Biosafety: Guidelines for Working with Pathogenic and Infectious Microorganisms

One of the most important emerging technologies used by microbiologists and other life scientists and laboratory workers that handle pathogenic and infectious agents is the technology that manifests in what is collectively referred to as biosafety. Biosafety measures designed to ensure the safety of laboratory workers include the use of various primary and secondary barriers, many of which are due to the advent of new technologies in the fields of material science and engineering. Persons carrying out the protocols in this manual may encounter potentially hazardous materials such as pathogenic and infectious biological agents, as well as toxic chemicals and carcinogenic, mutagenic, or teratogenic reagents (see *UNIT 1A.3*). In the case of biological agents, it has long been recognized that laboratory workers can acquire infections from the agents they manipulate thus making the very nature of their work an occupational hazard. Bacterial agents cause the most commonly acquired laboratory infections but pathogenic agents belonging to all categories of microorganisms can cause infections.

New biosafety technologies and associated evolving guidelines have emerged to significantly improve ways to safely handle microbiological material. In addition, a better understanding of the risks associated with various manipulations of many agents transmissible by different routes has facilitated our ability to apply appropriate biosafety practices to specific laboratory arenas. As this knowledge base grows and new biosafety technologies emerge, evolving safety guidelines will continue to benefit laboratory workers. A combination of engineering controls, management policies, work practices and procedures, as well as medical interventions, collectively defines these safety guidelines.

Several biosafety levels, described in this unit, have been developed for microbiological and biomedical laboratories to provide increasing levels of personnel and environmental protection. *UNIT 1A.2* will provide information related to biosafety practices associated with potential agents of biocrime and biowarfare. *UNIT 1A.3* will provide guidelines for the safe use of hazardous chemicals.

It is important to note that most governments regulate the use of biohazardous materials. Therefore, it is essential that they be used in strict accordance with local and national regulations (see *APPENDIX 1B*). Cautionary notes are included in many instances throughout the manual, and some specific guidelines are provided below (and in references therein). However, we emphasize that users must proceed with the prudence and precautions associated with good laboratory practice, under the supervision of personnel responsible for implementing laboratory safety programs at their institutions. Guidelines for the safe use of radioisotopes are presented in *APPENDIX 1C*.

Precautions described in this unit should be applied to the routine handling of viable pathogenic microorganisms, as well as all human-derived materials, because they may harbor dangerous pathogens such as human immunodeficiency virus (HIV), hepatitis B virus (HBV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and a host of bacterial pathogens. In addition to the guidelines provided herein, experimenters can find a wealth of information about handling infectious agents in the appropriate government publications (see Literature Cited and *APPENDIX 1B*).

Current Protocols in Microbiology (2005) 1A.1.1-1A.1.8

GENERAL BIOSAFETY GUIDELINES

Routine Precautions When Working with Biohazards

The following practices are recommended for all laboratories handling potentially dangerous microorganisms, whether pathogenic or not:

1. Decontaminate all work surfaces after each working day using an appropriate disinfectant. Decontaminate all spills of viable material. See discussion under Disinfectants for Biohazards.
2. Decontaminate all liquid or solid wastes that have come in contact with viable material.
3. Do not pipet by mouth.
4. Do not allow eating, drinking, smoking, or application of cosmetics in the work area. Do not store food in refrigerators that contain laboratory supplies.
5. Wash hands with disinfectant soap or detergent after handling viable materials and before leaving the lab. Do not handle telephones, doorknobs, or other common utensils without disinfecting hands.
6. When handling viable materials, minimize creation of aerosols.
7. Wear lab coats (preferably disposable) when in work area, but do not wear them away from the work area.
8. Wear disposable latex gloves when handling viable materials. These should be disposed of as biohazardous waste. Change gloves if they are directly contaminated.
9. Control pest populations. Windows in the lab that can be opened must be equipped with screens to exclude insects.
10. Use furniture that is easy to clean—i.e., with smooth, waterproof surfaces and as few seams as possible.
11. Keep biohazard waste in covered containers free from leaks. Use orange bags or red biohazard bags (or other appropriate color in accordance with local regulations) as required by institutional procedure. Autoclave and dump hazardous waste without undue delay.

See discussion under Disposal of Biohazards (below) for more information.

Disinfectants for Biohazards

Major laboratory suppliers sell disinfectants based on quaternary ammonium compounds that are acceptable for routine biohazard decontamination (see *SUPPLIERS APPENDIX*). These include Roccal (Baxter), Vesphene II (Fisher), and industrial disinfectants such as concentrated Lysol. Additionally, 10% chlorine bleach may also be used for decontamination. An antimicrobial liquid soap (e.g., Vionex; Fisher) should be provided in a dispenser near the sink so that no one need handle the outside of the container to use it.

Disposal of Biohazards

Most institutions have defined procedures for disposal of biohazardous waste, but the following are common to all of these systems:

1. All contaminated material should be placed in autoclavable bags, which should be contained in a plastic trash pail or wire frame. If large numbers of disposable pipets or other pointed instruments are being used, it may be necessary to double-bag the material. All major laboratory supply houses sell autoclavable biohazard bags. In some institutions it is necessary to color code the biohazard waste (e.g., orange bags

for less dangerous waste, red ones for suspected HIV-containing material). All of these bags are marked with the universal biohazard symbol.

2. At time of disposal, the bags are loosely closed (not completely sealed) with temperature-sensitive autoclave tape (also widely available from supply houses), placed in an autoclavable basin, and sterilized at 121°C. When the tape indicates that sterilization temperature has been achieved, it is then possible to dispose of the waste by ordinary means.
3. At many institutions, contaminated hypodermic needles, scalpels, broken glass, and other sharp objects must be disposed of separately. These must be placed in appropriate "sharps" containers (e.g., Baxter), which may be autoclaved when full.

BIOSAFETY LEVELS

For each biosafety level there are specific supervisory qualifications as assurance that laboratory workers are provided appropriate role models and knowledgeable mentors. Various types of specialized equipment are used to provide primary barriers between the microorganism and the laboratory worker. These range from disposable gloves and other personnel protective equipment to complex biosafety cabinets or other containment devices.

The laboratory director is specifically and primarily responsible for the safe operation of the laboratory. His/her knowledge and judgment are critical in assessing risks and appropriately applying these recommendations. The recommended biosafety level represents those conditions under which the agent can ordinarily be safely handled. Special characteristics of the agents used, the training and experience of personnel, and the nature or function of the laboratory may further influence the director in applying these recommendations.

The U.S. Centers for Disease Control and Prevention (CDC; see Internet Resources) defines four levels of biosafety, which are outlined below. Selection of an appropriate biosafety level for work with a particular agent or animal study (see Animal Facilities) depends upon a number of factors. Some of the most important are the virulence, pathogenicity, biological stability, route of spread, and communicability of the agent; the nature or function of the laboratory; the procedures and manipulations involving the agent; the endemicity of the agent; and the availability of effective vaccines or therapeutic measures.

Table 1A.1.1 provides a summary of recommended biosafety levels for infectious agents. For regulations and guidelines applicable outside of the U.S., please refer to *APPENDIX 1B* and Internet Resources.

NOTE: The following information has been adapted from *Biosafety in Microbiological and Biomedical Laboratories*, 4th Ed. (BMBL, 4th Ed.; GPO S/N 017-040-00547-4), which is published jointly by the U.S. Centers for Disease Control and Prevention (CDC) and National Institutes of Health (NIH), and is available online at *http://www.cdc.gov/od/ohs/biosfty/bmbl4/bmbl4toc.htm* (see Internet Resources for other online versions). Readers are strongly urged to review this publication prior to initiating any experiment outlined in this manual.

Biosafety Level 1 (BSL-1)

BSL-1 is appropriate for working with microorganisms that are not known to cause disease in healthy human humans. BSL-1 practices, safety equipment, and facility design and construction are appropriate for undergraduate and secondary

Table 1A.1.1 CDC Summary of Recommended Biosafety Levels for Infectious Agents[a,b]

Biosafety level	Agent characteristics	Practices	Safety equipment (primary barriers)[c]	Facilities (secondary barriers)
BSL-1	Not known to consistently cause disease in healthy adults	Standard microbiological practices	None required	Open bench-top sink
BSL-2	Associated with human disease, hazard from percutaneous injury, ingestion, mucous membrane exposure	Standard microbiological practices Limited access Biohazard warning signs "Sharps" precautions Biosafety manual defining any needed waste decontamination or medical surveillance policies	Class I or II biosafety cabinets (BSCs) or other physical containment devices used for all manipulations of agents that cause splashes or aerosols of infectious materials Laboratory coats and gloves Face protection as needed	Open bench-top sink Autoclave
BSL-3	Indigenous or exotic agents with potential for aerosol transmission; disease may have serious or lethal consequences	All BSL-2 practices Controlled access Decontamination of all waste Decontamination of lab clothing before laundering Baseline serum	Class I or II BSCs or other physical containment devices used for all open manipulations of agents Protective lab clothing and gloves Respiratory protection as needed	Open bench-top sink Autoclave Physical separation from access corridors Self-closing, double-door access Exhausted air not recirculated Negative airflow into laboratory
BSL-4	Dangerous/exotic agents which pose high risk of life-threatening disease, aerosol-transmitted lab infections; or related agents with unknown risk of transmission	All BSL-3 practices Clothing change before entering Shower on exit All material decontaminated on exit from facility	All procedures conducted in Class III BSCs, or Class I or II BSCs *in combination with* full-body, air-supplied, positive pressure personnel suit	All BSL-3 facilities plus: Separate building or isolated zone Dedicated supply and exhaust, vacuum, and decontamination systems Other requirements as outlined in the text

[a] Adapted from Biosafety in Microbiological and Biomedical Laboratories, 4th Ed. (GPO S/N 017-040-00547-4), available online at *http://www.cdc.gov/od/ohs/biosfty/bmbl4/bmbl4toc.htm*. Also see Internet Resources.

[b] The practices, and primary and secondary barriers required for a given biosafety level include those of the all lower levels, as well as the additional required practices, equipment, and/or facilities described for the BSL in question.

[c] See *http://www.cdc.gov/od/ohs/biosfty/bsc/bsc.htm* for more information concerning biological safety cabinets (BSCs).

educational training and teaching laboratories, and for other laboratories in which work is done with defined and characterized strains of viable microorganisms not known to consistently cause disease in healthy adult humans. *Bacillus subtilis*, *Naegleria gruberi*, infectious canine hepatitis virus, *Escherichia coli* K-12 (see BMBL for restrictions), and exempt organisms under the *NIH Recombinant DNA Guidelines* (*http://www4.od.nih.gov/oba/rac/guidelines/guidelines.html*) are representative of microorganisms meeting these criteria. Many agents not ordinarily associated with disease processes in humans are, however, opportunistic pathogens and may cause infection in

the young, the aged, and immunodeficient or immunosuppressed individuals. Vaccine strains that have undergone multiple in vivo passages should not be considered avirulent simply because they are vaccine strains.

BSL-1 represents a basic level of containment that relies on standard microbiological practices with no special primary or secondary barriers recommended, other than a sink for hand washing.

In this manual, when BSL-1 conditions are appropriate to the experiments described, the following note will appear in the unit introduction.

> *CAUTION: <organism name>* is a Biosafety Level 1 (BSL-1) organism. Such organisms are not known to consistently cause disease in healthy adult humans, and are of minimal potential hazard to laboratory personnel and the environment. Standard microbiological practices should be followed when working with these organisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*).

Biosafety Level 2 (BSL-2)

The facility, containment devices, administrative controls, and practices and procedures that constitute BSL-2 are designed to maximize safe working conditions for laboratorians working with agents of moderate risk to personnel and the environment. BSL-2 practices, equipment, and facility design and construction are applicable to clinical, diagnostic, teaching, and other laboratories in which work is done with the broad spectrum of indigenous moderate-risk agents that are present in the community and associated with human disease of varying severity. With good microbiological techniques, these agents can be used safely in activities conducted on the open bench, provided the potential for producing splashes or aerosols is low. Hepatitis B virus, HIV, *E. coli* O157:H7, the *Salmonella*, and *Toxoplasma* spp. are representative of microorganisms assigned to this containment level.

Biosafety Level 2 is also appropriate when work is done with any human-derived blood, body fluids, tissues, or primary human cell lines where the presence of an infectious agent may be unknown. Laboratory personnel in the United States working with human-derived materials should refer to the U.S. Occupational Safety and Health Administration (OSHA) *Bloodborne Pathogen Standard* (OSHA, 1991), available online at *http://www.osha.gov/pls/oshaweb/owadisp.show_document?p_table=STANDARDS&p_id=10051*, for required precautions. For guidelines and regulations appropriate to locations outside the U.S., please refer to *APPENDIX 1B* and Internet Resources.

Primary hazards to personnel working with these agents relate to accidental percutaneous or mucous membrane exposures, or ingestion of infectious materials. Extreme caution should be taken with contaminated needles or sharp instruments. Even though organisms routinely manipulated at Biosafety Level 2 are not known to be transmissible by the aerosol route, procedures with aerosol or high splash potential that may increase the risk of such personnel exposure must be conducted in primary containment equipment, or in devices such as a biological safety cabinet (BSC) or safety centrifuge cups. Other primary barriers should be used as appropriate, such as splash shields, face protection, gowns, and gloves.

Secondary barriers such as hand washing sinks and waste decontamination facilities must be available to reduce potential environmental contamination.

When BSL-2 conditions are appropriate to the organism under investigation, the following note is included in the unit introduction.

CAUTION: <organism name> is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

When BSL-2 conditions are appropriate due to the use of human-derived materials, the following note is included in the introduction.

CAUTION: Follow all appropriate guidelines and regulations for the use and handling of human-derived materials. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

Biosafety Level 3 (BSL-3)

BSL-3 is suitable for work with infectious agents, which may cause serious or potentially lethal diseases as a result of exposure by the inhalation route. This may apply to clinical, diagnostic, teaching, research, or production facilities in which work is done with indigenous or exotic agents with potential for respiratory transmission, and which may cause serious and potentially lethal infection. *Mycobacterium tuberculosis*, St. Louis encephalitis virus, and *Coxiella burnetii* are representative of the microorganisms assigned to this level. Primary hazards to personnel working with these agents relate to autoinoculation, ingestion, and exposure to infectious aerosols.

At BSL-3, more emphasis is placed on primary and secondary barriers to protect personnel in contiguous areas, the community, and the environment from exposure to potentially infectious aerosols (see Table 1A.1.1). For example, all laboratory manipulations should be performed in a BSC or other enclosed equipment, such as a gas-tight aerosol generation chamber. Secondary barriers for this level include controlled access to the laboratory and ventilation requirements that minimize the release of infectious aerosols from the laboratory.

When BSL-3 conditions are appropriate to the organism under investigation, the following note is included in the unit introduction.

CAUTION: <organism name> is a Biosafety Level 3 (BSL-3) pathogen. Follow all appropriate guidelines for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

When BSL-3 conditions are appropriate due to the use of human-derived materials, the following note is included in the introduction.

CAUTION: Follow all appropriate guidelines and regulations for the use and handling of human-derived materials. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

Biosafety Level 4 (BSL-4)

BSL-4 practices, safety equipment, and facility design and construction are applicable for work with dangerous and exotic agents that pose a high individual risk of life-threatening disease, which may be transmitted via the aerosol route, and for which there is no available vaccine or therapy. Agents with a close or identical antigenic relationship to Biosafety Level 4 agents also should be handled at this level. When sufficient data are obtained, work with these agents may continue at this or a lower level. Viruses such as Marburg or Congo-Crimean hemorrhagic fever are manipulated at Biosafety Level 4.

The primary hazards to personnel working with Biosafety Level 4 agents are respiratory exposure to infectious aerosols, mucous membrane or broken skin exposure to infectious

droplets, and autoinoculation. All manipulations of potentially infectious diagnostic materials, isolates, and naturally or experimentally infected animals, pose a high risk of exposure and infection to laboratory personnel, the community, and the environment.

The laboratory worker's complete isolation from aerosolized infectious materials is accomplished primarily by working in a Class III BSC or in a full-body, air-supplied, positive-pressure personnel suit. The BSL-4 facility itself is generally a separate building or completely isolated zone with complex, specialized ventilation requirements and waste management systems to prevent release of viable agents to the environment.

As of this printing, there are no experiments described in this manual which specifically require BSL-4 conditions.

ANIMAL FACILITIES

The CDC defines four biosafety levels for activities involving infectious disease work with experimental animals. These combinations of practices, safety equipment, and facilities are designated **Animal Biosafety Levels 1**, **2**, **3**, and **4**, and provide increasing levels of protection to personnel and the environment.

In this manual, when these conditions are necessary, a note is provided in the unit or protocol introduction with the following format, where *x* is the appropriate ABSL.

> *CAUTION:* Protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals. This experiment requires Animal Biosafety Level *x* (ABSL-*x*) conditions. Follow all appropriate guidelines for the use and handling of infected animals. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

For more information, refer to the Section IV of the BMBL, 4th Ed., available online at *http://www.cdc.gov/od/ohs/biosfty/bmbl4/bmbl4s4.htm*.

CLINICAL LABORATORIES

Clinical laboratories, especially those in health care facilities, receive clinical specimens with requests for a variety of diagnostic and clinical support services. Typically, the infectious nature of clinical material is unknown, and specimens are often submitted with a broad request for microbiological examination for multiple agents (e.g., sputa submitted for "routine," acid-fast, and fungal cultures). It is the responsibility of the laboratory director to establish standard procedures in the laboratory, which realistically addresses the issue of the infective hazard of clinical specimens.

Except in extraordinary circumstances (e.g., suspected hemorrhagic fever), the initial processing of clinical specimens and serological identification of isolates can be done safely at Biosafety Level 2 (see above), the recommended level for work with bloodborne pathogens such as hepatitis B virus and HIV. The containment elements described in BSL-2 are consistent with the OSHA standard, *Occupational Exposure to Bloodborne Pathogens* (Richmond, 1994) from the Occupational Safety and Health Administration (OSHA; see Internet Resources). This requires the use of specific precautions with *all* clinical specimens of blood or other potentially infectious material (Universal or Standard Precautions; MMWR, 1988). Additionally, other recommendations specific for clinical laboratories may be obtained from the U.S. National Committee for Clinical Laboratory Standards (NCCLS, 1977).

Biosafety Level 2 recommendations and OSHA requirements focus on the prevention of percutaneous and mucous membrane exposures to clinical material. Primary barriers

such as BSCs (Class I or II; see *http://www.cdc.gov/od/ohs/biosfty/bsc/bsc.htm*) should be used when performing procedures that might cause splashing, spraying, or splattering of droplets. BSCs should also be used for the initial processing of clinical specimens when the nature of the test requested or other information suggests the likely presence of an agent readily transmissible by infectious aerosols (e.g., *M. tuberculosis*), or when the use of a BSC (Class II) is indicated to protect the integrity of the specimen.

The segregation of clinical laboratory functions and limited or restricted access to such areas is the responsibility of the laboratory director. It is also the director's responsibility to establish standard, written procedures that address the potential hazards and the required precautions to be implemented.

Biosafety Practices Associated with Potential Agents of Biocrime and Biowarfare

Effective biosafety is built on the concept that some microorganisms present more risk of laboratory-acquired infection or unintended release than others. The risk-assessment process, described in *UNIT 1A.1*, is based on the nature of the microorganism and likelihood of infection, or release, as a result of an unintentional laboratory exposure. Biosecurity, the topic of this unit, is also most effectively applied based on a similar risk assessment. The same features of the microbe, coupled with the likelihood of ill effects from a stolen, misused, or intentionally released organism, are the key factors in a biosecurity risk assessment.

Biosecurity is best applied based on determining (1) what research materials are at risk of being intentionally removed (risk identification); (2) the likelihood of misuse and subsequent damage (risk assessment); and (3) what measures can be applied to limit this risk (risk management).

To begin to consider the security of research materials, a general philosophy must be established. Few researchers would argue that a reasonable level of security is necessary. However, it is less commonly acknowledged that security is, by its nature, inconvenient. There is no "silver bullet" that will render materials secure, while allowing unimpeded access to every person desiring that access. The research environment should include basic laboratory biosecurity as part of good laboratory practice.

It is important to note that, in most cases, an appropriate level of laboratory biosecurity can be achieved without relying on expensive technologies or unusually burdensome procedures. However, some countries require certain pathogens to be strictly secured, regardless of the relative level of risk; thus, the regulations for each locality must be consulted to determine what risk management methods are required by regulation (also see *APPENDIX 1B* and *http://www.absa.org*). Lack of regulations, however, must not be construed to mean that security is unnecessary. Indeed, basic and prudent measures, as described below, are warranted for all laboratories using biological material.

RISK IDENTIFICATION

To most effectively determine appropriate biosecurity measures, an inventory of assets is warranted. In other words, laboratory directors should ask themselves and their research staff, "What needs protection from theft or removal?" The scenarios presented in this unit are most specifically directed towards protection of potentially dangerous microorganisms and toxins, but research activities also involve many other assets such as research equipment (e.g., analytical balances, computer equipment), proprietary materials, chemicals, radioisotopes, research animals, experimental data, and more. Stolen research materials, at the very least, are likely to represent a loss of time and intellectual capital.

RISK ASSESSMENT

While a biosafety risk assessment is based on identifying the potential for the microbe to cause infection and/or illness during routine laboratory use, a biosecurity risk assessment involves evaluating the same organism for its potential for intended removal and malicious use, and the consequences of such use. In addition, an assessment of laboratory activities (e.g., multiple transfers) or an enhanced threat environment (e.g., suspicious activities) are factors in completing a biosecurity risk assessment.

Many dangerous pathogens may present limited biosecurity risk because they are difficult to grow or to disseminate in the form of an active bioweapon. Likewise, other less virulent, easily contained microbes may be of a lower safety concern but may represent a desirable tool for bioterrorism.

A risk assessment for malicious use of biological agents includes consideration of factors that influence both the potential for an organism to be used in a threatening manner (threat potential) and the consequences that might result from the intentional use of the agent to inflict harm (Fig. 1A.2.1). Factors influencing the risk for malicious use have been described by Gaudioso et al. (2005).

Determining the consequences of the release of the agent can include the following:

Contributed by LouAnn C. Burnett
Current Protocols in Microbiology (2006) 1A.2.1-1A.2.5

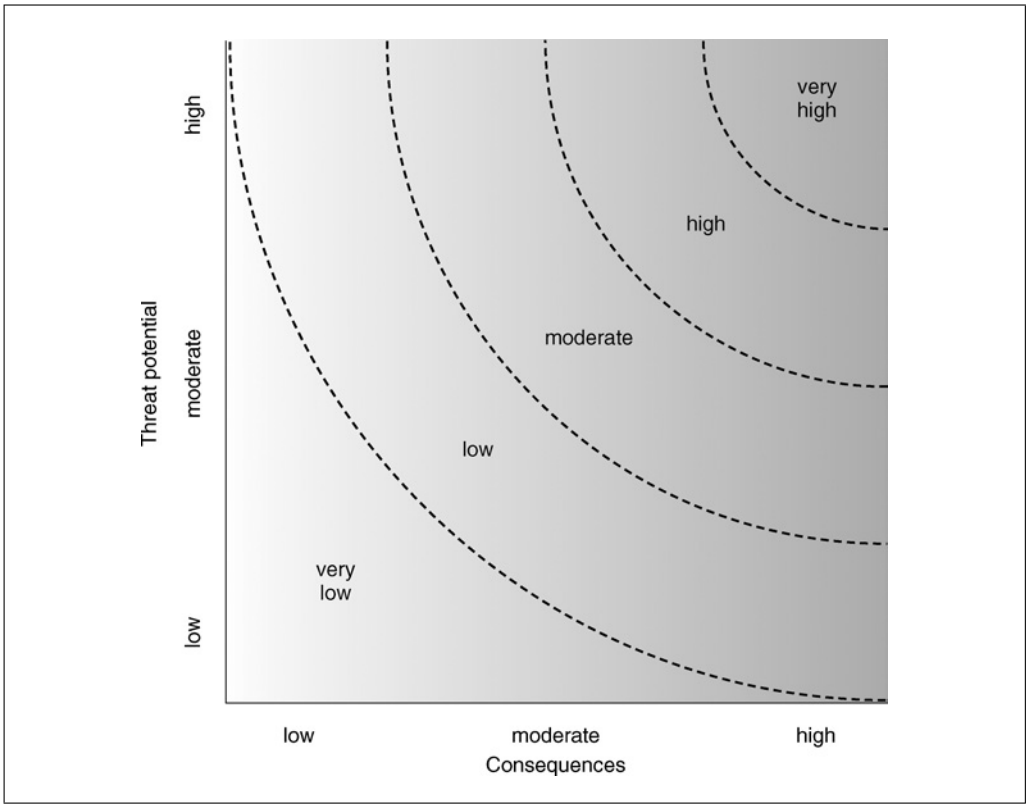

Figure 1A.2.1 Graphic guideline for determining the risk for malicious use of a biological agent. Based on a graphic developed by Sandia Laboratories and used with their kind permission.

(1) level of contagiousness, (2) its ability to cause severe illness or death, (3) its occurrence in the natural local environment (endemic versus exotic agents), and (4) its economic impact and potential for infrastructure disruption.

The threat potential is evaluated by assessing how likely a biological agent could be acquired and manipulated in a manner that favors its release in an infectious state. The evaluation includes: (1) ease of acquisition; (2) ease of growth, processing, and storage; (3) ease of dissemination (e.g., aerosol, ingestion); and (4) environmental stability.

A lesson can be taken from the October 2001 anthrax letters released in the United States. Anthrax is not contagious and, in this case, was associated with a low mortality rate. However, thousands of people were provided preventive treatment and emergency responders worldwide were called on to address false alarms involving "white powder." The potential for weaponization of this microbe contributed to this vast economic and infrastructure disruption.

However, application of these factors in conducting a risk assessment will soon show that few microorganisms present a high risk for malicious use. Therefore, unless otherwise required by regulation, limited risk management techniques will be sufficient to secure the majority of research materials.

RISK MANAGEMENT

Both the World Health Organization (WHO, 2004) and the U.S. Centers for Disease Control and Prevention (CDC/NIH, 1999; MMWR, 2002) have recently included biosecurity discussions as part of commonly used biosafety guidelines. As described by these discussions and elaborated by Sandia National Laboratories (2005), the key components to managing biosecurity risks are (1) physical security measures, (2) personnel security/reliability, (3) materials control and accountability, (4) transfer security, and (5) information security. All of these components are overlapping and interactive in nature (Fig. 1A.2.2). Of particular importance to individuals in microbiology laboratories are physical security, personnel reliability, and materials control and accountability.

Physical Security

Physical security is intended to deter and detect unauthorized access to research areas containing materials of concern. Physical security may be as simple as keeping doors closed at all times and locking the doors when

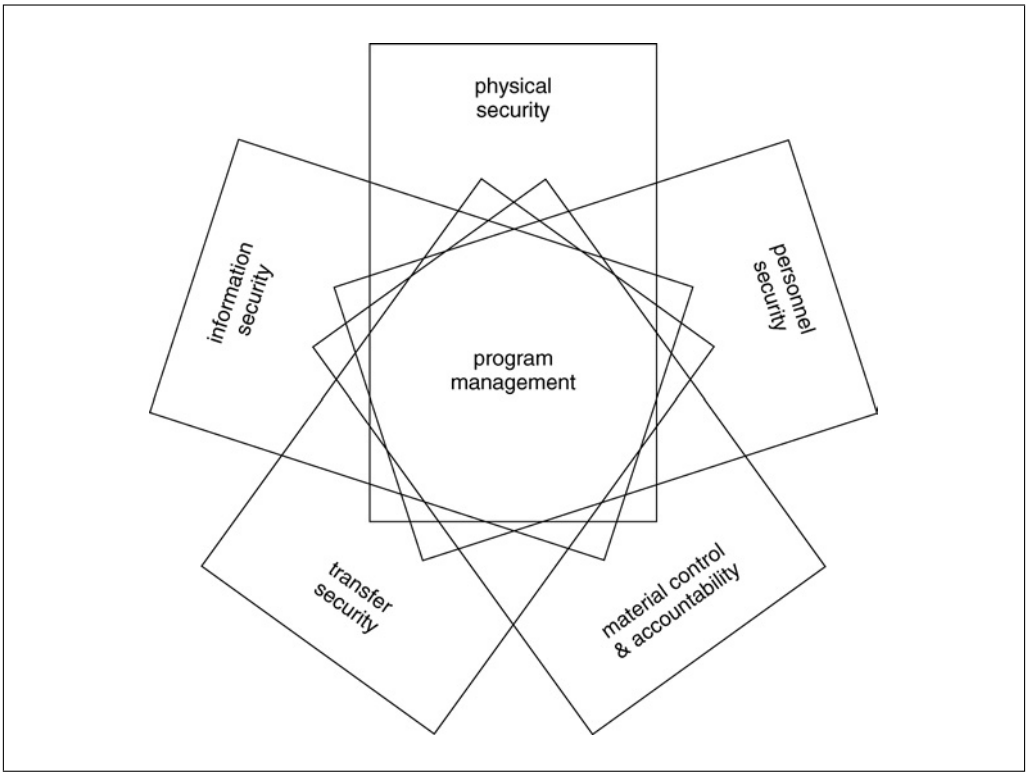

Figure 1A.2.2 Overlapping and interactive components of a comprehensive biosecurity program. Based on a graphic developed by Sandia Laboratories and used with their kind permission.

no one is present. Protecting higher risk assets may require single or multiple keycard or biometric access points or even, in the extreme, checkpoints with security guards. Placing research areas with higher risk assets deeper within a facility may also serve to deter access and intentional removal. In addition, access to these more restricted areas must be monitored, actively or passively, for unauthorized access or attempts at access.

Other considerations to establishing physical security in even benign research settings include: (1) establishing specified access hours; (2) defining what a "suspicious activity" is and how it must be reported; (3) developing a procedure to secure research materials in case of emergencies or to contact security officials if the materials must be left unsecured; and (4) implementing enforcement of security policies—violations must have consequences—e.g., consider revocation of unescorted access into restricted areas.

Personnel Reliability

Physical security may deter an outsider, but will present no barrier to an insider with full access. Personnel reliability is critical in limiting concerns for insider theft. Clearly not all positions within an institution require the same level of scrutiny—the determination of which positions present limited risk or those that carry the most risk is a decision best made by the institution. The type of scrutiny necessary will change depending on the different phases of employment.

Pre-employment screening should include an interviewing process designed to explore reliability issues, and also include a background check.

At time of employment and prior to assignment of access, the following should occur: (1) completion of required employment forms, including appropriate disclosure and conflict of interest declarations, (2) completion of safety and security training, and (3) appropriate medical screening, health evaluations, and immunizations.

During employment, the following options should be considered: (1) assignment of identification badges that clearly indicate access privileges, (2) enforcement of security policies, and (3) availability of employee assistance programs to help resolve personal issues that could contribute to overall stresses.

When an employee is transferred to another area or is terminated, out-processing should include: (1) completion of transfer/termination paperwork; (2) re-inventory of research (and other sensitive) materials and transfer of accountability to another responsible party;

(3) retrieval of security badges, keys, electronic equipment, etc.; and (4) deactivation of computers and electronic access accounts.

Very few, if any, research operations function without requiring access for some sort of visitor. There are several factors to consider with regard to visitors. Determine the different categories of visitors—some visitors are repair or sales persons who provide critical expertise and products for a laboratory, some are observers, and some are working visitors with various lengths of stay. Also, host and escorting procedures and assignments must be documented and followed.

Material Control and Accountability

Physical security and personnel reliability must be coupled with strict attention to material control and accountability. This process works to establish (1) what and where materials are present; (2) how they are stored, used, and transferred securely; and 3) who is accountable for the materials at any given time.

Materials

It is impossible to describe microorganisms in an absolute number because amplification and inactivation are so easily accomplished. A general accounting of the number of containers is more reasonable in this case. A basic inventory is required for the organisms held in repositories, working stocks, master stocks, clinical specimens, genetic material, as well as contaminated materials, such as waste.

Control

Controls are developed to assure that materials stay, or are transported, as intended and that they are used for an authentic, stated purpose by appropriately authorized persons. Physical control may be as simple as a locked freezer. Operational control involves incorporating attention to security issues into standard laboratory procedures. An example of this would be keeping a log to record access to materials of concern. Such a log would be dependent on the nature of the laboratory, the equipment used, and the materials secured. At a minimum, the log should include a brief description of the material, the name of the person accessing the material, the date and time, and when the material was replaced (Fig. 1A.2.3). It is a matter of debate how much information should be kept on a log that could be viewed by persons not involved in the research, but the information recorded must be useful in conducting an investigation if materials are missing. Controls must be developed with regard to both normal and abnormal conditions. For example, the means to secure materials should remain active or be appropriately substituted in the case of a fire alarm where magnetically locked doors are often released.

Other examples of control measures include: (1) confinement to restricted areas, (2) appropriate labeling for accurate identification of materials, (3) clearly documented procedures and inventory for inactivation and disposal, and (4) conducting frequent physical inventories of cataloged research materials.

Accountability

While it is important to inventory and provide control measures for materials of concern, it is imperative that the responsibility for

those materials be clearly assigned to a single, specified person. The person who is the most familiar with the nature of the material, as well as its use and storage, is the best candidate to be held accountable. Other persons who become involved in transfers of materials must also meet appropriate and documented criteria for gaining access to, and accountability for, materials.

An invaluable tool in material control and accountability is the use of a detailed chain of custody document, which records and tracks the materials, control procedures, and the person accountable at each point in the process.

While these processes seem relatively simple, the reality is that material control and accountability are quite complex in microbiological and biomedical research settings. Research materials are routinely transferred between the lab, storage units, and other repositories. Portions of these samples may be divided among different stocks and experiments in progress, involving several different researchers. The daily routine of a laboratory may include transfer of microbes to different persons for the purposes of shipment, destruction, or testing.

DUAL-USE RESEARCH

A parallel concern to laboratory biosecurity of research materials is the concept of "dual-use" research. Dual-use research is that which is conducted for a legitimate purpose but also holds the potential to be misused for bioterrorism. In general, the concern for misuse will not be realized until the research is made public through presentation or publication (National Research Council, 2004). The process of identifying so-called "experiments of concern" is being debated on national and international levels. In the U.S., deliberations of the National Science Advisory Board for Biosecurity (NSABB; see Internet Resources) are focused on permitting critical research to proceed unimpeded, while addressing security issues for research with a potential for misuse. The various groups that are studying the balance between open science and security issues acknowledge that to be truly effective, any decision on how to manage "dual-use" research must be made and implemented internationally.

Safe Use of Hazardous Chemicals

Persons carrying out the protocols in this manual may encounter toxic chemicals, including carcinogenic, mutagenic, or teratogenic reagents (see Table 1A.3.1). Most governments regulate the use of these materials; it is essential that they be used in strict accordance with local and national regulations. Cautionary notes and some specific guidelines are included in many instances throughout the book; however, users must proceed with the prudence and precautions associated with good laboratory practice, under the supervision of those responsible for implementing laboratory safety programs at their institutions. Guidelines for the safe use of radioisotopes are presented in *APPENDIX 1C*.

It is not possible in the space available to list all the precautions required for handling hazardous chemicals. Many texts have been written about laboratory safety (see Literature Cited and Key References). Obviously, all national and local laws should be obeyed, as well as all institutional regulations. Controlled substances are regulated by the Drug Enforcement Administration (*http://www.usdoj.gov/dea*). By law, Material Safety Data Sheets (MSDSs) must be readily available. All laboratories should have a Chemical Hygiene Plan (29 CFR Part 1910.1450); institutional safety officers should be consulted as to its implementation. Help is (or should be) available from your institutional Safety Office: use it.

Chemicals must be stored properly for safety. Certain chemicals cannot be easily or safely mixed with and should not be stored near certain other chemicals, because their reaction is violently exothermic or yields a toxic product. Some examples of incompatibility are listed in Table 1A.3.2. When in doubt, always consult a current MSDS for information on reactivity, handling, and storage. Chemicals should be separated into general hazard classes and stored appropriately. For example, flammable chemicals such as alcohols, ketones, aliphatic and aromatic hydrocarbons, and other materials labeled flammable should be stored in approved flammable storage cabinets, with those also requiring refrigeration being kept in explosion-proof refrigerators. Strong oxidizers must be segregated. Strong acids (e.g., sulfuric, hydrochloric, nitric, perchloric, and hydrofluoric) should be stored in a separate cabinet well removed from strong bases and from flammable organics. An exception is glacial acetic acid, which is both corrosive and flammable, and which must be stored with the flammables.

Facilities should be appropriate for working with hazardous chemicals. In particular, hazardous chemicals should be handled only in chemical fume hoods, not in laminar flow cabinets. The functioning of the fume hoods should be checked periodically. Laboratories should also be equipped with safety showers and eye-wash facilities. Again, this equipment should be tested periodically to ensure that it functions correctly. Other safety equipment may be required depending on the nature of the materials being handled. In addition, researchers should be trained in the proper procedures for handling hazardous chemicals as well as other laboratory operations—e.g., handling of compressed gases, use of cryogenic liquids, operation of high-voltage power supplies, and operation of lasers of all types.

Before starting work, know the physical and chemical hazards of the reagents used. Wear appropriate protective clothing and have a plan for dealing with spills or accidents; coming up with a good plan on the spur of the moment is very difficult. For example, have the appropriate decontaminating or neutralizing agents prepared and close at hand. Small spills can probably be cleaned by the researcher. In the case of larger spills,

Table 1A.3.1 Commonly Used Hazardous Chemicals[a,b]

Chemical	Hazards	Remarks
Acetic acid, glacial	Corrosive, flammable liquid	
Acetonitrile	Flammable liquid, teratogenic, toxic	
Acridine orange	Carcinogenic, mutagenic	See Basic Protocol 2
Acrylamide	Carcinogenic, toxic	Use dust mask; polyacrylamide gels contain residual acrylamide monomer and should be handled with gloves; acrylamide may polymerize with violence on melting at 86°C
Alcian blue 8GX		See Basic Protocol 2
Alizarin red S (monohydrate)		
p-Amidinophenylmethanesulfonyl fluoride (APMSF)	Enzyme inhibitor	See Basic Protocol 11
7-Aminoactinomycin D (7-AAD)	Carcinogenic	
4-(2-Aminoethyl)benzenesulfonyl fluoride (AEBSF)	Mutagenic, enzyme inhibitor	See Basic Protocol 11
Ammonium hydroxide, concentrated	Corrosive, lachrymatory, toxic	
Azure A	Mutagenic	See Basic Protocol 2
Azure B	Mutagenic	See Basic Protocol 2
Benzidine (BDB)	Carcinogenic, toxic	See Basic Protocol 1
Bisacrylamide	Toxic	
Boron dipyrromethane derivatives (BODIPY dyes)	Toxic	
Brilliant blue R	Carcinogenic, mutagenic	See Basic Protocol 2
5-Bromodeoxyuridine (BrdU)	Mutagenic, teratogenic, photosensitizing	
Cetylpyridinium chloride (CPC)	Toxic	
Cetyltrimethylammonium bromide (CTAB)	Corrosive, teratogenic, toxic	
Chloroform	Carcinogenic, teratogenic, toxic	
Chlorotrimethylsilane	Carcinogenic, corrosive, flammable liquid, toxic	Reacts violently with water; see Basic Protocol 3
Chromic/sulfuric acid cleaning solution	Carcinogenic, corrosive, oxidizer, toxic	Replace with suitable commercially available cleanser
Chromomycin A3 (CA3)	Teratogenic, toxic	
Congo red	Mutagenic, teratogenic	See Basic Protocol 2
Coomassie brilliant blue G	Mutagenic	See Basic Protocol 2
Crystal violet		See Basic Protocol 2
Cresyl violet acetate	Mutagenic	See Basic Protocol 2
Cyanides (e.g., KCN, NaCN)	Toxic	Contact with acid will liberate HCN gas; see Basic Protocol 4
Cyanines (e.g., Cy3, Cy5)	Toxic	
Cyanogen bromide (CNBr)	Toxic	See Basic Protocol 4

continued

Table 1A.3.1 Commonly Used Hazardous Chemicals[a,b], *continued*

Chemical	Hazards	Remarks
2′-Deoxycoformycin (dCF, pentostatin)	Teratogenic, toxic	
4′,6-Diamidino-2-phenylindole (DAPI)	Mutagenic	
Diaminobenzidine (DAB)	Carcinogenic	See Basic Protocol 1
1,4-Diazabicyclo[2,2,2]-octane (DABCO)	Toxic	Forms an explosive complex with hydrogen peroxide
Dichloroacetic acid (DCA)	Carcinogenic, corrosive, toxic	
Dichlorodimethylsilane	Corrosive, flammable liquid, toxic	See Basic Protocol 3
Dichloromethane (methylene chloride)	Carcinogenic, mutagenic, teratogenic, toxic	
Diethylamine (DEA)	Corrosive, flammable liquid, toxic	
Diethylpyrocarbonate (DEPC)	Carcinogenic, toxic	
Diethyl sulfate	Carcinogenic, teratogenic, toxic	See Basic Protocol 5
Diisopropyl fluorophosphate (DFP)	Highly toxic, cholinesterase inhibitor, neurotoxin	See Basic Protocol 11
Dimethyl sulfate (DMS)	Carcinogenic, toxic	See Basic Protocol 5
Dimethyl sulfoxide (DMSO)	Flammable liquid, toxic	Enhances absorption through skin
Diphenylamine (DPA)	Teratogenic, toxic	
2,5-Diphenyloxazole (PPO)	Toxic	
Dithiothreitol (DTT)	Toxic	
Eosin B		See Basic Protocol 2
Erythrosin B	Carcinogenic, mutagenic	See Basic Protocol 2
Ether	Flammable liquid, toxic	May form explosive peroxides on standing; do not dry with NaOH or KOH
Ethidium bromide (EB)	Mutagenic, toxic	See Basic Protocol 2 or 6
Ethyl methanesulfonate (EMS)	Carcinogenic, toxic	See Basic Protocol 5
Fluorescein and derivatives	Carcinogenic, toxic	
5-Fluoro-2′-deoxyuridine (FUdR)	Teratogenic, toxic	
Fluoroorotic acid (FOA)	Toxic	
Formaldehyde	Carcinogenic, flammable liquid, teratogenic, toxic	
Formamide	Teratogenic, toxic	
Formic acid	Corrosive, toxic	May explode when heated $>180^{\circ}C$ in a sealed tube
Glutaraldehyde	Corrosive, teratogenic, toxic	
Guanidinium thiocyanate	Toxic	
Hoechst 33258 dye	Mutagenic, toxic	
Hydrochloric acid, concentrated	Corrosive, teratogenic, toxic	

continued

Table 1A.3.1 Commonly Used Hazardous Chemicals[a,b], *continued*

Chemical	Hazards	Remarks
Hydrogen peroxide (30%)	Carcinogenic, corrosive, mutagenic, oxidizer	Avoid bringing into contact with organic materials, which may form explosive peroxides; may decompose violently in contact with metals, salts, or oxidizable materials; see Basic Protocol 7
Hydroxylamine	Corrosive, flammable, mutagenic, toxic	Explodes in air at >70°C
3-β-Indoleacrylic acid (IAA)	Carcinogenic	
Iodine	Corrosive, toxic	See Basic Protocol 8
Iodoacetamide	Carcinogenic, mutagenic, toxic	
Janus green B	Carcinogenic, mutagenic	See Basic Protocol 2
Lead compounds	Carcinogenic, toxic	
2-Mercaptoethanol (2-ME)	Stench, toxic	
Mercury compounds	Teratogenic, toxic	See Basic Protocol 9
Methionine sulfoximine (MSX)	Teratogenic, toxic	
Methotrexate (amethopterin)	Carcinogenic, mutagenic, teratogenic, toxic	
Methylene blue	Mutagenic, toxic	See Basic Protocol 2
Methyl methanesulfonate (MMS)	Carcinogenic, toxic	See Basic Protocol 5
N-Methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG)	Carcinogenic, mutagenic, teratogenic	Explodes when heated or under impact; contact with base produces toxic, explosive, carcinogenic diazomethane; see Basic Protocol 12
Mycophenolic acid (MPA)	Teratogenic, toxic	
Neutral red	Mutagenic	See Basic Protocol 2
Nigrosin, water soluble		See Basic Protocol 2
Nitric acid, concentrated	Corrosive, oxidizer, teratogenic, toxic	
Nitroblue tetrazolium (NBT)	Toxic	
Orcein, synthetic		See Basic Protocol 2
Oxonols	Toxic	
Paraformaldehyde	Toxic	
Phenol	Carcinogenic, corrosive, teratogenic, toxic	Readily absorbed through the skin
Phenylmethylsulfonyl fluoride (PMSF)	Enzyme inhibitor	See Basic Protocol 11
Phorbol 12-myristate 13-acetate (PMA)	Carcinogenic, toxic	
Phycoerythrins (PE)	Toxic	
Piperidine	Flammable liquid, teratogenic, toxic	
Potassium hydroxide, concentrated	Corrosive, toxic	Produces a highly exothermic reaction when solid is added to water
Propane sultone	Carcinogenic, toxic	See Basic Protocol 5
Propidium iodide (PI)	Mutagenic	See Basic Protocol 2 or 6

continued

Table 1A.3.1 Commonly Used Hazardous Chemicals[a,b], *continued*

Chemical	Hazards	Remarks
Pyridine	Flammable liquid, toxic	
Rhodamine and derivatives	Toxic	
Rose Bengal	Carcinogenic, teratogenic	See Basic Protocol 2
Safranine O	Mutagenic	See Basic Protocol 2
Sodium azide	Carcinogenic, toxic	Adding acid liberates explosive volatile, toxic hydrazoic acid; can form explosive heavy metal azides, e.g., with plumbing fixtures—*do not* discharge down drain; see Basic Protocol 10
Sodium deoxycholate (Na-DOC)	Carcinogenic, teratogenic, toxic	
Sodium dodecyl sulfate (sodium lauryl sulfate, SDS)	Sensitizing, toxic	
Sodium hydroxide, concentrated	Corrosive, toxic	A highly exothermic reaction ensues when the solid is added to water
Sodium nitrite	Carcinogenic	
Sulfuric acid, concentrated	Corrosive, oxidizer, teratogenic, toxic	Reaction with water is very exothermic; always add concentrated sulfuric acid to water, *never* water to acid
SYTO dyes	Toxic	
Tetramethylammonium chloride (TMAC)	Toxic	
N,*N*,*N*′,*N*′-Tetramethyl-ethylenediamine (TEMED)	Corrosive, flammable liquid, toxic	
Texas Red (sulforhodamine 101, acid chloride)	Toxic	
Toluene	Flammable liquid, teratogenic, toxic	
Toluidine blue O	Mutagenic, toxic	See Basic Protocol 2
*N*α-*p*-Tosyl-L-lysine chloromethyl ketone (TLCK)	Toxic, enzyme inhibitor	See Basic Protocol 11
N-*p*-Tosyl-L-phenylalanine chloromethyl ketone (TPCK)	Toxic, mutagenic, enzyme inhibitor	See Basic Protocol 11
Trichloroacetic acid (TCA)	Carcinogenic, corrosive, teratogenic, toxic	
Triethanolamine acetate (TEA)	Carcinogenic, toxic	
Trifluoroacetic acid (TFA)	Corrosive, toxic	
Trimethyl phosphate (TMP)	Carcinogenic, mutagenic, teratogenic	May explode on distillation
Trypan blue	Carcinogenic, mutagenic, teratogenic	See Basic Protocol 2
Xylenes	Flammable liquid, teratogenic, toxic	

[a]*CAUTION:* These chemicals should be handled only in a chemical fume hood by knowledgeable workers equipped with eye protection, lab coat, and gloves. The laboratory should be equipped with a safety shower and eye wash. Additional protective equipment may be required.
[b]For extensive information on the hazards of these and other chemicals as well as cautionary details, see Bretherick (1990), Lunn and Sansone (1994a), Bretherick et al. (1999), Lewis (1999), Furr (2000), and O'Neil (2001).

Table 1A.3.2 Examples of Chemical Incompatibility

Chemical	Incompatible with
Acetic acid	Aldehydes, bases, carbonates, chromic acid, ethylene glycol, hydroxides, hydroxyl compounds, metals, nitric acid, oxidizers, perchloric acid, peroxides, phosphates, permanganates, xylene
Acetone	Acids, amines, concentrated nitric and sulfuric acid mixtures, oxidizers, plastics
Acetylene	Copper, halogens, mercury, oxidizers, potassium, silver
Alkali metals, alkaline earth metals	Acids, aldehydes, carbon dioxide, carbon tetrachloride or other chlorinated hydrocarbons, halogens, ketones, plastics, sulfur, water
Ammonia (anhydrous)	Acids, aldehydes, amides, calcium hypochlorite, hydrofluoric acid, halogens, heavy metals, mercury, oxidizers, plastics, sulfur
Ammonium nitrate	Acids, alkalis, chlorates, chloride salts, flammable and combustible materials, metals, organic materials, phosphorus, reducing agents, sulfur, urea
Aniline	Acids, aluminum, dibenzoyl peroxide, oxidizers, plastics
Arsenical materials	Any reducing agent
Azides	Acids, heavy metals, oxidizers
Bromine	Acetaldehyde, alcohols, alkalis, amines, ammonia, combustible materials, ethylene, fluorine, hydrogen, ketones (e.g., acetone, carbonyls), metals, petroleum gases, sodium carbide, sulfur
Calcium oxide	Acids, ethanol, fluorine, organic materials, water
Carbon (activated)	Alkali metals, calcium hypochlorite, halogens, oxidizers
Carbon tetrachloride	Sodium
Chlorates	Acids, ammonium salts, finely divided organic or combustible materials, powdered metals, sulfur
Chlorine	Acetylene or other hydrocarbons, alcohols, ammonia, benzene, butadiene, butane, combustible materials, ethylene, flammable compounds (e.g., hydrazine), hydrogen, hydrogen peroxide, iodine, metals, methane, nitrogen, oxygen, propane (or other petroleum gases), sodium carbide, sodium hydroxide
Chlorine dioxide	Ammonia, hydrogen, hydrogen sulfide, mercury, methane, organic materials, phosphine, phosphorus, potassium hydroxide, sulfur
Chromic acid, chromic oxide	Acetic acid, acetone, alcohols, alkalis, ammonia, bases, benzene, camphor, flammable liquids, glycerin (glycerol), hydrocarbons, metals, naphthalene, organic materials, phosphorus, plastics
Copper	Acetylene, calcium, hydrocarbons, hydrogen peroxide, oxidizers
Cumene hydroperoxide	Acids (organic or inorganic)
Cyanides	Acids, alkaloids, aluminum, iodine, oxidizers, strong bases
Flammable liquids	Ammonium nitrate, chromic acid, halogens, hydrogen peroxide, nitric acid, oxidizing agents in general, oxygen, sodium peroxide

continued

Table 1A.3.2 Examples of Chemical Incompatibility, *continued*

Chemical	Incompatible with
Fluorine	All other chemicals
Hydrocarbons (liquid or gas)	See flammable liquids
Hydrocyanic acid	Alkali, nitric acid
Hydrofluoric acid	Ammonia, metals, organic materials, plastics, silica (glass, including fiberglass), sodium
Hydrogen peroxide	All organics, most metals or their salts, nitric acid, phosphorus, sodium, sulfuric acid
Hydrogen sulfide	Acetylaldehyde, fuming nitric acid, metals, oxidizers, sodium, strong bases
Hydroperoxide	Reducing agents
Hypochlorites	Acids, activated carbon
Iodine	Acetylaldehyde, acetylene, ammonia, hydrogen, metals, sodium
Mercury	Acetylene, aluminum, amines, ammonia, calcium, fulminic acid, lithium, oxidizers, sodium
Nitric acid	Acids, nitrites, metals, most organics, plastics, sodium, sulfur, sulfuric acid
Nitrites	Acids
Nitroparaffins	Amines, inorganic bases
Oxalic acid	Mercury, oxidizers, silver, sodium chlorite
Oxygen	All flammable and combustible materials, ammonia, carbon monoxide, grease, metals, oil, phosphorus, polymers
Perchloric acid	All organics, bismuth and alloys, dehydrating agents, grease, hydrogen halides, iodides, paper, wood
Peroxides, organic	Acids (organic or mineral), avoid friction, store cold
Phosphorus (white)	Air, alkalis, oxygen, reducing agents
Potassium chlorate	Acids, ammonia, combustible materials, fluorine, hydrocarbons, metals, organic materials, reducing agents, sugars
Potassium perchlorate	Alcohols, combustible materials, fluorine, hydrazine, metals, organic matter, reducing agents, sulfuric acid
Potassium permanganate	Benzaldehyde, ethylene glycol, glycerin, sulfuric acid
Selenides and tellurides	Reducing agents
Silver	Acetylene, ammonium compounds, fulminic acid, oxalic acid, ozonides, peroxyformic acid, tartaric acid
Sodium	Acids, carbon dioxide, carbon tetrachloride, hydrazine, metals, oxidizers, water
Sodium nitrate	Acetic anhydride, acids, metals, organic matter, peroxyformic acid, reducing agents
Sodium peroxide	Acetic anhydride, benzaldehyde, benzene, carbon disulfide, ethyl acetate, ethyl or methyl alcohol, ethylene glycol, furfural, glacial acetic acid, glycerin, hydrogen sulfide, metals, methyl acetate, oxidizers, peroxyformic acid, phosphorus, reducing agents, sugars, water
Sulfides	Acids
Sulfuric acid	Alcohols, bases, chlorates, perchlorates, permanganates of potassium, lithium, sodium, magnesium, calcium

the area should be evacuated and help should be sought from those experienced in and equipped for dealing with spills—e.g., the institutional Safety Office.

Protective equipment should include, at a minimum, eye protection, a lab coat, and gloves. In certain circumstances, other items of protective equipment may be necessary (e.g., a face shield). Different types of gloves exhibit different resistance properties (Table 1A.3.3). No gloves resist all chemicals, and no gloves resist any chemicals indefinitely. Disposable gloves labeled "exam" or "examination" are primarily for protection from biological materials (e.g., viruses, bacteria, feces, blood). They are not designed for and usually have not been tested for resistance to chemicals. Disposable gloves generally offer *extremely* marginal protection from chemical hazards in most cases and should be removed immediately upon contamination before the chemical can pass through. If possible, design handling procedures to eliminate or reduce potential for contamination. Never assume that disposable gloves will offer the same protection or even have the same properties as nondisposables. Select gloves carefully and always look for some evidence that they will protect against the materials being used. Inspect all gloves before every use for possible holes, tears, or weak areas. Never reuse disposable gloves. Clean reusable gloves after each use and dry carefully inside and out. Observe all common-sense precautions—e.g., do not pipet by mouth, keep unauthorized persons away from hazardous chemicals, do not eat or drink in the laboratory, wear proper clothing in the laboratory (sandals, open-toed shoes, and shorts are not appropriate).

Order hazardous chemicals only in quantities that are likely to be used in a reasonable time. Buying large quantities at a lower unit cost is no bargain if someone (perhaps you) has to pay to dispose of surplus quantities. Substitute alcohol-filled thermometers for mercury-filled thermometers, which are a hazardous chemical spill waiting to happen.

Although any number of chemicals commonly used in laboratories are toxic if used improperly, the toxic properties of a number of reagents require special mention. Chemicals that exhibit carcinogenic, corrosive, flammable, lachrymatory, mutagenic, oxidizing, teratogenic, toxic, or other hazardous properties are listed in Table 1A.3.1. Chemicals listed as carcinogenic range from those accepted by expert review groups as causing cancer in humans to those for which only minimal evidence of carcinogenicity exists. No effort has been made to differentiate the carcinogenic potential of the compounds in Table 1A.3.1. Oxidizers may react violently with oxidizable material (e.g., hydrocarbons, wood, and cellulose). Before using any of these chemicals, thoroughly investigate all its characteristics. Material Safety Data Sheets are readily available; they list some hazards but vary widely in quality. A number of texts describing hazardous properties are listed at the end of this unit (see Literature Cited). In particular, Sax's *Dangerous Properties of Industrial Materials*, 11th ed. (Lewis, 2004), and the *Handbook of Reactive Chemical Hazards*, 6th ed. (Bretherick et al., 1999), give comprehensive listings of known hazardous properties; however, these texts list only the known properties. Many chemicals, especially fluorochromes, have been tested only partially or not at all. Prudence dictates that, unless there is good reason for believing otherwise, all chemicals should be regarded as volatile, highly toxic, flammable human carcinogens and should be handled with great care.

Waste should be segregated according to institutional requirements, for example, into solid, aqueous, nonchlorinated organic, and chlorinated organic material, and should always be disposed of in accordance with all applicable federal, state, and local regulations. Extensive information and cautionary details along with techniques for the disposal of chemicals in laboratories have been published (Bretherick, 1990; Lunn and Sansone, 1994a; O'Neil, 2001; Furr, 2000). Some commonly used disposal procedures are outlined in Basic Protocols 1 to 12. Incorporation of these procedures into laboratory protocols

can help to minimize waste disposal problems. Alternate Protocols 1 to 9 describe decontamination methods for some of the chemicals. Support Protocols 1 to 10 describe analytical techniques that are used to verify that reagents have been decontaminated; with modification, these assays may also be used to determine the concentration of a particular chemical.

DISPOSAL METHODS

A number of procedures for the disposal of hazardous chemicals are available; protocols for the disposal and decontamination of some hazardous chemicals commonly encountered in microbiology laboratories are listed in Table 1A.3.4. These procedures are necessarily brief; for full details consult the original references or a collection of these procedures (see Lunn and Sansone, 1994a).

CAUTION: These disposal methods should be carried out only in a chemical fume hood by workers equipped with eye protection, a lab coat, and gloves. Additional protective equipment may be necessary.

BASIC PROTOCOL 1

DISPOSAL OF BENZIDINE AND DIAMINOBENZIDINE

Benzidine and diaminobenzidine can be degraded by oxidation with potassium permanganate (Castegnaro et al., 1985; Lunn and Sansone, 1991a). This protocol presents a method for decontamination of benzidine and diaminobenzidine in bulk. It can also be adapted to the decontamination of benzidine and diaminobenzidine spills (see Alternate Protocol 1). Alternatively, these compounds can be removed from solution using horseradish peroxidase in the presence of hydrogen peroxide (see Alternate Protocol 2). Destruction and decontamination are >99%. Support Protocol 1 is used to test for the presence of benzidine and diaminobenzidine.

Materials

Benzidine or diaminobenzidine tetrahydrochloride dihydrate
0.1 M HCl (for benzidine)
0.2 M potassium permanganate: prepare immediately before use
2 M sulfuric acid
Sodium metabisulfite
10 M potassium hydroxide (KOH)
Additional reagents and equipment for testing for the presence of aromatic amines (see Support Protocol 1)

1. For each 9 mg benzidine, add 10 ml of 0.1 M HCl *or* for each 9 mg diaminobenzidine tetrahydrochloride dihydrate, add 10 ml water. Stir the solution until the aromatic amine has completely dissolved.
2. For each 10 ml of solution, add 5 ml freshly prepared 0.2 M potassium permanganate and 5 ml of 2 M sulfuric acid. Allow the mixture to stand for ≥10 hr.
3. Add sodium metabisulfite until the solution is decolorized.
4. Add 10 M KOH to make the solution strongly basic, pH >12.

   CAUTION: *This reaction is exothermic.*
5. Dilute with 5 vol water and pass through filter paper to remove manganese compounds.
6. Test the filtrate for the presence of aromatic amines (i.e., benzidine or diaminobenzidine; see Support Protocol 1).
7. Neutralize the filtrate with acid and discard.

DECONTAMINATION OF SPILLS INVOLVING BENZIDINE AND DIAMINOBENZIDINE

ALTERNATE PROTOCOL 1

Additional Materials *(also see Basic Protocol 1)*

Glacial acetic acid
1:1 (v/v) 0.2 M potassium permanganate/2 M sulfuric acid: prepare immediately before use
Absorbent material (e.g., paper towels, Kimwipes)
High-efficiency particulate air (HEPA) vacuum (Fisher)
Additional reagents and equipment for testing for the presence of aromatic amines (see Support Protocol 1)

CAUTION: This procedure may damage painted surfaces and Formica.

1. Remove as much of the spill as possible using absorbent material and high-efficiency particulate air (HEPA) vacuuming.
2. Wet the surface with glacial acetic acid until all the amines are dissolved, then add an excess of freshly prepared 1:1 (v/v) 0.2 M potassium permanganate/2 M sulfuric acid to the spill area. Allow the mixture to stand $\geq$10 hr.
3. Ventilate the area and decolorize with sodium metabisulfite.
4. Mop up the liquid with paper towels. Squeeze the solution out of the towels and collect in a suitable container. Discard towels as hazardous solid waste.
5. Add 10 M KOH to make the solution strongly basic, pH $\geq$12.

   CAUTION: *This reaction is exothermic*.
6. Dilute with 5 vol water and filter through filter paper to remove manganese compounds.
7. Test the filtrate for the presence of aromatic amines (i.e., benzidine or diaminobenzidine; see Support Protocol 1).
8. Neutralize the filtrate with acid and discard it.
9. Verify complete decontamination by wiping the surface with a paper towel moistened with water and squeezing the liquid out of the towel. Test the liquid for the presence of benzidine or diaminobenzidine (see Support Protocol 1). Repeat steps 1 to 9 as necessary.

DECONTAMINATION OF AQUEOUS SOLUTIONS OF BENZIDINE AND DIAMINOBENZIDINE

ALTERNATE PROTOCOL 2

The enzyme horseradish peroxidase catalyzes the oxidation of the amine to a radical which diffuses into solution and polymerizes. The polymers are insoluble and fall out of solution.

Additional Materials *(also see Basic Protocol 1)*

Aqueous solution of benzidine or diaminobenzidine
1 N HCl or NaOH
3% (v/v) hydrogen peroxide
Horseradish peroxidase (see recipe)
1:1 (v/v) 0.2 M potassium permanganate/2 M sulfuric acid
5% (w/v) ascorbic acid
Porous glass filter *or* Sorvall GLC-1 centrifuge or equivalent

Additional reagents and equipment for testing for the presence of aromatic amines (see Support Protocol 1)

1. Adjust the pH of the aqueous benzidine or diaminobenzidine solution to 5 to 7 with 1 N HCl or NaOH as required, and dilute so the concentration of aromatic amines is $\leq$100 mg/liter.
2. For each liter of solution, add 3 ml of 3% hydrogen peroxide and 300 U horseradish peroxidase. Let the mixture stand 3 hr.
3. Remove the precipitate by filtering the solution through a porous glass filter or by centrifuging 5 min at room temperature in a benchtop centrifuge to pellet the precipitate.

   The precipitate is mutagenic and should be treated as hazardous waste.

4. Immerse the porous glass filter in 1:1 (v/v) 0.2 M potassium permanganate/2 M sulfuric acid. Clean the filter in a conventional fashion and discard potassium permanganate/sulfuric acid solution as described for benzidine and diaminobenzidine (see Basic Protocol 1).
5. For each liter of filtrate, add 100 ml of 5% ascorbic acid.
6. Test the filtrate for the presence of aromatic amines (see Support Protocol 1).
7. Discard the decontaminated filtrate.

SUPPORT PROTOCOL 1

ANALYTICAL PROCEDURES TO DETECT BENZIDINE AND DIAMINOBENZIDINE

Reversed-phase HPLC (Snyder et al., 1997) is used to test for the presence of aromatic amines. The limit of detection is 1 μg/ml for benzidine and 0.25 μg/ml for diaminobenzidine.

Materials

Decontaminated aromatic amine solution
10:30:20 (v/v/v) acetonitrile/methanol/1.5 mM potassium phosphate buffer (1.5 mM K_2HPO_4/1.5 mM KH_2PO_4) (benzidine) *or* 75:25 (v/v) methanol/1.5 mM potassium phosphate buffer (diaminobenzidine)
250-mm × 4.6-mm-i.d. Microsorb C-8 reversed-phase HPLC column (Varian) or equivalent
Additional reagents and equipment for reversed-phase liquid chromatography (Snyder et al., 1997)

Analyze the decontaminated aromatic amine solution by reversed-phase HPLC using a 250-mm × 4.6-mm-i.d. Microsorb C-8 column or equivalent (Snyder et al., 1997). To detect benzidine, elute with 10:30:20 (v/v/v) acetonitrile/methanol/1.5 mM potassium phosphate buffer at a flow rate of 1.5 ml/min and UV detection at 285 nm. To detect diaminobenzidine, elute with 75:25 (v/v) methanol/1.5 mM potassium phosphate buffer at a flow rate of 1 ml/min and UV detection at 300 nm.

BASIC PROTOCOL 2

DISPOSAL OF BIOLOGICAL STAINS

Biological stains (Table 1A.3.5), as well as ethidium bromide and propidium iodide, can be removed from solution using the polymeric resin Amberlite XAD-16. The decontaminated solution may be disposed of as nonhazardous aqueous waste and the resin as hazardous solid waste. The volume of contaminated resin generated is much smaller than the original volume of the solution of biological stain, so the waste disposal problem is greatly reduced. The final concentration of any remaining stain should be less than the

Table 1A.3.5 Decontamination of Biological Stains

Compound	Time required for complete decontamination	Volume of solution (ml) decontaminated per gram resin
Acridine orange	18 hr	20
Alcian blue 8GX	10 min	500
Alizarin red S	18 hr	5
Azure A	10 min	80
Azure B	10 min	80
Brilliant blue R	2 hr	80
Congo red	2 hr	40
Coomassie brilliant blue G	2 hr	80
Cresyl violet acetate	2 hr	40
Crystal violet	30 min	200
Eosin B	30 min	40
Erythrosin B	18 hr	10
Ethidium bromide	4 hr	20
Janus green B	30 min	80
Methylene blue	30 min	80
Neutral red	10 min	500
Nigrosin	2 hr	80
Orcein	2 hr	200
Propidium iodide	2 hr	20
Rose Bengal	3 hr	20
Safranine O	1 hr	20
Toluidine blue O	30 min	80
Trypan blue	2 hr	40

limit of detection (see Support Protocol 2 and Table 1A.3.5). In each case, decontamination should be >99%. This protocol describes a method for batch decontamination in which the resin is stirred in the solution to be decontaminated and removed by filtration at the end of the reaction time. Large volumes of biological stain can be decontaminated using a column (see Alternate Protocol 3). For full details refer to the original literature (Lunn and Sansone, 1991b) or a compilation (Lunn and Sansone, 1994a).

Materials

Amberlite XAD-16 resin (Supelco)
100 μg/ml biological stain in water
Additional reagents and equipment for testing for the presence of biological stain (see Support Protocol 2)

For batch decontamination of 20 ml stain

1a. Add 1 g Amberlite XAD-16 to 20 ml of 100 μg/ml biological stain in water.

For aqueous solutions having stain concentrations other than 100 μg/ml, use proportionately greater or lesser amounts of resin to achieve complete decontamination.

For solutions of erythrosin B, use 2 g Amberlite XAD-16 for 20 ml stain.

2a. Stir the mixture for at least the time indicated in Table 1A.3.5.

For batch decontamination of larger volumes of stain

1b. Add 1 g Amberlite XAD-16 to the volume of 100 μg/ml biological stain in water indicated in Table 1A.3.5.

2b. Stir the mixture for at least 18 hr.

3. Remove the resin by filtration through filter paper.

4. Test the filtrate for the presence of the biological stain (see Support Protocol 2).

5. Discard the resin as hazardous solid waste and the decontaminated filtrate as liquid waste.

ALTERNATE PROTOCOL 3

CONTINUOUS-FLOW DECONTAMINATION OF AQUEOUS SOLUTIONS OF BIOLOGICAL STAINS

For treating large volumes of dilute aqueous solutions of biological stains (Table 1A.3.6), it is possible to put the resin in a column and run the contaminated solution through using a continuous-flow system (Lunn et al., 1994). Limited grinding of the Amberlite XAD-16 resin increases its efficiency.

Additional Materials *(also see Basic Protocol 2)*

25 μg/ml biological stain in water
Methanol (optional)
300-mm × 11-mm-i.d. glass chromatography column fitted with threaded adapters and flow-regulating valves at top and bottom nut and insert connectors, and insertion tool (Ace Glass) *or* 300-mm × 15-mm-i.d. glass chromatography column (Spectrum 124010, Fisher)
Glass wool
1.5-mm-i.d. × 0.3-mm-wall Teflon tubing
Waring blender (optional)
Rubber stopper fitted over a pencil
QG 20 lab pump (Fluid Metering)
Additional reagents and equipment for testing for the presence of biological stain (see Support Protocol 2)

Using a slurry of Amberlite XAD-16

1a. Prepare a 300-mm × 11-mm-i.d. glass chromatography column. To prevent clogging of the column outlet, place a small plug of glass wool at the bottom of the chromatography column. Connect 1.5-mm-i.d. × 0.3-mm wall Teflon tubing to the adapters using nut and insert connectors. Attach the tubing using an insertion tool.

2a. Mix 10 g Amberlite XAD-16 and 25 ml water in a beaker and stir 5 min to wet the resin.

Using a finely ground Amberlite XAD-16 slurry

1b. Prepare a 300-mm × 15-mm-i.d. glass chromatography column. To prevent clogging of the column outlet, place a small plug of glass wool at the bottom of the chromatography column.

2b. Grind 20 g Amberlite XAD-16 with 200 ml water for exactly 10 sec in a Waring blender.

3. Pour the resin slurry into the column through a funnel. As the resin settles, tap the column with a rubber stopper fitted over a pencil to encourage even packing. Attach a QG 20 lab pump.

Table 1A.3.6 Breakthrough Volumes for Continuous-Flow Decontamination of Biological Stains

Compound	Breakthrough volume (ml)		
	Limit of detection	1 ppm	5 ppm
Acridine orange	465	>990	>990
Alizarin red S	120	150	240
Azure A	615	810	>975
Azure B	630	882	>1209
Cresyl violet acetate	706	>1396	>1396
Crystal violet	1020	>1630	>1630
Ethidium bromide	260	312	416
Janus green B	170	650	>870
Methylene blue	420	645	1050
Neutral red	>2480	>2480	>2480
Safranine O	365	438	584
Toluidine blue O	353	494	606

4. Pump the 25-μg/ml biological stain solution through the column at 2 ml/min.

   Alternatively, gravity flow coupled with periodic adjustment of the flow-regulating valve can be used.

5. Check the effluent from the column for the presence of biological stain (see Support Protocol 2). Stop the pump when stain is detected.

   Table 1A.3.6 lists breakthrough volumes at different detection levels for a number of biological stains.

6. Discard the decontaminated effluent and the contaminated resin appropriately.

7. Many biological stains can be washed off the resin with methanol so the resin can be reused. Discard the methanol solution of stain as hazardous organic liquid waste.

ANALYTICAL PROCEDURES TO DETECT BIOLOGICAL STAINS

SUPPORT PROTOCOL 2

Depending on the biological stain, the filtrate or eluate from the decontamination procedure can be analyzed using either UV absorption (A) or fluorescence detection (F).

