especially intriguing to note that undirected song also triggers a much larger IEG response in the AFP than does directed song (Jarvis et al., 1998). This provides another, yet rather novel, association of IEG expression with neuroplasticity and learning; in this case, the plasticity is a context-dependent increase in variability of spike rate, which may provide the substrate for long-term learning by trial, error, and selection.

3.2.3 Do Songbirds Dream Song?

For most models of song learning that involve error correction at the level of HVC and RA, confounding the problem is the lack of evidence that neurons in these nuclei respond to the natural auditory feedback

generated during the bird's own singing (McCasland and Konishi, 1981; Konishi, 2004). Intriguingly, however, individual neurons in RA respond to BOS playbacks when the bird is asleep with a firing pattern that is similar to the pattern they generate during wakeful singing (Dave and Margoliash, 2000). Moreover, spontaneous activity of these neurons during sleep matches their sensorimotor activity. This raises the possibility that mechanisms of critical aspects of sensorimotor learning, integration, and template-matching may occur "offline," during sleep [see Margoliash (2002), for detailed discussion].

Further support for this has recently come from a careful daily analysis of song ontogeny, which showed a fascinating contrast: song performance deteriorated after overnight sleep during periods of learning, and yet the birds showing more post-sleep deterioration ended up producing better imitations of the tutor song at the end of the learning period (Deregnaucourt et al., 2005). Do birds need to sleep, dream, and forget—the better to learn?

In humans and in other species, sleep is critical for memory consolidation (Walker et al., 2003; Walker and Stickgold, 2004) and is associated with major changes in gene expression (Cirelli and Tononi, 2000b; Cirelli et al., 2004). Some learning-associated IEGs are suppressed during sleep (Cirelli and Tononi, 2000a; Cirelli and Tononi, 2000c). Yet *zenk* itself may be activated specifically during REM sleep after periods of waking stimulation (Ribeiro et al., 1999). The role of sleep in the song-learning process is an important emerging area of research, and analysis of state-dependent changes in gene expression may be especially critical.

3.2.4 Song Crystallization

A striking feature of the mature song performance, especially in zebra finches, is its stereotypy and resistance to change. The process of song crystallization may be delayed by social isolation or auditory interference, but once a bird is given the opportunity to hear his own song in a normal social context, song moves inevitably over about a month toward a highly stereotyped performance (Funabiki and Konishi, 2003). Song crystallization may also be induced prematurely by androgen treatment (Marler et al., 1988; Korsia and Bottjer, 1991). Once crystallized, learned song is a tenacious motor memory. Changes in song pattern may not emerge for many weeks (if at all) even in birds deafened with no auditory feedback (Nordeen and Nordeen, 1992), or with active perturbation of auditory feedback (Leonardo and Konishi, 1999), or after sudden perturbation of song performance via peripheral nerve injury (Williams and McKibben, 1992).

To what degree is crystallization an active process or just the passive endpoint of some developmental trajectory? This distinction potentially has significant implications for the underlying molecular and cellular biology of neural plasticity. For example, singing activity triggers *zenk* gene expression in song nuclei, even in adult zebra finches past the age of crystallization (Jarvis et al., 1998). How can the stability of song performance be reconciled with the active recruitment of a molecular mechanism associated with plastic change (Clayton, 2000)?

One possibility is that the "plasticity" signals in the adult song system simply have the effect of reinforcing existing physiological organization, in the absence of any mismatch between template memory and current performance. What happens then if mismatch is introduced, e.g., by deafening? Brainard and Doupe (2000, 2001) found that changes in song induced by deafening could be suppressed by lesioning LMAN, the output nucleus of the AFP. Thus, the AFP is necessary not only for initial song learning, but also for song plasticity induced in adulthood by altered sensory feedback. This does not clarify whether song crystallization is truly a default state, which may be overridden by instructive signals from the AFP only in cases of sensorimotor mismatch; or whether the AFP continually provides some reinforcing signal, which only has demonstrable influence in the absence of auditory feedback [but see Kao et al. (2005)].

In a technical tour de force, Leonardo (2004) recorded from single neurons in LMAN of awake unanaesthetized adult zebra finches, and used a computer-controlled system to perturb auditory feedback during singing. The goal was to test whether spike activity in LMAN is sensitive to auditory perturbations, as one would predict from a model in which the AFP performs a comparison of auditory feedback to an auditory memory and delivers an error correction signal. Contradicting such a model, spike activity in

LMAN was insensitive to auditory perturbations. One interpretation of this result is that, at least in the adult zebra finch, the AFP provides an "efference copy" of the song, i.e., a sequence that predicts the motor patterns associated with the desired output (Troyer and Doupe, 2000a, b). A caveat is that in this study, activity was only recorded during directed song, when the hypothesized sensorimotor error correction process may be taken offline (Jarvis et al., 1998; Hessler and Doupe, 1999b). Clearly, more work needs to be done to clarify the physiological role of the AFP in song system function—but this stands as an exceptionally promising system that may eventually illuminate the relationships between neural systems design, physiological function, molecular regulation, and behavioral endpoint.

3.2.5 Gene Expression Across the Critical Period

As the previous sections should demonstrate, song-production learning is a complex affair. Moreover, it is occurring simultaneously with the primary formation of the central HVC–RA projection in the telencephalon, and in young animals as they progress from parental dependency to independence and sexual maturity. So perhaps it comes as no surprise that the list of regulated genes, proteins, and signals in the developing song system is long. As reviewed elsewhere (Clayton, 1997, 2004a), developmental changes have been described in the expression of at least 20 different gene products in the song system. A partial list appears here:

1. Androgen receptor (Arnold and Saltiel, 1979; Bottjer, 1987; Nordeen et al., 1987a; Perlman et al., 2003; Kim et al., 2004)
2. Aromatase (Perlman and Arnold, 2003)
3. BDNF (Akutagawa and Konishi, 1998), [but see Dittrich et al. (1999), Johnson et al. (2000)]
4. CaM Kinase II phosphorylation (Singh et al., 2005)
5. Catecholaminergic innervation (Sakaguchi and Saito, 1989; Bottjer, 1993; Soha et al., 1996)
6. Cholinergic innervation (Sakaguchi and Saito, 1989; Sakaguchi and Saito, 1991)
7. Cyp17 (London et al., 2003)
8. Estrogen receptor (Gahr and Konishi, 1988; Konishi and Akutagawa, 1988; Jacobs et al., 1999; Perlman and Arnold, 2003)
9. Metabolic activity measured by cytochrome oxidase (Adret and Margoliash, 2002)
10. NMDA receptors in song nuclei (Aamodt et al., 1995; Aamodt et al., 1996; Basham et al., 1996; Livingston and Mooney, 1997; Basham et al., 1999; White et al., 1999; Livingston et al., 2000; Singh et al., 2000; Heinrich et al., 2002; Heinrich et al., 2003; Singh et al., 2003; Scott et al., 2004)
11. Retinaldehyde dehydrogenase (Denisenko-Nehrbass et al., 2000)
12. Synelfin/alpha-synuclein mRNA in LMAN cell bodies and protein in presynaptic terminals onto RA (Jin and Clayton, 1995; Jin and Clayton, 1997b)
13. Trk B (Wade, 2000)
14. Zenk mRNA levels in both NCM/CMM and in RA (Jin and Clayton, 1997a)

Attempts to establish causal links between any of these changes and steps in song production learning have for the most part been unsastisfying (Clayton, 1997, 2004a). The subject of the most intensive study has been the NMDA receptor, reviewed in detail in Nordeen and Nordeen (2004). But despite its apparent developmental regulation in the song system, and the obvious potential that might have to enable or suppress song learning, the evidence does not support the hypothesis that NMDA gene regulation sets the boundaries of song learning in the zebra finch critical period (Nordeen and Nordeen, 2004).

3.3 Critical Issues for the Molecular Biology of Song Learning

The great limitation of molecular-level analyses of song learning so far is that they have been almost entirely correlational. Some aspect of learning occurs (song-response habituation, singing crystallization) and

changes in gene expression are observed to occur in some temporal relationship. Are those changes a cause or an effect? In model systems with a strong basis in experimental genetics (i.e., drosophila, mouse), tools are available to produce transgenic animals in which specific gene regulation is altered. Methods may eventually be refined for efficient production of transgenic zebra finches, but a more direct strategy may be to exploit the high degree of anatomical definition in the song system for cannula-directed delivery of gene expression vectors and interfering agents (antisense oligonucleotides, RNAi). Intracerebral delivery of steroids, peptides, and other pharmacological agents has been widely effective in songbird research (Grisham et al., 1994; Basham et al., 1996; Johnson et al., 1997; Maney et al., 1997; Goodson, 1998a, b; Maney and Wingfield, 1998; Nordeen et al., 1998; Goodson and Adkins-Regan, 1999; Rasika et al., 1999; Brenowitz and Lent, 2002; Alvarez-Borda et al., 2004; Goodson et al., 2004).

4 Song Pathway Development: Sex Differences, Sex Hormones, and Neuronal Replacement

4.1 Sex Differences in Song-Control System

In the brain of zebra finches and many other species, the song nuclei differ greatly in volume between the sexes (Nottebohm and Arnold, 1976; Arnold and Saltiel, 1979; Gahr et al., 1993; Arnold et al., 1996; Brenowitz et al., 1996; Gahr et al., 1998). Not only are the nuclei larger in males than in females, but the primary motor output pathway (HVC–RA) does not develop in the female zebra finch (Konishi and Akutagawa, 1985; Mooney and Rao, 1994; Holloway and Clayton, 2001). Recent studies have defied expectations that these sex differences could be explained simply by the differential production of gonadal steroids in the sexes acting on a common brain substrate—the situation as it is understood in mammals (Schlinger et al., 2001; Wade and Arnold, 2004). Instead, it now appears that the genotype of the zebra finch brain itself has a significant role in determining whether the song system develops in masculine or feminine form.

The most striking evidence for this comes from an analysis of a rare spontaneous occurrence of a gynandromorphic zebra finch, in which the right half of the brain was genetically male and the left half genetically female (Agate et al., 2003). The neural song circuit on the right-hand side had a more masculine phenotype than that on the left, despite the fact both sides were exposed to a common gonadal hormone environment. An implication of this and other work [reviewed in Arnold (2004), Wade and Arnold (2004)] is that the sex-linked genes act locally within the nervous system to influence the way specific circuits develop. Clearly, one would like to identify these genes. An important advance that may help is the completion of the first draft genomic sequence of the chicken (Hillier et al., 2004), and the planned production of a zebra finch genomic sequence and physical map in the near future (http://www.genome.gov/11007951).

4.2 Sex Hormone Production in the Brain

Ironically, the mechanism by which sex-linked genes act directly within the brain may be to influence the production of androgen and estrogens—but by the brain itself and not from gonadal sources. The surprising capacity of the zebra finch brain for producing sex steroids was first indicated by studies showing high activities in the brain of aromatase, the enzyme responsible for producing estradiol-17-beta from testosterone (Schlinger and Arnold, 1991; Schlinger et al., 1994; Shen et al., 1994). Further studies have identified in the brain all the enzymes necessary to synthesize estrogens from cholesterol (Schlinger et al., 1995; Wade et al., 1995; Vanson et al., 1996; Freking et al., 1998; Schlinger et al., 1999; London et al., 2003; Soma et al., 2004).

A direct demonstration of functional brain estrogen production in song-circuit development was obtained from a study of cultured tissue slices prepared from juvenile zebra finches at 25 days of age, just before HVC axon begin their extension toward RA 2–3 mm below (Holloway and Clayton, 2001). After

1 week in culture, slices from both sexes formed a projection that reached the boundaries of RA. After 2–3 weeks the projection had entered RA in the male slices, but appeared to avoid the interior of the nucleus in the female slices. When both sexes were cultured together, both developed a male-like projection. Pharmacological inhibition of aromatase or the estrogen receptor blocked masculine development in male and cocultured female slices. Estradiol-17-beta was detected in the slice culture medium even after 3 weeks, and the levels were significantly higher in the male cultures than the females during the first culture week.

Key questions now are to identify more precisely the actual sites of steroid synthesis and action in the song system. Possibilities to consider include the cellular targets within RA; the tract leading from HVC to RA; existing neurons within HVC (and their associated glia) that are mounting the projections; and neuronal precursors arising from the ventricular zone that may be stimulated or recruited by local steroids (see next section). It should be possible to resolve these issues through a combination of localizing the synthetic enzymes (e.g., London et al., 2003) and microapplication of agonists and antagonists within the cultured slice or brain of the intact animal. Results of two studies indirectly favor the hypothesis of actions at the level of HVC of the associated neurogenic ventricular zone. First, BDNF is increased within RA-projecting cells in HVC of males relative to females, by day 30–35; levels are low in RA itself (Dittrich et al., 1999). BDNF levels in HVC were prematurely stimulated by estrogen (estradiol-17-beta) treatment, suggesting a mechanism by which estrogens acting in HVC might promote recruitment and survival of new neurons or stimulate axonal outgrowth. Second, a study of the effects of intracerebral testosterone implants in the white-crowned sparrow observed growth in ipsilateral HVC, RA, and Area X when the implants were placed near HVC but not RA (Brenowitz and Lent, 2002). It would be interesting to see the results of similar analyses using estradiol in the young zebra finch.

The significance of sex steroids produced locally in the brain may not be limited just to development. Estrogens have neuroprotective effects (Wise, 2002). Injury in the zebra finch brain results in an acute localized increase in aromatase activity, the enzyme that produces estradiol from testosterone, and the effect of this appears to be neuroprotective (Peterson et al., 2001; Wynne and Saldanha, 2004; Peterson et al., 2004). Aromatase is coexpressed with NMDA receptors in some neurons, and estradiol increases somal size and innervation of these neurons and the frequency of their presynaptic NMDA receptors (Saldanha et al., 2004).

4.3 Regulation of Neuronal Birth, Death, and Replacement

New neurons are continually added to various parts of the adult avian forebrain. This was first discovered through a study of seasonal changes in the volume of song nuclei in canaries (Goldman and Nottebohm, 1983; Nottebohm, 2004). Neurons are born at sites along the lateral ventricles and migrate to destinations that include HVC, Area X, and NCM, where they may be incorporated to replace dying neurons of the same type (Scharff et al., 2000). Song nucleus HVC sits adjacent to the neurogenic ventricular zone and incorporates a particularly large number of neurons. As much as 50% of the RA-projecting neurons in HVC can be replaced in a 6-month period (Kirn and Nottebohm, 1993).

Nottebohm hypothesized that the continual replacement of neurons could provide a mechanism for new learning (Nottebohm, 1989; Nottebohm, 2002). Many studies have now been performed in various songbird species to assess this idea. In a detailed and thoughtful review, Wilbrecht and Kirn (2004) concluded that the linkage to learning per se was rather indirect: "song instability, rather than song learning, may be a better correlate of new HVC neuron recruitment levels. . .new neurons may provide the raw variability in song upon which a new song can be sculpted" (p. 670).

Regardless of their precise relationship to song learning, the phenomena of adult neurogenesis are of considerable interest for insights they may offer into neuronal development and for the potential application of these insights into strategies for brain repair. A number of influences on neuronal recruitment and survival have been identified. One is the target site for neuronal incorporation, as neurons are recruited into HVC but not LMAN in the nidopallium. They are recruited into Area X, but not RA (Alvarez-Buylla and Kirn, 1997). In HVC, they replace RA projecting neurons, but not X-projecting neurons (Alvarez-Buylla et al., 1988; Nordeen and Nordeen, 1988).

Another factor may be "access" or "space," as periods of increased neuronal incorporation in the canary appear to follow seasonal periods of increased cell death (Kirn et al., 1994), and targeted ablation of neurons in HVC results in compensatory replacement (Scharff et al., 2000). These effects may be mediated by local production of neurotrophic factors. For example, IGF-I is produced by radial cells (Jiang et al., 1998), which are the probable stem cells for adult neurogenesis (Alvarez-Buylla et al., 1990; Goldman et al., 1996; Alvarez-Buylla and Temple, 1998). In HVC, X-projecting cells produce IGF-II and the protein is accumulated by RA-projecting cells, the population of which is turning over (Holzenberger et al., 1997). Neuronal recruitment and survival can be influenced by testosterone and estradiol (Rasika et al., 1994; Hidalgo et al., 1995), use and activity (Alvarez-Borda and Nottebohm, 2002; Lipkind et al., 2002; Wilbrecht et al., 2002a,b), and photoperiod (Kirn and Schwabl, 1997). BDNF enhances survival of a subset of young neurons (Alvarez-Borda et al., 2004), and it appears to mediate some of the effects listed earlier as its production is boosted by testosterone (Rasika et al., 1999), estradiol (Dittrich et al., 1999), and singing activity (Li et al., 2000).

5 Social and Environmental Integration

One of the most compelling aspects of songbird model is the clear influence of an array of modulatory factors on singing behavior, song learning, and associated brain anatomy. These factors can reveal how underlying cellular and molecular processes are integrated and embedded in the world of natural experience. Differential gene expression is likely to play a central role in these processes. Gene regulation works to establish the receptor systems and circuits that mediate integrative processes, and the genome itself plays a dynamic role in the responses to social and environmental stimuli, as the following examples show.

5.1 Influence of Social Factors on Song-System Molecular Biology

Social factors have an obvious role in song learning, as a young bird must interact with one or more tutors to acquire a learned song model (Clayton, 1987a; Slater et al., 1988). A male zebra finch modulates its vocal response to the calls of its female partner based on the presence and mating status of other birds in the "audience" (Vignal et al., 2004). In cowbirds, social transmission of courtship behaviors has been described (Freeberg, 2004).