Materials

Filtrate or eluate from biological stain decontamination (see Basic Protocol 2 or Alternate Protocol 3)
DNA solution: 20 μg/ml calf thymus DNA in TBE electrophoresis buffer, pH 8.1 (*APPENDIX 2A*)
1 M KOH solution
pH 5 buffer (see recipe)

Test the filtrate or eluate from the biological stain decontamination procedure using the appropriate method as indicated in Table 1A.3.7.

Traces of acid or base on the resin may induce color changes in the stain. Accordingly, with cresyl violet acetate or neutral red, mix aliquots of the filtrate with 1 vol pH 5 buffer before analyzing. With alizarin red S and orcein, mix aliquots of the filtrate with 1 vol of 1 M KOH solution before analyzing.

Table 1A.3.7 Methods for Detecting Biological Stains[a]

Compound	Reagent[b]	Procedure	Wavelength(s) (nm)	Limit of detection (ppm)
Acridine orange	DNA solution	F	ex 492, em 528	0.0032
Alcian blue 8GX		A	615	0.9
Alizarin red S	1 M KOH	A	556	0.46
Azure A		A	633	0.15
Azure B		A	648	0.13
Brilliant blue R		A	585	1.0
Congo red		A	497	0.25
Coomassie brilliant blue G		A	610	1.7
Cresyl violet acetate	pH 5 buffer	F	ex 588, em 618	0.021

Safranine O		F	ex 460, em 582	0.03
Toluidine blue O		A	626	0.2
Trypan blue		A	607	0.22

[a] Abbreviations: A, absorbance; em, emission; ex, excitation; F, fluorescence.
[b] See Support Protocol 2.

Increase the fluorescence of solutions of acridine orange, ethidium bromide, and propidium iodide by mixing an aliquot of the filtrate with an equal volume of DNA solution. Let the solution stand 15 min before measuring the fluorescence.

BASIC PROTOCOL 3

DISPOSAL OF CHLOROTRIMETHYLSILANE AND DICHLORODIMETHYLSILANE

Silane-containing compounds are hydrolyzed to hydrochloric acid and polymeric silicon-containing material (Patnode and Wilcock, 1946).

1. Hydrolyze silane-containing compounds by cautiously adding 5 ml silane to 100 ml vigorously stirred water in a flask. Allow the resulting suspension to settle.
2. Remove any insoluble material by filtration and discard it with the solid or liquid hazardous waste.
3. Neutralize the aqueous layer with base and discard it.

DISPOSAL OF CYANIDES AND CYANOGEN BROMIDE

BASIC PROTOCOL 4

Inorganic cyanides (e.g., NaCN) and cyanogen bromide (CNBr) are oxidized by sodium hypochlorite (NaOCl; e.g., Clorox) in basic solution to the much less toxic cyanate ion (Lunn and Sansone, 1985a). Destruction is >99.7%.

Materials

Cyanide (e.g., NaCN) or cyanogen bromide (CNBr)
1 M NaOH
5.25% (v/v) sodium hypochlorite (NaOCl; i.e., standard household bleach)
Additional reagents and equipment for testing for the presence of cyanide (see Support Protocol 3)

1. Dissolve cyanide in water to give a concentration ≤25 mg/ml *or* dissolve CNBr in water to give a concentration ≤60 mg/ml.

   If necessary, dilute aqueous solutions so the concentration of NaCN or CNBr does not exceed the limit.

2. Mix 1 vol NaCN or CNBr solution with 1 vol 1 M NaOH and 2 vol fresh 5.25% NaOCl. Stir the mixture 3 hr.

   IMPORTANT NOTE: *With age, bleach may become ineffective; use of fresh bleach is strongly recommended.*

3. Test the reaction mixture for the presence of cyanide (see Support Protocol 3).

4. Neutralize the reaction mixture and discard it.

ANALYTICAL PROCEDURE TO DETECT CYANIDE

SUPPORT PROTOCOL 3

This protocol is used to detect cyanide or cyanogen bromide at ≥3 μg/ml.

Materials

Cyanide or cyanogen bromide decontamination reaction mixture (see Basic Protocol 4)
Phosphate buffer (see recipe)
10 mg/ml sodium ascorbate in water: prepare fresh daily
100 mg/liter NaCN in water: prepare fresh weekly
10 mg/ml chloramine-T in water: prepare fresh daily
Cyanide detection reagent (see recipe)
Sorvall GLC-1 centrifuge or equivalent

1. If necessary to remove suspended solids, centrifuge two 1-ml aliquots of the cyanide or cyanogen bromide decontamination reaction mixture 5 min in a benchtop centrifuge, room temperature. Add each supernatant to 4 ml phosphate buffer in separate tubes.

2. If an orange or yellow color appears, add 10 mg/ml freshly prepared sodium ascorbate dropwise until the mixture is colorless, but do not add more than 2 ml.

3. Add 200 μl of 100 mg/liter NaCN to one reaction mixture (control solution).

4. Add 1 ml freshly prepared 10 mg/ml chloramine-T to each tube. Shake the tubes and let them stand 1 to 2 min.

5. Add 1 ml cyanide detection reagent, shake, and let stand 5 min.

A blue color indicates the presence of cyanide. If destruction has been complete and the analytical procedure has been carried out correctly, the treated reaction mixture should be colorless and the control solution, which contains NaCN, should be blue.

6. If necessary, remove suspended solids by centrifuging tubes 5 min at room temperature. Measure the absorbance at 605 nm with appropriate standards and blanks.

BASIC PROTOCOL 5

DISPOSAL OF DIMETHYL SULFATE, DIETHYL SULFATE, METHYL METHANESULFONATE, ETHYL METHANESULFONATE, DIEPOXYBUTANE, AND 1,3-PROPANE SULTONE

Dimethyl sulfate is hydrolyzed by base to methanol and methyl hydrogen sulfate (Lunn and Sansone, 1985b). Subsequent hydrolysis of methyl hydrogen sulfate to methanol and sulfuric acid is slow. Methyl hydrogen sulfate is nonmutagenic and a very poor alkylating agent. The other compounds can be hydrolyzed with base in a similar fashion (Lunn and Sansone, 1990a). Destruction is >99%. A method to verify that decontamination is complete is also provided (see Support Protocol 4).

NOTE: The reaction times given in the protocol should give good results; however, reaction time may be affected by such factors as the size and shape of the flask and the rate of stirring. The presence of two phases indicates that the reaction is not complete, and stirring should be continued until the reaction mixture is homogeneous.

Materials

Dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, or 1,3-propane sultone
5 M NaOH
Acid
Additional reagents and equipment for testing for the presence of dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, or 1,3-propane sultone (see Support Protocol 4)

For bulk quantities of dimethyl sulfate

1a. Add 100 ml dimethyl sulfate to 1 liter of 5 M NaOH. Stir the reaction mixture.

2a. Fifteen minutes after all the dimethyl sulfate has gone into solution, neutralize the reaction mixture with acid.

For bulk quantities of diethyl sulfate

1b. Add 100 ml diethyl sulfate to 1 liter of 5 M NaOH. Stir the reaction mixture 24 hr.

2b. Neutralize the reaction mixture with acid.

For bulk quantities of methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, and 1,3-propane sultone

1c. Add 1 ml methyl methanesulfonate, ethyl methanesulfonate, or diepoxybutane, or 1 g of 1,3-propane sultone to 10 ml of 5 M NaOH. Stir the reaction mixture 1 hr for 1,3-propane sultone, 2 hr for methyl methanesulfonate, 22 hr for diepoxybutane, or 24 hr for ethyl methanesulfonate.

2c. Neutralize the reaction mixture with acid.

3. Test the reaction mixture for the presence of the original compound (see Support Protocol 4).

4. Discard the decontaminated reaction mix.

ANALYTICAL PROCEDURE TO DETECT THE PRESENCE OF DIMETHYL SULFATE, DIETHYL SULFATE, METHYL METHANESULFONATE, ETHYL METHANESULFONATE, DIEPOXYBUTANE, AND 1,3-PROPANE SULTONE

SUPPORT PROTOCOL 4

This protocol is used to verify decontamination of solutions containing dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, or 1,3-propane sultone. The detection limit for this assay is 40 μg/ml for dimethyl sulfate, 108 μg/ml for diethyl sulfate, 84 μg/ml for methyl methanesulfonate, 1.1 μg/ml for ethyl methanesulfonate, 360 μg/ml for diepoxybutane, and 264 μg/ml for 1,3-propane sultone.

Materials

Reaction mixture containing dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, or 1,3-propane sultone
98:2 (v/v) 2-methoxyethanol/acetic acid
5% (w/v) 4-(4-nitrobenzyl)pyridine in 2-methoxyethanol
Piperidine
2-Methoxyethanol

1. Dilute an aliquot of the reaction mixture with 4 vol water.
2. Add 100 μl diluted reaction mixture to 1 ml of 98:2 (v/v) 2-methoxyethanol/acetic acid. Swirl to mix.
3. Add 1 ml of 5% (w/v) 4-(4-nitrobenzyl)pyridine in 2-methoxyethanol. Heat 10 min at 100°C, then cool 5 min in ice.
4. Add 0.5 ml piperidine and 2 ml of 2-methoxyethanol.
5. Measure the absorbance of the violet reaction mixture at 560 nm against an appropriate blank.

   The absorbance of a decontaminated solution should be 0.000.

DISPOSAL OF ETHIDIUM BROMIDE AND PROPIDIUM IODIDE

BASIC PROTOCOL 6

Ethidium bromide and propidium iodide in water and buffer solutions may be degraded by reaction with sodium nitrite and hypophosphorous acid in aqueous solution (Lunn and Sansone, 1987); destruction is >99.87%. This reaction may also be used to decontaminate equipment contaminated with ethidium bromide (see Alternate Protocol 4; Lunn and Sansone, 1989) and to degrade ethidium bromide in organic solvents (see Alternate Protocol 5 and Alternate Protocol 6; Lunn and Sansone, 1990b). Ethidium bromide and propidium iodide may also be removed from solution by adsorption onto Amberlite XAD-16 resin (see Basic Protocol 2).

Materials

Ethidium bromide– or propidium iodide–containing solution in water, buffer, or 1 g/ml cesium chloride
5% (v/v) hypophosphorous acid: prepare fresh daily by diluting commercial 50% reagent 1/10
0.5 M sodium nitrite: prepare fresh daily
Sodium bicarbonate
Additional reagents and equipment for testing for the presence of ethidium bromide or propidium iodide (see Support Protocol 5)

1. If necessary, dilute the ethidium bromide– or propidium iodide–containing solution so the concentration of ethidium bromide or propidium iodide is ≤0.5 mg/ml.
2. For each 100 ml solution, add 20 ml of 5% hypophosphorous acid solution and 12 ml of 0.5 M sodium nitrite. Stir briefly and let stand 20 hr.
3. Neutralize the reaction mixture by adding sodium bicarbonate until the evolution of gas ceases.
4. Test the reaction mixture for the presence of ethidium bromide or propidium iodide (see Support Protocol 5).
5. Discard the decontaminated reaction mixture.

ALTERNATE PROTOCOL 4

DECONTAMINATION OF EQUIPMENT CONTAMINATED WITH ETHIDIUM BROMIDE

Glass, stainless steel, Formica, floor tile, and the filters of transilluminators have been successfully decontaminated using this protocol. No change in the optical properties of the transilluminator filter could be detected, even after a number of decontamination cycles.

Materials

Equipment contaminated with ethidium bromide
Decontamination solution (see recipe)
Sodium bicarbonate
Additional reagents and equipment for testing for the presence of ethidium bromide (see Support Protocol 5)

1. Wash the equipment contaminated with ethidium bromide once with a paper towel soaked in decontamination solution.

   The pH of decontamination solution is 1.8. If this is too corrosive for the surface being decontaminated, wash with a paper towel soaked in water instead.

2. Wash the surface five times with paper towels soaked in water using a fresh towel each time.
3. Soak all the towels 1 hr in decontamination solution.
4. Neutralize the decontamination solution by adding sodium bicarbonate until the evolution of gas ceases.
5. Test the decontamination solution for the presence of ethidium bromide (see Support Protocol 5).
6. Discard the decontamination solution and the paper towels as nonhazardous liquid and solid wastes.

ALTERNATE PROTOCOL 5

DECONTAMINATION OF ETHIDIUM BROMIDE IN ISOPROPANOL SATURATED WITH CESIUM CHLORIDE

Materials

Ethidium bromide
Isopropanol saturated with cesium chloride
Decontamination solution (see recipe)
Sodium bicarbonate
Additional reagents and equipment for testing for the presence of ethidium bromide (see Support Protocol 5)

1. If necessary, dilute the ethidium bromide in isopropanol saturated with cesium chloride so the concentration of ethidium bromide is ≤1 mg/ml.
2. For each volume of ethidium bromide solution, add 4 vol decontamination solution. Stir the reaction mixture 20 hr.
3. Neutralize the reaction mixture by adding sodium bicarbonate until the evolution of gas ceases.
4. Test the reaction mixture for the presence of ethidium bromide (see Support Protocol 5).
5. Discard the decontaminated solution.

DECONTAMINATION OF ETHIDIUM BROMIDE IN ISOAMYL ALCOHOL AND 1-BUTANOL

ALTERNATE PROTOCOL 6

Materials

Ethidium bromide
Isoamyl alcohol or 1-butanol
Decontamination solution (see recipe)
Activated charcoal
Sodium bicarbonate
Separatory funnel
Additional reagents and equipment for testing for the presence of ethidium bromide (see Support Protocol 5)

1. If necessary, dilute the ethidium bromide in isoamyl alcohol or 1-butanol so the concentration is ≤1 mg/ml final.
2. For each volume of ethidium bromide solution, add 4 vol decontamination solution. Stir the two-phase reaction mixture rapidly for 72 hr.
3. For each 100 ml of reaction mixture, add 2 g activated charcoal. Stir another 30 min.
4. Filter the reaction mixture.
5. Neutralize the filtrate by adding sodium bicarbonate until the evolution of gas ceases. Separate the layers using a separatory funnel.

   More alcohol may tend to separate from the aqueous layer on standing.
6. Test the alcohol and aqueous layers for the presence of ethidium bromide.
7. Discard the alcohol and aqueous layers appropriately. Discard the activated charcoal as solid waste.

   The aqueous layer contains 4.6% 1-butanol or 2.3% isoamyl alcohol.

ANALYTICAL PROCEDURE TO DETECT ETHIDIUM BROMIDE OR PROPIDIUM IODIDE

SUPPORT PROTOCOL 5

This protocol is used to verify that solutions no longer contain ethidium bromide or propidium iodide. The limits of detection are 0.05 parts per million (ppm) for ethidium bromide and 0.1 ppm for propidium iodide.

Materials

Reaction mixture containing ethidium bromide or propidium iodide
TBE buffer, pH 8.1 (*APPENDIX 2A*)
20 μg/ml calf thymus DNA in TBE buffer, pH 8.1

1. Mix 100 µl reaction mixture containing ethidium bromide or propidium iodide with 900 µl TBE buffer, pH 8.1.
2. Add 1 ml of 20 µg/ml calf thymus DNA in TBE, pH 8.1. Prepare a blank solution (100 µl water + 900 µl TBE + 1 ml of 20 µg/ml calf thymus DNA) and control solutions containing known quantities of ethidium bromide or propidium iodide. Let the mixtures stand 15 min.
3. To detect ethidium bromide, measure the fluorescence with an excitation wavelength of 540 nm and an emission wavelength of 590 nm. To detect propidium iodide, measure the fluorescence with an excitation wavelength of 350 nm and an emission wavelength of 600 nm.

   If a spectrophotofluorometer is not available, fluorescence of ethidium bromide can be qualitatively determined using a hand-held UV lamp on the long-wavelength setting (Lunn and Sansone, 1991c).

BASIC PROTOCOL 7

DISPOSAL OF HYDROGEN PEROXIDE

Hydrogen peroxide can be reduced with sodium metabisulfite (Lunn and Sansone, 1994b).

Materials

30% hydrogen peroxide
10% (w/v) sodium metabisulfite
10% (w/v) potassium iodide
1 M HCl
1% (w/v) starch indicator solution

1. Add 5 ml of 30% hydrogen peroxide to 100 ml of 10% sodium metabisulfite. Stir the mixture at room temperature until the temperature starts to drop, indicating that the reaction is over.
2. Test for the presence of hydrogen peroxide by adding a few drops of the reaction mixture to an equal volume of 10% potassium iodide. Add a few drops of 1 M HCl to acidify the reaction mixture, then add a drop of 1% starch indicator solution.

   A deep blue color indicates the presence of excess oxidant. If necessary, add more 10% sodium metabisulfite until the starch test is negative.

3. Discard the decontaminated mixture.

BASIC PROTOCOL 8

DISPOSAL OF IODINE

Iodine is reduced with sodium metabisulfite to iodide (Lunn and Sansone, 1994b).

Materials

Iodine
10% (w/v) sodium metabisulfite
1 M HCl
1% (w/v) starch indicator solution

1. Add 5 g iodine to 100 ml of 10% sodium metabisulfite. Stir the mixture until the iodine has completely dissolved.
2. Acidify a few drops of the reaction mixture by adding a few drops of 1 M HCl. Add 1 drop of 1% starch indicator solution.

   A deep blue color indicates the presence of iodine. If reduction is not complete, add more sodium metabisulfite solution.

3. Dispose of the decontaminated solution.

DISPOSAL OF MERCURY COMPOUNDS

BASIC PROTOCOL 9

Solutions of mercuric acetate can be decontaminated using Dowex 50X8-100, a strongly acidic gel-type ion-exchange resin with a sulfonic acid functionality. Solutions of mercuric chloride can be decontaminated using Amberlite IRA-400(Cl), a strongly basic gel-type ion-exchange resin with a quaternary ammonium functionality. The final concentration of mercury is <3.8 ppm (Lunn and Sansone, 1994a). On a small scale it is most convenient to stir the resin in the solution to be decontaminated, but on a larger scale, or for routine use, it may be more convenient to pass the solution through a column packed with the resin. Although the volume of waste that must be disposed is greatly reduced using this technique, a small amount of waste (i.e., the resin contaminated with mercury) remains and must be discarded appropriately. Resin can be regenerated by washing with acid, but the concentrated metal-containing solution generated by this must also be disposed of appropriately. Mercury may also be removed from laboratory waste water using a column of iron powder (see Alternate Protocol 7). Support Protocol 6 is used to detect the presence of mercury.

Materials

Solution containing ≤1600 ppm mercuric acetate *or* ≤1350 ppm mercuric chloride
Dowex 50X8-100 ion-exchange (mercuric acotate) *or* Amberlite IRA-400(Cl) ion-exchange (mercuric chloride) resin
Additional reagents and equipment to test for the presence of mercury (see Support Protocol 6)

1a. *For mercuric acetate:* For each 200 ml of solution containing ≤1600 ppm mercuric acetate, add 1 g Dowex 50X8-100 ion-exchange resin. Stir the mixture 1 hr, then filter through filter paper.

1b. *For mercuric chloride:* For each 200 ml of solution containing ≤1350 ppm mercuric chloride, add 1 g Amberlite IRA-400(Cl) ion-exchange resin. Stir the mixture 6 hr, then filter through filter paper.

The speed and efficiency of decontamination will depend on factors such as the size and shape of the flask and the rate of stirring.

2. Test the filtrate for the presence of mercury (see Support Protocol 6).

3. Discard the decontaminated filtrate and the mercury-containing resin appropriately.

DECONTAMINATION OF WASTE WATER CONTAINING MERCURY

ALTERNATE PROTOCOL 7

Laboratory waste water that contains mercury is decontaminated by passing it through a column of iron powder. The mercury forms mercury amalgam and stays on the column. Some metallic mercury remains in solution but this can be removed by aeration. The final concentration of mercury is <5 ppb (Shirakashi et al., 1986).

Materials

Iron powder, 60 mesh
Waste water containing ≤2.5 ppm mercury
6-mm-i.d. column

1. Pack a 6-mm-i.d. column with 1 g of 60-mesh iron powder.

Use a fresh column for each treatment.

2. Pass ≤2 liters of water containing ≤2.5 ppm of mercury through the column at a flow rate of 250 ml/hr.

Solutions containing a higher concentration of mercury may also be treated, but this will result in a higher final concentration of mercury (e.g., treating a 100-ppm solution in this fashion yielded 33 ppb final).

Some iron ends up in solution and can be removed by adjusting the pH to 8. The resulting precipitated $Fe(OH)_3$ can then be removed by filtration.

3. Aerate the resulting effluent to remove traces of metallic mercury and continue aeration 30 min after the last of the effluent has emerged from the column. Vent the metallic mercury removed from the solution by aeration into the fume hood or capture it in a mercury trap.

The effluent contains <5 ppb mercury. The presence of iodide or polypeptone may necessitate several treatments to reduce the mercury to an acceptable level.

SUPPORT PROTOCOL 6

ANALYTICAL PROCEDURE TO DETECT MERCURY

Atomic absorption spectroscopy with detection at 253.7 nm, a slit width of 0.7 nm, and a limit of detection of 3.8 ppm can be used to determine the concentration of mercury in solution for experiments involving ion-exchange resins. A Hiranuma mercury meter model HG-1 can be used for experiments involving iron powder.

BASIC PROTOCOL 10

DISPOSAL OF SODIUM AZIDE

Sodium azide can be oxidized by ceric ammonium nitrate (Manufacturing Chemists Association, 1973) to nitrogen (Mason, 1967) or by nitrous acid (National Research Council, 1983) to nitrous oxide (Mason, 1967); destruction is >99.996%. Sodium azide in buffer solution may also be degraded by the addition of sodium nitrite (Lunn and Sansone, 1994a). The reaction proceeds much more readily at low pH, but if sufficient sodium nitrite is added, it will proceed to completion even at high pH. At low pH, it may be possible to completely degrade the azide present in the buffer with less than the amount of sodium nitrite indicated. However, the reaction mixture must be carefully checked to ensure that no azide remains (see Support Protocol 7). At high pH, it is possible for unreacted azide to remain in the presence of excess nitrite. Residual nitrite can be detected using Support Protocol 8.

CAUTION: Some toxic nitrogen dioxide may be produced as a by-product of these reactions, so they should always be carried out in a chemical fume hood.

Materials

Sodium azide or solution containing sodium azide
Ceric ammonium nitrate
10% (w/v) potassium iodide
1 M HCl
1% (w/v) starch indicator solution
Sodium nitrite
4 M sulfuric acid

Additional reagents and equipment to test for the presence of sodium azide (see Support Protocol 7) *or* nitrite (see Support Protocol 8)

Decontamination using ceric ammonium nitrate

1a. For each gram of sodium azide, add 9 g ceric ammonium nitrate to 30 ml water, and stir until it has dissolved.

2a. Dissolve each gram of sodium azide in 5 ml water. Add this solution to the ceric ammonium nitrate solution at the rate of 1 ml each min. Stir 1 hr.

If the reaction is carried out on a larger scale, an ice bath may be required for cooling.

3a. Check that the reaction is still oxidizing by adding a few drops of the reaction mixture to an equal volume of 10% potassium iodide. Acidify the mixture with 1 drop of 1 M HCl and add 1 drop of 1% starch indicator solution.

The deep blue color of the starch-iodine complex indicates that excess oxidant is present. If excess oxidant is not present, add more ceric ammonium nitrate.

4a. Test for the presence of sodium azide (see Support Protocol 8).

5a. Discard the decontaminated reaction mixture.

Decontamination using sodium nitrite

1b. For each 5 g sodium azide, dissolve 7.5 g sodium nitrite in 30 ml water.

2b. Dissolve each 5 g sodium azide in 100 ml water. Add the sodium nitrite solution with stirring. Slowly add 4 M sulfuric acid until the reaction mixture is acidic to litmus. Stir 1 hr.

CAUTION: *It is important to add the sodium nitrite, then the sulfuric acid. Adding these reagents in reverse order will generate explosive, volatile, toxic hydrazoic acid.*

CAUTION: *If the reaction is carried out on a large scale, an ice bath may be required for cooling.*

3b. Check that there is excess nitrous acid in the reaction. Add a few drops of the reaction mixture to an equal volume of 10% potassium iodide. Acidify the mixture with 1 drop 1 M HCl. Add 1 drop starch indicator solution.

The deep blue color of the starch-iodine complex indicates that excess nitrous acid is present. If excess nitrous acid is not present, add more sodium nitrite.

4b. If excess nitrous acid is present, test for the presence of sodium azide (see Support Protocol 7).

5b. Discard the decontaminated reaction mixture.

Decontamination of sodium azide in buffer

1c. If necessary, dilute the buffer solution with water so the concentration of sodium azide is $\leq$1 mg/ml.

2c. For each 50 ml buffer solution add 5 g sodium nitrite. Stir the reaction 18 hr.

3c. Test for the presence of sodium azide (see Support Protocol 7).

4c. Discard the decontaminated reaction solution.

ANALYTICAL PROCEDURES TO DETECT SODIUM AZIDE

SUPPORT PROTOCOL 7

Sodium azide is analyzed by reacting azide ion with 3,5-dinitrobenzoyl chloride to form 3,5-dinitrobenzoyl azide, which can be detected by reversed-phase HPLC. The limit of detection of this assay is 0.2 μg/ml sodium azide. This protocol works only in the absence of nitrite; verify that all of the nitrite has been destroyed by sulfamic acid by using the method detailed later in this unit (see Support Protocol 8).

Materials

Reaction mixture from sodium azide treated with ceric ammonium nitrate or sodium nitrite
1 M KOH
Acetonitrile
Sodium azide indicator solution (see recipe)
0.2 M HCl

20% (w/v) sulfamic acid
3,5-dinitrobenzoyl chloride
50:50 (v/v) acetonitrile/water

Sorvall GLC-1 centrifuge or equivalent
25-cm × 4.6-mm-i.d. Microsorb C-8 reversed-phase HPLC column (Varian) or equivalent

Additional reagents and equipment for reversed-phase liquid chromatography (Snyder et al., 1997)

To analyze for azide in the presence of ceric salts

1a. To a 10-ml aliquot of the reaction mixture from sodium azide treated with ceric ammonium nitrate, add 40 ml water. Add 5 ml of this diluted solution to 3 ml of 1 M KOH and mix by shaking.

If <3 ml of 1 M KOH is used, precipitation of ceric salts will not be complete.

2a. Centrifuge the mixture 5 min, room temperature.

3a. Remove 2 ml supernatant and add to 1 ml acetonitrile. Add 1 drop sodium azide indicator solution, add 0.2 M HCl dropwise until the mixture turns yellow, then add 1 drop more.

To analyze for azide in the presence of nitrite

1b. To 5 ml of the reaction mixture from sodium azide treated with sodium nitrite, add ≥1 ml sulfamic acid to remove excess nitrite. Let stand ≥3 min.

More sulfamic acid solution may be required for strongly basic reaction mixtures or those containing high concentrations of nitrite. Complete removal of nitrite can be checked by using a modified Griess reagent (see Support Protocol 8).

At high pH the reaction between azide and nitrite is quite slow, so the presence of excess nitrite does not mean that all the azide has been degraded.

2b. Add 1 drop sodium azide indicator solution, then basify the mixture by adding 1 M KOH until it turns purple (typically, 3 to 10 ml are required).

3b. Add 2 ml acetonitrile. Add 0.2 M HCl dropwise until the mixture turns yellow, then add 1 drop more.

If >1 ml sulfamic acid is used, add 4 ml acetonitrile.

4. Prepare a 10% (w/v) solution of 3,5-dinitrobenzoyl chloride in acetonitrile.

5. Add 50 µl of 10% dinitrobenzoyl chloride/acetonitrile to the reaction mix (step 3a or 3b). Shake the mixture and let it stand ≥3 min.

Longer standing times have no effect on the HPLC analysis. However, it is crucial to use freshly prepared 3,5-dinitrobenzoyl chloride solution within minutes of its preparation. It is generally most convenient to prepare all the analytical samples with the fresh solution at the beginning of the day and analyze them over the course of the day.

6. Analyze 20 µl of each reaction mixture by reversed-phase HPLC (Snyder et al., 1997) using a 25-cm × 4.6-mm-i.d. Microsorb C-8 reversed-phase HPLC column or equivalent, and a mobile phase of 50:50 (v/v) acetonitrile/water with a flow rate of 1 ml/min and UV detection at 254 nm.

The peak for 3,5-dinitrobenzoyl azide elutes at −9 min.

ANALYTICAL PROCEDURE TO DETECT NITRITE

SUPPORT PROTOCOL 8

This protocol uses a modified Griess reagent to test for the presence of nitrite. The limit of detection of this assay is 0.06 μg/ml nitrite. A similar procedure uses *N*-(1-naphthyl)-ethylenediamine (Cunniff, 1995).

Materials

α-Naphthylamine
15% (v/v) aqueous acetic acid
Sulfanilic acid solution (see recipe)
Reaction mixture treated to remove excess nitrite (see Support Protocol 7, step 1b)

1. Prepare the modified Griess reagent by boiling 0.1 g α-naphthylamine in 20 ml water until it dissolves. While the solution is still hot, pour it into 150 ml of 15% aqueous acetic acid. Add 150 ml sulfanilic acid solution.

   CAUTION: *α-Naphthylamine is a carcinogen.*

   This reagent should be stored at room temperature in a brown bottle.

2. Add 3 ml of the reaction mixture treated to remove excess nitrite to 1 ml modified Griess reagent. Let stand 6 min at room temperature.

3. Measure the absorbance at 520 nm against a suitable blank.

DISPOSAL OF ENZYME INHIBITORS

BASIC PROTOCOL 11

The enzyme inhibitors *p*-amidinophenylmethanesulfonyl fluoride (APMSF), 4-(2-aminoethyl)benzenesulfonyl fluoride (AEBSF), phenylmethylsulfonyl fluoride (PMSF; Lunn and Sansone, 1994c), diisopropyl fluorophosphate (DFP; Lunn and Sansone, 1994d), *Nα-p*-tosyl-L-lysine chloromethyl ketone (TLCK), and *N-p*-tosyl-L-phenylalanine chloromethyl ketone (TPCK; Lunn and Sansone, 1994c) may be degraded by reaction with 1 M NaOH. Destruction is >99.8% (except TPCK >98.3%). The exact reaction conditions depend on the solvent (see Table 1A.3.8). The solutions that were decontaminated are representative of those described in the literature.

Materials

Solutions of APMSF, AEBSF, PMSF, DFP, TLCK, or TPCK in buffer, DMSO, isopropanol, or water
1 M NaOH
Glacial acetic acid

Additional reagents and equipment for testing for the presence of the enzyme inhibitors (see Support Protocol 9)

1. If necessary, dilute the solutions with the same solvent so that the concentrations given in Table 1A.3.8 are not exceeded.

   Bulk quantities of AEBSF, PMSF, and TPCK may be dissolved in isopropanol and bulk quantities of APMSF and TLCK may be dissolved in water at the concentrations shown in Table 1A.3.8. Bulk quantities of DFP (a liquid) may be mixed directly with 1 M NaOH, taking care to make sure that all the DFP has mixed thoroughly, in the ratio shown in Table 1A.3.8 (e.g., 40 μl DFP with 1 ml of 1 M NaOH).

2. Add 1 M NaOH so that the ratio of solution to 1 M NaOH is that listed in Table 1A.3.8.

3. Shake to ensure complete mixing, check that the solution is strongly basic (pH ≥12), and allow to stand for the time given in Table 1A.3.8.

Table 1A.3.8 Conditions for the Destruction of Enzyme Inhibitors

Compound	Concentration	Solvent	Ratio[a]	Time
AEBSF	1 mM	Buffer (pH 5.0-8.0)	1:0.1	1 hr
AEBSF	20 mM	DMSO	1:10	24 hr
AEBSF	20 mM	Isopropanol	1:10	24 hr
APMSF	2.5 mM	Buffer (pH 5.0-8.0)	1:0.1	1 hr
APMSF	25 mM	DMSO	1:5	24 hr
APMSF	25 mM	50:50 isopropanol:pH 3 buffer	1:5	24 hr
APMSF	100 mM	Water	1:5	24 hr
DFP	10 mM	Buffer (pH 6.4-7.2)	1:0.2	18 hr
DFP	200 mM	DMF	1:2	18 hr
DFP	pure	—	1:25	1 hr
DFP	10 mM	Water	1:0.2	18 hr
PMSF	10 mM	Buffer (pH 5.0-8.0)	1:0.1	1 hr
PMSF	100 mM	DMSO	1:5	24 hr
PMSF	100 mM	Isopropanol	1:5	24 hr
TLCK	1 mM	Buffer (pH 5.0-8.0)	1:0.1	18 hr
TLCK	5 mM	DMSO	1:5	18 hr
TLCK	5 mM	Water	1:0.1	18 hr
TPCK	1 mM	Buffer (pH 5.0-8.0)	1:0.1	18 hr
TPCK	1 mM	DMSO	1:0.1	18 hr
TPCK	1 mM	Isopropanol	1:0.1	18 hr

[a]Ratio refers to the proportion of solution to sodium hydroxide, i.e., solution (compound + solvent):1 M NaOH.

4. Neutralize the reaction mixture with glacial acetic acid and test for the presence of residual enzyme inhibitor (see Support Protocol 9).

5. Discard the decontaminated reaction mixture.

SUPPORT PROTOCOL 9

ANALYTICAL PROCEDURES TO DETECT ENZYME INHIBITORS

DFP can be detected using a complex procedure involving the inhibition of chymotrypsin activity. For more information, refer to Lunn and Sansone (1994d). A gas chromatographic method has also been described by Degenhardt-Langelaan and Kientz (1996). AEBSF, APMSF, PMSF, TLCK, and TPCK may be detected by reversed-phase HPLC (Snyder et al., 1997). The chromatographic conditions and limits of detection are shown in Table 1A.3.9 (Lunn and Sansone, 1994c).

Table 1A.3.9 HPLC Conditions for Enzyme Inhibitors

Compound	Mobile phase	UV detector wavelength	Retention time	Limit of detection
AEBSF	40:60 (v/v) acetonitrile:0.1% trifluoroacetic acid	225 nm	9.5 min	0.1 μg/ml
APMSF	40:60 (v/v) acetonitrile:0.1% trifluoroacetic acid	232 nm	7.7 min	0.5 μg/ml
PMSF	50:50 (v/v) acetonitrile:water	220 nm	8 min	0.9 μg/ml
TLCK	40:60 (v/v) acetonitrile:0.1% trifluoroacetic acid	228 nm	9.5 min	0.37 μg/ml
TPCK	48:52 (v/v) acetonitrile:10 mM pH 7 phosphate buffer	228 nm	10.5 min	2 μg/ml

Materials

Decontaminated enzyme inhibitor solutions
Acetonitrile, HPLC grade
Water, HPLC grade
0.1% (v/v) trifluoroacetic acid in water
10 mM phosphate buffer, pH 7
Compound of interest
250-mm × 4.6 mm-i.d. Microsorb C-8 reversed-phase HPLC column (Varian) or equivalent
Additional reagents and equipment for reversed-phase liquid chromatography (Snyder et al., 1997)

Analyze the decontaminated enzyme inhibitor solutions by reversed-phase HPLC using a 250-mm × 4.6-mm-i.d. Microsorb C-8 reversed-phase column, or equivalent, using the conditions shown in Table 1A.3.9. In each case, the injection volume was 20 μl, the separation occurred at ambient temperature, and the flow rate was 1 ml/min. Check the analytical procedures by spiking an aliquot of the acidified reaction mixture with a small quantity of a dilute solution of the compound of interest.

DISPOSAL OF *N*-METHYL-*N′*-NITRO-*N*-NITROSOGUANIDINE (MNNG)

BASIC PROTOCOL 12

Bulk quantities and solutions in methanol or ethanol of *N*-methyl-*N′*-nitro-*N*-nitrosoguanidine (MNNG) may be degraded by reaction with sulfamic acid in the presence of strong acid (Castegnaro et al., 1983); destruction is >99.5%. This reaction may also be used to decontaminate equipment contaminated with MNNG (see Alternate Protocol 8) and to decontaminate spills (see Alternate Protocol 9; Lunn and Sansone, 1988).

Note that the following procedures may only be used to degrade bulk quantities of MNNG, solutions in methanol (or ethanol), contaminated glassware, or spills. Also the methods are not appropriate for other nitrosamides (e.g., *N*-methyl-*N*-nitrosourea) or the chemically similar nitrosamines (e.g., dimethylnitrosamine). For a full discussion of procedures for the degradation of these compounds see Lunn and Sansone, 1994a.

Materials

N-Methyl-*N′*-nitro-*N*-nitrosoguanidine (MNNG) as a solid or in solution in methanol or ethanol
6 M hydrochloric acid (*APPENDIX 2A*)
Sulfamic acid
Neutralizing solution (e.g., aqueous NaOH)
Additional reagents and equipment for detecting the presence of MNNG (see Support Protocol 10)

1. Take up bulk quantities of MNNG in methanol so that the concentration does not exceed 30 g/L. If necessary, dilute methanol or ethanol solutions with the same solvent so that the concentration of MNNG does not exceed 30 g/liter.
2. Slowly add an equal volume of 6 M HCl with stirring.
3. For each 1 liter of the resulting solution, add 35 g sulfamic acid. Stir 24 hr.
4. Neutralize the reaction mixture, e.g., with sodium hydroxide solution.
5. Test the reaction mixture for the presence of MNNG (see Support Protocol 10).
6. Discard the decontaminated reaction mixture.

ALTERNATE PROTOCOL 8

DECONTAMINATION OF GLASSWARE CONTAMINATED WITH *N*-METHYL-*N′*-NITRO-*N*-NITROSOGUANIDINE (MNNG)

Materials

Glassware contaminated with *N*-methyl-*N′*-nitro-*N*-nitrosoguanidine (MNNG)
Methanol
70 g/liter sulfamic acid in 2 M HCl
Neutralizing solution (e.g., aqueous NaOH)
Additional reagents and equipment for detecting the presence of MNNG (see Support Protocol 10)

1. Soak the contaminated glassware in a mixture of equal volumes of methanol and 70 g/liter sulfamic acid in 2 M HCl.
2. After 6 hr, drain the glassware and clean it in a conventional fashion.
3. Neutralize the reaction mixture, e.g., with sodium hydroxide solution.
4. Test the reaction mixture for the presence of MNNG (see Support Protocol 10).
5. Discard the decontaminated reaction mixture.

ALTERNATE PROTOCOL 9

DECONTAMINATION OF SPILLS OF *N*-METHYL-*N′*-NITRO-*N*-NITROSOGUANIDINE (MNNG)

Materials

Methanol
70 g/liter sulfamic acid in 2 M hydrochloric acid
Neutralizing solution (e.g., aqueous NaOH)
Additional reagents and equipment for detecting the presence of MNNG (see Support Protocol 10)

1. Soak the area in methanol until the nitrosamide appears to be dissolved, then add an approximately equal volume of 70 g/liter sulfamic acid in 2 M HCl.
2. After 6 hr, remove the reaction mixture and clean the area in a conventional fashion.
3. Check for completeness of destruction by using a wipe soaked in methanol and analyzing it for the presence of the compound (see Support Protocol 10).
4. Neutralize the reaction mixture, e.g., with sodium hydroxide solution.
5. Test the reaction mixture for the presence of MNNG (see Support Protocol 10).
6. Discard the decontaminated reaction mixture.

ANALYTICAL PROCEDURE TO DETECT *N*-METHYL-*N*′-NITRO-*N*-NITROSOGUANIDINE

Reversed-phase HPLC (Snyder et al., 1997) is used to test for the presence of MNNG.

Materials

Neutralized reaction mixture
12:88 methanol/3.5 mM $(NH_4)H_2PO_4$
250-mm × 4.6-mm-i.d. Microsorb C-8 reversed-phase column (Varian) or equivalent
Additional reagents and equipment for reversed-phase liquid chromatography (Snyder et al., 1997)

Analyze the neutralized reaction mixture(s) by reversed-phase HPLC using a UV detector operating at 254 nm and a 250-mm × 4.6-mm-i.d. Microsorb C-8 column (Lunn et al., 1988). Elute with a mobile phase of 12:88 methanol/3.5 mM $(NH_4)H_2PO_4$ flowing at 1 ml/min at ambient temperature. Check the analytical procedure by spiking the neutralized reaction mixture with an aliquot of a dilute solution of MNNG.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cyanide detection reagent

Stir 3.0 g barbituric acid in 10 ml water. Add 15 ml of 4-methylpyridine and 3 ml concentrated HCl while continuing to stir. Cool and dilute to 50 ml with water. Store at room temperature.

CAUTION: *This reaction is exothermic.*

Decontamination solution

Dissolve 4.2 g sodium nitrite (0.2 M final) and 20 ml hypophosphorous acid (3.3% w/v final) in 300 ml water. Prepare fresh.

Horseradish peroxidase

Dissolve hydrogen-peroxide oxidoreductase (EC 1.11.1.7 [Type II]; specific activity 150 to 200 purpurogallin U/mg, Sigma) in 1 g/liter sodium acetate to give 30 U/ml. Prepare fresh daily.

For small-scale reactions, a more dilute solution can be used to avoid working with inconveniently small volumes.

pH 5 buffer

2.04 g potassium hydrogen phthalate (0.05 M final)
38 ml 0.1 M potassium hydroxide (15 mM)
H_2O to 200 ml
Store at room temperature

Phosphate buffer

13.6 g monobasic potassium phosphate (KH_2PO_4; 0.1 M final)
0.28 g dibasic sodium phosphate (Na_2HPO_4; 2 mM final)
3.0 g potassium bromide (KBr; 25 mM final)
1 liter H_2O
Store at room temperature

Potassium bromide is necessary to make the assay for cyanide work correctly.

Sodium azide indicator solution

0.1 g bromocresol purple (0.4% final)
18.5 ml 0.01 M potassium hydroxide (KOH; 7.4 mM final)
H_2O to 25 ml
Store at room temperature

Sulfanilic acid solution

Dissolve 0.5 g sulfanilic acid in 150 ml of 15% (v/v) aqueous acetic acid. Use immediately.

Safe Use of Radioisotopes

The use of radioisotopes to label specific molecules in a defined way has greatly furthered the discovery and dissection of biochemical pathways. The development of methods to synthesize such tagged biological compounds inexpensively on an industrial scale has enabled them to be used routinely in laboratory protocols, including many detailed in this manual. Although most of these protocols involve the use of only microcurie (μCi) amounts of radioactivity, some (particularly those describing the metabolic labeling of proteins or nucleic acids within cells) require amounts on the order of tens of millicuries (mCi). In all cases where radioisotopes are used, depending on the quantity and nature of the isotope, certain precautions must be taken to ensure the safety of laboratory personnel. This unit outlines a few such considerations relevant to the isotopes most frequently used in biological research.

In designing safe protocols for the use of radioactivity, the importance of common sense, based on an understanding of the general principles of isotopic decay, and the importance of continuous monitoring with a hand-held radioactivity monitor (e.g., Geiger counter) cannot be overemphasized. In addition, it is also critical to take into account the rules, regulations, and limitations imposed by the specific institution. These are usually not optional considerations: an institution's license to use radioactivity normally depends on strict adherence to such rules.

Many of the protocols described here have evolved (and are still evolving) over the years at the Department of Molecular and Cell Biology at the Salk Institute. The authors are indebted to those who have trained them in the safe use of radioactivity, in particular to the members of the Salk Institute Radiation Safety Department. Most of the designs for the shields and other safety equipment shown in Figures 1A.4.1A, 1A.4.2, and 1A.4.3 were created at the Salk Institute in collaboration with Dave Clarkin, Mario Tengco, and Steve Berry. Safety equipment of similar design is available from several commercial vendors, including CBS Scientific and Research Products International (see *SUPPLIERS APPENDIX*).

BACKGROUND INFORMATION

The Decay Process

As anyone who has taken a basic chemistry course will remember, each element is characterized by its atomic number (*Z*), defined as the number of protons in the atom's nucleus. Isotopes of a given element exist because some atoms of each element, while by definition having the same number of protons, have a different number of neutrons and therefore a different nuclear weight (*A*), equivalent to the atomic mass number which reflects the total number of nucleons (protons plus neutrons). It should be noted that the number of electrons outside the nucleus remains the same for all isotopes of a given element, and so all isotopes of a given element are equivalent with respect to their chemical reactivity.

Radioactive decay occurs when energy is released from the nucleus of an atom of a particular isotope. This often results in the conversion of an atom of one isotope to an isotope of a different element, a process termed transmutation, as the number of protons in the atom changes after decay. The energy released from naturally occurring radioisotopes can be particulate (α and β particles), or nonparticulate (γ rays).

α particles

An α particle is essentially the nucleus of a helium atom, or two protons plus two neutrons. It is a relatively large, heavy particle that moves slowly and usually only across short distances before it encounters some other atom with which it interacts. These particles are released from isotopes with large nuclei (atomic number >82; e.g., thorium, uranium); such isotopes are not commonly used in biological research except for specific applications such as electron microscopy and X-ray diffraction studies.

β particles

In contrast to α particles, β particles are light, high-speed, charged particles. Negatively charged β particles are essentially electrons of nuclear origin that are released when a neutron is converted to a proton. Release of a β particle thus changes the atomic number and elemental status of the isotope.

Current Protocols in Microbiology (2006) 1A.4.1-1A.4.12

γ radiation

γ radiation has both particle and wave properties; its wavelength falls within the range of X-ray wavelengths. Presently, γ radiation is defined as that originating from an atomic nucleus, and X-ray radiation as that originating from the electron cloud surrounding the nucleus. Unlike β-particle release, the release of γ radiation by itself produces an isotopic change rather than an elemental one; however, the resultant nuclei are unstable and often decay further, releasing β particles.

Isotopic decay

The energy of all α particles and γ rays (measured in electron volts, eV) is fixed, because they are of specific composition or wavelength. The energy of β particles, however, varies depending on the atom from which they originate (and on the concomitant release of neutrinos or antineutrinos that serve to balance the conservation of energy aspect of the decay equation). Thus, relatively high-energy β particles are released during the decay of ^{32}P and low-energy β particles are released when tritium (^{3}H) decays.

Isotopic decay usually involves a chain or sequence of events rather than a single loss of a particle, because the resultant, equally unstable atoms try to achieve equilibrium. During this course of decay, secondary forms of radiation can be generated that may also pose a hazard to workers. For example, when high-energy β particles released during the decay of ^{32}P encounter the nuclei of atoms with a large atomic number, a strong interaction occurs. The β particle loses some energy in the form of a photon. Such photons are called bremsstrahlung radiation and are detectable using a monitor suitable for the detection of γ or X-rays.

Following their release, α, β, and γ emissions (as well as secondary forms of radiation) travel varying average distances at varying average speeds, depending on their energy and the density of the material through which they are moving. The distance they actually travel before encountering either the electrons or nucleus of another atom is termed their degree of penetrance, or range. This value is expressed as an average for each type of particle. The energy of the particles released (and therefore their potential penetrance) thus dictates what type of shielding, if any, is necessary for protection against the radiation generated by the decay of a given isotope. α, β, and γ emissions all have the potential, upon encountering an atom, to knock out its electrons, thereby creating ions. Thus, these three types of emissions are called ionizing radiation. The formation of such ions may result in the perturbation of biological processes: therein lies the danger associated with radioactivity!

Measuring Radioactivity and Individual Exposure to It

The radioactivity of a given substance or sample is measured in terms of its ionizing activity. A curie, by definition, is the amount of radioactive material that will produce 3.4×10^{10} disintegrations (ions) per second (dps). This, not coincidentally, happens to be the number of disintegrations that occur during the decay of 1 g of radium and its decay products. Exposure to such radiation is measured as the amount of energy absorbed by the recipient, which, of course, is directly related to the potential damage such radiation may cause. One rad is the dose of radiation that will cause 100 ergs of energy to be absorbed per gram of irradiated material. The unit commonly used to measure radiation doses to humans is the rem; this is related to the rad but takes into account a "quality factor" based on the type of ionizing radiation being received. For β particles and γ or X-rays this factor is 1; therefore, rems of β equal rads of β. In contrast, the quality factor associated with α particles is 20, so an exposure of one rad due to α particles would be recorded as 20 rem.

The amount or dose of radiation received by materials (e.g., cells, scientists) near the source depends not only on the specific type and energy (penetrance) of the radiation being produced, but also on the subject's distance from the source, the existence of any intervening layers of attenuating material (shielding), and the length of time spent in the vicinity of the radiation source. To best measure such doses, every person working with or around radioactivity should wear an appropriate type of radiation detection badge (in addition to carrying a portable radiation monitor that can give an immediate, approximate reading). This is normally a requirement (not an option) for compliance with an institution's license to use radioisotopes. Such badges are usually furnished by the safety department and collected at regular intervals for reading by a contracted company. Most institutions currently use either TLDs (thermoluminescent) or OSLDs (optically stimulated luminescent) dosimeters. TLDs take advantage of chemicals such as calcium or lithium fluorides, which, following exposure to ionizing radiation, will luminesce at temperatures below their normal thermal

luminescence threshold. OSLDs are read after stimulating their powdered aluminum trioxide wafer with a laser. Different types of badges are sensitive to different types of radiation: always be sure to wear one that is appropriate for detecting exposure to the isotope being used! Most often, workers will be asked to wear a radiation detection badge on the labcoat lapel in order to measure whole-body radiation. Pregnant women may be asked to wear a dosimeter over or near their stomach area to better monitor their (and the developing fetus's) exposure. When working with >1 mCi ^{32}P or ^{125}I, it is also advisable to wear a ring badge to measure exposure to the unshielded (though gloved!) fingers (extremities). The limit set for "acceptable" exposure to whole-body radiation is several-fold less than the limit set for extremities. Nevertheless, we have found that the exposure recorded on ring badges is often significant with respect to the limit for extremities set by our institution.

What is known about the effects on humans of exposure to low levels of radiation (i.e., levels which would be received when briefly handling mCi or μCi amounts of radioactivity)? Not much, for the obvious reason that direct studies have not been undertaken. Accordingly, guidelines for exposure levels are set using extrapolations—either by extrapolating down from population statistics obtained following accidents or disasters e.g., (the Chernobyl meltdown, atomic bombings) or by extrapolating up from numbers obtained from animal experiments. Each form of extrapolation is subject to caveats, and given that predictions based on such extrapolations cannot be perfect, most health and safety personnel aim for radiation exposure levels said to be ALARA ("as low as reasonably achievable"). An extensive discussion of both the studies and the statistics on which exposure limits are based, updated on a regular basis, may be found in the BEIR series (Biological Effects of Ionizing Radiations; BRER, 2005, available online in an open-book form at *http://www.nap.edu/books/030909156X/html*).

Limiting exposure to radiation can be accomplished by adjusting several parameters: the duration of exposure, distance from the source, and the density of the material (air, water, shielding) between the individual and the source.

Time is of the essence

When designing any experiment using radioactivity, every effort should be made to limit the time spent directly handling the vials or tubes containing the radioactive material. Speed should be encouraged in all manipulations, though not to the point of recklessness! Have everything needed for the experiment ready at hand before radioactivity is introduced into the work area.

Distance helps to determine dose

When possible, experiments involving radioactivity should be performed in an area separate from the rest of the lab. Many institutions require that such work be performed in a designated "hot lab"; however, if many people in the laboratory routinely use radioisotopes, it is less than feasible to move them all into what is usually a smaller space. No matter where an individual is working, it is his or her responsibility to monitor the work area and ensure his or her own safety and the safety of those working nearby by using adequate shielding. Obviously, when handling the radioactive samples, it is necessary to work behind all required shielding. To protect bystanders, remember that the intensity of radiation from a source (moving through air) falls off in proportion to the square of the distance. Thus, if standing 1 foot (~30 cm) away from a source for 5 min would result in an exposure of 45 units, standing 3 feet (~90 cm) away for the same amount of time would result in an exposure $(1/3)^2$ of 45 units, or 5 units. This factor is also relevant when considering the storage of large (mCi) amounts of radioactivity, particularly ^{125}I or ^{32}P, as no amount of shielding can completely eliminate radiation.

Shielding is the key to safety

As mentioned above, the energy of the particle(s) released during the decay of an isotope determines what, if any, type of shielding is appropriate. β particles released during the decay of ^{14}C and ^{35}S possess roughly ten times the energy of those released when ^{3}H decays. All three β particles are of relatively low energy, do not travel very far in air, and cannot penetrate solid surfaces. No barriers are necessary for shielding against this type of β radiation. The major health threat from these isotopes occurs through their accidental ingestion, inhalation, or injection.

β particles released during the decay of ^{32}P have 10-fold higher energy than those released from ^{14}C, and thus pose a more significant threat to workers. (One reported hazard is the potential for induction of cataracts in the unshielded eye.) The fact that these high-energy β particles can potentially generate significant

amounts of bremsstrahlung radiation is the reason that low-density materials are used as the primary layer of shielding for β radiation from ^{32}P. Water, glass, and plastic are suitable low-density materials (as opposed to lead). Obviously water is unsuitable as a shielding layer for work on the bench, although it does a reasonable job when samples are incubating in a water bath. Shields made from a thickness of glass sufficient to stop these particles would be extremely heavy and cumbersome (as well as dangerous if dropped). Fortunately, plastic or acrylic materials—variously called Plexiglas, Perspex, or Lucite—are available for shielding against β radiation from ^{32}P. Shields, as well as storage boxes, constructed of various thicknesses of Plexiglas are necessary equipment in laboratories where ^{32}P is used. When mCi amounts of ^{32}P are used at one time, it is necessary to also block the bremsstrahlung radiation by adding a layer of high-density material (such as 4 to 6 mm of lead) to the outside of the Plexiglas shield (covering the side farthest from the radioactive source).

γ rays released during the decay of ^{125}I have much higher penetrance than the β particles from ^{32}P decay; this radiation must be stopped by very-high-density material, such as lead. Lead foil of varying thicknesses (0.5 to 6 mm) can be purchased in rolls and then cut and molded to cover any container, or taped to a Plexiglas shield (used in this instance for support). Obviously this latter arrangement has the disadvantage that it is impossible to see what one is doing through the shield. For routine shielding of manipulations involving ^{125}I, it is useful to purchase a lead-impregnated Plexiglas shield that is transparent, albeit inevitably very heavy (as well as relatively expensive).

Although it seems logical that the use of more radioactivity necessitates the use of thicker layers of shielding, it is also true that no shielding material is capable of completely stopping all radiation. When deciding how thick is "thick enough," consult the half-value layer measurement for each type of shielding material. This number gives the thickness of a given material necessary to stop half the radiation from a source. In general, 1 to 2 cm of Plexiglas and/or 0.02 mm of lead are sufficient to shield the amounts of radioactivity used in experiments performed in the author's laboratory.

GENERAL PRECAUTIONS

Before going on to a discussion of specific precautions to be taken with individual isotopes, a short list of general precautions to be taken with all isotopes seems pertinent:

1. Know the rules. Be sure that each individual is authorized to use each particular isotope and uses it in an authorized work area.

2. Don the appropriate apparel. Whenever working at the lab bench, it is good safety practice to wear a labcoat for protection; when using radioactivity, wearing a labcoat is imperative almost everywhere. Disposable paper/synthetic coats of various styles are commercially available at relatively low cost. These may be conveniently thrown out if contaminated with radioactivity during an experiment, rather than held for decay as might be preferable with more expensive cloth coats. As an alternative, disposable sleeves can be purchased and worn over those of the usual cloth coat. Other necessary accessories include radiation safety badges, gloves, and protective eyewear. It is convenient to wear two pairs of gloves at once when using radioactivity: when the outer pair becomes contaminated, it is possible to strip it off and continue working without interruption. Contaminated gloves should always be removed over a bench or waste container so that microdroplets of contamination do not fall on the floor and get tracked about!

3. Protect the work area as well as the workers. Laboratory benches and the bases of any shields used should be covered with some sort of disposable, preferably absorbent, paper sheet. Underpads or diapers (the kind normally used in hospitals) are convenient for this purpose.

4. Use appropriate designated equipment. It is very convenient, where use justifies the expense, to have a few adjustable pipettors dedicated for use with each particular isotope. Likewise, it is good practice to use only certain labeled centrifuges and microcentrifuge rotors for radioactive samples, to avoid contamination of all rotors in the laboratory. Although such equipment should be cleaned after each use, complete decontamination is often not possible. A few pipettors or a single microcentrifuge can easily be stored (and used) behind appropriate shielding. Actually, contamination of the insides and tip ends of pipettors can be greatly reduced by using tips supplied with internal aerosol barriers such as those used for PCR reactions. To prevent contamination of the outside of the pipettor's barrel, simply wrap the hand-grip in Parafilm, which can be discarded later.

5. Know where to dispose of radioactive waste, liquid and solid. Most institutions require that radioactive waste be segregated by

isotope. This is done not only so that appropriate shielding can be placed around waste containers, but so that some waste can be allowed to decay prior to disposal in the normal (nonradioactive) trash. With a decreasing number of radioactive waste disposal facilities able or willing to accept radioactive waste for burial (and a concomitant increase in dumping charges from those that still do), this practice of on-site decay can save an institution thousands of dollars a year in disposal charges.

6. Label your label! It is only common courtesy (as well as common sense) to alert coworkers to the existence of anything and everything radioactive that is left where they may come in contact with it! A simple piece of tape affixed to the sample box—with the investigator's name, the amount and type of isotope, and the date—should suffice. Yellow hazard tape printed with the international symbol for radioactivity is commercially available in a variety of widths.

7. Monitor radioactivity early and often. Portable radiation detection monitors are essential equipment for every laboratory using radioactivity. No matter how much or how little radioactivity is being used, the investigator should keep a hand-held monitor nearby—and it should be on! Turn it on before touching any radioactivity to avoid contaminating the monitor's switch. Always check the batteries! Use a monitor with the appropriate detection capacity (β for ^{35}S and ^{32}P; γ for ^{125}I) before, during, and after all procedures. The more frequently fingers and relevant equipment are monitored, the more quickly a spill or glove contamination will be detected. Such timely detection will keep both the potential mess and cleanup time to a minimum. While it is tempting to cover the monitor's detection tube with Parafilm to protect it from contamination, remember that this will preclude the detection of the weaker β of ^{35}S! Because low-energy β emitters such as ^{3}H cannot be detected at all using such monitors, wipe tests of the bench and equipment used, followed by scintillation counting of the wiped samples, are necessary to ensure that contamination of the work area did not occur.

SPECIFIC PRECAUTIONS

The following sections describe precautions to be taken with individual isotopes in specific forms. Although the sections dealing with ^{35}S- or ^{32}P-labeling of proteins in intact cells are presented in terms of mammalian cells, most of the instructions are also pertinent (with minimal and obvious modifications) to the labeling of proteins in other cells (e.g., bacterial, insect, plant).

Working with ^{35}S

As discussed above, the β radiation generated during ^{35}S decay is not strong enough to make barrier forms of shielding necessary. The risk associated with ^{35}S comes primarily through its ingestion and subsequent concentration in various target organs, particularly the testes. As reported several years ago (Meisenhelder and Hunter, 1988), ^{35}S-labeled methionine and cysteine, which are routinely used to label proteins in intact cells and by in vitro translation, break down chemically to generate a volatile radioactive component. The breakdown occurs independently of cellular metabolism. Thus, the radioactive component is generated to the same extent in stock vials as in cell culture dishes. The process seems to be promoted by freezing and thawing ^{35}S-labeled materials. The exact identity of this component is not known, although it is probably SO_2 or CH_3SH. What is known is that it dissolves readily in water and is absorbed by activated charcoal or copper.

The amount of this volatile radioactive component released, despite stabilizers added by the manufacturers, is about 1/8000 of the total radioactivity present. The amount of this radioactivity that a scientist is likely to inhale while using these compounds is presumably even smaller. Nevertheless, such a component can potentially contaminate a wide area because of its volatility, and also tends to concentrate in target organs. Thus, it is advisable to thaw vials of ^{35}S-labeled amino acids in a controlled area such as a hood equipped with a charcoal filter. This charcoal filter will become quite contaminated and should be changed every few months. If such an area is not available, the stock vial should be thawed using a needle attached to a charcoal-packed syringe to vent and trap the volatile compound.

Anyone who has ever added ^{35}S-labeled amino acids to dishes of cells for even short periods knows that the incubators used for such labelings quickly become highly contaminated with ^{35}S. Such contamination is not limited to the dish itself, nor to the shelf on which the dish was placed. Rather, the radioactive component's solubility in water allows it to circulate throughout the moist atmosphere of the incubator and contaminate all of the inside surfaces. For this reason, in laboratories where such metabolic labelings are routine, it is highly convenient to designate one incubator to be used solely for working with ^{35}S-labeled

samples. Such an incubator can be fitted with a large honeycomb-style filter, the size of an incubator shelf, made of pressed, activated charcoal. These filters are available from local air-quality-control companies. Such a filter will quickly become quite contaminated with radioactivity and should therefore be monitored and changed as necessary (usually about every three months if the incubator is used several times a week). The water used to humidify the incubator will also become quite "hot" (contaminated with radioactivity); keeping the water in a shallow glass pan on the bottom of the incubator makes it easy to change it after every use, thus preventing contamination from accumulating. Even with the charcoal filter and water as absorbents, the shelves, fan, and inner glass door of the incubator will become contaminated, as will the tray on which the cells are carried and incubated. Routine wipe tests and cleaning when necessary will help to minimize potential spread of this contamination.

If such labelings are done infrequently or there is no "spare" incubator, dishes of cells can be placed in a box during incubation. This box should be made of plastic, which is generally more easily decontaminated than metal. Along with the dishes of cells, a small sachet made of activated charcoal wrapped loosely in tissue (Kimwipes work well) should be placed in the box. If the box is sealed, it will obviously need to be gassed with the correct mixture of CO_2; otherwise small holes can be incorporated into the box design to allow equilibration with the incubator's atmosphere. In either case, the incubator used for the labeling should be carefully monitored for radioactivity after each experiment.

Working with ^{32}P

Microcurie (μCi) amounts of ^{32}P

The amount of ^{32}P-labeled nucleotide used to label nucleic acid probes for northern or Southern blotting is typically under 250 μCi, and the amount of [γ-^{32}P]ATP used for in vitro phosphorylation of proteins does not usually exceed 50 μCi for a single kinase reaction (or several hundred microcurie per experiment). However, handling even these small amounts, given the time spent on such experiments, can result in an unacceptable level of exposure if proper shielding is not employed. With no intervening shielding, the dose rate 1 cm away from 1 mCi of ^{32}P is 200,000 mrad/hr; the local dose rate to basal cells resulting from a skin contamination of 1 μCi/cm^2 is 9200 mrad/hr (Shleien, 1987). Such skin contamination could easily occur though careless pipetting and the resultant creation of an aerosol of radioactive microdroplets, because the concentration of a typical stock solution of labeled nucleotide may be 10 μCi/μl.

For proper protection during this sort of experiment, besides the usual personal attire (glasses, gloves, coat, and ring and lapel safety badges) it is necessary to use some form of Plexiglas screen between the body and the samples (see Fig. 1A.4.1A). Check the level of radiation coming through the outside of the shield with a portable monitor to be sure the thickness of the Plexiglas is adequate. Consult your Radiation Safety Officer if the monitor reads more than 4000 cpm. Hands can be shielded from some exposure by placing the sample tubes in a solid Plexiglas rack, which is also useful for transporting samples from the bench to a centrifuge or water bath (see Fig. 1A.4.1B).

Experiments of these types often include an incubation step performed at a specific temperature, usually in a water bath. Although the water surrounding the tubes or hybridization bags will effectively stop β radiation, shielding should be added over the top of the tubes (where there is no water)—e.g., a simple flat piece of Plexiglas. If the frequency of usage justifies the expense, an entire lid for the water bath can be constructed from Plexiglas. When hybridization reactions are performed in bags, care should be taken to monitor (and shield) the apparatus used to heat-seal the bags.

The waste generated during the experiments should also be shielded. It is convenient to have a temporary waste container right on the bench. Discard pipet tips and other solid waste into a beaker lined with a plastic bag and placed behind the shield. This bag can then be emptied into the appropriate shielded laboratory waste container when the experiment is done. Liquid waste can be pipetted into a disposable tube set in a stable rack behind the shield (see Fig. 1A.4.1C).

When radiolabeled probes or proteins must be gel-purified, it may be necessary to shield the gel apparatus during electrophoresis if the samples are particularly hot. Be advised that the electrophoresis buffer is likely to become very radioactive if the unincorporated label is allowed to run off the bottom of the gel; check with your Radiation Safety Officer for instructions on how to dispose of such buffer. It is also prudent to check the gel plates with a portable detection monitor after the electrophoresis is completed, because they sometimes become contaminated as well.

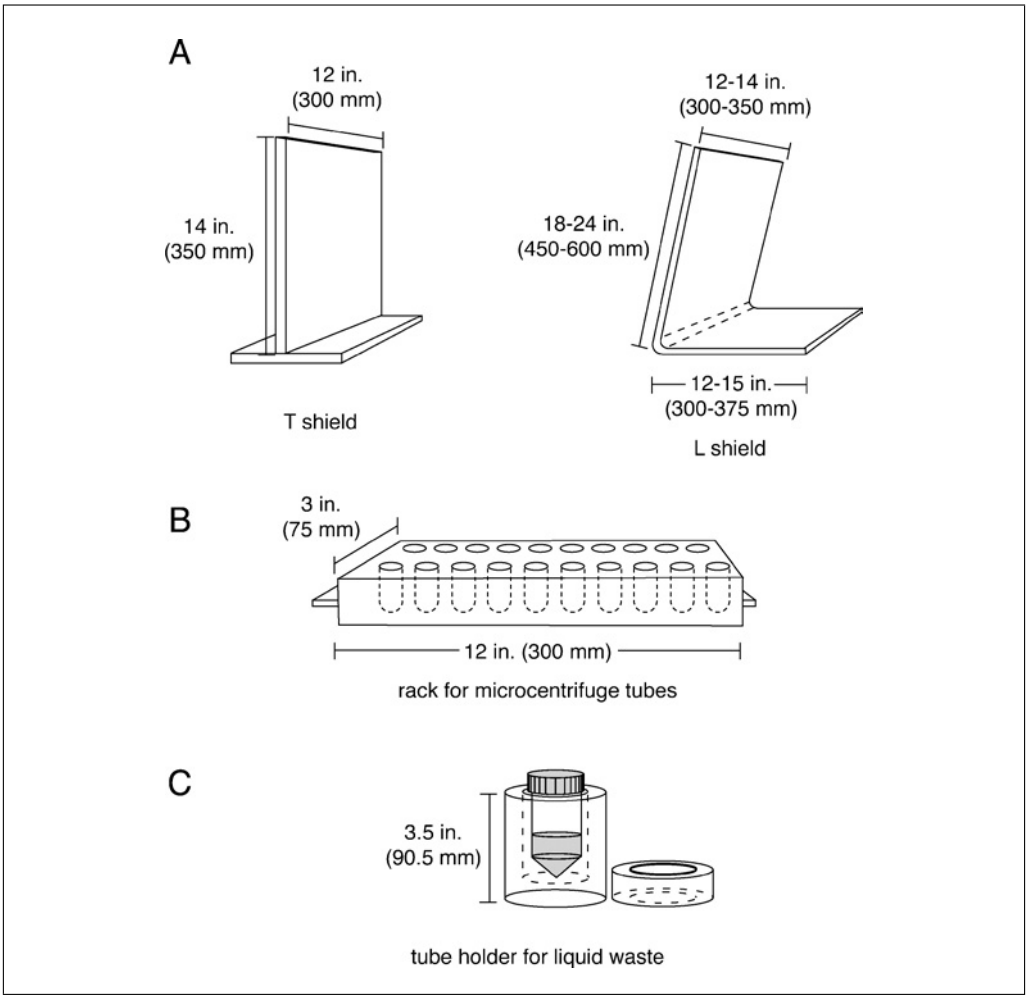

Figure 1A.4.1 Plexiglas shielding for ^{32}P. (**A**) Two portable shields (L and T design) made of 0.5-in. (12.5 mm) Plexiglas. Either can be used to directly shield the scientist from the radioactivity he or she is using. Turned on its side, the L-shaped shield can be used to construct two sides of a cage around a temporary work area, providing shielding for other workers directly across or to the sides of the person working with ^{32}P. (**B**) Tube rack for samples in microcentrifuge tubes. (**C**) Tube holder for liquid waste collection.

Millicurie (mCi) amounts of ^{32}P

In order to study protein phosphorylation in intact mammalian cells, cells in tissue culture dishes are incubated in phosphate-free medium with ^{32}P-labeled orthophosphate for a period of several hours or overnight, to label the proteins. The amount of ^{32}P used in such labelings can be substantial. Cells are normally incubated in 1 to 2 mCi of ^{32}P per ml labeling medium; for each 6-cm dish of cells, 2.5 to 5 mCi ^{32}P may be used. When this figure is multiplied by the number of dishes necessary per sample, and the number of different samples in each experiment, it is clear that the amount of ^{32}P used in one experiment can easily reach 25 mCi or more. Because so much radioactivity is used in the initial labeling phase of such experiments, it is necessary for a researcher to take extra precautions in order to adequately shield him or herself and coworkers.

When adding label to dishes of cells, it is important to work as rapidly as possible. An important contribution to the speed of these manipulations is to have everything that will be needed at hand before even introducing the label into the work area. Prepare the work area, arranging shielding and covering the bench with diapers, in advance. Set out all necessary items, including any pipettors and tips needed, a portable detection monitor, extra gloves, and a cell house (see Fig. 1A.4.2A).

Work involving this much radioactivity should be done behind a Plexiglas shield at least 3/4 in. (~2 cm) thick; the addition of a layer of lead to the outside lower section of this shield to stop bremsstrahlung radiation is also needed. If one shield can be dedicated to this

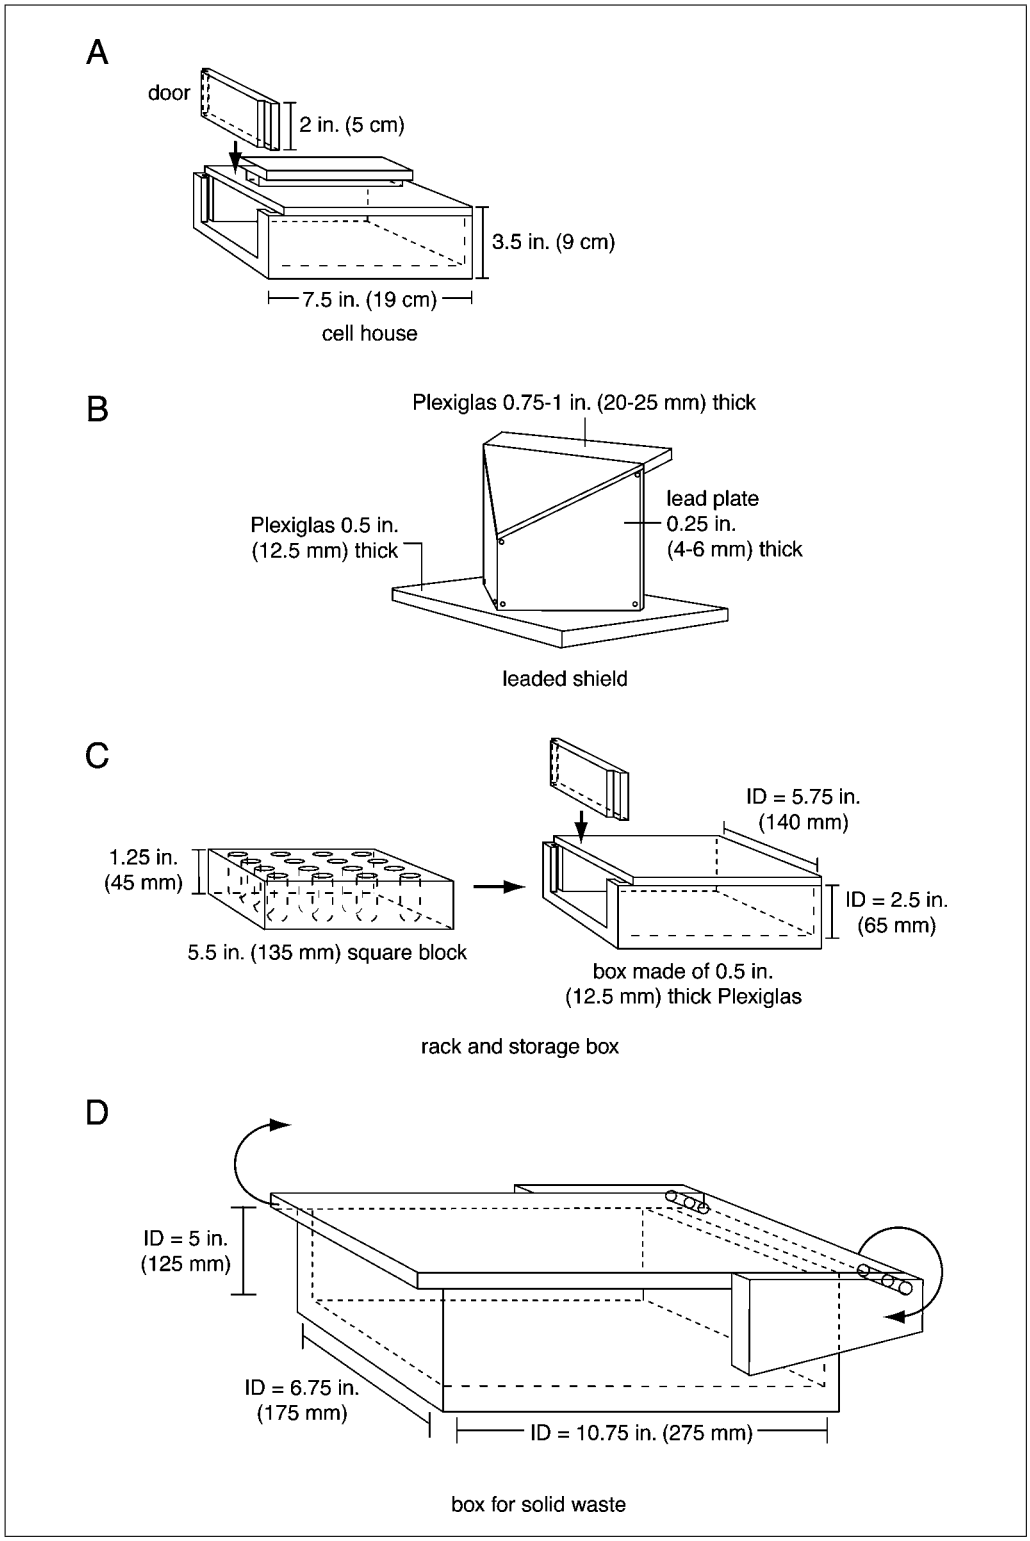

Figure 1A.4.2 (**A**) Box for cell incubation (a “cell house”). (**B**) Box for solid waste collection made of 0.5-in. Plexiglas. (**C**) Sample storage rack and box made of 0.5-in. Plexiglas. (**D**) Box for solid waste collection made of 0.5-in. Plexiglas. Abbreviations: ID, interior dimension.

purpose at a specific location, a sheet of lead several centimeters thick can be permanently screwed to the Plexiglas (as shown in Fig. 1A.4.2B); however, lead makes the shield extremely heavy and therefore less than portable. If space constraints do not permit the existence of such a permanent labeling station, a layer or two of lead foil can be taped temporarily to the outside of the Plexiglas shield.

Again, each worker should take care to shield not only him or herself but also bystanders on all sides. Handling of label should be done away from the central laboratory, if possible, to take maximum advantage of distance as an additional form of shielding. It is also advisable not to perform such experiments in a tissue culture room or any other room that is designed for a purpose vital to the whole laboratory. An accident involving this much ^{32}P would seriously inconvenience future work in the area, if not make it altogether uninhabitable! If care is taken to minimize the amount of time the dish of cells is open when adding the label, use of a controlled air hood to prevent fungal or bacterial contamination of the cells should not be necessary.

Plexiglas dish covers. In the course of doing experiments to determine which hand receives the most exposure during such cell labelings, the authors discovered that extremity exposure can vary as much as seven-fold depending on the finger on which the ring is worn, with the index finger of the left hand receiving the most exposure for a right-handed person (Bursik et al., 1999). As would be expected, the most exposure is received as the worker adds label to the dishes of cells and as the cells are lysed (see below). In order to mitigate this extremity exposure, we designed Plexiglas dish covers to shield each individual dish: the tissue culture dish fits snugly into the bottom Plexiglas piece while the top Plexiglas piece is joined to the top of the tissue culture dish using tape, so that the two lids can be handled together as one unit. Tissue culture dishes of cells are fitted/taped into the Plexiglas dish covers immediately before adding the ^{32}P. As the top and bottom pieces of the dish covers do not form a seal, the medium can equilibrate with the CO_2 of the incubator for proper pH adjustment. Use of such dish covers reduces extremity exposure 8- to 10-fold, despite the stream of radioactivity that passes through the crack between the top and bottom. Figure 1A.4.3 shows a researcher preparing to remove the medium from a dish of cells using the Plexiglas dish covers.

Cell houses. Once the label has been added to the dishes of cells (and whether or not one is using the dish covers discussed above), the dishes will also need to be shielded for transport to and from the incubator and other work

Figure 1A.4.3 Use of Plexiglas dish shields for ^{32}P labels reduces extremity exposure.

areas. Plexiglas boxes that are open at one end (for insertion of the dishes) and that have a handle on top (for safe carrying) make ideal cell houses (see Fig. 1A.4.2A). A Plexiglas door that slides into grooves at the open end is important to prevent dishes from sliding out if the box is tilted (even minutely) during transport. If this door is only two-thirds the height of the house wall, the open slot thus created will allow equilibration of the CO_2 level within the house with that in the incubator. Obviously, this slot will also allow a substantial stream of radiation to pass out of the cell house, so the house should be carried and placed in the incubator with its door facing away from the worker (and others)! Use of the Plexiglas dish covers adds considerable bulk; larger cell houses designed with handles on their sides and a hinged lid are more easily handled (see Fig. 1A.4.3).

Dealing with lysis products. Following incubation with label and any treatments or other experimental manipulations, the cells are usually lysed in some type of detergent buffer. It is during this lysis procedure that a worker's hands will receive their greatest exposure to radiation, because it is necessary to directly handle the dishes over a period of several minutes. It is therefore very important to streamline this procedure and use shielding whenever possible. If the cell lysates must be made at 4°C, as required by most protocols, working on a bench in a cold room is preferable to placing the dishes on a slippery bed of ice. In either case, make the lysate using the same sort of shielding (with lead if necessary) that was used when initially adding the label. Pipet the labeling medium and any solution used to rinse unincorporated radioactivity from the cells into a small tube held in a solid Plexiglas holder (shown in Fig. 1A.4.1C). The contents of this tube can later be poured into the appropriate liquid waste receptacle. If possible, it is a good practice to keep this high-specific-activity ^{32}P liquid waste separate from the lower-activity waste generated in other procedures, so that it can be removed from the laboratory as soon as possible following the experiment. If it is necessary to store it in the laboratory for any time, the shielding for the waste container should also include a layer of lead.

The solid waste generated in the lysis part of these experiments (pipet tips, disposable pipets, cell scrapers, and dishes) is very hot and should be placed immediately into some sort of shielded container to avoid further exposure of the hands. A Plexiglas box similar in design to that in Figure 1A.4.2 is convenient; placed to the side of the shield and lined with a plastic bag, it will safely hold all radioactive waste during the experiment and is light enough to be easily carried to the main laboratory waste container where the plastic bag (and its contents) can be dumped after the experiment is done. If the lid of the box protrudes an inch or so over the front wall, it can be lifted using the back of a hand, thus decreasing the possibility of contaminating it with hot gloves.

When scraping the cell lysates from the dishes, it is good practice to add them to microcentrifuge tubes that are shielded in a solid Plexiglas rack; this will help to further reduce the exposure to which the hands are subjected. At this point, the lysates are usually centrifuged at high speed ($\sim$10,000 $\times$ g) to clear them of unsolubilized cell material. Use screw-cap tubes for this clarification step, as these will contain the labeled lysate more securely than flip-top tubes, which may open during centrifugation. No matter what type of tube is used, the rotor of the centrifuge often becomes contaminated, most probably because of tiny drops of lysate (aerosol) initially present on the rim of the tubes that are spun off during centrifugation. Monitor the rotor and wipe it out after each use.

The amount of ^{32}P taken up by cells during the incubation period varies considerably, depending on the growth state of the culture as well as on the cell type and its sensitivity to radiation. This makes it difficult to predict the percentage of the radioactivity initially added to the cells that is incorporated into the cell lysate; however, this figure probably does not exceed 10%. Thus, the amount of radioactivity being handled decreases dramatically after lysis, making effective shielding much simpler. However, at least ten times more radioactivity than is usual in other sorts of experiments is still involved! It is easy to determine if the shielding is adequate—just use both β and γ portable monitors to measure the radiation coming through it. If the meter reads more than 5000 cpm, additional shielding is needed. Again, be sure to check that people working nearby (including those across the bench) are also adequately shielded. It is sometimes necessary to construct a sort of cage of Plexiglas shields around the ice bucket that contains the lysates.

Storage. At the end of the day or the experiment, it may be necessary to store radioactive samples; in some experiments, it may be desirable to save the cell lysates. These very hot

samples are best stored in tubes placed in solid Plexiglas racks that can then be put into Plexiglas boxes (see Fig. 1A.4.2C). Such boxes may be of similar construction to the cell houses described above; however, they should have a door that completely covers the opening. Be sure to check the γ radiation coming through these layers and add lead outside if necessary.

Working with ^{33}P

Using ^{33}P-labeled nucleotides to label nucleic acid probes or proteins

Several of the major companies that manufacture radiolabeled biological molecules also sell nucleotides labeled with ^{33}P (both α- and γ-labeled forms). ^{33}P offers a clear advantage over ^{32}P with respect to ease of handling, because the energy of the β particles emitted lies between that of ^{35}S and ^{32}P; thus, ^{33}P does not require as many layers of Plexiglas and lead shielding as ^{32}P. In fact, the β radiation emitted can barely penetrate gloves and the surface layer of skin, so the hazard associated with exposure to even millicurie amounts of ^{33}P is thought to be insignificant (as reported in the NEN Life Science product brochure). Gel bands visualized on autoradiograms of ^{33}P-labeled compounds are sharper than bands labeled with ^{32}P because the lower-energy β radiation does not have the scatter associated with ^{32}P. The half-life of ^{33}P is also longer (25 days compared to 14 days for ^{32}P). Despite its higher cost, these features have led many researchers to choose ^{33}P-labeled nucleotides for use in experiments such as band/gel shift assays where discrimination of closely spaced gel bands is important.

The best way to determine what degree of shielding is needed when using ^{33}P is to monitor the source using a portable β monitor and add layers of Plexiglas as necessary, as described previously for ^{32}P.

Working with ^{125}I

Using ^{125}I to detect immune complexes (immunoblots or western blots)

^{125}I that is covalently attached to a molecule such as staphylococcal protein A is not volatile and therefore is much less hazardous than the unbound or free form. Most institutions do not insist that work with bound ^{125}I be performed in a hood, but shielding of the γ radiation is still necessary. Lead is a good high-density material for stopping these γ rays; its drawbacks are its weight and opacity. Commercially available shields for ^{125}I are made of lead-impregnated Plexiglas—though heavy, these are at least see-through. Alternatively, a piece of lead foil may be taped to a structural support, although this arrangement does not provide shielding for the head as a worker peers over the lead!

Incubations of the membrane or blot with the [^{125}I]protein A solution and subsequent washes are usually done on a shaker. For shielding during these steps, a piece of lead foil may simply be wrapped around the container. Solutions of ^{125}I can be conveniently stored for repeated use in a rack placed in a lead box.

Using ^{125}I to label proteins or peptides in vitro

Any experiments that call for the use of free, unbound ^{125}I should be done behind a shield in a hood that contains a charcoal filter to absorb the volatile iodine. Most institutions require that such experiments be done in a special hot lab to which access is limited. Ingested or inhaled iodine is concentrated in the thyroid; a portable γ monitor should therefore be used to scan the neck and throat before beginning and 24 to 36 hr after completing each experiment. Similar thyroid bioassays should routinely be performed on all members of any laboratory in which unbound iodine is used.

DEALING WITH ACCIDENTS

Despite the best intentions and utmost caution, accidents happen. Accidents involving spills of radioactivity are particularly insidious because they can be virtually undetectable yet pose a significant threat to laboratory workers. For this reason, in any laboratory where radioisotopes are routinely used, it is best to foster a community spirit—a sense of cooperativity that extends from shielding each other properly to helping each other clean up when such accidents occur.

The specific measures to be taken following an accident involving radioactivity naturally depend on the type and amount of the isotope involved, the chemical or biological hazards of the material it is associated with, and the physical parameters of the spill (i.e., where and onto what the isotope was "misplaced"). However, following any accident, there are several immediate steps that should be taken:

1. Alert coworkers as well as institutional Radiation Safety personnel to the fact that there has been an accident. This will give them the opportunity to shield themselves if necessary—and to help clean up as well!

2. Restrict access to and away from the site of the accident to ensure that any uncontained radioactive material is not spread around the laboratory. When leaving the site, be sure to monitor the bottoms of the shoes as well as the rest of the body.

3. Take care of all contaminated personnel first, evacuating others if necessary. If anyone's skin is contaminated, first use a portable monitor to identify specific areas of contamination, then wipe these areas with a damp tissue to remove as much surface radioactivity as possible. Try to scrub only small areas at a time to keep the contamination localized. If the contamination is not easily removed with paper tissues, try a sponge or an abrasive pad, but be careful not to break the skin! Sometimes soaking is required: do this only after all easily removed contamination is gone and keep the soaked area to a minimum. Contaminated strands of hair can be washed (or perhaps a new hairstyle may be in order).

4. When attempting to clean any contaminated equipment, floors, benches, etc., begin by soaking up any visible radioactive liquid with an absorbent material. Use a small amount of soap and water to clean the contaminated area, keeping the area wiped each time to a minimum to avoid smearing the contamination over an even greater surface. There are quite a range of foams and sprays available commercially that are made specifically to decontaminate radioactivity. A dilute solution of phosphoric acid works well to pick up ^{32}P. Decontamination of centrifuge rotors can be tricky, as their anodized surfaces are sensitive to many detergents; check with the rotor manufacturer for appropriate cleansing solutions. Many surfaces prove resistant to even Herculean cleaning efforts; in these instances, the best that can be done is to remove all contamination possible and then shield whatever is left until the radioactivity decays sufficiently for safety.

Growing and Analyzing Static Biofilms

There are a variety of systems available for examining the formation of bacterial biofilms. In this unit, several approaches are described that are useful for studying, in particular, the earlier stages of formation of these communities. Static biofilm systems may be preferable to chemostatic or continuous-flow methods for a number of reasons. First, static assays are particularly useful for examining early events in biofilm formation, in some cases detecting biofilm formation in <60 min. For example, these assays can be used to identify signals that modulate the transition from a planktonic to a biofilm mode of existence. A second major advantage of these systems is the simplicity of the protocols: these assays can be executed primarily using common laboratory equipment. Furthermore, several of the assays outlined below have a relatively high throughput and can easily be adapted to study a variety of biofilm formation conditions, making them excellent tools for performing genetic screens. In addition, simple changes in the configurations of these screens (e.g., media used, medium replacement regimens, incubation time, washing vigor) allow examination of different aspects of these bacterial communities, such as formation or dispersal.

The static nature of these systems does have some drawbacks. Because most of the cultures are neither continuously supplied with fresh medium nor aerated, there may be limitation of nutrients, and an inability to easily generate mature biofilms may be encountered. Continuous-flow and chemostat systems for the production of mature biofilms are described in other units in this chapter.

Presented in this unit are four basic protocols for the growth and analysis of biofilms in static systems. The microtiter plate biofilm assay (see Basic Protocol 1) is a useful method for assessing bacterial attachment by measuring the staining of the adherent biomass. Because it utilizes a 96-well plate format, it is suitable as a tool for screening large numbers of bacterial strains or species. The air-liquid interface (ALI) assay (see Basic Protocol 2) is complementary to the microtiter plate biofilm assay in that it provides a mechanism for direct microscopic viewing of the live attached microbes. A colony-based biofilm system is also described (see Basic Protocol 3), with this system being especially useful for monitoring cell death in biofilms treated with antimicrobial agents. Finally, the Kadouri system (see Basic Protocol 4) is a "low-flow" system that can serve as a bridge between the static assays discussed in this unit and continuous-flow systems.

CAUTION: Follow all appropriate biosafety requirements relevant to the microorganism under investigation. Refer to *UNIT 1A.1* and other pertinent resources (see *APPENDIX 1B*) for instructions on safe handling of microorganisms.

MICROTITER PLATE BIOFILM ASSAY

BASIC PROTOCOL 1

This experimental system, whose most common format is often referred to as the 96-well plate assay, is a simple high-throughput method used to monitor microbial attachment to an abiotic surface. While popularized in the mid-to-late 1990s (Mack et al., 1994; O'Toole et al., 1999), the assay in its typically used form is derived from a protocol published by Christensen et al. (1985). Examples of bacteria studied in this manner are listed in Table 1B.1.1, although in theory, the protocol could be applied to any species amenable to growth in the prescribed format. In brief, cells are grown in microtiter dishes for a desired period of time, and then the wells are washed to remove planktonic bacteria. Cells remaining adhered to the wells are subsequently stained with a dye that allows visualization of the attachment pattern. This surface-associated dye can also be solubilized for semiquantitative assessment of the biofilm formed.

Current Protocols in Microbiology (2005) 1B.1.1-1B.1.17

Table 1B.1.1 Typical Conditions for Developing and Performing Microtiter Plate Biofilm Assays

Organism	Incubation temperature (°C)	Solvent for solubilization of stained biofilms	Reference
Agrobacterium tumefaciens	28	100% dimethyl sulfoxide (DMSO)	Danhorn et al., 2004
Escherichia coli	25	80% ethanol/20% acetone	O'Toole et al., 1999
Pseudomonas aeruginosa	25-37	95% ethanol	O'Toole et al., 1999
Pseudomonas fluorescens	25-30	95% ethanol	O'Toole et al., 1999
Staphylococcus aureus	37	33% glacial acetic acid	Stepanovic et al., 2001
Streptococcus mutans	37	95% ethanol or 100% DMSO	O'Toole et al., 1999
Vibrio cholerae	25-30	100% DMSO	O'Toole et al., 1999

Materials

Bacterial strains of interest
Appropriate media for bacteria under study (*APPENDIX 2C*)
70% ethanol
0.1% (w/v) crystal violet in water
Solvent (e.g., 95% v/v ethanol; see Table 1B.1.1 for other options) for solubilizing dye and biofilm biomass
96-well microtiter plates, not tissue culture–treated (Becton Dickinson catalog no. 353911) with lids (Becton Dickinson catalog no. 353913)
96-prong inoculating manifold, sterile (DanKar Scientific)
Small trays (e.g., large pipet tip boxes) sufficient in size to hold 96-well microtiter plates
Optically clear flat-bottom 96-well plates, nonsterile
Plate reader or spectrophotometer

For small sample numbers (<20 strains or species):

1a. Inoculate each bacterium of interest in a 3-to-5-ml culture and grow to stationary phase.

2a. Dilute cultures 1:100 in the desired media. Pipet 100 µl of each diluted culture into each of four wells in a fresh microtiter plate which has not been tissue culture treated. Cover plate and incubate at optimal growth temperature for the desired amount of time.

Lids for the microtiter dishes may be reused. Clean lids with 70% (v/v) ethanol and air-dry prior to each experiment.

The time course for attachment varies depending on the organism and must be determined empirically, although when using this system, many organisms commonly studied will form a biofilm within 48 hr.

For large screens (>20 strains or species):

1b. Inoculate cells directly into sterile microtiter plates filled with 100 µl of the appropriate medium per well, using four wells per strain or species. Incubate overnight.

2b. Inoculate biofilm assay plates directly in 100-µl medium per well from the overnight microtiter plate cultures using a sterile 96-prong inoculating manifold. Cover assay plates and incubate at optimal growth temperature for desired amount of time.

3. Set up four small trays in a series and add 1 to 2 inches of tap water to the last three.

The first tray is used to collect waste, while the others are used to wash the assay plates.

4. Remove planktonic bacteria from each microtiter dish (step 2a or 2b) by briskly shaking the dish out over the waste tray. To wash wells, submerge plate in the first water tray and then vigorously shake out the liquid over the waste tray. Replace water when it becomes cloudy.

5. Add 125 µl of 0.1% crystal violet solution to each well. Stain 10 min at room temperature.

6. Shake each microtiter dish out over the waste tray to remove the crystal violet solution. Wash dishes successively in each of the next two water trays (i.e., the two not used in step 4), and shake out as much liquid as possible after each wash.

   This step will remove any crystal violet that is not specifically staining the adherent bacteria. The wash trays can be reused for a number of plates, but the water should be replaced when its color becomes dark or when the efficiency of the washes is observed to decrease.

7. Invert each microtiter dish and vigorously tap on paper towels to remove any excess liquid. Allow plates to air-dry.

   At this stage, the staining is stable and the dried plates may be stored at room temperature for at least several weeks.

8. Add 200 µl of 95% ethanol (or another appropriate solvent) to each stained well. Allow dye to solubilize by covering plates and incubating 10 to 15 min at room temperature.

   A number of reagents may be used to solubilize biofilms. Some suggestions are listed in Table 1B.1.1, but solvents should be tested empirically for each organism.

9. Briefly mix the contents of each well by pipetting, and then transfer 125 µl of the crystal violet/ethanol solution from each well to a separate well in an optically clear flat-bottom 96-well plate. Measure the optical density (OD) of each of these 125-µl samples at a wavelength of 500 to 600 nm.

   The authors suggest four replicate wells for each strain or species used in step 2. The absorbance values from these replicates are sufficient to determine an average and standard deviation for each strain or species and thus provide a measure of the extent of biofilm formation. The number of replicates can be increased as desired.

   The OD wavelengths are presented as a range to allow for variations in the capabilities of plate readers.

DIRECT ENUMERATION OF BACTERIA IN BIOFILMS

ALTERNATE PROTOCOL 1

The biofilm formed in the microtiter dish can also be quantitated by directly enumerating the bacteria adhering to the surface. This method, while more time consuming, avoids one drawback of the crystal violet assay—crystal violet stains not only cells, but essentially any material adhering to the surface of the plate (for example, matrix components), and therefore, crystal violet staining may overestimate the number of adherent bacteria.

Additional Materials *(also see Basic Protocol 1)*

PBS (*APPENDIX 2A*), sterile
Agar plates of appropriate medium
Multichannel pipettor
8-ml plastic tubes with caps
Sonicator (e.g., Sonics and Materials VC-505)
Additional reagents and equipment for counting viable cells (Phelan, 1996)

1. Inoculate biofilm assay plates as described in Basic Protocol 1, steps 1a and 2a or steps 1b and 2b.

2. Wash wells six times, each time using a multichannel pipettor to add 100 µl sterile PBS per well and then vigorously shaking out the liquid over a waste container to remove planktonic cells.

3. Use scissors to cut each individual well from the microtiter plate. Add 100 µl PBS to each well.

4. Add each well (i.e., the actual plastic well plus its contents) to a separate 8-ml tube containing 1.9 ml PBS (for a final liquid volume of 2 ml). Cap before and after addition.

   This step is performed so that each sample can be sonicated (step 5) in an 8-ml tube. Microtiter wells are not suitable for use as sonication vessels, as they are too small.

5. Insert sonicator microtip and sonicate the contents of each tube for 8 sec at 40% power. Perform viable counts (Phelan, 1996) on the resulting suspensions by plating on agar medium to enumerate bacteria that were attached to the microtiter well surface.

   To verify that the sonication procedure does not reduce cell viability, perform viable counts on a separate culture of planktonic cells before and after sonication. If reduced cell viability is seen, adjust the sonication regimen accordingly.

   If desired, use crystal violet staining followed by microscopy to determine the efficacy of sonication in dislodging attached cells from microtiter well walls. Perform crystal violet assay as in Basic Protocol 1. Lack of a crystal violet ring indicates that the bacterial cells have been removed from the wall of the well.

BASIC PROTOCOL 2

AIR-LIQUID INTERFACE ASSAY

Often, a great deal can be learned about the biofilm formation behavior of a particular bacterium simply by observing the early stages of this process, including attachment and early microcolony formation. This point may be particularly relevant for mutants identified in the 96-well plate assay described above.

The air-liquid interface (ALI) assay provides a simple system for microscopic analysis of biofilm formation over a time range of ~4 to 48 hr (Caiazza and O'Toole, 2004). A 24-well plate is placed at an angle of 30° to 50° relative to horizontal, and stationary-phase cultures are diluted and slowly applied to these wells such that the upper edge of each culture aliquot is positioned at the center of a well's bottom. The bacteria of interest are allowed to grow in this manner for an appropriate length of time, and then the wells are rinsed gently and viewed by phase-contrast microscopy. See Background Information for a more thorough discussion of this assay.

Materials

Bacterial strains of interest
Appropriate media for bacteria under study (*APPENDIX 2C*)
Flat-bottom 24-well plate, sterile, with lid
Large paper clips or microcentrifuge tube rack and lab tape
Inverted microscope

1. Adjust a sterile, flat-bottom, 24-well plate so that it sits at a 30° to 50° angle from horizontal.

   The method used will depend on the brand of plate and the available materials. One approach is to affix four large paperclips to one end of the plate. The paperclips stably elevate the end of the plate to which they are attached, while the opposite end remains low (see Fig. 1B.1.1). Alternatively, one end of the plate may be rested on a microcentrifuge tube rack (or anything of the desired height) and stabilized with tape to prevent slipping.

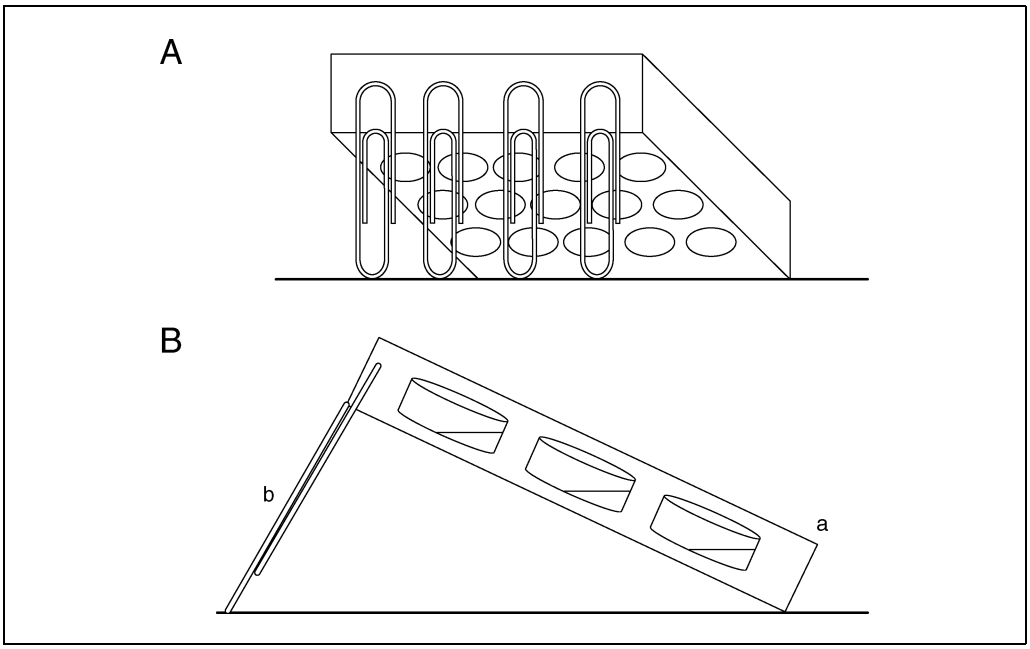

Figure 1B.1.1 (**A**) Schematic of angled plate for air-liquid interface (ALI) assay (back view). (**B**) Side view of ALI assay setup. An angled plate (a) is supported by paper clips (b). The ALI occurs at the center of the bottom of each well, where a meniscus forms.

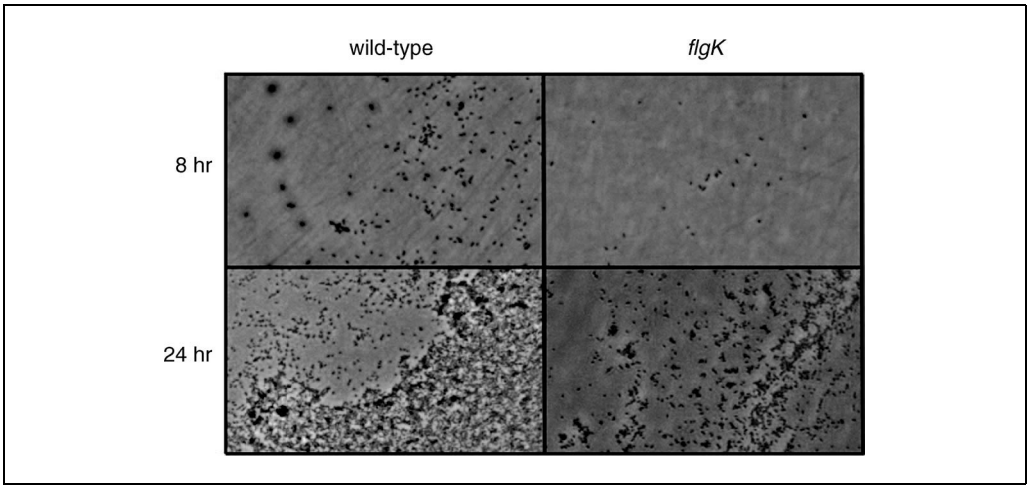

Figure 1B.1.2 Phase-contrast micrographs taken at the air-liquid interfaces of biofilms formed by the wild-type *Pseudomonas aeruginosa* PA14 strain and a nonflagellated mutant (*flgK*), both grown as described in Basic Protocol 2.

If possible, set up the angled plate in the warm room or incubator to be used for sample culturing, and load the wells there (step 4) to avoid potential disruption of the sample meniscuses upon transport.

2. Inoculate each bacterium of interest in a 3- to 5-ml culture and grow to stationary phase (or to some other appropriate stage of growth).

3. Dilute the stationary-phase (or other appropriate) cultures 1:100 in appropriate media.

   Approximately 300 μl diluted culture will be needed for each well that is to be inoculated in the angled 24-well dish.

4. Carefully pipet an aliquot (~300 μl) of each diluted culture into a separate well in the angled 24-well plate such that the upper edge of the aliquot just reaches the center of the bottom of the well. Cover plate with lid and incubate at appropriate temperature for desired period of time.

When inoculating each well, it is important to slowly add the culture down the lower wall to avoid wetting the entire bottom of the well. The meniscus of the liquid should pass through the center of the well, which is often the most optically clear part. This will ensure that the air-liquid interface is appropriately positioned for viewing.

5. Aspirate culture from the wells and gently wash twice, each time by adding 400 µl sterile medium and then aspirating. After completing these two washes, add ~200 µl medium (i.e., enough to cover the bottom of the well) to each well.

   Washing should remove most of the unattached bacteria from the wells. This is important, as planktonic cells can make viewing more difficult and can continue to colonize surfaces, potentially obscuring the air-liquid interface.

6. Lay the plate flat on the stage of an inverted microscope and visualize by phase-contrast or epifluorescent microscopy. Focus just above the center of the bottom of the well to observe bacteria at the air-liquid interface.

   Depending on the bacterial species and conditions, the bacteria may form a well-defined aggregations at the ALI. The ALI will occur wherever the meniscus of the culture was in contact with the plastic, but it will be most visible in the center of the well, where the well tends to be the most optically clear. If desired, the ALI may be circled on the bottom of the plate with a wax pencil prior to microscopic analysis to aid in its identification. Some sample results obtained with Pseudomonas aeruginosa are shown in Figure 1B.1.2.

ALTERNATE PROTOCOL 2

AIR-LIQUID INTERFACE COVERSLIP ASSAY

If an inverted microscope is not available, a plastic or glass coverslip can be placed in a well of a in a 24-well plate such that the air-liquid interface of the culture is in the approximate center of the coverslip. After an appropriate incubation, the coverslip is rinsed, stained with crystal violet, and visualized by conventional microscopy using an upright microscope.

Additional Materials (*also see Basic Protocol 2*)

0.1% (w/v) crystal violet in water
Flat-bottom multiwell (e.g., 12-well) plates, sterile, with lids
Glass or plastic coverslips (e.g., Fisherbrand unbreakable 22-mm^2 coverslips; Fisher Scientific catalog no. 12-547)
Conventional, upright microscope

1. Inoculate each bacterium of interest in a 3- to 5-ml culture and grow to stationary phase (or to some other appropriate stage of growth).

2. Dilute the stationary-phase (or other appropriate) cultures 1:100 in appropriate media.

3. Use each diluted culture to fill a well in a flat-bottom multiwell plate to approximately half of its capacity.

   Almost any size multiwell dish is acceptable for use in this assay, as coverslips are available in a variety of sizes. Plastic coverslips, such as those listed above, can easily be cut to the appropriate size with a pair of scissors.

4. Insert a coverslip into each well so that it is held at a 90° angle relative to the bottom of the well (i.e., perpendicular to the bottom of the well) so that the meniscus of the medium is at the center of the coverslip. Cover plate and incubate at appropriate temperature for desired period of time.

5. Remove each coverslip from its well and rinse off nonadherent cells by dipping in sterile medium.

6. Stain bacteria by submerging coverslips in 0.1% crystal violet for 10 min.

7. Rinse off excess dye by dipping each coverslip in two successive water baths, and then allow coverslips to air-dry.
8. Visualize the bacteria at the air-liquid interface on each coverslip by microscopy.

COLONY BIOFILM ASSAY

BASIC PROTOCOL 3

A colony biofilm is grown on a semipermeable membrane that sits on an agar plate (Fig. 1B.1.3). The bacteria in this type of biofilm can be given a new supply of nutrients simply by relocating the membrane-grown cells to a fresh agar plate. One therefore can easily change the carbon source or type of drug treatment while avoiding the need to wash the cells. The colony biofilm has been especially useful in the study of the antibiotic-resistant properties of cells. The method provided below is an example of the use of a colony biofilm to study the effects of antibiotic treatment.

The other biofilm systems presented in this unit involve attachment of bacteria to a surface while bathed in liquid medium. This is the only protocol where the substratum to which the bacteria attach themselves is also the avenue for meeting nutritional needs and removing waste. For that reason, this assay is more analogous to growing bacteria on plates rather than in broth. In this protocol, however, the colonies can grow much larger, because they are periodically relocated to fresh plates and thus have a fresh supply of nutrients. An advantage of this system is that the biofilms formed are derived from clonal growth of the original population of bacteria deposited on the filter, whereas in liquid media, motile bacteria may be able to "invade" an aggregation of cells. Likewise, in the system described below, bacteria have limited ability to detach and migrate or drift away from the biofilm formed. The stable and spatially restricted nature of this system makes the colony biofilm especially useful for observing the effects of antimicrobial agents, as changes in cell number can be more easily attributed to cell death rather than detachment.

Materials

Bacterial strain of interest
Appropriate liquid medium for bacterial strain under study (*APPENDIX 2C*)
Appropriate agar medium with and without antibiotic (or other) supplementation
PBS (*APPENDIX 2A*), sterile
Forceps, sterilized (e.g., autoclaved or flame-sterilized in 70% v/v ethanol)
Poretics 25-mm-diameter black polycarbonate membranes with pore size of 0.22 μm (GE Osmonics catalog no. K02BP02500)
100-mm-diameter Petri dishes, sterile
UV light source (e.g., UVP 8-W multiple-ray laboratory lamp)
15-ml tubes, sterile, with tightly fitting lids
Vortex mixer

1. On the night before the colony biofilm assay is to be started, inoculate the bacterium of interest in 3- to 5-ml cultures and grow overnight (i.e., to stationary phase).

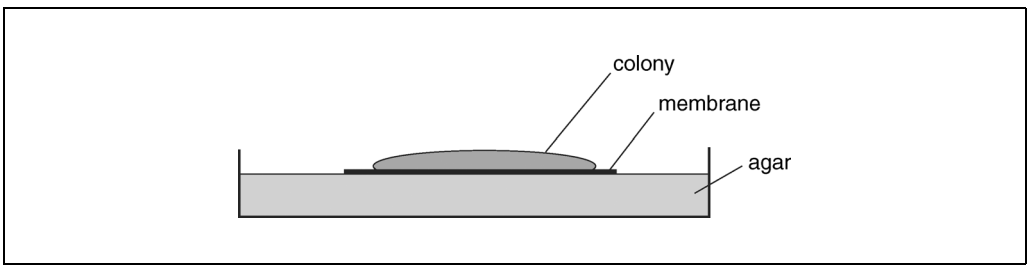

Figure 1B.1.3 Side view of a colony biofilm assay.

2. Using sterilized forceps, place 25-mm black polycarbonate membranes with a pore size of 0.22 μm in a sterile Petri plate. Position plate ~30 cm from a UV light source and treat with UV light in a sterile environment (e.g., a biological control hood) for 10 min per side, using the sterilized forceps to flip the plate.

   Here and in all subsequent steps, the Petri plate should be kept covered whenever possible to maintain the sterility of the membranes.

   The number of membranes needed depends on the desired length of the experiment. Two membranes are required for the initial baseline count of cells (in duplicate), and four more are needed for each time point (for duplicate sampling of treated and untreated cells). Additionally, a few extra membranes may be desirable as backups. For example, starting with sixteen membranes per strain for an experiment with a 72-hr antibiotic treatment period will allow duplicate sampling of treated and untreated cells every 24 hr, leaving two extra backup membranes per strain.

3. Dilute stationary-phase cultures (step 1) in the appropriate medium to an OD_{600} of 0.05 (~1.64×10^8 cfu/ml).

4. Place a membrane (step 2) with its shiny side up on an agar medium plate not containing antibiotic, and inoculate with 5 μl diluted culture. Repeat this procedure for all remaining membranes from step 2, inoculating up to six membranes on the same agar plate. When the liquid on the membranes has dried, incubate plates upright at appropriate temperature for 24 hr.

5. Using sterile forceps, gently lift each membrane off of its agar plate and transfer to a fresh agar plate at up to six membranes per plate. Incubate plates 24 hr at appropriate temperature.

   Flame-sterilized forceps must be cooled before touching the membranes.

   The entire surface of the membrane should be in direct contact with the agar in the fresh plate. Air bubbles may be removed simply by gently lifting the membrane and repositioning it on the plate.

   Following this step, the colony biofilms will have been grown for a total of 48 hr. Membranes are transferred to new plates every 24 hr hereafter to provide a fresh nutrient supply or to expose the colony biofilms to fresh antimicrobial agents.

6. After the incubation in step 5 is complete, sample biofilm growth in the following way.
   a. Aseptically transfer a membrane to each of two separate 15-ml tubes containing 10 ml sterile PBS, such that each tube contains a single membrane.

      The membrane can be gently folded over onto itself before it is lifted off the plate. Doing so will allow the membrane to fit easily into a 15-ml tube.

   b. Cap tubes and vortex samples for two pulses of 60 sec each (or as necessary) to detach all bacteria.
   c. Prepare dilution series of the vortexed samples, and plate each dilution on a separate agar plate. Incubate plates overnight at the appropriate temperature and determine the average number of colony-forming units (cfu) per membrane.

      The counts obtained here will serve as the baseline for future experimentation; this sampling time point is designated $T = 0$ with respect to the start of experimental treatments.

7. Transfer half of the remaining membranes (step 5) to fresh agar plates not containing antibiotic, and transfer the other half to agar plates supplemented with antibiotic at the appropriate concentration. Incubate all plates at appropriate temperature for 24 hr.

8. When incubation is complete, sample biofilm growth (as in step 6) in two untreated membranes and two treated membranes. Transfer the remaining untreated membranes to fresh agar plates not containing antibiotic, and transfer the remaining treated membranes to fresh agar plates supplemented with antibiotic at the appropriate concentration. Incubate plates at appropriate temperature for another 24 hr.
9. Repeat step 8 until all colony biofilms have been sampled.

KADOURI DRIP-FED BIOFILM ASSAY

BASIC PROTOCOL 4

This system overcomes one limitation of the other static systems presented in this unit by constantly refreshing the bacterial growth medium. Bacterial growth can therefore be maintained for a much longer period, allowing formation of mature biofilms. A 6-well plate is inoculated with culture, and growth medium is pumped into each well through a needle that has been inserted through the plate lid; waste and planktonic cells exit through a second needle and are pumped away from the well. Biofilm formation can be monitored as desired by visualizing the bottom of each well using an inverted microscope. See Background Information for a more thorough discussion of this assay.

Materials

Silicone sealant
Sodium hypochlorite
70% (v/v) ethanol
Bacterial strain of interest
Appropriate liquid medium for bacterial strain under study (*APPENDIX 2C*)
20-G needles, sterile (Becton Dickinson catalog no. 305175)
Flat-bottom 6-well plates, sterile, with lids
1/16 × 1/16–in. (~0.16 × 0.16–cm) straight and 90°-elbow, barbed, polypropylene fittings (such as those included in Cole-Parmer catalog no. 6365-90)
0.8- to 1.6-mm-i.d. silicone tubing (e.g., Watson-Marlow catalog no. 913.A008.016 or 913.A016.016)
2-liter flasks
Two-hole rubber stopper (no. 8) equipped with a long glass tube (i.e., one that can reach almost to the bottom of a 2-liter flask) and a short glass tube (for gas exchange)
Peristaltic pump (e.g., Watson-Marlow PumpPro) equipped with Marprene manifold tubing (inner diameter, 0.8 mm; e.g., Watson-Marlowe catalog no. 978.0165.000)
Inverted microscope (*UNIT 2A.1*)

Modify 6-well plate lid

1. Heat a 20-G needle in the flame of a Bunsen burner. Push the heated needle through the lid of a 6-well plate such that it enters directly above one side of a well. Remove the needle and repeat this process to make a hole in the lid directly above the opposite side of the same well.

   The holes should be large enough for the needle to pass through freely.

   These holes will serve as ports for connecting a peristaltic pump that will supply growth medium to and carry waste away from the well. If desired, multiple wells may be prepared on the same plate and/or multiple plates may be run from the same pump simultaneously, depending on the number of channels the pump has for tubing.

2. Obtain two straight 1/16 × 1/16–in. (~0.16 × 0.16–cm) barbed polypropylene fittings (i.e., the type used to connect two pieces of tubing). Using a sharp razor blade, carefully cut off one of the two male ends on each fitting to give a modified fitting with one male end and a flat base (see Fig. 1B.1.4).

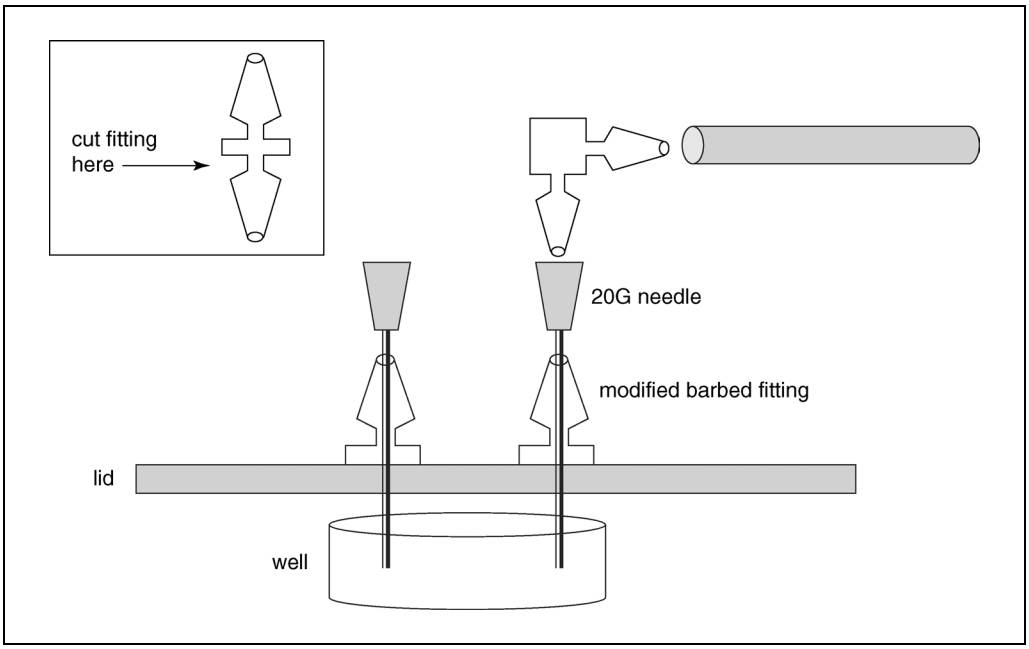

Figure 1B.1.4 Side view of modified 6-well plate lid for Kadouri system.

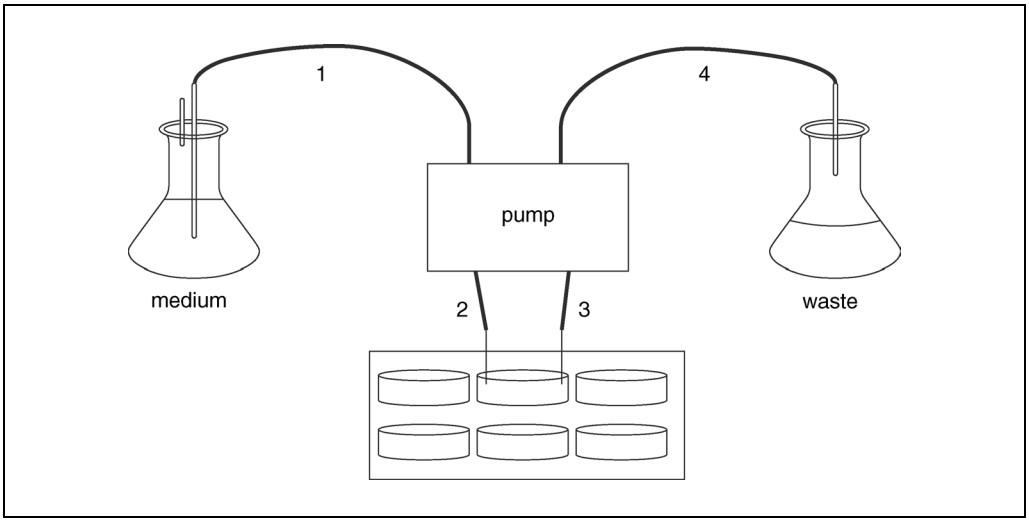

Figure 1B.1.5 Diagram of Kadouri drip-fed biofilm system. Fresh culture medium is pumped onto a biofilm grown in the bottom of a well in a 6-well plate, while planktonic bacteria and spent medium are removed through a needle placed on the opposite side of the well. Numbers are explained in Basic Protocol 4, step 4.

3. Set the flat base of each modified fitting on top of the 6-well plate lid (step 1) such that the hole in the fitting lines up with one of the holes in the lid, and then pass a 20-G needle through both the fitting and the hole in the lid to maintain the alignment. Secure each fitting to the lid of the plate using a silicone sealant, and let the sealant dry completely (see Fig. 1B.1.4).

   Once constructed, this modified lid can be sterilized with ethanol or UV irradiation and reused multiple times with fresh plates in subsequent experiments.

Set up pump apparatus

4. Taking into account the Marprene manifold tubing already installed at the various ports on the peristaltic pump, cut lengths of silicone tubing to sizes appropriate for the following connections (Fig. 1B.1.5): (1) medium reservoir to pump; (2) pump to 6-well plate; (3) 6-well plate back to pump; and (4) pump to waste receptacle. Attach 90°-elbow fittings to the tube ends that are to be connected to the modified plate lid.

Prepare to run the system

5. Fill a 2-liter flask with 500 ml water and fit with a no. 8, two-hole, rubber stopper equipped with one long and one short glass tube. Cover the tube ends with foil. Fill separate 2-liter Erlenmeyer flasks with 1.5 liters water, 500 ml water, and 1.5 liters of medium appropriate for growing the biofilm of interest.

   The 500-ml portion of autoclaved water in the stoppered flask will be used to adjust the liquid flow rate in step 8. The other 500-ml portion of autoclaved water will serve as the solvent for the hypochlorite solution used to sterilize the pumping system in step 10, and the 1.5-liter portion of autoclaved water will be used to rinse the hypochlorite solution out of the system in step 11.

6. Submerge the silicone tubing from step 4, not including the Marprene manifold tubing already installed on the pump, in a beaker containing distilled water and cover with foil. Autoclave along with the flasks prepared in step 5.

7. Connect the plate lid to the medium reservoir line and the waste line as follows (also see Fig. 1B.1.5).
   a. Using polypropylene fittings, connect one of the intake lines on the pump to the silicone tubing that will eventually lead to the medium reservoir. Connect the corresponding outflow line to the end opposite the 90° elbow on one of the silicone tubes that will eventually connect to the modified plate lid.
   b. Connect another outflow line on the pump to the silicone tubing that will eventually lead to the waste receptacle. Connect the corresponding intake line to the end opposite the 90° elbow on the other silicone tube that will eventually connect to the modified plate lid (Fig. 1B.1.5).
   c. Attach a sterile 20-G needle to the elbow fitting on each of the two silicone tubes that are to be connected to the modified plate lid.

8. Adjust the growth medium influx and efflux rates in the following way.
   a. Place a sterile, capped microcentrifuge tube in a rack and make two small, diametrically opposed holes in the lid using a 20-G needle heated over a flame.
   b. Pipet ~1 ml of flow-adjustment water (step 5) into the open tube, close the lid, and then insert the 20-G needles from step 7 through the holes in the lid.
   c. Return the two-hole rubber stopper to the flask containing the flow-adjustment water. Connect the silicone tubing that will eventually serve as the growth medium intake line to the long glass tube on the stopper, and place the open end of the appropriate silicone tube in the waste receptacle.
   d. Start the peristaltic pump at a flow rate of 12 ml/hr (2.0 rpm on a Watson-Marlow PumpPro). Adjust the tension on the manifold tubing such that the water level in the microcentrifuge tube is steady or slightly decreasing.

      The purpose of this step is to adjust the liquid flow such that the well will neither dry out nor overflow during the actual experiment. Increasing the flow rate and observing for a period of time will make subsequent recognition of steady or slightly decreasing water levels easier.

9. Stop the pump, remove the 20-G needles from the microcentrifuge tube, and insert them into the modified fittings on the 6-well plate lid.

10. To 500 ml sterile H_2O (step 5), add sodium hypochlorite to a final concentration of 0.05% (v/v). Remove the two-hole rubber stopper (still connected to the eventual growth medium intake line) from the flask containing the flow-adjustment water, squirt 70% ethanol around its sides, and transfer it to the flask containing the sodium hypochlorite solution. Restart the pump and run the sodium hypochlorite solution through the system for at least 3 hr at a flow rate of 12 ml/hr.

Rinsing with 70% ethanol solution will help ensure sterility each time the rubber stopper is transferred to a new flask. In addition, flushing with sodium hypochlorite sterilizes the pump's Marprene tubing, which cannot be autoclaved.

11. Turn off the pump and aseptically transfer the two-hole rubber stopper (still connected to the eventual growth medium intake line) to the flask containing 1.5 liters of sterile water for rinsing. Restart the pump and flush the system with this water for 3 hr or overnight, adjusting the flow rate as necessary to equalize the inflow and ouflow of liquid.

    This rinsing step removes the sodium hypochlorite from the system and helps ensure that the input and output flow are balanced.

Grow and monitor biofilm

12. Inoculate the bacterium of interest in a 3- to 5-ml culture and incubate overnight at appropriate temperature.

13. Dilute the stationary-phase culture 1:100 in appropriate medium, and inoculate ~3 ml of this diluted culture into the appropriate well of a new 6-well plate (i.e., a well whose position on the plate will allow the bacteria to receive growth medium through the modified plate lid). Allow bacteria to adhere to the well for 3 hr or as appropriate for the organism of interest.

14. At the end of the adhering period, pipet excess medium from the well and replace with ~3 ml fresh medium.

15. Turn off the pump and transfer the two-hole rubber stopper (still connected to the growth medium intake line) to the flask containing 1.5 liters sterilized medium.

16. Transfer the modified plate lid (still connected to the peristaltic pump through two 20-G needles) to the 6-well plate from step 14. Pass medium into the well of interest by restarting the pump at a rate of 10 ml/hr, and maintain this flow throughout biofilm growth.

17. Establish biofilm by incubating the system at appropriate temperature and replenishing the growth medium reservoir flask as necessary.

18. Monitor biofilm growth at desired intervals in the following way.
    a. Pause the pump, transfer the modified lid to another sterile 6-well plate, and place a new sterile lid over the biofilm-containing plate for transport.
    b. Gently remove planktonic cells from the biofilm-containing well by pipetting off the liquid medium, and then wash the well twice, each time by adding 1.0 ml sterile medium and aspirating.
    c. Cover the bottom of the well with a small amount of fresh medium to keep the biomass hydrated, and then view through an inverted microscope.
    d. When viewing is complete, reconnect the plate to the pump system (through the modified plate lid) and resume the flow of growth medium.

Dismantle system and prepare for reuse

19. Upon completion of experiment, detach the modified 6-well plate lid and 20-G needles from the elbow fittings on the silicone tubing, and then use a small (~15-cm) piece of silicone tubing to bridge the two elbow fittings.

20. Sterilize the system by flushing with 0.05% sodium hypochlorite as in step 10, and then rinse by flushing with sterile water as in step 11.

21. Dismantle all tubing and coil it gently into the bottom of a 1-liter beaker. Cover with distilled water, cover beaker with foil, and autoclave to sterilize.

After autoclaving, the tubing may be reused for future experiments; however, before setting up a new system, be sure to examine the entire length of each piece of tubing for clogs or holes that could cause pressure build-ups or leaks.

COMMENTARY

Background Information

Microtiter plate assay

Permutations of the microtiter dish biofilm assay (see Basic Protocol 1) have been in use for a number of years, due to their ease of use and the adaptability of the general protocol to a variety of applications. This assay is equally well suited to the analysis of tens or hundreds of strains or species and is particularly useful as the basis of a genetic screen for mutants defective in surface attachment capabilities. Once conditions have been determined in which the wild-type strain forms a biofilm, a library of mutants can be screened to identify those that differ in terms of the extent or kinetics of attachment. Additionally, slight modifications to this system would allow one to look at the influence of other variables that may affect biofilm formation, such as nutritional provision (e.g., the carbon or nitrogen source used or the availability of phosphate or iron) or the presence of antibiotics or detergents. It is important to keep in mind that due to the indirect nature of biofilm assessment in this system, it is desirable to pair this assay with another method to further examine biofilm formation. For example, using direct microscopic observation of the biofilm to confirm the crystal violet staining pattern is suggested.

Air-liquid interface assay

This technique (see Basic Protocol 2) emerged from a simple adjustment to the typical practice of growing biofilms in multiwell plates. Many bacteria are limited to or prefer aerobic growth and therefore are most prone to forming biofilms at the interface between the medium and air. By tilting the 24-well plate such that the air-liquid interface (ALI) falls on an optically clear portion of the plate, the potential for microscopic analysis is improved. This system makes an excellent companion to the microtiter dish assay (see Basic Protocol 1), as both are useful at many of the same time points and stages of biofilm formation. This assay also allows the visualization of live bacteria without the need for crystal violet staining; therefore, real-time interactions of the bacteria with the surface can be monitored (Caiazza and O'Toole, 2004). The ALI assay can be extended to later time points by replacing the growth medium periodically, but for an accurate study of a mature biofilm, a system in which the medium is continually replaced, such as the Kadouri system (see Basic Protocol 4) or a flow cell–based system (*UNIT 1B.2*), is recommended.

Colony biofilms

Colony biofilms (see Basic Protocol 3) have typically been used for the purpose of determining antibiotic resistance (Anderl et al., 2000; Walters et al., 2003). Such systems are well suited to studies of the viability of cells within a biofilm in response to various assaults, such as exposure to antimicrobial agents or UV light.

Kadouri system

The Kadouri drip-fed biofilm system (named for the postdoctoral researcher who developed it) is a close relative of the continuous-flow biofilm systems presented in other units in this chapter. Although the medium is constantly being exchanged in this system (see Basic Protocol 4), the shear forces on the bacteria are minimal; therefore, this system may apply less mechanical stress to the biofilms. Planktonic cells in this system are not swiftly swept away but may linger in the well for longer periods. Hence, the system may be more closely representative of an equilibrium state between the attached and planktonic lifestyles. This system is typically considered a "low-flow" scheme and serves as an intermediate regimen between static assays and standard flow cell systems; however, because the system involves continuous feeding with growth medium, it allows observation of the entire process of biofilm formation, from reversible to irreversible attachment and on to microcolony formation, macrocolony formation, and detachment. One advantage this system provides is the potential to generate and easily access a relatively large amount of biomass that can be scraped from the bottom of the well and used for applications such as DNA microarrays and proteomics. This system is also useful for many of the microscopy assays typically done by flow cell–based methods. The 6-well plate format also has the advantage of being

easily adaptable to the testing of multiple growth conditions or bacterial species.

Critical Parameters and Troubleshooting

Microtiter plate assay

When using the microtiter plate assay, it is important to have a strong positive control (i.e., a wild-type strain) and, if possible, a negative control (e.g., uninoculated medium) on each test plate. Enough variability can emerge in terms of incubation conditions or washing so that intraplate comparisons are preferable, especially when one strives to observe a subtle difference between bacterial species or strains. Additionally, it is important to note that there are factors that can affect the results of this assay other than an organism's ability to adhere to the surface. For example, a growth defect could easily be mistaken for a lack of attachment capability.

The microtiter plate suggested for the studies described in this protocol is U-shaped, nonsterile, and relatively inexpensive. Nonsterile plates work well with fast-growing organisms such as *E. coli* or pseudomonads, which easily outcompete contaminants in the 8 to 10 hr it takes to complete the biofilm assay. For slow-growing or fastidious organisms, however, it is recommended that sterile plates be used. For nonmotile organisms, such as staphylococci, sterile, flat-bottom plates are recommended.

ALI assay

Although the ALI assay involves a relatively simple system, there are a few important points necessary for successful execution. The ALI should be a well-defined boundary, so care must be taken to avoid wetting the entire bottom of the well during inoculation. Setting up the angled plate in an incubator or warm room and inoculating it in place is a simple way to prevent disturbances to the system. Placement of the air-liquid interface at the center of the bottom of the well will provide the best opportunity for obtaining sharp images by phase-contrast microscopy. In addition, the wells should never be allowed to dry out. If this is a problem, consider adding more medium in the initial setup, decreasing the incubation time, or placing the entire system inside a humidified chamber, which can be improvised by placing some dampened paper towels in the bottom of a plastic container with a lid.

Occasionally, there may be difficulty in locating the air-liquid interface for microscopic examination. There are a number of situations that could lead to this problem. If the initial inoculum has a low cell count and the incubation time is short, there may be an insufficient number of bacteria adhered to the surface at the time of viewing, and this may make identification of the ALI more difficult. If this is the case, consider starting with a less dilute inoculum or increasing the incubation time. Alternatively, circling the ALI with a wax pencil may make it easier to locate under the microscope. Stringent washing of the wells is useful for removing any unattached bacteria; this wash step will help prevent colonization of the formerly dry portion of the well after the whole well has been bathed in medium. Even under the best washing conditions, bacteria can detach from surfaces and colonize other portions of the well. For this reason, it is important to work quickly and analyze plates on a microscope immediately after they have been prepared for observation. If there are many strains or species to analyze, it may be advisable to distribute them over a number of plates so that only a few need be prepared for viewing at one time.

Colony biofilms

One important aspect of this assay is the predetermination of appropriate experimental conditions (e.g., antibiotic concentration). The resistance of a bacterium to antimicrobial agents in a colony biofilm may differ significantly from the resistance of the same bacterium in a different biofilm system, such as the microtiter plate biofilm assay system described earlier in this unit (see Basic Protocol 1). It is recommended that the organism be tested on various concentrations of antibiotic to find appropriate experimental conditions.

The initial inoculation of the colony biofilm is an important step that can affect the success of the experiment. It is important to ensure that each membrane receives an equal amount of cells and that there is only a single point of inoculation in the center of the membrane. To prevent any of the culture from spraying elsewhere on the membrane, touch the drop of liquid at the end of the pipet tip gently to the membrane before depressing the pipet plunger to its final stop. A single, carefully centered spot will ensure the greatest experimental reproducibility, as the counting is no longer accurate if the bacteria have grown off the edges of the membrane. In addition, complete and uniform removal of the bacteria from the membrane is important for accuracy. Empirically testing different conditions to maximize removal of bacteria from the membrane during the vortexing step while preserving viability is recommended.

Kadouri system

Two common problems that are experienced in this system are overflow and drying out of the wells. Both can be addressed by very carefully calibrating the influx and efflux rates (see Basic Protocol 4, step 8). If the medium is evaporating too quickly from the system, consider increasing the influx rate to compensate. Likewise, ensuring that there is sufficient medium in the reservoir is especially crucial when the system will be left unattended for long periods. Due to the nature of biofilm-forming bacteria, it is also important to carefully monitor the tubing prior to each experiment. The waste tubes are especially prone to being colonized, and the colonizing bacteria can completely block the flow, causing pressure to build up and rupture the junctions between pieces of tubing. If blockage is found, the piece of tubing must be trimmed to remove the clogged portion, or else the entire section must be replaced.

This system is designed for observation of biofilms forming on the bottoms of the wells, but depending on the conditions and the strain or species used, the cells may in addition (or instead) form a biofilm, known as a pellicle, at the air-liquid interface. To prevent this, the environment at the bottom of the plate should be made as hospitable as possible for the bacteria. A common problem is the lack of oxygen at the bottom of the well. This may be overcome by increasing the flow rate in the system to deliver more oxygenated medium to the cells while more rapidly removing unattached bacteria. In some cases, adjusting the composition of the medium (e.g., by providing an alternative electron acceptor) will decrease the requirement for oxygen. As with all of the systems presented in this unit, optimal conditions must be determined empirically for each organism.

After the setup is complete, this system requires little daily attention as the cells grow. It should be monitored periodically (twice a day) for overflow or evaporation of the media in the wells and for potential rupture of tubing, and also to ensure that there is an ample supply of medium in the reservoir. However, biofilms may take over a week to develop to the desired stage (as determined by microscopic observation), and this should be taken into consideration when planning experiments.

Anticipated Results

Microtiter plate assay

Using the microtiter plate assay is an effective way to monitor bacterial attachment to an abiotic surface over time. In general, if this assay were performed over several time points, one would expect to see a progressive increase, possibly followed by a decrease, in attached biomass. The eventual decrease in crystal violet staining is presumed to occur because the lack of nutrients may stimulate the bacteria to detach from the surface (Sawyer and Hermanowicz, 1998; Hunt et al., 2004). The time course of biofilm growth must be determined empirically for each organism and set of conditions used. The staining pattern also varies from one organism to another. For example, when *P. aeruginosa* is grown with only oxygen as an electron acceptor, a ring of staining forms at the air-medium interface. In contrast, when this species is grown on arginine, a carbon source used aerobically and anaerobically by *P. aeruginosa*, the entire well shows positive crystal violet staining. Examples of typical results with this assay for *P. aeruginosa* are shown in Figure 1B.1.6.

Direct enumeration of bacteria from microtiter plate assay

When bacteria are grown in the microtiter plate assay, one generally expects to see increased adherent biomass over a period of time followed by a decrease as the bacteria detach or die. The number of cfu eluted from each well is expected to correlate with the amount of crystal violet staining obtained at the corresponding time point.

ALI assay

For bacterial species that form a ring around the well in the microtiter plate assay, the air-liquid interface should be heavily colonized with attached bacteria in this system. For nonmotile or facultative anaerobic bacteria, the boundary may not be as well defined. Some typical results obtained with the bacterium *P. aeruginosa* are displayed in Figure 1B.1.2.

ALI coverslip assay

The results for this variation of the ALI assay should be very similar to those noted above, with the exception that the crystal violet staining kills the bacteria. Because of this, the stained coverslips are relatively stable and may be stored upwards of a week prior to microscopy.

Colony biofilms

The colony biofilm protocol allows assessment of the effects of antibiotics (or other experimental treatments) on a colony of bacteria grown on a solid substratum. Typically, it is expected that bacteria within a biofilm will

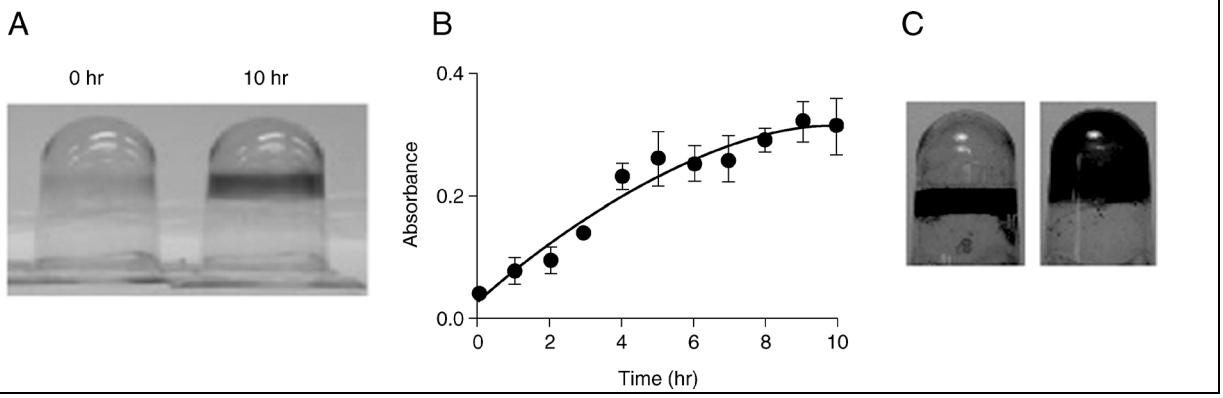

Figure 1B.1.6 Microtiter plate biofilm assay of *Pseudomonas aeruginosa.* (**A**) Crystal violet–stained wells from a microtiter dish at 0 and 10 hr postinoculation. The bacteria were grown on glucose supplemented with casamino acids. Wells were inverted to facilitate photography. (**B**) Quantification of staining at various time points over 10 hr, based on absorbance readings made at 600 nm. (**C**) The wells show formation of a biofilm when *P. aeruginosa* is grown on LB (left; requires aerobic growth) or on arginine (right; can be utilized anaerobically).

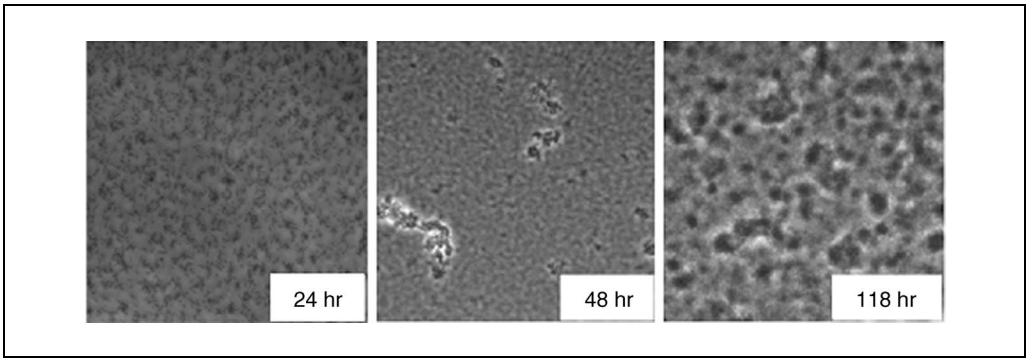

Figure 1B.1.7 Using the Kadouri system, a biofilm of *P. aeruginosa* was grown in minimal medium supplemented with arginine at room temperature and photographed by phase-contrast microscopy at 24, 48, and 118 hr. Microcolonies can be observed as early as 24 hr, with large macrocolonies formed by 118 hr.

display a greater resistance to bacteriocidal agents than will planktonic bacteria.

Kadouri system

Various stages of biofilm formation can be observed with this system. An example of the formation of a *P. aeruginosa* biofilm over 48 hr is shown in Figure 1B.1.7.

Time Considerations

Microtiter plate assay

After the biofilm plates have been inoculated from stationary-phase cultures, results may be obtained in 2 to 30 hr. This, of course, depends on the desired time course and the size of the experiment. Only a small percentage of this time involves hands-on work, however, including the initial inoculation, staining of plates, and dye solubilization. If only a few bacterial strains or species are being tested, these steps may take as little as an hour in total. Alternate Protocol 1, in which viable counts are performed to enumerate the attached bacteria, will take longer, as more handling is involved and the plated bacteria will need to be incubated for another 12 to 24 hr for the colonies to grow large enough to be counted.

ALI assay

The ALI assay follows a time course similar to that of the microtiter plate assay. The length of the assay will again depend on the desired time frame to be studied. Washing of plates followed by microscopic analysis takes ~15 min per well. Alternate Protocol 2 is similar to the ALI assay in terms of its time requirements.

Colony biofilms

During the growth of colony biofilms, the bacteria require little attention, except that the membranes must be transferred to fresh plates every 24 hr. Over the course of an experiment, the separation of bacteria from the membrane and subsequent enumeration are the

most labor-intensive steps. An important consideration regarding the experimental timing in this protocol is the requirement for pregrowth of the colony biofilm (i.e., growth prior to the experimental treatment). This requires membranes to be inoculated 48 hr in advance of antibiotic testing.

Kadouri system

The amount of time required to grow a biofilm in this system depends on the desired maturity, the growth conditions (e.g., medium, temperature), and the organism used. In general, it can be expected that a biofilm will be able to reach maturity within a week of inoculation. Setup of the apparatus should be done 24 hr before inoculation to allow sufficient time for bleaching and rinsing of the system prior to use.

Growing and Analyzing Biofilms in Flow Cells

This unit describes methods for growing and analyzing biofilms under hydrodynamic conditions in flow cells. The flow in these cells is essentially laminar, which means that the biofilm can be grown under highly controlled conditions and that perturbations such as addition of antibiotics or change of the growth medium can be done efficiently at a defined time point. The Basic Protocol includes inoculation of the flow cells, running of the system, microscopic inspection and imaging of flow cell–grown biofilms, image capture and analysis, and disassembly and cleaning of the flow cells. Support Protocols 1, 2, and 3 describe, respectively, construction of a flow cell system, construction of a bubble trap, and procedures related to fluorescent in situ hybridization (FISH) of species-identifying probes for a biofilm that has been grown in a flow cell.