Three examples show that social factors can modulate gene expression and cellular metabolism within the songbird brain. The act of singing induces *zenk* gene expression in the male zebra finch song-control system—but the anatomical pattern in which the gene response occurs differs depending upon the audience. Intriguingly, and perhaps counterintuitively, gene activation is more intense and widespread when the bird is singing by himself (undirected song) than when he is presenting essentially the same vocal performance to a female (directed song). The significance and mechanistic basis for this is yet unknown, although a favorite speculation is that undirected singing represents the explicit rehearsal of singing, during which genome-dependent processes of plasticity are brought online (Jarvis et al., 1998). Enforced isolation and restraint of a zebra finch change the selectivity of the *zenk* response to sounds (conspecific versus heterospecific songs or noise). Selectivity for conspecific song is greatest when the bird is free to move and has experienced shorter periods of social isolation (Park and Clayton, 2002). As a third example, social environment influences the recruitment and survival of new neurons in song processing centers in the adult zebra finch brain. Birds placed in a large heterosexual group for 40 days had more new neurons than birds kept singly or as male–female pairs (Lipkind et al., 2002).

5.2 Seasonal and Photoperiod Effects

The discovery of robust adult avian neurogenesis followed on the heels of a previous discovery of "a brain for all seasons: cyclical anatomical changes in song-control nuclei of the canary brain" (Nottebohm, 1981). Further analyses eventually showed photoperiod effects on neuronal death and replacement in canaries,

independent of chronic changes in gonadal steroid hormone levels (Kirn and Schwabl, 1997; Huang et al., 1998). Photoperiod effects at the level of *zenk* gene responsiveness to preferred songs have also been demonstrated (Sockman et al., 2002). The extensive literature on seasonal and photoperiod effects in the song-control nuclei is reviewed in detail elsewhere (Tramontin and Brenowitz, 2000; Ball et al., 2004; Ball and Balthazart, this volume; Brenowitz, 2004).

5.3 Linking Environment to Genome

The mechanisms by which social and environmental factors have both immediate and long-term effects on brain gene activity and neuronal survival are not understood. There are quite a few possibilities, however, four of which are considered briefly here [see also Ball et al. (2004), Ball and Balthazart (this volume)].

5.3.1 Dopamine and Other Catecholamines

Catecholamine cell groups project to forebrain song-control nuclei [reviewed in Ball et al. (2003)]. Simulated territorial intrusion activates immediate early gene expression (*c-fos*) in two of these groups in the brainstem, AVT, and midbrain central gray (Maney and Ball, 2003). Lesioning of noradrenergic inputs selectively suppresses courtship singing (Barclay et al., 1996). Given the evidence that dopamine exerts presynaptic depression on glutamatergic inputs to neurons in Area X (Ding et al., 2003), these observations suggest mechanisms for how the social context of singing (directed versus undirected song) alters the *zenk* gene response in basal ganglia component of the AFP, Area X (Jarvis et al., 1998).

5.3.2 Adrenocorticoids

Zebra finches maintain lifelong pair bonds, and both members of a pair can recognize their mates' vocalizations (Miller, 1979a; Vignal et al., 2004). A study of the effects of mate separation showed behavioral alterations and rises in plasma corticosterone; these effects were reversed upon reunion of mates but not upon exposure to other same-sex individuals or opposite-sex partners (Remage-Healey et al., 2003). Thus, a circulating hormonal signal is modulated by social perceptions.

5.3.3 Gonadal Steroids

Testosterone may be a transducer for aspects of natural experience, such as agonist interactions. For example, in a study of free-living male song sparrows, birds with increased exposure to testosterone-treated males (who behaved more aggressively) had higher circulating testosterone levels themselves (Wingfield, 1984). Testosterone in turn can have a variety of neural effects, both direct and indirect, including suppression of song plasticity (Marler et al., 1988), modulation of NMDA receptors (White et al., 1999), regulation of catecholamine levels (Ball et al., 2003), and elevation of BDNF in HVC (Rasika et al., 1999).

5.3.4 Endocannabinoids

Cannabinoids, the active constituents of marijuana, have diverse effects on learning and memory, perception, and feeding behavior. They act through abundant receptors in the brain, which are responsive to endogenous cannabinoids, lipids related to arachidonic acid. The normal function of the endocannabinoid system is not well understood. Soderstrom and colleagues turned to the zebra finch model to gain some insight, and reported that cannabinoid treatment alters song learning,but not production of song after it has been learned (Soderstrom and Johnson, 2003; Soderstrom and Tian, 2004). Birds treated during

juvenile learning learned fewer notes, and their song was less stereotyped yet also tended to contain more repetitive note production. An intriguing integrative role for endocannabinoids, penetrating to the level of gene response modulation, is suggested by the observation that cannabinoid treatment reduces the *zenk* response to song in NCM—yet it has no effect on the responses in primary auditory Fields L1 and L3. Moreover, agonist treatment during 2 days of training exposures apparently blocked habituation of the *zenk* response (when tested on the third day in the absence of the drug) (Whitney et al., 2003). Furthermore, endocannabinoid levels are elevated in response to periods of limited food availability, and limited food availability also suppresses the *zenk* response (much as does cannabinoid treatment). This suggests a functional integration of hunger and food availability with the *zenk*-mediated tendency to form auditory memories and associations, all linked through an endocannabinoid mechanism (Soderstrom et al., 2004).

6 Diversity and Evolution

Songbird research has tended to focus on just a handful of species, and the zebra finch in particular. Zebra finches are especially attractive for laboratory studies because they are easy to breed in captivity, and the sharp dichotomy in behavior and brain anatomy of males and females immediately suggests incisive experimental comparisons. However, the new tools of molecular genomics make it easier to move between and compare species at a deep level (Clayton, 2004a), and songbirds as a group offer exciting opportunities for comparative analyses.

The species diversity of Order Passeriformes is comparable to that of living mammals (Barker et al., 2004). The diversification of oscines began only about 65 million years ago, and much of it occurred in the last 10–20 million years (*Figure 9-5*). Efforts to map out the evolutionary pathways and relationships are increasingly directed to the study of specific nuclear gene sequences, including some genes of special interest to neurophysiology, e.g., *zenk* (Long and Salbaum, 1998; Chubb, 2004a, b), *c-myc* (Ericson and Johansson, 2003), and *rag-1* (Ericson and Johansson, 2003; Barker et al., 2004).

At the moment, the primary focus is on refining the avian evolutionary tree as a basis for consideration of biogeography, history, and broad mechanisms of adaptive evolution (Grant and Grant, 1997). As this research progresses, however, it may become feasible to mine the phylogenetic tree for specific events in gene evolution that correlate with emergence of specific phenotypic characteristics, such as the ability to learn and modify song. There are already a few examples that illustrate this line of research.

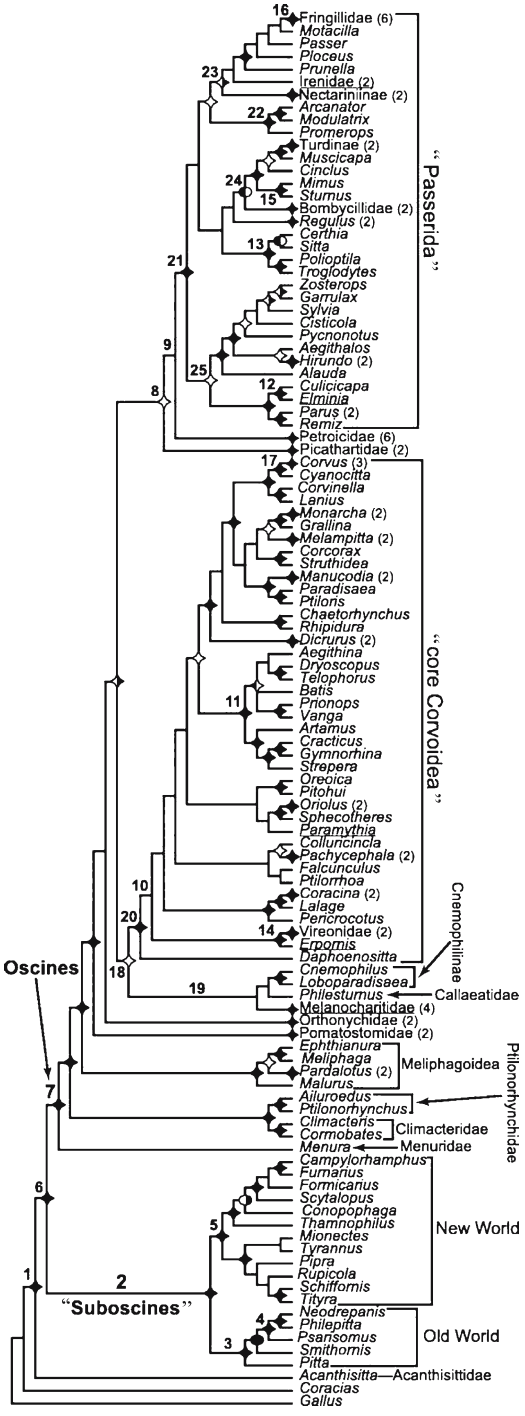
6.1 Aromatase and Estrogen Receptor

Although songbirds (oscines) predominate in the Order Passeriformes, there are also suboscines in the order that did not evolve a song system and do not show evident song-learning ability. Saldanha et al. (2000) asked whether one such species, the golden-collared manakin, expresses aromatase (estrogen synthase) in the telencephalon at high levels like the zebra finch (oscine passerine) or at low levels like the quail (nonpasserine). Restriction of aromatase to oscines would support the hypothesis that evolution of the song-learning ability occurred in concert with evolution of brain estrogen production. The results, however, show high aromatase in several telencephalic loci of the manakin brain (despite absence of detectable song nuclei). Thus, forebrain aromatase may have emerged in passerines before the divergence of oscines.

Figure 9-5

Avian phylogeny emphasizing passerines, including both oscines (songbirds) and suboscines (no vocal learning) (reprinted with permission from Barker et al., 2004). Relationships are based on analysis of combined *rag-1* and *-2* sequences (146 taxa, 4,126 aligned nucleotide positions). The topology presented is the best ML estimate, rooted using Gallus and Coracias. Multiple exemplars of genera and certain higher taxa have been collapsed for clarity (number of species indicated in parentheses after genus or group). See original reference for further description (Barker et al., 2004)

Figure 9-5 (continued)



Brain distribution of estrogen receptor itself was examined in 26 different avian species, including 3 suboscines (nonsongbirds in Passeriformes) and nine species outside Passeriformes (Gahr et al., 1993). Immunoreactivity in song nuclei (or the general areas in which song nuclei are embedded) was observed only in the songbirds. There were also differences among the songbird species. For example, adult males of the Estrildinae had much lower numbers of estrogen receptor immunoreactive cells than did adult males of the Fringillidae, Paridae, Sturnidae, and Ploceinae. It may be interesting to note that the SNAg antigen, discussed in *Section 2.1*, is reported to be specific for Estrildinae (Akutagawa and Konishi, 2001).

6.2 *ZENK* Expression

Although oscines are the most common, they are not the only avian order in which vocal learning ability evolved. Analysis of *zenk* gene activation during vocal behavior revealed the presence of seven functionally homologous forebrain areas active during singing in oscines and the other avian vocal learners, parrots, and hummingbirds (Jarvis and Mello, 2000; Jarvis et al., 2000). These three groups have been thought to have evolved vocal learning independently, and the similarities in patterns of vocal activation in the brain may indicate specific constraints on the organization of vocal learning systems.

6.3 FoxP2

FoxP2 is a transcription factor, mutations in which are genetically linked to abnormalities in human speech production. Two research groups investigated the possibility that FoxP2 might serve a convergent role in songbird vocal learning as well (Haesler et al., 2004; Teramitsu et al., 2004). Although some evidence was found for regulated expression in Area X during developmental (zebra finch) and seasonal (canary) plasticity (Haesler et al., 2004), expression patterns in other nonvocal-learning species undermine any simple specific association of FoxP2 with vocal learning ability.

6.4 Beyond the Song

Although the focus of this review (and a lot of research) has been on phenomena related to song communication, the taxonomic richness and accessibility of songbirds have made them favored subjects for a variety of other research endeavors. Drent and colleagues are reshaping the study of genetics and personality through consideration of songbirds (Marchetti and Drent, 2000; Carere et al., 2001; Dingemanse et al., 2003; Drent et al., 2003; Dingemanse et al., 2004; van Oers et al., 2004a, b, c). Comparison of mainland versus island white-winged fairy wrens recently led to appreciation of the divergent evolution of melanin production and the melanocortin receptor locus (Doucet et al., 2004). And nearly 200 years after inspiring Charles Darwin with their patterns of diversity and relatedness, the songbird species of the genus *Geospiza* revealed variations in expression patterns of a growth factor, Bmp4, that may account for some of the morphological variations Darwin observed (Abzhanov et al., 2004).

7 Critical Issues for the Future

We have reviewed five broad areas of research involving the biology of bird song, which define fundamental issues of molecular neurobiology:

1. How does a neural "system" (the song system) map onto and emerge from the underlying code of the genome?
2. Within such a system, how does the genome limit or promote learning and behavioral plasticity?

3. How do genes regulate the formation of specific neural circuits (e.g., sex-specific song-control pathways) and the turnover of neurons within those circuits?
4. How is all this molecular biology coordinated and integrated to result in adaptive responses to social and environmental exigencies?
5. How did the sophisticated and adaptive neurobiology of learned vocal communication evolve, across the thousands of different songbird species extant on planet Earth?

Each of the studies reviewed in this article focused on one or at most a handful of gene products. However, there is no reason to think that any of the questions given earlier can be answered by consideration of a single gene product. Indeed, a paradigm shift is underway in how molecular biological research is framed and conducted. With the tools of modern genomics, literally thousands of gene products can be studied simultaneously (e.g., high throughput sequencing, microarray hybridizations, mass spectrometry-based protein analysis). This not only increases the rate of discovery, but it also makes possible a new kind of observation, of multigenic interactions and gene networks.

7.1 Gene Network Analysis

For the songbird community, the infrastructure for this new kind of research is now being developed. In the US, there are two organized efforts to produce large systematic collections of mRNA sequences expressed in the zebra finch brain ("Expressed Sequence Tags," ESTs). EST collections are produced using robotics to partially determine the sequences of randomly selected cDNA clones prepared from the tissue of interest. The term "tag" is used because the sequences are typically incomplete, but are large enough to be useful for identifying and measuring the gene products. ESTs can be used to assess whether a particular protein sequence has been conserved in songbirds, and whether detection reagents (e.g., antibodies) developed in other species should crossreact with songbird material. The ESTs themselves can be used to generate nucleic acid probes for measuring the specific mRNAs from which they were derived. Moreover, the ESTs can be used as a basis for microarray development, which allows measurement of literally thousands of mRNA simultaneously in a single experiment (below).

As of the time of writing this article, more than 60,000 zebra finch brain ESTs have been sequenced by the two groups in the US, and these define more than 22,000 unique gene products (http://titan.biotec.uiuc.edu/songbird/). The efforts now underway in the songbird research community should lead to the initial identification in the near future of ESTs representing most of the 30,000 genes expressed in the songbird brain (Clayton, 2004a). Information about these efforts as well as progress toward whole-genome sequencing is available at: http://www.songbirdgenome.org.

EST sequencing provides information about the sequences of mRNAs, but not about the DNA sequences associated with the corresponding gene in the chromosome. To obtain the complete genomic DNA sequence for a given gene, other approaches are needed. The complete sequence may not be important for investigators only interested in knowing which proteins are expressed in their tissue of interest, or using microarrays to measure the amount of mRNA produced by various genes. However, to understand the mechanisms that regulate the expression of any gene, one must eventually consider the structure of its genomic DNA and the sequence of the gene's promoter. This sort of analysis in songbirds has recently been facilitated by the construction of a zebra finch brain Bacterial Artificial Chromosome (BAC) library. BAC clones are large fragments of foreign chromosomal DNA maintained in a relatively stable form by bacteria. Additional information about this resource may be found at this URL: www.genome.arizona.edu. The recent availability of the draft sequence of the chicken genome (Hillier et al., 2004) should facilitate the analysis of the other avian genomes, by providing an evolutionarily "recent" high-resolution template for physical mapping and functional annotation.

Another major tool under development for bird song molecular neurobiology is the DNA microarray, which allows measurement of expression levels for many genes simultaneously. The rich literature on this topic includes early examples (Schena et al., 1995; DeRisi et al., 1997), detailed methodological reviews

(Churchill, 2002; Nadon and Shoemaker, 2002; Yang and Speed, 2002; Simon and Dobbin, 2003), and an initial proof-of-concept study of microarray development for songbird research (Wade et al., 2004). Using robotics, thousands of different DNA probes are arrayed on a single support, the size of a standard microscope slide. RNAs extracted from tissues of interest are then labeled with fluorescent dyes and hybridized to the DNA probes on the glass slide, and the intensity of binding monitored by computerized optical methods.

For songbird researchers, microarrays will have at least two broad uses: functional diagnostics and gene discovery. In functional diagnostics, the investigator uses patterns of gene expression known to be associated with a particular cell type or physiological state to assess the status of a biological sample. For example, a songbird researcher might want to monitor how gene profiles associated with neurogenesis or synaptic plasticity change across seasons or during the juvenile song acquisition period. In gene discovery, an investigator compares tissues that differ in a specific functional property of interest and seeks to discover genes whose expression is correlated with that functional difference.

7.2 Targeted Gene Manipulation

A technical frontier with a longer horizon in songbird research is the development of genetic methods for direct manipulation of the genes—either within the germline (whole organism) or within specific targeted regions of the developing or adult brain. These methods include organized breeding programs to isolate distinct strains for conventional genetic mapping, and gene transfer methods for targeted introduction of specific engineered gene sequences into the organism. Potential methods of gene transfer applicable to songbird research include variations on the "transgenic" approach (whereby a new gene sequence is stably integrated into the chromosomes of germ cells followed by breeding and rearing), and the "expression vector" approach (whereby a DNA or RNA sequence is delivered directly into targeted brain cells in the juvenile or adult organism). Such methods are central to research with mice, fruit flies, and several other common model organisms in biological science, but researchers are just beginning to explore their application in songbirds (see also *Section 3.3*).