Confocal laser scanning microscopy (CLSM) is used for monitoring and imaging of structure development in the flow cell–grown biofilms. For a detailed description of CLSM, see *UNIT 2C.1*. The COMSTAT image-analysis program is used for calculation of objective parameters such as surface coverage, biofilm thickness, and biovolume from the acquired biofilm images.

CAUTION: Follow all biosafety requirements relevant to the microorganism under investigation. Refer to *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for instructions on safe handling of microorganisms.

USE OF FLOW CELLS FOR GROWTH AND ANALYSIS OF BIOFILMS

BASIC PROTOCOL

The flow cells are inoculated by preparing a solution of the microorganisms in a syringe, stopping the medium flow, inserting the syringe needle in the tubing close to the flow cell inlet, carefully injecting the microorganisms, and resuming the medium flow. The flow cell is mounted directly on a microscope for microscopic investigation and imaging of the biofilm.

Materials

Inoculum, e.g., fresh overnight culture of desired microorganisms
70% and 96% (v/v) ethanol
Medium (e.g., see *APPENDIX 2C*)
Silicone glue (3M Super Silicone Sealant Clear)
Flow cell system (BioCentrum-DTU, Technical University of Denmark, or see Support Protocol 1)
Syringes with needles (e.g., Terumo LU-100, 27-G (0.4 × 12 mm), 0.5 ml)
Clamps
Microscope (Zeiss LSM5 META; Chapter 2)
Scalpels
Computer software:
  Imaris (Bitplane; *http://www.bitplane.com*)
  COMSTAT (BioCentrum-DTU, Technical University of Denmark)
  Matlab (required for COMSTAT; MathWorks; *http://www.mathworks.com*)

Contributed by Claus Sternberg and Tim Tolker-Nielsen
Current Protocols in Microbiology (2005) 1B.2.1-1B.2.15

Inoculate the flow cell

1. Load a 0.5-ml sterile syringe with inoculum, typically a dilution of a fresh overnight culture. Stop the medium flow in the flow system. Wipe the flow cell inlet silicone tube with 70% ethanol and penetrate the silicone tubing with the 27-G syringe needle as near to the flow cell as possible.

   Dilution depends on strain and experiment, e.g., for Escherichia coli an OD_{450} of 0.01 is suitable for most experiments.

2. Inject the inoculum carefully into the flow chamber. Wipe the tubing with 70% ethanol after removing the needle. Reseal the tubing by applying a thin layer of silicone glue at the needle hole.

3. After inoculation of all flow channels, clamp the effluent tubes immediately after the flow cell and place the entire flow cell on a flat surface with the substratum downward to allow cell adhesion to the substratum.

4. After 1 hr, remove the clamps, turn the flow cell over, and resume the medium flow.

   The substratum is now on top of the flow cell.

Run the system

5. During the first hours of running, inspect the system periodically for possible leaks, which must be dealt with quickly (see Critical Parameters and Troubleshooting). Ensure uninterrupted supply of medium and adequate disposal of effluent waste during the entire run.

   The system typically runs for several days or weeks.

Perform microscopic inspection and imaging of flow cell–grown biofilms

Microscopy techniques are described in detail in Chapter 2. Only a few comments relevant to microscopy of a biofilm grown in a flow cell with transparent substratum are given here.

6. Mount the flow cell directly on the microscope stage. If the microscope has automatic resetting of the stage, adjust the zero-level by focusing on the substratum.

   CAUTION: *This adjustment is necessary since the flow cell is much thicker than a normal microscope slide and must be accommodated to prevent the microscope focus motor from moving the objective into the flow cell and destroying the sample.*

7. Once the flow cell is on the microscope stage, manipulate the system on site, e.g., by injecting reagents into the flow channels, stopping the flow, changing the flow rate, or switching the medium.

   Take care to avoid air bubbles at this point, since most changes must be performed downstream of the bubble traps.

8. Record images at desired time points or upon manipulation of the system.

   When recording time series or videos, ensure that temperature control is applied both to the environment and to the microscope stage and objective, or focus drift may occur.

Disassemble and clean flow cell

9. At the conclusion of the flow cell experiment, fill the system with air and detach all tubing. Massage and flush with water any tubing with notable cell growth inside (typically effluent tubing).

10. Remove the substratum from the flow cell using a scalpel.

    If the substratum is made of glass, it will inevitably break in the process.

11. Remove any remaining silicone glue using 96% ethanol.

Perform image analysis (optional)

12. Prepare images for presentation using a suitable software package, e.g., Imaris.

    The Imaris software can process CLSM image stacks to create three-dimensional images, or different sections. Furthermore, the software can make virtual fly-throughs and fly-bys where the observer experiences the sample displayed from several angles in an animation. Imaris has also the capability to allow 3-D measurements of the samples.

13. Calculate objective parameters from the acquired images by using suitable software such as the COMSTAT image-analysis program. Parameters include:

    Biovolume
    Area occupied by biomass in each layer
    Thickness distribution and average thickness
    Area distribution of microcolonies at substratum level
    Volumes of microcolonies identified at the substratum level
    Fractal dimension of each microcolony identified at substratum level (Minkovski method)
    Fractal dimension (cross-correlation function method)
    Roughness coefficient
    Distribution of diffusion distances and average diffusion distance
    Surface area (substratum coverage) and surface to volume ratio
    Maximum thickness of the biofilm.

    The COMSTAT program and user instructions are available from http://www.im.dtu.dk/comstat. The parameters obtained from COMSTAT analysis can be paired and plotted in a diagram for ease of interpretation. By inspecting the diagrams, it is possible to compare several samples and determine if a sample is more similar to one group of samples than to another group, e.g., Figure 1B.2.1. For a detailed description of parameters see Heydorn et al. (2000b).

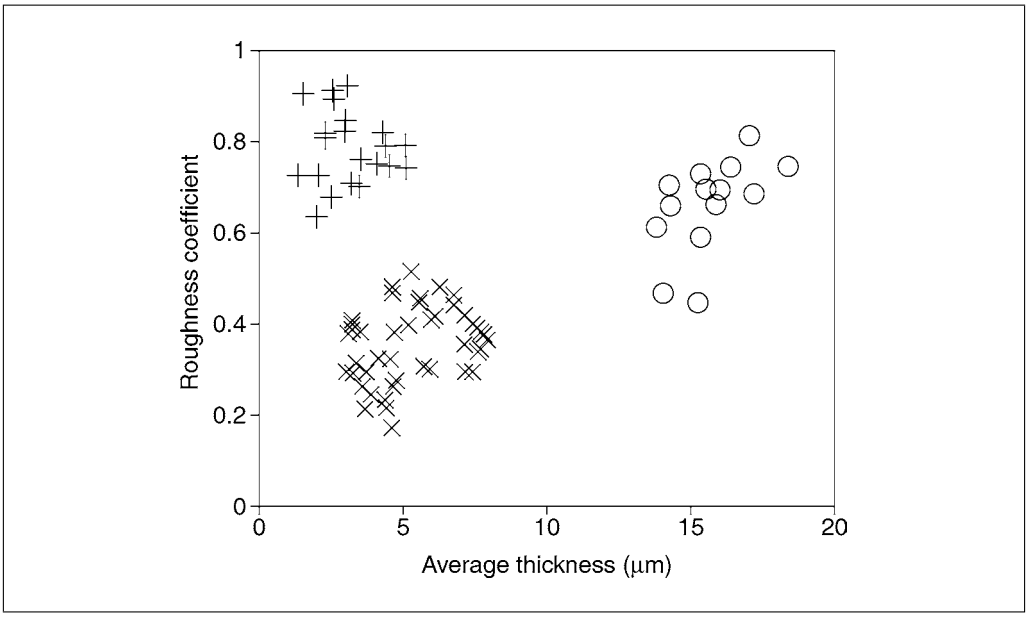

Figure 1B.2.1 COMSTAT analysis of biofilms formed by three different bacterial species. Each point represents roughness and average thickness calculated from one biofilm CLSM image. The symbols ×, +, and ○ represent each of the three species. The two-dimensional analysis of the correlation between the roughness coefficient and average thickness of the biofilms reveals that it is possible to categorize biofilms produced by the three species into three separate groups. Analysis based on either one of the two parameters alone would not indicate a characteristic specific to each of the three species. Combining several of the COMSTAT parameters can refine the analysis further.

SUPPORT PROTOCOL 1

CONSTRUCTION OF A FLOW CELL SYSTEM

The flow cell system consists of a medium bottle, a peristaltic pump, bubble traps, the flow cell, a waste container, tubing, and various connectors. The flow cell described here consists of a plastic base with holes for inlet and outlet tubing and with channels on which coverslips are glued. The bubble trap consists of a syringe mounted on top of a plastic base with an inlet and an outlet (see Support Protocol 2). The system is assembled with tubing and connectors so that the medium can flow from the medium bottle through the peristaltic pump, to the bubble traps, through the flow cell, and to the waste container. The flow system is sterilized with 0.5% sodium hypochlorite, then washed with water, after which the flow of medium can be started. Several suppliers (e.g., BioCentrum-DTU, Technical University of Denmark) offer single- or multiple-use flow cell systems, but many researchers use homemade devices. One particular design modified from a flow cell originally developed by Wolfaardt et al. (1994) is described here.

Materials

Silicone glue (3M Super Silicone Sealant Clear)
Medium appropriate for organisms and type of biofilm being grown (see *APPENDIX 2C*)
70% and 96% (v/v) ethanol
0.5% (w/v) sodium hypochlorite
H_2O, sterile
1% hydrogen peroxide

Polycarbonate sheet plastic, 6 and 35 mm thick
CNC tooling machine, or a drilling machine mounted on an upright stand and equipped with a milling drill-tool (3 mm)
Substratum: 50 × 24–mm glass coverslips or other appropriate material
2-ml syringe (Terumo)
Tubing:
  Silicone, 3 mm outer diameter, 1 mm inner diameter
  Silicone, 4 mm outer diameter, 2 mm inner diameter
  Silicone, 7 mm outer diameter, 5 mm inner diameter
  Marprene, 3 mm outer diameter, 1 mm inner diameter (Watson-Marlow)

Peristaltic Pump (Watson-Marlow, 205S)
Medium bottles (Schott or BIO 101)
Rubber stoppers (to fit medium bottles) with holes for glass tubes
Glass tubes, 6 mm outer diameter, 3 mm inner diameter
Air filter, autoclavable (optional)
Clear polypropylene plastic connectors and T-connectors (Cole Parmer, E-06365-*xx*), 1/8 in. (3.175 mm) and 1/16 in. (1.588 mm)
Bubble traps (BioCentrum-DTU, Technical University of Denmark, or see Support Protocol 2)
Microscope (*UNIT 2A.1*)
Rolling cart for flow systems and pumps (optional)
Waste container

Construct the flow cell

1. Construct the flow cell from a 6-mm thick sheet of polycarbonate according to the working drawing shown in Figure 1B.2.2 using a CNC tooling machine, or a drilling machine mounted on an upright stand and equipped with a milling drill-tool (3 mm).

2. Cut a 6 × 76 × 26–mm flow cell base from a sheet of polycarbonate. Mill 8 mm into the plastic base from each end to remove the top 5 mm.

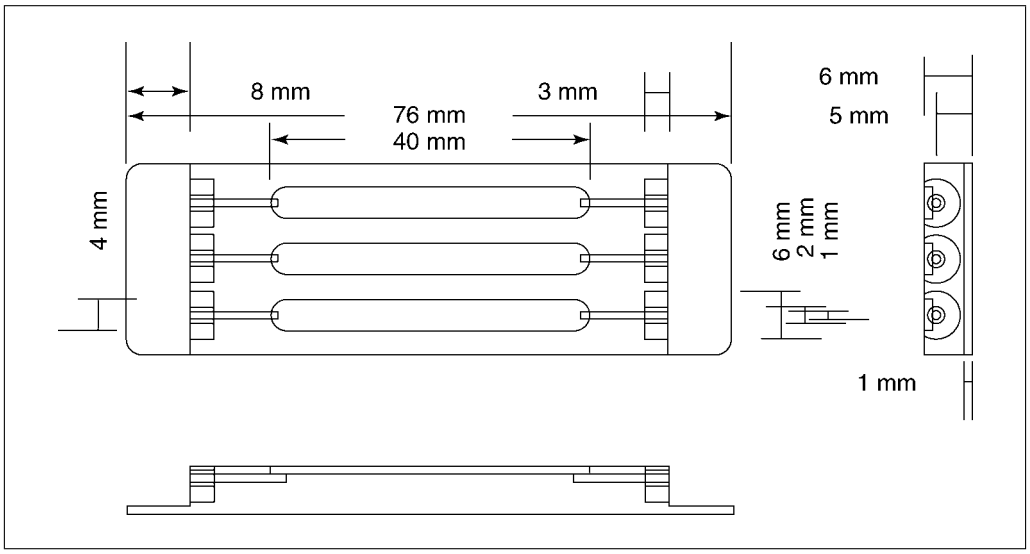

Figure 1B.2.2 Working drawing of the flow cell base (design, copyright Biocentrum-DTU, 2005).

This leaves a central base portion (60 × 26 mm, 6 mm thick) with two 8 × 26–mm ends, each 1 mm thick. The ends facilitate the mounting of the flow cell on a standard microscope specimen holder, like a normal microscope slide.

3. Mill three channels, 1 mm deep and 40 mm long, in the central base portion of the plastic base. If advanced tooling equipment is available, carve connectors to the tubing from the plastic (see Fig. 1B.2.2). Otherwise, still using the milling tool, vertically drill 3-mm wells into the base at each end of the channels and horizontally drill pipes (3-mm drill) from the ends of the central portion of the flow cell, until the pipes connect to the wells.

4. Glue substratum of suitable material and size (e.g., a 50 × 24–mm glass coverslip) to the flow cell base using silicone glue. Apply the silicone glue as very thin threads using a 2-ml syringe. Place the threads between each channel and along the perimeter of the top of the base. Avoid holes in the glue threads to prevent liquid leakage from the flow cell.

5. Place the substratum on top of the glue and press the substratum gently onto the flow cell base. Inspect the glue through the substratum (if transparent) to ensure that the glue is effectively sealing the substratum to the flow cell.

   The handle of the syringe piston is an excellent tool for pressing the substratum onto the flow cell base.

6. If areas with insufficient gluing at the edges are observed, reseal by applying extra glue outside the flow cell adjacent to the potential leak. If the gluing is insufficient between the channels, remove the substratum, clean the base with 96% ethanol, and repeat the mounting procedure (steps 4 and 5).

7. If the flow cell has connectors, attach silicone tubing to them; otherwise, place tube ends inside the drilled holes and attach with silicone glue.

Assemble the flow cell system

The flow system is assembled with autoclaved tubing, bubble traps, and flow cells as shown in Figure 1B.2.3. Use silicone tubing except for the part that goes through the peristaltic pump, where Marprene tubing should be used. Assemble all tubing, except for the connection between the medium supply bottle and the down-stream parts.

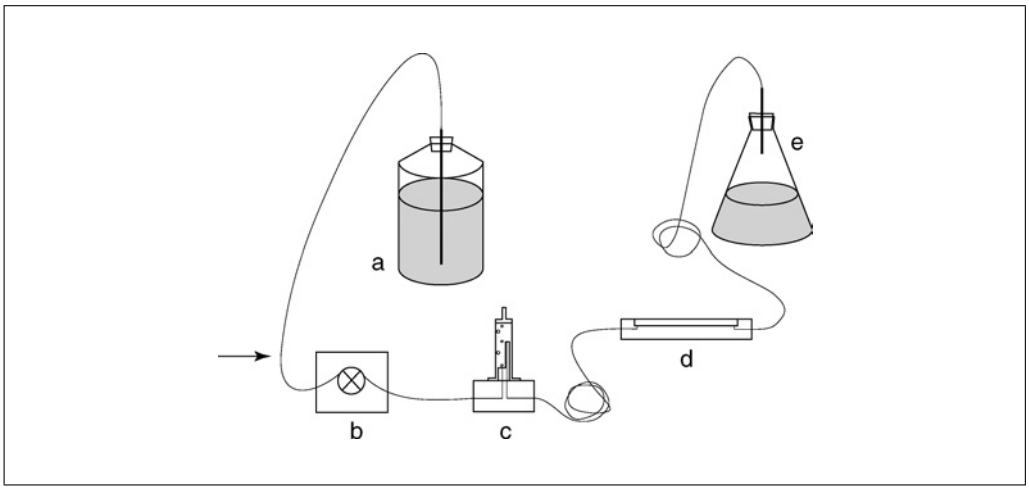

Figure 1B.2.3 Schematic of the flow cell system: a, medium bottle; b, peristaltic pump; c, bubble trap; d, flow cell; e, waste container. Silicone tubing with inner diameter (i.d.) of 2 mm and outer diameter (o.d.) of 4 mm goes from the medium bottle to the point (arrow) where the tube is fanned out. All other tubing has an i.d. of 1 mm and o.d. of 3 mm and is made of silicone, except for the segment that goes through the pump, which consists of Marprene tubing. The connectors used for assembly of the system are listed under Materials in Support Protocol 1.

8. Equip the medium bottle with a rubber stopper of a suitable size with two holes. Place one glass tube, long enough to almost reach the bottom of the medium bottle, into one of the holes (to be used as a siphon tube for medium). Place another glass tube, short enough to not reach into the liquid, into the other hole (to be used as an air vent). Cover the short glass tube with metal foil or mount an air filter via a short connecting plastic tube.

9. Connect the siphon tube to the feed silicone tubing (3 mm i.d., ~1 m long). Mount a straight connector in the end of the feed line to enable easy attachment to the downstream part of the system after autoclaving. Cover this connector with metal foil. Assemble and autoclave the remaining parts of the system together.

   Connect all tubing either directly to the flow cells or bubble traps, or use straight or T-shape connectors between the individual pieces of tubing.

   Do not attach the medium bottle until the system is sterilized.

10. Split a common feed tube into the required number of channels in the experiment by using T-connectors to fan out the feed supply line and reduce the tube dimension from 3- to 1-mm i.d.

11. For each individual channel in the experiment perform the following steps:

a. Connect Marprene tubing to the feed tubing. Connect silicone tubing from the Marprene tubing to the bubble traps.

b. Connect the bubble traps to the flow cell inlet tubing. Connect outlet tubing from the flow cell so that it can reach a waste container.

   Make sure that the inlet and outlet tubes are sufficiently long to allow the flow cell to be moved to the microscope stage.

Sterilize the flow system

12. Cover the free ends of the assembled components with foil and autoclave. Assemble the autoclaved flow cell system as in Figure 1B.2.3 and place the assembled flow cell system near the microscope or, preferably, on a rolling cart. Fill the system with sterile distilled water, and observe for possible leaks. If leaks are present, seal them before using the system.

13. Remove the stoppers from the top of the bubble traps and place them in 70% ethanol. Fill the system with 0.5% sodium hypochlorite solution by pumping at a high flow rate for 5 to 10 min.

    The liquid will pour from the top of the bubble traps; there will be minimal flow downstream from the traps.

14. Place the stoppers back onto the bubble traps and remove any air bubbles from the system components by tapping onto a hard surface while the pump is still running. Continue pumping the disinfectant through the system for 5 to 10 min.

    After replacing the stoppers onto the bubble traps, the remainder of the system will quickly fill with disinfectant.

15. Stop the flow and continue sterilization by allowing the sodium hypochlorite solution to stand in the system from 2 hr to overnight.

16. Remove all traces of sodium hypochlorite by emptying the disinfectant from the system and filling and emptying it with sterile distilled water two to three times. Ensure all disinfectant is removed by purging the system with air between each pass of water. Conclude by passing 1 to 2 liters sterile distilled water through the system at lower flow rate overnight (e.g., 0.2 mm/sec, ~3 ml/hr).

    Emptying and purging the system with air is accomplished by running the pump with the feed tubing taken out of the liquid.

17. Additionally, pass a solution of 1% hydrogen peroxide through the system, as this will eliminate biomass not cleaned by the sodium hypochlorite solution.

    This is mainly for systems that are not autoclaved.

18. Purge the system with air and fill with medium just prior to starting the experiment. Set the laminar flow in the channels to ~0.2 mm/sec (corresponding to 3 ml/hr/channel in the flow cells described here).

CONSTRUCTION OF THE BUBBLE TRAP

SUPPORT PROTOCOL 2

A bubble trap is a simple device basically consisting of a liquid-filled vertical cylinder mounted on top of the medium line. Any air bubble that passes the bubble trap will float to the top of the cylinder and be prevented from passing to the downstream segment. Two types of bubble traps are described here, one that can be made using very simple tools, and an advanced model that requires a CNC tooling machine. Inspect the working drawing shown in Figure 1B.2.4 before constructing the bubble trap.

Materials

10-mm-thick polycarbonate sheet plastic (simple trap) or 35 × 80 × 45–mm polycarbonate block (advanced trap)

Drilling machine mounted on an upright stand and equipped with a 3-mm milling drill-tool and an 8-mm pointed drill (simple trap) or CNC tooling machine (advanced trap)

2-ml syringes with inner diameter of 8.5 mm (simple trap) or 5-ml syringes with inner diameter of 12.5 mm (advanced trap)

9 × 2–mm rubber gaskets (advanced trap; M-seals, 221355; *http://www.m-seals.dk/cms.ashx*)

Silicone glue (3M Super Silicone Sealant Clear)

Silicone tubing, 3 mm outer diameter (simple trap)

Stoppers (e.g., EFD; 5113-B; *http://www.efd-inc.com/catalogs/EFD-Barrel-Reservoirs.pdf*)

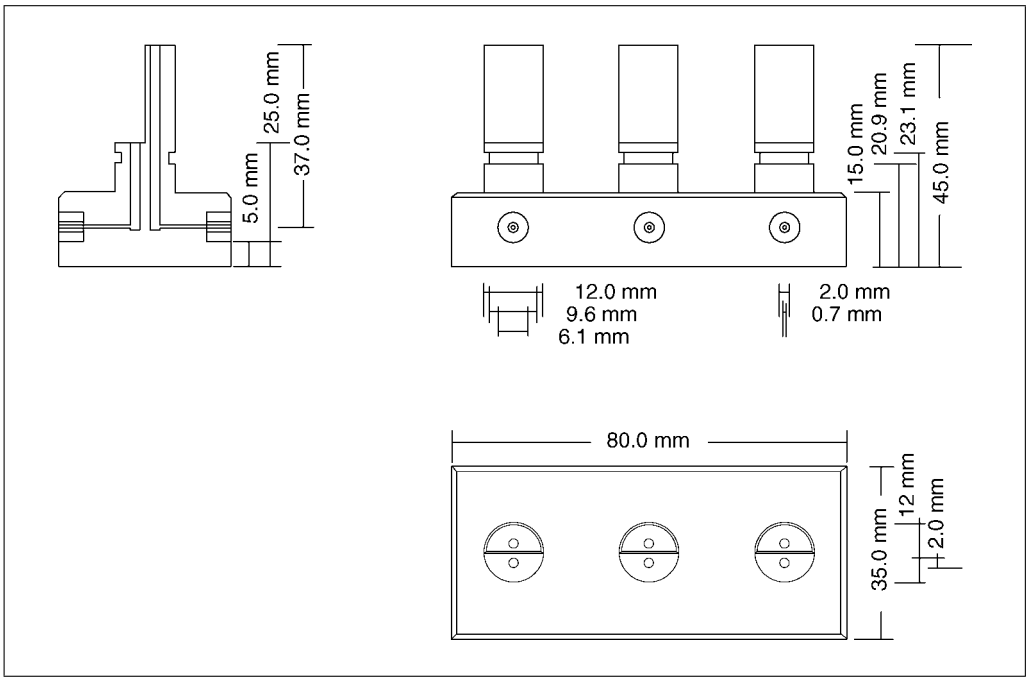

Figure 1B.2.4 Working drawing of the advanced bubble trap base (design copyright Biocentrum-DTU, 2005).

For simple bubble trap

1a. For construction of the simple bubble trap, cut a piece of 10-mm-thick polycarbonate or Plexiglas to 30 × 110 × 10 mm. Drill holes 8 mm into the base using an 8-mm drill. Use a 3-mm drill to create the connecting holes from each side, the center of the drill placed 4 mm from the top of the base.

2a. Glue 2-ml syringes (without the piston) on top of each 8-mm hole. Insert 3-mm-o.d. silicone tubing covered with silicone glue near the ends, 10 mm into the side holes.

3a. Allow the bubble trap to dry at least 24 hr.

Note that this device is somewhat sensitive to physical handling and the syringes can easily break off.

For advanced bubble trap

1b. Cut the plastic base from a single block of polycarbonate using a CNC tooling machine, according to Figure 1B.2.4. Drill holes into the sides and carve connectors directly into the base of the bubble trap in the same way as done for the flow cells (see Support Protocol 1, step 3), eliminating the need for glue when connecting silicone tubing to the base.

2b. Place rubber gaskets on the ring near the top of the three vertical columns.

3b. Press 5-ml syringes (i.d., 12.5 mm; without the piston) onto the vertical columns.

The rubber gaskets seal the trap efficiently and no glue is required.

4. Put a stopper on top of the syringe.

EMBEDDING AND FLUORESCENT IN SITU HYBRIDIZATION OF A FLOW CELL–GROWN BIOFILM

Embedding of a biofilm in acrylamide preserves the three-dimensional structure and allows subsequent FISH for in situ species identification. The embedding procedure presented here describes volumes of reagents specific to flow cells of the dimensions described in Support Protocol 1. Modify the protocol if the dimensions of the flow channels at hand do not match that description.

Materials

Biofilms adhered to the substratum of flow cell system (see Basic Protocol)
Paraformaldehyde fixative (see recipe)
1× phosphate buffered saline (PBS; see recipe)
20% (w/v) acrylamide monomer (200:1 acrylamide:bisacrylamide)
N,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED)
1% (w/v) ammonium persulfate (APS) activator, freshly prepared
Fluorescently labeled oligonucleotide probes (e.g., FITC, Cy3, Cy5; e.g., Eurogentec)
FISH prehybridization buffer (see recipe)
FISH hybridization buffer (prehybridization buffer with an appropriate concentration of formamide; see Stahl and Amann, 1991)
FISH washing buffer (see recipe)
Antifade agent (e.g., SlowFade, Molecular Probes)

Clamps
50-ml beaker
2-ml microcentrifuge tubes
Humidified storage container (e.g., Petri dish with wetted paper or cotton)
Microscope slides with 8- to 10-mm diameter wells for FISH (Novakemi AB)
Incubation chamber (50-ml polypropylene centrifuge tube with FISH hybridization buffer–saturated paper toweling)
Microscope slides and coverslips
Rubber gaskets, 0.7 mm thick
Additional reagents and equipment for calibrating oligonucleotide probes (e.g., Stahl and Amann, 1991)

Fix the biofilm

1. Stop the feed pump and clamp off the effluent tubes from the flow chambers. Cut off the inlet tubes so that 3 to 4 cm of inlet tube is left on the flow chamber (i.e., enough to reach the bottom of a 2-ml microcentrifuge tube).

2. Place the pump on the effluent side of the flow cell, and, after mounting the tubes to the pump, gently remove the clamps. Using reverse flow, slowly activate the pump so that a drop of medium appears on the end of the inlet tubes.

3. Put paraformaldehyde fixative in a 50-ml beaker and submerge the inlet tube into the fixative. Draw the fixative into the channels using a flow rate of ~0.2 mm/sec for 15 min. Stop the flow and allow the fixative to work for 1 hr.

   CAUTION: *Paraformaldehyde is carcinogenic. Handle in a ventilated fume hood, wearing suitable gloves (see UNIT 1A.3).*

Embed the biofilm

4. Wash the fixed biofilm for 20 min by pumping 1× PBS through the flow channel at a rate of 0.2 mm/sec.

5. Mix 1 ml 20% acrylamide monomer and 8 µl *N*,*N*,*N′*,*N′*-tetramethylethylenediamine (TEMED) in 2-ml microcentrifuge tubes. Immediately before starting the embedding, add 20 µl freshly prepared 1% ammonium persulfate (APS) activator, and invert the reaction tube only once.

   CAUTION: *Acrylamide is carcinogenic and toxic. Handle in a ventilated fume hood, wearing suitable gloves.*

   Because small differences in concentrations, residual oxygen, and ambient temperature can affect the solidification process, test the solidifying time prior to embedding. An optimal solidifying time is 3 to 5 min. If it is shorter, adjust the amount of APS and test again. Because the solidification occurs relatively quickly, it is important to have a working routine, and it is recommended that the technique be tried on empty flow cells before embedding important samples. The acrylamide solution is sufficient for embedding of two 4 mm × 1 mm × 40–mm flow cells. Use the peristaltic pump as described above.

6. Reverse the flow briefly to let a small drop appear on the end of the inlet tubes. Then insert the tubes into the activated acrylamide solution and draw it into the flow channel at a pump speed of 0.5 mm/sec.

   Note that the pump rate is increased to ensure that the chamber is filled with the acrylamide solution quickly before it starts to solidify. In the described system, this takes exactly 1 min, 50 sec. It is recommended that the time it takes to fill the flow cell chamber be measured using an empty channel.

7. Gently clamp off the effluent tubing and remove the pump. Allow to the acrylamide to solidify for at least 1 hr at room temperature.

Prepare the embedded biofilm for FISH

8. Remove the substratum from the flow cell using a scalpel and transfer the solidified acrylamide slab to a humidified storage container. Cut the slab in suitable pieces, 0.5 cm in length.

   Note the orientation of the slabs, since the biofilm is located at the edge that was adjacent to the substratum.

   The solidified sample can be stored in the sealed container for several months at 4°C.

9. Clean used equipment, taking special care to remove solidified acrylamide from the flow channels and the inlets and outlets of the flow cells. Use a dishwashing brush for the channels and a needle for the inlets and outlets.

Perform FISH on embedded biofilm

10. Place the acrylamide slab in a well on a microscope slide with 8- to 10-mm diameter wells, the biofilm side facing downward.

11. Calibrate the fluorescently labeled oligonucleotide probes before use, in order to determine the optimal concentration of formamide in the FISH hybridization buffer (e.g., Stahl and Amann, 1991).

12. Saturate the embedded biofilm with FISH prehybridization buffer by adding 50 µl to each well containing an acrylamide slab and incubating for 30 min at 37°C in a formamide-saturated incubation chamber.

    Make the incubation chamber from a large centrifuge tube (to accommodate a microscope slide), and place a piece of paper towel in the tube, wetted with FISH prehybridization buffer to keep the air saturated with formamide.

13. Meanwhile, add the probe(s) to 30 µl-aliquots of FISH hybridization buffer for a final concentration of ~2.5 µg/ml.

    More than one probe can be used in each hybridization.

14. Remove the FISH prehybridization buffer from the wells containing the slabs, add the hybridization solution containing the probes, and incubate in the formamide-saturated incubation chamber at 37°C, in the dark for 2 hr or longer.

15. After incubation, remove the hybridization solution and wash the slabs as follows:

    a. Add 50 µl FISH prehybridization buffer, and incubate 30 min.

    b. Remove the FISH prehybridization buffer, add 50 µl FISH washing buffer, and incubate 30 min.

    c. Remove the washing buffer, add distilled water, leave for 15 to 30 sec, and remove the water.

    The incubations in the washing steps are also performed in the formamide-saturated incubation chamber at 37°C, in the dark.

16. Mount the slabs on microscope slides with the biofilm facing up. Place a rubber gasket to protect the embedded biofilm from being squashed by the coverslip.

17. Before sealing the sample, add a drop of antifade agent to the slab. Seal the sample with tape and store in a dark cool place until microscopy is performed.

    The mounted samples can be stored for several months at 4°C if kept moist and in the dark.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

FISH prehybridization buffer

x% formamide
0.9% NaCl
0.1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.1% SDS
Store at 4°C for several weeks

The concentration of formamide is determined by calibrating the probes (see Stahl and Amann, 1991).

FISH washing buffer

0.1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.9 M NaCl
Store indefinitely at room temperature

Paraformaldehyde fixative

Add 2.0 g of paraformaldehyde and 10 µl of 10 M NaOH to 33 ml distilled water. Stir at 60°C until all paraformaldehyde is dissolved (~5 min). Next, add 16.5 ml of 3× PBS (see recipe) and cool on ice. Prepare fresh and hold on ice.

CAUTION: *Paraformaldehyde is carcinogenic. Prepare and store this solution in the fume hood.*

Phosphate-buffered saline (PBS), 1× and 3×

390 mM NaCl
30 mM sodium phosphate buffer, pH 7.2 (*APPENDIX 2A*)
If indicated, dilute to 1× before use
Store indefinitely at room temperature

COMMENTARY

Background Information

Studies of the fouling of industrial tubular systems in the early 1980s required reliable and reproducible microscopic observations of biofilm development and encouraged the design of the first flow cells. One of the first flow cells used for biofilm research was the Robbins device (McCoy et al., 1981). This apparatus is constructed of admiralty brass and does not allow direct microscopic inspection but rather has replaceable plugs with sampling surfaces allowing microscopic inspection of relatively undisturbed biofilm. The emerging realization in the mid-1980s of the importance of biofilms in medical context prompted the development of a modified Robbins device which was constructed from an acrylic block, and contained plugs with medically relevant surfaces such as catheter material (Nickel et al., 1985). A need for direct microscopic observation of developing biofilms led to the development of flow cells with glass surfaces mountable on microscopes. One of the first flow cells of this type consisted of two microscope slides, two cover slips, and silicone tubing, and was assembled with silicone adhesive (Caldwell and Lawrence, 1986). Doug Caldwell's group at the University of Saskatchewan subsequently developed the flow cell constructed of Plexiglas and mounted with a microscope slide similar to the flow cell described in detail in this unit (Wolfaardt et al., 1994). These flow cells are well suited for laminar flow conditions, whereas studies of biofilm development under high-shear turbulent flow conditions may use other systems such as square glass tubing flow cells (Stoodley et al., 1999). Biofilm growth in traditional flow cells results in relatively little biomass, but in cases where a large amount of biomass is needed, e.g., for proteome or transcriptome analysis, the biofilms can be grown in silicone tubing (Sauer et al., 2002). To estimate the extent of biofilm development in the silicone tubing, a glass capillary with a square cross-section can be inserted into the tubing during the setup of the system to provide a window for microscopic investigation (Sauer et al., 2002).

Although conventional light microscopy can be used, confocal laser scanning microscopy (CLSM) is particularly well suited for monitoring of three-dimensional structure formation in flow cell–grown biofilms. As a result of its noninvasiveness and nondestructive character, CLSM allows imaging of the three-dimensional structure of microbial biofilms in their naturally hydrated form (Lawrence et al., 1991). The fluorescence required for CLSM can be emitted from the bacteria if they are hybridized with fluorescently labeled nucleic acid probes or are stained with fluorescent dyes. Staining with fluorescently labeled lectins may visualize extracellular substances that surround and interconnect the bacteria in biofilms (e.g., see Neu et al., 2001). In addition, the microorganisms studied in flow cells are often manipulated so that they harbor genes encoding fluorescent proteins to allow analysis by CLSM or epifluorescence microscopy. A description of these tagging techniques is outside the scope of this unit, but useful information on this can be found in Nielsen et al. (2000), Hentzer et al. (2002), and Klausen et al. (2003).

In order to analyze structural biofilm development objectively, it is often necessary to subject the acquired micrographs to image analysis (e.g., see Heydorn et al., 2000a). Korber et al. (1992) devised procedures for determining statistically representative areas suitable for image analysis of the inherent heterogeneous biofilms. The Image Structure Analyzer (ISA) software package, developed at Montana State University, enables the calculation of a number of textural and areal parameters from two-dimensional biofilm images taken by light microscopy or CLSM (Yang et al., 2000). One of the first programs for objective analysis of three-dimensional CLSM biofilm images allows calculation of surface coverage and biovolume (Kuehn et al., 1998). The COMSTAT program, which is described briefly in this unit, enables the calculation of a variety of parameters from three-dimensional CLSM images (Heydorn et al. 2000b). Although the image-analysis procedures are objective, they contain the subjective operation of thresholding, where the operator attempts to find the value of the image grayscale pixels that best represents the distinction between biomass and void space. An image-analysis program with integrated objective threshold selection, enabling fully automated biofilm morphology quantification from CLSM imaging, was developed by Xavier et al. (2003).

Critical Parameters and Troubleshooting

Leakage

The main problem with flow cell experiments is leakage. Even a small leak will render the entire channel useless if not corrected. It is usually very difficult to seal leaks once the system is filled with liquid, which makes it very important to be careful when assembling the system. The primary component vulnerable to leakage is the actual flow cell. If the bubble traps are home-made, using syringes glued to a plastic base, they too can leak.

If the flow cell leaks while mounted on the microscope, it can become critically dangerous to the equipment: either immediately attempt to reseal the leak or remove the flow cell from the microscope. When recording time series, it is particularly important to make sure that no leaks are present, as leaks occurring during the unattended run of time series can cause problems.

If the system is in preparation for an experiment that has not been started, empty the leaking component and dry it. Cover the area of the leak with a layer of silicone glue and allow it to dry for at least a few hours, preferably overnight, before filling the system again. A better method is to have spare components at hand and replace the failing unit with a new one.

While running an experiment, it is not possible to drain the system or even stop the flow temporarily. Clean and dry the area containing the leak as well as possible, and keep a piece of paper towel at hand to repeatedly soak away leaking fluid. Apply a large excess of silicone glue to the leak and continue to remove leaking liquid until it stops.

Air bubbles

Since air bubbles can destroy or alter the three-dimensional structure of biofilms, care must be taken to prevent them from entering the flow cells. Two important measures are taken. First, the system contains bubble traps (see Support Protocol 2) to catch air in the medium supply. Second, the authors recommend not cooling the medium after autoclaving, but rather placing it immediately at the correct temperature for the experiment. If the medium is colder than the ambient temperature of the experiment, air bubbles tend to emerge throughout the system if it is running as the temperature of the medium rises.

Backgrowth

In the standard flow cell setup, there are no special precautions to prevent fouling of the tubing upstream of the flow cells. In most cases there will be little backgrowth, but, if the cells are highly motile, it may occur. Because biofilm in the upstream tubing will use substrate components and release waste products, it may affect the biofilm in the flow cell and result in less controlled conditions: therefore, it should be removed. For the same reasons, microscopic inspection and bioimaging of flow cell–grown biofilms should be done near the inlet. One way to reduce backgrowth is to quickly disconnect the inlet tubing from the flow cell periodically (e.g., once a day), cut off a few centimeters, and reconnect. It may also be necessary to exchange effluent tubes if they become heavily fouled.

Arrangement of the effluent tubes

The effluent tubes must be arranged carefully, to avoid reverse siphoning from the waste container (by placing the end of the tubes above the surface of the waste reservoir), and to avoid accidental entrance of air in case of leaks (by placing the effluent tubes above the level of the flow cells).

Flow stoppage

The biofilms formed by some microbial species are intolerant to interruption of medium flow, and even short periods of flow stoppage will result in detrimental effects, notably complete dispersal of the biofilm. Hence, it is important to plan ahead of the experiment. For instance, if the growth of the biofilms is carried out in a different room than the one to be used for microscopic analysis, electrical power must be available for the pump along the route from one room to another, e.g., by having a very long power cord. Also, when the supply flasks are exchanged, it must be done very quickly, with the pump running. The small amount of air that enters the medium lines at this point is removed by the bubble traps.

Selection

The researcher should keep in mind that flow cell experiments are selection experiments. Biofilms are dynamic systems, and mutants may efficiently out-compete wild-type organisms. Biofilm experiments should therefore always be done in replicates, and biofilm development properties of organisms from

mature biofilms should be retested to verify that the organisms have not undergone irreversible changes during the experiment.

Anticipated Results

Because many different aspects of biofilm biology can be investigated, many different results can be expected. Some of the more general results include: information about biofilm formation steps including adhesion, microcolony formation, and further structural biofilm development; information about structure-function relationships in complex biofilms, including multispecies biofilms; quantitative data to compare biofilms, e.g., those formed by a mutant and its wild-type.

Time Considerations

Assembly and sterilization of the flow cell system will take 1 to 2 days. After that, the system may run for several weeks, but many biofilms reach a mature state within 5 to 7 days. Embedding and FISH labeling can take up to two days, after which the sample can be examined; however, live systems can be observed instantly. Image analysis can take several days.

Growing and Analyzing Biofilms in Fermenters

The study of biofilms has stimulated the development of laboratory-based model systems which can be used to recreate various features of natural biofilm communities. Whereas naturally formed biofilms are sufficiently complex that they are not experimentally tractable, model systems can provide controlled conditions and reproducible sample sets. In a biofilm model, questions may be asked and conditions altered so that specific elements of the biofilm structure, physiology, metabolism, and gene expression can be described. Batch culture and flow-cell models are described in *UNITS 1B.1 & 1B.2*, this unit describes two continuous culture laboratory systems, and *UNIT 1B.4* describes the study of natural biofilms in the field. Most biofilm researchers will find that different model systems should be used, or standard methods optimized, to properly address their questions.

In this unit, two models for the growth of biofilms under continuous culture conditions using spinning discs (see Basic Protocol 1) and silicone tubes (see Basic Protocol 2) are described. The spinning disc model consists of a plastic plate with an integrated stir bar and slots for eighteen small glass or plastic chips. The spinning disc is submerged in a reactor flask containing medium and incubated on a stir plate under continuous flow. The silicone tube model consists of a length of silicone tubing through which a medium is supplied under continuous flow. Both model systems provide multiple samples for viable count analyses, and tube-grown biofilm samples may also be used for protein and transcriptional expression profiling and biochemical analysis.

In comparison to the flow cells and static systems, the spinning disc and tube biofilm models have advantages and disadvantages. For example, the biofilms which grow on the chips of a spinning disc reactor are similar in structure and metabolic profile, providing reproducible and statistically clean results. In contrast, more heterogeneous biofilms are generated in flow cells and tube biofilms as nutrient and waste gradients are formed along the length of the reactor and flow characteristics are altered. In static culture biofilms, steep oxygen and nutrient gradients contribute to the formation of extremely heterogeneous biofilms. Tube-grown biofilms are also advantageous in that they can provide a homogeneous biofilm and large amounts of biomass for expression analyses. Generally, spinning disc and tube-grown biofilms are not easily studied microscopically, although tube biofilms may be grown in such a manner that nondestructive microscopic examination is possible. For such studies, flow cell or static culture biofilms are more appropriate.

CAUTION: Follow all biosafety requirements relevant to the microorganism under investigation. Refer to *UNIT 1A.1* and other pertinent resources (see *APPENDIX 1B*) for instructions on safe handling of microorganisms.

BIOFILM CULTURE ON SPINNING DISCS

BASIC PROTOCOL 1

This protocol describes the use of the spinning disc reactor for the study of *Pseudomonas aeruginosa* biofilms. This method was first described by Pitts et al. (2001) for use in the study of toilet bowl biofilms. The method has since been adapted for use with *Pseudomonas aeruginosa* and *Staphylococcus aureus* (Hentzer et al., 2001; Boles et al., 2004; Lee et al., 2004; Lin et al., 2004). As demonstrated by the diversity of these studies, several elements of the protocol, including the substrate materials, may be adapted to the specific requirements of virtually any microbial biofilm former. Whereas the original

Current Protocols in Microbiology (2005) 1B.3.1-1B.3.14

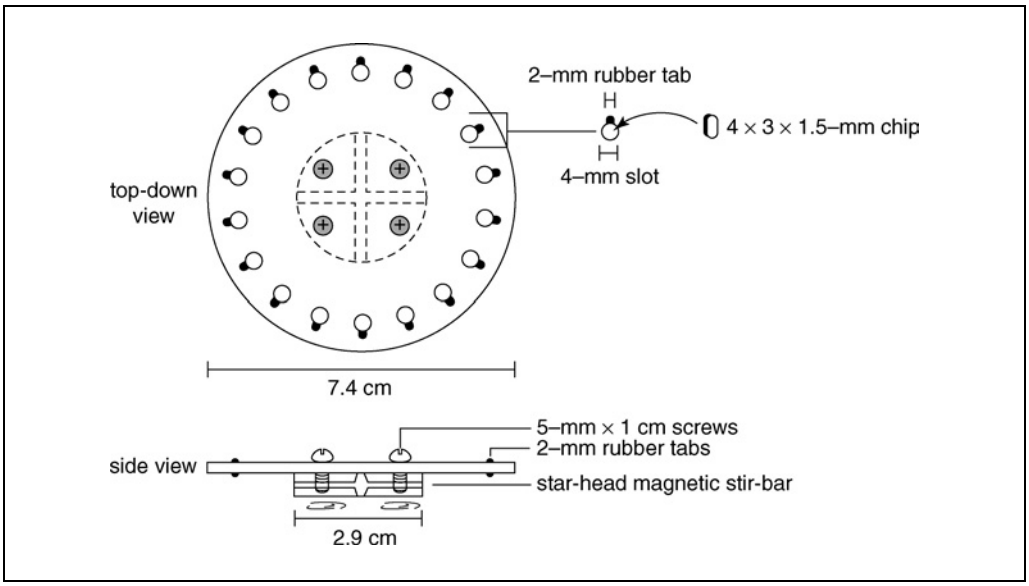

Figure 1B.3.1 The spinning disc is made of polyvinylchloride into which eighteen slots have been drilled, 4-mm wide and 1.5-mm deep. The biofilm substrate (chips) are made of ground glass and placed into the slots and held in place by red silicone rubber tabs. Also visible in the top-down view are the screws that hold the star-head magnetic stir-bar in place to the underside of the disc. The side view shows the placement of the stir bar relative to the chips.

Table 1B.3.1 Timeline for Culturing Biofilms on Spinning Discs

	Action	Steps
Day 1	Assemble and set up medium reservoir and reactor assembly, prepare culture, inoculate biofilm reactor	1–17
Day 2	Culture biofilms (flow phase)	18
Day 3	Test antimicrobial sensitivity	19–27
Day 4	Calculate experimental results	28

protocol utilized porcelain discs, recent adaptations have utilized stainless steel, glass, and plastic discs. The most important piece of equipment in this protocol is the spinning disc. Made of Teflon or polyvinylchloride and silicone rubber, the disc is attached to a magnetic stir bar on the underside, with chips of varying materials on the upper side (see Fig. 1B.3.1). In the protocol described here, the disc is fitted with eighteen glass chips. The biofilm reactor consists of a 1-liter glass beaker with an overflow port. Lastly, an adjustable-speed peristaltic pump is required. Ideally, a multichannel pump is used to allow multiple experiments to be run simultaneously. Because the bacterial culture within the reactor is continually supplied with fresh medium, the culture is maintained in the logarithmic phase, as in a chemostat. The chemostat allows the culture to approach steady-state so that biofilm growth is uncoupled from the planktonic growth phase. Therefore, observed changes in the biofilms will be independent of growth phase phenomena. Chip-grown biofilms are particularly well-suited for antimicrobial susceptibility and viability testing, and will yield highly reproducible results.

Table 1B.3.1 presents a timeline for the procedures involved in this method.

Materials

Silicone glue
Starter culture (mid-log phase bacterial culture)
Rich medium (e.g., LB, TBS, or other; *APPENDIX 2C*)
95% ethanol
Antibiotic solution
PBS or KPBS (*APPENDIX 2A*)
Agar medium plates (for viable counting; see *APPENDIX 2C*)

1-liter glass (e.g., Pyrex) beaker with overflow effluent port (see Fig. 1B.3.2)
Rubber stopper (no. 15; 100-mm top diameter, 81-mm bottom diameter) with four predrilled holes
Glass tubing, 5-mm o.d. or sized to fit holes in stopper, of appropriate length
Flexible silicone tubing, autoclavable: 12-mm o.d./6-mm i.d. and 6-mm o.d./3-mm i.d., and of size appropriate to fit through peristaltic pump (Marprene Manifold tubing from Watson-Marlow, cat. no. 978.0102.000, if Watson-Marlow peristaltic pump is used)
0.22-μm filter cartridges
Small test tube or vial with bottom removed
Medium reservoir and waste bottle: 2-liter, 4-liter, or larger-capacity autoclavable plastic bottles (e.g., Nalgene jugs)
Elbow joint (Cole-Parmer), 0.25-in. (~0.625 cm)
Peristaltic pump (e.g., Watson Marlow; *http://www.watson-marlow.com*)
Incubator with shaker
Aluminum foil
Sandblasted ground-glass biofilm chips
Spinning disc (Fig. 1B.3.1)
Magnetic stir bar
Tube clamps
Stir plate
96-well microtiter plate
Hemostats and forceps, sterile
1.5-ml microcentrifuge tubes
Bath sonicator or tissue homogenizer

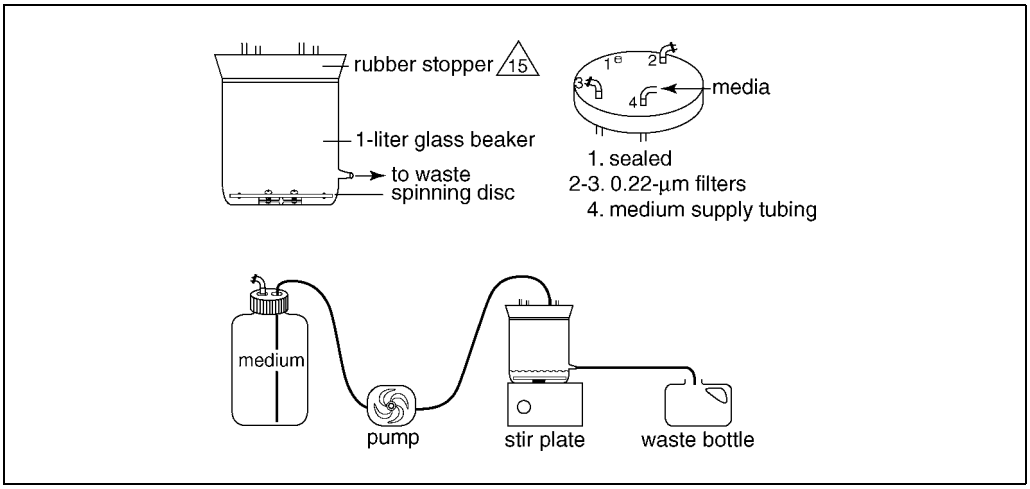

Figure 1B.3.2 The reactor set-up consists of a 1-liter Pyrex jar with an overflow spout and a no. 15 rubber stopper. The ports in the rubber stopper are fitted with (1) a cap, (2-3) filter units, and (4) medium supply tubing, as shown. When fully assembled, medium is pumped from the reservoir (bottom left) through a peristaltic pump and into the reactor. The reactor is placed on a stir plate with the spinning disc inside. Waste medium and culture fluid flows through the overspill spout to the waste bottle.

Assemble reactor

1. Set up the spinning disc biofilm reactor using a 1-liter glass beaker that has an overflow effluent port and a no. 15 rubber stopper with four pre-drilled holes (ports). See Figure 1B.3.2 for a schematic diagram.

   It is best to buy a solid stopper and drill holes in it. Three of the holes should be ∼5 mm in diameter. The fourth port is optional, providing clean access to the planktonic culture during the experiment (e.g., for OD readings); if such access is desired, create an access port sized to fit a small capped vial or test tube.

2. Insert short segments of rigid tubing (e.g., 10-cm lengths of 5-mm i.d. glass tubing) through the small ports in the rubber stopper to provide solid support for ventilation and medium inlets. Using short segments of flexible, autoclavable tubing (silicone, 3-mm i.d.), connect 0.22-μm filter cartridges to two of the inlets to allow for ventilation and prevent contamination. Fit the access port with a small test tube or vial from which the bottom has been removed. Cap the tube/vial.

3. Prepare the medium reservoir as follows.

   a. Create a port for medium delivery by drilling a hole in the lid and fitting it with a segment of 6-mm i.d. silicone tubing that is long enough to reach the bottom of the reservoir and is linked to the exterior of the lid with a 0.25-in. (∼0.625-cm) elbow joint.

   b. Create a port for ventilation in the lid of the medium reservoir by attaching a 0.22-μm filter to the lid using rigid and flexible tubing (as described in step 2 for the stopper of the reactor) *or* create a ventilation port in the shoulder of the medium reservoir by directly inserting the filter, without the use of tubing adapters.

4. To the exterior of the medium outlet, attach silicone tubing long enough to reach from the medium reservoir, through the peristaltic pump, and to the reactor vessel, in three segments connected by barbed mini-tube fittings.

   The first and third segments are of 3-mm i.d. and 6-mm o.d. The middle segment of tubing must be of appropriate size to fit through the peristaltic pump. If a Watson-Marlow pump is used, manifold tubing is available for this purpose.

   The medium reservoir should be sized appropriately with respect to the amount of medium required for the experiment, such as a 2-liter, 4-liter, or larger autoclavable Nalgene jug.

5. Use silicone glue to seal the tubing into the lid of the biofilm reactor and medium reservoir. Cap and seal the fourth port on the stopper.

6. Fit another length of tubing (12-mm o.d./6-mm i.d.) to the outflow port on the side of the 1-liter reactor flask. Use sufficient tubing to reach from the reactor to the waste bottle.

Prepare culture

7. In the morning of day 1, inoculate a 5-ml starter culture from an isolated colony or overnight culture, and incubate with shaking at the appropriate temperature.

   The reactor, growth medium reservoir, and starter culture should be prepared on the same day.

   It is best to use a primary culture, such as an overnight culture or isolated colony grown under antibiotic selection to inoculate the starter culture, as this will ensure culture purity and growth phase when the culture is used later in the day to inoculate the reactor. Using starter cultures of similar age/growth phase also helps ensure consistency between experiments.

Set up medium reservoir and reactor

8. Prepare 4 liters medium, and place it in the medium reservoir (4-liter Nalgene bottle).

   Depending on the planned length of the experiment, it may be necessary to make a much larger volume of medium. Be sure to adjust the autoclave time to accommodate the medium volume used.

9. Replace the lid to the reservoir, with the supply tubing on the interior (tubing must be long enough to rest on the bottom of the reservoir). Use aluminum foil to cover the exterior end of the hard support tubing, as well as the filter units.

10. Wash eighteen biofilm chips one time with 95% ethanol and three times with distilled water, then place the chips into the slots of the spinning disc.

    Neither the discs nor the chips are commercially available to the specifications described in Fig. 1B.3.1. They can be easily constructed or fabricated by a university machine/instrument shop. Alternatively, a similar reactor can be purchased from Biosurface Technologies.

11. Place the spinning disc into the reactor, making sure that the chip side faces up and the stir-bar side is on the bottom.

    The spinning disc may be autoclaved separately, wrapped in aluminum foil. It is best to do this on the dry setting, but if the liquid setting is used, place the foil-wrapped disc in an empty pipet tip box to keep it dry. Use extra caution when assembling the reactor if this alternative method is chosen. An experimental timeline for this alternative technique is described below.

12. Fill the reactor with ~250 ml water and cover with the tube-fitted rubber stopper.

13. Place tube clamps on every tube to avoid backflow and contamination. Cover the ends of the tubing and the filter units with aluminum foil.

14. Autoclave the reactor assembly and medium reservoir on the liquid setting.

Inoculate the biofilm reactor—batch phase

15. Replace the water in the reactor with ~250 ml sterile medium.

16. At the end of day 1, inoculate the reactor with 1 ml of the 5-ml starter culture started that morning (step 7).

17. Stir the reactor at 250 rpm on a stir plate and incubate overnight at room temperature.

Start biofilm culture—flow phase

18. In the morning of day 2, connect the inflow tubing to the supply port of the medium reservoir, fitting it through the peristaltic pump, and remove all of the clamps to allow flow through the entire system. Then, start the pump in a clockwise direction.

    Remember to remove the clamp from the effluent tubing to permit flow through the system.

    Pump settings vary by model. Set the pump so that the flow rate is ~0.5 ml/hr.

    Flow can also be altered to determine the specific growth rate of the test strain.

Test antimicrobial sensitivity

19. In a 96-well microtiter plate, add 100 µl medium to the wells in rows B through H for the first four columns.

    During the test, the cells should not double. Therefore, if a rich medium is used in the reactor, use 1× PBS or KPBS as the diluent in the reactor plate.

20. In row A, add the desired amount of antibiotic solution to the medium for a total volume of 200 µl. Mix the wells in row A and transfer 100 µl from row A to row B. Continue the serial dilution down the column to row G; transfer 100 µl from row G to waste, leaving row H with only 100 µl medium.

    For example, to achieve a final concentration of 1 mM for a given antimicrobial agent, in row A, add 20 µl of 10 mM stock solution to 180 µl medium.

    Modify the concentrations and the dilution schemes for specific experimental needs. Maintain the 200-µl volume for convenience and ease of use in the microtiter plate.

21. Twenty four hours after starting the flow phase of the reactor culture (day 3), stop the reactor and take a 1-ml sample of the planktonic culture and set aside on ice (source of samples for susceptibility testing in parallel with the biofilm samples that will be harvested). Measure the optical density (OD_{600}) of this sample and/or perform a viable count to determine the planktonic culture density.

    It may be necessary to dilute this sample. To ensure comparable results, expose the same number of planktonic and biofilm cells to the antimicrobial stress in the microtiter plate.

22. Remove the disc by reaching into the reactor and pulling it out without touching the biofilm chips. Remove the chips from the disc with sterile forceps and dip each one into fresh medium to remove any loosely attached cells. Place one chip into each well in columns 1 and 2 of the 96-well microtiter plate, and 10 µl planktonic culture into the wells of columns 3 and 4. Mix well.

23. Incubate the plate 5 hr at 37°C.

    Temperature and incubation time may vary depending on the organism used and the experiment at hand.

24. Transfer the chips into 1.5-ml microcentrifuge tubes containing 1 ml of 1× PBS or KPBS. Likewise, transfer 100 µl of the planktonic cultures into 1.5-ml microcentrifuge tubes containing 900 µl of 1× PBS or KPBS.

25. Sonicate the tubes for 10 min, and then briefly vortex.

    Alternatively, a homogenizer can be used to disperse the cells. Place the chips, cells, and PBS or KPBS solution in sterile, capped tubes.

26. Serially dilute the cells from each tube by taking 10 µl cells and mixing with 90 µl PBS or KPBS. Spot 10 µl of each dilution in triplicate onto pre-dried agar plates of appropriate medium.

27. Incubate the plates overnight at 37°C.

Calculate experimental results

28. On the following day (day 4), remove plates from the incubator and count colonies.

29. Clean the entire apparatus with mild soap and water, rinse in distilled water, and allow to dry. Replace the 0.22-µm filters only if they have become soiled or wet. After washing, store the chips in a petri dish until needed; wash in ethanol before reuse.

    There is no need to completely disassemble the tubing. Replace individual segments as needed, should they become dirty or clogged after multiple cleaning/autoclaving cycles.

CONTINUOUS FLOW CULTURE INOCULATION OF SPINNING DISCS

ALTERNATE PROTOCOL 1

The execution of this modified technique is nearly identical to that described in Basic Protocol 1. The critical difference is the residence time of the spinning disc reactor in culture. Whereas Basic Protocol 1 allows for substrate adherence during the batch culture phase, this alternative method begins the biofilm culture during the continuous flow (chemostat) phase, when the planktonic culture has reached near steady-state.

The reservoir and reactor are assembled and sterilized as described in Basic Protocol 1, with one exception; a stir bar is placed in the reactor before autoclaving, and the spinning disc is wrapped in an envelope of aluminum foil and autoclaved separately.

As described in Basic Protocol 1, steps 16 to 18, the reactor is inoculated and batch culture incubation is begun. In this case, however, the culture is simply stirred with a stir bar. On the morning of day 2, start the chemostat phase of the culture by attaching the medium reservoir to the reactor, unclamping the tubing, and starting the pump. Allow the chemostat to run for the day, and in the evening begin the biofilm culture. To do this, aseptically remove the stir bar from the reactor, and replace it with the spinning disc. This must be done very carefully, taking care not to touch the spinning disc as the foil envelope is peeled away. The disc should be gently dropped into the tilted reactor, so that the biofilm chips face upward. Replace the reactor on the stir plate, begin stirring and restart the flow.

IMPORTANT NOTE: Remember to clamp the influent and effluent tubing whenever the pump is stopped; this will prevent backflow in the system. Do not forget to unclamp the tubing when restarting the pump.

Perform biofilm sampling and testing as described in Basic Protocol 1, steps 19 to 21.

BIOFILM CULTURE IN TUBES

BASIC PROTOCOL 2

Tube reactors are a commonly used model system for the study of biofilms, particularly those of clinical relevance. Biofilms may be grown in tubing of varying composition and diameter and under varying flow rates. Medium composition may reflect clinical situations, such as artificial urine or saliva, or may be comprised of standard laboratory media (*APPENDIX 2C*). The effects of shear stress can be tested by varying the flow rate of the supplied medium. The tube biofilm model provides both biofilm and planktonic samples that may be used for viability and antibiotic susceptibility testing, but more complex tests may also be applied. In its most basic form, a tube biofilm model experiment is simple to perform and requires a minimum of special equipment—a little more than tubing, medium, and a peristaltic pump. The biofilm material may be used for antimicrobial susceptibility and viability testing, and can also provide sample material for expression analyses, including both β-galactosidase-based and microarray analyses. The protocol described here offers numerous opportunities for adaptation and specialization.

Materials

30% (v/v) hydrogen peroxide (H_2O_2)
1:8 diluted LB or other rich medium (*APPENDIX 2C*)
Mid-log phase bacterial culture
95% ethanol
PBS or KPBS (*APPENDIX 2A*)
Petri plates containing appropriate solid medium
30% H_2O_2

Medium reservoir (see Basic Protocol 1)
Silicone tubing (2- to 3-mm i.d.)

Mini tube fittings, barbed (Cole-Parmer)
Multichannel peristaltic pump (e.g. Watson-Marlow)
Marprene Manifold tubing from Watson-Marlow, cat. no. 978.0102.000, if Watson-Marlow peristaltic pump is used (or other size silicone tubing compatible with peristaltic pump used)
Bubble traps (*UNIT 1B.2*; optional)
Aluminum foil
Tube clamps
Incubator with shaker
Spectrophotometer
1-ml syringe with a 12-G needle attached
Petri dishes
Razor or scalpel blades
1.5-ml microcentrifuge tubes
50-ml conical tubes (optional)
Bath sonicator (optional)
96-well microtiter plate

Assemble reactor tube

1. Set up a medium reservoir in the same manner as described in Basic Protocol 1, steps 3 and 5.

   The medium reservoir can be as small or as large as needed for each particular experiment.

   The reactor may be assembled and autoclaved the day before beginning the experiment, but it is best to perform the system-cleansing flushes (with peroxide and sterile water) on the same day as the inoculation.

2. Set up parallel silicone tubing for the desired number of experiments (usually eight or twelve, depending on the number of available channels on the pump in use).

   The tubing should be long enough to accommodate the distance from the medium reservoir to the peristaltic pump. The tubing that passes through the pump must be compatible with the pump mechanism.

3. Cut 3- or 8-in. pieces of silicone tubing (2- to 3-mm i.d.) in which the biofilms will be grown.

   The length and inner diameter of tubing used depends on the experimental goals. These lengths are simply recommendations, but the i.d. of the tubing can be ≥12 mm. Remember that changes in tube diameter will change the flow dynamics: see Reynold's equation for determining turbulent flow (step 16).

4. From the medium reservoir, run a piece of silicone tubing leading to the eight parallel pump tubes. Connect the pump tubing with barbed mini tube fittings and segments of silicone tubing to the bubble traps, which are directly connected to the biofilm tubing. Connect the biofilm tubing to another length of tubing that leads to the waste bottle.

   If preferred, use self-sealing septa placed just upstream of the biofilm tubing. The septa can be used for inoculation of the system, but it is equally straightforward to inoculate directly into the tubing (see steps 15 and 16).

   This experiment can be performed without the use of bubble traps. Be certain to seal all joints completely to avoid the introduction of air into the system.

5. Wrap loose tubing ends in aluminum foil and autoclave the entire system.

6. Prepare 500 ml of 0.6% hydrogen peroxide (10 ml of 30% H_2O_2/500 ml).

   Prepare hydrogen peroxide fresh before every use. Hydrogen peroxide is a strong oxidant, and will degrade over time, especially when exposed to light.

7. Flush the system with the 0.6% hydrogen peroxide solution for 2 hr at a pump setting of 14 rpm. Be sure to fill the bubble traps, if used.

8. Using aseptic technique, switch from 0.6% hydrogen peroxide to sterile water, and flush the system for an additional 2 hr at a pump setting of 14 rpm. Be sure to fill the bubble traps, if used.

9. Again using aseptic technique, switch from sterile water to sterile medium. Flush the system for 2 hr at a pump setting of 14 rpm, making sure to fill the bubble traps, if used.

10. Stop the flow and clamp the tubing just upstream of the inoculation site.

Prepare inoculum

11. Prepare a 5-ml starter culture as described in Basic Protocol 1, step 7. Incubate with shaking at 37°C to a culture OD_{600} of 0.1.

    At this point, it is ready to be used as an inoculum in the tube reactor.

    The medium used for this inoculum culture should be the same as that to be used in the biofilm reactor.

Inoculate biofilm reactor

12. Thoroughly clean the inoculation site with 95% ethanol.

13. Using a 1-ml syringe with a 12-G needle attached, inoculate each tube with the culture at an OD_{600} of 0.1 (step 11). For a 3-in. long biofilm tubing, inoculate with a 0.5-ml culture volume; for an 8-in. long biofilm tubing, inoculate with 1 ml culture.

    IMPORTANT NOTE: Do not inject air into the system.

    Use caution in handling the needle and syringe to avoid injury, and dispose of used needles in properly labeled sharps containers.

    Make sure that the inoculum culture and the medium in the tubing are at the same temperature and that the system remains at experimental temperature for the remainder of the experiment.

    To maintain consistency between experiments, ensure that the inocula are identical. They should each be at OD_{600} 0.1. If the OD of the inoculum is > 0.1, dilute the culture with sterile LB, using the following relation:

$$(OD_{current})(volume_{culture}) = 0.1 \times 10 \text{ ml}$$

Equation 1B.3.1

$$volume_{fresh\ LB} = 10 \text{ ml} - volume_{culture}$$

Equation 1B.3.2

14. Inoculate samples as quickly as possible, and allow the incubated tubing to sit undisturbed for 30 min at experimental temperature.

15. Adjust the rpm setting on the peristaltic pump before unclamping the tubes and starting the flow.

Some researchers suggest that the biofilm tubing should be incubated in a vertical orientation to prevent settling over the duration of the experiment. This may be of particular importance when using a low flow rate.

16. Check the flow rate after initiating the experiment, as well as before each sample harvest, by collecting the effluent in a graduated cylinder for a predetermined amount of time, then calculating the flow rate as milliliters per hour.

Although this step is not critical, it may serve as a useful gauge of the biofilm conditions, particularly at later time points.

Calculate the flow characteristics of the system (laminar, transitional, or turbulent) using the following Reynold's equation:

$$R = \rho VD / \mu$$

Equation 1B.3.3

where ρ is the fluid density, V is the fluid velocity, D is the tube diameter, and μ is the fluid viscosity. Flow is laminar at R values up to 2000. At R values >4000, the flow is turbulent. R values between 2000 and 4000 are considered to reflect transitional flow, where regions of both turbulent and laminar currents may be found.

17. When harvesting tube samples, place the end of the tubing from the bubble trap (the inflow tubing) into a petri dish containing 95% ethanol (this will help maintain sterility in the system).

Harvest tube biofilms

18. Remove the biofilm tubing from the flow path. Cut off the sections of tubing where the connectors attach. Measure the length of tubing that remains.

Steps 19 to 25 comprise a stringent method for biofilm harvesting. A more simple technique involves clamping the biofilm tubing at either end, then manually massaging the portion of tubing between the clamps. This will dislodge the biofilm from the tube walls. To remove the cells from the tubing, unclamp one end of the tube and inject 1 ml of 1× PBS or KPBS buffer through the other end. Collect the effluent cell suspension in a test tube and proceed with the experiment as described, starting from step 26.

19. Cut the tubing into two or three pieces using a sterile scalpel or razor blade. Wipe the outside of the tube with 95% ethanol, and let evaporate to dryness.

20. If using a 3-in. piece of biofilm tubing, place the cut and surface-sterilized pieces into a sterile 1.5-ml microcentrifuge tube. For an 8-in. piece of biofilm tubing, place the pieces into a sterile 50-ml conical tube. Add 800 µl of 1× PBS or KPBS.

21. Sonicate for 1 min and incubate on ice for an additional 1 min. Vortex vigorously for 1 min. Repeat this step for a total of four times.

22. Remove the biofilm tube pieces, and place them in a fresh sterile tube.

    a. If using a 1.5-ml microcentrifuge tube, centrifuge 5 min at 7500 × *g*, 4°C, to remove residual liquid or cells from the silicone tubing.

    b. If using a 50-ml conical tube, centrifuge 5 min at <7000 × *g*, 4°C, to remove residual liquid or cells from the silicone tubing.

    After centrifugation, carefully remove the biofilm tubing. Use a pipet to transfer the liquid to the tubes in step 20.

23. If the samples are for an early timepoint, combine multiple biofilm tubes into a single sample.

    This is useful if enough biomass is needed to perform OD measurements.

24. Thoroughly vortex the tube containing the cells for 1 min. Then sonicate, chill on ice, and vortex, 1 min each, for a total of two times. Make sure the culture appears homogeneous. If clumps are still visible, repeat the sonicate/chill/vortex cycle until the culture looks homogeneous.

25. Record the total liquid volume of this tube.

Analyze samples

26. Remove 10 µl of the cell suspension for cfu enumeration.

27. Prepare a 96-well microtiter plate with 90 µl of 1× PBS or KPBS in each well (eight wells/row/sample). Add the 10 µl from step 26 to the first well, and serially dilute the cells in a range from 10^{-1} to 10^{-8}.

    Fewer dilutions may be required at early time points, when the biomass coverage is low. Until the behavior of the bacterium is characterized, however, it may be best to use a broad range.

28. Spot 10 µl of each dilution, in triplicate, onto the appropriate solid medium. Incubate the plates upside down overnight at 37°C.

    Allow the spotted plates to dry before turning them over.

    Using a small volume and multiple dilutions in this manner allows for viable count assays to be performed very quickly and uses far fewer plates than the traditional viable count assay, in which larger volumes are spread, i.e., one dilution per plate. Typically, up to six 10-µl spots can fit on a standard petri plate.

    Although LB medium has been referenced throughout these protocols, choose a medium according to the needs of the organism and experimental design.

29. On the following day, count colony forming units (CFUs) for each dilution, where possible.

    For the limited spot size, ~20 organisms is an ideal number.

30. Calculate the number of organisms per tube surface area. Average the triplicate colony counts (*N*) for the dilution to be used:

$$\frac{N \times \mathrm{vol_{total}(\mu l)}}{\mathrm{vol_{spot}(\mu l)} \times \mathrm{dilution}} = \frac{\mathrm{no.\ of\ cells}}{\mathrm{SA\ (mm^2)}}$$

Equation 1B.3.4

    where $\mathrm{vol_{total}}$ is the total harvest volume (usually ≥1000 µl), $\mathrm{vol_{spot}}$ is the volume of the dilution that is plated onto the solidified medium (usually 10 µl), dilution refers to how diluted this sample is relative to the cell harvest (e.g., 10^{-5}), and SA refers to the surface area of the biofilm tube in square millimeters (this can be calculated from the tube diameter and length, recorded in step 20).