7.3 Conclusion

The widespread utility and appeal of songbirds for biological research justifies a significant and ongoing investment in the development of new tools, technologies, and experimental strategies for songbird molecular genetic analysis. In bird song, nature offers us an extraordinary model for appreciating the deep relationships of genes, brains, and behavior.

Acknowledgments

The author thanks the many colleagues who have inspired, instructed, and challenged him over the years—and especially the dozen or so graduate students who have shared his path of discovery. This work was supported by NIH grants RO1 NS045264 and RO1 MH52086.

5 Conclusion 447

Abstract: Birdsong is a complex learned motor skill that is used in the context of territory defense and mate choice. Songbirds have evolved a specialized neural circuit that controls the learning, production, and perception of song. Studies of the hormonal regulation of neurotransmitter systems in this specialized circuit provide an opportunity for neuroscientists to investigate the cellular neurochemistry of complex behaviors. In this review, we review the hormonal regulation of seasonal neuroplasticity in this circuit with special emphasis on the action of androgens including their estrogenic and androgenic metabolites. One theme that emerges is that androgens can induce seasonal changes in the morphology of the song circuit but that the ability of testosterone to be metabolized into androgenic or estrogenic metabolites also changes seasonally. The basic chemical neuroanatomy of the song system is reviewed and possible sites for the modulation of these transmitter systems by androgens are identified.

Lsit of Abbreviations: A, arcopallium; α_2, α_2- adrenergic receptors; Ach, acetylcholine; Achesterase, acetylcholine esterase; AF, aspiny fast-firing neurons; ant.Di, anterior diencephalon; AP5, 2-amino-5-phosphonovaleric acid; APH, area parahippocampalis; AR, androgen receptors; β1, Beta1 adrenergic receptors; β2, Beta2 adrenergic receptors; BDNF, brain-derived neurotrophic factor; BST, bed nucleus of the stria terminalis; BSTM, bed nucleus of the stria terminalis, medial part; CA, commissura anterior; Cereb, Cerebellum; ChAT, Choline acetyl transferase; DA, Dopamine; DBC, decussatio brachiorum conjunctivorum; DHEA, dehydroepiandrosterone; 5α-DHT, 5α-dihydrotestosterone; 5β-DHT, 5β-dihydrotestosterone; DLM, dorsolateral thalamic nucleus; DM, dorsomedial portion of the nucleus intercollicularis; DSD, decussatio supraoptica dorsalis; DSP-4, N-[2-chloroethyl]-N-ethyl-2-bromobenzylamine; E, Entopallium; ERα, Estrogen Receptors of the Alpha Subtype; ERβ, Estrogen Receptors of the Beta Subtype; FLM, fasciculus longitudinalis medialis; GABA, γ-amino butyric acid; GAD, glutamic acid decarboxylase; GCt, substantia grisea centralis (=mesencephalic central gray); GLv, nucleus geniculatus lateralis pars ventralis; GnRH, gonadotropin-releasing hormone; GP, globus pallidus; HA, accessory part of the hyperpallium; ^{3}H, tritium; HVC, Used as the proper name for the nucleus; ICC, immunocytochemistry; ISH, *in situ* hybridization; ICo, nucleus Intercollicularis; Km, estimated affinity; LMAN, lateral magnocellular nucleus of the anterior nidopallium; LSt, lateral striatum; LTP, Long Term Potentiation; M, mesopallium; MLd, nucleus mesencephalicus lateralis, pars dorsalis; Musc, Muscarinic Cholinergic Receptors; mRNA, messenger ribonucleic acid; N, nidopallium; NC, caudal nidopallium; NE, Norepinephrine; Nico, Nictotinic cholinergic receptors; Nif, nucleus interfacialis (=interface); NMDA, N-methyl-D-aspartic acid; OV, nucleus ovoidalis; PMH, Posterior nucleus of the medial hypothalamus; nXIIts, tracheosyringeal part of the nucleus of the XIIth cranial nerve; O.L, Optic Lobes; POA, Preoptic region; POM, medial preoptic nucleus; post.Di, posterior diencephalon; PVN, paraventricular nucleus; RA, robust nucleus of the arcopallium; Ram, nucleus retroambigualis; Rt, nucleus rotundus; rVRG, rostral Ventral Respiratory Group; SN , spiny neurons; T, Testosterone; Tel, Telencephalon; TH, tyrosine hydroxylase; TnA, nucleus taeniae of the amygdala; TSM, septopallial mesencephalic tract; Tu, nucleus tuberis; VIP, vasoactive intestinal polypeptide; Vmax, maximum velocity; VMN, Ventromedial nucleus of the hypothalamus; VTA, Ventral tegmental area; VT, vasotocin; X, area X of the medial striatum; ZENK, zif-268, egr-1, NGFI-A, or Krox-24

1 Birdsong and the Song System

1.1 Why is Song Interesting from a Neuroendocrine/Neurochemical Perspective?

Among vertebrate species, neurochemistry has been studied in most detail in mammalian species, especially rats and mice. The initial rationale for the overwhelming focus on these species is that they are convenient to study in the laboratory and by elucidating principles of neurochemical organization and function in these species, one can glean a general understanding of neurochemistry applicable to all mammals including humans. With the recent development of sophisticated genetic tools, various strains of the house mouse (*Mus musculus*) have emerged as an especially attractive group for investigation. Comparative neurochemistry is a relatively underdeveloped field. One obvious reason for this underdevelopment is that a reductionist approach to

structure and function of neural circuits requires that one builds on previous discoveries, and replicating basic investigations in a variety of species is generally considered to be time consuming and wasteful. Therefore, so-called alternative species for investigation at this level of analysis should be selected with care. Why then would the neurochemistry and neuroendocrinology of a particular behavior (song) produced by a particular taxon of birds (songbirds) be of general interest to neuroscientists? First, it should be observed that there is a long tradition in neurobiology of studying a particular species if it facilitates our understanding of a fundamental principle of nervous system functioning. For example, the basic properties of synaptic transmission were first explicated in the giant axons of squid (Hodgkin, 1976). Kandel and colleagues initiated studies of the mollusc *Aplysia californica* in order to understand synaptic changes associated with learning (Kandel, 1995). Songbirds are a taxon that possesses a neural circuit that controls a learned complex species-typical vocalization, song, and many properties of this circuit are of general interest to neuroscientists (Arnold, 1990; Brenowitz et al., 1997; Doupe and Kuhl, 1999; Nottebohm, 2004). In this review, we first concisely describe these properties and then outline the scope of coverage of the paper.

1.2 Brief Description of Songbirds, Song, and the Song System

The term "songbird" defines an order in the avian class. Songbirds are by far the largest avian order (Passeriformes), which contains over half of the living bird species whose number exceeds 9000 (Sibley and Monroe, 1990). All songbirds have a repertoire of up to 20 or so distinct vocal sounds that they use for communication about danger, food, sex, or group movements, and for other purposes (Nottebohm, 1975; Marler, 2004). In general, the most complex vocalization produced from a prominent perch in a stereotypic fashion is referred to as the bird's "song." The main functions that have been ascribed to song behavior are territory defense (or spacing behavior) and mate attraction, as opposed to calls, which are involved in such functions as signaling danger or food and maintaining flock cohesion (Catchpole and Slater, 1995). Songs, especially among songbird species in the temperate zone, are usually produced by males (Nottebohm, 1975). Among tropical species, females as well as males often sing (Morton, 1996). In some species, males and females sing a co-ordinated song that is known as a duet (Morton, 1996).

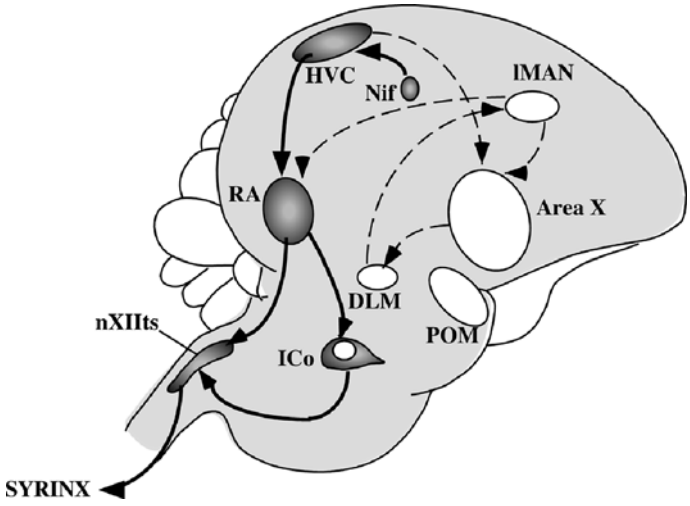
Unlike most calls, songs are learned: they develop abnormally if a young male is reared out of the hearing range of the sounds of adults. A common consequence of this dependence on learning among oscine songbirds (i.e., members of the large suborder of Passeriformes that exhibit vocal learning) is the emergence of local song dialects, varying on much the same geographic scale as dialects in human speech. Songbirds are unique among animals in the many analogies that can be struck between song learning and the acquisition of human speech (Ball and Hulse, 1998; Doupe and Kuhl, 1999). Avian vocal development provides one of the few tractable animal models for studying the behavioral, hormonal, and neural bases of vocal plasticity (Ball and Hulse, 1998). No nonhuman primate is known that depends on learning for the development of its natural vocal repertoire though learning does influence usage (Seyfarth and Cheney, 1997). Other than humans, cetaceans and perhaps some bats are the only mammals that appear to rely on learning for vocal development (Tyack and Sayigh, 1997). The avian groups known to have learned songs include hummingbirds, parrots, and all oscine songbirds (Jarvis, 2004).

Songbirds have evolved, in association with their very sophisticated vocal abilities, a suite of neural specializations that include an interconnected circuit of telencephalic, diencephalic, mesencephalic, and myencephalic nuclei that regulate the learning, production, and perception of song (Brenowitz et al., 1997). This circuit can be divided into two main parts: a caudal motor pathway and a more rostral forebrain pathway mostly involved in song learning and auditory feedback needed to maintain adult song (See *Figure 10-1*). The caudal pathway consists of nucleus HVC (used as a proper name; sometimes referred to as the high vocal center), the robust nucleus of the arcopallium (RA) of the telencephalon and the intercollicular complex (ICo) in the mesencephalon (see Reiner et al., 2004 for the recently revised nomenclature of the avian brain).

HVC (originally misnamed as hyperstriatum ventrale, pars caudale see Brenowitz et al., 1997; Reiner et al., 2004) is a telencephalic nucleus that appears to be unique to species in the songbird suborder

Figure 10-1

Generalized view of the songbird vocal control system. Several of these telencephalic nuclei including HVC, RA, and lMAN represent neural specializations for vocal learning that are observed only in songbird species. One forebrain pathway HVC to RA to ICo and nXIIts is involved in song production. Another pathway HVC to X to lMAN to RA is involved in song learning during ontogeny and song maintenance in adulthood. The POM a key area in the control of male sexual behaviors is also illustrated. See text for more detail



(Nottebohm, 1980; Kroodsma and Konishi, 1991; Ball, 1994; Brenowitz, 1997). It is a key part of the song system involved in the learning, production, and perception of song (Nottebohm, 1980, 1993; Brenowitz, 1997; Wild, 2004). HVC projects to the nucleus robustus arcopallialis (RA) that in turn projects to nucleus intercollicularis (ICo), in particular the dorsomedial portion of this complex (DM). Both RA and DM project to several medullary components of this circuit including the tracheosyringeal part of the nucleus of the XIIth cranial nerve (nXIIts) that innervates the vocal production organ the syrinx as well as to nucleus retroambigualis (RAm) and the rostral ventral respiratory group of neurons (rVRG) that co-ordinate respiratory activity with song production (Wild, 1994; 2004).

This pathway (HVC → RA → ICo → nXIIts) is involved in the motor production of song: lesions to nuclei in the pathway block song production (Nottebohm et al., 1976; Simpson and Vicario, 1990), and both immediate early gene induction studies (Jarvis and Nottebohm, 1997; Kimpo and Doupe, 1997) and electrophysiological studies (Yu and Margoliash, 1996; Leonardo and Fee, 2005) indicate that neurons in these nuclei are active in association with song production.

The second major pathway is an anterior forebrain pathway that includes HVC, area X of the medial striatum (homolog of the caudate/putamen) and the lateral magnocellular nucleus of the anterior nidopallium (LMAN), all of these are in the telencephalon. Another nucleus in this circuit is in the diencephalon, the medial part of the dorsolateral thalamic nucleus (DLM). This pathway is organized as follows HVC → X → DLM → lMAN → RA (*Figure 10-1*; see Doupe et al., 2005 for a review). LMAN also projects to area X.

Thus, there are two projection pathways that go from HVC to RA. The caudal pathway, described above, is clearly essential for song production based on lesion studies (Nottebohm et al., 1976; Simpson and Vicario, 1990), immediate early gene induction (Jarvis and Nottebohm, 1997; Kimpo and Doupe, 1997), and electrophysiological recordings (Yu and Margoliash, 1996; Leonardo and Fee, 2005). The anterior forebrain pathway that consists of a series of more indirect projections between HVC and RA plays a role in song learning (see Bottjer and Johnson, 1997; Doupe et al., 2005, for reviews) and in the maintenance of stereotypic adult song (Benton et al., 1998), but lesions to nuclei within this pathway do not block adult

song production (Bottjer et al., 1984; Sohrabji et al., 1990; Scharff and Nottebohm, 1991). Nuclei such as area X exhibit immediate early gene induction in singing male zebra finches that is context dependent (Jarvis et al., 1998). Males singing song that is directed at a female exhibit almost no induction of the immediate early gene ZENK in area X whereas ZENK induction is high in males singing in isolation or in the presence of other males (Jarvis et al., 1998). Similar findings have been reported for electrophysiological activity, in which multiunit activity in area X is much lower when the birds are engaging in song directed at a female than when they are singing in social isolation (Hessler and Doupe, 1999a, b). These findings suggest that this anterior forebrain circuit may modulate song output in adulthood, but may not be directly responsible for the motor output. Currently, one favored hypothesis is that the anterior forebrain pathway conveys an error correction signal between the learned auditory memory that the birds are trying to produce and the ongoing vocal output providing the feedback necessary to maintain high-quality learned song (Brainard, 2004). Blocking auditory feedback via deafening (Nordeen and Nordeen, 1992) or distorting it via a delayed feedback procedure (Leonardo and Konishi, 1999) results in a decline in the quality of song production due to an interruption in ongoing auditory feedback. Two studies by Brainard and colleagues, in particular, support the hypothesis that the anterior forebrain pathway mediates the corrective effects of auditory feedback that maintain stereotypic high-quality ongoing song production (Brainard and Doupe, 2000; Kao et al., 2005). In one case, it was shown that subsequent lesions to a nucleus in the anterior forebrain pathway essentially reverse the negative effects of deafening (Brainard and Doupe, 2000). This study suggests that if the active error correction signal provided by the anterior forebrain pathway is removed, the song does not deteriorate. In another study, the song-induced microstimulation of lMAN, the key output nucleus of the anterior forebrain pathway, was found to disrupt the ongoing song again, suggesting that this pathway mediates the ongoing auditory feedback needed to maintain stereotypic song behavior (Kao et al., 2005). Overall, this work supports the notion that one key function of the anterior forebrain pathway is to maintain ongoing song via an error correction process.

1.3 Strategy and Scope of Chapter

Song behavior and the neural circuit regulating song are profoundly regulated by steroid hormones, in particular androgens and estrogens (Schlinger, 1997; Ball and Balthazart, 2002; Ball et al., 2002; Brenowitz, 2004). Therefore, a major component of this review will be to document hormone effects on song behavior, the chemical neuroanatomy of how such hormones can regulate this behavior, and the regulation of hormone receptors and metabolizing enzymes that are involved in this regulation. We also describe the organization of neurotransmitter systems relevant to song and propose a theory concerning the role played by these different systems in song regulation. We also consider how hormones regulate these transmitter systems. One of the most interesting features of the song system is the pronounced degree to which adult neuroplasticity is exhibited within key forebrain nuclei in the song system such as HVC, RA, and area X (Ball et al., 2002; Brenowitz, 2004). This neuroplasticity can be observed at a rather gross histological level by comparing changes in nuclear volume as defined in Nissl-stained material in birds collected during different seasons and/or in different hormonal conditions. The cellular basis of these changes in volume involve changes in cell number in some nuclei such as HVC as well as changes in cell size and shape as seems to be the case in RA (Brenowitz, 2004). Thus, the major theme of the chapter is how one can discern general principles about how steroid hormones can induce changes in neurochemistry and brain morphology in adult animals.

2 Neuroendocrinology of the Song System

2.1 Hormone Effects on Song Behavior

The link between sex steroid hormone action and song behavior was first made based on the field studies correlating seasonal changes in gonadal size and other aspects of endocrine physiology with changes in song behavior. These descriptive studies have been reviewed in some detail (Ball, 1999; Tramontin and

Brenowitz, 2000) and only major features of these findings will be presented here. First, many male temperate-zone songbirds sing at high rates in the spring as compared to other seasons (e.g Cox, 1944; Slagsvold, 1977; see Catchpole and Slater, 1995 for a review). In these species, seasonal differences in male song are positively correlated with dramatic seasonal increases and decreases in aspects of reproductive physiology such as gonadal size and plasma hormone concentrations (Wingfield and Farner, 1993). However, among these temperate-zone birds there is interspecific variability in the degree to which maximal rates of singing are observed outside the breeding period. For example, robins (*Erithacus rubecula*) living in northern Europe sing at relatively high rates throughout the year (Hoelzel, 1986) only pausing in July (Cox, 1944) whereas most other songbirds living in the same region do not. Birds that sing outside the breeding season do exhibit seasonal cycles in gonad size and endocrine secretions that are similar to other temperate-zone species. Studies of selected species that exhibit territorial song production in the autumn such as song sparrows (*Melospiza melodia*) in the western USA, mockingbirds, and the European robin clearly suggest that song behavior in the fall can be elicited by the appropriate stimulus in the absence of substantial concentrations of testosterone (T) of gonadal origin (Logan and Wingfield, 1990; Schwabl and Kriner, 1991; Wingfield, 1994; Wingfield and Hahn, 1994). Interestingly, in the case of the song sparrow there is evidence that this autumnal singing does involve estrogen acting in the brain even though the gonad is inactive (Soma et al., 2000). The source of this neuroactive estrogen in this case does not appear to be from T of gonadal origin that is then locally metabolized (Soma et al., 2000). It could be derived from the neural aromatization of a substrate, (potentially dehydroepiandrosterone, DHEA) produced by the adrenals or synthesized de novo from cholesterol in the brain (i.e., a neurosteroid, Soma and Wingfield, 2001; Soma et al., 2002, 2004). Overall, these data indicate that there is not necessarily a tight correlation between endocrine activity and song rate in all temperate-zone species.

However, seasonal changes in reproductive physiology in these species may relate to changes in other aspects of song such as repertoire size or stereotypy. For example, seasonal changes in song repertoires have been observed in European starlings (*Sturnus vulgaris*, Eens, 1997) and canaries (Nottebohm et al., 1986), where the number of song types and other measures of song complexity may change. Additionally, seasonal changes in other measures of song such as stereotypy have been described in white-crowned sparrows (*Zonotrichia leucophrys*, Smith et al., 1995) and song sparrows (*Melospiza melodia*, Smith et al., 1997a).

A careful consideration of behavioral data from temperate-zone songbirds suggests that although song output is positively correlated with various measures of reproductive physiology, including hormone concentration in the plasma, there is not necessarily a strong causal relationship between the two as is the case for sex steroids and certain reproductive behaviors such as lordosis in rats (Pfaff et al., 1994), the bow coo display in male ring doves (Lehrman, 1965), or male-typical copulatory behaviors in Japanese quail (Balthazart et al., 2004). Experimental studies on the effects of exogenous hormone administration or castration with hormone replacement on song have been performed on a relatively small number of species but these studies confirm this view of the relationship between steroids and song behavior. Administering exogenous T can clearly increase song rate (e.g., Nowicki and Ball, 1989; Hunt et al., 1997). Several independent studies of zebra finches have shown that castration greatly reduces but does not eliminate male-typical song (e.g., Arnold, 1975; Harding et al., 1983), whereas in red-winged blackbirds castration was reported to eliminate adult song production (Harding et al., 1988). In the case of song sparrows in the western USA, castrated males were able to maintain fall territories and sang at high rates in response to territorial challenge in a manner that was indistinguishable from intact controls (Wingfield, 1994). The hormonal control of song behavior therefore appears to be a clear case of a hormone-enhanced, rather than hormone-dependent behavior. Species-typical stimulus factors (the presence of a conspecific male and/or female as well as a nest site or a favorable environment) promote song production in males. The presence of gonadal steroids in the plasma can increase the probability and intensity of these behavioral responses to the appropriate stimulus but this presence is not essential for behavioral activation (Wingfield, 1994). Therefore, one should not be surprised by the reports of substantial song production being observed in association with low steroid hormone concentrations in some cases. The stimulus factors releasing song can be so strong in some cases that high gonadal steroid concentrations are not necessary for song production to be observed.

In some cases, T effects on song may be limited to certain social contexts. For example, castrated European starlings continue to express high basal rates of singing but fail to exhibit an increase in singing rate when presented with a female (Pinxten et al., 2002). A female-induced increase in singing rate was, however, observed in castrates treated with T (Pinxten et al., 2002). Breeding season song in starlings usually declines after mating. If male starlings are treated with T during the incubation period, there is a robust increase in the song rate while a similar treatment during the nestling feeding period has little effect (De Ridder et al., 2000). The authors interpret the function of these findings as follows. In the population they studied in Belgium, during the incubation period there are still a large number of reproductively active females for the males to direct their song while by the time the nestling feeding stage starts there are few receptive females available (De Ridder et al., 2000). Thus, T was only effective in inducing an increase in song in breeding starlings when females available for mating were present. Finally, comparing the effects of a female on male song rate in starlings in the spring when T concentrations are high and the fall when they are low reveals an enhancing effect of a female only in the spring (Riters et al., 2000). These data are all consistent with the notion that in starlings, T is effective in enhancing the song produced in response to the presence of a female.

Although T does not appear to be necessary for the initiation of song production in all cases, it does appear to influence aspects of song quality such as stereotypy. For example, castration prevents the onset of crystallized (i.e., stereotyped) adult song in 1-year old song and swamp sparrows singing for the first time in the spring (Marler et al., 1988). Upon receiving T, the song rapidly crystallizes (Marler et al., 1988). As mentioned previously, in both white-crowned sparrows and song sparrows, fall song in the presence of low concentrations of T is less stereotypic than spring song produced in the presence of high concentrations of testosterone (Smith et al., 1995, 1997a). Overall, the data indicate that song can be produced (though at a low rate) in the presence of low concentrations of T but that, the stereotypic quality of the song is also regulated by the presence of T.

Finally, some steroid hormone replacement studies indicate that both androgenic and estrogenic metabolites of T are needed to fully restore high rates of singing (e.g., Harding et al., 1983, 1988). In zebra finches, it has been suggested that estrogenic metabolites selectively promote female-directed song (Walters et al., 1991). Similarly, in canaries there are data suggesting that estradiol selectively activates syllables that are particularly attractive to females while other aspects of song are activated by androgenic metabolites (Rybak and Gahr, 2004). These studies indicates that there may be selective actions of the two primary metabolites of testosterone on song behavior.

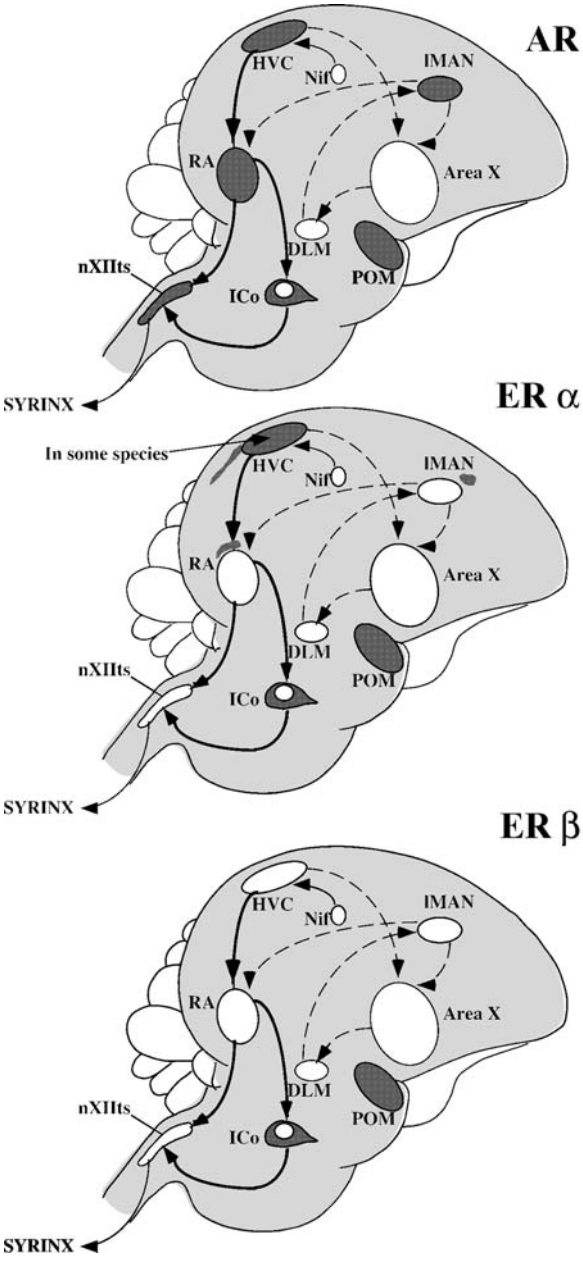
2.2 Localization of Sex Steroid Hormone Receptors in the Song System and Other Areas Relevant to Reproductive Behavior

Singing activity is enhanced by T in many songbird species, and the song control circuit is a neural specialzation that controls song production. Therefore, some of the first questions asked by behavioral neuroendocrinologists concerned whether T is able to act directly on song control nuclei to activate song and whether T acts via androgenic or estrogenic metabolites at these brain sites. Initial autoradiographic studies using [^{3}H] T revealed uptake in several of the forebrain song control nuclei (Arnold et al., 1976; Arnold and Saltiel, 1979). Subsequent studies using immunocytochemistry (ICC) to identify the receptor protein or in situ hybridization (ISH) to localize the corresponding messenger RNA have confirmed the presence of steroid-sensitive neurons in these nuclei. These studies have also allowed for the specification as to whether the sites accumulating radioactivity that had been detected by in vivo autoradiography with [^{3}H] T as the ligand correspond to androgen (AR) or estrogen receptors (ER). This presence of brain areas that highly express AR in discrete nuclei in the telencephalon represents a neural specialization that distinguishes songbirds from other vertebrates (Kelley and Pfaff, 1978; Morrell and Pfaff, 1978). In this section, we will review briefly what is known about the distribution of AR and ER in the song control system (see ❯ *Figure 10-2* for a summary).

Androgen Receptors. In general, the distribution of AR in birds is restricted to the septal-preoptic area, and to the various nuclei in the hypothalamus and in the midbrain (for review, Balthazart, 1983; Ball, 1990; Brenowitz, 1991; Ball and Balthazart, 2002) as is commonly observed in all vertebrate classes (Morrell et al.,

Figure 10-2

Schematic illustration the distribution of androgen receptors (AR), estrogen receptors alpha (ERα), and estrogen receptors beta (ERβ) in the song control nuclei and in the medial preoptic nucleus (POM) that also participates to the activation of singing behavior. The nuclei of the forebrain pathway involved in song production (HVC, RA, ICo, and nXIIts) are connected by black arrows. Nuclei of the anterior forebrain pathway involved in song learning during ontogeny and song maintenance in adulthood (HVC, area X, DLM, IMAN, and RA) are connected by dashed arrows. The presence of crosshatches in or near a given nucleus means that the receptor is expressed in the brain area. In the case of ERα in HVC there is species diversity in this expression. See text for more detail



1975; Pfaff, 1976; Stumpf and Sar, 1978). In addition to these receptors in brain areas common to all avian (and vertebrate) species, songbirds possess androgen-sensitive brain areas that are part of the song control system (Arnold et al., 1976; Nottebohm, 1980; Konishi, 1985; Nottebohm et al., 1990). HVC, RA, and MAN contain AR based on both autoradiographic (Zigmond et al., 1973; Arnold et al., 1976; Lücke and Haase, 1980; Zigmond et al., 1980; Gahr, 1990; for review: Ball, 1990; Brenowitz, 1991; Ball and Balthazart, 2002) and binding assay (Harding et al., 1984) methods (see *Figure 10-2* top panel).

Additional autoradiographic studies using the nonaromatizable androgen [^{3}H] dihydrotestosterone as a ligand (Arnold and Saltiel, 1979; Nordeen et al., 1987a; Sohrabji et al., 1989) have confirmed that these telencephalic-binding sites, identified by T autoradiography, are specific for androgens (not estrogens derived by aromatization). The presence of AR in these nuclei has also been confirmed by ICC (Balthazart et al., 1992b; Smith et al., 1996; Soma et al., 1999b). The AR has also been cloned and sequenced in canaries (Nastiuk and Clayton, 1994; Gahr and Metzdorf, 1997) and starlings (Bernard et al., 1999) and probes based on these studies have been used to localize the AR mRNA in the canary (Nastiuk and Clayton, 1995; Metzdorf et al., 1999; Fusani et al., 2000) and starling brain (Bernard et al., 1999; Maney et al., 2001). These ISH studies have largely confirmed the AR distribution identified by in vivo autoradiography or ICC. Interestingly, however, AR have also been identified by ISH within the area X of adult starlings (Bernard et al., 1999) and this presence was recently confirmed in the developing zebra finch brain (Perlman et al., 2003).

Weakly labeled AR-ir cells can also be observed in a position adjacent to the canary RA, in a "hook-like" structure that runs laterally from RA and then turns in a ventral direction (Balthazart et al., 1992b). This area had been previously identified in zebra finches as a region receiving projections from the lateral MAN (Bottjer et al., 1989) and labeled by the a high density of α_2 adrenergic receptors in starlings (Ball, 1990; 1994). This area should thus be considered as part of the song system. Several medullary nuclei that receive inputs from RA, such as the nucleus hypoglossus pars tracheosyringealis (syringeal motonucleus or nXIIts), the nucleus retroambigualis (RAm), and the rostroventral respiratory group (rVRG) (Wild, 1997; Wild et al., 1997; Reinke and Wild, 1998) are also defined by the presence of AR in songbirds (Gahr and Wild, 1997). However, these areas appear to be devoid of these receptors in most other birds (Gahr, 2000; or at least there is no report on the topic), with the exception of the Anna's hummingbird (*Calypte anna*), a species that belongs to another bird family where song learning has been identified. Caution should be exercised when making definitive conclusions about species variation in the absence of many studies. For example, it has been reported that AR are present in the syringeal motor nucleus of chickens, though they are absent in quail (Shaw and Kennedy, 2002). These data raise questions concerning the general nature of the presence of these receptors in the nXIIts of songbirds as opposed to other avian species and studies in additional species should be undertaken to understand the rules governing expression of AR in this motor nucleus.

Estrogen Receptors of the Alpha Subtype (ERα). Estrogen receptors, as was the case for AR, were originally studied in songbirds by in vivo autoradiography. In the late 1990s, a new ER was cloned in mammals (Kuiper et al., 1996; Mosselman et al., 1996; Tremblay et al., 1997) and later identified in avian species (Lakaye et al., 1998; Bernard et al., 1999; Foidart et al., 1999). This second ER was called estrogen receptor beta (ERβ) to distinguish it from the previously described receptor it was then renamed as ERα. We first review here, work that was performed before the second receptor was known and we now think primarily concern the first identified form of receptor (ERα). The distribution of ERβ will be considered subsequently.

The distribution of ER without regard to subtype was investigated in several avian species, including songbirds, by a variety of methods (in vivo autoradiography, in vitro-binding, ICC and, in a few cases, ISH). Similar to what has been observed for AR, ER binding sites appear to be restricted to the hypothalamic and limbic structures, and to the mesencephalic intercollicular nucleus in nonsongbirds and songbirds (e.g., Martinez-Vargas et al., 1975; 1976; Kim et al., 1978; Watson and Adkins-Regan, 1989), but additional binding sites are found in telencephalic song nuclei of oscines (e.g., Nordeen et al., 1987b).

Immunocytochemistry has also been used to analyze the distribution of ERα in zebra finches and canaries first (Gahr et al., 1987) and then in many avian species ($n = 26$) belonging to a large number of avian orders (Gahr et al., 1993). The distribution of ERα immunoreactive cells in the diencephalic and

limbic structures is very similar across all species. All songbirds, however, also display significant numbers of ERα–expressing cells in three structures of the nonlimbic forebrain: the caudal nidopallium including in some species HVC, the dorso-rostral area surrounding RA, and an area in the rostral forebrain, dorsal to the lamina mesopallialis and rostral to the nucleus MAN (*Figure 10-2* middle panel). ERα was also cloned in zebra finches and canaries and the distribution of the corresponding mRNA was analyzed in the brain of these species by ISH. These studies confirmed with a few exceptions the results that were previously established by autoradiographic and ICC methods (e.g., presence of ERα in the nido- and arcopallial areas adjacent to HVC and RA, see Jacobs et al., 1996). One noticeable difference between canaries and zebra finches should be highlighted here, however, ERα mRNA and protein are present within HVC in canaries but not in zebra finches where they are located in the surrounding nidopallium but not specifically in HVC itself (Gahr and Metzdorf, 1997; Metzdorf et al., 1999; Fusani et al., 2000).

Estrogen Receptors of the Beta Subtype (ERβ).The identification of a second type of ER with a distinct neuroanatomical distribution (Kuiper et al., 1996; 1998) suggested new ways in which estrogens could act in the brain. Several species, for example, do not express ERα in HVC (e.g., the zebra finch or starling) and the discovery of the new receptor type raised the possibility that estrogens could act in this nucleus via binding to ERβ if it were expressed in this nucleus. ERβ was cloned and sequenced in Japanese quail (Foidart et al., 1999; Lakaye et al., 1998) and then European starlings (Bernard et al., 1999), and a specific riboprobe was used to analyze the neuroanatomical distribution of the mRNA in the starling brain with a special focus on the brain areas containing the song control nuclei (Bernard et al., 1999). ERβ mRNA was not expressed at detectable levels in any forebrain song control nucleus (*Figure 10-2* bottom panel). A low level of expression was observed in the caudomedial nidopallium close to but not within HVC, with a pattern of distribution distinct from ERα. As was observed in a nonsongbird species, the Japanese quail (Foidart et al., 1999), a high level of expression was observed in starlings in the medial preoptic nucleus (POM), bed nucleus of the stria terminalis (BST), and in the nucleus taeniae of the amygdala (TnA), a number of brain areas that are implicated in the mediation of sexual behavior (Panzica et al., 1996; Balthazart et al., 1998; Thompson et al., 1998; Absil et al., 2002). These data therefore provide no evidence that ERβ directly mediates the control of singing in the telencephalic song control nuclei.

2.3 Localization of Steroid Hormone Metabolizing Enzymes in the Song System

As discussed previously, estrogenic and androgenic stimulation is usually required for the optimal activation of singing behavior (Harding et al., 1983, 1988; Walters et al., 1991). It is therefore important to investigate the neural sites where testosterone can be metabolized into behaviorally active steroids and to analyze the control of these enzymatic activities.