31. At the very end of the experiment, run fresh hydrogen peroxide solution through all of the tubing and bubble traps. Thoroughly wash the bubble traps and tubing with mild soap and water. Rinse thoroughly with distilled water before autoclaving.

COMMENTARY

Background Information

Spinning disc

The biofilm culture method detailed here has been used previously, with minor adaptations, to study the effects of various antibiotics and genetic mutations on biofilm formation, and on survival of biofilm populations (Pitts et al., 2001; Teitzel and Parsek, 2003; Lee et al., 2004). It is commonly referred to in the literature as a rotating disc reactor, but is not to be confused with the Rototorque and the rotating annular reactor (Characklis, 1990; Lawrence et al., 2000). The first iteration of the spinning disc reactor model was developed to study biofilm formation on ceramic surfaces under intermittent flow conditions, as found in toilets (Pitts et al., 2001). Biofilm growth and susceptibility to chlorine were studied using a rotating Teflon disc carrying six ceramic chips that was placed in an open-air reactor through which alternate flushes of medium and tap water were passed. The method was found to yield highly reproducible and statistically sound results, making it an excellent candidate for adaptation to other applications.

The Pitts protocol was adapted to the study of *Pseudomonas aeruginosa* to test the efficacy of photodynamic antimicrobial chemotherapy (PACT; Lee et al., 2004). The Teflon rotor in this case was fitted with 24 stainless steel chips and biofilms were incubated under both batch and flow conditions before samples were removed and subjected to treatment with photosensitizing agents and subsequent irradiation. As demonstrated earlier by Pitts et al., the modified model provided statistically sound, reproducible results (Pitts et al., 2001; Lee et al., 2004). The Pitt model has been further adapted for the study of *P. aeruginosa*, using discs carrying eighteen glass chips (Hentzer et al., 2001; Singh et al., 2002; Teitzel and Parsek, 2003; Boles et al., 2004).

This method utilizes both batch and continuous flow conditions to establish biofilms on small chips held in a disc fitted with a magnetic stir bar. The benefits of this method rest in its adaptability and the reproducible results it provides: rotating discs can be designed to hold any number of chips of varying sizes and materials, including glass, plastic, metal, and porcelain. Spinning disc–grown biofilms can be inoculated at any point in the growth curve, harvested in replicates at any time point, and the resulting biofilm populations can be assayed for resistance to metals, antibiotics, and biocides.

Tube biofilm culture

Culturing biofilms in tube reactors is an essentially simple method, but can be used for a wide variety of analytical tests, ranging from simple viability testing to microarray analyses, and even magnetic resonance imaging (MRI; Manz et al., 2003; Bagge et al., 2004a,b). Very fragile, thin-walled glass capillaries may be substituted for silicone tubing, allowing for powerful microscopy to be performed on the biofilms growing inside. Tube biofilm reactors are particularly relevant to the study of clinical pathogens, as many nosocomial infections are the product of microbial colonization of indwelling medical devices such as urinary catheters, endotracheal and tracheotomy tubes, and nasogastric feeding tubes (Adair et al., 1999; Leibovitz et al., 2003; Saint and Chenoweth, 2003; Perkins et al., 2004). Tube biofilm reactors can also be used to study microbes that colonize water treatment systems and dental-unit water systems (Walker et al., 2000; Smeets et al., 2003).

As with the spinning disc model, the tube model is easily adaptable. The tube model can provide a large amount of sample material and virtually unlimited replicates for subsequent testing and analysis (Bagge et al., 2004b). Tube-grown biofilms can be incubated for extended periods but, as the tubing becomes occluded with bacterial growth, flow may be obstructed. Nutrient gradients will tend to develop in some tube biofilms, depending on the flow characteristics, the metabolic rate of the bacteria, and the length and diameter of tubing used. The researcher must keep such factors in mind when analyzing data, as they may yield artifactual results. It is also important to remember that samples taken from tube biofilms represent a somewhat heterogeneous population. A number of studies have revealed the metabolic heterogeneity that arises in biofilms (Okabe et al., 1999a,b; Sternberg et al., 1999). Because of the heterogeneity inherent within a biofilm community the results of, for example, expression analyses of a tube biofilm represent an average over the whole population. Different methods and growth models must be used to study the activities of subpopulations within a complex biofilm. Heterogeneity must always be considered as a factor in biofilm research, regardless of the model system used. The key to the models described in this unit

is the reduction of variation between biofilm samples, not the variation that is inherent to any individual biofilm.

Critical Parameters and Troubleshooting

The greatest hindrance to any long-term chemostat culture is contamination. It is, therefore, critical to pay attention at every step to maintain asepsis within the biofilm culture system. Use a medium reservoir that is large enough for the entire length of the experiment without having to change out reservoirs midcourse. This is one of the most common points where contaminants are introduced. It is also critical that the medium reservoir is prepared and autoclaved properly. Seal the tubing into the reservoir and reactor ports with silicone. Both biofilm systems described here are open to the environment at specific points, and these should be protected at all times. The air inlet of the medium reservoir is protected by a filter cassette, as is the reactor vessel in the spinning disc model. The effluent tube is the only other open point of the system, and care must be taken to avoid backflow from this point. Use a clamp to prevent backflow whenever you turn off the pump. Wipe down the tubing and your gloved hands with ethanol before handling and manipulating the system once it has been autoclaved. Because both model systems described here yield samples for viable counting, sterility must be maintained throughout the harvesting and processing stages of the experiment.

It is important to avoid introducing air bubbles in the tube biofilm reactor. Not only will air bubbles interrupt the flow, but they can also interfere with the biofilm and may cause artifactual results. Prevent air accumulation by ensuring that all tubing joints are tightly secured, and that no air is introduced when injecting bacteria into the system. Many researchers use bubble traps in their biofilm reactors. A variety of bubble trap designs are available (e.g., see *UNIT 1B.2*) but they are not a guarantee that the system will remain bubble-free. It remains up to the individual whether a bubble trap is used in the tube biofilm system.

To maintain consistency between experiments, always use inocula that have been grown under similar conditions and to the same stage of growth. Typically, mid-log phase culture inocula will provide the most consistent results.

To maintain constant conditions within a tube biofilm experiment, check the flow rate before inoculation and before harvesting. If running a long time course, check the flow rate at other points during the incubation. As the biomass within the tube increases, not only will the flow rate change, but the flow dynamics as well, both of which may affect biofilm structure and behavior (Beyenal and Lewandowski, 2002; Manz et al., 2003; Leon et al., 2004).

Anticipated Results

The experiments described here will yield, at the minimum, viable counts which will reflect the amount of biomass in either the tube-grown biofilm or on the biofilm chips. In both cases, biofilms may be subjected to treatments with biocides and tested for survival. When compared with the results of planktonic cells processed in parallel, data can be obtained regarding the different susceptibilities of these bacterial populations to various treatments. The tube-grown biofilms can provide sufficient biomass to perform various expression analyses. The cells may be processed for microarray analysis to determine wide-scale differences in expression between biofilm populations and their planktonic counterparts. More simply, engineered reporter strains may be utilized in β-galactosidase assays to examine the expression levels of specific genes. Similarly, reporter genes may be fused to GFP and the bacterial populations examined microscopically for expression.

Time Considerations

A spinning disc biofilm experiment can be run in a minimum of 4 to 5 days, from the point of assembly through harvest. However, the experiment may be run for a longer period, to obtain data over a time course, or for a shorter period, if the data required are from the earliest stages of biofilm formation.

The tube biofilm experiment will take a minimum of 3 to 4 days, but may also run longer if time course data is desired.

Preparing for Biofilm Studies in the Field

Robert J.C. McLean[1] and Thomas R. Simpson[1]

[1]Department of Biology, Texas State University-San Marcos, San Marcos, Texas

ABSTRACT

In their natural environments, microorganisms are under constant environmental selection to form biofilms. Using aquatic biofilms as an example, this unit illustrates general concepts in field biology and practical suggestions for designing, conducting, and analyzing biofilm experiments at varying distances from the laboratory. The unit also addresses an example of a special situation (space flight) where experimentation must be done by proxy through another individual or machine. *Curr. Protoc. Microbiol.* 10:1B.4.1-1B.4.14. © 2008 by John Wiley & Sons, Inc.

Keywords: biofilm • bacteria • field studies

INTRODUCTION

Field studies of biofilms present an exciting challenge to a microbiologist. Unlike in the laboratory, microorganisms in nature exist in mixed populations and are under constant environmental selection to adhere to surfaces and form biofilms. As a result, field experimentation would offer the most rigorous and realistic conditions for the testing of materials to attract or repel biofilms or for the isolation of organisms best suited for biofilm growth. Conditions in nature are rarely predictable. Rapid changes in weather, uncooperative wildlife, or a support vehicle's mechanical condition may affect carrying out field studies, which, consequently, require a certain amount of foresight, planning, and adaptability on the part of the microbiologist.

There are a number of logistical issues that may need to be addressed. These include accessibility of the sampling site; experimental design in the field, including sample collection, storage of specimens, and transport to the laboratory; and even issues related to investigator safety. Specimen analysis should also be considered during planning. For viable counts with dilution plating, samples are generally collected and stored unaltered at lower temperatures, to restrict further growth. Ideally, samples will be analyzed as quickly as possible. In the case of other types of analyses, specimens may need to be manipulated on site for initial preservation. This includes the use of fixatives (for microscopy), addition of TE buffer for a PCR-based detection such as denaturing gradient gel electrophoresis (DGGE; *UNIT 1E.1*), or preservatives such as RNase inhibitors for RNA-based detection. Statistical analysis must also be a consideration in the choice of sampling sites and the planning and location of experimental replicates.

It would be impractical to address every conceivable field situation here. Rather, we shall assume that the investigator may have limited field experience. To that end, we have included a section on general field biology and safety. Other sections deal with the type of environment to be sampled and the proximity of the field site to the investigator's laboratory. Some field sites may have a laboratory on site, which can greatly assist in the processing of data; others may not, and so specimen storage and transport will need to be considered. To address these different considerations, this unit provides examples of three types of field studies: (1) those that are in proximity to a laboratory, (2) those in a more remote location requiring overnight accommodation, and (3) field studies by proxy, in which the investigator may need another individual or a remotely controlled device to conduct some or all of the experimentation.

TECHNIQUE REFINEMENT AND TESTING

It is often prudent to test and develop some sampling and processing techniques prior to going into the field. In the case of water experiments, aquaria offer a readily accessible microcosm for developing specific techniques and identifying equipment and supplies needed for mixed culture work and sample processing. One can also assess the potential for specimen storage conditions to alter microbial community composition. For example,

Current Protocols in Microbiology 1B.4.1-1B.4.14, August 2008
Published online August 2008 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/9780471729259.mc01b04s10

aseptically acquire a 100- to 500-ml sample of aquarium (or pond, lake, or river) water. Mix the sample and then divide it into two aliquots, processing one immediately and the other after a delay under simulated field storage conditions.

Several strategies can be used to evaluate the influence of simulated field storage conditions on microbial survival and diversity. One fairly simple approach would be to employ dilution plating to measure bacterial survival by standard plate counts. One could also get a crude estimate of microbial diversity by the range of colony morphologies observed on the growth medium both before and after storage. DGGE (described in detail in *UNIT 1E.1*) is a PCR-based approach by which microbial diversity can be estimated by means of DNA fingerprinting. Comparing the DGGE analysis of the two samples (quickly processed samples and stored specimens) can determine whether banding patterns in the two samples are very similar (ideal situation implying no changes) or different (implying an artifact). It has been our experience that DNA templates, once prepared, can be stored at –20°C for several months without noticeable change. For DNA template preparation see, e.g., *UNIT 1.E.1* or use a kit, e.g., DNeasy (Qiagen).

GENERAL ASPECTS OF FIELD RESEARCH

Once at the field site, it is prudent to select and map sites for experimentation. If possible, photographs should also be taken of the sampling sites and sampling methodology in order to keep an accurate record. Several factors influence the final choice of sampling sites, including: site accessibility, safety of personnel, equipment limitations, and the likelihood that the chosen sites will provide a representative scientific evaluation of the study site.

Permits and Access to Study Sites

Collecting permits are very often required for field activities (addressed in part in *APPENDIX 1B*). One or more permits may be needed for the following:

Access to a site

Activities on the field site (including camping)

Sample collection

Sample transport.

Permits may be required by many organizations, including university, state, and federal agencies. For example, in the United States, national park collecting permits can be obtained through the National Park Service Research Permit and Reporting System (*http://science.nature.nps.gov/research/ac/ResearchIndex*). Collecting permits may or may not address permission for access. Some specimen transport issues are addressed by the National Park Service. However, in cases where potential human, animal, or plant pathogens are to be handled and transported, other agencies will be involved. In the United States, these include the Department of Agriculture (*http://www.aphis.usda.gov/programs/ag_selectagent/index.html*) and Centers for Disease Control (*http://www.cdc.gov/od/ohs/default.htm*). All such specific details should be checked ahead of time. Public as well as private lands often have restricted access and regulations addressing specific activities that may be conducted on the site. The importance of communication and respect for the wishes of the land owner or regulatory agency cannot be overemphasized, particularly if one wishes to have continued access to study sites.

IMPORTANT NOTE: The Web sites provided are current at the time of publication but may change.

Safety

First aid

Adequate provisions should be made for first aid and treatment of small cuts, burns, and other minor injuries. Ideally, at least one member of the field party should be trained in basic first aid (see *http://www.redcross.org/services/hss/courses*). Serious injuries must be treated by a physician or trained emergency personnel. Inquiries should be made in advance to obtain phone numbers for and directions to the nearest medical facility. If necessary, cell phones, radios, or satellite phones should be secured for emergencies.

Infectious disease safety

Although avian influenza (H5N1 influenza virus) is currently highly profiled in the media, there are a number of other infectious diseases that are also of concern for investigators in the field. These include other viral infections (e.g. hanta virus and rabies), vector-borne diseases (e.g., malaria); zoonotic (transmitted between animals and humans) bacterial infections (e.g., anthrax and tularemia); and wound infections (e.g., tetanus). The *United States Field Manual of Wildlife Diseases* (Friend and Franson, 1999), containing a number of practical suggestions,

can be downloaded from (*http://www.nwhc.usgs.gov/publications/field_manual*). Vaccination information can be obtained from the Centers for Disease Control Web site (*http://wwwn.cdc.gov/travel/contentVaccinations.aspx*).

Additional precautions for remote areas

Accidents such as sprained limbs or fractures may turn fieldwork at remote sites into life-threatening situations. As a precaution, one should take appropriate survival gear (e.g., clothing, water, food) and inform others as to travel plans, as well as anticipated date and time of return. In the event of a delay, authorities can be alerted for a potential rescue operation. Obviously, it is equally important to inform individuals or authorities as soon as possible following the safe completion of a trip to avoid the expense and hazards of unnecessary rescue operations.

Accessibility

Vehicle accessible

Equipment and personnel can be moved to research sites without problems. Emphasis can be on taking a number of supplies, backup equipment, and spare parts.

Inaccessible by vehicle

As equipment may have to be carried in by backpack, pack animal, boat, or aircraft, the emphasis must be on lightweight essentials. Carrying duplicate equipment and spare parts is usually prohibitive. These restrictions apply especially to personal equipment.

Accommodations and Personal Equipment

Accommodations

Accommodations can have a dramatic impact on field research. Even a minimum of amenities on-site will reduce the amount of personal gear required and permit more collection equipment to be included. Adverse conditions (e.g., heat, cold, precipitation) need to be addressed with personal as well as collection equipment. Batteries are especially sensitive to temperature extremes.

Food

Keep meals simple. Limit perishable items, particularly if backpacking, canoeing, or camping in an area lacking refrigeration.

Camping gear

Modern camping supplies (e.g., gas stoves, water filters) are small and take up little space. Efforts should be made to bring sufficient supplies to prepare meals at a campsite. This will avoid the unnecessary time and expense of traveling from the field to purchase a meal.

Personal gear

New field clothes, especially synthetics, provide protection from the elements (e.g., sun, heat, cold, rain) to a remarkable degree. The most important personal items are durable but comfortable field shoes or boots, a good hat for protection from sun or cold, suitable clothing (preferably layers of clothing that allow adjustments for changes in temperature), and a sleeping bag and mat.

Animal concerns

Animal interference can arise at a number of environments. In North America, nuisance animals can include raccoons, bears, or rodents. Check on these issues before going to the field. As a general precaution to avoid "unwanted guests," never store food in a tent.

Human concerns

In some instances, vandalism or some other human activity (e.g., swimming in a sampling area with possible inadvertent contact with scientific equipment) may represent a problem. Aside from the loss of scientific data, there is also concern for public safety and liability (e.g., if a swimmer should get cut on a microscope slide).

Equipment

Tables provide a general description of equipment (Table 1B.4.1) and a representative list of suppliers (Table 1B.4.2), as well as checklists for general supplies (Table 1B.4.3), microbiology supplies (Table 1B.4.4), and personal supplies (Table 1B.4.5). A brief explanation of some items is provided below.

Containers for liquids

Presterilized, lightweight containers such as 15- and 50-ml plastic centrifuge tubes with screw caps and individually wrapped, plastic urine specimen cups (~100-ml volume) can be used for a variety of purposes, including liquid collection, storage of biofilm-colonized substrata, and containers for ethanol sterilization of equipment. We also recommend bringing along sheets of Parafilm, plastic bags, and tape to use for additional protection against leakage. Aside from the loss of a

Table 1B.4.1 General Equipment for Field Work[a,b]

Item	Comments
Spare parts for repairs (generally applicable for larger pieces of equipment)	
Fuses	Variety of voltage ratings, Buss fuses, automotive style (as appropriate for equipment)
Hoses and clamps	Variety of sizes for pumps, fuel, liquids
Electrical wiring, terminals, splices	Variety of sizes for repairing connections, splicing, wiring extensions
Light bulbs	Equipment-specific variety of bulb types with different brightness and working times
Power sources	
Batteries	Variety of rechargeable batteries (e.g., gel-cell, Ni-Cad, lithium); check equipment for specific sizes and voltages
Chargers	Battery chargers that charge from vehicle electrical systems, as well as standard AC to DC
Power converters	Vehicle power converters to allow AC equipment to be run from DC automobile systems; for international studies, adapters for electrical power differences (voltage and current)
Equipment for repairs	
Duct tape	Useful for a variety of repairs
Electrician's tape	Nonconducting tape, useful for electrical repairs
Oatley or Devcon epoxy putty	Two-part pliable putty that cures in 5 min; useful for repairs to odd shapes and locations on equipment; will not drip or run
Small tool kit with assorted screwdrivers, pliers, and a set of Allen wrenches	For very small items, jeweler's screwdrivers, forceps, hemostats (very useful for clamping tubing)
Geologist's hammer	Useful for collecting rocks and may also serve as a general-purpose hammer
Measuring tape	At least 6 m
Containers	
Plastic containers	Various sizes of vials and bottles for sample collection; plastic or Nalgene will not break under rough use in the back country; individually wrapped urine specimen containers (~100 ml) and sterile centrifuge tubes (10 and 50 ml) are most useful
Reclosable plastic bags	Reclosable plastic bags (e.g., Ziploc) provide cheap waterproofing; available in a variety of sizes and designs
Waterproof/weatherproof cases and bags	Numerous designs and sizes of waterproof cases available from Pelican; waterproof gear bags of several sizes for travel in boats, canoes, and kayaks available from SealLine, Dry Pack, and others
Documentation	
Field book	Fundamental piece of equipment; vital for recording of observations and experimental protocols; paper of high rag/cotton content (e.g., Rite in the Rain); use waterproof and fade-proof ink or a pencil (not ball point or gel ink pens)
Cameras (digital and 35 mm)	Invaluable for observations; single lens reflex cameras preferable, but compact point-and-shoot cameras offer advantages of compactness, versatility, and more than adequate image quality; include coin or other object of known size in photographs for scale

continued

Table 1B.4.1 General Equipment for Field Work[a,b], *continued*

Item	Comments
GPS units	Provides precise recording of locations for documentation (often requested by many permitting and funding agencies)
Maps and compass	Obtain best maps prior to trip; topographical, digital orthophoto quarter-quadrangle (DOQQ) available from federal and state agencies, private mapping firms, or Internet sources
First aid	
Standard first aid kit	Complete units available at most outdoor and recreation supply stores
Nonstandard first aid items	Extractor venomous snake and insect kit; can be effective if administered quickly according to directions
	Topical ointments for relief from insect bites, plant allergies, and injuries
	Phone numbers and directions to the nearest local medical facility; Arizona Poison and Drug Information Center, Tucson, Arizona, is a clearinghouse for information on what to do in case of snakebite or other poisonous animals and plants (800-222-1222 or 520-626-6016; (*http://www.pharmacy.arizona.edu/outreach/poison/venom.php*); Web site accurate as of publication date
Vital medical information	Note any special medical needs of field team members and have information readily available; especially important to medical personnel in remote areas
Personal supplies	
Insect repellent	Prevents infection by arthropod vectors (e.g., ticks and mosquitoes) for diseases of current concern, such as Lyme Disease and West Nile; DEET proven effective
Sun screen	Use SPF rating 35 or higher; really works!
Backpack	Many designs and sizes for all needs
String, rope, elastic bands, or cords	Packing, securing items for transport
Head lamps, flashlights, spotlights	Do not scrimp; adequate nighttime lighting prevents mistakes and injuries; new LED lights provide bright lighting with less power drain and longer bulb life
Lanterns, light sources	Standard gas powered lanterns; new florescent and LED lanterns provide lighting without heat and fuel (batteries may be the limiting factor)
Binoculars	Useful for observing and identifying distant objects; can serve as a field microscope if one looks through them backwards
Water for drinking	Micropore filters and sterilizing tablets can be used for treatment of spring or stream water
Labeling tape	If needed for field processing
Permanent marking pen	Sharpie or equivalent (bring extras)
Knife or Leatherman tool	Handy for multiple small jobs
Hat, footwear, and other protective clothing	Will vary according to location and season (see Table 1B.4.5)

continued

Table 1B.4.1 General Equipment for Field Work[a,b], *continued*

Item	Comments
Tape measure and/or ruler	Useful for measurements
Instruments to measure environmental conditions	Portable thermometer and other instruments (e.g., pH paper or probe) very useful for collecting physical data from site
Sample storage	
Coolers	For ice or dry ice; store in shade, if possible
Preservatives	For samples to be processed for DNA or RNA, add TE buffer or a preservative such as RNAlater (Ambion); some change likely to occur to biological samples between collection and processing in the laboratory
Sample collection and field processing	
Gloves	For moving plants in desert and other environments, leather (thorn-resistant) gloves; for sterility during sample collection, latex or nitrile gloves, rinsed immediately before using with 70% ethanol
Sterile water	Very useful for dilutions and processing; autoclave and carry in plastic bottles; can also serve as emergency drinking water supply
95% ethanol for on-site ethanol sterilization	Dip object in 95% ethanol and flame with match or lighter
Sterile urine collection cups	Individually wrapped and ~100 ml
Sterile plastic tubes	50- and 15-ml presterilized tubes
Scalpel blades	Purchased sterile and individually wrapped; very useful for scraping natural biofilms from surfaces
Aluminum foil	Very lightweight and can be folded and autoclaved to provide a sterile working surface in the field when unfolded
Microscope slides	Useful as biofilm colonization substrata; can be anchored with paper clamps and string
Petri dishes, sterile	Can also function as sterile working surface
Syringes, individually wrapped sterile	For water samples, use larger syringes (e.g., 30 to 50 ml) to filter volumes of water (to collect planktonic bacteria)
Filters for concentrating planktonic samples from large volumes of water	
Filter holder units (autoclavable)	GE Healthcare (formerly Poretics/Osmonics) and SPI
Filters	0.2-μm pore size, 25-mm diameter; black polycarbonate filters available from GE Healthcare (formerly Poretics/Osmonics) or Structure Probe, great for epifluorescence or CSLM because of limited background fluorescence; other filter types OK, but not as useful; store used filters in plastic tubes
Filter tweezers	Can be ethanol sterilized in the field (see above)
Fresh filters	Purchase as individually wrapped and presterilized or, alternatively, place several in aluminum foil, label, and autoclave

[a]These items are used for a variety of purposes. Some items may not be applicable for all trips.
[b]See Table 1B.4.2 for a representative list of suppliers.

CampMor	*http://www.campmor.com*
Forestry Suppliers	*http://www.forestry-suppliers.com*
REI	*http://www.rei.com*

Table 1B.4.3 General Checklist

Items	Comments
Permits: university, local, state, federal	Collecting, on-site activities, sample collecting, transport
Maps, GPS equipment	For documenting locations
First aid and emergency information	First aid supplies
	Phone numbers and locations for medical assistance
	Personal medical information for each team member (if applicable)
Cell phone and other communication equipment	Useful only if coverage is available
Vehicle	Have vehicle inspected prior to departure
	Check all fluid levels, belts, hoses, tire condition (special attention to spare tire)
	Appropriate equipment for changing tires
	Fill with gasoline before entering remote area
Sampling equipment	See Table 1B.4.4
Personal equipment	See Table 1B.4.5

valuable sample, leakage can damage clothing or field notes. Permanent markers can be used to label containers. For measuring liquids in the field, one can use markings on a container or, if necessary, sterile plastic syringes or pipets (along with a pipetting bulb). Due to weight and breakage considerations, the use of glass is strongly discouraged.

Syringes and filters

Sterile syringes (10, 30, or 50 ml) are quite useful for sampling large volumes of water and removing planktonic organisms by filtration. Typically, we have used autoclavable filter holders (e.g., 25-mm filter holder; Pall Corporation).

Unlike traditional white filters, black polycarbonate filters (0.2-μm pore size, 25-mm diameter; Structure Probe, part B0225-MB) are especially useful for fluorescence and confocal microscopy applications because they do not fluoresce under ultraviolet light. These filters and filter holders are assembled in the laboratory prior to the trip and wrapped individually in aluminum foil, labeled, and autoclaved. Labeling will permit easy identification of wrapped packages under field conditions.

Cutting and Trimming

For some sampling operations (e.g., plant-adherent bacteria), it may be necessary to cut materials in the field. One has several options. Tissue sections may be removed using individually packaged sterile scalpel blades. Larger specimens can be trimmed using scissors and tweezers (both of which can be sterilized with

Table 1B.4.4 Microbiology Checklist

Function	Item
Containers for specimen collection	Sterile specimen cups
	Sterile centrifuge vials
	Syringes
	Filter units (sterilized)
	Microscope slides
	Clips for holding microscope slides
	String for anchoring microscope slides
	Other biofilm colonization substrata (if needed)
	Reclosable plastic bags (e.g., Ziploc) or other containers for small items; autoclave bags for larger items
Specimen manipulation	Scalpel blades
	Tweezers
	Scissors (if needed)
	Ethanol (bring 95%)
	Sterile water
	Nitrile gloves
	Aluminum foil (sterilized and folded)
	Petri dishes
	Matches or lighter for ethanol sterilization
Other	Camera

in the field; see Disinfection and Field Sterilization, below). Sterile petri dishes are very useful for providing a small, sterile, working area. Should a larger sterile working area be necessary, we advise using sheets of aluminum foil of a desired size (e.g., 0.5 m^2), folding as necessary, and putting a small amount of indicator tape onto the sheet. Several of these sheets can be placed into an autoclave bag and autoclaved, prior to going to the field. In this fashion, a sterile work surface or wrapping agent is readily available. The sterilized autoclave bag can also be used as a sterile container to transport larger specimens or to gather waste.

Disinfection and Field Sterilization

Ethanol is a great disinfectant because it is quite effective, yet biodegradable. For ethanol sterilization, dip the object to be sterilized into 95% ethanol, and then light the ethanol-coated item with a match or lighter. Ethanol will burn with a fairly cool flame and provide adequate field sterilization. During this procedure, be careful that burning ethanol does not spill onto clothing or other materials. For disinfection in the field, we recommend diluting 95% ethanol with sterile water to obtain 70% ethanol. This dilution process is done easily in the field by filling a container three quarters full with 95% ethanol, filling the remainder of the container with sterile water, and mixing to achieve a final concentration of ~70%. Unlike 95% ethanol, 70% ethanol does not burn as readily and so, under field conditions, provides a measure of safety.

If sterile washing is necessary, autoclave and bring several containers of sterile water. It is usually best to pack several smaller plastic containers (e.g., 500 or 1000 ml), rather than a single 10-liter or larger container. Smaller containers are lighter and if one container of liquid accidentally gets contaminated, there are still spare containers that can be used.

Laboratory gloves are very useful if aseptic manipulation of samples is to be done. Nitrile gloves are especially useful. They are lightweight and can be easily disinfected in the field by rinsing with 70% ethanol.

Table 1B.4.5 Personal Supplies Packing List

Item	Comments
Footwear	Sturdy, comfortable, and protective (i.e., boots, water shoes); bring an extra pair
Protective clothing	Jeans/long pants, cool shirts recommended; layers for cool weather (some alpine environments can get close to freezing even in midsummer)
Rain gear (poncho)	Even in the desert it rains in July
Hat	For protection from sun or for warmth
Gloves	Cotton or leather
Swimsuit/shorts	For seining
Bedroll/sheets/pillow/cot	Most places provide a bed or mattress
Towel, toiletries, first aid	Include topical ointment for itching or irritation, band aids, medications (e.g., analgesics)
Tents	When needed; arrange to share with others
Field guides	Useful for identifying birds, plants, rocks, and wildlife
Field notebook/card catalog/index cards	Essential for recording experimental observations; cards can be useful for labeling larger specimens
Water container/canteen	Absolutely essential for carrying drinking water when away from camp
Binoculars	Bring your own; very useful for spotting distant objects, including animals and birds
Cup/mug, eating utensils	Needed for eating and drinking
Gatorade/water	*VITAL:* At least 2 quarts per day
Food	Plan for two meals per day plus snacks; orient all activities around completion of fieldwork, not the dinner table; quick breakfast at 6:00 a.m., midday snack (if back at camp), and a late evening meal; minimal supplies, no elaborate meals, simple is best: e.g., bagels, breakfast muffins, sandwiches

Tables 1B.4.1 to 1B.4.5 list equipment the field researcher should carry, as well as representative suppliers. Be sure to inventory equipment before leaving for the field. Often the item left behind is the one most needed. Carefully pack and cushion fragile equipment for transport. Check and double-check the integrity and functionality of all fittings, hoses, cables, batteries, tape, pens, and other equipment.

The closer the sampling site is to the laboratory or vehicle, the more materials are readily available. In the event of remote sites, limit supplies to essential lightweight items along with items needed for investigator camping, safety, and other needs, notably water. With respect to vehicle transport, materials may need to be secured and insulated against damage from vibration, particularly if the vehicle needs to be driven over rough terrain.

Special Issues Related to DNA and RNA-Based Studies

Few specialized pieces of equipment required for nucleic acid studies (e.g., thermal cyclers, spectrophotometers, centrifuges) are available in the field, and most such studies will be performed in the laboratory. In these cases, sample collection must be done in the context of the experimental data desired. For

example, for a nucleic acid–based community profile, the sample should be collected so as to preserve DNA or RNA. Preservation of specimen viability may not be necessary, and indeed, in some cases where viability is maintained, differential growth and survival of organisms in specimen containers (sometimes referred to as the "bottle effect") may actually be detrimental to the scientific analysis. Where feasible, the simplest approach for DNA preservation is to freeze the sample (−20°C or colder), and store frozen until processed. Should vehicle access be available, specimens can be placed in Styrofoam containers or coolers along with dry ice (frozen CO_2). Packaging materials, used to ship refrigerated or frozen biochemical reagents, are often very useful for this purpose. As a safety precaution, these containers need to be in a well ventilated place so as to avoid asphyxiation of the investigators by elevated CO_2 levels.

For RNA analysis (and even DNA analysis), a stabilizing agent (e.g., RNAlater, Ambion) is often used. This reagent stabilizes RNA and genomic DNA, but will denature many proteins (see *http://www.ambion.com/techlib/tn/113/6.html*). Once samples are placed in RNAlater, they can be stored for several days at ambient temperatures or up to one month at 4°C. Under field conditions, storage in coolers along with ice, will maintain temperatures close to 4°C. The use of fixatives such as glutaraldehyde or formaldehyde, while useful for microscopy, is strongly discouraged. These and other chemicals can be detrimental to downstream specimen processing with DNA polymerase, or reverse transcriptase.

FIELD STUDIES IN PROXIMITY TO LABORATORY FACILITIES

Biofilm studies performed in proximity to the laboratories have an advantage over those done in more remote environments in that unusual or time-sensitive procedures can be used. In addition, traditional biofilm colonization substrates such as glass microscope slides can also be used. Examples of two unusual protocols are biofilm formation on sycamore leaves (*Platanus occidentalis*; Dunn et al., 1997) and abiotic (limestone; Whiteley et al., 2001) surfaces. These studies were conducted on Texas State University property within 2 km of the laboratory, thus permitting ready access to laboratory equipment and supplies. As these studies were performed on Texas State University property, no permits were needed. The purpose of this research was to study the influence of epiphytic biofilms on leaf fossilization (Dunn et al., 1997) and identify population interactions in karst aquifer biofilm bacteria (Whiteley et al., 2001).The purpose of the discussion here is to address some practical aspects of experimentation; for the biological implications of the studies, see the references provided.

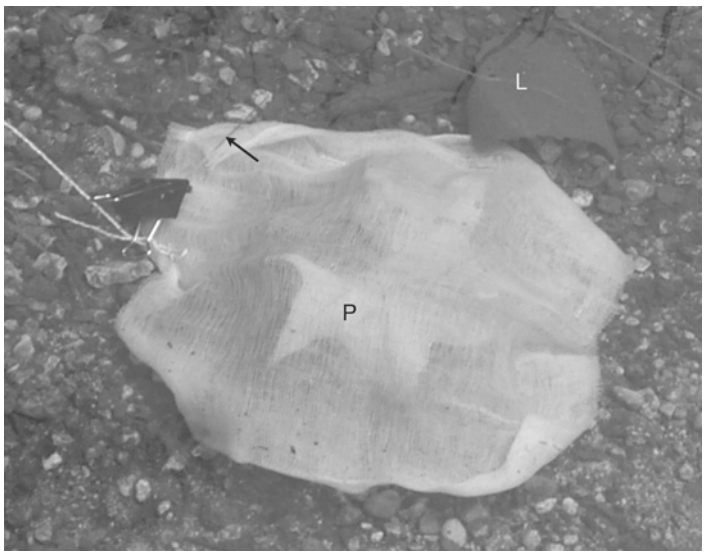

Figure 1B.4.1 Collection of biofilms in streams. During field studies of biofilm growth in streams, biological material such as a *Platanus* leaf (P) can be retained within a porous container such as cheesecloth. A glass slide (arrow) can be used as a representative abiotic surface. Note the presence of naturally occurring biofilms on substrata such as a leaf (L) and the gravel sediment.

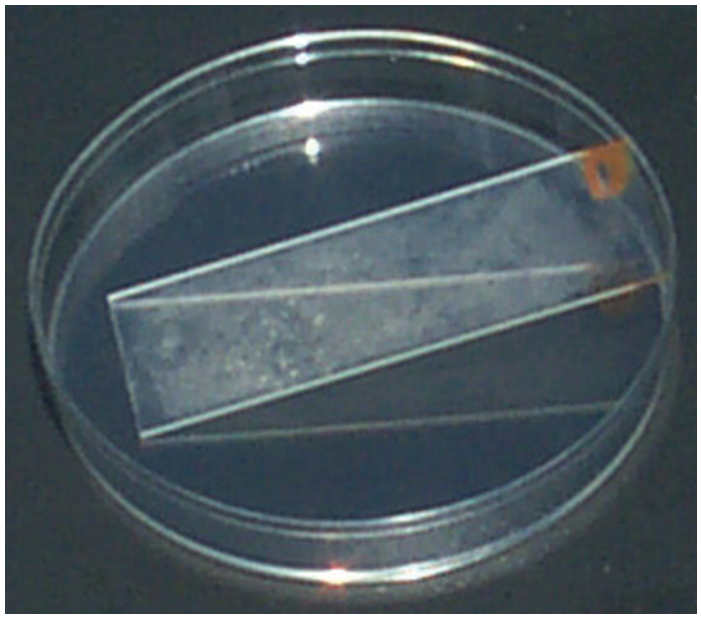

Figure 1B.4.2 Growth of biofilms on glass microscope slides. Biofilms readily form on glass microscope slides that are placed in aquatic environments.

Depending upon the environment, colonization substrata can be placed onto a surface (e.g., river sediment) or suspended at a selected depth in the water column by a paperclip or other clamping material, which is then anchored to a string as shown in Figure 1B.4.1. Such experimentally grown biofilms mimic natural biofilms on the biotic (leaf) and abiotic (rock) surfaces naturally found in that environment (also shown in Fig. 1B.4.1). While biofilms often form quite readily, surface coverage is typically quite variable. A representative biofilm grown on a glass microscope slide is shown in Figure 1B.4.2.

Collection of Epiphytic Biofilms

This study was undertaken to determine whether aquatic biofilms could enhance fossil formation in leaves (Dunn et al., 1997). The rationale was threefold: (1) leaf surfaces are typically hydrophobic due to a waxy cuticle, (2) biofilms would form readily on any submerged surface in aquatic environments (including leaves), and (3) by virtue of their anionic surface properties, bacteria and biofilms would readily bind metal ions thus enhancing mineral formation and fossilization.

Unique equipment

The local river environment presented several challenges. The river flow (typically 0.3 to 0.5 m/sec) caused leaves and other submerged materials to drift, and the grazing activities of fish and invertebrates (notably snails) would damage submerged leaves and their epiphytic biofilms. To circumvent these problems, the leaves were confined in cheesecloth bags (constructed by folding in half a piece of cheesecloth $\sim$70 $\times$ 35 cm and stapling the sides; see Fig. 1B.4.1) and the bags immobilized with rocks and string. Cheesecloth is also very useful for containing other biofilm colonization substrata, including small gravel and fiberglass. Nonbiological colonization substrata can be placed into cheesecloth, autoclaved (if desired), and then transported to the field site in sterile containers (S. Nath and R.J.C. McLean, pers. comm.).

Procedure

To maintain sterility in the field, nitrile gloves, disinfected by rinsing with 70% ethanol were used. We have found these to be much more comfortable than other materials and are also suitable for people with allergies to latex.

Approximately 50 leaves from several representative trees were collected by breaking leaves at the base of the leaf stem. At least 10 of these should be used to determine size and mass of leaves. One could also calculate area of these leaves by placing individual leaves on a scanner, obtaining an image, and then calculating the area using image analysis software (e.g., NIH Image).

For aquatic biofilm formation, one or more leaves were placed into a cheesecloth bag, which was stapled shut, attached by string to a rock, and submerged in the stream for several days (see Fig. 1B.4.1). Biofilms, largely consisting of endogenous heterotrophic bacteria, formed on the leaves.

At conclusion of field exposure, the cheesecloth bag was removed from stream, placed in a sterile container (e.g., a presterilized autoclave bag), and transported to the lab for analysis.

Growth of Epilithic Biofilm Bacteria in Groundwater

This study was undertaken in part to investigate epilithic bacteria in a karst aquifer environment (Whiteley et al., 2001).

Unique equipment

Cheesecloth bags were constructed as described above. As an alternative, nylon window screen mesh (available at any hardware store) can be substituted for added strength. These bags were filled with small rocks (~1 to 2 cm^3) as colonization substrata. A length of rope was then securely attached to the bag. The bags with the rocks were placed into an autoclave bag, fastening one end of the rope to the outside of the bag (permitting ready access at the field site, yet preserving sterility of contents) and then autoclaved 30 to 60 min. This extended autoclaving time is necessary to ensure that endolithic microorganisms within the rocks are killed. Sterilized autoclave bags keep the rocks sterile during transport to and from the field site.

Procedure

Groundwater access can be obtained by several means including wells, artesian springs, and access caves. In this particular study (Whiteley et al., 2001), access to the groundwater was obtained through an access cave named Rattlesnake Cave. Prior to entering the cave, precautions were taken to ensure this cave was not occupied by rattlesnakes (*Crotalus* spp.) or other wildlife. Samples were suspended below the water table for several days to ensure the growth and maturation of biofilms on the rocks. During specimen retrieval, autoclaved aluminum foil (to provide a sterile working surface in the field) and autoclave bags (for specimen transport) were used at the field site.

Analysis of Adherent Microbial Populations

Analysis can be accomplished by either molecular or plate-counting techniques. For plate counting assays, samples must be analyzed as quickly as possible (typically within 1 to 2 hr) because microbial numbers will change relatively quickly. Samples for DNA analysis including DGGE analysis (see *UNIT 1E.1*) can be held in TE buffer at −20°C or placed in RNAlater (Ambion) until analyzed. In either case, adherent bacteria can be removed from the substrata by bath sonication. Alternatively, if a flat surface such as a microscope slide is used for biofilm colonization, the surface can be scraped into a sterile buffer or H_2O using a sterile scalpel blade and then sonicated. The shear forces generated by sonication are used to disrupt adherent bacteria and bacterial clumps into individual organisms. We typically use a bath sonicator rather than a probe sonicator in order to minimize cell damage (*UNIT 1E.1*).

Challenges of Epiphytic and Epilithic Biofilm studies

Unlike microscope slides, rocks and leaves have very uneven surfaces, and calculating surface areas and biofilm concentrations can be problematic and will lead to considerable data variation. In addition, biofilm colonization on these substrata is typically uneven because some microorganisms preferentially colonize in crevices. The best approach for epilithic bacteria is to measure the dimensions (height length and width) of the rock and to estimate its surface area, assuming it has the shape of a cube. Most leaf surfaces are relatively flat. If necessary, 1-cm^2 sections can be cut from leaves prior to sonication.

COLLECTION OF BIOFILM SAMPLES REMOTE FROM THE LABORATORY

It may be necessary to conduct biofilm studies some distance from the laboratory. Vehicle accessibility will determine the amount and types of supplies that can be taken. With respect to microbial samples, it may be a number of hours or even days before the samples can be returned to a laboratory. Sample storage and transport are issues because changes in microbial populations will occur; these issues have been addressed in an earlier section (see Technique Refinement and Testing).

In the event of travel, especially across international boundaries, one should plan ahead (often 2 to 3 months or more) and check with appropriate government and courier agencies for permits required for travel, access to field sites, and shipment of any supplies or specimens. Given the political and security issues that have arisen in the past few years, the U.S.A. and other countries have adopted strict regulations for the transport of biological materials. Often, it is best to ship a sample, along with appropriate documentation, via a courier.

We have experience in conducting fieldwork in several remote sites involving lengthy trips by vehicle (Big Bend National Park, U.S.A.) or air (Viterbo, Italy and Yellowstone National Park, U.S.A.). For remote trips, space may be quite limited, particularly if supplies need to be transported in luggage. In these cases, the use of lightweight, sterile, plastic containers and microscope slides can be quite useful for a number of experiments. Often one will need to improvise with available local materials; bringing extra tape, pens, markers, string, magnifying glass, a knife, camera, and notebook is advisable.

Questions to Be Addressed Prior to the Trip

Site accessibility

Determine accessibility and characteristics of site as well as limitations (including dates and times of access) on sampling and experimentation, and obtain necessary permits. If necessary, coordinate sampling dates with all personnel involved.

Transportation

One must plan for transportation to and from site and the corresponding weight and volume limitations on materials to be transported. This will influence the number and types of samples that can be collected.

Materials and supplies

Decide on and prepare materials to be transported. For example, Luer-Lok filter units (for use with a syringe) can be assembled, individually wrapped in aluminum foil, and autoclaved. Small plastic (LDPE) bottles can be labeled, filled with water and autoclaved. Ethanol (95%) can also be packed into small plastic bottles for use as an on-site disinfectant.

Accommodation

Is camping gear needed? This subject is addressed under General Aspects of Field Research.

Support laboratory or system at or near site

It is prudent to assume that any necessary laboratory equipment and supplies will need to be transported.

Additional personnel

Are local support personnel, or alternatively, laboratory support personnel needed, and does scheduling need to be coordinated?

Specimen transport

Plan procedures for shipment of materials back to lab, along with necessary permits.

Tasks to be Performed at the Site

Access

Verify access to site and locations for experimentation. For example, in a spring-fed pond, one might sample as close to the spring outflow as possible, as well as at several representative sites away from the outflow.

Documentation of location

In the field book, draw a map of the site and location of experimental work. If possible, enter GPS coordinates.

Documentation of environmental conditions

Test and record physical and chemical data—e.g., temperature, pH, Eh (oxidation-reduction potential)—as well as weather, date, and time. Water samples can be collected for chemical analyses.

Scheduling

A number of factors may influence field results. These include, e.g., diurnal, seasonal, and weather-related effects. As a result, it may be necessary to modify scheduling of experiments.

In some instances, it may be desirable to get samples to the laboratory as quickly as possible. These samples should be collected immediately prior to departure and analyzed as quickly as possible upon return to the laboratory. Alternatively, they can be collected and shipped quickly for analysis by laboratory support personnel.

SAMPLING BY PROXY

For any number of reasons (e.g., safety, access to a particular environment or equipment), it may be impractical for an investigator to personally conduct an experiment. As an alternative, the experiment will need to be conducted by some other individual or device. Based on

our experience with experiments flown on the Space Shuttle (McLean et al., 2001, 2006), several issues need to be addressed:

1. Gaining access to the equipment or facilities that will enable the experiment to be conducted.

2. Planning and working within the constraints of the equipment, personnel, and scheduling involved.

3. Being flexible, as launching or landing schedules may be disrupted for a number of reasons, e.g., weather, mechanical problems, or other unforeseen issues.

In the case of spacecraft experiments, payload volume and mass are very limited, and all materials present (including organisms and experimental chemicals) must pass a rigorous scientific peer-review and safety review before being included. Due to the considerable expense, a typical space flight may carry several dozen scientific experiments. Consequently, one must design small volume experiments, capable of flying in a device that has been shown to be compatible with spacecraft. Ideally, the equipment involved would either be automated or rely on a very few manual operations because flight personnel may be simultaneously conducting multiple experiments. The commercially developed, dual materials dispersion apparatus (DMDA, Instrumentation Technology Associates) represents one such device (Cassanto and Wood, 1998). We have conducted biofilm experiments on two shuttle flights, STS-95 and STS-107 (NASA Space Transport System designation used for space shuttle flights), using this device (McLean et al. 2001, 2006). During the planning for a shuttle flight, we were initially limited to three 140-µl sample compartments. Just prior to flight, additional compartments became available through the generosity of our commercial partner, Instrumentation Technology Associates.

CONCLUSION

The techniques and approaches used for field biofilm acquisition are quite variable because they will relate to the questions being addressed and the limitations of the environment and available equipment. Nevertheless, several key issues arise which are fundamental to any scientific investigation: reproducibility, quality of data, and quality of data analysis. These issues must be addressed during all stages of experimentation from initial planning, through the actual fieldwork, to the final analysis and reports. Both successes and failures must be recorded and analyzed because they will provide invaluable information for future work. Although practical issues have been addressed in this unit, one may often need to improvise in the field when presented with unexpected obstacles or opportunities.

Growing Oral Biofilms in a Constant Depth Film Fermentor (CDFF)

Jonathan Pratten[1]

[1]University College London, Eastman Dental Institute, London, England

ABSTRACT

In order to grow organisms in such a manner as to mimic their physiological growth state in vivo, it is often desirable to grow them as biofilms in the laboratory. There are numerous systems available to accomplish this; however, some are more suited to the growth of oral biofilms (dental plaque) than others. The operating parameters of one such model, the constant depth film fermentor (CDFF), are given in this unit. This model is particularly suited to studying the varied biofilms which exist in the oral cavity because environmental factors such as the substratum, nutrient source, and gas flow can be altered. *Curr. Protoc. Microbiol.* 6:1B.5.1-1B.5.18. © 2007 by John Wiley & Sons, Inc.

Keywords: constant depth film fermentor • oral biofilms • dental plaque

INTRODUCTION

The mouth provides a large number of diverse surfaces, e.g., the soft shedding tissues of the mucosa and hard nonshedding surfaces of the teeth, on which a wide variety of complex biofilms form. These biofilms (dental plaque) consist of a microbial community embedded in a matrix of polymers of bacterial and salivary origin. Dental plaque has high species diversity and contains numerous microenvironments within gradients of nutrients, oxygen, redox potential, and pH. For these reasons, mature dental plaque is a highly dynamic community. Small alterations in the environment can lead to ecological shifts and subsequent population changes, and in certain specific cases may result in predisposition to a more pathogenic microbial community. Such biofilm-related oral infections are implicated in the etiology of two of the most prevalent diseases affecting industrial societies: caries and periodontal disease. Prevention of these conditions involves constant mechanical removal of the plaque from the tooth surface, although there is often difficulty in maintaining an effective mechanical oral regime. Hence, there is considerable interest in the use of antimicrobial agents in the prevention and treatment of these diseases.

In order to study biofilm development and its perturbation, it is useful to generate steady-state systems. One approach to producing biofilms in a steady-state is to develop a constant depth reactor where the surface growth is periodically removed to maintain a constant geometry (Kinniment et al., 1996). Such a device, the constant depth film fermentor (CDFF; Fig. 1B.5.1), was first described by Coombe et al. (1982), to investigate the growth of dental plaque organisms, and was further developed by Peters and Wimpenny (1988). The CDFF consists of a glass vessel with stainless steel end-plates; the top-plate has ports for the entry of medium and gas and for sampling, while the bottom one has a medium outlet port. The vessel houses a stainless steel disk containing fifteen polytetrafluoroethylene (PTFE) sampling pans which rotate under a PTFE scraper bar that smears the incoming medium over the pans and maintains the biofilms, once formed, at a constant predetermined depth. Each sampling pan has five cylindrical holes containing PTFE plugs, which are recessed to a set depth to create a space in which the biofilms form. The sampling pans can be removed aseptically during the course of an experimental run.

Figure 1B.5.1 The constant depth film fermentor complete with power unit and accessories.

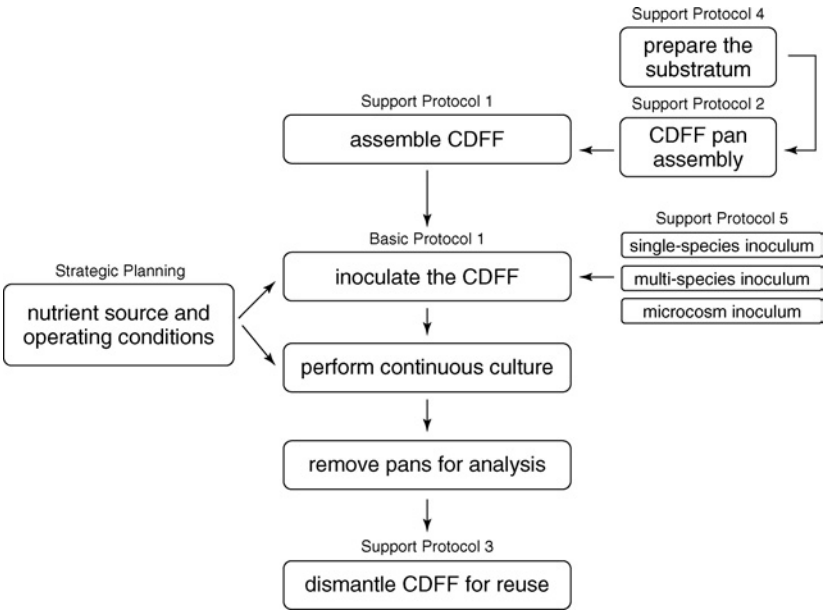

Figure 1B.5.2 Schematic representation of the interrelationship of procedures for growing biofilms in a constant depth film fermentor (CDFF) and their related protocols.

As well as being used for the study of bacterial perturbation (Pratten et al., 1998; Pratten and Wilson, 1999; Deng et al., 2005), the CDFF has been used in studies evaluating endodontic microleakage (Matharu et al., 2001), oral malodor generation (Pratten et al., 2003), corrosion potential of dental plaque (Wilson et al., 1995), and gene transfer in oral biofilms (Roberts et al., 2001). It is a sophisticated apparatus that can generate large numbers of individual biofilms and has been used extensively to investigate factors that may influence the growth of bacterial communities in the oral ecosystem. Figure 1B.5.2 provides a schematic representation of how the procedures detailed in this manuscript interrelate.

CAUTION: Follow all appropriate safety requirements relevant to the microorganism under investigation. Refer to *UNIT 1A.1* and other pertinent resources (see *APPENDIX 1B*) for instructions on safe handling of microorganisms.

STRATEGIC PLANNING

Nutrient Source and Operating Conditions

Supragingival plaque biofilms

Many studies use a simple mucin-containing artificial saliva (Pratten et al., 1998; Roberts et al., 1999) modified from the studies of Russell and Coulter (1975) and Shellis (1978; also see recipe); however, there are more defined growth media described in the literature (Wong and Sissons, 2001). The artificial saliva is delivered at a rate of 0.5 ml/min, corresponding to the resting salivary flow rate in humans (Pratten et al., 1998). Additionally, an aqueous solution of 2% (w/v) sucrose can also be pumped over the biofilms for periods of 30 min at the same speed via a second peristaltic pump. The sucrose pulsing can be carried out four times a day; during this period the artificial saliva supply should be maintained. The pH curve measured from the biofilm effluent under sucrose supplementation conditions has shown to be typical of the Stephen curve, i.e., falling and rising pH levels in response to sucrose supplementation (Zanin et al., 2005).

Subgingival plaque biofilms

Artificial gingival crevicular fluid (GCF; see recipe) is pumped into the CDFF at a rate of 50 μl/min, as an approximation of the flow rate of GCF during gingivitis. To model the periodontal region, an anaerobic atmosphere of 5% CO_2, 95% N_2 is provided by connecting a gas cylinder to the fermentor's air-inflow port. The pressure used should be 1 bar (100 kPa) and the flow rate 100 cm^3/min. Reinforced 5/16-mm i.d. PVC tubing is needed to connect the gas pressure gauge and the flow meter. Silicon tubing with an 8-mm i.d. connects the flow meter to the CDFF. The gas should be passed through air filters to maintain sterility. A Y-branch tubing connector can be used to supply gas to both the fermentor and the inoculum flask if required.

Perturbation

One of the main advantages of using this model is the ability to carry out antimicrobial and antiplaque testing over time. An agent can be pulsed in via one of the free inlet ports at appropriate times to mimic in vivo use, for example, pulsing twice daily (e.g., 9:00 a.m. and 5:00 p.m.) for 1 minute with 10 ml of 0.2% (w/v) chlorhexidine gluconate. To carry out pulsing at higher flow rates, wider bore pump tubing may be required. Additionally, a timer can be added to the power supply for the peristaltic pump to deliver a challenge to the CDFF without the operator being present.

With this setup, biofilms can also be removed from the CDFF and placed into an agent. In this case it is advisable to place the whole PTFE pan into the solution (5 ml in a 25-ml conical skirted-base tube to cover the pan) in order to reduce disruption of the biofilms. Using this method, it is possible to generate minimum inhibitory concentration (MIC)-like data for the biofilms.

INOCULATING THE CONSTANT DEPTH FILM FERMENTOR

BASIC PROTOCOL

Once the CDFF is sterilized with the pans in place (Support Protocols 1 and 2), the system is ready to inoculate with single-species or microcosm plaque inoculum (Support Protocol 5). When using a mixed-species inoculum, a direct inoculum method is used (see Support Protocol 5).

Materials

Bacterial growth medium (appropriate for the organisms being used)
10 ml single-species inoculum *or* 2 ml pooled saliva (see Support Protocol 5)
70% (v/v) ethanol
Phosphate-buffered saline (PBS; *APPENDIX 2A*), sterile

Air filters (e.g., Hepa-vent; Whatman)
Inoculum vessel: 500-ml Erlenmeyer flask with silicon rubber stopper having two metal tubes going through
3- and 5-mm bore silicone tubing (depending upon bore of stainless steel tubing), 15-cm and other lengths (depending upon setup)
Connectors and clips for silicone tubing (e.g., Sigma-Aldrich Z12, 654-3 and Z12, 651-9)
Couplers for connecting silicone tubing of different size bores (e.g., Value Plastics N220/210-6)
Nylon straps (for securing tubing)
Foil
Magnetic stir bar
Incubator, appropriate for inoculum used (see Support Protocol 5)
Magnetic stirrer
CDFF (sterilized; see Support Protocol 1), with motor and power supply unit
Peristaltic pump, precalibrated to desired flow rate
10- or 20-liter Pyrex glass bottles (for effluent collection and medium reservoir; size depending on flow rate used) with silicone rubber stoppers having two metal tubes going through
Glass grow-back traps (Hampshire Glassware)
Retort stand and clamp
Portable butane burner
Sample tool (wrapped in foil and autoclaved; provided with CDFF; see Support Protocol 1)
Forceps, sterile (e.g., flame sterilized in 70% v/v ethanol just before use or autoclaved)

Prepare CDFF inoculum vessel

1. Attach an air filter to the outside of one metal tube of the inoculum vessel stopper. To the other metal tube, attach a length of silicone tubing reaching down to the bottom of the flask (see Fig. 1B.5.3). On the opposite side of that metal tube connect a short length of pump tubing, using appropriate sized silicone tubing and couplers, as necessary to be able to pass the pump tubing through the peristaltic pump. Finally, add a connector to the end of the silicone tubing.

2. For any unused ports, place a piece of silicone tubing on the metal tubing and clamp.

3. Cover all connectors in foil. Add 500-ml medium and a magnetic stir bar to the vessel.

4. Autoclave the inoculum vessel with 500 ml bacterial growth medium 15 min at 121°C, leaving the stopper ajar. Also autoclave the effluent bottle with its attached air filter and tubing with coupling insert (with the stopper ajar).

   If the medium cannot be autoclaved, autoclave the vessel and tubing alone and then add the medium aseptically.

   The effluent bottle has two ports: one containing an air filter and the other a section of tubing and a coupling insert, which needs to be autoclaved with the stopper ajar.

   For convenience, the continuous culture medium and reservoir could also be autoclaved at this time (see steps 15 to 18).

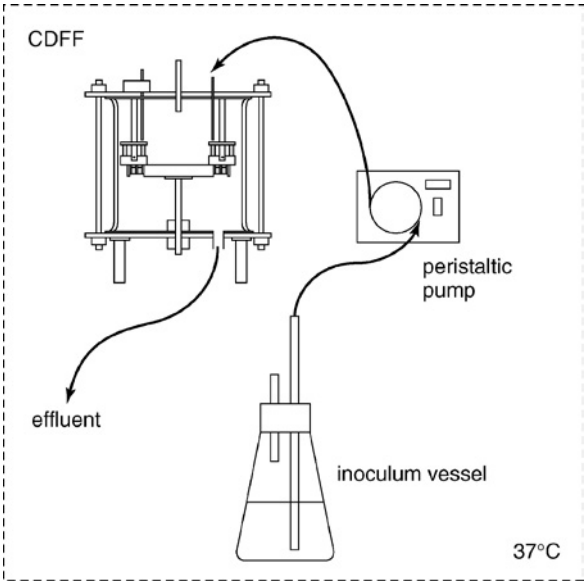

Figure 1B.5.3 Schematic of the setup required for inoculation of the constant depth film fermentor (CDFF).

5. As soon as it is safe to open the autoclave, quickly add any supplements, push the stopper firmly into place, and open the clamps to the air filters. Cool the medium to 22°C.

Inoculate the CDFF

6a. *For a single-species or microcosm inoculum:* Place either 10 ml single-species inoculum or 2 ml pooled saliva (see Support Protocol 5) into the inoculum vessel medium and proceed to step 7.

6b. *For a mixed-species inoculum:* Inoculate the CDFF as described in Support Protocol 5 and proceed to step 15 to perform continuous culture.

7. Put the inoculum vessel into the incubator on a magnetic stirrer.

8. Place the CDFF motor and power supply unit into the incubator and place the fermentor on top, ensuring the shaft for the turntable fits squarely into the motor section.

   NOTE: *This only applies to the v3 CDFF; previous versions require the motor to be attached to the CDFF turntable with four screws.*

9. Place the peristaltic pump into the incubator; feed the electric power cord through the hole in the top of the incubator.

10. Take the tubing from the inoculum vessel that has the pump tubing included and pass it through the pump before connecting to one of the inlet ports in the top-plate of the fermentor.

    It is best to loosen the foil on both, then aseptically join the two.

11. Switch on the pump at maximum speed to prime the line.

    The direction of flow can be changed once the tubing is connected.

12. When the inoculum starts to drip onto the turntable in the fermentor, switch on the turntable motor at ~3 rpm.

13. At this stage, turn the pump down to achieve the desired flow rate and pass the inoculum through the system for 8 to 24 hr at 37°C (see Support Protocol 5).

    NOTE: *The pump needs to be calibrated beforehand.*

14. Finally, attach the effluent bottle (while the fermentor is being inoculated) prepared in step 4.

    The vessel can sit on the laboratory floor (within an appropriate spill tray) to allow flow via gravity. If this is not possible an additional peristaltic pump may be required.

Set up and perform continuous culture

15. Attach a piece of silicone tubing to one of the ports in the medium reservoir reaching down to the bottom of the bottle (see Fig. 1B.5.4). On the opposite side of the stopper, attach 15-cm silicone tubing with a coupling body on the end.

16. Attach an air filter to the second port.

17. Add 8 liters bacterial growth medium to the medium reservoir and autoclave with the stopper ajar.

    Ideally, place the autoclave temperature probe (if available, set at 121°C) directly into the liquid.

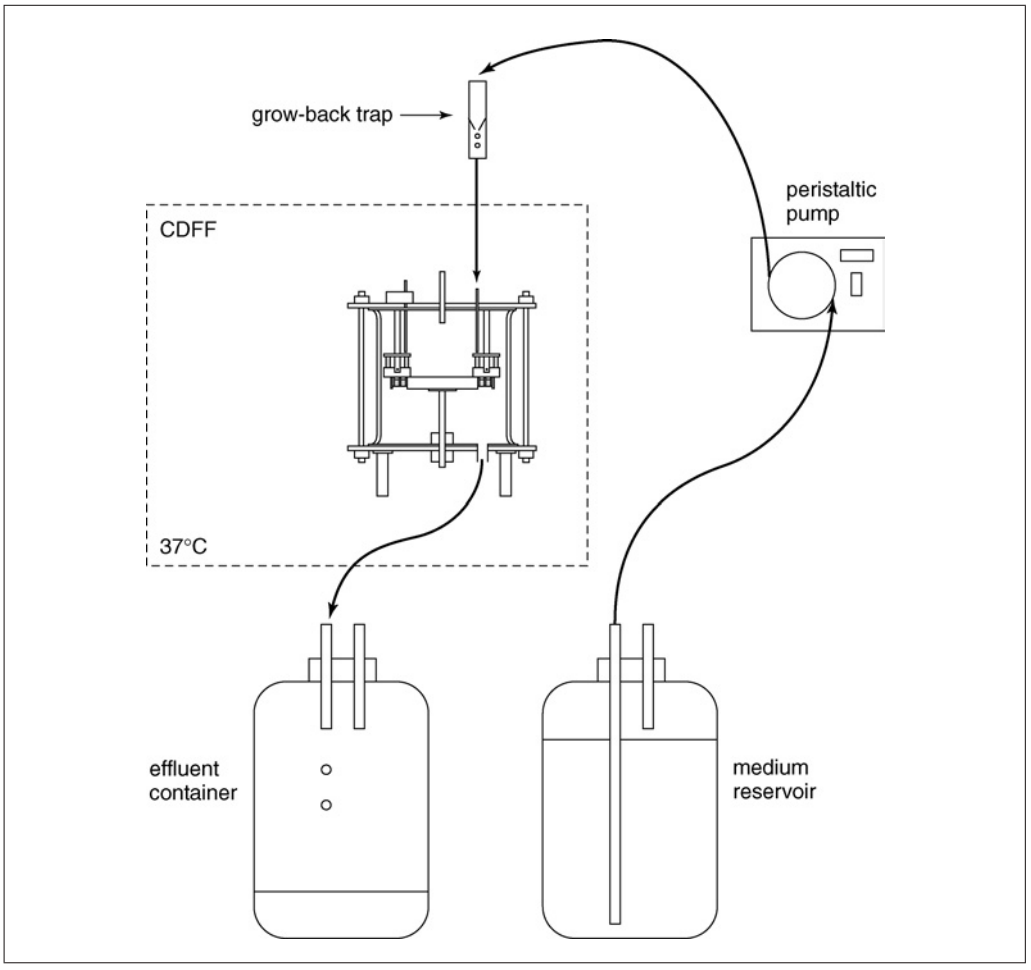

Figure 1B.5.4 Schematic of the constant depth firm fermentor (CDFF) system setup when running continuously. The dotted line represents the incubator. The feed line required from the peristaltic pump to the CDFF (including the grow-back trap) is described in the Basic Protocol.

18. As soon as it is safe to open the autoclave door, push in the stopper and unclamp the air filters.

19. Construct the feed line for the medium as follows by attaching a connector to a 30-cm piece of silicone tubing and link to a short piece of pump tubing, using appropriate couplers. Add an additional 15-cm piece of silicone tubing.

20. Add a glass grow-back trap between this piece of tubing and a further 15 cm of tubing ending with a connector to attach to the CDFF. Ensure that the grow-back trap is aligned so that the medium drips towards the CDFF.

    Further tubing may be required if different bore lengths of tube do not fit together. For example, a 5-mm bore tube will not fit the pump tubing connector, and in this case a length of 3-mm bore will be needed to join the two.

21. Cover the connectors of each feed line with foil and sterilize.

22. Switch off the pump and disconnect the inoculum vessel. Remove the pump from the incubator and place on top of the incubator together with the medium reservoir.

23. Attach the feed line to a retort stand on top of the incubator by clamping onto the grow-back trap.

24. Link the connector of the feed line (closest to the grow-back trap) to the connector of the second fermentor inflow and the second connector of the feed line to the medium vessel.

25. Pass the pump tubing of the feed line through the peristaltic pump.

26. Set the pump to maximum to prime the line until the medium starts to drip on to the rotating turntable. After this time, turn the speed of the pump down to the desired rate.

    The continuous system is fully set up.

Remove biofilm-containing pans

27. When the biofilms have developed to the desired state (typically ~2 weeks, maximum 1 month), switch off the turntable such that the desired pan comes to rest under the sample port.

28. Flame the sample port using 70% (v/v) ethanol and a portable butane burner.

29. Unscrew the port and insert the sample tool to remove a pan. Screw the sample port back into place as quickly as possible.

    During this process, the author suggests wearing a mask to avoid contamination.

30. Switch the turntable back on.

31. Remove the substratum from the sample pan by aseptically pushing each plug from below and removing the disk with sterile forceps.

32. Use biofilms either intact or place into sterile PBS. Vortex to remove the biofilm from the substratum.

33. Dismantle CDFF (Support Protocol 3).

SUPPORT PROTOCOL 1

SETUP FOR THE CONSTANT DEPTH FILM FERMENTOR (CDFF)

This protocol describes the assembly of the CDFF. Figure 1B.5.5 illustrates how the PTFE pans (see Support Protocol 2) fit into the assembled CDFF.

Materials

Spray lubricant (e.g., WD-40), optional
Silicon high-vacuum grease (VWR)

Constant depth film fermentor (CDFF; see Fig. 1B.5.1; contact Professor A. Peters for purchasing information; *APeters@UWIC.ac.uk*) including:
Motor
Power supply
15 PTFE pans, each with 5 plugs (see Support Protocol 2 for preparation)
Recess tools

8-G × 12 in. stainless steel needle tubing for CDFF inlet ports and vessels (e.g., SLS Scientific SRY700 8H)
3- and 5-mm bore silicone tubing (depending upon bore of stainless steel tubing), 15-cm and other lengths (depending upon setup)
Connectors and clips for metal tubing (e.g., Sigma-Aldrich Z12, 654-3 and Z12, 651-9)
Air filters (Hepa-vent; Whatman)
Nylon straps for securing tubing
Couplers for connecting pump tubing to 3-mm tubing (e.g., Value Plastics N220/210-6)
Foil
Autoclave tape
Incubator with ports at the top and side (for media in and effluent out) and gas tanks, as required (see Support Protocol 5) *or* 37°C room

Assemble CDFF

1. Place main fermentor tripod on the bench (Fig. 1B.5.6A).
2. Place the drive shaft of the stainless steel turntable through the hole in the base-plate of the main fermentor tripod: it should rotate freely (Fig. 1B.5.6B).

   A lubricant spray such as WD-40 can be used, if necessary.

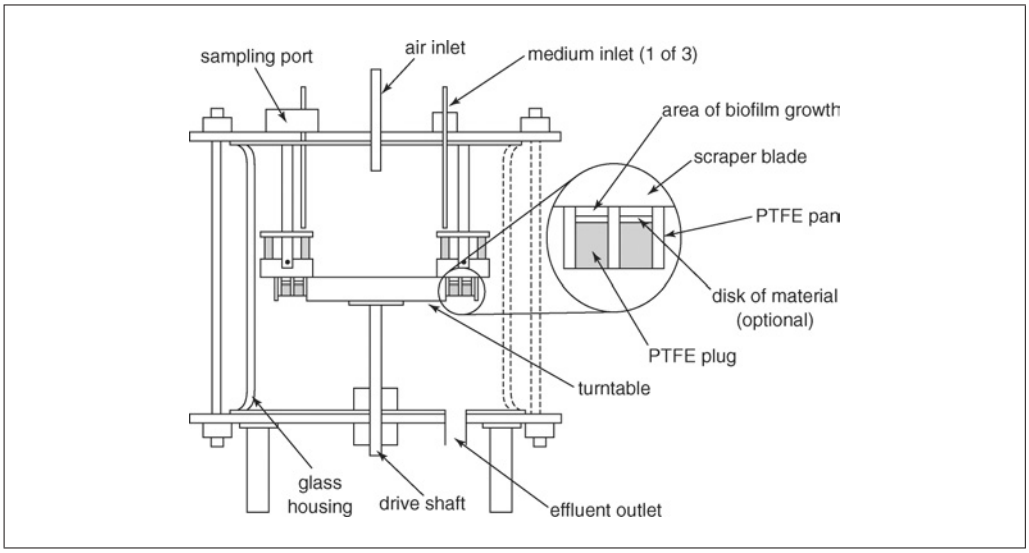

Figure 1B.5.5 Vertical schematic of the constant depth film fermentor (CDFF) highlighting one of the removable polytetrafluoroethylene (PTFE) pans.

3. *Optional:* Put PTFE pans in place.

   The PTFE pans can be assembled and put in place at this point or later.

4. Liberally smear the convex side of one PTFE seal with silicone high-vacuum grease, placing the grease downwards on the base plate of the main fermentor tripod (Fig. 1B.5.6C).