In the avian brain, three enzymes catalyze the transformation of T into behaviorally relevant metabolites (Balthazart, 1989; Hutchison, 1991): aromatase leads to the production of estrogens, 5α-reductase produces 5α-dihydrotestosterone (5α-DHT), and 5β-reductase leads to the formation of the behaviorally inactive 5β-dihydrotestosterone (5β-DHT) which apparently represents an inactivation shunt for T (Hutchison and Steimer, 1981; Steimer and Hutchison, 1981). These transformations are thermodynamically irreversible, at least in physiological conditions.

The presence of these three enzymes has been confirmed in the brain of zebra finches and starlings during in vitro experiments (Vockel et al., 1990b; Schlinger and Arnold, 1991, 1992a; Riters et al., 2001). The presence of an active aromatase and 5β-reductase has also been identified in zebra finches in vivo (Schlinger and Arnold, 1992a). With only a few exceptions (Hutchison et al., 1986; Schlinger and Arnold, 1992a), all available data concerning T metabolism in the avian brain are derived from in vitro studies carried out on brain homogenates. These studies demonstrate the presence of the enzymes in the central nervous system but the measures of activity obtained in such studies may ignore some regulatory mechanisms that could play a key role in the live animal. Some caution should therefore be exercised when using these assay data to interpret physiological phenomena.

Interestingly, there is an inverse relationship between the estimated affinity (Km) and maximum velocity (Vmax) of the three enzymes that irreversibly metabolize T (see Vockel et al., 1988; for data in zebra finches). Enzymes that produce biologically active metabolites such as aromatase and 5α-reductase have a high affinity (small Km) for T and therefore a privileged access to the substrate (T), but they have a limited maximum velocity and cannot produce very large amounts of these biologically active substances (E2 and 5α-DHT). Conversely, the enzyme that produces biologically inactive steroids, such as the 5β-reduced androgens does not have a priority of access to the substrate but can metabolize large amounts of the substrate (high Vmax). In physiological conditions where a relatively low concentration of T is available, the steroid should thus be preferentially transformed into estrogens by aromatase, but if higher amounts of substrate are present (e.g. after the injection of exogenous T), a larger proportion could be inactivated into 5β-reduced steroids that have no hormonal activity by themselves.

The activity of aromatase, 5α-, and 5β-reductase was originally measured by radioenzyme assays in zebra finch brain nuclei that had been dissected by the Palkovits punch technique (Vockel et al., 1990a, b). The 5α-reductase activity was more or less evenly distributed in all brain nuclei that were considered with the noticeable exception of RA, where enzyme activity was twice as high as in all other regions (*Figure 10-3a*). High levels of 5β-reductase activity were found throughout the brain (note the very different scale on the graph) but especially in MAN, HVC, and in the medial part of the bed nucleus stria terminalis (BST). These two reductases were even present in two steroid-insensitive regions that had been included in the study as controls, the entopallium (formerly, ectostriatum; see Reiner et al., 2004) and the nucleus rotundus.

High levels of aromatase were observed in the diencephalic and limbic nuclei that are well known to express this enzyme in mammals and other avian species, namely the nucleus preopticus anterioris (POA), the nucleus periventricularis magnocellularis (PVN), the nucleus medialis hypothalami posterioris (PMH, named more accurately as the ventromedial nucleus of the hypothalamus, VMN), BST, and TnA. Interestingly, these studies also reported the presence of significant levels of aromatase activity in telencephalic song control nuclei such as the area X, MAN, HVC, and RA. They also indicated that the area parahippocampalis (APH) that had originally been selected as a control region was characterized by a surprisingly high level of enzymatic activity, greater in fact than in any of the diencephalic or limbic nuclei that had been studied (Vockel et al., 1990b). Additional studies confirmed the presence of a very high aromatase activity in the dorsal telencephalon and demonstrated that the enzyme is actually present in the entire roof of the forebrain in the nidopallium (formerly neostriatum), hippocampal, and parahippocampal region. This high level of telencephalic aromatase activity was independently confirmed (Schlinger and Arnold, 1991, 1992a) and a series of elegant studies based on the injection of radioactive androgens in the brain or periphery combined with blood collection in the jugulars or carotids has provided experimental evidence indicating that brain aromatase substantially contributes to the circulating levels of estrogens in the Zebra Finch (Schlinger and Arnold, 1992a, 1993).

More recently, the distributions of the aromatase protein or mRNA have been described at a cellular level of resolution in a number of songbird species (e.g., zebra finch, canary, pied flycatcher) by ICC or ISH (Balthazart et al., 1990; Shen et al., 1994, 1995; Balthazart et al., 1996; Foidart et al., 1998; Metzdorf et al., 1999; Saldanha et al., 2000). All studies confirmed the presence of aromatase and its mRNA in the diencephalic and limbic regions such as the POA, PVN, VMN, BST, and TnA that are implicated in the control of reproduction where a high level of enzyme activity had been measured. Unexpectedly, however, all telencephalic song control nuclei were found to contain only minimal, often nondetectable, concentrations of the protein or its mRNA. The presence of large amounts of aromatase (protein and mRNA) in the nidopallium has been confirmed and its distribution was characterized. At the level of HVC, or in slightly more rostral parts of the telencephalon, aromatase and its mRNA are present in broad areas of the medial nidopallium adjacent to the lateral ventricles. At more caudal levels, the cluster of aromatase-expressing cells extends more medially as a band coursing along the dorsal edge of the lamina arcopallialis dorsalis; they are also present in the ventrolateral aspects of the nidopallium (See *Figure 10-3b* for an illustration of this distribution in male pied flycatchers, similar data were obtained in the other investigated species). Based on these detailed anatomical data, it is likely that the aromatase activity that had been detected in HVC and RA by radioenzyme assays performed on nuclei microdissected by the Palkovits punch technique

originated from a contamination by nidopallial or arcopallial tissue immediately surrounding these nuclei. A number of aromatase-immunoreactive neuronal processes originating in the adjacent nidopallium (Saldanha et al., 2000) or in other aromatase-immunoreactive neurons (neurons in Nif express aromatase mRNA and project to HVC; Saldanha et al., 2000) seem to enter HVC where they could release locally produced estrogens. These immunopositive fibers may also partially explain the significant level of aromatase activity detected by radioenzyme assays in this song control nucleus.

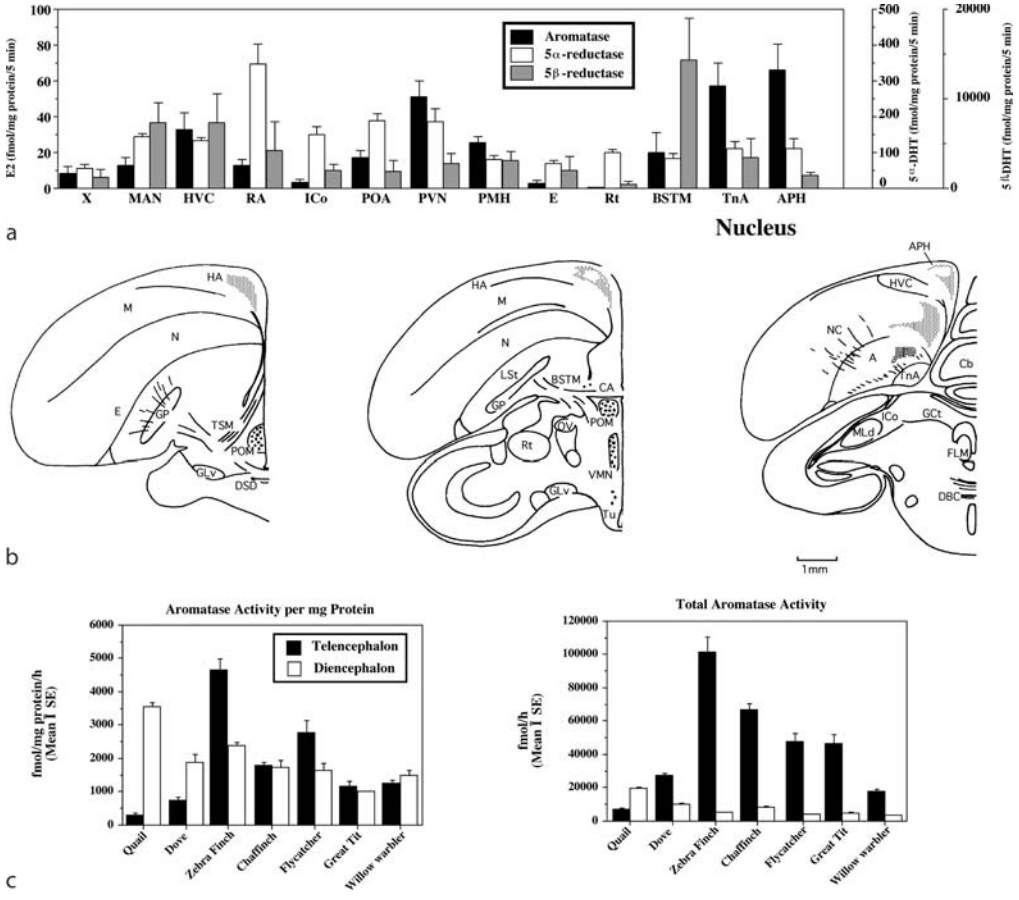
Interestingly, enzyme assays performed on cell fractions separated by differential centrifugation of the quail preoptic area (Schlinger and Callard, 1989) or the telencephalon of zebra finches (Schlinger and Arnold, 1992b) indicate that aromatase activity is found not only in the microsomal but also in synaptosomal (pinched-out nerve terminals) subfractions. The presence of aromatase-immunoreactive material has furthermore been confirmed in cell processes of the quail brain that have an axonal morphology (Evrard et al., 2004; Foidart et al., 1994) and, at the electron microscope level, it was confirmed that aromatase-immunoreactive material is present in high density at the level of presynaptic boutons (Naftolin et al., 1996; see Peterson et al., 2005 also for recent data in songbirds). This local production of estrogens in the close vicinity of synapses may provide steroid signals that could affect brain activity independent of the binding to nuclear receptors acting as transcription factors (i.e., by nongenomic mechanisms). It is known that estrogens are able to modify the electrical activity of the neuronal membranes within seconds after their application, which essentially rules out the possibility of a classical steroid receptor-mediated effect on protein synthesis (for additional discussion, see Blaustein and Olster, 1989; Schumacher, 1990; McEwen, 1994; Ramirez et al., 1996). Other effects of estrogens on brain functioning that appear to be independent of their binding to intracellular receptors have also been described (e.g., Thompson and Moss, 1994; Pasqualini et al., 1995; Mermelstein et al., 1996). Whether the presence of aromatase activity in brain areas such as part of the nidopallium that are apparently devoid of intracellular ER relates to these membrane effects of estrogens is unknown at present.

Most of the studies described so far on androgen metabolizing enzymes used laboratory-reared, domesticated species (e.g., Japanese quail, ring dove, zebra finch) and their relevance for free-living species was difficult to establish. One unusual feature of songbirds that was suggested by this work is the presence of surprisingly high levels of aromatase activity in the dorsal telencephalon as compared to limbic and

Figure 10-3

Distribution of testosterone metabolizing enzymes in the brain of songbirds. (a) Formation of estradiol (aromatization), 5α-dihydrotestosterone (5α-reduction) and 5β-dihydrotestosterone (5β-reduction) by different brain areas of adult male zebra finches dissected by the Palkovits punch technique. Data represent the mean ± SE of 6–11 replicates in each case. Different scales have been used to represent the activity of the three enzymes. X: area X of the medial striatum (formerly lobus parolfactorius); MAN: nucleus of the anterior nidopallium; HVC: used a a proper name (formerly high vocal center); RA: robust nucleus of the arcopallium; ICo: nucleus intercollicularis; POA: nucleus preopticus anterioris; PVN: nucleus periventricularis magnocellularis; PMH: nucleus medialis hypothalami posterioris (or VMN); E: entopallium; Rt: nucleus rotundus; BSTM: nucleus stria terminalis pars medialis; TnA: nucleus taeniae of the amygdala; APH: area parahippocampalis. Based on data from Vockel et al., (1990b). (b) Schematic representation of the distribution of aromatase immunoreactive cells in the male pied flycatcher brain. Successive rostral to caudal levels are shown from left to right. Darkly labeled cells are indicated by dots in the diencephalon. In the telencephalon, the distribution of cells showing a weaker immunoreactivity is indicated by the shaded areas. A group of slightly darker cells is indicated by a darker shading in the ventromedial corner of the neostriatum and archistriatum Abbreviations: A: arcopalium; APH: area parahippocampalis; BSTM: nucleus stria terminalis pars medialis; Cb: cerebellum; CA: commissura anterior; DBC: decussatio brachiorum conjunctivorum; DSD: decussatio supraoptica dorsalis; E: Entopallium; FLM: fasciculus longitudinalis medialis; GCt: substantia grisea centralis; GLv: nucleus geniculatus lateralis pars ventralis; GP: globus pallidus, formerly paleostriatum primitivum; HA: accessory part of the hyperpallium; Hp: hippocampus; HVC: song control nucleus formerly known as high vocal center; ICo: nucleus intercollicularis; LSt: lateral striatum formerly paleostriatum augmentatum; M: mesopallium (formerly hyperstriatum ventrale); MLd: nucleus mesencephalicus lateralis pars dorsalis; N: nidopallium; NC: caudal nidopallium; OV: nucleus ovoidalis; POM: nucleus

preopticus medialis; Rt: nucleus rotundus; TnA: nucleus taeniae of the amygdala; TSM: septopallial mesencephalic tract; Tu: nucleus tuberis; VMN: nucleus ventromedialis hypothalami. Modified from data in Foidart et al., (1998). (c) Comparison of the aromatase activity in the telencephalon and diencephalon of five species of songbirds and in quail or doves. Each data point represents the mean ± SE of 5–7 determinations except for doves where $n = 2$. Data are expressed as enzyme activity per hour per mg protein (left) or for the entire brain region considered (right). Modified from the data in Silverin et al. (2000)



hypothalamic areas. Although, it was quite tempting to generalize these features of the zebra finch aromatase to the entire songbirds order (passeriformes), data supporting this generalization were missing with the exception of limited studies devoted to a few species such as the brown-headed cowbird (*Molothrus ater*), white-crowned sparrow, or house sparrow (*Passer domesticus*) (Schlinger et al., 1992; Schlinger, 1996; Saldanha and Schlinger, 1997). Considering that zebra finches studied in the laboratory are derived from semidomesticated stocks and they represent a non- (or only marginally) photoperiodic species that inhabits the Australian deserts (see Bentley et al., 2000), their use as a model species for the songbird group that contains many photoperiodic species originating from the temperate zone appears questionable. We investigated whether the high level of telencephalic aromatase that had been detected in zebra finches would also be found in a variety of European songbird species caught in the wild during the breeding season. Within the same experiment, aromatase activity was thus measured in the brain of five songbirds species from different families including chaffinches (*Fringilla coelebs*, Fringillidae), pied flycatchers (*Ficedula hypoleuca*, Muscicapidae), great tits (*Parus major*, Paridae), willow warblers (*Phylloscopus trochilus*,

Sylviidae), and zebra finches (*Taeniopygia guttata*, Estrildidae) and in two nonsongbird species, the Japanese quail (*Coturnix japonica*, Phasianidae) and ring dove (*Streptopelia roseogrisea* [= *risoria*]).

Aromatase activity was measured in triplicate in five different brain regions: the telencephalon, diencephalon, optic lobes, cerebellum, and brain stem. The enzyme activity, expressed per mg protein, was larger in the telencephalon than in the diencephalon in zebra finches but not in quail and doves (see *Figure 10-3c*, left panel). The same situation as in zebra finches was observed in the flycatcher but not in the other songbird species that were considered (chaffinch, tit, warbler), therefore questioning the generalization of this pattern to the passeriformes order. It is important to note that the telencephalon mass is at least one order of magnitude larger than the diencephalon. When aromatase activity was therefore calculated for the entire brain area, the activity difference between the telencephalon and the diencephalon became more prominent (5–20 fold excess) in all songbird species but not in quail and dove (see *Figure 10-3c*, right panel). Aromatase activity was low in all other brain regions (see Silverin et al., 2000 for detail). These data thus support the notion that songbirds are characterized by a high level of telencephalic aromatase activity by comparison with other avian groups. The difference is, however, not as dramatic as previously assumed on the basis of the zebra finch data.

Aromatase activity is present in the telencephalon of all species studied so far including nonsongbirds. The evolutionary significance of the high or low ratio between telencephalic and diencephalic aromatase activities remains unclear at present and will probably be impossible to specify, until the enzyme has been studied in a larger number of species originating from a broad range of families and displaying a variety of ecological life styles. The role of this high level of estrogen production in broad areas of the telencephalon that often do not express nuclear ER also remains to be identified. The presence of aromatase at the presynaptic level suggests that a paracrine mode of action is possible (see (Ball and Balthazart, 2002) for a broader discussion of this topic). The demonstration that infusion of radioactive androstenedione in the zebra finch telencephalon results in increased levels of radioactive estrogens in the jugular blood (Schlinger and Arnold, 1992a, 1993) even suggests an endocrine action for brain aromatase.

2.4 Localization of Receptors for Other Hormones in the Song Control System

Although it has been hypothesized for many years that pineal melatonin exerts important effects on brain function, it was not until the 1980s that autoradiographic procedures were developed that allowed for the reliable visualization of melatonin receptors. In birds, the surprise that emerged based on initial studies in chicks is that binding sites for iodomelatonin are widely distributed throughout the visual system involving both thalamic nuclei such as the lateral geniculate nucleus, and the optic tectum, as well as telencephalic structures such as the entopallium (Rivkees et al., 1989). Subsequently, detailed autoradiographic studies were carried out in zebra finches (Gahr and Kosar, 1996), house sparrows (Whitfield-Rucker and Cassone, 1996), and European starlings (Bentley and Ball, 2001). The striking finding for songbirds is that the song nucleus HVC exhibits high receptor density in all species investigated, whereas RA also exhibits significant receptor binding though at lower densities than HVC. Area X is more variable, but this is probably due to the fact that melatonin receptors in this nucleus exhibit a marked seasonal regulation in both starlings and house sparrows (Whitfield-Rucker and Cassone, 1996; Bentley and Ball, 2001). In starlings, it is clear that receptor densities are high when birds are photosensitive and photorefractory but not when photostimulated, and this regulation is independent of gonadal steroid hormones (Bentley and Ball, 2001).

2.5 Hormonally Regulated Adult Neuroplasticity in the Song Control System: Seasonal and Sex Differences

Along with the seasonal changes in the gonads and T described above, one can observe seasonal changes in the volumes of several song control nuclei and aspects of song behavior. These correlated changes could reflect direct actions of steroids on the song control nuclei and on song expression, but alternative mechanisms have also been suggested.

Since the discovery of seasonal anatomical changes in the song control system of canaries by Fernando Nottebohm (1981), studies in several songbird species have revealed strong positive relationships between the volumes of song nuclei, typically HVC, RA, and area X, and both seasonal fluctuations in T and aspects of song production (e.g., Nottebohm et al., 1986, 1987; Smith et al., 1997a; Riters et al., 2000; Tramontin and Brenowitz, 2000). The primary environmental factor influencing the volumes of song nuclei is day length. In the laboratory, male songbirds exposed to artificial photoperiods typical of spring have significantly larger song control nuclei and elevated T concentrations than males housed under fall-like photoperiod conditions (Bernard and Ball, 1995). Similarly, in males captured from the field, seasonal peaks in T, associated with long day lengths in spring in most temperate-zone songbirds, correspond to increases in the volumes of song control nuclei (e.g., Smith, 1996; Smith et al., 1997a, b; Brenowitz et al., 1998; Soma et al., 1999b). A recent study of wild song sparrows carefully correlated the late winter and spring onset of testis growth and other measures of reproductive development with the growth of the song system in wild sparrows and found that increases in HVC volume clearly preceded the growth and development of the reproductive system (Tramontin et al., 2001). Similar results have also been reported for blue tits (*Parus caeruleus*) in Corsica (Caro et al., 2005). Thus, the maximal concentrations of T associated with breeding are not needed for the growth of HVC to be observed (Tramontin et al., 2001; Caro et al., 2005).

In addition to day length, several additional environmental factors interact to influence the volumes of song control nuclei including social factors (Tramontin and Brenowitz, 2000; Tramontin et al., 2001) and interactions between T concentrations and day length (Bernard and Ball, 1997). Not all song control nuclei show the same pattern of volume change (e.g., Smith et al., 1997a), but in general HVC changes are followed by changes in RA and area X depending on the species and whether the bird is studied in captivity or captured from the wild (see Tramontin et al., 2000 for general discussion of this sequence). Compared to laboratory-housed males, males captured in the field are exposed to a much fuller array of environmental stimuli. This likely accounts for differences sometimes observed in the volumes of song control nuclei in males studied in the laboratory compared with males captured in the field. For example, in starlings exposed to a spring-like photoperiod, only the volume of HVC was enlarged relative to males under fall-like photoperiod conditions (Bernard and Ball, 1995, 1997; Bentley and Ball, 2000). In contrast, males captured in the field and housed in outdoor aviaries HVC, RA, and area X displayed significant seasonal changes in volume (Riters et al., 2002).

The changes in the volumes of song control nuclei reflect changes in the number of neurons, the size of the neurons, or changes in dendritic fields within the nuclei. In RA, seasonal changes in volume do not appear to reflect an increase or decrease in neuron number, but they reflect changes in the size of the neurons, spacing between neurons, and changes in dendritic arborization (Smith et al., 1997a; Tramontin et al., 1998). Similary, studies of the cellular basis of seasonal changes in the volume of area X in song sparrows indicate that the 75% variation in volume between spring and fall birds is due to changes in neuronal size and neuronal density (Thompson and Brenowitz, 2005). In contrast to RA and area X, new neurons are incorporated into HVC seasonally (Nottebohm, 1989; Brenowitz et al., 1991; Goldman et al., 1992; Smith et al., 1997c). Given that HVC tends to be at its largest extent when T concentrations are highest (e.g., Kirn et al., 1994; Riters et al., 2002) though see (Tramontin et al., 2001), and cell death in HVC is associated with low concentrations of T (Kirn et al., 1994; Nottebohm, 1987; Nottebohm et al., 1987), it was suggested that these cellular changes are associated with changes in song behaviors (Nottebohm et al., 1987; Kirn et al., 1994). It was also hypothesized that T regulates the incorporation of new neurons into HVC, possibly by influencing neurotrophic factors (Rasika et al., 1999). There is now direct evidence that this is the case (Alvarez-Borda and Nottebohm, 2002). Furthermore manipulations of the neurotrophin, brain-derived neurotrophic factor (BDNF) induce song variability in adult zebra finches suggesting that T exerts morphological and behavioral effrects via actions on BDNF in HVC (Rasika et al., 1999; Kittelberger and Mooney, 2005).

Although seasonal changes in T and the volumes of song nuclei have been reported for several songbird species, the precise behavioral function of seasonal changes in the song control system is still a matter of debate. Based on work in canaries, the original hypothesis was that seasonal changes in the volumes of song nuclei reflected seasonal changes in song learning (e.g., Nottebohm et al., 1986). Male canaries learn new songs each year outside of the breeding season. During song learning, the songs that are produced are

variable and the volumes of song control nuclei are small. However, with the increase in T concentrations during the breeding season, song becomes much more stable and stereotyped, and the volumes of HVC and RA increase 99% and 76%, respectively (Nottebohm, 1981), suggesting that volume increases play a role in the storage of a learned song. However, more recent studies have called this possibility into question (Brenowitz et al., 1995; Bernard et al., 1997; Smith et al., 1997b). For example, in rufous-sided towhees seasonal changes in the volumes of song control nuclei are observed in a species that does not learn to produce new songs in adulthood (Brenowitz et al., 1991). An alternative to the hypothesis that changes in nuclei relate to song learning is that seasonal changes in song nuclei are related to seasonal changes in aspects of song performance such as the amount of song produced or changes in song structure (Ball, 1999; Tramontin and Brenowitz, 2000). As in canaries, in song sparrows the largest volumes of HVC and RA were observed at times of the year when male song is extremely stereotyped, whereas smaller volumes were associated with times during which song was more variable (Smith et al., 1997b). Given that song sparrows do not learn new songs each year, seasonal changes in the volume of nuclei do not seem to relate to changes in song learning, but seem instead to relate to changes in song structure. Like canaries and song sparrows, male starlings sing at relatively high rates for most of the year (Feare, 1984). Unlike song sparrows, starlings appear to be able to learn new songs throughout their lives (Chaiken et al., 1994) and unlike canaries song learning in starlings does not appear to be restricted to a particular season (Böhner et al., 1990). However, in starlings the volumes of HVC, RA, and area X change considerably across an annual cycle (Riters et al., 2002), again suggesting that changes in volume do not correspond well to song learning. It is unknown whether starlings display seasonal changes in stereotypy; however, starlings do sing a longer song bout in spring than in fall indicating that some structural changes do occur seasonally in this species (Riters et al., 2000). Furthermore, during spring a strong relationship was identified in male starlings between the volumes of HVC and RA and song rate (Bernard et al., 1996). Together these data build a strong case for the idea that changes in the volumes of song control nuclei underlie seasonal changes in aspects of song production such as stereotypy or other aspects of song structure.

2.6 Seasonal Dynamics in the Steroid Metabolizing Enzymes

Aspects of the hormonal mechanisms regulating song and song system exhibit variation as a function of sex, seasonal, or hormonal condition besides the morphology of the song control system. For example, biochemical studies carried out on microdissected brain regions demonstrated that the activity of the T-metabolizing enzymes in zebra finches is markedly affected by the age and sex of the birds as well as by their endocrine condition (i.e., castrates treated or not treated with exogenous T (Balthazart et al., 1986; Vockel et al., 1988, 1990a, b). The most dramatic changes observed after treatment with exogenous T concerned aromatase activity and fewer changes in the activity of the two reductases (5-alpha and 5-beta) were detected. In the hypothalamic and preoptic nuclei of zebra finches, aromatase activity was, as in other vertebrates, much higher in males than in females and this sex difference appeared to result mainly if not exclusively from the presence of higher T levels in males. Gonadectomy reduced the enzyme activity to basal levels and treatment with T usually induced high levels of enzymatic activity in both sexes (Vockel et al., 1990a). This pattern is very similar to what had been previously described for many hypothalamic structures in other avian species such as the quail and dove (Balthazart, 1989; Ball and Balthazart, 2002 for reviews) and in mammals (Roselli et al., 1985, 1987; Roselli and Resko, 1989; Roselli, 1991).

A different pattern emerged however in telencephalic samples. In areas such as the dorsal nidopallium or the area parahipocampalis, no clear sex difference in enzyme activity could be detected in sexually mature, gonadally intact birds. Furthermore, gonadectomy associated or not with a treatment with exogenous T, did not seem to have much of an effect on enzyme activity (Vockel et al., 1990a). The data therefore suggested that telencephalic aromatase is not sexually differentiated and not regulated by T. A lack of a sex difference in the telencephalic aromatase activity was also reported independently in young zebra finches (Schlinger and Arnold, 1992b). This differential regulation of aromatase in telencephalic and limbic areas suggested that different mechanisms regulate aromatase expression in these two parts of the brain, and more recent studies characterizing the promoters of the aromatase gene actually provide some support

for this idea (Ramachandran et al., 1999). As already discussed previously, zebra finches are not a typical photoperiodic species so that extrapolation of the control mechanisms observed in this species to other songbirds that live in the temperate or boreal zones may be hazardous.

Seasonally breeding species show marked seasonal changes in testis mass and in plasma T levels. These variations are paralleled by pronounced behavioral modifications. The high level of aggressiveness that characterizes the establishment of the territory is generally lost during the period of incubation and feeding of nestlings (Silverin, 1993). Both aggressive and reproductive male behaviors are activated by T in many vertebrate species (Silver et al., 1979; Balthazart, 1983; Wingfield, 1985) and the central aromatization of T appears to be a critical step in the activation of male copulatory behavior and also possibly of parts of the aggressive repertoire (Balthazart, 1989; Balthazart et al., 2004). Little data are available concerning the neuroanatomical distribution and functional regulation of the aromatase enzyme in the brain of free-living species. In the recent years, a few studies have begun to characterize the seasonal variations in the activity of T-metabolizing enzymes in free-living songbirds. This will be illustrated here by studies carried out in three wild species.

2.6.1 Lapland Longspur

The Lapland longspur (*Calcarius lapponicus*) is an Arctic-breeding songbird that exhibits rapid behavioral changes during a short breeding season. Changes in plasma T in the spring are correlated in this species with singing activity but not with territorial aggression. Furthermore, T treatment increases fall song but not aggression in this species. Soma and collaborators (1999a) asked whether localized or temporal differences in the activity of T-metabolizing enzymes could explain these differential relationships between hormones and behavior in this species. The activity of aromatase and of the two reductases was measured in seven brain regions at three different stages of the breeding season (display, mate guarding, and incubation periods). Significant changes in aromatase and 5α-reductase activities were found in several brain regions but the activity of the 5β-reductase changed only in one area, the caudal telencephalon. The most dramatic changes that were observed concerned aromatase activities in the rostral and caudal hypothalamus. In particular, a very pronounced drop of aromatase activity was observed during incubation in the rostral hypothalamus corresponding to the period when the plasma levels of T sharply decrease. This might explain why exogenous testosterone does not activate aggression at that time. These data also provided a first indication that the production of behaviorally relevant metabolites of T changes seasonally in one species of free-living bird.

2.6.2 Pied Flycatcher

Seasonal changes in aromatase activity were also studied during the spring breeding season in male pied flycatchers *Ficedula hypoleuca*, a migratory species common in northern Europe. The pied flycatcher is a polyterritorial, hole-nesting bird that breeds preferentially in deciduous forests (Silverin, 1983a, b). Male pied flycatchers arrive in the breeding area and occupy territories before the females arrive. When a female settles in a territory, she starts nest building more or less immediately. Within just a day or two, the male is found to have drastically increased plasma T titers that remain elevated during the early part of the nest-building period (Silverin and Wingfield, 1982). Egg laying is followed by an early and extremely rapid gonadal regression starting during the later part of the incubation period so that males have basal T levels at the time of egg hatching (Silverin, 1975; Silverin and Wingfield, 1982; Silverin, 1983b).

Males were captured at two different stages of the breeding cycle: in late May/early June when they defend a secondary territory and in late June, when they had returned to their primary territory and were helping females in feeding the nestlings. The existence of a statistically significant drop in plasma T levels and in testicular mass was confirmed between these two stages. Aromatase activity was then measured by the radioenzyme assay in six brain regions: the telencephalon (Tel.), the anterior diencephalon (ant.Di., corresponding to the preoptic area and rostral hypothalamus), the posterior diencephalon (post.Di., including the ventromedial nucleus of the hypothalamus and the tuberal region), the optic

lobes (O.L.), the cerebellum (Cereb.), and the brain stem (B.S.); see Foidart et al., (1998) for a full description of these results.

As already reported in other species, the highest level of aromatase activity was observed in the telencephalon where enzyme activity clearly exceeded the activity detected in any other brain area including the anterior or posterior parts of the diencephalon (see *Figure 10-4a*). Low to nondetectable levels of enzyme activity were observed in the other brain regions. Aromatase activity per mg protein was approximately twice higher in the telencephalon than in the diencephalon, a difference that, given the large size of the telencephalon, translates into a 20-fold excess when total activities are computed for the entire area.

There was a very marked change in aromatase activity in some of the brain areas (*Figure 10-4a*); the activity was significantly higher in the territorial males than in males feeding nestlings in the anterior and posterior diencephalon. This difference was not present in the other brain regions including the telencephalon. These data therefore confirm the existence of seasonal changes in aromatase activity in parallel with changes in plasma T in some brain areas but not in others.

2.6.3 European Starlings

European starlings are widely distributed seasonal breeders that also show marked seasonal fluctuations in circulating T concentrations and reproductive behaviors (*Figure 10-4b*). In the spring, T and its metabolites act within portions of the diencephalon to regulate the pituitary-gonadal axis and activate courtship, including singing and copulation. Song in male starlings is critical for mate attraction during the breeding season (Eens, 1997); it is regulated by steroid-sensitive nuclei in the telencephalon and diencephalon (Ball et al., 2002). Outside the breeding season, T is low to undetectable in the plasma but males continue to sing at high rates (Eens, 1997). Singing outside of the breeding season might thus not be T-dependent or alternatively, singing when T is low might continue to be regulated by T due to an increased sensitivity of the brain to the action of the steroid. This increase in sensitivity could be mediated by changes in intracellular T metabolism leading to increased production of active or decreased production of inactive metabolites.

This hypothesis was tested by measuring the activity of T-metabolizing enzymes (aromatase, 5α-reductase, and 5β-reductase) in the diencephalon and telencephalon in every month throughout an annual cycle (Riters et al., 2001). In the anterior and posterior diencephalon, the highest aromatase actvity was observed in spring when this region is critical for courtship and copulation (*Figure 10-4c–e*). A different pattern of seasonal changes was observed in the telencephalon, where aromatase activity was highest and 5β-reductase activity was lowest throughout the winter months well prior to the reproductive season. This enzymatic balance presumably maximizes T-activity within this region during the winter (high production of the active metabolite, estradiol, and decreased production of the behaviorally inactive 5β-reduced metabolites). Although these data do not indicate whether the metabolic changes occur specifically within song nuclei, these findings are consistent with the idea that singing in male starlings outside the breeding season may be regulated by steroids despite the presence of low serum T concentrations, because brain sensitivity to these low levels is maximized by the pattern of T-metabolizing enzymatic activities.

In conclusion, it can be confidently stated at this point that T metabolism is exquisitely regulated during the annual cycle in the brain of songbirds and that these temporal changes present a high degree of neuroanatomical specificity. This makes it possible, in theory, to modulate specifically the action of T on a variety of behaviors. There are still many questions about the exact contribution provided by these metabolic changes to the control of the seasonal cycle in the behavior of songbirds.

3 Neurochemistry of the Song System

The chemical phenotype of the connections of the various song control nuclei is, as one would expect, based on the basic vertebrate pattern of brain organization and chemical neuroanatomy (Deutch and Roth, 2003). That is to say that amino acid transmitters mediate most connections among the song nuclei. Extrinsic

Figure 10-4

Seasonal changes in the activity of steroid metabolizing enzymes in the brain of songbirds. (a) Mean levels of aromatase activity (fmoles per mg protein per hour) observed in six parts of male flycatcher (*Ficedula hypoleuca*) brains that were either defending a secondary territory or feeding nestlings. * = $p < 0.05$; * = $p < 0.01$ by comparison with territory birds. Modified from the data in Foidart et al. (1998). (b) Changes in serum concentrations of T (a) and in the activity of aromatase (b), 5α-reductase (c), and 5β-reductase (d) in the telencephalon, anterior diencephalon, and posterior diencephalon of male starlings sacrificed each month from September to August. Data are mean ± SEM. Modified from the data in Riters et al. (2001)

projections from aceytlcholine and catecholamines to these nuclei modulate this ongoing amino acid transmission. In this section, we therefore start with a discussion of the projections mediated by excitatory and inhibitory amino acid transmitters.