5. Liberally grease one end of the glass housing and place the greased end down onto the PTFE seal (Fig. 1B.5.6D).

6. Liberally grease the other end of the glass housing and put the second PTFE seal down on top of it (Fig. 1B.5.6E and F).

7. Liberally grease the PTFE seal and carefully place the fermentor top-plate down, ensuring that the scraper blades do not touch any of the grease. Secure the top-plate by tightening the screws using a wrench (Fig. 1B.5.6G).

8. Feed stainless steel tubing through the silicone stoppers of all three inlet ports of the top-plate of the fermentor.

9. Attach to these metal tubes 15 cm lengths of silicone tubing with a connector (coupling body) on the end (Fig. 1B.5.6H).

   It is easier to have all the connectors on the CDFF the same; this way when the tubing is connected, there will be no confusion about which connector type to use.

10. Attach silicone tubing with two air filters, with tubing between them, to the end of the port in the middle of the top-plate, which is for air-inlet (Fig. 1B.5.6H). Clamp off the filters at each end of the tubing with nylon straps before autoclaving.

    All tubing joints need to be secured using nylon straps.

11. Connect a length of silicone tubing with a connector on one end to the single drain hole on the base plate.

    The length of the tubing will depend upon the distance between the CDFF and the effluent bottle via the port in the incubator.

Sterilize CDFF

12. Cover all four connectors with tin foil and secure with autoclave tape (Fig. 1B.5.6H).

    If the connectors being used are not the self-seal type, then tubing clips will need to be added.

13. Place a piece of foil over the sample port, with the sample port open and the autoclave probe inserted into the fermentor. Autoclave the fermentor 15 min at 121°C.

14. As soon as the autoclave door can be safely opened (i.e., ideally while everything is still hot) remove the probe; quickly and aseptically screw the sample port tightly shut.

15. Remove the fermentor from the autoclave and open the clips on the filter tubing. Place into the incubator or 37°C room.

    Opening the clips will allow the air to enter the fermentor as it cools. Once cooled, the CDFF is ready for immediate use but could be stored until required.

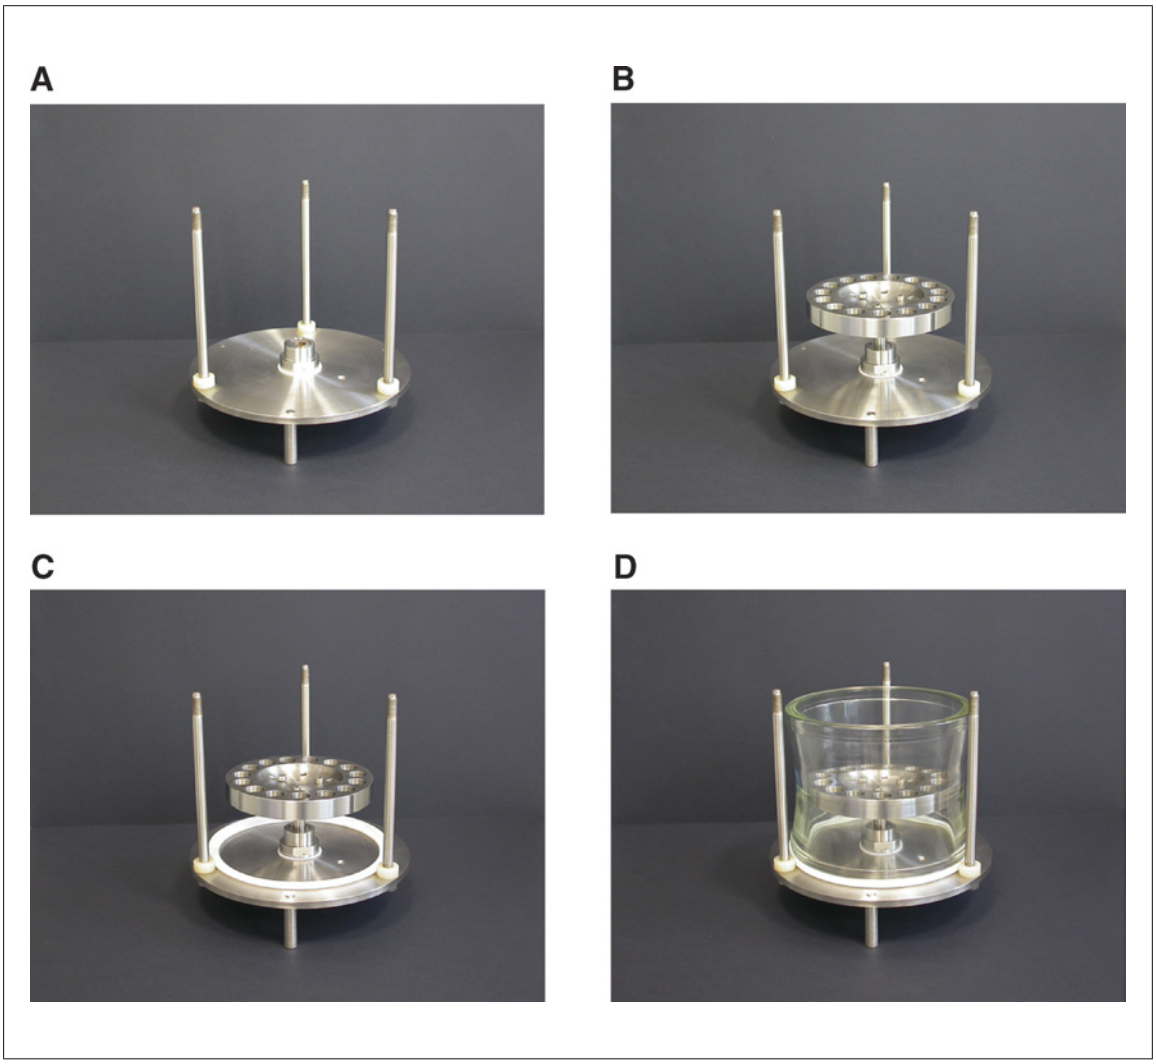

Figure 1B.5.6 (*continues on next page*) Pictures demonstrating the CDFF assembly procedure. The components are assembled in the following order: (**A**) fermentor tripod, (**B**) stainless steel turntable, (**C**) PTFE (polytetrafluoroethylene) seal, (**D**) glass housing, (**E**) application of silicone high vacuum grease, (**F**) second PTFE seal, (**G**) top plate, and (**H**) silicone tubing with connectors.

SUPPORT PROTOCOL 2

CONSTANT DEPTH FILM FERMENTOR PAN ASSEMBLY

Pan assembly can be carried out as part of the fermentor assembly, especially when using an inert substratum. However, certain materials may need to be kept wet, and it may be more convenient to assemble the fermentor and add the pans at the last moment before autoclaving. If the material cannot be autoclaved, it is possible to sterilize the CDFF as described in Support Protocol 1 and, in a sterile flow hood, remove the top-plate of the CDFF and place in pans/substratum which have been sterilized using an alternative method suitable for the material of choice. Pans should be stored placed within the CDFF. If left for a long period of time the pans can initially feel very tight, they will however loosen after an autoclave cycle. This can be carried out by autoclaving the turntable and pans alone before assembly, if necessary.

Generally the PTFE pans have five holes (each 5 mm in diameter) arranged around a central threaded hole into which the sampling tool is inserted (see Fig. 1B.5.7). When assembling the pans, it is important to have the central threaded hole uppermost. It is advisable to modify the pans by drilling a small hole (2 mm diameter) in the bottom of the threaded hole to allow liquid to pass through when sampling.

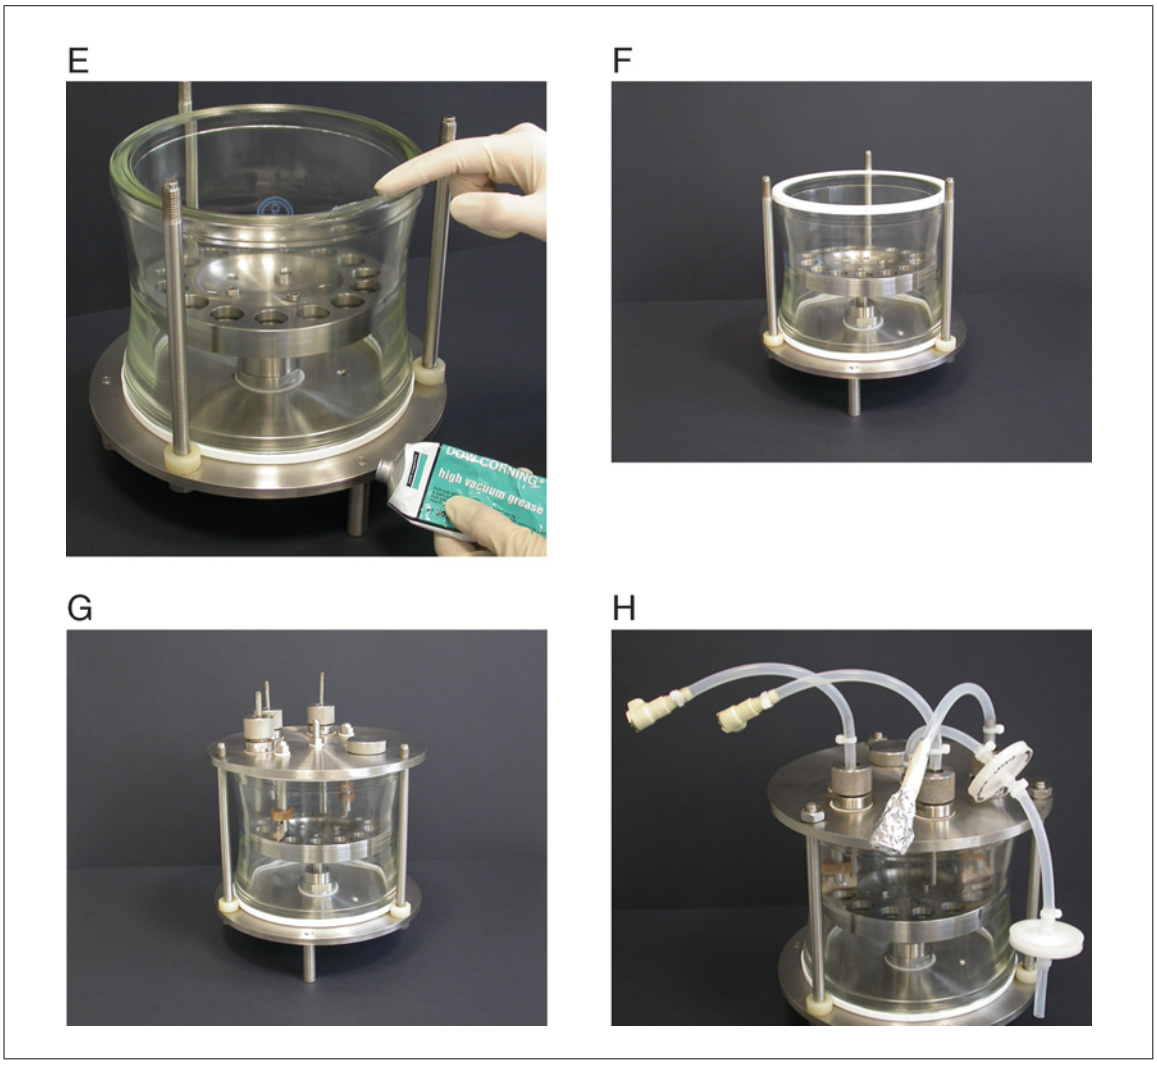

Figure 1B.5.6 (*continued*)

Materials

Silicone grease
Plugs: PTFE (supplied with CDFF; see Support Protocol 1)
PTFE pans (supplied with CDFF; see Support Protocol 1): drilling a 2-mm small hole in the bottom of the threaded hole recommended
Recess tool (supplied with CDFF; see Support Protocol 1)
Substratum (e.g., see Support Protocol 4)
CDFF turntable (supplied with CDFF; see Support Protocol 1)
Flat tool (supplied with CDFF; see Support Protocol 1)

1. Place the plugs into the holes in the pans (central threaded hole uppermost) with their flat surface uppermost.

2a. *For PTFE substratum:* Push the plugs level with the top of the pan and use the recess tool to push the plug down by the required depth.

The recess tool is simply a metal rod with a machined protrusion of known height. Two recess tools are supplied with the CDFF, allowing depths of 100, 200, 300, and 400 μm to be made; however, custom tools can also be made.

2b. *For other substratum:* Place a small amount of silicone grease between the PTFE and the chosen substratum to hold the material in place during autoclaving.

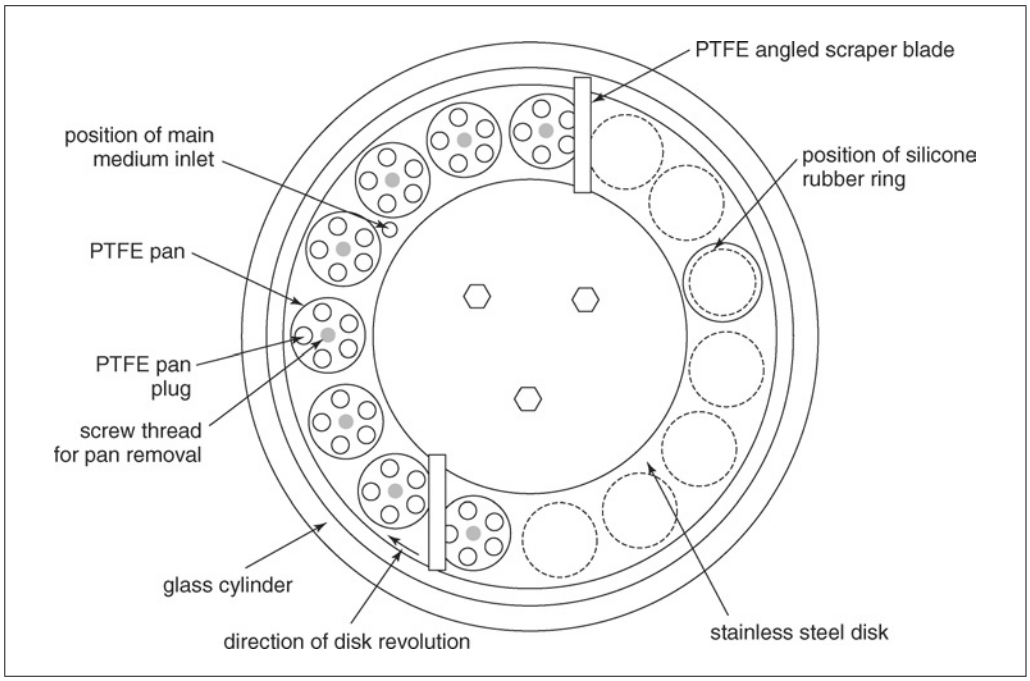

Figure 1B.5.7 Sectional schematic showing the arrangement of PTFE pans within the stainless steel turntable of the CDFF. Abbreviations: CDFF, constant depth film fermentor; PTFE, polytetrafluoroethylene.

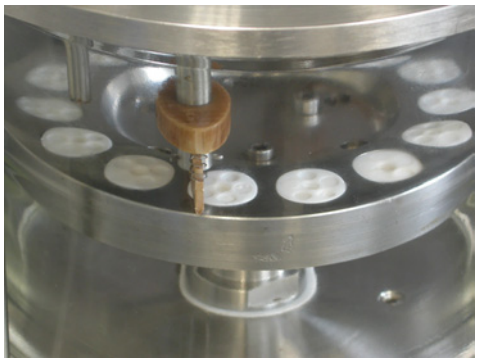

Figure 1B.5.8 Placement of pans in the CDFF.

i. Starting with the plugs slightly raised above the pan, place a small amount of silicone grease on the PTFE plug, place the disk on top of the plug, push down, and wipe off excess grease.
ii. Push the plug up again slightly from underneath and then push down with the appropriate recess tool.

3. Place the pans into the holes of the stainless steel turntable (Fig. 1B.5.8) using a flat tool to ensure they are flush.

SUPPORT PROTOCOL 3

DISMANTLE THE CONSTANT DEPTH FILM FERMENTOR AND PREPARE FOR REUSE

After the experiment has been carried out, it is important to ensure that the CDFF and effluent bottle are sterilized prior to cleaning.

Materials

CDFF with biofilm-containing pans removed (Basic Protocol)
(0.01% v/v) Decon acid rinse (Decon Laboratories)

1. Switch off the turntable motor.
2. Switch off the pump and release the tubing from the pump head.
3. Disconnect from the effluent bottle and medium inflow tubing.
4. Remove the air filter and ensure that the sample port is open.
5. Autoclave the CDFF on a kill cycle.
6. Autoclave the effluent bottle on the same cycle as above, placing the temperature probe (if available, set at 121°C) into the liquid.
7. Take apart the CDFF and leave to soak overnight in dilute (0.01% v/v) Decon acid rinse.

After autoclaving, the tubing may be reused for future experiments; however, before setting up a new system, be sure to examine the entire length of each piece of tubing for holes that could cause leaks.

PREPARING THE SUBSTRATUM

SUPPORT PROTOCOL 4

Several options are available in choosing the appropriate substratum to be used in the CDFF. Biofilms may be formed directly on the surfaces of the PTFE plugs of the sample pan. The number of plugs per pan will depend on their diameter, usually (but not necessarily) 5 mm, allowing five biofilms per pan. Custom pans can be manufactured with plugs of different diameter. Alternatively, the plugs may be used to support disks of any other material of interest to support biofilm growth, as long as the material can be machined to form a substratum of appropriate diameter and tolerance. CDFF studies have successfully used the following substrata: enamel (Zanin et al., 2005), hydroxyapatite (Pratten et al., 2003), dentine (Deng et al., 2005), glass (Allan et al., 2002), denture acrylic (Lamfon et al., 2005), intra-oral magnets (Wilson et al., 1995), dental composite materials (Leung et al., 2005) and dental amalgam (Ready et al., 2007).

Hydroxyapatite

Hydroxyapatite disks may be purchased from Clarkson Chromatography Products. Alternatively, they may be made by pressing hydroxyapatite powder into 5-mm diameter disks (3 mm depth) in a 5-mm pellet die under a pressure of 250 kg. The disks are then sintered 1 hr at 1000°C in a furnace.

Denture acrylic

Denture acrylic (polymethylmethacrylate cold-cure acrylic; e.g., Dentsply Limited) disks can be prepared, according to the manufacturer's instructions, using self-cure acrylic. In order to produce disks of the correct size, the CDFF pans can be used as 5 × 1–mm molds.

Enamel and dentine

Enamel and dentine disks can be prepared using extracted teeth (sterilized and washed). They are cut into 5-mm-diameter cylinders using a trepanning tool on a metal worker lath/drill before being sectioned using a rotary diamond saw. Further information can be found in Matharu et al. (2001).

INOCULATING THE CONSTANT DEPTH FILM FERMENTOR

Single-species inoculum

Inoculate 10-ml of medium (e.g., artificial saliva; see recipe) from a single colony (e.g., obtained from the National Collection of Type Cultures) and incubate for the desired time. Adjust the inoculum to an optical density of 1.0 at 600 nm. Carry out inoculation and culture in the CDFF as described in the Basic Protocol for a minimum of 8 hr, depending upon the expected growth rate of the particular organism.

NOTE: Some oral microorganisms may not be able to produce biofilms as single species. For example, late colonizers such as *Porphyromonas gingivalis* will not be able to adhere directly to the substrate when cultured alone.

Mixed-species inoculum

Inoculate 10-ml of medium (e.g., artificial saliva; see recipe) for each bacterial species from a single colony and incubate for the desired time for each of the species being used. Adjust the optical density of each culture to 1.0 at 600 nm and store separately in 1.0-ml aliquots up to 3 months at −80°C. Prior to inoculating the CDFF, thaw two cryovials of each bacterial suspension at room temperature, transfer the contents to a 10-ml sterile universal, and vortex mix. Using a 10-ml sterile pipet, carefully add the suspension to the rotating pans via the sample port of the CDFF. Allow to rotate an additional 1 hr. After this time, connect the CDFF to a reservoir of sterile medium and culture as described in the Basic Protocol, starting at step 15.

Microcosm plaque biofilms

Human saliva can be used as an inoculum to provide a multispecies biofilm consisting of microorganisms found in the oral cavity. Collect saliva from at least ten healthy individuals, preferably who have not taken antibiotics in the previous three months. Pool equal volumes from each of the subjects. Store in 1-ml aliquots up to 3 months at −80°C for subsequent use. To grow biofilms, proceed as in the Basic Protocol, using two 1-ml aliquots to inoculate 500 ml sterile growth medium in step 6 and culturing 8 hr in the CDFF at a flow rate of 1 ml/min in step 13.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Artificial gingival crevicular fluid (GCF)

40% horse serum (not heat-inactivated) in RPMI with L-glutamine (Sigma) containing 5 μg/ml hemin and 0.5 μg/ml menadione (see Dalwai et al., 2006). Store up to 1 month at 4°C.

Artificial saliva

1 g Lab-lemco powder (Oxoid)
2 g yeast extract
5 g proteose peptone (Oxoid)
2.5 g hog gastric mucin (Sigma)
0.35 g sodium chloride
0.2 g calcium chloride
0.2 g potassium chloride
Adjust volume to 1 liter with H_2O
Autoclave, then add 1.25 ml of 40% (w/v) urea
Store up to 1 month at 4°C

continued

The artificial saliva formulation given is the same as "complete saliva" in Pratten et al., 1998. Due to the light-weight nature of hog gastric mucin extra care should be taken when weighing.

COMMENTARY

Background Information

Models of oral biofilms, including laboratory, animal, and human in situ models, contrast noticeably in their microbiological complexity. Animal models have proven unequivocally that formation of dental caries is an infectious and transmissible disease. Use of biofilm models has enabled comparisons to be made of the cariogenic potential of different bacterial species, the role of the diet, and the effects of potential anticaries agents. In situ human models created using devices such as the Leeds in situ plaque-generating device have been designed to permit the development of "natural" plaque on standardized enamel surfaces freely exposed to the human oral environment (Robinson et al., 1997).

However, there are problems with the ethics associated with animal and human models. In addition, dental diseases are site specific, and the plaque biofilm is heterogeneous, which can lead to problems with sampling. Further, these intra-oral models suffer from the inability to use them for testing experimental products, especially in terms of safety to the patient. These restrictions have led to the development of laboratory-based models that simulate oral biofilms in vitro. Such models range from simple batch culture systems (e.g., the Zürich Biofilm Model; Guggenheim et al., 2004), to the development of artificial mouths.

In chemostat models there is a controlled fluid environment and planktonic phase, with a nutritionally limited growth rate. A number of replicate samples and a variety of surfaces can be placed within the chemostat, and properties such as the pH can be controlled. However, the large fluid phase is not consistent with the in vivo situation where shear forces and a thin film of fluid are present on the oral surfaces.

The flow cell (see *UNIT 1B.2*) is often the system of choice for short-term adhesion and colonization studies because it enables the nondestructive observation of biofilm development in real time (Busscher and van der Mei, 1995). The flow cell may be constructed in a number of ways but typically consists of a transparent chamber of fixed depth through which the growth medium passes. When mounted on a microscope stage, this system allows the biofilm development inside the chamber to be observed in real time. Other models which produce biofilms under flow conditions include the Modified Robbins Device (MRD) and the Annular Reactor. The MRD contains six or more individual ports in a linear array along a channel of rectangular cross-section. Biofilms can be removed during the course of an experiment, and the model has been used extensively to generate oral biofilms. In contrast, the Annular Reactor produces biofilms under shear conditions in a steady-state system in a similar manner as a chemostat.

Historically, so-called "artificial mouths" have been used to grow dental plaque in vitro, before the implementation of the biofilm models described previously. Artificial mouths are specifically constructed to mimic the situation in the oral cavity although most studies have focused on dental caries. In such systems, dental plaque formation is studied on a human tooth inoculated with saliva and then supplied with artificial saliva. For example, Pigman and Elliott (1952) developed a model for studying early carious lesions in order to evaluate the anticaries effects of several topical agents used as dentifrice components. The development of such models has led to sophisticated systems such as the multiple artificial mouth (MAM). This is a computer-controlled model which delivers nutrients, reagents, and gas, and continuously acquires pH data, including real-time pH changes of plaque. The system has proven to be a powerful and flexible tool for continuous monitoring of plaque growth and metabolism (Sissons et al., 1991).

All of these models are compromises between the reality of the in vivo ecosystem and the simplification and controllability necessary to gain meaningful, useful results in the laboratory. As described, there are many experimental systems available for the generation and study of in vitro dental plaques, such that a suitable system can be chosen to meet the requirements of almost any investigation. The CDFF is not principally designed to study early biofilm formation or for studies where a high shear-rate is required. However, some of the advantages of this model for experiments on oral biofilms include:

1. It represents a good simulation of the oral environment in that the fluid phase (e.g., saliva or GCF) is continuously smeared in a thin layer over the biofilms/substrata. In this

way it is an improvement over many laboratory models that involve immersing the substratum in a large excess of fluid.

2. Mechanical shearing of the biofilms by the scraper blades mimics the shearing that takes place in vivo due to tongue movements, biting, chewing etc.

3. It allows intermittent pulsing (or continuous application) of the antimicrobial agents and/or additional nutrients such as sucrose.

4. It allows easy sampling of the biofilm (with large numbers of replicates) at various intervals during the course of a run.

5. Biofilms of different thicknesses can be investigated.

6. Pure or mixed cultures of bacteria, saliva, or homogenized-plaque samples can be used as an inoculum.

7. A number of substrata can be investigated.

8. It enables the determination of the effects of long-term exposure of biofilms to antimicrobial agents.

Critical Parameters

The most debated parameter when carrying out studies on oral biofilms is the choice of microorganism or microorganisms. This is no different for the CDFF where, as already described, the operator can use single-species, multiple-species, or microcosm biofilms. Issues arise as to whether the studies are associated with biofilm formation (e.g., where primary colonizer such as *Streptococcus sanguis* is studied) or a particular disease (e.g., caries where only *S. mutans* is of interest). When considering the criteria for a community study, the organisms selected need to originate from a pool of species common to the oral environment and important components of that community. Further, the group of species should form a stable community where, under standard conditions, all members are retained over the course of the experiment. To further produce biofilms which are more representative of the in vivo scenario, the establishment of laboratory microcosms in association with a suitable substratum and nutrient source is useful.

Another important consideration is the medium to be used. Examples of an artificial saliva and artificial GCF are given in this unit. Through its chemical and physical properties, saliva exerts a profound influence on the adhesive interactions that occur in the mouth, and thus choosing a suitable artificial saliva is important. Due to the obvious difficulty in using large volumes of human saliva, a synthetic substitute will be needed to reproduce features of saliva which are considered important in cultural studies of plaque bacteria while remaining relatively inexpensive and simple to produce (see Strategic Planning).

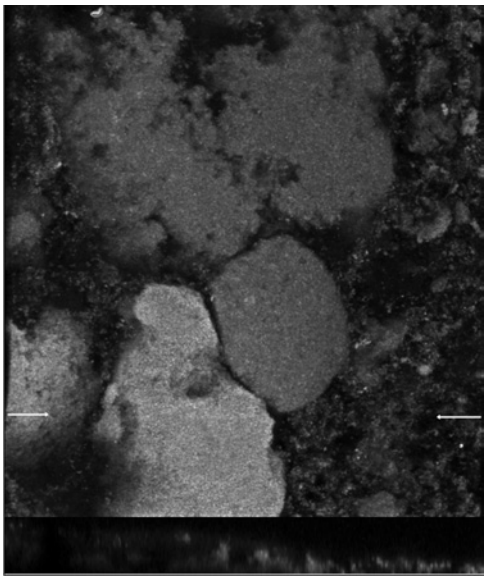

Figure 1B.5.9 Three-dimensional confocal scanning laser microscopy (CLSM) reconstruction of a supragingival plaque biofilm based on a series of *x,y* projections. The arrows indicate the position of the sagittal section (6 μm thick).

Anticipated Results

It has been shown that using the CDFF model, quasi steady-state biofilms can be generated after 4 to 7 days of growth, depending upon the organisms being studied. Such biofilms typically contain $\sim 1 \times 10^8$ cfu/mm^2. The reproducibility of the model has been shown to be good, both between pans within one experiment and between experiments. This is particularly true with work on single-species biofilms. However, as might be expected in studies on microcosms where the inoculum contains a diverse bacterial population, the resultant biofilms are far more heterogeneous. These results are less comparable, in terms of the defined bacterial population, although this depends upon the sensitivity of the technique used for quantification (McBain et al., 2003).

The microstructure of oral biofilms, as shown by confocal laser scanning microscopy (CLSM), has revealed stacks of bacteria developing over time, separated by clear channels (Fig. 1B.5.9). Additionally, the distribution of viable bacteria in biofilms grown in the CDFF has been shown to be similar to those in dental plaque in vivo. This suggests that the CDFF produces in vitro biofilms which are comparable to their in vivo counterparts in terms of both structure and the spatial distribution of viable bacteria.

When biofilms generated in the CDFF are challenged with an antimicrobial, the results are sensitive enough to be able to compare different treatment regimes. Such data has been shown to be comparable, in terms of ranking agents, to data from clinical trials.

Methods for Analysis of Bacterial Autoinducer-2 Production

BASIC PROTOCOL

Many bacteria possess homologs of the *luxS* gene, which is responsible for the production of the quorum-sensing signal autoinducer-2 (AI-2). This unit describes a biological assay for detecting and quantifying AI-2 present in bacterial culture fluids. The procedure employs a bioluminescent bacterial reporter strain, *Vibrio harveyi* BB170, which produces light in response to AI-2. The first step of the protocol involves the collection of cell-free culture fluids. In the second step, the cell-free culture fluids are added to the *V. harveyi* reporter strain, and the resulting light production is measured using a luminometer or scintillation counter. AI-2 activity is calculated as the induction of luminescence of *V. harveyi* BB170. This protocol focuses on techniques for determining the growth conditions under which AI-2 is produced by a bacterial strain of interest. The procedure can also be used to quantify AI-2 produced by various bacterial mutants, as well as AI-2 produced in vitro. The assay is a simple and relatively inexpensive method for quantifying AI-2 and can, therefore, be used to screen a large number of samples.

Materials

Bacterial strain to be tested
Growth medium specific for bacterial strain
V. harveyi strain in BB152 (*luxM*::Tn5), frozen glycerol stock
V. harveyi strain in BB170 (*luxN*::Tn5), frozen glycerol stock
AB medium (see recipe)

Sterile syringe filters, 0.2-μm pore size
1-ml syringes
Sterile 1.5-ml microcentrifuge tubes
Luminometer, scintillation counter, or equivalent device for measuring light

CAUTION: *V. harveyi* is a Biosafety Level 1 (BSL-1) organism. Such organisms are not known to consistently cause disease in healthy adult humans, and are of minimal potential hazard to laboratory personnel and the environment. Standard microbiological practices should be followed when working with these organisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

NOTE: If measuring a large number of samples, use a 96-well microtiter filter plate with a sterile 96-well plate for collection rather than individual syringes, syringe filters, and microcentrifuge tubes.

NOTE: BB170 and BB152 strains (Bassler et al., 1993) are available at American Type Culture Collection (*http://www.atcc.org*) with strain ATCC #BAA-1117 and ATCC #BAA-1119, respectively.

Prepare cell-free culture fluids

1. Inoculate the bacterial strain to be tested for AI-2 production into appropriate medium and grow to saturation.

   Do not add antibiotics to the growth medium as they can inhibit the reporter strain's growth, bioluminescence, or both (see Critical Parameters).

2. Dilute the culture 1:1000 into fresh medium and resume growth.

Contributed by Michiko E. Taga
Current Protocols in Microbiology (2005) 1C.1.1-1C.1.8

3. Remove 1-ml aliquots at time points of interest. Remove cells by passing through 0.2-μm syringe filters into sterile 1.5-ml microcentrifuge tubes. Use a separate syringe and filter for each sample.

   If using a 96-well filter plate, remove 0.2-ml aliquots and filter directly into a sterile 96-well plate.

   If the AI-2 production profile of the organism has not been characterized, measure AI-2 production over a time course of growth. This is important because many bacteria produce AI-2 only during a particular phase of growth. For example, maximal AI-2 accumulation in V. harveyi occurs in the stationary phase, whereas in Salmonella typhimurium, AI-2 is detectable transiently during exponential growth (Surette and Bassler, 1998). For bacteria with rapid doubling times, collect cell-free culture fluids every hour after the initial dilution, and continue until the culture reaches the stationary phase.

   In some cases, it is necessary to use the cell-free culture fluids immediately or the day after collection. The cell-free culture fluids of some bacteria such as V. harveyi can be stored at −20°C without loss of AI-2 activity, while the AI-2 activity of other bacteria such as E. coli diminishes during storage, especially with repeated freezing and thawing.

4. Collect cell-free culture fluids from a culture of *V. harveyi* strain BB152 (i.e., AI-2$^+$) grown overnight in AB medium to use as a positive control. Store this sample indefinitely at −20°C and use in future experiments.

Perform BB170 bioassay

5. Inoculate *V. harveyi* strain BB170 from a glycerol frozen stock into 5 ml AB medium. Incubate overnight (~14 hr) at 30°C with aeration until the culture is turbid (OD_{600} = ~0.7 to 1.2).

   Inoculation from a frozen stock is preferable to inoculation from a colony or liquid culture, as cultures begun from frozen stocks produce maximum light.

   Never store V. harveyi cultures in a refrigerator or cold room because this will dramatically decrease the viable cell number.

6. Verify that the culture is bright by examining in a darkroom or by using a luminometer. Dilute the BB170 overnight culture 1:5000 into fresh AB medium.

   The volume required will depend on the number of samples to be tested and the method of light detection (see step 7).

7. Set up a series of duplicate mixtures containing 10% (v/v) cell-free culture fluids prepared in step 3 and 90% (v/v) diluted BB170 culture prepared in step 6. Incubate at 30°C with aeration.

   If using a 96-well microtiter plate reader for light measurement, set up 100-μl samples per well (i.e., 10 μl cell-free culture fluids and 90 μl diluted BB170) in clear-bottomed black microtiter plates such as Corning 3603 or clear assay plates such as Falcon 353911. If using a luminometer that holds individual tubes, prepare 2- to 5-ml samples in glass test tubes.

8. In each experiment, include the following control samples in duplicate:

   Negative control: 10% AB medium
   Medium control: 10% bacterial growth medium used in step 2
   Positive control: 10% cell-free culture fluids prepared from *V. harveyi* BB152 (step 4).

9. Using a luminometer, measure the light produced in each sample at a wavelength of 490 nm (for some luminometers, this setting is the chemiluminescent mode). Take measurements every 30 min for 5 to 7 hr, i.e., until the medium control sample has produced the lowest amount of light (see Background Information; also see Anticipated Results).

If using a 96-well microtiter plate reader, measure the light output from each well. If using a luminometer that holds individual tubes, remove 100-μl aliquots from each sample and measure the light output.

Any one of a variety of light detection devices can be used in this assay, from a simple photomultiplier tube to an automated microplate reader. The optimal device for the assay will depend on the number of samples per experiment, frequency of use, and economical considerations.

REAGENTS AND SOLUTIONS

Use Milli-Q water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

AB medium

Dissolve the following ingredients in 960 ml H_2O:
2.0 g Casamino acids, vitamin-free (0.2% w/v final)
12.3 g magnesium sulfate heptahydrate (50 mM final)
17.5 g sodium chloride (0.3 M final)
Adjust pH to 7.5 with potassium hydroxide
Sterilize by autoclaving
When cool, add the following sterile ingredients to give the following final concentrations:
1 mM L-arginine from 100× stock (pass stock through a 0.2-μm filter and store indefinitely at 4°C)
1% (v/v) glycerol from 50× stock (sterilize stock by autoclaving and store indefinitely at room temperature)
10 mM potassium phosphate buffer, pH 7.0 (*APPENDIX 2A*) from 100× stock (sterilize stock by autoclaving and store indefinitely at room temperature)
Store indefinitely at room temperature

Never add glucose to the medium. Glucose inhibits bioluminescence of V. harveyi (see Critical Parameters).

COMMENTARY

Background Information

Autoinducers are signaling molecules that bacteria secrete and detect to regulate the expression of specific genes based on cell population density. This process, known as quorum sensing, was initially discovered as the mechanism by which marine *Vibrio* species coordinately control bioluminescence of the population (Nealson and Hastings, 1979). Though initially considered a curious phenomenon limited to luminous marine bacteria, quorum sensing has since been shown to regulate a variety of functions in >100 different bacterial species, including virulence, sporulation, antibiotic production, and motility (Miller and Bassler, 2001; Federle and Bassler, 2003).

The autoinducer termed AI-2 was identified as one of two signaling molecules that control bioluminescence in *Vibrio harveyi* (Bassler et al., 1994). AI-2 is of particular interest because it deviates from the quorum-sensing paradigm in three significant ways. First, most autoinducer/detection systems are specific to a single species of bacteria. In contrast, the AI-2 synthase, LuxS, is broadly distributed throughout the bacterial world, and AI-2 production has been demonstrated in >50 species of bacteria (Bassler et al., 1997; Surette et al., 1999). Second, it is clear that AI-2, like other autoinducers, functions as a quorum-sensing signal in some bacteria, as AI-2 regulates virulence, biofilm formation, antibiotic production, and iron acquisition in various bacterial species (Fong et al., 2001; McNab et al., 2003; Xavier and Bassler, 2003; Sircili et al., 2004). However, AI-2 may also function in processes unrelated to quorum sensing in some bacteria (Winzer et al., 2002; McNab and Lamont, 2003). Third, in most quorum-sensing systems, the concentration of autoinducer is considered to be an indicator of cell population density, with the highest concentration of autoinducer occurring when the bacteria are most dense. In some bacteria, AI-2 production

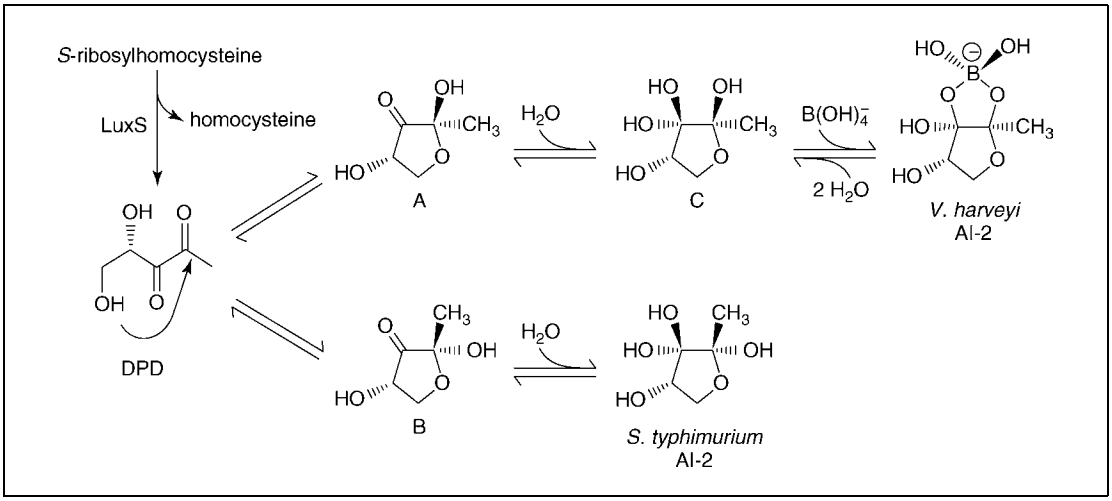

Figure 1C.1.1 Proposed pathway for formation of AI-2 molecules. DPD cyclizes spontaneously to form two stereoisomers, A and B. Spontaneous addition of water to A and B results in formation of C and *S. typhimurium* AI-2, respectively. *V. harveyi* AI-2 is formed by addition of boric acid to C (Modified from Miller et al., 2004).

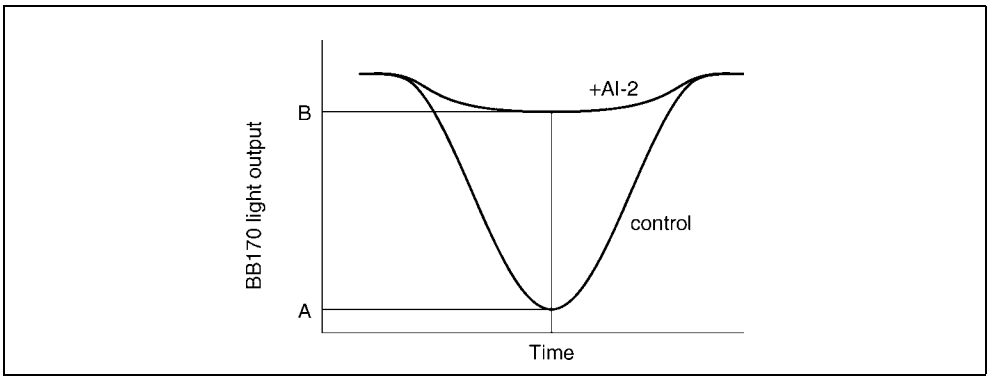

Figure 1C.1.2 Light production in the BB170 bioassay. Induction of bioluminescence is calculated at the time point marked by the vertical line.

follows this pattern, while in others, such as *S. typhimurium*, AI-2 is degraded in late exponential phase (Surette and Bassler, 1998, 1999; Taga et al., 2001).

The term "AI-2" refers to a family of molecules derived from 4,5-dihydroxy-2,3-pentanedione (DPD), the product of the LuxS reaction (Miller et al., 2004). LuxS catalyzes the formation of DPD from *S*-ribosylhomocysteine, a product of the *S*-adenosylmethionine utilization pathway (Schauder et al., 2001). DPD, in turn, cyclizes spontaneously to form an assortment of different stable compounds (Fig. 1C.1.1). Structural studies of two AI-2 receptors, *V. harveyi* LuxP and *S. typhimurium* LsrB, revealed that each AI-2 receptor specifically binds one molecule from this pool (Chen et al., 2002; Miller et al., 2004).

In BB170, the sensor for AI-1, another *V. harveyi* autoinducer, is mutated, and thus BB170 produces light exclusively in response to AI-2 (Bassler et al., 1994, 1997). Additionally, the *luxS* gene (i.e., the AI-2 synthase) is intact, so this strain produces AI-2 and induces light production at a high cell density (Bassler et al., 1994). In the absence of exogenously supplied AI-2, light production in the BB170 bioassay decreases initially for the first 3 to 5 hr. At later time points, the AI-2 produced by BB170 accumulates and induces light production (Fig. 1C.1.2, control). AI-2 added exogenously (i.e., in cell-free culture fluids) begins to induce light production in BB170 at a time point prior to self-induction by AI-2 (Fig. 1C.1.2, +AI-2; Bassler et al., 1993). The amount of AI-2 in the cell-free culture fluids being tested must be calculated at the time point immediately preceding self-induction of BB170 (Fig. 1C.1.2, vertical line), because eventually, all samples produce maximal light.

Table 1C.1.1 Troubleshooting Guide for BB170 Bioassay

Problem	Probable cause	Solution
There is no detectable light in the bioassay after several hours	The initial culture of BB170 was not bright due to contamination or a problem with AB medium	Examine the initial (undiluted) culture of BB170 in a darkroom. If the culture is turbid but no light is detectable, prepare fresh AB medium and begin the assay again.
	The luminometer is not functioning correctly	Examine the initial (undiluted) culture of BB170 in a darkroom. If the culture is bright (i.e., produces light), measure the light produced using the luminometer. If no light is detected, check the settings or contact the manufacturer.
	The temperature of the incubator is not set to 30°C	*V. harveyi* does not grow at low temperatures and does not produce light at temperatures >30°C. Perform all manipulations of *V. harveyi* at 30°C.
All samples are bright in the bioassay, including the negative control and the medium control	The bioassay has gone too long	Take readings every 30 min in order to find a time point with the lowest bioluminescence in the medium control.
	The initial dilution of BB170 contained too many cells	Grow the initial BB170 culture for no longer than 14 hr. Alternatively, perform the assay with a 1:10,000 initial dilution of BB170.
	The AB medium is contaminated with bacteria producing AI-2	AI-2-producing bacterial contaminants in the media can induce bioluminescence of BB170. Perform the assay with sterile AB medium and culture fluids.
	The wrong plates are being used (if using a 96-well plate reader)	Use clear-bottomed black microtiter plates. For best results, leave at least one empty well between samples.
The medium control alone induces bioluminescence of BB170, but the negative control does not	The bacterial growth medium includes boron or another agent that induces bioluminescence in *V. harveyi*	Reduce the amount of boric acid in the bacterial growth medium to <10 μM. If the medium control induces bioluminescence but does not contain boric acid, prepare cell-free culture fluids from bacteria grown in a different medium.
The positive control induces light production, but the cell-free culture fluids do not	The strain of bacteria being tested does not produce AI-2 at the time points examined	In step 2, use a smaller initial inoculum before collecting cell-free culture fluids to reduce the effect of AI-2 degradation. Collect cell-free culture fluids at shorter time intervals during all phases of growth. Examine the sequence of the *luxS* gene and promoter to determine whether it is likely to be expressed.
	The bacteria do not produce AI-2 under the conditions being tested	Vary the growth parameters of the bacteria being tested. For example, change the medium, temperature, aeration, and addition of host factors.

continued

Table 1C.1.1 Troubleshooting Guide for BB170 Bioassay, *continued*

Problem	Probable cause	Solution
	The bacterial growth medium inhibits bioluminescence or is toxic to *V. harveyi*	Determine whether induction of bioluminescence occurs at late time points in the medium control. If no induction occurs, prepare cell-free culture fluids from bacteria grown in a different medium.
	The bacteria produce an agent that inhibits bioluminescence or is toxic to *V. harveyi*	If the bacteria are known to produce a toxic agent, such as an antibiotic, collect cell-free culture fluids under conditions in which the agent is not produced.
		Alternatively, perform the bioassay using 1% cell-free culture fluids.
The light output is inconsistent between duplicate samples	The luminometer is not optimized for the bioassay	Examine the manufacturer's instructions and adjust the settings of the luminometer.
	The *V. harveyi* culture is not aerated properly	Always grow *V. harveyi* with aeration: the luciferase reaction requires oxygen.

V. harveyi strain BB170 is the most reliable reporter for AI-2 activity that presently exists. The difference in the timing of light production in response to the AI-2 in the culture fluids being tested versus AI-2 produced endogenously is critical for the quantification of AI-2 activity. Additionally, self-induction by BB170 is an important indicator that the assay is functioning properly and is particularly helpful in the initial characterization AI-2 production by a bacterium. Another *V. harveyi* reporter with a *luxS* mutation has been constructed (Chen et al., 2002). Because self-induction with AI-2 does not occur in this strain, it is not possible to calculate induction of bioluminescence by the method used for BB170, and therefore, it is generally used only in specific circumstances such as examining the effect of boron on light production (Chen et al., 2002; Miller et al., 2004). AI-2 reporter strains of *S. typhimurium* also exist, but these strains are ~100-fold less sensitive to AI-2 than the *V. harveyi* reporters and typically cannot detect AI-2 in cell-free culture fluids (Taga et al., 2001; Taga et al., 2003).

The AI-2 detection procedure described in this unit is a biological assay that relies on the AI-2 detection system of *V. harveyi*. BB170 is extremely sensitive to the level of AI-2, as it varies its light output over three orders of magnitude in response to changes in the amount of AI-2 present; however, because it is a biological assay, it is limited by the requirement for the *V. harveyi* reporter strain to produce light in the presence of the added agents. Any compounds that inhibit bioluminescence or are toxic to *V. harveyi* interfere with this bioassay (DeKeersmaecker and Vanderleyden, 2003).

Critical Parameters

To perform the bioassay accurately, it is important to avoid conditions that can adversely affect the growth or bioluminescence of the *V. harveyi* reporter strain. Factors that inhibit the growth or bioluminescence of *V. harveyi* include the presence of glucose, low pH, temperatures above or below 30°C, and various toxic compounds. Additionally, the presence of boric acid enhances light production of BB170 and limits its ability to distinguish between different levels of AI-2 added. Therefore, it is important to monitor the light production of the medium control samples to ensure that the reporter strain is not affected by factors within it.

In order to calculate AI-2 activity, light must be measured at the time point at which the medium control produces the least amount of light. Because the timing of the response to AI-2 varies with each assay, it is important to measure light production every 30 min to ensure that data can be obtained before all samples become bright.

Troubleshooting

A number of factors contribute to the overall success of the BB170 bioassay. A guide for resolving problems with the bioassay is presented in Table 1C.1.1.

Table 1C.1.2 Results Typical of *S. typhimurium*

Cell-free culture fluid of *S. typhimurium*	cpm at optimal time point	Induction of bioluminescence
Medium control	15,288	N/A[a]
0 hr	33,296	2.2
2 hr	92,954	6.1
3 hr	3,473,248	227.2
4 hr	8,061,968	527.3
5 hr	88,466	5.8
6 hr	26,842	1.8

[a]N/A, not applicable.

Anticipated Results

Calculate the induction of bioluminescence for each sample using data only from the optimal time point, i.e., the point at which the medium control sample produces the lowest amount of light (Figure 1C.1.2, vertical line): induction of bioluminescence = light output of the sample/light output of the control.

In the example shown in Figure 1C.1.2, induction of bioluminescence is calculated as light output (B)/light output (A).

The light output is typically measured as counts per minute (cpm). Sample data from the optimal time point of an assay of *S. typhimurium* cell-free culture fluids collected over a time course of growth are presented in Table 1C.1.2. In this example, induction of bioluminescence is calculated as cpm of the sample/15,288.

Time Considerations

The time required for the collection of cell-free culture fluids varies depending on the growth properties of the bacteria being tested, with a minimum of 6 hr for bacteria with rapid doubling times. The bioassay takes ~6 to 8 hr, including 30 min to set up the samples and 30 min for the analysis.

LacZ-Based Detection of Acyl-Homoserine Lactone Quorum-Sensing Signals

Many bacteria synthesize and secrete small molecules to the surrounding environment, and as the cell density increases, accumulation of these molecules eventually reaches a threshold concentration which, in turn, regulates gene expression. This process is called quorum sensing. Many Gram-negative bacteria use acyl-homoserine lactones (AHL) as the quorum-sensing signal molecule. Detecting AHLs from bacterial samples is an important step in investigating and identifying novel cell-to-cell communication systems. The protocols described in this unit can help to detect and identify unknown AHLs from various spent bacterial media and environmental samples (Brelles-Mariño and Bedmar, 2001). For detection of AI-2 (a non-AHL autoinducer molecule) using a bioluminescent bacterial reporter strain, refer to *UNIT 1C.1*.

Basic Protocol 1 describes a simple method to quickly assay for AHL activity in a sample, by quantitatively measuring β-galactosidase activity of a reporter fusion gene of an AHL bioassay strain grown in various concentrations of sample filtrates (assay filtrates should first be tested at 10% to test for sensitivity and toxicity to the bioassay strain, then adjusted as needed by dilution). This includes two parts; first, the assay samples are prepared and, second, the bioassay strains with sample filtrates are incubated and the enzyme activity assay is performed.

Basic Protocol 2 describes a method using thin-layer chromatography (TLC) to identify AHL molecules. This protocol should be used if the initial AHL liquid assay is positive and the AHL content and structure needs to be determined. Performing TLC separates AHLs based on structure and polarity. Detection of AHLs on the TLC plate is performed by coating the TLC plate with bioassay cells in agar medium containing Xgal and examining for blue spots indicating *lacZ*-based Xgal hydrolysis induced by the presence of AHLs. The relative R_f of the spots will allow for AHL identification.

The Support Protocol provides instruction for preinducing *Agrobacterium tumefaciens* KYC55 (pJZ372)(pJZ384)(pJZ410), which is used as the AHL bioassay strain in both basic protocols.

CAUTION: Follow all biosafety requirements relevant to the assay sample strain under investigation. Refer to *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for instructions on safe handling of microorganisms.

CAUTION: Agrobacterium tumefaciens is a Biosafety Level 1 (BSL-1) organism. Such organisms are not known to consistently cause disease in healthy adult humans, and are of minimal potential hazard to laboratory personnel and the environment. Standard microbiological practices should be followed when working with these organisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

DETECTION OF ACYL-HOMOSERINE LACTONE ACTIVITY USING A BIOASSAY STRAIN

BASIC PROTOCOL 1

This protocol consists of two basic steps. The first step requires the preparation of the assay sample strains, which must be grown under the desired conditions. The culture supernatant must then be collected at various time points and filtered to remove all bacterial cells to ensure that no AHL molecules or β-galactosidase from any native *lacZ*$^+$ strains are being produced during the actual assay step. Alternatively, samples can be

Contributed by Adam C. Joelsson and Jun Zhu
Current Protocols in Microbiology (2006) 1C.2.1-1C.2.9

extracted with organic solvents, such as ethyl acetate, to concentrate the AHL molecules (see Basic Protocol 2).

The second part of the protocol consists of running the actual assay. First, AT medium, with various concentrations of assay filtrates, are inoculated with the bioassay strains (include necessary controls here, e.g., synthetic autoinducers and medium blanks) and are grown for 12 to 16 hr at 28°C. After sufficient growth (OD_{600} reaches 0.2 to 1), the β-galactosidase assay is ready to be performed. This is done by lysing the cells and introducing *O*-nitrophenyl-β-D-galactoside (ONPG), which is cleaved in the presence of β-galactosidase, turning the solution yellow. This assay is timed and care should be taken to record the start time and stop times of each sample. The solution is centrifuged after stopping to pellet cell debris and the OD_{420} of the supernatant is taken. Levels of *lacZ* induction by AHL are then reported in Miller units.

Materials

Bacteria of interest
Medium appropriate to organism under study (e.g,. see *APPENDIX 2C*)
Preinduced cells (Support Protocol)
AT medium (see recipe) without antibiotics
Synthetic autoinducer
Z buffer (see recipe)
0.05% (w/v) SDS solution in H_2O
Chloroform
4 mg/ml *O*-nitrophenyl-β-D-galactoside (ONPG) in H_2O
1 M Na_2CO_3
10-ml syringe and 0.2-μm syringe filter

Prepare sample

1. Grow bacteria of interest to different time points in 2 ml appropriate medium.

   Time points are best established experimentally, a good starting point would be low (early log phase), medium (mid to late log phase), and high (stationary phase) cell densities to pinpoint at what time the bacteria of interest may produce autoinducer and to test for conditions favorable for AHL stability.

   Occasionally, the production of lactonases or medium pH changes caused by some strains may degrade the AHL produced. Therefore, it is necessary to collect samples at various growth points.

2. Microcentrifuge cells 1 min at 16,000× *g*, room tempereture. Remove the pellets and filter assay supernatants using a 0.2-μm syringe filter and 10-ml syringe. Use immediately or freeze up to 1 month at −20°C until use.

   Alternatively, culture filtrates can be extracted by ethyl acetate and resuspended in the medium (see Basic Protocol 2).

Perform assay

3. Thaw one vial of preinduced cells on ice. For each filtrate to be assayed, inoculate 2 μl preinduced cells into 2 ml AT medium without antibiotics plus the desired amount (up to 10%) of assay filtrate, synthetic autoinducer, or medium used to culture the bacteria of interest. Grow ~16 hr, until OD_{600} reaches 0.2 to 1 at 28°C.

   Antibiotics are not needed as they may interfere with β-galactosidase activity. In this incubation time frame plasmids will not be lost.

   Make a stock solution of cells in AT medium; for example, make a 20-ml solution with 20 μl preinduced cells for ten assay samples to be analyzed simultaneously. This ensures that all samples have the same starting concentration of the bioassay strain.

Controls should be included at this step as well. A positive control of synthetic AHLs or cultures known to have AHL activity should be used, as well as media blanks (AT medium and the medium used to grow assay strain).

4. Measure OD_{600} of the total cell suspensions. Combine 0.2 ml preinduced bacterial cells in AT medium, 0.8 ml Z buffer, 2 drops (~10 µl) of 0.05% SDS solution, and 3 drops (~15 µl) of chloroform in 2-ml microcentrifuge tubes.

   The 2 ml culture volume is to ensure optimal conditions for growth while shaking, and to keep a consistent inoculation ratio between samples. For ten samples, 20 ml can be inoculated and divided into 2 ml volume aliquots prior to addition of the filtrate.

5. Vortex vigorously for at least 10 sec and then add 0.1 ml of 4 mg/ml ONPG. Record time (T_0).

   Add ONPG quickly to assay tubes to ensure a consistent T_0.

6. When the solution turns yellow, add 0.6 ml of 1 M Na_2CO_3 to stop the reaction, and record the time in minutes (T_s).

   If no appreciable yellow is seen, stop assay at 120 min.

7. Centrifuge cell debris 3 min at 16,000 × *g*, room temperature, and measure OD_{420} of the supernatant.

8. Calculate results in Miller units as follows:

$$\text{Miller units} = \frac{1000 \times OD_{420}}{OD_{600} \times (T_s - T_0) \times 0.2}$$

   Time is in minutes.

   For more information regarding β-galactosidase assays and Miller units, refer to Miller (1972). See Raleigh et al. (2002) for a more recent review of the Lac operon.

DETECTING ACYL-HOMOSERINE LACTONE MOLECULES BY THIN-LAYER CHROMATOGRAPHY

BASIC PROTOCOL 2

This protocol describes a method developed by S.K. Farrand and colleagues to visualize AHLs using thin-layer chromatography (Shaw, 1997; Meyers, 2001). AHLs in assay samples are first separated on a C18 reversed-phase TLC plate. Agar medium containing the *lacZ*-based bioassay strain and Xgal is then overlaid on the TLC plate. AHLs with various retention factors (R_f) on TLC plates then activate the *lacZ* reporter to produce β-galactosidase and hydrolyze the Xgal to form blue spots.

Materials

Bacteria of interest
Medium appropriate to organism under study (e.g,. see *APPENDIX 2C*)
Ethyl acetate
60:40 (v/v) methanol/water
Preinduced cells (Support Protocol)
2× AT buffer (1:10 dilution of 20× AT buffer; see recipe)
1.5% water-agar (see recipe), 45°C
20 mg/ml 5-bromo-4-chloro-3-indolyl β-D-galactopyranoside (Xgal) in dimethylformamide (DMF)
10-ml syringe and 0.2-µm syringe filter
2-ml glass vial
TLC tank (30-cm diameter × 10-cm width × 27-cm height)
C18 reversed-phase TLC plates (200-mm layer; Baker or Whatman)

28° and 45°C water bath
Tape (to seal TLC plates)
Sealable plastic container to accommodate TLC plate

Additional reagents and equipment for thin-layer chromatography (TLC; Meyers, 2001)

1. Grow bacteria of interest to different time points in 2 ml appropriate medium.

   Time points are best established experimentally, a good starting point would be low (early log phase), medium (mid to late log phase), and high (stationary phase) cell densities to pinpoint at what time the bacteria of interest may produce autoinducer and to test for conditions favorable for AHL stability.

   Occasionally, the production of lactonases or medium pH changes caused by some strains may degrade the AHL produced. Therefore, it is necessary to collect samples at various growth points.

2. Microcentrifuge cells 1 min at 16,000× *g*, room temperature, remove the pellets and filter supernatants using a 0.2-μm syringe filter and 10-ml syringe. Use immediately or freeze up to 1 month at −20°C until use.

3. Extract 5 ml filtered culture supernatants by adding 5 ml ethyl acetate to the supernatant in a 50-ml flask and agitate vigorously until the ethyl acetate is evenly distributed. Let stand for 5 min to separate phases.

4. Transfer upper phase to a 25-ml beaker using a pipet. Repeat the extraction to the bottom phase and add the new upper phase to the same 25-ml beaker, for a total volume of 10 ml.

5. Evaporate or vacuum dry the collected upper phase solvent inside a hood. Resuspend the dried sample in 50 μl ethyl acetate to produce a concentrated AHL solution. Store the AHL sample in a 2-ml glass vial up to 1 month at −20°C.

6. Add 200 ml of 60:40 methanol/water to the TLC tank. Close the lid and let equilibrate 2 hr.

7. Use a pencil to draw a line 2 cm away from the bottom of the TLC plates. Apply 1 to 5 μl of the AHL samples along the line with a space of at least 1.5 cm between samples, and let air dry (∼5 min).

   Apply samples one at a time, and allow them to air dry between additions. This prevents the sample from diffusing too much, creating a more contained elution.

   Standards, such as synthetic AHLs, should be used here as a positive control. Culture medium can be used as a negative control if desired.

8. Place the TLC plate in the tank and develop until the solvent front runs to the top. Remove the plate and air dry.

   Make sure the sample loading line is not immersed in the solvent.

9. Thaw one vial of preinduced cells on ice. For each filtrate to be assayed, inoculate 2 μl preinduced cells into 2 ml AT medium without antibiotics. Grow ∼16 hr, until OD_{600} reaches 0.2 to 1 at 28°C.

   Antibiotics are not needed as they may interfere with β-galactosidase activity. In this incubation time frame plasmids will not be lost.

   Make a stock solution of cells in AT medium; for example, make a 20-ml solution with 20 μl preinduced cells for ten assay samples to be analyzed simultaneously. This ensures that all samples have the same starting concentration of the bioassay strain.

10. Prepare the detecting culture mix by combining 50 ml of the overnight culture of KYC55 (pJZ372)(pJZ384)(pJZ410) with 50 ml room temperature 2× AT buffer and 50 ml of 1.5% water-agar (maintained at 45°C). Add Xgal to a final concentration of 60 μg/ml. Mix thoroughly and maintain at 45°C.

    Melt water-agar in microwave and maintain resulting solution in a 45°C water bath before addition of 2× AT medium with the bioassay strain and Xgal. Upon addition of these ingredients, immediately place solution back in 45°C water bath until use.

11. Seal the dried TLC plate with tape along edges forming a "wall" of tape ~1-cm high around the plate. Spread the culture mix over the surface evenly to a thickness of ~0.5 cm.

    Use burner flame to get rid of bubbles when overlaying the detecting agar.

12. After the agar has solidified, incubate the coated plate for 12 to 18 hr in a 28°C water bath in a sealed plastic container and then examine for blue Xgal hydrolysis.

PREPARATION OF PREINDUCED AHL BIOASSAY STRAIN

SUPPORT PROTOCOL

The bioassay strain must be prepared and grown in minimal medium. This is called preinduction and is done to ensure that these cells will grow rapidly in minimal medium during the assay, so that assay results are reproducible. Once this stock has been prepared, it can be kept indefinitely with proper storage at −80°C.

Materials

AHL bioassay strain *Agrobacterium tumefaciens* KYC55 (pJZ372)(pJZ384)(pJZ410); see Zhu (2003)
LB medium (*APPENDIX 4A*) containing 1 μg/ml tetracycline, 100 μg/ml spectinomycin, and
100 μg/ml gentamycin
AT medium (see recipe) with and without 1 μg/ml tetracycline, 100 μg/ml spectinomycin, and 100 μg/ml gentamycin
15% (v/v) glycerol, sterile
28°C orbital shaker
2-ml microcentrifuge tubes

1. Grow AHL bioassay strain *Agrobacterium tumefaciens* KYC55 (pJZ372)(pJZ384)(pJZ410) in LB medium supplemented with antibiotics. Incubate on an orbital shaker to late-log phase (OD_{600} of 1; ~1×10^9 cfu/ml) at 28°C.

    This bioassay strain is used as an example. It cannot produce AHLs and has three plasmids containing P_{T7}-traR, a T7 polymerase gene, and a reporter traI-lacZ fusion.

2. Inoculate 1 ml LB culture into 100 ml AT medium supplemented with antibiotics. Incubate cultures on an orbital shaker to mid-log phase at 28°C.

3. Transfer cultures into 2-ml microcentrifuge tubes and collect cells by microcentrifuging 10 min at 12,000 rpm, room temperature, and discarding supernatants.

4. Resuspend cell pellets in 15% sterilized glycerol (1/20 of original volume). Divide into 100-μl aliquots and store indefinitely at −80°C.

    These cells are now preinduced.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

AT buffer, 20×

Per liter:
214 g KH_2PO_4
Adjust pH to 7.3 with KOH
Autoclave then cool to room temperature
Store up to 6 months at room temperature

AT medium

50 ml 20× AT salts (see recipe)
50 ml 20× AT buffer (see recipe)
10 ml 50% (w/v) glucose (see recipe)
890 ml H_2O
Store up to 6 months at room temperature

Autoclave salts and buffer separately, then cool solutions to room temperature. Filter sterilize glucose solution.

AT salts, 20×

Per liter:
40 g $(NH_4)_2SO_4$
1.56 g $MgSO_4$
0.152 g $CaCl_2$
0.1 g $FeSO_4 \cdot 7H_2O$
0.044 g $MnSO_4 \cdot H_2O$
Autoclave, then cool to room temperature
Store up to 6 months at room temperature

Glucose, 50% (100×)

Prepare a 50% (w/v) solution of glucose in H_2O
Filter sterilize
Store up to 6 months at room temperature

Water-agar, 1.5%

15 g agar per liter H_2O
Sterilize by autoclaving
Store up to 6 months at room temperature

Z buffer

Per liter:
16.1 g $Na_2HPO_4 \cdot 7H_2O$
5.5 g $NaH_2PO_4 \cdot H_2O$
0.75 g KCl
0.245 g $MgSO_4 \cdot 7H_2O$
2.7 ml 2-mercaptoethanol
Adjust to pH 7.0 using HCl
Store up to 6 months at 4°C

COMMENTARY

Background Information

A number of bacterial processes, such as antibiotic production, motility, and biofilm formation (see Section 1B), are regulated by the exchange of chemical signals that permit a bacterial community to coordinate its responses to environmental challenges or opportunities. The exchange of these signals enables all of the individuals in a community to participate in reaching a consensus, and is known as quorum sensing (Dunny, 1999; Miller, 2001; Whitehead, 2001). In many proteobacteria, these chemical signals consist of a set of diffusible acyl-homoserine lactones (AHLs), also called autoinducers. The key regulatory components of these signaling systems are LuxI-type proteins, which act as AHL synthases, and LuxR-type proteins, which serve as AHL receptors and AHL-dependent transcription factors (Fuqua, 1994; Zheng, 2006). All known AHLs contain invariant homoserine lactone moieties with highly variable fatty acyl groups. These acyl groups range in length from 4 to 18 carbon atoms. The C-3 carbon can be fully reduced or can bear hydroxyl or ketone substituents (Fuqua, 2001).

Detection and identification of cognate signal molecules has led to the discovery of new bacterial cell-cell signaling systems. Specifically, the detection of AHL molecules involved in quorum sensing has been facilitated by the development of a variety of bioassay strains. Such strains contain an easily assayable reporter gene and lack all AHL synthases, such that reporter activity requires exogenous AHLs for activation. Various reporter genes have been described, including *lacZ*, GFP, *lux*, and the production of an endogenous pigment. The *Agrobacterium tumefaciens* bioassay strain described here uses the T7 expression system to strongly overexpress the regulator TraR and, thus, increases sensitivity and broadens the molecule detection range in an *A. tumefaciens* AHL-synthase mutant. In the presence of exogenous AHLs, TraR can then activate a *traI-lacZ* reporter fusion, resulting in production of β-galactosidase (Zhu 1998, 2003). Because of the great sensitivity and broad range of AHL detection with this bioassay strain, it is a useful tool for detecting extremely low concentrations of AHLs, or possibly other

Table 1C.2.1 Troubleshooting ACL Detection Assays

Problem	Possible cause	Solution
Low *lacZ* activity	AHL concentration not high enough	Extract samples with ethyl acetate
High *lacZ* background	Rich medium	Change medium (the poorer medium, the better)
TLC spots diffused	AHL concentration is too high	Reduce the amount of sample loading
Xgal hydrolysis not seen over TLC plate/low *lacZ* activity in β-gal assay	Bacteria of interest do not produce AHL-type autoinducers under chosen time points	Try taking culture samples at earlier and later time points to adjust for molecule degradation or effects of cell density on AHL production
	Bacteria do not produce AHL molecules under these conditions	Change growth conditions, such as temperature and nutrient broth
	Culture conditions toxic to bioassay strains	Reduce the sample amount or extract samples with ethyl acetate before addition to assay culture
Bioassay strains fail to grow or grow too slowly	Toxicity in the sample	Reduce the sample amount or extract samples with ethyl acetate before addition to assay culture

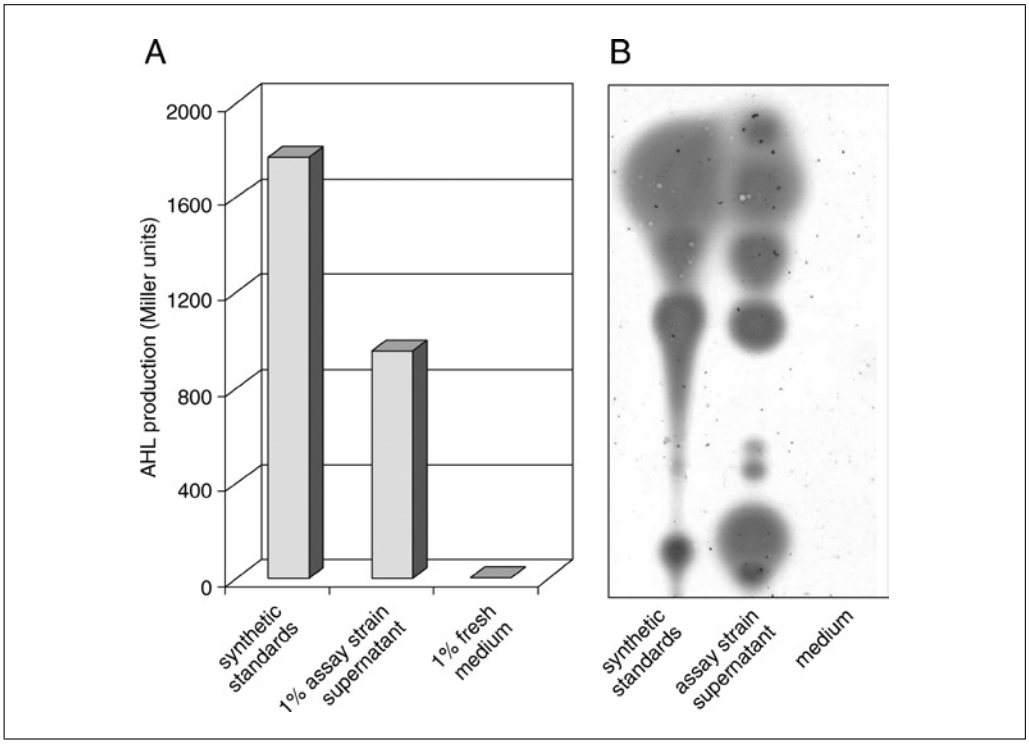

Figure 1C.2.1 An example of applying KYC55 (pJZ372)(pJZ384)(pJZ410) to detect AHL-like molecules from the spent medium of a specified Gram-negative bacterium using the liquid assay (**A**) and the TLC assay (**B**).

bioactive signal molecules. It could also have applications in AHL detection in dilute environmental samples or genomic libraries. Examples can be found in Williamson et al. (2005) and Zheng et al. (2006).