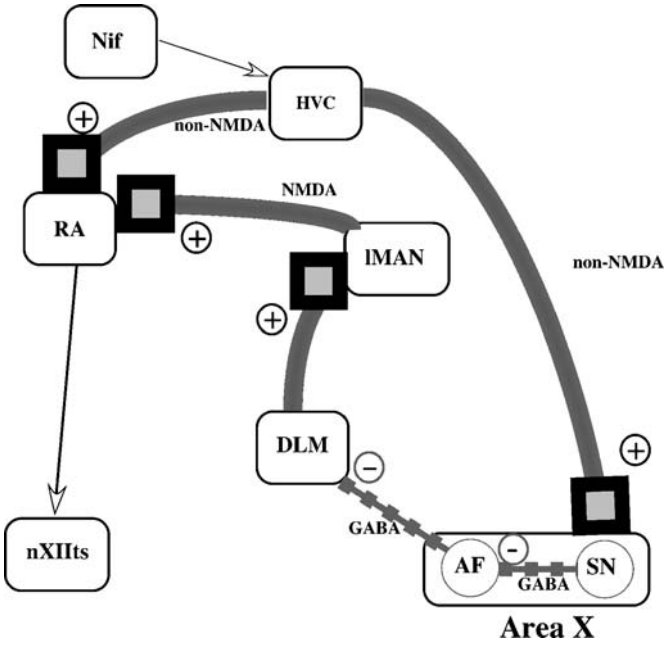
3.1 Amino Acid Transmitters

Most of our knowledge about the transmitters mediating synaptic transmission among the key forebrain song control nuclei are based on in vitro studies of brain slices derived from male zebra finches that contain subsets of the song nuclei (Sakaguchi et al., 1987; Kubota and Saito, 1991; Mooney and Konishi, 1991; Luo and Perkel, 1999a; Farries and Perkel, 2002). For example, studies of this type indicate that the synaptic contacts resulting from the HVC projections to area X and RA involve the release of the excitatory amino acid transmitters, glutamate and aspartate (Mooney and Konishi, 1991; Sakaguchi et al., 1992; Farries and Perkel, 2002; see *Figure 10-5*).

Similarly, synapses associated with the projection from lMAN to RA involve the release of glutamate and aspartate (Sakaguchi et al., 1992). The appropriate receptors for glutamatergic transmission are also present. The majority (21 out of 26) of the known amino acid transmitter receptor subunits have been subcloned in zebra finches and their distributions are mapped based on ISH histochemistry procedures that localize the mRNA on brain slices (Wada et al., 2004). These receptor subtypes exhibit a complex distribution in the forebrain song control system of male zebra finches with some subtypes more enriched in the song control areas than surrounding structures, whereas others are expressed at a lower level

Figure 10-5

Schematic presentation of the excitatory and inhibitory amino acid transmissions in the song system. Glutamatergic non-NMDA- and NMDA-mediated transmissions and GABAergic transmission are indicated by different symbols and associated with plus and minus signs for excitatory and inhibitory inputs, respectively. Two types of neurons present in area X use GABAergic transmission, the spiny neurons (SN), and the aspiny fast-firing (AF) neurons



(Wada et al., 2004). These studies of the mRNA expression reveal patterns similar to what has been described based on autoradiographic studies localizing specific glutamatergic-binding sites. This is the case for HVC in zebra finches which is outlined from the surrounding neostriatum by a lower density of NMDA glutamatergic receptors (Aamodt et al., 1992, 1995), based on autoradiographic labeling of receptors.

In vitro studies with specific receptor blockers have revealed diversity in the receptor types that mediate neurotransmission among the major projections of the song nuclei. For example, the projection from HVC to RA involves binding to receptors of the non-NMDA ionotropic subtype while the lMAN to RA projection involves those of the NMDA subtype. The HVC to area X excitatory synapse on spiny-type neurons in X is also mediated by non-NMDA ionotropic glutamatergic receptors (Ding et al., 2003; see *Figure 10-5*).

In contrast to these excitatory synapses, the projection from area X to DLM appears to use the major inhibitory amino acid transmitter, γ-amino butyric acid (GABA) (Luo and Perkel, 1999a, b). GABAergic cells have been localized in male and female zebra finches based on an immunohistochemical study of GABA (Grisham and Arnold, 1994). As would be expected for such a ubiquitous transmitter, GABA immunoreactive cells were found in all the song control nuclei studied, including HVC, area X, RA, MAN, and ICo. Most of these labeled cells are in all probability local interneurons. However, in the case of cells that project from area X to DLM there is now a convincing amount of evidence demonstrating that these are also GABAergic. Cell bodies staining positive for the GABA synthesizing enzyme glutamic acid decarboxylase (GAD) are present in X but only terminals are observed in the target nucleus DLM (Luo and Perkel, 1999b). These terminals in DLM are greatly reduced when X is subjected to excitotoxic lesions (Luo and Perkel, 1999b). In vitro studies of brain slices containing the X to DLM projection found strong inhibitory postsynaptic potentials resulting from the activation of afferents from X that were unchanged in the presence of glutamate antagonists but blocked by the $GABA_A$ receptor antagonist bicuculline methiodide (Luo and Perkel, 1999a). This inhibitory projection raised questions about the processing of auditory information in the anterior forebrain pathway that includes X, given that auditory input derived from HVC is measurable upstream in this pathway in X and downstream in lMAN (Kimpo et al., 2003).

How can this auditory coding be maintained when the projections through the pathway move from excitatory to inhibitory and then back to excitatory? Detailed studies by Farries and Perkel (2002) of the physiology of different cell types within X have led to the proposal that X has properties characteristic of the mammalian striatum as well as the globus pallidus. Farries and Perkel propose that there are two inhibitory synapses between HVC and DLM outputs that ultimately result in an excitatory signal from HVC to DLM. HVC stimulates spiny neurons in X, which would then inhibit the long projecting aspiny fast-firing cells (AF), reducing their spontaneous activity which would in turn transiently reduce tonic inhibition in DLM cells allowing them to fire (Farries and Perkel, 2002). In mammals, the spiny neurons are characteristic of the striatum but the long projecting AF neurons are more characteristic of the globus pallidus. Other chemical neuroanatomical studies are consistent with the idea that although area X is essentially striatal in nature some cell groups do have pallidal characteristics (Carrillo and Doupe, 2004). In any case, this hypothesis requires further testing to be confirmed in detail (Perkel, 2004), but there is no question that a complex inhibitory projection is present from HVC to X to DLM.

The situation for interneurons within HVC is complex and a clear picture is just emerging. Although these interneurons clearly use amino acid transmitters, their transmitter phenotype does not distinguish different cell types. Rather the identity of calcium-binding proteins expressed by the interneurons seems to be a key variable (Wild et al., 2005). Double and triple-label studies using antibodies against paralbumin, calbindin, and calretinin indicate that long projecting cells to area X or HVC in male zebra finches tend not to express calcium-binding proteins (Wild et al., 2005). Some interneurons tend to express two or three calcium-binding proteins and these cells tend to have a fast-spiking physiological profile while other interneurons that tend not to express any calcium-binding protein tend to have a slow-spiking profile (Wild et al., 2005). The story emerging from this work and other physiological studies is that HVC contains a microcircuit of X and RA projecting cells whose activity is co-ordinated by interneurons so that motor output to RA and some sort of efferent copy to the X and the anterior forebrain circuit can be co-ordinated (Mooney and Prather, 2005).

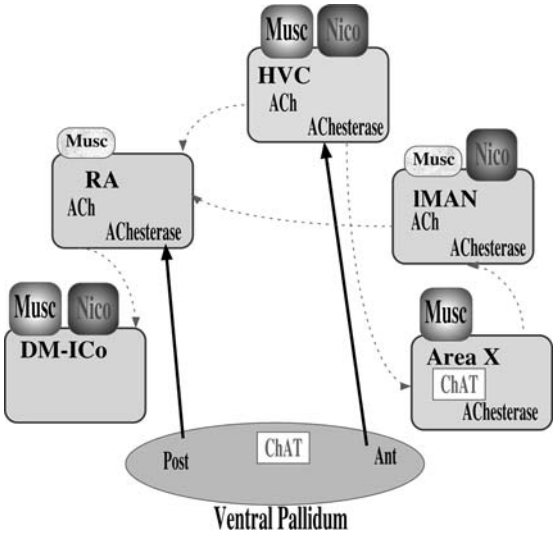
3.2 Localization of Catecholamines and Acetylcholine

3.2.1 Acetylcholine

Another feature of the neurochemistry of the song system is that amine transmitters such as acetylcholine and the catecholamines are synthesized in brain areas outside the song system per se, but these areas send long distance projections that modulate ongoing neural activity. This pattern is again in common with the basic vertebrate pattern of brain organization. In the case of acetylcholine, there is intrinsic synthesis in some areas such as area X of the medial striatum and in other cases such as HVC, RA, and lMAN acetylcholine is synthesized outside the nucleus in brain areas that project to these song control nuclei (Li and Sakaguchi, 1997; *Figure 10-6*).

Figure 10-6

Schematic presentation of cholinergic innervation and neurotransmission in the song system. Although most song control nuclei contain acetylcholine (ACh), acetylcholine esterase (AChesterase), and the corresponding muscarinic (Musc) and nicotinic (Nico) receptors, evidence for ACh synthesis (i.e. presence of Choline acetyl transferase, ChAT) is only available for area X. Large and small symbols for receptors indicate that a receptor density is respectively higher or lower in the nucleus than in the surrounding tissue. Tract-tracing studies have indicated that the Ach is present in HVC, and RA is produced in the anterior and posterior parts of the ventral pallidum (VP), respectively



Arnold and collaborators originally demonstrated that several song control nuclei, including HVC, RA, lMAN, and X can be identified in zebra finch brain sections by the presence of markers of cholinergic transmission such as the enzyme involved in transmitter degradation, acetylcholinesterase, or the acetylcholine receptors of the muscarinic subtype (Ryan and Arnold, 1981). Subsequent autoradiographic work using a ligand that is not subtype selective identified muscarinic receptors in the song nuclei of European starlings (Ball et al., 1990; Bernard et al., 1993; Ball et al., 1994) and various nicotinic receptor receptor subtypes in similar brain area of male zebra finches (Watson et al., 1988). Again, as was observed in the case of glutamate receptors, the pattern of receptor density was such that in some cases such as RA the density appeared lower than the surrounding arcopallium, whereas in other cases such as area X the density of muscarinic receptors was higher than the surrounding medial striatum (Ryan and Arnold, 1981; Ball et al., 1990, 1994). Subsequent studies of the synthesizing enzyme choline acetyltransferase and the degrading enzyme acetylcholinesterase indicated

that most of the song nuclei receive cholinergic input, but clear evidence for intrinsic synthesis was only apparent in X (Zuschratter and Scheich, 1990). Tract tracing studies combined with the ICC localization of choline acetyltransferase identified the ventral pallidum (VP) as the source of cholinergic input to HVC and RA, but could not identify the source of the innervation of lMAN (Li and Sakaguchi, 1997). VP appears homologous to the mammalian basal forebrain cholinergic system that includes the nucleus Basalis of Meynert (Li and Sakaguchi, 1997).

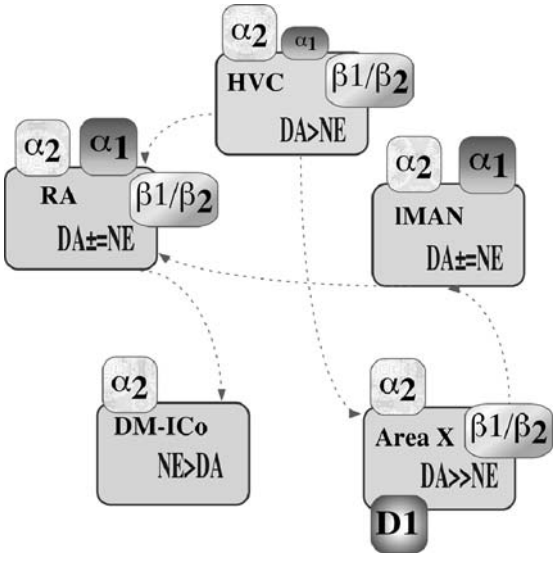
3.2.2 Catecholamines

A prominent catecholaminergic innervation of the song control system has been demonstrated in several songbird species, most notably zebra finches by the presence of fibers immunoreactive for the catecholamine synthesizing enzymes tyrosine hydroxylase (TH; Bottjer, 1993; Soha et al., 1996) and/or dopamine beta-hydroxylase (Mello et al., 1998). Similarly, ICC studies of TH in male canaries have found that the boundaries of HVC and RA can be defined in a manner in agreement with Nissl-defined boundaries by a higher density of fibers immunoreactive for tyrosine hydroxylase compared to the surrounding neostriatum (Appeltants et al., 2001).

High concentrations of NE and DA have accordingly been measured in the song control nuclei of zebra finches (Barclay and Harding, 1988; 1990; Sakaguchi and Saito, 1989) (*Figure 10-7*). Autoradiographic studies have revealed binding sites for [^{3}H] RX821002, a ligand specific for α_2-adrenergic receptors, to be enriched in forebrain song control nuclei of this species (Riters and Ball, 2002). In European starlings, high densities of noradrenergic receptors of the α_2 and $\beta1/\beta2$ subtypes are also present in several song control nuclei (HVC, RA, and area X; Ball, 1994; Ball et al., 1994; Riters et al., 2002) and high densities of dopamine

Figure 10-7

Schematic presentation of catecholaminergic innervation and neurotransmission in the song system. The relative concentration of dopamine (DA) and norepinephrine (NE) in each nucleus is illustrated by the >, <, or = signs. The presence of dopaminergic (D1) or noradrenergic (α1, α 2, β1, and β2) receptors is also indicated for each nucleus. Large and small symbols indicate a receptor density that is respectively higher or lower in the nucleus than in the surrounding tissue (based mainly on the data in Ball, 1990, 1994; Barclay and Harding, 1988; 1990; Casto and Ball, 1994; Riters et al., 2002)

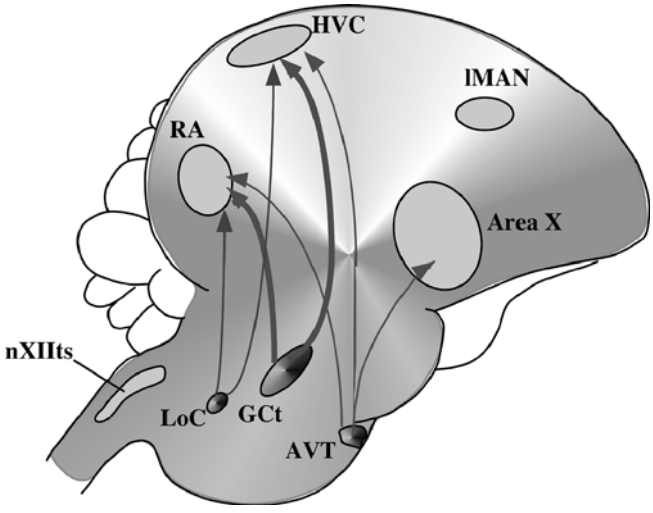


D1 receptors have been described in area X of the medial striatum in the same species (Casto and Ball, 1994). In these cases, boundaries of these song control nuclei can be defined based on the high receptor densities compared to the surrounding brain area that are consistent with Nissl-defined boundaries.

The cells that synthesize catecholamines and give rise to the catecholaminergic innervation of the song control nuclei have been investigated by tract-tracing studies in canaries (*Figure 10-8*). HVC receives dopaminergic inputs mainly from the mesencephalic central gray (GCt; group A11 in the nomenclature of

Figure 10-8

Generalized view of the songbird vocal control system schematically illustrating the catecholaminergic innervation of the song control nuclei (based on the data in Lewis et al., 1981; Appeltants et al., 2000, 2002a)



Dahlström and Fuxe 1964; Reiner et al., 1994, for a review of this nomenclature use in birds) and to a lesser extent from the ventral tegmental area (VTA; formally, area ventralis of Tsai; group A10) and noradrenergic inputs from the complex of the locus coeruleus (Loc; group A6) (Appeltants et al., 2000). Similarly, dopaminergic inputs to RA come mostly from the A11 (mesencephalic central gray) and A10 (VTA) cell groups, and noradrenergic inputs come from the locus coeruleus and subcoeruleus (A6) (Appeltants et al., 2002a). In contrast, area X, a key nucleus of the rostral forebrain pathway controlling song learning, but not song production, seems to receive CA inputs exclusively from VTA (Lewis et al., 1981). These data thus suggest that different populations of CA cell groups could control the motor and anterior forebrain pathways.

3.2.3 Neuropeptide Systems

Of the many neuropeptides that are known to be active as neurotransmitters or neuromodulators in the brain, only a subset has been investigated in the song control system. In most cases, these neuropeptides have been localized to the song nuclei via immunohistochemistry, but we know little about the receptors they employ or whether the peptides are synthesized within the song nuclei or by cells outside the nuclei that project to these brain regions.

The neuropeptide methionine (Met) enkephalin was shown to label several song nuclei in zebra finches and two other songbird species, the song sparrow and the European starling (Ryan et al., 1981; Ball et al., 1988). Vasoactive intestinal polypeptide (VIP) has also been found to be widely localized in forebrain song

control nuclei including HVC and lMAN (Ball et al., 1988) (Bottjer and Alexander, 1995; Ball and collaborators (1988) similarly showed that several neuropeptides (Met-enkephalin, cholecystokinin, substance P) are distributed in a unique manner in the song control nuclei of two songbird species, the song sparrow and the European starling. Neuropeptides such as VIP or Met-enkephalin are also specific markers for HVC and RA in zebra finches, and the volumes defined by these peptidergic innervations match closely the volumes defined by more traditional histological methods (Ball et al., 1995a).

Neurochemistry has also been used to demonstrate the existence of a sex difference in the nucleus interfacialis (Nif) that cannot be observed by traditional histological methods. Nif specifically projects to HVC and is considered as part of the motor circuit of the song control system. Nif was originally identified by retrograde tract tracing from HVC (Nottebohm et al., 1982), but it is not readily visible in Nissl stained sections. It is however characterized by an accumulation of Met-enkephalin and VIP-immunoreactive fibers and the volume occupied by these immunoreactive fibers is larger in males than in females (Ball et al., 1995b).

Several of these neurochemical markers of song control nuclei are neuropeptides (e.g., VIP, met-enkephalin) that are not contained in neurons located within HVC or RA but are present in fibers originating from neurons, whose location has not been identified. Given that the song nuclei defined by these fibers are different in males and females, these projections and the cell groups from which they originate may also be sexually dimorphic. Studies combining retrograde tract tracing with ICC should be carried out to identify these sexually dimorphic cell groups.