Critical Parameters

Agrobacterium strains have to grow at 28° to 30°C; they fail to grow at 37°C. Synthetic AHL standards are needed as positive controls and can be purchased from various companies (e.g., Sigma). It is important to note that many factors can affect the AHL content in experimental samples. For example, high medium pH and production of AHL lactonases may degrade AHLs in the supernatant. Thus, it may be necessary to test the AHL production under various growth conditions. For further details, consult the Troubleshooting section.

Troubleshooting

Commonly encountered problems with the procedures outlined in this unit, along with their possible causes and potential solutions, are given in Table 1C.2.1.

Anticipated Results

The bioassay for AHL-like signals described here is quite sensitive. Figure 1C.2.1 shows an example of the use of this bioassay to detect the AHL molecules from the supernatant of an unspecified bacterium. The liquid β-galactosidase activity assay showed over a 200-fold increase of *traI-lacZ* reporter induction as compared to the medium control. The same supernatant contained at least six different AHL-like molecules when assayed using the TLC plate. Practically, depending on the concentration of the sample assayed, a minimum of a ten-fold increase over the medium control is considered significant.

Time Considerations

Expect the complete autoinducer detection assay procedure to take ~2 days to complete. Sample preparation time varies depending on the rate at which the sample bacteria grow and what time points the sample cultures are removed. Expect the supernatant preparation (cell pelleting and filtration) to take ~5 to 10 min per sample. *LacZ* induction (overnight growth of bioassay strain) takes 12 to 16 hr to reach the proper concentration (OD_{600} of 0.2 to 1). Assaying for β-galactosidase using ONPG takes ~2 to 3 hr depending on the rate at which samples reach the desired endpoint.

The TLC assay will take ~2 days to complete (Meyers, 2001). Preparing the TLC assay sample (if extract is evaporated under vacuum), tank, and plate will take 2 to 4 hr. The

actual development of the TLC plate in the tank will take ~2 to 3 hr plus drying time. Overlaying the plate will take ~30 min. The coated TLC plate then needs to be incubated for 12 to 18 hr before assay results can be analyzed.

The prepared samples can be stored long term at −20°C. The preparation of the preinduced bioassay cells takes 2 days. This can be done ahead of time and the strains can be stored indefinitely at −80°C.

Detection and Analysis of Quorum-Quenching Enzymes Against Acyl Homoserine Lactone Quorum-Sensing Signals

Quorum sensing (QS) is a microbial community genetic regulation mechanism that controls biological functions of medical, agricultural, and industrial importance. Bacteria produce, detect, and respond to QS signals to synchronize target gene expression and thereby coordinate biological activities among a local population. *N*-acyl homoserine lactones (AHLs) are one family of the widely conserved signals in Gram-negative bacteria, and they regulate a range of important biological functions, including virulence and biofilm formation (Zhang and Dong, 2004). Several groups of AHL-degrading enzymes, including AHL-lactonase, AHL-acylase, and paraoxonases (PONs), have recently been identified in a range of living organisms, including bacteria and eukaryotes (Dong et al., 2000, 2002; Leadbetter and Greenberg, 2000; Zhang et al., 2002; Lin et al., 2003; Yang et al., 2005). Given their efficiency in degrading AHLs and blocking QS signaling, these inactivating enzymes are also known as quorum-quenching enzymes (Dong and Zhang, 2005).

This unit provides methods for detecting and analyzing enzyme activity related to AHL inactivation. The Basic Protocol describes an AHL diffusion plate bioassay, which when combined with Support Protocol 1, is suitable for rapid, large-scale screening and identification of AHL-inactivating enzymes. Procedures in Support Protocol 2 aim to determine whether the AHL-inactivating enzyme is a lactonase. Support Protocol 3 provides methods that allow quantitative determination of relative enzyme activity. Support Protocol 4 describes enzyme assays using cell-free protein extracts. Support Protocols 5 and 6 use HPLC to definitively characterize AHL-inactivating enzymes as AHL-lactonases or AHL-acylases, based on the physical and chemical properties of the enzyme reaction products, which can be distinguished by the high resolution power of HPLC with a suitable chromatographic column-solvent combination.

CAUTION: Follow all biosafety requirements relevant to the microorganism under investigation. All uncharacterized bacterial isolates are potentially infectious; handle them with care and dispose of them only after sterilization. Refer to *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for instructions on safe handling of microorganisms.

CAUTION: Dimethyl sulfoxide (DMSO), dimethylformamide, methanol, and tetracycline are hazardous; see *UNIT 1A.3* for guidelines on handling, storage, and disposal.

QUALITATIVE DETECTION OF AHL-INACTIVATING ENZYMES

BASIC PROTOCOL

This protocol describes a procedure for qualitative detection of AHL-inactivating activity. The protocol is based on two principles: (1) AHL signals diffuse easily in an agar plate (Zhang and Kerr, 1991), and (2) a sensitive reporter strain (biosensor) produces blue colonies on an agar plate supplemented with X-gal when sensing AHL signals (Piper et al., 1993; Zhang et al., 1993; Lin et al., 2003).

Materials

Biosensor organism: *Agrobacterium tumefaciens* NT1(*traR*, *tra*::*lac*Z749; Piper et al., 1993)

Contributed by Hai-Bao Zhang, Lian-Hui Wang, and Lian-Hui Zhang
Current Protocols in Microbiology (2007) 1C.3.1-1C.3.15

YEB medium with and without 50 μg/ml kanamycin and 10 μg/ml tetracycline (see recipe)
Glycerol (optional)
Test organisms (e.g., bacteria from soil, water, and plant or animal tissues)
10 μM *N*-3-oxo-octanoyl-L-homoserine lactone (3OC8HSL) and other AHLs (see Zhang et al., 1993; Sigma-Aldrich; Cayman Chemical): dilute in YEB medium
Minimal medium agar plates supplemented with 50 μg/ml X-gal (see recipe)

250-ml culture flasks
28°C incubator
Rotary shaker
96-well tissue-culture plates
UV chamber (Stratagene)
Marker pen
Ruler
Scalpel, sterile
Microcentrifuge with (optional) 96-well plate rotor
Plastic film (for sealing 96-well plates)

Prepare AHL biosensor and bacterial isolates

1. Grow AHL biosensor *A. tumefaciens* NT1(*traR*, *tra*::*lacZ*749) in a 250-ml flask containing YEB medium supplemented with 50 μg/ml kanamycin and 10 μg/ml tetracycline at 28°C, with shaking at 200 rpm to an OD_{600} of ~1.5.

   A. tumefaciens NT1(traR, tra::lacZ749) harbors two plasmids expressing TraR and the reporter gene lacZ under the tra promoter, respectively (Piper et al., 1993).

   The antibiotics are used to maintain the presence of the two plasmids, which also carry genes for resistance to the antibiotics.

2. If not using the biosensor cell cultures immediately, add glycerol to 20% (v/v) and store up to 1 year at −80°C.

3. Prepare individual bacterial isolates from soil, water, and plant or animal tissues using standard techniques (see Collins et al., 1989).

4. Inoculate individual bacterial colonies into 150 μl YEB medium in 96-well plates and incubate overnight at 28°C, with shaking at 200 rpm.

   Bacteria are the rich sources of novel enzymes. Incubations are generally at 28°C, and the overnight cultures are usually ready for analysis of AHL inactivation, typically performed in 96-well plates.

   Fresh cultures of other living organisms such as fungi, plant, and animal tissues can also be prepared using an appropriate medium (see Chun et al., 2004; Yang et al., 2005).

Set up AHL-inactivating reaction

5. Add 50 μl of 10 μM 3OC8HSL into each well, then add 50 μl fresh bacterial cultures or YEB medium (as a positive control). Incubate 3 to 5 hr at 28°C.

   For screening of AHL-inactivating enzymes, the authors recommend including 3OC8HSL, which is a common substrate for all the known AHL-inactivating enzymes. It is also the most sensitive signal for the biosensor A. tumefaciens NT1(traR, tra::lacZ749), which can detect levels of 3OC8HSL as low as 10 nM on diffusion plates (5 μl sample, equal to 0.05 pmol).

Prepare AHL bioassay plates

6. After solidification, aseptically cut the agar medium in the plate into separated bars of 1-cm width by removing 2- to 3-mm slices of between the agar bars, using a marker pen, a ruler, and a sterile surgical scalpel.

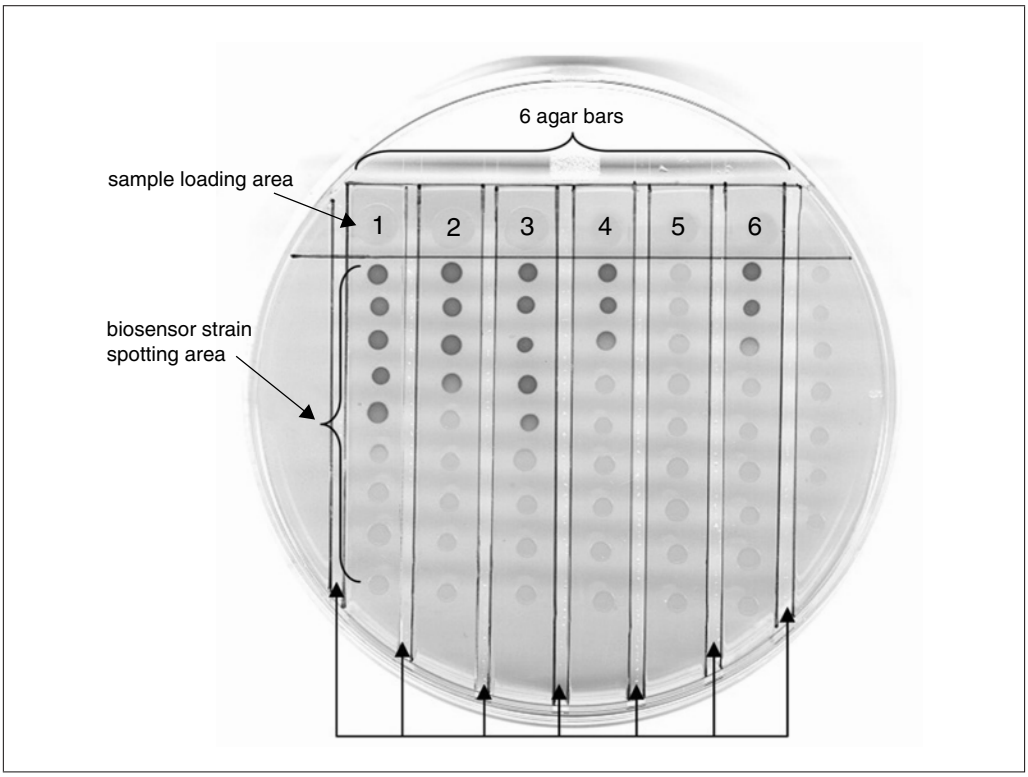

Figure 1C.3.1 The AHL bioassay plate. Blue spot indicates that the diffusible AHL signals were detected by the biosensor cells. Bar 1: the positive control (5 μM 3OC8HSL in YEB medium) was added. Bars 2 to 6: the reaction supernatants of five bacterial isolates were added, separately. The shorter distance of blue spots from the sample loading area in bars 2, 4, and 6 suggests that the bacterial samples may have AHL-inactivating activity, whereas no blue spot in bar 5 indicates a strong AHL-inactivating activity.

For the convenience of comparing different samples and measurement of distance, the agar bars in plate can be prepared as rectangles of equal length by cutting off the top and bottom parts. In general, six agar bars can be made from each 90-mm-diameter plate (see Lin et al., 2003 and Fig. 1C.3.1).

The minimal medium agar bars are used as the supporting material for both AHL diffusion and the growth of biosensor.

Perform the inactivation assay

7. Centrifuge the 96-well reaction plates (from step 4) 5 min at top speed in a microcentrifuge (or transfer the mixtures to microcentrifuge tubes for centrifugation).
8. Transfer 50 μl of each reaction supernatant to a well in a 96-well tissue culture plate and place the plate under UV light in a UV chamber for 0.5 hr to kill any remaining bacterial cells.
9. Add 5 μl reaction supernatant from each sample to one end of an agar bar.
10. Dilute the fresh culture or −80°C glycerol stock of *A. tumefaciens* NT1(*traR, tra::lacZ749*), to OD_{600} ~0.5 before use.
11. Using a micropipettor, spot ~0.5 μl drops at progressively further distances from the end of the agar bar loaded with samples. Include a positive control (the reaction mixture with only YEB medium and no bacteria) with 3OC8HSL solution; see step 4) in each plate for easy comparison.
12. Seal the plate using thin plastic film after the samples and the bacterial spots on the agar bars are absorbed and incubate 24 hr at 28°C.

13. After incubation, examine the bioassay plates for the presence of blue spots and measure their distance from the origin.

    The biosensor spot will turn blue in the presence of detectable AHL signal (e.g., see Lin et al., 2003 and Fig. 1C.3.1). Typically, the positive control with a final concentration of 5 μM 3OC8HSL produces several blue spots with more than a 2 cm diffusion distance. Any sample producing no blue spots or significantly fewer blue spots than the positive control suggests potential AHL-inactivating activity and is considered a positive bacterial isolate.

SUPPORT PROTOCOL 1

CONFIRM ENZYMATIC AHL INACTIVATION

AHL inactivation can be due to enzymes (Dong et al., 2000; Lin et al., 2003; Yang et al., 2005) or nonenzyme factors (Byers et al., 2002). This protocol describes a procedure to confirm that the AHL inactivation observed using the Basic Protocol is due to an enzymatic reaction. The procedure is based on the principle that protein enzymes are usually not heat stable and that an enzymatic reaction shows a relatively gentle progressive curve.

Additional Materials *(also see Basic Protocol)*

Bacterial isolate showing positive AHL-inactivating activity (identified using the Basic Protocol)

1. Transfer 100 μl fresh culture of each positive bacterial isolate (see Basic Protocol, step 13 annotation) into separate microcentrifuge tubes in duplicate.
2. Place one tube in boiling water bath for 10 min to kill bacterial cells and denature proteins.
3. Add the same volume of YEB medium containing 10 μM 3OC8HSL to each tube and incubate at 30°C with gentle shaking.
4. Remove 30 μl reaction mixture from both tubes at different time points (for example, 30, 60, 90, 120, min) after addition of AHL and place each into a well in a 96-well plate.
5. Assay as described in the Basic Protocol, steps 7 to 13.

   Progressive inactivation of AHL signals by the bacterial cells and loss of inactivation activity after boiling indicate the presence of a quorum-quenching enzyme.

SUPPORT PROTOCOL 2

DETERMINE WHETHER THE AHL-INACTIVATING ENZYME IS A LACTONASE

Several types of enzymes, including AHL-lactonase, PONs, and AHL-acylase, are capable of inactivating AHL signals (Dong and Zhang, 2005). This protocol describes a procedure for determining if the AHL-inactivating enzyme belongs to the lactonase group (including AHL-lactonases and PONs). It is based on the principle that the product of lactonases can be relactonized in acidic solution. This procedure can be used following the Support Protocol 1 after confirmation of the enzymatic AHL inactivation.

Additional Materials *(also see Basic Protocol)*

Bacterial isolate with confirmed AHL-inactivating enzyme (Support Protocol 1)
1 M HCl solution

1. Using bacteria confirmed as having AHL-inactivating enzymes (see Support Protocol 1), prepare a complete AHL-inactivating reaction as in the Basic Protocol, step 5, but double the volumes of 3OC8HSL and bacterial cultures.

2. Divide the reaction mixture into two 100-µl aliquots in microcentrifuge tubes.
3. To one aliquot, add 10 µl of 1 M HCl to acidify the reaction mixture (pH 1 to 2), and add 10 µl of water to the other aliquot as a control.
4. Incubate both tubes at room temperature.
5. Remove 5 µl of reaction mix from each treatment and control tube at different time points (5, 30, and 60 min after acidification) and assay as described in the Basic Protocol, steps 10 to 13.

   Progressive restoration of AHL activity in the acidified solution indicates a lactonase enzyme. Typically, >90% of degraded activity can be restored within 60 min after acidification (e.g., see Yang et al., 2005). In contrast, if the AHL activity is not restored under the acidic condition, then the enzyme that hydrolyzes AHL in the reaction mixture may be an AHL-acylase or other enzyme that has not yet been identified.

QUANTITATIVE ANALYSIS OF QUORUM-QUENCHING ENZYME ACTIVITY

SUPPORT PROTOCOL 3

This protocol describes a procedure for quantitative analysis of AHL-inactivating enzyme activity in bacterial isolates. It is based on the finding that the signal concentration-diffusion distance relationship can be accurately described by an exponential equation (Dong et al., 2000). Therefore, the amount of the AHL signal before and after the reaction can be calculated based on the diffusion distances of the signals in corresponding samples. The data are essential for determination and comparison of relative enzyme activity of different bacterial samples. The general assay procedure is the same as the Basic Protocol, with the addition of the steps on measurement of diffusion distances and calculation of a standard curve.

Additional Materials *(also see Basic Protocol)*

Methanol
Equation-fitting program (e.g., Microsoft Excel)

Establish a standard AHL diffusion curve

1. Prepare a 4 mM 3OC8HSL stock solution in methanol. Use this to produce a series of dilutions (e.g., 200, 20, 2, 0.5, 0.1, 0.05, and 0.01 µM).

   Standard AHL samples are used to determine the quantitative relationship between AHL quantity and its diffusion distance on the agar bars.

   For 3OC8HSL, the linear concentration range of detection by biosensor A. tumefaciens NT1(traR, tra::lacZ749) is from 20 nM to 200 µM using this diffusion plate method. For other AHL signal with six-carbon fatty acid side chain and more, the recommended detection range is from 200 nM to 200 µM. For detection of four-carbon fatty acid side chain signal, such as N-butyryl-L-homoserine lactone, another biosensor, Chromobacterium violaceum strain CV026, should be used (McClean et al., 1997).

   Because the methanol in solution might affect the signal diffusion as well as enzyme activity, it is recommended that the final concentration of methanol in each dilution be kept constant and <6%. For example, to prepare a series of 3OC8HSL working solutions in 5% methanol, one can prepare the high end 3OC8HSL working solution (i.e., 200 µM) in 5% methanol, then prepare the other working solutions (i.e., 20 µM, 2 µM, 0.2 µM etc) by diluting sequentially with 5% methanol (Table 1C.3.1).

2. Load 5 µl of each dilution onto a diffusion plate as described in the Basic Protocol, step 9, and incubate 24 hr at 28°C.

Table 1C.3.1 Preparation of AHL Dilutions in 5% Methanol

	AHL[a] dilutions (μM)					
	200	20	2	0.5	0.1	0.05
AHL solution	10 μl of 4 mM AHL in methanol	20 μl of 200 μM AHL	20 μl of 20 μM AHL	50 μl of 2 μM AHL	40 μl of 0.5 μM AHL	100 μl of 0.1 μM AHL
Water (μl)	195	0	0	0	0	0
5% methanol (μl)	0	180	180	150	160	100
Total volume (μl)	200	200	200	200	200	200

[a]For example, N-3-oxo-octanoyl-L-homoserine lactone (3OC8HSL).

3. After incubation, measure the distance from the last induced blue spot to the origin of the 3OC8HSL spot in each agar bar to determine the diffusion distance of 3OC8HSL.

4. Establish the relationship between the concentration of 3OC8HSL loaded on the agar bar (y, micromolar) and the 3OC8HSL diffusion distance (x, centimeters) by fitting a set of x and y values to a logarithmic equation (Fig. 1C.3.2) using Microsoft Excel.

   The relationship between 3OC8HSL concentration and diffusion distance has been empirically determined to be logarithmic, i.e., the coefficient of determination (R^2) for the logarithmic curve is higher relative to other curves (e.g., linear or exponential), indicating the best fit.

   A typical logarithmic equation describing the relationship between the concentration of 3OC8HSL loaded on agar bar (y, micromolar) and the 3OC8HSL diffusion distance (x, centimeters) is as follows:

   $\log y = 2.033x - 4.382$

   The coefficient of determination (R^2) of the above logarithmic equation is equal to 0.991, indicating a highly correlated relationship between the concentration and diffusion distance on agar plate of the signal.

   The above equation can be generally used to determine relative 3OC8HSL concentration for any sample using 5 μl of sample in the diffusion plate assay described above. However, for accurate concentration determinations, it is recommended that each experimenter build up a standard curve for each AHL signal of interest to take into account individual differences in patterns of sample handling and measurement.

   It is now possible to quantitatively determine and compare the relative enzyme activities of the positive bacterial isolates identified.

Quantify the remnant AHL in a reaction mixture

5. Follow the Basic Protocol to conduct the bioassay for detection of the remnant AHL signals at different time points after initiation of the reaction.

   The same procedures can be adopted for analysis of purified AHL-degrading enzyme (Dong et al., 2000), by scaling down the amount of purified enzyme used in each reaction (10 to 50 ng).

6. Determine the concentration of remaining AHL in reaction mixture using the standard equation. Calculate the amount of degraded AHL by deducting the remnant AHL from the total amount of AHL used in reaction.

   The enzyme activity can be expressed as AHL degraded (pmol) per minute per milliliter of culture ($OD_{600} = 1$) or per microgram total protein or per nanogram enzyme, depending on the nature of testing sample.

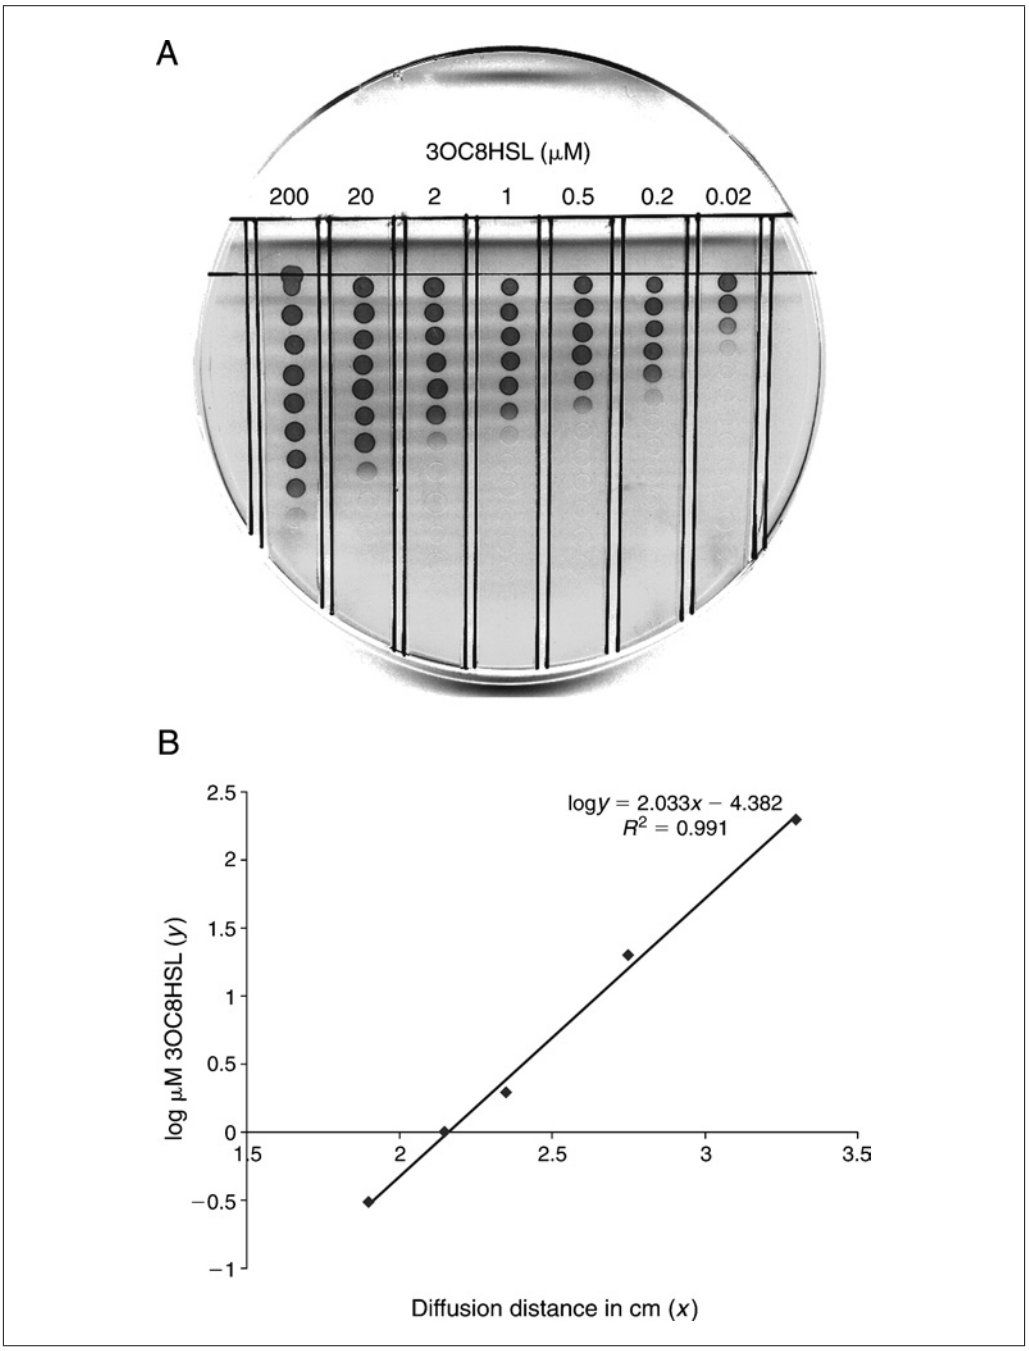

Figure 1C.3.2 Establishment of a standard curve for quantification of AHL. (**A**) Bioassay results for 3OC8HSL dilutions. (**B**) The standard curve for 3OC8HSL concentrations (μM) versus their corresponding diffusion distances in an agar bar (cm) generated by the Microsoft Excel program.

ASSAYING ENZYME ACTIVITY USING CELL-FREE TOTAL PROTEIN EXTRACTS

SUPPORT PROTOCOL 4

As an alternate to using bacterial or other organism cultures as samples for assay of AHL-inactivating activity, AHL-inactivating enzyme activity can also be assayed using cell-free protein extracts after confirming that the inactivation is enzymatic (Support Protocol 1). This protocol describes the procedures for total protein extraction from bacterial cultures and subsequent AHL-inactivation routine assay using Basic Protocol. In combination with Support Protocols 2 and 3, this protocol allows qualitative and quantitative analysis of AHL-inactivating enzymes in protein extracts.

Additional Materials *(also see Basic Protocol)*

Phosphate-buffered saline containing potassium (KPBS; *APPENDIX 2A*)
Sonicator (e.g., Digital Sonifier; Branson Ultrasonics)

1. Inoculate bacterial cells into 50 ml YEB medium. Incubate overnight at 28°C, with shaking at 200 rpm.
2. Centrifuge cultures 5 min at 10,000 × *g*, 4°C.
3. Wash the cell pellet once by adding 50 ml ice-cold KPBS and centrifuging as in step 2.
4. Resuspend the bacterial cells in 2 ml KPBS and sonicate on ice following the manufacturer's instructions. Centrifuge 20 min at 10,000 × *g*, 4°C. Retain the supernatant (cell-free total protein extracts).
5. Determination protein concentration using Bradford method (*APPENDIX 3A*) and reagents from Bio-Rad.
6. Place supernatant aliquots containing ~100 to 500 μg total proteins into two 1.5-ml microcentrifuge tubes for each sample. Keep one tube on ice. Boil the other tube for 5 min and then place on ice.
7. To each aliquot, add 3OC8HSL to a final concentration of 20 μM and mix. Incubate the reaction mixture at 37°C.
8. At different reaction time points (e.g., 0, 15, 30, 45, and 60 min), place a 20-μl aliquot of reaction mixture into a microcentrifuge tube. Heat the removed aliquots in a boiling water bath for 3 min to terminate the reaction.
9. Centrifuge the timed samples and take 5 μl supernatant from each tube to perform a diffusion plate bioassay using the Basic Protocol.
10. Using Support Protocol 3, calculate the enzyme activity in the total protein samples based on the amount of AHL inactivated, the amount of total proteins used in reaction, and the reaction time.

SUPPORT PROTOCOL 5

HPLC IDENTIFICATION OF AHL-LACTONASE HYDROLYSIS PRODUCTS

The Basic Protocol in combination with Support Protocol 1 provides a simple quantitative AHL diffusion plate assay, which is suitable for rapid and large-scale screening of bacterial strains capable of inactivating AHL. Support Protocol 2 describes an easy way to predict a lactonase as the AHL inactivating factor. If acidification of the reaction mixture described in Support Protocol 2 is able to restore the AHL activity, the enzyme of interest is likely to be a lactonase. HPLC analysis (optimized following the methods described by Dong et al., 2001) can be reliably used to confirm that the enzyme of interest is a lactonase (e.g., AHL-lactonase or PON) by showing that the enzymatic hydrolysis product has an identical retention time as 3OC8HS.

Additional Materials *(also see Support Protocol 4)*

50:50 methanol (HPLC grade, Merck)/water (HPLC grade or Milli-Q-purified)
50 mM *N*-3-oxo-octanoyl-L-homoserine lactone (3OC8HSL; Sigma-Aldrich) stock solution in methanol
10 mM *N*-3-oxo-octanoyl-L-homoserine (3OC8HS) stock solution: prepared by incubating 10 mM 3OC8HSL (Sigma-Aldrich) in 100 μl 200 mM NaOH and 100 μl DMSO for 4 hr at 25°C

HPLC column: C18 reverse-phase column, 4.6 × 250 mm, 5 μm (Symmetry)
HPLC system: Alliance 2690 separations module, and 996 photodiode array detector (Waters)
0.45-μm PTFE filter (Waters)

Additional reagents and materials for preparing bacterial cell-free extracts (Support Protocol 4)

1. Connect a C18 reverse-phase column to a Waters Alliance 2690 separation module and a Waters 996 photodiode array detector. Equilibrate by eluting isocratically with 50:50 methanol/water (v/v) at a flow rate of 1 ml/min for at least 1 hr.
2. Prepare bacterial cell-free protein extracts as described in Support Protocol 4, steps 1 to 5.

   If the gene encoding AHL-inactivating enzyme has been cloned, it is convenient to purify the enzyme by routine techniques (for references, see Dong et al., 2000; Lin et al., 2003).
3. To 0.3 ml of the cell-free protein extracts containing ~500 μg total proteins (or 50 ng purified enzyme), add 3OC8HSL to final concentration of 1 mM in a 1.5-ml microcentrifuge tube with a final reaction volume of 0.4 ml.
4. Add the same concentration of 3OC8HSL and 3OC8HS to KPBS buffer as a negative and positive control, respectively.
5. Incubate the reaction mixture 30 to 60 min at 37°C with gentle shaking.

   Typically, >80% of AHL should be degraded in the first 30 min of enzymatic reaction.
6. Denature the proteins in the reaction mixture by boiling in a water bath for 3 min.
7. Filter the reaction mixture through a 0.45-μm PTFE filter. Collect the filtrate for HPLC analysis.

   The purpose of filtration is to get rid of undissolved particles, which could block or even damage the HPLC system.
8. Inject 20 μl of filtered reaction mixture and negative and positive controls, at separate times, into the calibrated C18 reverse-phase column. Elute isocratically with 50:50 methanol/water at a flow rate of 1 ml/min.

   The retention times of 3OC8HSL and 3OC8HS are ~8.1 and 3.8 min, respectively.

   If HPLC analysis shows that the enzymatic hydrolysis product has an identical retention time as 3OC8HS, the AHL-inactivating enzyme under investigation should be a lactonase (e.g., AHL-lactonase or PON).

   The retention times of AHL and its degradation products are provided as reference only. They may vary depending on the make and age of HPLC column even when using the same solvent system.

   Under the conditions used in this protocol, all AHLs can be measured with different retention time from ~4 min to more than 30 min, depending on the acyl chain of AHLs. The retention time of these signals can be adjusted to ~10 min by altering the composition of the mobile phase, i.e., the percentage of methanol and water (see Table 1C.3.2). AHL should be dissolved in methanol as a stock solution of 50 mM, which can be diluted with water to an indicated concentration before analysis.

   Unlike gradient elutions where a continuous change in the composition of the mobile phase is employed, isocratic separations are performed with a constant concentration of the eluent or mobile phase.

Table 1C.3.2 Retention Times and Mobile Phase for Representative AHLs

AHL	Retention time (min)	Mobile phase (methanol:water)
3-HO-C4-HSL	7.2	35:65
C4-HSL	7.7	40:60
3-oxo-C6-HSL	9.3	40:60
C6-HSL	8.6	45:55
3-oxo-C8-HSL (3OC8HSL)	8.1	50:50
C8-HSL	9.6	50:50
3-oxo-C10-HSL	12.5 or 15.3	60:40 or 50:50
C10-HSL	11.8	65:35
3-oxo-C12-HSL	9.9	75:25

SUPPORT PROTOCOL 6

HPLC IDENTIFICATION OF AHL-ACYLASE HYDROLYSIS PRODUCTS

If the AHL-inactivating enzymes identified using the Basic Protocol and Support Protocol 1 are not predicted to be lactonases using the methods in Support Protocol 2 (i.e., if acidification of the reaction mixture is not able restore the AHL activity), the enzyme of interest is likely to be an AHL-acylase (Leadbetter and Greenberg, 2000; Lin et al., 2003). AHL-acylases hydrolyze the amide bond of AHL to generate two products: homoserine lactone (HSL) and a fatty acid. Because HSL is extremely hydrophilic and hard to resolve from the buffer fraction in HPLC analysis, it is difficult to detect the HSL product peak with the HPLC regime designated for AHL analysis (Lin et al., 2003). However, the HSL fraction can be resolved using a dansylation technique. Dansylation increases the hydrophobicity of HSL, making it more readily resolved during HPLC separation and enabling reliable identification of the AHL-inactivating enzyme as an acylase.

Materials

N-3-oxo-octanoyl-L-homoserine lactone (3OC8HSL; Sigma-Aldrich) in KPBS (see *APPENDIX 2A* for KPBS; for purified enzyme assay)
Purified enzyme (Lin et al., 2003)
3OC8HSL (solid; for cell debris assay)
Cell debris from 2 ml bacterial cultures (Support Protocol 4, step 4 pellet)
Homoserine lactone (HSL; Sigma-Aldrich) standard
2.5 mg/ml DANSYL chloride (Sigma-Aldrich) in acetone
0.2 M HCl

Additional reagents and equipment for HPLC (see Support Protocol 5)

1. Equilibrate a C18 reverse-phase column as described in Support Protocol 5, step 1.

2a. *When using purified enzyme:* Incubate 3 mM 3OC8HSL in 0.5 ml KPBS with ~100 ng purified enzyme 3 hr at 37°C.

The final concentration of KPBS is not critical.

2b. *When using cell debris:* Incubate 3 mM 3OC8HSL in 0.5 ml cell debris 3 hr at 37°C. Mix the reaction solution constantly by shaking until completion of the digestion (~3 hr), then centrifuge 10 min at 10,000 × *g*, and collect the supernatants for step 3.

Complete digestion can be confirmed by using the Basic Protocol. Because the free amino acids in cell-free protein extracts can interact with the dansylation reagent, i.e., DANSYL chloride, which increases the difficulty to resolve the DANSYL-HSL fraction,

it is recommended to use the purified AHL-inactivating enzyme (Lin et al., 2003) or the KPBS buffer–washed cell debris because the cell membrane fraction (cell debris) contains significantly higher AHL-acylase activity than cell-free protein extracts.

3. For DANSYL chloride derivatization, add 100 µl of the digested mixture and a 1.5 mM HSL standard to an equal volume of 2.5 mg/ml DANSYL chloride, respectively. Incubate 4 hr at 40°C.
4. After evaporation to dryness, add 50 µl of 0.2 M HCl to the sample to hydrolyze any excess DANSYL chloride.
5. Conduct HPLC analysis as in Support Protocol 5, steps 7 and 8; dilute the samples when necessary before injection.

   It is necessary to dilute the sample when the UV absorbance is >2.

   If the enzymatic digestion mixture has a product peak with identical retention time as the dansylated HSL standard (about 2.9 min under the above conditions), and shares a similar UV spectrum, the AHL-inactivating enzyme under investigation is identified as an AHL-acylase.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Minimal medium agar supplemented with 50 µg/ml X-gal

To 1 liter H_2O add:
2.0 g mannitol
2.0 g $(NH_4)_2SO_4$
10.5 g K_2HPO_4
4.5 g KH_2PO_4
0.2 g $MgSO_4.7H_2O$
5 mg $FeSO_4$
10 mg $CaCl_2$
2 mg $MnCl_2$
15 g agar
Adjust pH to 7.2 with 1 M HCl or 1 M NaOH, if necessary
Autoclave
Cool to ~50°C
Add 1 ml X-gal 50 mg/ml 5-bromo-4-chloro-3-indolyl-ß-D-galactopyranoside (X-gal; prepare in pure dimethylformamide and store up to 6 months at −20°C)
Pour into 90-mm petri dishes using 20 ml per plate
Store up to 2 weeks at 4°C

YEB medium with and without 50 µg/ml kanamycin and 10 µg/ml tetracycline

To 1 liter H_2O add:
10 g Bacto-tryptone
5 g yeast extract
5 g NaCl
5 g sucrose
0.5 g $MgSO_4.7H_2O$
Adjust pH to 7.0 with 1 M HCl or 1 M NaOH, if necessary
Autoclave
Cool to <50°C

continued

Add 50 mg/ml kanamycin (prepare stock in water and store up to 6 months at −20°C) to 50 μg/ml

Add 10 mg/ml tetracycline (prepare stock in 100% ethanol and store up to 6 months at −20°C) to 10 μg/ml

Store up to 2 weeks at 4°C

COMMENTARY

Background Information

The exciting findings that QS signals are involved in regulation of a range of important biological functions—in particular, the expression of virulence genes and formation of biofilms (Section 1B)—provide an important impetus for screening novel enzymes and inhibitors that interfere with bacterial QS. The first gene encoding an AHL-inactivating enzyme (*aiiA*) was cloned from soil bacterial isolates belonging to a Gram-positive *Bacillus* species, after screening more than 500 bacterial isolates and strains using the diffusion plate assay described in the Basic Protocol (Dong et al., 2000). The enzyme was later characterized as an AHL-lactonase (Dong et al., 2001).

Shortly after the discovery of the first enzyme, a bacterial strain (*Variovorax paradoxus*) capable of using AHL molecules as the sole sources of energy and nitrogen was reported (Leadbetter and Greenberg, 2000). Presence of homoserine lactone in the AHL metabolic mixture of *V. paradoxus* suggested that the bacterium might carry a second enzyme, an AHL-acylase. The same diffusion plate protocol helped to identify and clone the first reported AHL-acylase gene (*aiiD*) from a *Ralstonia* species as the result of collaboration by three laboratories (see Lin et al., 2003). These two groups of quorum-quenching enzymes (AHL-lactonases and AHL-acylases) have now been identified in numerous bacterial strains belonging to more than ten bacterial species (for a more recent review, see Dong and Zhang, 2005).

Intriguingly, lactonase-like enzyme activity was recently found in certain human tissues (Chun et al., 2004) and in the sera of all mammalian species tested (Yang et al., 2005). The purified human paraoxonases, especially PON2, hydrolyze several tested AHL signals (Draganov et al., 2005). Expression of mouse PON1, PON2, and PON3 enzymes in animal cells significantly boosted their ability to degrade a range of AHL signals (Yang et al., 2005). The mammalian paraoxonase family consists of three members: PON1, PON2, and PON3. PON1 was initially identified by its ability to hydrolyze toxic organophosphate and was subsequently shown to play a role in protection against atherosclerosis by hydrolyzing the derivatives of oxidized cholesterol and phospholipids (for a review, see Draganov and La Du, 2004).

The known AHL-inactivating enzymes can be grouped into two categories based on the site of action in the AHL substrates (for a review, see Dong and Zhang, 2005). AHL-lactonases and paraoxonases (PONs) belong to the lactonase group that catalyze the hydrolysis of the lactone ring of AHL signals to produce corresponding acyl homoserines (Dong et al., 2001; Zhang et al., 2002; Yang et al., 2005), whereas AHL-acylases break the amide linkage of AHLs to release homoserine lactone and the corresponding fatty acids (Leadbetter and Greenberg, 2000; Lin et al., 2003). In an acidic buffer, the acyl-homoserine can reform into AHL by restoration of the lactone ring. In contrast, the amide linkage between homoserine lactone and fatty acid cannot be restored under the same conditions (see Fig. 1C.3.3 for illustration).

Evidence is emerging regarding the roles of these quorum-quenching enzymes in microorganisms and eukaryotes. The AHL-lactonase produced by *Bacillus* species was shown to play a role in microbe-microbe interactions (Dong et al., 2004). The same enzyme produced by *Agrobacterium tumefaciens* is implicated in quorum sensing signal turnover when the bacterial pathogen encounters starvation stresses (Zhang et al., 2002; Zhang et al., 2004). However, the physiological role(s) and natural substrates of AHL-acylases and PON enzymes are far from clear (Leadbetter and Greenberg, 2000; Lin et al., 2003; Draganov and La Du, 2004; Yang et al., 2005). Microbe-microbe and pathogen-host interactions are ubiquitous in natural ecosystems, and diverse bacterial species adopt QS mechanisms to regulate a range of important biological functions relating to infection and survival. Given these observed phenomena, investigation of the roles of such enzymes in their natural hosts could provide new insights about immunity in mammalian species and about complexity and mechanisms of microbial interactions in ecosystems (Zhang and Dong, 2004).

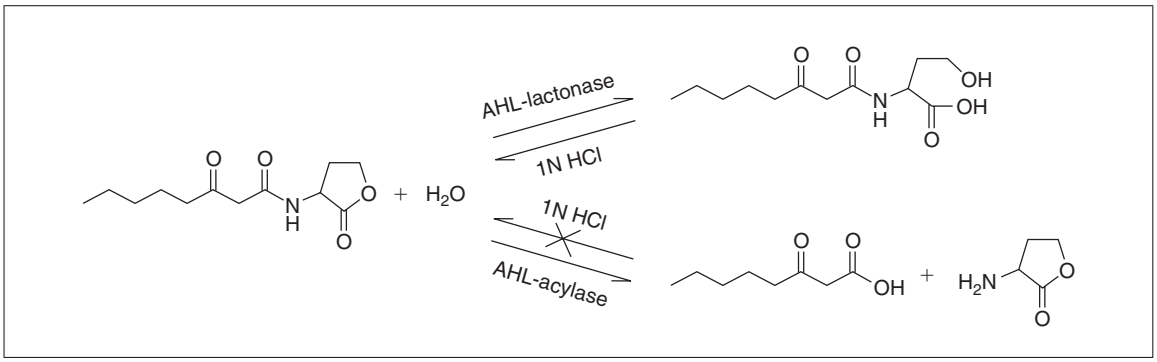

Figure 1C.3.3 Enzymatic inactivation of AHL by AHL-lactonase and AHL-acylase. Unlike the AHL-acylase hydrolysis products, the hydrolysis product of AHL-lactonase or paraoxonases (PONs) can reform AHL by acidification.

The quorum-quenching enzymes appear to have much potential in biotechnological applications. These enzymes have been used as tools for probing the biological functions of AHL signals in bacterial pathogens (Dong et al., 2000; Lin et al., 2003; Molina et al., 2005). Expression of these enzymes in transgenic plants efficiently quenches microbial QS signaling and blocks pathogenic infections (Dong et al., 2001; Zhang, 2003). Detection and analysis of quorum-quenching enzymes have become routine in microbial research in exploring new ways of controlling bacterial infections.

Critical Parameters

AHL signals are not very stable in aqueous solutions; enzymatic reactions should not proceed for more than 6 hr.

AHL biosensor strains other than those described in this unit may be used provided they are sensitive to the low level of AHL signals used in this unit.

For those biosensor strains with the reporter gene carried on a plasmid, it is important to supply appropriate antibiotics in growth medium to prevent loss of the plasmid construct during propagation of cultures.

Certain enzymes such as AHL-acylase (Lin et al., 2003) are membrane associated. When AHL-inactivating activity is detectable using bacterial cultures but not using cell-free total protein extracts, one can use the cell debris suspension to replace total protein extracts for enzyme activity assay.

Support Protocol 3 is designed for quantitative analysis of relative enzyme activity of different samples. The accuracy of analysis is dependent on the reliability of standard curve and accurate determination of diffusion distance.

Anticipated Results

The Basic Protocol is designed for rapid and reliable screening of biological samples with AHL-inactivating enzyme activities. Numerous bacterial isolates carrying either AHL-lactonase or AHL-acylase have been identified using this protocol or similar ones; however, there may be other types of AHL-inactivating enzymes. In theory, there could be at least four types of enzymes that could degrade AHL signals, including lactonases and decarboxylases that could hydrolyze the lactone ring as well as acylases and deaminases that might separate the homoserine lactone moiety and the acyl side chain (for details, see Dong and Zhang, 2005).

The lactone ring broken by a decarboxylase should not be restorable by acidification; the product of an AHL-decarboxylase should have an HPLC retention time different from that of an AHL-lactonase because the products differ in hydrophobicity. Therefore, both the acidification procedure (Support Protocol 2) and the HPLC method (Support Protocol 5) described in this unit should be sufficient for distinguishing a lactonase from a decarboxylase.

Degradation of AHL by a deaminase will produce a fatty acid amide molecule, which could also be dansylated by DANSYL chloride. The HPLC regime described in the Support Protocol 5 might not be able to resolve short chain (less than six carbons) dansylated fatty acid amide from dansylated homoserine lactone. But the potential problem could be resolved by analyzing several AHL signals of different acyl side chain lengths.

By measuring the peak area of AHL and its product using the built-in software in the HPLC equipment, Support Protocols 5 and 6 can also be used to quantify quorum-quenching enzyme activity. It is particularly

useful for analysis of enzyme kinetics against a range of AHL substrates (Wang et al., 2004).

Time Considerations

For the Basic Protocol, initiating growth of biosensor and bacterial isolates can be done in the morning of the first day; setting up the reaction and bioassay will use the morning and afternoon, respectively, of day 2; results will be obtained on day 3. Confirmation of enzymatic AHL inactivation (Support Protocol 1) and testing AHL-lactonase (Support Protocol 2) can be performed simultaneously and can be completed within 3 days. Preparation of a standard curve (Support Protocol 3) will take 2 days if the biosensor is ready. For HPLC analysis (Support Protocols 5 and 6), growth of bacterial cells and preparation of protein extracts or purification of enzyme will take ~2 days; the enzymatic reaction and HPLC analysis can be accomplished within one day for each type of enzyme.

Example of Real-Time Quantitative Reverse Transcription–PCR (Q-RT-PCR) Analysis of Bacterial Gene Expression during Mammalian Infection: *Borrelia burgdorferi* in Mouse Tissues

Quantitative reverse transcription–PCR (Q-RT-PCR) is an important tool used to measure the expression level(s) of a gene(s) of interest in a wide variety of experimental settings. An important application of this procedure involves the detection and quantification of bacterial transcript levels within infected mammalian host tissues. This unit focuses on Q-RT-PCR analysis of the spirochete *Borrelia burgdorferi* within infected mouse tissues. As bacterial infection progresses, the number of bacteria within a tissue decreases. Q-RT-PCR is the most powerful and reliable method for detecting gene expression by a bacterial population whose numbers greatly reduce as infection time increases. Specifically, this unit details the extraction of RNA from infected mouse tissues, removal of contaminating genomic DNA from the purified RNA, preparation of cDNA and genomic DNA standards, LightCycler-based PCR, and a relative quantification analysis of the cDNA.

CAUTION: Borrelia burgdorferi is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

NOTE: Protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals. Follow all appropriate guidelines for the use and handling of infected animals. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

EXTRACTION OF RNA FROM *B. BURGDORFERI*-INFECTED MOUSE TISSUES

BASIC PROTOCOL 1

This protocol describes the pulverization of frozen *B. burgdorferi*–infected mouse tissues with a frozen RNase-free crucible and pestle, homogenization with a tissue homogenizer, and RNA extraction with a Trizol reagent (Chomczynski and Sacchi, 1987). Although the procedures described herein are for *B. burgdorferi*, the instructions given for the storage, handling, and processing of infected tissues are universally applicable. In addition, Trizol reagent has been widely used to extract RNA from numerous Gram-positive and Gram-negative bacteria cultivated under a variety of experimental settings (Chomczynski and Sacchi, 1987; Chomczynski and Mackey, 1995).

CAUTION: Trizol contains phenol, which is a poison and skin irritant. 1-Bromo-3-chloropane is also hazardous. Use in a certified fume hood and consult the Material Safety Data Sheets (MSDS) accompanying these chemicals for instructions on personal protection, use, storage, and disposal.

IMPORTANT NOTE: The use of RNase-free solutions, containers, pipettors, and benchtops is tantamount to the success of this protocol. Hands are significant sources of RNases, therefore, wear gloves at all times and change them frequently. Solutions are made RNase-free via the addition of DEPC (di-ethyl-pyrocarbonate) or RNA Secure (Ambion; also see *APPENDIX 2A*). Spray benchtops and micropipettors with RNase-Away (Fisher Scientific), and bake glassware in an oven to kill RNases. Only use sterile, RNase-free polyethylene

Contributed by Jennifer C. Miller
Current Protocols in Microbiology (2005) 1D.3.1-1D.3.28

or polypropylene test tubes. If possible, keep a separate set of pipettors used only for RNA-extraction procedures. See Sambrook et al. (1989) for detailed instructions on maintaining RNase-free conditions.

Materials

RNase-Away (Fisher Scientific)
Dry ice
Trizol reagent, stored at 4°C
RNAsecure resuspension solution (Ambion), stored at −20°C
Cryotubes containing *B. burgdorferi*–infected tissue, −80°C
Sterile, DEPC-treated, double-distilled water (*APPENDIX 2A*)
5% (w/v) SDS (prepared in sterile, DEPC-treated water)
1-Bromo-3-chloropane
2- Propanol (isopropanol)
75% ethanol (diluted in sterile, DEPC-treated water)

Powder-free exam gloves
Microcentrifuge tube racks
1-ml, 200-µl, and 20-µl micropipettors and corresponding RNase-free barrier tips
4 9/16–in. (~11.59-cm) blunt forceps
Ceramic crucible and pestle
Variable speed digital Dremel homogenizer (Fisher Scientific)
Ice buckets with lids
Aluminum foil cut into ~2 × 2–in. (~5 × 5–cm) squares
Sterile 12 × 75–mm, 5-ml polystyrene round-bottom conical tubes
Sterile, RNase-free 5-ml conical tubes (Ambion)
Sterile, RNase-free 1.5-ml microcentrifuge tubes (Ambion)
60°C heating block
50-ml polypropylene conical tubes, sterile
Refrigerated microcentrifuge, 4°C
Freezer boxes

Prepare equipment and reagents for homogenization

1. Wearing gloves, spray work bench, tube racks, micropipettors, forceps, crucible and pestle, and dremel portion of homogenizer with RNase-Away. Allow to air dry.

   To ensure successful RNA extraction, all equipment and work areas must remain RNase free for the duration of these experiments.

2. Fill one ice bucket with dry ice and place the 4 9/16–in. (~11.59-cm) blunt forceps, crucible, and pestle into the bucket. Place one ~2 × 2–in. (~5 × 5–cm) square of aluminum foil inside the crucible. Place lid on ice bucket and allow equipment to equilibrate.

   The items in the bucket will become sufficiently cold within 10 to 15 min. During equilibration, the remaining preparation steps listed below may be carried out.

3. Label 5-ml conical tubes (one per tissue) and 1.5-ml microcentrifuge tubes (two per tissue) with a permanent ink pen. Change gloves.

   Gloves must be changed frequently to maintain RNase-free conditions.

4. Using a 1-ml micropipettor, pipet 1 ml Trizol reagent into each labeled 5-ml conical tube.

5. Fill the second ice bucket with ice and place the 5-ml conical tubes containing Trizol reagent on the ice.

6. Remove the RNAsecure resuspension solution from −20°C and place in a 60°C heating block.

   The RNAsecure resuspension solution must be pre-equilibrated to 60°C before RNA can be resuspended in this solution.

Homogenize frozen B. burgdorferi–infected tissue samples

7. Once the equipment placed on dry ice have sufficiently equilibrated, remove one cryotube containing *B. burgdorferi*–infected tissue from −80°C, and place on dry ice. Change gloves.

   If working with spleen, proceed directly to step 10. Due to the high amount of RNase activity present within spleen tissue, this organ is directly homogenized without prior pulverization. This technique consistently results in increased quantities of high-quality RNA. For all other tissues, proceed to step 8.

8. Working quickly over the dry ice bucket, remove the frozen tissue from cryotube with forceps and wrap in the frozen aluminum foil square. Place wrapped tissue in the frozen crucible on dry ice.

9. Using the frozen pestle, quickly pulverize the foil-wrapped tissue within the crucible.

   For most frozen tissues, two to three applications of the pestle are sufficient to break the frozen tissue into pieces suitable for homogenization. Do not allow the pestle or tissue to thaw, as RNases can more easily degrade the RNA if samples or equipment become warm.

10. Quickly unwrap the foil. Using the forceps, quickly and carefully place all pulverized tissue pieces into the 5-ml conical tube containing Trizol reagent and place tube back on ice.

11. Keeping the tube on ice, use setting five on the tissue homogenizer to completely homogenize the tissue pieces within the Trizol reagent.

    This setting is sufficient to completely homogenize most tissues with only three to four strokes. Due to the presence of bone, joints require an initial homogenization with the seven setting. The five setting can then be used to complete the homogenization.

Clean tissue homogenizer

12. To clean the tissue homogenizer, pour ∼30 ml sterile, DEPC-treated water into a 50-ml centrifuge tube. Place the Dremel end of the homogenizer into the water and homogenize on setting five for 5 to 10 sec. Remove the homogenizer.

    The homogenizer must be thoroughly cleaned after the homogenization of each individual tissue sample to prevent cross-contamination of RNAs isolated from different tissues.

13. Dispense ∼30 ml of 5% SDS solution into a 50-ml centrifuge tube. Place the Dremel end of the homogenizer into the SDS solution and homogenize on setting five for 5 to 10 sec. Remove the homogenizer.

14. Repeat step 12 three more times. Wipe off excess water from the Dremel end of the tissue homogenizer with a Kimwipe.

15. Spray Dremel end of tissue homogenizer with RNase-Away. Wipe off excess RNase-Away with a Kimwipe.

16. To process another tissue sample, go back to step 7 and proceed with the remaining protocol steps.

Extract RNA

17. Change gloves. Using the 1-ml micropipettor, transfer each homogenized sample from its 5-ml conical tube to a 1.5-ml microcentrifuge tube. Incubate 5 min at room temperature.

18. Change gloves. Add 100 µl of 1-bromo-3-chloropane to each sample. Shake each tube vigorously to mix contents. Incubate 3 min at room temperature.

    Alternatively, 200 µl of chloroform can be added to each sample. RNA extracted using chloroform is suitable for northern blot analyses. However, chloroform inhibits the reverse transcriptase reaction used to synthesize cDNA from RNA (Chomczynski and Mackey, 1995). For this reason, 1-bromo-3-chloropane is used in this protocol.

    Do not vortex the sample as the RNA will shear.

19. Centrifuge samples in a refrigerated microcentrifuge 15 min at 12,000 × *g*, 4°C.

20. Change gloves. Using the 200-µl micropipettor, carefully transfer the aqueous phase of each sample into a new 1.5-ml microcentrifuge tube. Leave a bit of the aqueous phase behind to ensure that the interphase is not disturbed during pipetting.

    The addition of 1-bromo-3-chloropane to the Trizol-containing samples results in a phase-separation reaction. The top phase is the aqueous phase and contains the RNA. The next two phases, the milky interphase and the pink organic phase, contain DNA and protein (Chomczynski, 1993). Tubes containing the interphase and organic phases may be discarded. Follow all institutional guidelines for the proper handling and disposal of hazardous chemical materials.

21. Change gloves. Add 500 µl isopropanol to each tube. Shake vigorously and incubate 10 min at room temperature. Centrifuge samples 10 min at 12,000 × *g*, 4°C.

    Isopropanol is added to precipitate the RNA out of solution. Following centrifugation, a small white pellet containing the RNA is usually visible at the bottom of the tube. For some very small tissues, such as bladder, this pellet may barely be visible.

22. Following centrifugation, carefully decant the supernatant into an appropriate waste container. Change gloves. Add 1 ml of 75% ethanol to each tube to wash the pellet. Centrifuge samples 5 min at 7500 × *g*, 4°C.

    The application of 75% ethanol helps wash impurities away from the pellet and makes it easier to resuspend.

23. Carefully decant the supernatant from the pellet. Change gloves. Allow the pellet 5 min to air-dry by placing the open 1.5-ml microcentrifuge tube upside-down onto a clean Kimwipe. Gently tap out all remaining drops of supernatant.

    It is critical that the pellet does not over-dry, as it becomes extremely difficult to resuspend. Do not allow drying time to exceed 10 min.

24. Change gloves. Using the appropriate micropipettor, resuspend each pellet in a suitable volume of RNAsecure resuspension solution that has been pre-warmed to 60°C (Table 1D.3.1). Gently flick the bottom of the tube to aid resuspension of the pellet. Immediately incubate all samples 10 min at 60°C.

Table 1D.3.1 Recommended Resuspension Volumes for RNA Pellets Obtained from Select *Borrelia burgdorferi*–Infected Mouse Tissues

Tissue	Resuspension volume (µl)
Bladder	10–30
Heart	50–60
Joints	50–60
Spleen	100
Ears	50–60

Alternatively, RNA pellets can be resuspended in sterile, DEPC-treated double-distilled water and then heated. The RNAsecure resuspension solution inactivates RNases when heated 10 min at 60°C, improving overall RNA quality and yield. Incubation of the samples at 60°C is instrumental in facilitating complete resuspension of the pellet in solution.

25. Store all RNA samples in freezer boxes up to ~1 year at −80°C.

Avoid repeated freeze-thaw cycles, and dispense RNA aliquots into several tubes, if necessary. Always thaw and work with RNA samples on ice. Alternatively, proceed to Basic Protocol 2 without freezing the RNA.

QUALITY CONTROL: REMOVAL OF CONTAMINATING GENOMIC DNA AND ASSESSMENT OF RNA QUALITY AND YIELD

BASIC PROTOCOL 2

In Basic Protocol 1, RNA was extracted from *B. burgdorferi*–infected mouse tissues. However, the RNA samples used in the protocol are not pure and are contaminated with both protein and DNA. Before cDNA can be reversely transcribed from the RNA samples, the contaminating genomic DNA must be removed. After the successful removal of contaminating DNA, the concentration of each RNA sample is determined spectrophotometrically, and the relative amount of contaminating protein present in each RNA sample is assessed. The quality of the extracted RNA is determined via agarose gel electrophoresis. Although the protocol described herein has been tailored for RNA samples extracted from *B. burgdorferi*–infected mouse tissues, they are broadly applicable to a wide variety of experimental systems.

CAUTION: Ethidium bromide is a mutagen. Wear gloves and avoid contact with skin.

CAUTION: Wear goggles or other suitable eye protection when using the UV light box. Avoid prolonged exposure and wear protective face shield, if necessary.

NOTE: Refer to Sambrook et al. (1989) for 5× TBE and 5× agarose gel electrophoresis loading dye recipes.

IMPORTANT NOTE: The use of RNase-free solutions, containers, pipets, and benchtops is tantamount to the success of this protocol. Hands are a significant source of RNase, therefore, wear gloves at all times and frequently change them. Solutions are made RNase-free via the addition of DEPC (di-ethyl-pyrocarbonate) or RNAsecure (Ambion). Benchtops, and micropipettors are sprayed with RNase-Away (Fisher Scientific), and glass containers are baked in an oven to kill RNases. Use only sterile, RNase-free polyethylene or polypropylene test tubes and conical tubes. If possible, keep a separate set of pipets used only for RNA-extraction procedures. See Sambrook et al. (1989) for detailed instructions on maintaining RNase-free conditions.

Materials

RNase-Away (Fisher Scientific)
RNA extracted from *B. burgdorferi*–infected tissues, –80°C
10× Turbo DNA-free buffer (Turbo DNA-free kit) treated with RNAsecure (Ambion)
25× RNAsecure solution (Ambion), stored at −20°C
DNase inactivation reagent (Turbo DNA-free kit) treated with RNAsecure (Ambion)
10 U/μl RNase-free DNase I (Roche Applied Science)
Agarose
1× TBE: dilute from 5× TBE stock (*APPENDIX 2A*; also see Sambrook et al., 1989) in sterile, DEPC-treated water (*APPENDIX 2A*) and treat with RNAsecure
Ethidium bromide staining solution (*APPENDIX 2A*)

5× DNA loading dye (prepared in sterile, DEPC-treated water and treated with RNAsecure; see Sambrook et al., 1989)
100-bp DNA ladder (New England Biolabs)
Takara 10× dNTPs (Fisher Scientific)
Takara 10× PCR buffer (Fisher Scientific)
30 μM *B. burgdorferi* Fla1 oligonucleotide primer (Miller et al., 2005)
30 μM *B. burgdorferi* Fla2 oligonucleotide primer (Miller et al., 2005)
Takara *Taq* polymerase (Fisher Scientific)

10-μl micropipettor and barrier tips
37° and 60°C heating blocks
Sterile, RNase-free 1.5-ml microcentrifuge tubes
Refrigerated microcentrifuge
Agarose gel casting apparatus, gel trays, and combs
Agarose gel electrophoresis gel box
Electrophoresis power supply
UV light box
RNase-free, sterile, thin-walled PCR tubes
Thermal cycler

Remove contaminating genomic DNA

1. Wearing gloves, spray work bench and micropipettors with RNase-Away. Let air-dry.
2. Remove RNA samples from −80°C freezer and thaw on ice.
3. Thaw 10× Turbo DNA-free buffer and DNase inactivation reagent on ice. When thawed, incubate 10 min in a 60°C heating block. Cool 5 min on ice.

   Incubation at 60°C activates the RNAsecure (Ambion) previously added to these reagents and inactivates any RNases present in these vials.

4. Change gloves. Remove 2 μl of each RNA sample and place into labeled, sterile, RNase-free 1.5-ml microcentrifuge tubes. Set these tubes aside on ice.

   These "dirty" RNA samples will be compared with the corresponding "clean" (DNA-free) samples by agarose gel electrophoresis, providing a method whereby the success of the DNase I treatment is evaluated.

5. Change gloves. Add 0.1 vol of 10× Turbo DNA-free buffer and 3 μl DNase I to each RNA sample. Gently flick the bottom of each tube to mix its contents. Pulse spin each sample in a refrigerated microcentrifuge so that all contents settle to the bottom of the tube.

   Alternatively, 1 μl DNase I may be used. However, for the majority of samples, this is not enough enzyme to digest all of the contaminating genomic DNA present. As a result, repeated DNase I treatments are necessary. Repeated 37°C incubations increase the potential for damaging RNase activity. For most samples, using 3 μl enzyme ensures that only one DNase I treatment is performed.

6. Incubate the samples 30 min in a 37°C heating block.
7. Remove the samples from the heating block and place on ice. Change gloves. Vortex the DNase inactivation reagent and add 10 μl to each tube. Flick the bottom of the tube to mix the contents. Incubate 2 min at room temperature, periodically flicking the tube to keep the contents mixed.

   The DNase inactivation reagent also removes any divalent cations that are present within the samples. This is important because some divalent cations act as co-factors for the activation of RNases.

8. Centrifuge the samples 5 min at 5000 × *g*, 4°C, to pellet the inactivation reagent. Change gloves and transfer the RNA to new microcentrifuge tubes. Place the tubes back on ice.

   It is necessary to transfer the RNA to new tubes because the DNase inactivation reagent could inhibit RT-PCR reactions. After this step, samples can be stored up to ∼1 year at −80°C or proceed directly to step 9.

Analyze extracted RNA by agarose gel electrophoresis

9. Spray all surfaces of the agarose gel casting apparatus, gel tray, comb, and gel box with RNase-Away. Set up gel tray and comb on casting apparatus, and place the lid on the gel box. Let the RNase-Away air-dry.

   Do not spray RNase-Away on the electrodes on the lid of the gel box. Instead, using a Kimwipe, carefully apply RNase-Away to the gel box lid.

10. Prepare a 1% agarose gel in RNase-free 1× TBE. When the agarose solution has cooled to ∼60°C, add ethidium bromide staining solution (2 µl for small gels, 4 µl for large gels). Gently swirl the flask to mix contents. Pour the solution into the gel tray set up in the casting apparatus and allow the gel to solidify.

    Refer to Sambrook et al. (1989) for instructions on the preparation and casting of agarose gels.

11. While waiting for the agarose gel to solidify, transfer 2 µl of each DNase I–treated RNA sample to labeled, sterile, RNase-free 1.5-ml microcentrifuge tubes and place on ice.

12. Add 8 µl RNase-free 1× TBE to each of the "dirty" RNA samples (set aside in step 4) and DNase I–treated ("clean") samples.

13. Add 2 µl RNase-free 5× DNA loading dye to each RNA sample. Flick the bottom of each tube to mix its contents and pulse spin to collect sample at the bottom of each tube. Place all tubes on ice.

14. Place the solidified agarose gel and its gel tray into the gel box. Add enough RNase-free 1× TBE buffer to completely cover the gel.

15. Pipet 5 µl of the 100-bp DNA ladder into one well of the gel.

16. For RNA-extracted samples, first pipet a "dirty" sample into a well, then add a "clean" sample into the next well.

    Applying the pre- and post-DNase I–treated aliquots of each RNA sample to the gel in this specific order allows a side-by-side comparison of each "dirty" and "clean" aliquot, therefore, assessing the efficacy of the DNase I treatment. In addition, if RNase-mediated degradation of the RNA has occurred, this method allows the scientist to determine whether this degradation occurred before or during DNase I treatment of the RNA.

17. Connect the electrodes of the gel box to the power supply and run the gel for 45 min to 1 hr at 125 (small gels) or 145 V (large gels).

    For more detailed instructions on the proper voltage to use for electrophoresis of agarose gels of varying sizes, consult Sambrook et al. (1989).

18. After electrophoresis has concluded, check the integrity of each RNA sample by illuminating the gel on a UV light box.

    As illustrated in Fig. 1D.3.1, at least two sharp discrete bands should be visible for each sample. Since RNA was extracted from mouse tissue, these two bands represent the mammalian 28S and 18S ribosomal RNAs (rRNAs). If one or both of these bands are missing or smeared, then RNase-mediated degradation of the RNA has occurred. Under

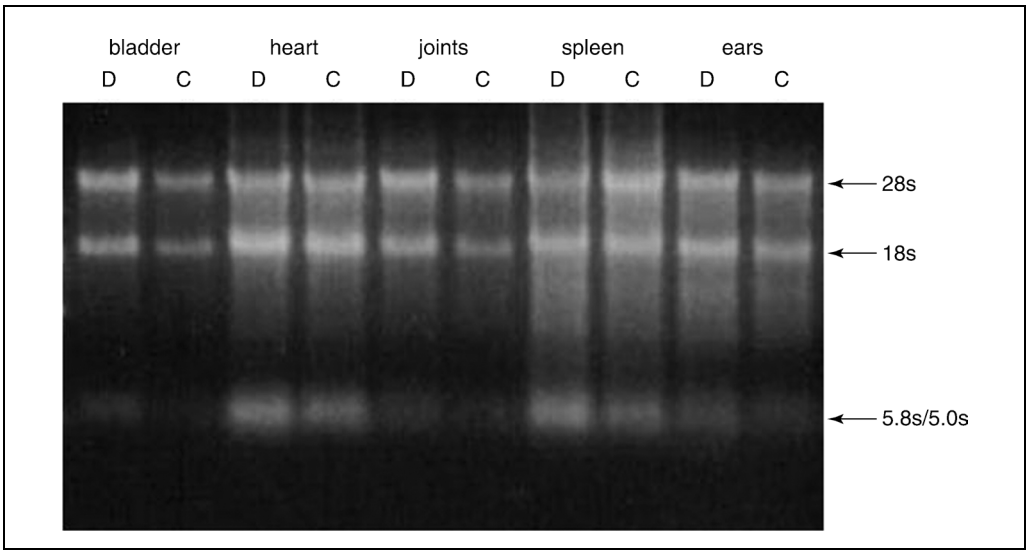

Figure 1D.3.1 Assessment of RNA integrity prior to, and following DNase I treatment. RNA was isolated from bladder, heart, joint, spleen, and ear tissues obtained from a *B. burgdorferi*-infected mouse. The integrity of each RNA sample was then assessed before (D = dirty) and after DNase I treatment (C = clean). A volume of 2 μl of each RNA sample was analyzed by agarose gel electrophoresis and resultant bands were visualized with ethidium bromide. Mouse 28S, 18S, and 5.8S/5.0S rRNA bands are indicated by arrows. Note the presence and clarity of all three rRNA bands.

these circumstances, the integrity of the sample is not good enough for Q-RT-PCR analysis. A third, higher molecular weight band is sometimes visible in the "dirty" samples, which represents the contaminating genomic DNA. This band should be absent in the "clean" samples if the DNase I treatment was successful.

Occasionally, the 5.8S/5.0S rRNAs are visible on the gel. If visible, they will appear as one very low molecular weight band, due to the limited resolution of the 1% agarose gel. However, due to their small size, these rRNAs are often not visible on a 1% agarose gel.

19. Determine RNA concentration by spectrophotometry (see Support Protocol 1).

Determine RNA purity by PCR analysis

20. Change gloves. To set up 100-μl PCR reactions, pipet 8 μl dNTPs and 10 μl of 10× PCR buffer into each clean, RNase-free, thin-walled PCR tube. Add 5 μl of 30 μM Fla1 and 5 μl of 30 μM Fla2 oligonucleotide primers to each tube. Place the tubes on ice.

This protocol is designed for 100-μl PCR reactions but can easily be modified for other volumes. In addition, a mastermix containing everything but RNA and DEPC-treated water can also be used. Add the RNA and water to each tube after the mastermix is dispensed into each tube. Fla1 and Fla2 are oligonucleotide primers designed to amplify the B. burgdorferi housekeeping gene, flagellin B (flaB). Primers specific for other bacterial housekeeping genes may also be used.

21. Change gloves. Add 1 μg of a DNase I–treated RNA sample and the appropriate volume of sterile, DEPC-treated water to each tube (to bring volume up to 100 μl). Place the tubes back on ice.

For each sample of RNA, 1 μg is used as the template for PCR reactions because this is the amount of RNA that will later be reverse-transcribed into cDNA.

22. Pipet 1 μl of *Taq* polymerase into each PCR tube.

23. Place the tubes into the thermal cycler. Using the following parameters, program the thermal cycler according to the manufacturer's instructions.

40 cycles:	1 min	94°C (denaturation)
	1 min	50°C (annealing)
	1 min	65°C (extension)

For this PCR reaction, 40 cycles are used because the LightCycler-based protocol (see Basic Protocol 3) used for cDNA amplification requires 40 cycles.

24. Change gloves. Pipet 10 µl of each completed PCR reaction and 2 µl of 5× DNA loading dye into clean, RNase-free microcentrifuge tubes. Analyze each PCR amplicon on a 1.5% agarose gel containing ethidium bromide. First load 5 µl of the 100-bp DNA ladder into one well of the gel, then load each PCR reaction. Run the gel for 1 hr at 135 V (for small gels) or 150 to 160 V (for large gels).

25. After electrophoresis, place the gel on a UV light box to examine the PCR results. If the DNAse I treatment was successful, only the DNA ladder should be visible. However, if genomic DNA is still present in the RNA samples, a band at ~450 bp will be visible. If such band is present, repeat the DNase I treatment. If no bands are present, either store the RNA up to 1 year at −80°C or proceed directly to the production of cDNA (see Basic Protocol 3).

SPECTROPHOTOMETRIC DETERMINATION OF RNA CONCENTRATION

SUPPORT PROTOCOL 1

To accurately assess the purity and concentration of the extracted RNA samples, both the A_{260} and A_{280} must be determined. The absorbance at 260 nm is used to quantify nucleic acids, whereas 280 nm is used to quantify protein. Therefore, the A_{280} is measured as an indicator of the amount of protein contamination present within the RNA sample (Chomczynski and Sacchi, 1987).

Materials

RNAsecure resuspension solution (Ambion), stored at −20°C
DNase I–treated RNA sample (see Basic Protocol 2)

RNase-free 1.5-ml microcentrifuge tubes
Spectrophotometer
Cuvettes

1. Using the RNA resuspension solution as diluent, prepare a 1:100 dilution of each DNase I–treated RNA sample. Dispense into clean, RNase-free 1.5-ml microcentrifuge tubes. Flick the bottom of each tube a few times to mix its contents and pulse spin to collect contents at the bottom of the tube. Place tubes on ice.

2. Pipet a suitable volume of RNA resuspension solution into a clean, RNase-free 1.5-ml microcentrifuge tube as the blank used to zero the spectrophotometer. Place the tube on ice.

   The blank and the diluent should always be the same solution in which the RNA was resuspended.

3. Set the wavelength for absorbance at 260 nm on the spectrophotometer. Carefully pipet the blank solution into a cuvette and place in the spectrophotometer. After the wavelength reading has stabilized, strike the zero key (or equivalent), where the A_{260} should read 0.00 nm. Remove the cuvette and set it aside.

4. Carefully pipet the first diluted RNA sample into a cuvette and place in spectrophotometer. Record the stabilized wavelength. Remove the cuvette and set it aside.

5. Change the wavelength on the spectrophotometer to 280 nm. Insert the blank cuvette and strike the zero key, where the A_{280} should read 0.00 nm. Remove the cuvette and set it aside.
6. Place the cuvette containing the first diluted RNA sample in the spectrophotometer. Record the stabilized wavelength. Remove the cuvette and discard, if disposable. If not disposable, rinse the cuvette out with water, followed by ethanol, and set it aside to dry.
7. Repeat steps 3 to 6 for all additional samples.
8. To determine the purity of each extracted RNA sample, divide the A_{260} value by the A_{280} value to obtain the A_{260}/A_{280} ratio. If the number obtained is ≥ 1.7, then the RNA is of sufficient purity for RT-PCR (Sambrook, et al., 1989).
9. To calculate the concentration of each RNA sample, multiply the A_{260} value by 100 (the dilution factor), and then by 40 (the value of 1 μl single-stranded RNA at an A_{260} of 1.0 is 40 ng). The resultant number is the concentration of RNA in nanograms per microliter (Sambrook, et al., 1989).

   The pathlength of the cuvette must also be considered in these calculations. Often, this value is 1 cm, so no multiplication factor is necessary. If the pathlength is not 1 cm, then the A_{260} must also be multiplied by this number. After the concentration has been determined, the RNA can be stored at −80°C.

BASIC PROTOCOL 3

QUANTITATIVE RT-PCR AND ANALYSIS

Basic Protocol 1 detailed the extraction and purification of RNA from *B. burgdorferi*–infected mouse tissues, and Basic Protocol 2 described the quality control procedures needed to ensure that the resultant RNA samples are of sufficient quality and purity for RT-PCR analyses. This protocol provides the step-by-step instructions necessary to synthesize cDNA from RNA and to assess the cDNAs for transcription of *B. burgdorferi* genes using a LightCycler-based approach. In addition, a method for determining the average relative expression of a gene of interest is also discussed. Although the procedures and examples described within this protocol have been adapted to examine *B. burgdorferi* gene expression, they are also appropriate for the analysis of genes from other bacteria.

IMPORTANT NOTE: The maintenance of RNase-free conditions is critical when handling RNA that will be converted to cDNA. DNA-free conditions are essential to prevent DNA contamination of cDNA or LightCycler PCR reagents. To maintain DNA-free conditions, spray all work areas and pipets with DNA-Away (Fisher). If possible, keep a separate set of pipets used only for Q-RT-PCR experiments. Also use separate boxes of RNase-free, DNA-free, sterile, barrier pipet tips. Hands are a significant source of DNA. Wear gloves at all times, and change them frequently.

NOTE: SYBR green is light-sensitive, therefore, do not expose to direct light for more than a few seconds. It is unstable or short-lived, therefore, do not subject to freeze-thaw cycles. Once SYBR green has been thawed and diluted, do not refreeze. Small, aliquoted volumes can be purchased to avoid this problem. SYBR green is more stable if diluted in TE buffer, than if diluted in water. Store small volume aliquots of diluted SYBR green suitable for single use. To avoid significant loss of activity, use all diluted aliquots of SYBR green within 3 months.

Materials

RNase-Away (Fisher Scientific)
DNA-free RNA sample
Sterile, DEPC-treated water (*APPENDIX 2A*)

DNA-Away (Fisher Scientific)
First-strand cDNA synthesis kit for RT-PCR (AMV; Roche) containing the following:
10× reaction buffer
25 mM $MgCl_2$
40 mM (10 mM each) dNTPs
0.04 A_{260} U/μl random primer p(dN)6
50 U/μl RNase-inhibitor
AMV reverse transcriptase
Enzyme diluent (Idaho Technology; also see recipe for SED in *APPENDIX 2A*)
10× dNTPs containing 2 mM each dNTP (Idaho Technology; also see *APPENDIX 2A*)
10× PCR buffer containing 30 mM $MgCl_2$ (Idaho Technology; also see *APPENDIX 2A*)
20 μM each of housekeeping gene primers Fla1 and Fla2 (Miller et al., 2005) *or* 20 μM of each oligonucleotide primer used to amplify gene of interest
Platinum *Taq* polymerase (Invitrogen)
Sterile TE buffer (made with sterile, DEPC-treated water; *APPENDIX 2A*)
10,000× SYBR green (Molecular probes) diluted 1000× in TE (final concentration 10×) in amber-colored, sterile, siliconized tubes
Genomic DNA standards (see Support Protocol 2)
2-, 10-, 20-, and 200-μl, and 1-ml micropipettors and RNase-free, DNA-free barrier pipet tips
Clear, sterile, RNase-free, DNA-free, siliconized 0.5-ml flat-top microcentrifuge tubes (Fisher Scientific)
42° and 99°C heating blocks
LightCycler centrifuge adapters in an aluminum cooling block (Roche), 4°C
20-μl LightCycler capillary tubes (Roche)
LightCycler thermal cycler with carousel (Roche)
Computer equipped with LightCycler software v. 3.5.3 (Roche)
Color printer

Prepare cDNA

1. Wearing gloves, spray work bench and RNA micropipettors with RNase-Away. Let air-dry.
2. Change gloves. Add 1 μg of each DNA-free RNA sample to sterile, RNase-free, DNA-free 0.5-ml microcentrifuge tubes and place tubes on ice.
3. Pipet the appropriate volume of sterile, DEPC-treated water into each tube such that the total volume of RNA plus water equals 8.2 μl. Set the tubes aside on ice.
4. Spray work bench and Q-RT-PCR micropipettors with DNA-Away. Let air-dry.
5. Change gloves. Prepare a master mix of the first-strand cDNA synthesis kit reagents needed to convert each RNA sample to cDNA in a sterile RNase-free, DNA-free 0.5-ml microcentrifuge tube. To establish the volume needed, multiply the following volumes, appropriate for one sample, by the number of samples being processed:

   2 μl 10× reaction buffer
   4 μl 25 mM $MgCl_2$
   2 μl 40 mM (10 mM each) dNTPs
   2 μl 0.04 A_{260} U/μl random primer p(dN)6
   1 μl 50 U/μl RNase-inhibitor
   0.8 μl AMV reverse transcriptase

   In this experimental setting, single-stranded cDNA is generated by the binding of the random primer to numerous nonspecific RNA sequences (Sambrook et al., 1989).

6. Flick the bottom of the tube a few times to mix its contents. Pulse centrifuge to collect the contents at the bottom of the tube. Change gloves. Aliquot 11.8 μl master mix into each tube containing 8.2 μl of RNA and DEPC-treated water (step 3).

   The total volume in each tube should now equal 20 μl.

7. Flick the bottom of each tube a few times to mix its contents. Pulse centrifuge the samples to collect the contents at the bottom of the tubes. Incubate 10 min at room temperature.

   This first incubation step is performed to allow the random primer to anneal to the RNA.

8. Incubate tubes 1 hr in a 42°C heating block.

   RNA is reverse transcribed into cDNA during this incubation period.

9. To inactivate the reverse transcriptase, incubate samples 5 min in a 99°C heating block. Remove tubes from the heating block and place 5 min on ice.

   If the reverse transcriptase is not heat-inactivated, it can interfere with PCR-based assays using the newly created cDNA (Kawasaki, 1990).

10. Store the cDNA up to 1 month at −20°C in a non-frost-free freezer. Alternatively, keep cDNA on ice and proceed directly to the LightCycler-based PCR (step 11).

Amplify genomic DNA standards and cDNA by LightCycler-based PCR

11. Change gloves. Spray work bench and Q-RT-PCR micropipettors with DNA-Away. Let air-dry.

12. Prepare a master mix of the reagents needed to conduct LightCycler-based PCR amplification of the genomic DNA standards and the cDNA synthesized from RNA extracted from *B. burgdorferi*-infected mouse tissues in a sterile, RNase-free, DNA-free, siliconized 0.5-ml flat-top microcentrifuge tube. To establish the needed volume, multiple the following volumes, appropriate for one sample, by the number of samples being processed:

    0.9 μl enzyme diluent
    1.0 μl 10× dNTPs
    1.0 μl 10× PCR buffer
    0.05 μl each 20 μM Fla 1 and 20 μM Fla 2 primers (final concentration 0.1 μM)
    or 0.2 μl of each 20 μM gene of interest primer (final concentration 0.4 μM)
    3.9 μl (or 3.6 μl) TE buffer
    0.1 μl Platinum *Taq* polymerase
    1.0 μl 10× SYBR green

    SYBR green binds double-stranded DNA. The LightCycler detects the amount of dye that is being incorporated into the newly synthesized PCR product and records this data as a function of the fluorescence incorporated versus temperature. The amount of SYBR green binding the DNA is decreased as the temperature increases. For more detailed information, consult the LightCycler operator's manual, version 3.5, and "Principles and Applications of the LightCycler" available online at http://www.Roche-applied-science.com/lightcycler-online.

13. Flick the bottom of the tube a few times to mix its contents. Pulse centrifuge to recollect the contents at the bottom of the tube. Set the tube aside on ice.

14. Remove the LightCycler centrifuge adapters located within the aluminum cooling block from 4°C. Change gloves. Place a 20-μl LightCycler capillary tube into the first adapter and aliquot 8 μl master mix into it.

15. Add 2 µl TE buffer (a negative control to ensure no DNA contamination of reagents), genomic DNA, or cDNA to the capillary tube. Place the cap firmly over the top of capillary tube to seal it.

    A minimum of ten samples will initially be analyzed with each primer set. A negative control and at least six genomic DNA standards are included. In addition, each cDNA sample is assessed in triplicate. The negative control should be the first sample prepared, followed by the genomic DNA standards and then each cDNA triplicate. Traditionally, each of these samples is first analyzed using the primers for the housekeeping gene (flaB in this example). Subsequent PCR assays are then set up using primers specific for a gene of interest. The data are then analyzed by comparing the values obtained for the gene of interest and the housekeeping gene (described in more detail below).

16. Repeat steps 14 and 15 for each sample to be analyzed.

17. After all of the samples have been aliquotted into the capillary tubes, carefully remove each adapter from the aluminum cooling block and place into a microcentrifuge. Collect the contents of each sample at the bottom of the capillary tube by centrifuging 1 min at 3000 × *g*, 4°C.

18. Carefully remove each adapter from the microcentrifuge and place it back into the cooling block. Carry samples over to the LightCycler thermal cycler using the cooling block.

19. Double click the LightCycler software icon on the computer desktop to open version 3.5.3 module.

20. Double click Run.

    This action opens a `new experiment`.

21. To set up the PCR reaction conditions that will be used for these samples, double click the Add button.

    The reaction conditions for these experiments have been previously reported (Gilmore et al., 2001; Miller et al., 2005).

22. When prompted for a program name, enter `denaturation`. Enter Type as `none`. Click the Ins button to insert the following cycling parameters:

    Cycles: `1`
    Temperature Target: `95°C`
    Hold Time: `120 sec`
    Slope: `20`
    2° Target Temp: `0`
    Step Size: `0`
    Acquisition Mode: `none`

    This program is needed to inactivate the hot-start enzyme that is bound to the Taq polymerase.

23. Double click the Add button and enter `amplification`. The Type is `quantification`. Prepare the program containing the cycling parameters for the PCR reaction in the following manner.

    a. Click Ins and enter the following information:
    Cycles: `40`
    Temperature Target: `94°C`
    Hold Time: `5 sec`
    Slope: `20`
    2° Target Temp: `0`

Step Size: 0
Acquisition Mode: none

b. Click Ins again and enter:
Temperature Target: 55°C
Hold Time: 5 sec
Slope: 20
2° Target Temp: 0
Step Size: 0
Acquisition Mode: none

c. Click Ins to add a third segment and enter:
Temperature Target: 72°C
Hold Time: 30 sec
Slope: 20
2° Target Temp: 0
Step Size: 0
Acquisition Mode: none

d. For *flaB* analyses, click Ins and enter a fourth segment with the following parameters:
Temperature Target: 82°C
Hold Time: 1 sec
Slope: 20
2° Target Temp: 0
Step Size: 0
Acquisition Mode: single

To conduct PCR using primers specific for a gene of interest, delete this fourth segment and change the acquisition mode on the third segment to single.

24. Double click the Add button and enter melting. The Type is melting curves. Enter the following segemnents

a. Click the Ins button and insert the following cycling parameters:
Cycles: 1
Temperature Target: 95°C
Hold Time: 0 sec
Slope: 20
2° Target Temp: 0
Step Size: 0
Acquisition Mode: none

b. Click Ins and insert a second segment with the following parameters:
Temperature Target: 65°C
Hold Time: 15 sec
Slope: 20
2° Target Temp: 0
Step Size: 0
Acquisition Mode: none

c. Click Ins again and enter a third segment with the following parameters:
Temperature Target: 95°C
Hold Time: 0 sec
Slope: 0.1
2° Target Temp: 0
Step Size: 0.2
Acquisition Mode: continuous

This program is necessary so that the software will perform a melting curve analysis of the data. One reason a melting curve analysis is important is because it indicates whether the primers selected for analysis are specific, and whether the peak(s) present correlates with the expected PCR amplicon(s) (visualized via agarose gel electrophoresis). Consult Wittwer (2001) for a more detailed explanation.

25. Double click the Add button and enter `cooling`. The Type is `none`. Click the Ins button to insert the following cycling parameters:

    Cycles: `1`
    Temperature Target: `40°C`
    Hold Time: `30 sec`
    Slope: `20`
    2° Target Temp: `0`
    Step Size: `0`
    Acquisition Mode: `none`

26. Double click Edit Samples to be directed to the module where sample information is entered. Type the sample name and indicate whether it is a `negative`, `standard`, or `unknown`. Earmark cDNA replicates and enter the concentration of each genomic DNA standard. At the bottom right of the screen, enter `ng` for concentration units. Click Done.

27. Double click on Save Experiment File and name the file.

    The protocol will now be saved in the `protocol` *folder.*

28. Carefully insert each capillary tube into the corresponding slot of the LightCycler carousel. Place the carousel into the LightCycler and gently close the lid.

29. Click Run. When prompted, name and save the experiment to the `Data folder`.

    The PCR assay will now be conducted.

    Roche Applied Science publishes several references that provide more detailed information on the LightCycler and the use of LightCycler software. The LightCycler operator's manual, version 3.5, and "Principles and Applications of the LightCycler" can be found online (http://www.Roche-applied-science.com/lightcycler-online). Another description of the methods and applications of LightCycler-based PCR can be found in print (Wittwer, 2001).

Analyze cDNA amplicons by LightCycler-based quantitative analysis

30. When the LightCycler assay has concluded, the Complete light will be illuminated on the thermal cycler and a data screen will be visible on the computer. Two analysis modules (quantification and melting curve analysis) will be applied to the data. Double click on Select a Program, located in the top left corner of the data screen. Select `amplification is a 40 cycle program...` Click the Quantification button on the data screen. The quantification module is now open.

31. There are two quantification modes available, the second derivative maximum and fit points methods. Select the second derivative maximum method.

    The second derivative maximum module automatically quantifies each sample based on the point at which the fluorescence curve first turns.

    This phenomenon is known as the crossing point of the sample and represents the beginning of the log-linear phase of PCR product amplification. The turning point is equal to the first maximum of the second derivative curve, which is how this analysis mode received its name. The fit points method allows the user to define the crossing points of the samples via experimental manipulation of the noiseband of the data (Roche Molecular Biochemicals, 2000; Wittwer, 2001). Under certain special circumstances, this analysis module is useful.

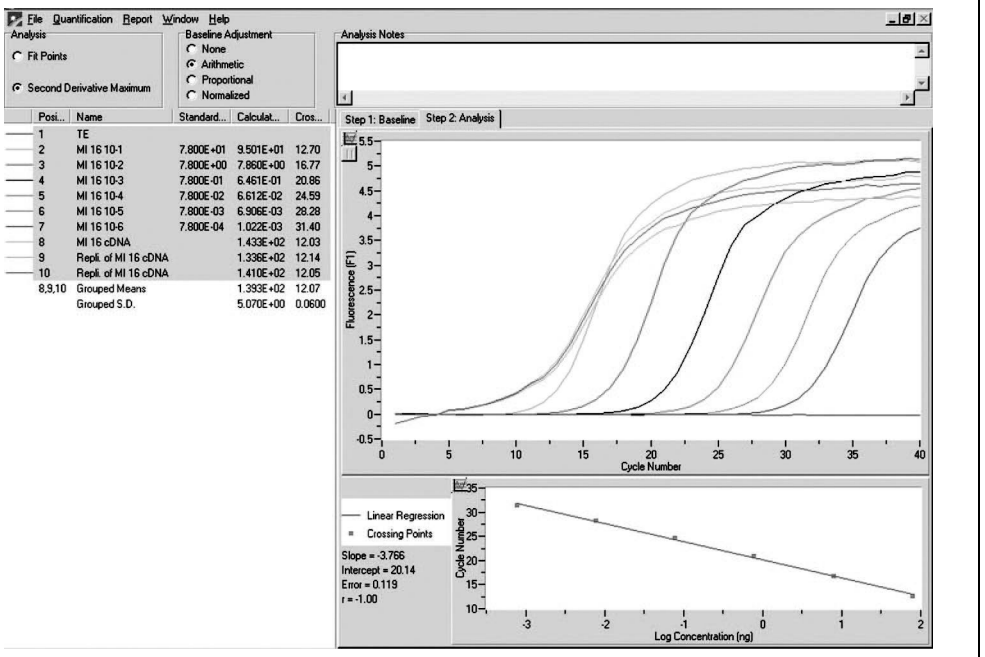

Figure 1D.3.2 Quantitative analysis of *B. burgdorferi flaB* gene expression within cultured bacteria. cDNA was obtained from *B. burgdorferi* B31-MI-16 bacteria cultivated to mid-logarithmic phase and 2 μl was analyzed for expression of the housekeeping gene *flaB*. The fluorescence curves (fluorescence versus the PCR cycle number) are displayed in the top right graph. A standard curve (bottom right corner) generated using known quantities (ng) of B31-MI-16 DNA (top left panel) was used by the LightCycler software to calculate the amount of *flaB* transcript present in each cDNA triplicate (top left corner). Note the ideal regression value of −1.00 obtained in this assay.

However, due to the inherent user bias present with this module, the automated second derivative maximum module is preferentially used to avoid this problem.

32. Three analysis steps will be now be present. Select `step 3: analysis`.

    Two graphs will be shown. The top graph displays fluorescence curves represented as the fluorescence versus the PCR cycle number. The bottom graph is the standard curve, which is represented as the crossing point number for each genomic DNA standard versus the log of the concentration (in ng) of each genomic DNA standard. Plotting of these data yields a linear regression line, from which the concentration of each unknown cDNA sample is calculated by the software. The slope of the line and an error value for the plotted data are also reported (Fig. 1D.3.2). A regression (r) value of −1.00 is ideal, and values ≤−0.95 are acceptable.

    The other two analysis steps, `step 1: baseline` *and* `step 2: noise band`*, individually display the baseline and noise band lines determined for the fluorescent curve graph by the software. As these features are not user-defined in the second derivative module, and the baseline is also shown in the analysis step, these first two steps are not as useful as the third step.*

33. Although the quantification results for each sample are displayed in the panel to the left of the graphs, not all the results are visible in the printable window. To view a summary of all results, including the average and standard deviation values obtained for each cDNA triplicate, click on Window and select Print Summary Report.

LightCycler-based melting curve analysis of cDNA amplicons

34. To exit the quantification mode and return to the main data analysis menu, click on Window and select `close window`.

35. Double click on Select a Program, and select Melting Curve is a . . . . Click the Melting Curve button on the data screen.

The melting curve module is now open and two graphs should be visible. The top graph displays the fluorescence versus the temperature and shows that the amount of SYBR green binding to the DNA is decreased as the temperature increases. The bottom graph replots this data as fluorescence (−d(F1)/dt) versus temperature such that the data is now displayed as a peak(s). Note how many major and minor peaks are present. If one PCR product is expected then only one major peak should be present (Fig. 1D.3.3A).

Melting curve analysis is important as the major peak(s) represents a melting temperature(s) that is unique for a specific PCR product(s) (Roche Molecular Biochemicals, 2000; Wittwer, 2001). Thus, melting curve analysis indicates whether a PCR amplicon of interest has been obtained and whether the PCR reaction was specific (minor peaks could indicate primer-dimers, other major peaks imply the primers or other PCR conditions utilized were not specific (see Troubleshooting).

36. To print the melting peaks, click on File and select Print Window.

Quantify expression for a gene(s) of interest

37. For each sample, divide the average computed for each cDNA triplicate for a gene of interest by that obtained for the *B. burgdorferi* housekeeping gene *flaB* (Gilmore et al., 2001; Miller et al., 2005). Refer to the average value computed for each cDNA triplicate, found on the "Quantification Summary" printout obtained in step 33. Note that the resultant number represents the average relative expression value for a gene of interest whose transcription levels are being measured within an infected tissue sample.

This is only one relative quantification method for tabulating and expressing the transcription data obtained for a particular gene(s) of interest. Other relative quantification approaches have also been utilized. In addition, absolute quantification methodologies have also been employed (http://www.Roche-applied-science.com/lightcycler-online, (Hodzic et al., 2002; Wittwer, 2001).

PREPARATION OF GENOMIC DNA STANDARDS

SUPPORT PROTOCOL 2

In Basic Protocol 3, the average relative expression for a gene of interest was calculated based on values obtained from standard curves generated using serial ten-fold dilutions of genomic DNA. The success of this quantification mode is critically dependent on the quality and integrity of the prepared genomic DNA. This protocol provides an easy method by which high-quality genomic DNA may be obtained.

Materials

DNA-easy tissue kit (Qiagen)
5-ml mid-logarithmic phase culture of *B. burgdorferi* strain of interest (*UNIT 12C.1*)
0.7% agarose gel
RNase-free TE buffer (*APPENDIX 2A*)
Spectrophotometer
Gel electrophoresis equipment
Sterile, RNase-free, DNA-free siliconized 0.5-ml microcentrifuge tubes

1. Using the DNA-easy tissue kit (Qiagen), extract genomic DNA from a 5-ml *B. burgdorferi* mid-logarithmic phase culture. Follow the manufacturer's directions. Remember to change gloves frequently to prevent DNA contamination of the kit reagents.

Other methods for extracting genomic DNA can also be used (Sambrook et al., 1989), as long as the resultant DNA is of high quality and purity. It is important that the B. burgdorferi strain used to generate the genomic DNA standards is the same as the strain used to infect the mice.

2. Use a spectrophotometer to determine the concentration of the extracted DNA.

   The concentration of double-stranded DNA at an A_{260} of 1.0 is 50 ng/μl. For more detailed information, consult Sambrook et al. (1989).

3. Analyze the quality of the extracted DNA via 0.7% agarose gel electrophoresis.

   One distinct band should be easily visualized on the agarose gel. If no band is present, or the band is smeared, then DNase-mediated degradation of the DNA has occurred. DNA that is partially or completely degraded is not suitable for LightCycler-based PCR analyses.

4. Change gloves. Using sterile, DNA-free TE buffer as diluent and sterile, RNase-free, DNA-free siliconized 0.5-ml microcentrifuge tubes, prepare at least six ten-fold serial dilutions of the extracted genomic DNA. Set these tubes aside on ice.

   To detect candidate genes which may be expressed at very low levels within B. burgdorferi–infected mouse tissues, a concentration range of 10 ng to 100 fg is recommended. These samples will be the genomic DNA standards that will be used to generate a standard curve during LightCycler PCR assays.

   Other concentration ranges may also be used as the LightCycler is sensitive enough to amplify templates of a wide range of concentrations. However, the level of detection achievable with the LightCycler is dependent on numerous other reagents, including the oligonucleotide primers utilized (see Critical Parameters and Troubleshooting and Table 1D.3.2).

5. Change gloves. Aliquot the remainder of the undiluted extracted genomic DNA into small volumes and place in sterile, DNA-free microcentrifuge tubes.

6. For long-term storage (weeks to years), keep the DNA in a frost-free −20°C freezer. If the DNA is to be used within 1 or 2 weeks, store at 4°C.

   Avoid freeze-thaw cycles. These cycles can result in broken, degraded DNA samples, which are not suitable for LightCycler-based PCR analyses.

BASIC PROTOCOL 4

VERIFICATION OF SPECIFICITY OF LIGHTCYCLER-BASED PCR REACTIONS

Although melting peak analysis will indicate whether a specific amplicon has been obtained, there are occasions when verification that a melting peak is a specific PCR product is necessary. An example of such an occasion would be to test if new primers are specific prior to using them on precious cDNA samples obtained from *B. burgdorferi*–infected mouse tissues. Alternatively, it may be necessary to confirm that amplification of a particular cDNA amplicon(s) is specific prior to scientific publication of the data. One method is to analyze the LightCycler reaction products via agarose gel electrophoresis for size and purity by comparing the reaction product to a positive control PCR product obtained using the same primers via conventional PCR analysis. Ideally, the positive control has already been sequenced to confirm that is the amplicon of interest. The second method is to sequence the LightCycler amplicons to confirm that they are the PCR products of interest.

Materials

Capillary tubes containing the LightCycler amplicons of interest (Basic Protocol 2)
1.5% agarose gel containing ethidium bromide
5× loading dye
100-bp DNA ladder
1.5-ml microcentrifuge tubes
UV lightbox
Microcon-100 microconcentrator filter (Ambion)
Spectrophotometer

1. Carefully remove the capillary tubes of interest from the LightCycler carousel and place each into an open 1.5-ml microcentrifuge tube.
2. Carefully remove the cap from each capillary tube. Place the open capillary tube into the microcentrifuge tube, with the cup portion of the capillary facing down into the tube.
3. Centrifuge each sample 2 min at 1000 × *g*, room temperature, to collect the sample at the bottom of the microcentrifuge tube.
4. Discard empty capillary tubes into proper waste containers.

For agarose gel analysis, proceed to step 5a. For instructions on preparing the amplicon for sequencing, go to step 5b.

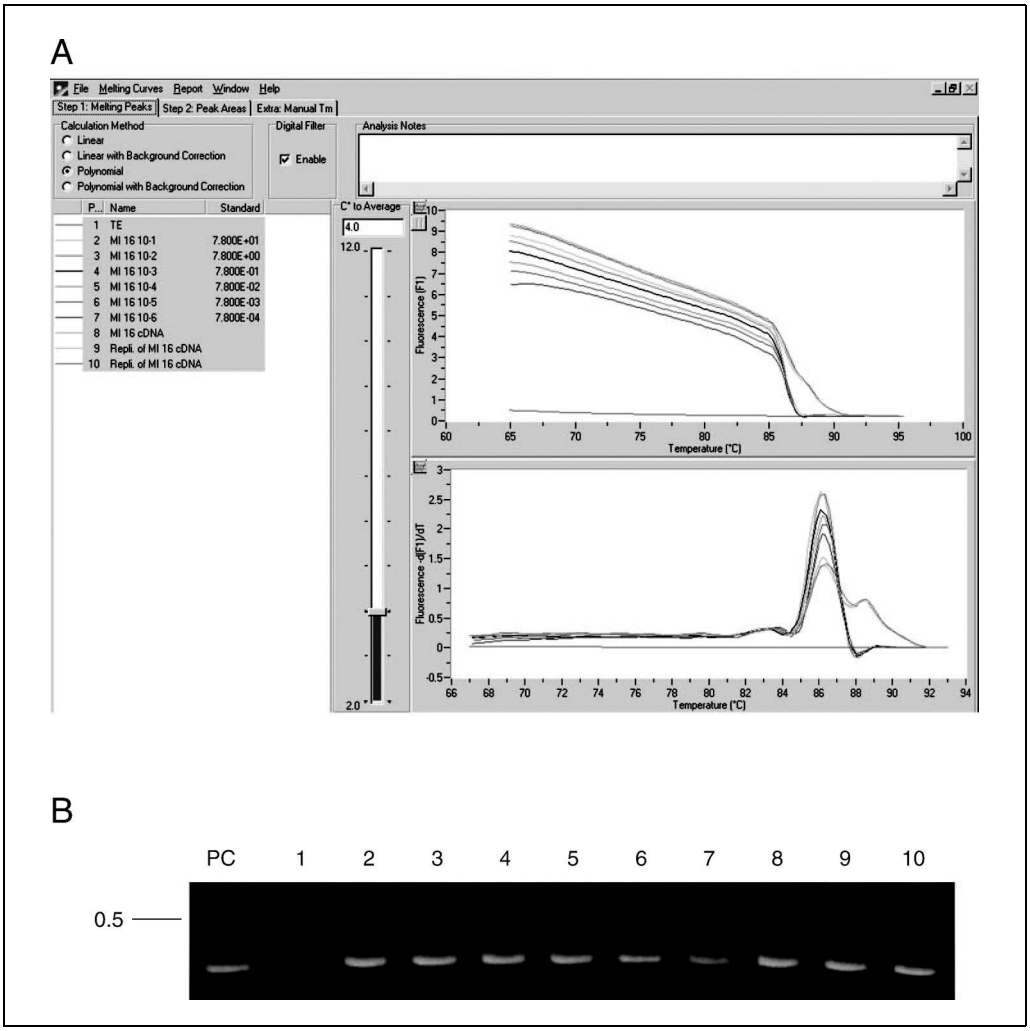

Figure 1D.3.3 Melting curve analysis of *B. burgdorferi flaB* gene expression within cultured bacteria. (**A**) The fluorescence versus temperature is displayed in the top graph. This graph demonstrates the decrease in SYBR green binding to the DNA that occurs as the temperature increases. The bottom graph replots this data and displays it as a peak(s). Note that one major peak, corresponding to the specific *flaB* amplicon, was obtained for each sample (except the negative control, TE). The minor peak obtained at 89°C for the three cDNA samples is non-specific and does not represent an amplification product (see Fig. 1D.3.3B). (**B**) Agarose gel electrophoresis analysis of the LightCycler reaction products obtained in the above experiment (Figs. 1D.3.2 and 1D.3.3A). Note that only one amplicon of the expected size was obtained for each sample (except the negative control, sample 1). Numbers above the lanes correspond with the numbers and samples listed in the top left panel of **A**. PC = positive control *flaB* PCR product, 0.5 = 0.5-kb DNA size marker.

To verify by gel electrophoresis

5a. For agarose gel electrophoresis analysis, prepare a 1.5% agarose gel containing ethidium bromide.

6a. Pipet 5 to 10 μl of each LightCycler PCR product, along with the appropriate amount of 5× loading dye (1 to 2 μl), into sterile microcentrifuge tubes. Next, pipet 10 μl positive control along with 2 μl loading dye into a sterile microcentrifuge tube.

7a. Load 5 μl of a 100-bp DNA ladder into the first lane of the gel, load the positive control into the second lane, and load each LightCycler amplicon into the remaining lanes of the gel.

8a. Run the gel for 1 hr at 135 V (small gels) or 150 to 160 V (large gels). When electrophoresis is complete, use a UV lightbox to visualize the bands on the gel.

For more detailed instructions on the proper voltage to use for electrophoresis of agarose gels of varying sizes, consult Sambrook et al. (1989).

If one specific LightCycler amplicon is expected, then there should be one band on the agarose gel of the same size and clarity as the band corresponding to the positive control. In turn, this should correlate with the presence of one major peak obtained during the melting curve analysis (Fig. 1D.3.3A,B).

To verify by sequencing

5b. Before the LightCycler amplicon can be sequenced, remove PCR buffers and other reagents by using a Microcon-100 microconcentrator filter. Follow the manufacturer's directions to obtain purified DNA.

6b. Determine the concentration of the DNA using a spectrophotometer.

7b. Sequence DNA.

COMMENTARY

Background Information

The Lyme disease spirochete *Borrelia burgdorferi* is maintained in nature within an enzootic cycle involving hard ticks of the genus *Ixodes* and mammals. If the appropriate antibiotic therapy is not administered, *B. burgdorferi* will persist within the mammalian host for at least several years (Schwan et al., 1999). Infected juvenile ticks feed upon rodents and other small mammals, making the mouse a useful model for studying *B. burgdorferi* gene expression within warm-blooded hosts. The borrelial genome consists of a small, ~900 kb linear chromosome and numerous extrachromosomal linear and circular plasmids (Fraser et al., 1997; Casjens et al., 2000). To date, all identified infection-associated genes are located on the plasmids, indicating that these minichromosomes assume an important role in the pathogenesis of *B. burgdorferi* (Casjens et al., 2000; Stevenson et al., 2001; Stewart et al., 2005). While expression of several well-characterized virulence genes by cultured borrelia is regulated by numerous factors including temperature, pH, and soluble chemicals (Schwan et al., 1995; Stevenson et al., 1995, 1996, 1998; Carroll et al., 1999, 2000; Porcella et al., 2000; Carroll et al., 2001; Babb et al., 2001; Hefty et al., 2001; Roberts et al., 2002; Yang et al., 2003), less is known about gene expression within infected mammalian hosts.

Initial studies focused on the examination of serum samples obtained from *B. burgdorferi*–infected hosts for the presence of antibodies that recognized certain proteins hypothesized to be involved in spirochetal pathogenesis (Akins et al., 1995; Suk et al., 1995; Wallich et al., 1995; Das et al., 1997; Stevenson et al., 1998; Miller et al., 2000a,b; Hefty et al., 2001, McDowell et al., 2001; Hefty et al., 2002; Miller and Stevenson, 2003; Miller et al., 2003). Results of such experiments indicate whether a particular protein is antigenic, but offer no information on gene transcription. The dialysis membrane chamber (DMC) model (see *UNIT 12C.4*) in which cultured *B. burgdorferi* are placed within dialysis tubing and then implanted into the peritoneum of a rat has often been used to analyze

bacterial gene expression, as the spirochetes adapt to the host environmental conditions (Akins et al., 1998). The drawback to this model system is that the spirochetes are contained within the dialysis tubing, preventing dissemination to other anatomical sites, which is a key feature of *B. burgdorferi* infection. Although northern blot analysis is the oldest method utilized to examine bacterial gene transcription, the technique is not very sensitive. Large amounts of RNA (a minimum of 10 μg) are needed (Sambrook et al., 1989) for successful execution of the experimental protocol, and less abundantly expressed genes may not be detected. Qualitative RT-PCR partially circumvents these problems, as it is a more sensitive technique that requires significantly less RNA (a maximum of 1 μg) (Sambrook et al., 1989; Kawasaki, 1990). In addition, RT-PCR is less time-consuming and messy than northern blot analysis. However, there are two significant limitations to qualitative RT-PCR: (1) differences in transcript levels cannot be quantified without a densitometer, and (2) it lacks the sensitivity required to detect non-abundant messages.

Quantitative RT-PCR (Q-RT-PCR) was developed to overcome the limitations of qualitative RT-PCR. It is much more sensitive than either northern blot analysis or qualitative RT-PCR. In addition, the reactions are carried out in sealed, thin-walled glass capillary tubes placed into a PCR thermal cycler called the LightCycler. This allows 32 samples to be assayed simultaneously, enabling high-throughput analysis. Q-RT-PCR utilizes a system of dyes. One example is SYBR green, which binds double-stranded DNA. The LightCycler detects the amount of SYBR green that is being incorporated into the newly synthesized PCR product and records this data as a function of the fluorescence incorporated versus temperature. This data can then be analyzed utilizing a melting curve module which provides detailed information about the number and specificity of the resultant PCR amplicons. Quantification results are calculated with either a relative or absolute quantification module, which determines the level of expression for a gene of interest based on results obtained from a standard curve (*http://www.Roche-applied-science.com/lightcycler-online*; Wittwer, 2001). Q-RT-PCR is routinely used to quantify the message levels of poorly expressed genes, and to assess the very small differences in expression that can exist between a set of genes. For these reasons, this technique is well-suited for the analysis of *B. burgdorferi* gene expression within infected mice, as the number of bacteria residing within tissues after dissemination is small, and the transcription of infection-associated genes by these bacteria is often several orders of magnitude below housekeeping gene expression.

Gilmore and colleagues (2001) were the first investigators to utilize Q-RT-PCR to analyze *B. burgdorferi* gene expression. In this landmark report, the transcript levels of several pathogenesis-associated genes were assessed within engorged larval and nymphal ticks harboring a *B. burgdorferi* infection. Shortly thereafter, the message levels of a few select genes were measured within infected mouse tissues (Hodzic et al., 2002, 2003). Following in the footsteps of these initial publications, several additional laboratories have recently utilized Q-RT-PCR to analyze *B. burgdorferi* gene expression within mouse tissues and cultured bacteria (Caimano et al., 2004; Lederer et al., 2004; Liang et al., 2004; Miller et al., 2005; Zhang et al., 2005).

Critical Parameters

Prior to beginning any experiment, the primers to be used for LightCycler-based PCR analysis should be designed and ordered. It is recommended that each primer length not exceed 24 bp, and that the target amplicon be between 350 and 500 bp. Amplicons that are 200 to 250 bp in size can be easily accommodated, but products approaching 1 kb (or larger) will require significant modification of the amplification protocol and/or $MgCl_2$ concentrations used for PCR amplification. In addition, oligonucleotide primers should be free of secondary structures, and should not exhibit melting temperatures (T_m) below 60°C. T_m lower than 60°C will require modifications of the annealing temperature used during the amplification program. Integrated DNA technologies (IDT) has a Website that is very useful for assessing the T_m and secondary structures of potential PCR primers (*http://www.Idt.com*).

If RNA is not to be extracted from *B. burgdorferi*–infected mouse tissues on the day of animal euthanasia, the infected tissues must be removed aseptically and immediately snap-frozen in liquid nitrogen. Tissues stored in this manner are good for ~9 months. It is extremely important that RNase-free conditions are maintained throughout the duration of all RNA-based protocols. In addition, frozen tissues must be kept cold on dry ice while being pulverized to prevent RNase-mediated degradation of the RNA. These experimental

Table 1D.3.2 Troubleshooting Guide for Commonly Encountered Problems

Protocol	Problem	Possible cause(s)	Solution(s)
RNA Isolation	RNA pellet difficult to resuspend and/or is gelatinous	Overdrying of pellet	Only allow pellet to air dry for 5–10 min
		Due to incomplete homogenization, proteinaceous particles may be present resulting in a gelatinous pellet	Homogenize samples more thoroughly or increase incubation time to 15–20 min at 60°C and flick tube every few minutes to facilitate pellet resuspension
	A_{260}/A_{280} <1.7	High level of protein contamination, due to disruption of the interphase between the aqueous and organic layers	Leave a bit of aqueous phase behind to ensure that the interphase is not breached
		Pellet not completely resuspended	Increase incubation time to 15–20 min at 60°C and flick tube every few minutes to facilitate pellet resuspension
		Too small a volume of Trizol used for tissue homogenization	Increase volume of Trizol used for tissue homogenization
	Concentration of RNA much lower than expected	Frozen tissues are older than 9 months	Only use frozen tissues <9- months old
		Improper storage/handling of frozen tissues	Tissues must be removed aseptically, immediately snap-frozen in liquid nitrogen, and stored at −80°C. Tissues must not be allowed to thaw during the homogenization process.
		Incomplete homogenization of tissue	Homogenize tissues thoroughly, breaking up all tissue fragments
		Too small a volume of Trizol used for tissue homogenization	Increase volume of Trizol used for tissue homogenization
		Insufficient removal of aqueous layer	Only leave a small amount of the aqueous layer behind
		RNase-mediated degradation of RNA	Ensure all benchtops, reagents, and equipment are kept RNase-free
	No RNA obtained	Frozen tissues are older than 9 months	Only use frozen tissues <9 months old
		Improper storage/handling of frozen tissues	Tissues must be removed aseptically, immediately snap-frozen in liquid nitrogen, and stored at −80°C. Tissues must not be allowed to thaw during the homogenization process.
		RNase-mediated degradation of RNA	Ensure all benchtops, reagents, and equipment are kept RNase-free

continued

Table 1D.3.2 Troubleshooting Guide for Commonly Encountered Problems, *continued*

Protocol	Problem	Possible cause(s)	Solution(s)
DNase I treatment/ agarose gel electrophoretic analysis of RNA	RNA remains contaminated following DNase I treatment	Sample heavily contaminated with genomic DNA	Increase incubation time to 1 hr at 37°C. Increase amount of DNase I and inactivation reagent used for each sample.
	RNA is no longer present, is smeared, or only one rRNA band is visible following DNase I treatment	RNase contamination of Turbo DNA-free buffer and/or inactivation reagent	Treat buffer and inactivation reagent with RNAsecure. Heat to inactivate RNases before and after use.
		DNase I contaminated with RNases	Maintain RNase-free conditions. Use only RNase-free DNase I and aliquot into small volumes to prevent contamination of entire stock vial.
	Prior to DNase I treatment, RNA is no longer present, is smeared, or only one rRNA band is visible	RNase-mediated degradation of RNA during Trizol extraction	Maintain RNase-free conditions. Only allow pellet to air dry for 5–10 min, by inverting tube over KimWipes used only for RNA extractions.
		Agarose gel electrophoresis reagents contaminated with RNases	Maintain RNase-free conditions. Use RNase-free solutions. Treat solutions with RNAsecure.
	Both rRNA bands are intact and well defined, but RNA has an overall smeared appearance	Sample is overloaded on gel (commonly seen with spleen tissue)	Load <5 μg of each sample into gel wells
		RNA is heavily contaminated with protein (commonly seen with spleen tissue)	Digest the homogenized sample with 20 μg/ml proteinase K for 1–3 hr at 55°C, prior to the addition of chloropane
LightCycler-based analysis	Capillary tube breaks while inserting into instrument carousel	Excessive force used to insert tube into carousel slot	Gently push tube down through slot. If resistance is encountered, stop and check the carousel slot for pieces of broken tube. Remove clog with a paperclip. Collect broken capillary pieces (if the tube did not completely shatter). Place in a microcentrifuge tube. Invert the cup portion in the bottom of the microcentrifuge tube and place the broken stalk on top of the inverted cup. Centrifuge briefly to collect the contents in the eppendorf tube. Pipet contents into a new capillary tube.

continued

Table 1D.3.2 Troubleshooting Guide for Commonly Encountered Problems, *continued*

Protocol	Problem	Possible cause(s)	Solution(s)
	Amplification of the "no-template" negative control occurs	Benchtop and/or LightCycler reagents are contaminated with DNA	Use DNA-Away to maintain DNA-free conditions. Change gloves frequently. Prepare reagents in DNA-free vessels that have never been used for bacterial cultivation.
	Melting peak analysis shows two large peaks, but only one was expected	Nonspecific template binding by oligonucleotide primers, resulting in nonspecific amplicons	Analyze reaction products on an agarose gel. (1) If the diagnostic gel electrophoresis indicates only the specific amplicon is present, decrease the primer concentration, and/or add 1–5 sec to the amplification step at the temperature where the nonspecific peak occurs. Be sure to modify the program to set the data acquisition to occur at this final step. (2) If the diagnostic gel electrophoresis indicates more than one PCR product is present, alter the annealing temperature of the amplification module and/or the Mg^{2+} concentration or design more specific oligonucleotide primers.
	Melting peak analysis shows the expected specific peak, but a much smaller peak is also present at a lower temperature	The primers are binding to each other, forming primer dimers	Decrease the primer concentration, and/or add 1–5 sec to the amplification step at the temperature where the nonspecific peak occurs. Be sure to modify the program to set the data acquisition to occur at this final step.
	The quantification curves are very flat and the fluorescence is extremely low	The SYBR green is no longer active	Order and use fresh SYBR green
	No melting peaks are obtained and the quantification curves are crooked straight lines	Reagents incorrectly added to the master mix: either two of the same primer were added or too much SYBR green was added	Add the correct volumes and concentrations of reagents to the master mix
	All reagents were correctly added to the master mix, and the SYBR green is fresh, but the quantification curves and melting peaks are flat for the more dilute standards and cDNAs	An inhibitor of the PCR reaction is present. Potential inhibitors: DEPC-treated Tris buffer (never DEPC-treat Tris containing compounds); DNase inactivation reagent (always move DNase-treated RNA into clean tubes); chloroform (always use chloropane instead of	Identify and remove inhibitor

continued

Table 1D.3.2 Troubleshooting Guide for Commonly Encountered Problems, *continued*

Protocol	Problem	Possible cause(s)	Solution(s)
		chloroform during RNA extraction); ethanol (always remove ethanol and dry RNA pellets for 5–10 min to allow residual ethanol to evaporate); protein contamination of RNA samples (too much protein inhibits RT-PCR)	
	The cDNAs and more concentrated standards are amplifying, but the more dilute standards are not	The DNA standards are not fresh	Prepare freshly diluted standards
		The genomic DNA is old and beginning to degrade	Extract more genomic DNA from cultured bacteria

precautions are absolutely critical, as the key to achieving good results from all of these protocols is the extraction and purification of high-quality RNA.

Once suitable RNA has been obtained, the appropriate protocol steps must be followed to completion to ensure that all contaminating genomic DNA is removed. RT-PCR data obtained using the LightCycler is useless if the RNA used to synthesize cDNA is contaminated with genomic DNA. Another critical quality control parameter involves the genomic DNA used to generate the standard curves during LightCycler-based PCR. This DNA must also be of high quality, and dilutions should be freshly prepared on a weekly basis. The sensitivity and accuracy of all LightCycler-based results is dependent on the genomic DNA standards. If the standards are not high quality, the assay will not work. Prior to cDNA synthesis and PCR amplification, DNA-free conditions must be maintained to prevent DNA contamination of reagents. Finally, the SYBR green utilized for LightCycler-based PCR must be diluted in TE buffer and properly stored in light-protected containers in a non-frost-free freezer. Most importantly, do not use SYBR green that is older than 3 months, as suboptimum results will be obtained.

Troubleshooting

There are several problems that can be encountered with each of the protocols described within this unit. Possible causes and solutions for each of these common problems are summarized in Table 1D.3.2.

Anticipated Results

The following yields can be expected upon extraction of RNA from *B. burgdorferi*–infected mouse tissues: 700 to 800 ng/μl from bladder, 2.0 to 2.2 μg/μl from heart, 1.2 to 1.4 μg/μl from joints, 5.0 to 7.0 μg/μl from spleen, and 2.0 to 2.3 μg/μl from ear. The conversion of RNA to cDNA by reverse transcriptase has a minimum efficiency of 30%, resulting in at least 300 ng of cDNA being synthesized from 1 μg of RNA (Sambrook et al., 1989).

Time Considerations

RNA can be feasibly extracted from a maximum of twelve tissues per day, processed in two groups containing six tissues each. If a small number of samples are being analyzed, the DNase I treatment, agarose gel electrophoresis analysis, and diagnostic PCR reactions can all be performed in 1 day. RT-PCR reactions and LightCycler-based PCR analysis of a small number of samples can be accomplished in 1 day, as the first-strand cDNA synthesis reaction takes just over 1 hr and LightCycler-based analyses only require 2 hr (1 hr to prepare 32 samples, and 1 hr for LightCycler-based PCR of the samples). To simultaneously analyze numerous samples, more time will be required to complete each phase of the protocol. Extracted RNA samples are stable for ~1 year at −80°C, and cDNA

samples can be maintained at −20°C in a non-frost-free freezer for ∼1 month, allowing the researcher weeks to months to complete the entire protocol, if necessary.

Characterization of Bacteria in Mixed Biofilm Communities Using Denaturing Gradient Gel Electrophoresis (DGGE)

Organisms within mixed culture biofilms are inherently difficult to study. Due to the wide range of microenvironments within biofilms (Costerton et al., 1994), the distribution of some organisms may be restricted to a few cells within a specialized microniche, whereas others may be more broadly distributed. Although traditional culturing techniques are widely used, they have an inherent bias in selecting those organisms capable of growing on a particular laboratory medium. Molecular-based detection methods are frequently used to detect bacteria in complex environments since they are unaffected by the limitations of bacterial culturability (Amann et al., 1992; Muyzer and Smalla, 1998).

Several molecular tools are currently available to aid in the quest to describe and identify the consortia within environmental biofilms. Fingerprinting assays like terminal restriction fragment length polymorphisms (t-RFLPs), which use PCR and restriction enzyme digestion, create a banding pattern unique to each environmental sample, enabling descriptions of changes in bacterial community structure with time or treatment (Diez et al., 2001). Cloning and sequencing of the PCR product of the 16S small ribosomal subunit rRNA gene is typically used for sequence-based identification of bacterial community members (Amann et al., 1992). However, fingerprinting assays are limited because they fail to identify community members; cloning assays are likewise limited because the number of clones that can be sampled and sequenced may fail to describe the overall diversity (Dunbar et al., 2002). Denaturing gradient gel electrophoresis (DGGE; see Basic Protocol) both reveals a community fingerprint and provides sequence information for identifying community members. This sequence information can then be used for fluorescence in situ hybridization (FISH) to determine the spatial distribution of individual bacteria (Tonolla et al., 2005).

CAUTION: Follow all biosafety requirements relevant to the microorganisms and biofilm substrates under investigation. Although the majority of organisms used with these protocols are environmental isolates, classified as biosafety level-1 (BSL-1) organisms, additional safety precautions would be needed for BSL-2 and BSL-3 organisms. Refer to *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for instructions on safe handling of microorganisms.

DENATURING GRADIENT GEL ELECTROPHORESIS

BASIC PROTOCOL

Denaturing gradient gel electrophoresis (DGGE) is an excellent molecular tool for examining biofilm bacteria in mixed communities, particularly where traditional culturing techniques are not possible (Muyzer et al., 1993; McLean et al., 2005). In brief, ~200- to 500-bp DNA fragments are amplified using PCR (Support Protocol 1), typically targeting the 16S rRNA gene with specially modified primers using as a template the total bacterial DNA extracted from an environmental sample (Support Protocol 2). This community template PCR product, containing fragments of differing guanine and cytosine (G+C) content, is then separated into individual bands by electrophoresis through an acrylamide gel with an increasing gradient of formamide and urea. Electrophoresis through the denaturing gradient causes partial denaturation of the PCR duplexes. Ideally, each unique sequence in the community PCR product will partially denature at a different spot in the gel. The banding pattern generated can be used as a bacterial community fingerprint, and

[a]Many other general and specific primers are available and described in the literature.

bands excised from the gel can give sequence-based identification of organisms detected in the biofilm (see Critical Parameters and Troubleshooting).

DGGE procedures should be performed according to the instructions provided by the equipment's manufacturer; the following procedure was designed for the Bio-Rad DGGE system. Successful DGGE requires careful optimization of the ideal denaturant concentration, time of electrophoresis, and voltage for each set of biofilm samples (Muyzer et al., 1993; Lyautey et al., 2005). The conditions described below should work well for biofilms from typical aerobic sites using the GC357F and 907R universal bacterial primer set (Table 1E.1.1).

Materials

6% acrylamide solutions containing 30% ("LO") and 50% ("HI") denaturant (see recipe)
0.5× TAE buffer: mix 100 ml 50× TAE (*APPENDIX 2A*) in a final volume of 10 liters H_2O for at least 1 hr; store up to 3 months at room temperature
Ammonium persulfate (APS): store up to 1 year at 4°C
N,N,N′,N′-tetramethylethylenediamine (TEMED): store up to 1 year at 4°C
PCR-amplified samples and standards (Support Protocols 1 and 3)
2× DGGE gel loading dye (see recipe)
Ethidium bromide staining solution (see recipe)
TE buffer (*APPENDIX 2A*)

DGGE System, e.g., DCode Universal Mutation Detection System (Bio-Rad) for 16-cm parallel gels, including:
  Glass plates with spacers (grooved, 1 mm), two pairs
  Sandwich clamps
  Sponges
  Casting stand
  Alignment card
  30-ml syringes, syringe sleeves, syringe cap screws, luer syringe locks, and luer couplings
  Tygon tubing
  Model 475 gradient former
  Y fitting
  16-well combs
  DCode lid stand
  Electrophoresis/temperature control module
  Electrophoresis tank
  Sandwich core
Absorbent bench paper
50-ml conical polypropylene tubes
20-G needle
250-ml beakers
Micropipettor with gene sequencing tips
Power supply (e.g., Bio-Rad Power Pac 300)

Plastic mesh shelf liner (available from many stores, e.g., Wal-Mart)
UV transilluminator
Scalpel, sterile
1.5-ml microcentrifuge tubes, sterile
Digital or other camera for gel documentation

Additional reagents and equipment for sequencing DNA (e.g., Slatko et al., 1999; optional)

Prepare gel sandwich equipment and denaturant gel solutions

1. Select one long plate (18 × 20 cm) and one short plate (16 × 20 cm) for each gel. Wash the plates using deionized water and allow to air dry.

   The Bio-Rad system is designed to fit two gels in the sandwich core to be run simultaneously. The authors typically run duplicates of the same samples on both gels for data redundancy. It is possible to run only one gel at a time. In that case, the second position in the sandwich core should hold the two glass plates with no spacer (see step 19 below). The following protocols are for running two gels.

2. Cover the bench with absorbent paper. Pipet 20 ml "HI" denaturant (50%) acrylamide solution into each of two labeled 50-ml conical tubes and allow it to come to room temperature in the dark. Pipet 20 ml of "LO" (30%) solution into each of two additional labeled 50-ml conical tubes and allow it to come to room temperature in the dark.

   CAUTION: *Unpolymerized acrylamide is a potent neurotoxin. Proper safety precautions such as gloves and lab coat should be worn throughout the DGGE protocol (also see UNIT 1A.3).*

   Bio-Rad recommends degassing the acrylamide solutions immediately before casting the gel. The authors have eliminated this degassing step and have noticed no difference in the time or quality of gel polymerization.

3. Assemble the gel sandwich.

   a. Lay the large plate down first and then place the spacers (1.0 mm thick) on the plate so that the notched opening of the spacers faces the sandwich clamps and grooves are down.
   b. Place the short glass plate on top of the spacers so that it is flush with the bottom edge of the long plate.
   c. Position a sandwich clamp on each side of the gel sandwich.

4. Assemble the gel-casting apparatus.

   a. Place the sandwich assembly in the alignment slot of the casting stand. Loosen the clamps.
   b. Insert the alignment card. Align the plates and spacers.
   c. Remove the alignment card and remove the sandwich assembly from the casting stand. Check that the plates and spacers are flush at the bottom.
   d. When good alignment is obtained, tighten the clamp screws finger-tight.

      The gel sandwich will leak if the glass plates and spacers are not aligned carefully and if the clamps are too loose.

5. Place the aligned sandwich assembly on a sponge in the casting stand and lock the assembly in place by securing the sandwich clamps in the stand.

6. Repeat steps 3 and 4 for the second gel to be cast, but set it aside. Do not place the second sandwich assembly into the casting stand until the first gel has been cast.

Prepare syringes, gradient former, and catalysts

7. Prepare two 30-ml syringes in the following manner:

   a. Label one syringe "LO" (for the 30% solution) and the other one "HI" (for the 50% solution).

   b. Slide a syringe sleeve on each such that the volume markings on the syringe can be seen in the front.

   c. Place a syringe cap screw on the plunger end of each syringe such that the catch screw on the cap is facing the back.

   d. Screw a luer syringe lock with ~8 in. (~20 cm) of Tygon tubing fitted on it onto each syringe.

      The catch screw will fit into the screw slide on the gradient former.

8. Place the Model 475 gradient former on the covered lab bench with the cam wheel on your right side. Rotate the cam wheel counterclockwise to the vertical or start position and tape the wheel in place so that it doesn't move when attaching the syringes.

   When first using this gradient former, filling both syringes with water, practicing putting them on and off the former, and delivering the water into a beaker is highly recommended. Getting a good feel for the gradient former will be critical to delivering the acrylamide solutions quickly in later steps of this protocol.

9. Attach a 20-G needle to the luer coupling on ~12 in. (~30 cm) of Tygon tubing which has a Y-fitting on the other end.

10. Place the needle (pointing down) at the top center of the sandwich assembly in the casting stand and insert it between the two glass plates ~1/4 in. (~0.63 cm) beveled side facing away. Tape the needle in place.

11. Prepare catalysts immediately prior to use:

    a. In a 1.5-ml microcentrifuge tube, prepare a 10% ammonium solution (APS) by adding 0.1 g APS and 1.0 ml deionized water. Vortex to dissolve.

    b. Aliquot ~90 µl TEMED into another 1.5-ml microcentrifuge tube.

       TEMED solution should be clear; if it is yellow replace it.

12. On the covered lab bench, place the rack with the 50-ml tubes with acrylamide, gradient former, and casting stand with sandwich assembly such that the Tygon tubes from the gradient former can attach to the Y-fitting on the needle. Prepare a beaker of water to rinse the tubes and an empty beaker for waste water.

    Steps 13 to 16 are time sensitive and need to be completed within 5 to 7 min. Ensure that the sandwich assembly, syringes, and gradient former are completely ready before proceeding.

Cast DGGE gels

13. Move one "HI" and one "LO" acrylamide tube to the front of the rack. Add the catalysts: 18 µl TEMED and then 180 µl 10% ammonium persulfate. Cap and mix by inverting several times.

    These steps will be repeated for the second gel to be cast.

    The final concentrations (each) of APS and TEMED are 0.09%.

14. With the syringe connected to the tubing, withdraw all of the high-density solution into the "HI" syringe. Carefully release any air and a bit of solution back into the tube with 19 ml remaining in the syringe. Place the syringe in the gradient former.

Parallel gels are a top-filling method, so the "HI" syringe is placed in the back position on the gradient former farthest from you. The cap screw on the syringe slides into the black groove on the gradient former, and the sleeve on the syringe is tightened into place with the white plastic screw on the gradient former.

15. Repeat step 14 for the low-density solution into the "LO" syringe and place in the front position on the gradient former.

16. Connect the tubing from each syringe to the Y-fitting with the needle. Rotate the cam wheel slowly and steadily to deliver the gel solution.

17. When finished, remove the needle from between the glass plates. Carefully insert the comb (16-well, 1.0 mm thick).

18. Place the tubing and needle into a beaker of water and reverse the cam to rinse any gel solution. Rinse tubing and fittings thoroughly. Discard all acrylamide-contaminated liquids into hazardous waste.

    The residual casting mixture in the conical tube solidifies fairly quickly (within minutes). If it remains liquid, or semisolid, there will be a problem with the gel. If the sandwich assembly leaks there will be puddles of acrylamide in the corners of the sandwich assembly, and air bubbles will form along the edges of the comb. Leaking disrupts the gradient and the well integrity; the gel will need to be cast again.

19. Place the second gel sandwich assembly in the casting stand carefully. Prepare and cast the second gel as in steps 7 to 18 above.

20. Let gels polymerize at least 60 min (up to 24 hr). If the gels are left overnight to polymerize, place a layer of damp paper towels soaked in 0.5× TAE buffer on top, then surround the top half of the sandwich assemblies in the casting stand with plastic wrap (go around two or three times). Place in a dark cupboard.

Prepare DGGE apparatus for electrophoresis

21. Fill the electrophoresis tank with ~7 liters of 0.5× TAE buffer (to the line that says "Fill"). Put the electrophoresis/temperature control module into the tank. Place the clear loading lid on the module.

    The authors place the DGGE tank on a rolling lab cart to allow easy access to the 10-liter carboy of buffer, to both sides of the core for loading samples and for moving the entire tank to the sink to dispose of used buffer.

22. Set the temperature controller to 60°C and set the ramp rate to 200°C/hr to allow the buffer to reach the desired temperature most quickly. Turn on both the heater and pump.

23. After the gels have polymerized, carefully remove one sandwich assembly from the casting stand. Remove the comb.

24. Rinse the wells two or three times with buffer using narrow gene sequencing tips that can slide between the glass plates or the 20-G needle and tubing on a syringe. Repeat for the second gel.

25. Assemble the upper buffer chamber of the sandwich core while it lies flat on the bench. Make sure the white core gaskets are clean and in place and lubricate the entire gasket with running buffer to obtain a good seal.

26. Snap the sandwich assembly onto the core by sliding the grooved sandwich clamps into the white posts on the core. Turn the core over and repeat with the other sandwich assembly, forming an upper chamber dam.

    The shorter gel plate should face the inside of the core buffer chamber.

If only one gel is to be run, assemble a set of glass plates without the spacers. Ensure that the bottoms of the plates are flush. Attach it to the other side of the core to form an upper chamber dam.

27. Pour 350 ml of 0.5× TAE running buffer into the upper buffer chamber. Check for leakage. If it leaks, remove both sandwich assemblies from the core and repeat steps 25 and 26.

28. Turn off the power on the electrophoresis/temperature module and remove it to the DCode lid stand. Place the sandwich core in the tank with the red electrode post on the right side of the tank and module. Replace the electrophoresis/temperature module and turn on once again.

Load and run DGGE gels

29. Thaw on ice the PCR-amplified samples and standards from Support Protocol 1.

30. Add one vol 2× gel loading dye to each DGGE sample and standard immediately prior to loading (i.e., for 10 μl PCR product add 10 μl dye). Mix contents of tube by flicking, and centrifuge briefly.

31. Remove the clear loading lid from the electrophoresis/temperature module.

    Look down into the upper buffer chamber and note the wells of the gel in the sandwich assembly on the opposite side of the tank. The samples are loaded through this opening while the temperature control module of the electrophoresis unit is running to maintain temperature.

32. Load the samples into the wells. Load one or two wells with the DGGE standards.

    Careful aim is critical while loading the samples and requires some practice. The sample will rush out of the tip of the pipet upon contact with the hot buffer in the tank. The authors find it helpful to allow a small air bubble at the tip of the pipet to allow a bit of time to position the tip before the sample flows out.

33. Place the clear loading lid on top of the temperature control module. Attach the electrical leads to the Bio-Rad Power Pac 300 power supply. Run the gel at 180 V for 7 hr at 60°C.

Remove and stain DGGE gels

34. After electrophoresis is complete, turn the power supply and system off. Disconnect the power cord and electrical leads. Remove the temperature control module and place it on the DCode lid stand. Remove the core and pour the buffer from the upper chamber into the sink.

35. Lay the core with sandwich assemblies on a covered laboratory bench. Remove the sandwich assembly from the core by pressing firmly on the black clamps on the core and pulling toward you. Turn the core over and remove the second sandwich assembly.

36. For each sandwich assembly, remove the clamps from the sandwich. Slide out the spacers. Carefully pry off the shorter glass plate.

    The gel is extremely thin and fragile but should stick to one plate or the other. (It doesn't matter which.)

37. Cut a piece of plastic mesh shelf liner that is slightly larger than the gel. Lay the mesh on top of the gel. Invert so that the mesh is now underneath and the gel is above, still attached to the glass plate.

38. Release the gel from the plate using a spacer damp with buffer to pull one corner of the gel loose from the plate while lifting that edge of the glass plate slowly.

39. Place each gel on its mesh into a plastic tub containing 500 ml ethidium bromide staining solution. Stain 20 to 30 min in the dark. Destain in another tub with 500 ml of deionized water 20 to 30 min in the dark.

    CAUTION: *Wear gloves for protection from DNA stains. See UNIT 1A.3 for more information regarding ethidium bromide, including methods of disposal.*

40. While staining and destaining, clean the DCode equipment. Pour out the running buffer in the electrophoresis tank and fill the tank with deionized water. Place the electrophoresis/temperature module back in the tank, turn on the pump, and run for 10 min. Rinse core, clamps, and other equipment with water and air dry.

41. Place the gel on a UV transilluminator using the mesh for transport, and photograph.

    CAUTION: *Wear UV eye protection and gloves.*

Extract DNA from DGGE gels

42. Excise the gel from the middle of the band using a sterile scalpel while the gel is on the UV transilluminator and place into a sterile 1.5-ml microcentrifuge tube. Minimize the amount of time the UV lamp is on and use protection from the UV light.

43. Add 20 µl TE buffer to each tube, crush the gel slice with the pipet tip, and soak overnight at 4°C.

44. Use 2.5 µl of the gel slice supernatant as template in a 50-µl PCR reaction, and concentrate the PCR product as if a pure culture to 100 to 200 ng (see Support Protocol 1, but reduce the reaction volume to 50 µl).

45. Perform DGGE to verify the presence of only one band.

    DGGE may promote heteroduplex formation (where two heterologous DNA strands anneal together). In subsequent DGGE analysis, heteroduplexes typically result in two or three bands as opposed to just one (see Critical Parameters and Troubleshooting for possible solutions to this problem).

46. If one band is confirmed, use another 2.5 µl of the gel slice supernatant from step 43 as template in a 50-µl reaction (see Support Protocol 1) to generate PCR product for sequencing.

    The 357F primer without the GC clamp should be used with the 907R primer. The GC-clamp will interfere with the sequencing reaction.

47. Sequence the amplified DNA, e.g., as described by Slatko et al. (1999), or submit samples to a sequencing laboratory.

PCR OF BIOFILM SAMPLES FOR DGGE

SUPPORT PROTOCOL 1

PCR parameters must be carefully optimized for DGGE samples to avoid artifacts in banding patterns and to maximize bands detected. There are several well established universal bacterial primers for DGGE targeting the 16S rRNA gene (Watanabe et al., 2001); however, group or even species-specific primers can be used with DGGE provided either the forward or reverse primer has a GC clamp (Muyzer et al., 1993; Diallo et al., 2004). The GC clamp is a string of alternating guanines and cytosines added to the 5′ end of the forward or reverse primer used in DGGE (see Table 1E.1.1). The addition of a 40-base-pair GC clamp to one primer prevents the duplex PCR product from completely

denaturing in the DGGE gel (Muyzer et al., 1993). DGGE can not resolve PCR fragments >600 bp (Muyzer and Smalla, 1998). To describe overall bacterial diversity, the authors recommend using universal bacterial primers GC357 F and 907 R targeting the V3 to V6 regions of the 16S rRNA gene (Table 1E.1.1; Watanabe et al., 2001).

Materials

Ampli*Taq* GOLD Polymerase, 5 U/μl (Applied Biosystems)
10× PCR buffer II (Applied Biosystems)
25 mM $MgCl_2$ (Applied Biosystems)
10 mM dNTP blend (Applied Biosystems)
Primers (Table 1E.1.1): dilute to 20 μM
DNA template: extracted from biofilm sample (Support Protocol 2)
Nuclease-free PCR water (Applied Biosystems)
Low mass DNA ladder (Invitrogen)
100% isopropanol
3 M sodium acetate pH 5.2 (*APPENDIX 2A*)
70% ethanol
TE buffer (*APPENDIX 2A*)

0.2-ml PCR tubes, sterile
Thermocycler with block for 0.2 ml tubes
−80°C freezer
Vacuum centrifuge (Savant; optional)

Additional reagents and equipment for performing agarose gel electrophoresis and ethidium-bromide staining (see Voytas, 2000)

Carry out PCR

1. Prepare the mix for PCR amplification as 100-μl reactions in sterile 0.2-ml PCR tubes containing the indicated final concentration of the components:

   0.5 μl 5 U/ml Ampli*Taq* Gold polymerase (2.5 U)
   10.0 μl 10× PCR buffer (1×)
   12.0 μl 25 mM $MgCl_2$ (3.0 mM)
   8.0 μl 10 mM dNTP blend (200 μM each)
   2.5 μl 20 μM GC 357F primer (0.5 μM; see Table 1E.1.1)
   2.5 μl 20 μM 907R primer (0.5 μM; see Table 1E.1.1)
   2.5 μl DNA template (2.5% v/v)
   62 μl nuclease-free PCR water.

   Volumes given are specific for 100-μl reactions. If less product is needed (e.g., in re-amplification of an extracted DGGE band or preparation of a particularly concentrated biofilm DNA extraction), the reaction volumes can be reduced to 25 or 50 μl. The primary reason to reduce the volumes of some reactions is to save reagents and avoid wasting Taq polymerase. In addition, the authors have found that contaminants in the biofilm matrix interfere with PCR less when the least amount of template is added to the PCR reaction.

   The performance of the AmpliTaq Gold polymerase has been consistent in the authors' experience.

   This recipe is optimized with low stringency for the universal primer set. With a more specific primer set it may be desirable to increase the stringency of the reaction by decreasing the $MgCl_2$ concentration or altering the primer concentration (Kramer and Coen, 2001).

2. Carry out PCR using the following amplification cycles:

Initial step:	10 min	96°C	(denaturation)
30 cycles:	45 sec	96°C	(denaturation)
	45 sec	46°C	(annealing)
	60 sec	72°C	(extension)
Final step:	30 min	72°C	(final extension)
	indefinitely	4°C	(hold).

Thermocycler parameters with universal eubacterial primers should include: a low annealing temperature to maximize universal primer binding, a low number of cycles to reduce bias caused by differential template binding, and a 30-min final extension step at 72°C to reduce heteroduplex formation.

3. Confirm the presence of PCR product using an ethidium bromide–stained agarose gel loaded with low mass DNA ladder (e.g., Voytas, 2000).

4. Estimate the amount of PCR product by comparing the brightness of sample bands with the brightness of the ladder bands to determine how many PCR reactions will need to be pooled to get 700 to 1000 ng of DNA per well with replicate DGGE runs, for sample consistency.

Typically 100 to 200 μl of PCR product will need to be pooled to obtain 700 to 1000 ng of DNA.

Concentration of the PCR product can also be estimated by measuring the A_{260}/A_{280} ratios on a spectrophotometer (