The distribution of vasotocin-immunoreactive (VT-ir) fibers has been studied in detail by ICC in the brain of the canary (Kiss et al., 1987; Voorhuis et al., 1990), zebra finch (Voorhuis and de Kloet, 1992) and Junco (*Junco hyemalis*; Panzica et al., 1999). VT-ir fiber endings are observed in broad areas of the telencephalon, but in particular a large supply of VT-ir fibers is present around RA (Kiss et al., 1987; Panzica et al., 1999) where they correspond to the presence of vasotocin-binding sites (Voorhuis et al., 1990). The mesencephalic song control nucleus ICo is also labeled by VT-ir fibers in both oscines and nonoscine birds.

3.3 Functional Studies of Neurotransmitter Systems

There is still much to be learned about the functional interactions among the transmitter systems that mediate neural transmission in the song control circuit. We highlight some major observations in this section. As would be expected based on the wealth of data in other systems, excitatory amino acid transmission acting via NMDA receptors is involved in the song learning process (Nordeen and Nordeen, 2004). For example, administering the NMDA receptor anatagonist, AP5 to nucleus lMAN just before a song tutoring session will significantly attenuate the number of songs reproduced by the pupil (Basham et al., 2004). Treatment on alternate days in which tutoring does not occur or infusing the compound to nonsong control regions has no effect (Basham et al., 2004). There are developmental changes in NMDA receptor subunits that correlate with the opening and closing of the sensitive period for song learning (Nordeen and Nordeen, 2004). However, experimental manipulations (such as early social deprivation or premature testosterone treatment) can modify the timing of the ability to learn song but they do not change the developmental progression of NMDA receptor subunits in parallel so these changes cannot in and of themselves explain the closing of the sensitive period for song learning (Nordeen and Nordeen, 2004). Consistent with the notion that excitatory amino acid transmission plays a potentially important role in the song learning process is the description of NMDA-dependent long term potentiation (LTP) in nucleus area X both in juvenile and in adult zebra finches (Ding and Perkel, 2004).

Specific modulatory roles for ascending amine transmitter systems on ongoing amino acid transmission have also been described. We will focus here on two specific examples, one involving cholinergic mechanisms and the other involving the noradrenergic system. Several forebrain nuclei in the song control circuit including HVC exhibit remarkable patterns of auditory responsivity. In anesthetized birds, cells in song nuclei in the anterior forebrain pathway are tuned to fire at high rates only to sounds of the bird's own song (Margoliash and Konishi, 1985; see Theunissen et al., 2004 for a review). These responses, though, are gated while birds are awake; they may or may not exhibit the responses depending on the particular

behavioral conditions (Schmidt and Konishi, 1999). While they are asleep they always exhibit such responses (Dave et al., 1998). This gating of auditory responsiveness to the bird's own song in HVC appears to be modulated by basal forebrain cholinergic projections to HVC (Shea and Margoliash, 2003). The administration of muscarinic cholinergic agonists to HVC was found to block the expression of neural responses to sounds from the bird's own song and this could be reversed by the administration of antagonists (Shea and Margoliash, 2003). Similarly, stimulation of the VP, the assumed source of the relevant cholinergic input also blocked physiological responses to these sounds (Shea and Margoliash, 2003).

Ascending noradrenergic projections to the song system have been implicated in the regulation of social modulation of gene expression in the song control circuit (Castelino and Ball, 2005). The act of singing drives the expression of an immediate early gene ZENK (acronym derived from homologues in other species; Mello et al., 1992) in several forebrain nuclei of the song control system in male zebra finches (Jarvis and Nottebohm, 1997). Zebra finch song is produced in different social contexts that result in dramatically different degrees of ZENK expression in song control nuclei (Jarvis et al., 1998). Motor-driven ZENK expression levels in song control nuclei are high as a result of solo song and much lower after male or female-directed song (Jarvis et al., 1998). This effect is most apparent in area X of the medial striatum where there is a qualitative shift in the pattern of gene expression from the solo/undirected context (very high expression) to the directed context (much lower expression; Jarvis et al., 1998). Systemic administration of the noradrenergic neurotoxin DSP-4 was found to result in a significant increase in the number of ZENK expressing cells in area X of male finches engaged in directed song (Castelino and Ball, 2005). The increase in ZENK expression after the administration of a neurotoxin that depletes noradrenergic concentrations in the song system supports the hypothesis that the noradrenergic system plays a key role in downregulating ZENK expression during directed song (Castelino and Ball, 2005).

Some of the ideas expressed in this section will be further developed in the next section, where steroid–neurotransmitter interactions are discussed.

4 Hormone–Neurotransmitter Interactions

4.1 Hormone Effects on Neurotransmitter Systems

As mentioned above, in songbirds, catecholamines and their synthetic enzymes are present at high concentrations in brain nuclei that control song (Barclay and Harding, 1988; Sakaguchi and Saito, 1989; Barclay and Harding, 1990; Bottjer, 1993; Soha et al., 1996; Mello et al., 1998; Appeltants et al., 2001). The boundaries of several song control nuclei can be defined by high densities of α_2-adrenergic (Ball, 1994; Ball et al., 1994) or dopaminergic (Casto and Ball, 1994) receptors.

Recent work has identified two brain sites outside the song control system proper where steroids could act to modify song production. The POM that regulates appetitive aspects of male sexual behavior in a variety of species (Panzica et al., 1996; Balthazart et al., 1998), including starlings (Riters and Ball, 1999; Riters et al., 2000), and the catecholaminergic nuclei of the mesencephalon and pons that send afferent projections to the song control nuclei. The anatomical connections between these brain areas and the neural circuit that controls singing are still poorly understood. No direct projection between the POM and the song control nuclei has been described to this date. Given the large number of tract-tracing studies that were previously carried out, it appears probable that such connections should have been detected if they exist. Available evidence suggests however one indirect link between these structures. It has been recently shown that in Japanese quail, the aromatase-immunoreactive cells of the POM massively project to the mesencephalic central gray (Absil et al., 2001). In canaries, dopaminergic cells of the central gray are known to be the major source of catecholaminergic inputs to HVC (Appeltants et al., 2000) and RA (Appeltants et al., 2002a). Recent work in starlings indicates that projections from the POM to central gray are also present similarly to what has been described in quail (Riters and Alger, 2004). These projections could therefore represent the anatomical substrate that coordinates the actions of POM and of song control nuclei on song production.

Interestingly, the prominent catecholaminergic innervation of the song control nuclei is modulated by steroids. This is demonstrated by ICC studies of tyrosine hydroxylase in canaries (including sex differences

detected in HVC and RA; Appeltants et al., 2001; increases in TH immunoreactivity following treatment with exogenous testosterone; Appeltants et al., 2003), by the presence of a steroid modulation of NE and DA baseline levels and turnover (Barclay and Harding, 1988, 1990), and by the observation that the density of α_2 noradrenergic receptors in HVC and RA varies seasonally in starlings (see later).

This steroid modulation of catecholaminergic inputs represents one possible way that steroids may influence song learning (Marler et al., 1988; Soha et al., 1996) and production (Harding et al., 1983; Bottjer and Johnson, 1997; Schlinger, 1997). Indeed functional interactions between steroids and catecholamines have been reported in many vertebrate species, and catecholamines are involved in the control of a variety of steroid-regulated reproductive behaviors (Balthazart and Ball, 1989; Blaustein and Olster, 1989; Barclay et al., 1991; Blaustein et al., 1995; Barclay et al., 1996). Thus, it has been speculated that steroids may influence song control nuclei and singing activity at least in part by a direct action at the level of catecholaminergic structures. However, the roles of NE and DA and of their specific receptors located within the song system are not well understood.

The specific function of the catecholaminergic afferent inputs to the song system has not been studied in great detail. In zebra finches, systemic injections of DSP-4, a specific noradrenergic neurotoxin that preferentially destroys catecholaminergic innervation of telencephalic regions (Fritschy and Grzanna, 1989; Zaczek et al., 1990) decreases male courtship behavior including female-directed singing (Barclay et al., 1991, 1996). This effect appears to result from attention deficits rather than from impairments of the motor aspects of song because in DSP-4-treated birds the latency to initiate singing was increased, but once song begun it was quite normal.

In female canaries, the pharmacological depletion of central norepinephrine levels obtained by injection of DSP4 decreases the incidence of copulation solicitation displays that are produced in response to the playback of sexually stimulating male songs (Appeltants et al., 2002b). This effect of DSP4 was observed in conditions when the sexually stimulating songs were partly masked by nonstimulating wild canary songs or heterospecific songs, but not when they were masked by simpler signals such as white noise. These data therefore suggest that central noradrenergic inputs (presumably to auditory areas such as Field L or to HVC) modulate sexual responsiveness of female canaries by affecting the auditory processing of the relevant information contained in sexually stimulating male songs.

Dave and colleagues (1998) also demonstrated that NE acting in HVC regulates in a gate-like fashion the auditory responsiveness of efferent neurons to RA. Studies of the modulation of the neural activity in the anterior forebrain pathway [area X, dorsolateral nucleus of the anterior thalamus (DLM) and nucleus magnocellularis of the anterior neostriatum (lMAN)] as a function of social context have also implicated ascending catecholaminergic projections (Jarvis et al., 1998; Hessler and Doupe, 1999b) as being responsible for the contextual regulation.

These studies suggest that catecholamines have an important role in the control of certain aspects of song behavior but there are still major lacunae in our knowledge about the chemical neuroanatomy of this system in songbirds.

One possibility is that NE is involved in differences in song expressed by males within and outside the context of reproduction. In a reproductive context, male song directed toward females is critical for mate attraction (Catchpole and Slater, 1995). Outside the context of reproduction, males often sing less and do not direct song toward females, or use song for purposes of dominance or territory maintenance (Wiley et al., 1993; Catchpole and Slater, 1995). NE levels within some song nuclei are positively correlated with courtship singing in male zebra finches (Barclay et al., 1991), and selective neurotoxic lesions of noradrenergic neurons produce specific behavioral deficits in male courtship song displays (Barclay et al., 1991; 1996), indicating a role for NE in song sung within a reproductive context. Song behavior is related to the activity of testosterone (T) and its metabolites, presumably acting within the song control system (Arnold, 1981). Estrogenic T metabolites, known specifically to increase female-directed courtship song in male zebra finches (Walters et al., 1991), increase NE turnover in the song system (Barclay and Harding, 1988; 1990), suggesting that the role of NE in song relates to T activity.

In contrast to zebra finches, a species that does not restrict breeding to a particular season, many temperate-zone songbirds display seasonal variation in T concentrations, song behavior, and reproductive activities (Wingfield and Farner, 1993; Ball, 1999). Changes in T are associated with changes in the context

in which males will sing. During both the breeding and nonbreeding seasons, when T is high and low respectively, song can be observed during intermale aggression and in males singing alone; however, only during the breeding season male song is observed to play a direct role in mate attraction (Wingfield and Farner, 1993; Catchpole and Slater, 1995; Eens, 1997; Ball, 1999).

The studies in zebra finches discussed above suggest that NE plays a role in the control of courtship song and that T (or its metabolite, estradiol) mediates this relationship. If this relationship exists, then in seasonally breeding birds, differences might be expected in NE or NE receptors in birds during the breeding season as compared with outside the breeding season. In agreement with this idea, T regulates concentration of NE and the density of its receptors in specific brain areas of at least one seasonally breeding bird (a nonsongbird, the Japanese quail; Balthazart and Ball, 1989; Balthazart et al., 1992a). These data suggest specifically that seasonal changes in T might be associated with variation in noradrenergic transmission within the brains of seasonally breeding birds. Several of these catecholaminergic cell groups express nuclear receptors for sex steroids (Maney et al., 2001) and could therefore represent alternative sites where steroids could act in the brain to control aspects of singing behavior.

4.1.1 Seasonal Changes in Alpha-Two Adrenergic Receptor Densities

In songbirds also, T can regulate the activity of catecholamines through the regulation of receptors. Consistent with this idea are studies of T and α_2-adrenergic receptors in songbirds. In seasonally breeding male starlings, seasonal changes in the density of α_2-adrenergic receptors were identified within HVC and RA (Riters et al., 2002), that correspond with changes in courtship song. These changes mirrored both seasonal changes in T concentrations and changes in HVC and RA volume. T-dependent seasonal decreases in NE within the song system might result in an upregulation of α_2-adrenergic receptors in fall, and a downregulation of receptors in spring, a pattern that would be consistent with the seasonal changes in density observed in starlings.

α_2-adrenergic receptors were least dense in spring when song is important for a male to attract a female. In contrast, during molt, fall, and winter nuclei were smallest, and α_2-adrenergic receptors were densest when males were likely not singing (during molt; Eens, 1997), or when song is not directly sung to attract mates for immediate reproduction (Feare, 1984; Eens, 1997). These data suggest that changes in α_2-adrenergic receptors might reflect differential NE involvement in female-directed spring song compared with undirected fall song, with NE possibly regulating the attention a male directs toward a potential mate during female-directed song, as proposed previously in zebra finches (Barclay et al., 1996).

A general concept emerging in the study of hormones and behavior is that the steroids may regulate brain morphology in areas important for reproductive behaviors not only by acting directly on cells in the brain area of interest, but also by acting indirectly (i.e., transsynaptically) via cells at a distant brain site that then projects to the site of interest and modifies neural activity (Beyer, 1987; Balthazart and Ball, 1995; 1998). This mode of action is well illustrated by studies of sex steroid feedback on the gonadotropin-releasing hormone system (GnRH). Sex steroids are known to exert negative feedback on GnRH immunoreactive cells but these neurons do not contain detectable levels of receptors for sex steroid hormones. Rather, the effects of steroids on these neurons are mediated by changes in the activity of peptidergic (e.g., opioids) and catecholaminergic (e.g., norepinephrine) inputs to the GnRH cells (Barraclough and Wise, 1982; Weiner et al., 1988; Herbison, 1998; Kelly and Ronnekleiv, 2002).

The presence of AR and/or ERα in the neural network mediating the learning, perception, and production of song in oscine songbirds has often been taken as evidence indicating that steroids control singing behavior by binding directly to these receptors. However, steroid receptors are also found in the catecholaminergic cell groups (Maney et al., 2001) that are known to project to the song control nuclei such as the locus coeruleus, the substantia nigra, and the ventral tegmental area (Lewis et al., 1981; Burd et al., 1986; Appeltants et al., 2000, 2002a) so that steroids could also affect song by modulating these catecholaminergic inputs. There would therefore be a direct action of steroids in the telencephalic song control nuclei and in an indirect action through the modulation of catecholaminergic inputs.

These indirect effects of steroids could themselves reflect two different modes of actions. Steroids are known to modify the release and thus turnover of NE and DA in song control nuclei. This possibly results from a direct nongenomic action at the level of the catecholaminergic terminals. Alternatively, steroid hormones could modify the expression of catecholamine synthesizing enzymes by acting genomically on catecholaminergic perikarya. This mode of action is mainly suggested by the observation that the treatment of castrated male canaries with testosterone increases the density of tyrosine hydroxylase immunoreactive fibers in HVC and RA (Appeltants et al., 2003). This change in immunoreactivity is likely to reflect changes in concentration of the enzyme that most likely are caused by increases in transcription of the corresponding protein. This effect thus has to take place at the level of the catecholaminergic perikarya that are at the origin of the tyrosine hydroxylase immunoreactive fibers, which innervate the song control nuclei. The presence of steroid receptors in the nuclei that contain these perikarya (Maney et al., 2001) clearly supports this mode of indirect action for steroids.

Taken together, the available data suggest that seasonal variation and/or steroid-induced changes in catecholaminergic afferent input into the song control system are the important factors regulating changes in the morphology of the vocal control system and in vocal learning or production.

5 Conclusion

In this review, we have tried to highlight the many facets of the neurochemistry and the neuroendocrinology of song and the song control circuit. We have focused on the role of steroid hormones in regulating forebrain nuclei in the song control circuit involved in the learning and production of song. This system is one of the few clear examples in the vertebrate brain where steroid hormones have well-documented and dramatic effects on the morphology and physiology of pallial structures. Steroids undoubtedly have important effects on pallial structures in other vertebrate taxa, but it may well be the case that fundamental insights will be gleaned in species exhibiting the most obvious effects such as songbirds.

11 Sex Differences in Neurotransmitters and Behavior: Development

M. M. McCarthy, PhD

1 Introduction 460

2 Historical Overview 460
2.1 Organizational/Activational Hypothesis 461
2.2 The Sensitive Period 462
2.2.1 Is There a Sensitive Period in Humans? 463
2.3 Organizational Hypothesis—Revised 463
2.4 Sex Differences Versus Hormonally Modulated Endpoints 464
2.5 The Aromatization Hypothesis 464

3 Morphometric Sex Differences in the Brain 465
3.1 Morphometric Sex Differences Correlate with Sex Differences in Physiology and Behavior 465

4 Sexual Differentiation of Sex Behavior 466
4.1 Masculinization, Defeminization, and Feminization 466
4.2 Prostaglandin E2 Mediates Behavioral Masculinization of Sex Behavior 467
4.3 Other Factors Contribute to Masculinization and Defeminization 469
4.4 The Sexually Dimorphic Nucleus of the Preoptic Area Does Not Correlate with Masculinization of Behavior 470
4.4.1 The SDN-POA Illustrates General Principles of Morphometric Sex Differences 470

5 Sexual Differentiation of Gonadotropin Secretion 471
5.1 A Neuroanatomical Circuit for Sex Differences in Positive Feedback 472
5.2 Are Sex Differences in Astrocyte Morphology Relevant to Positive Feedback? 473

6 Sexual Differentiation of Cognition 474
6.1 What is the Evidence of Sex Differences in the Hippocampus? 475

7 Sexual Differentiation of Stress and Anxiety 477

8 Evidence for Sexual Differentiation of the Human Brain 477

9 Why is It Important to Study Sexual Differentiation of the Brain? 479

10 Conclusions and Future Directions 479
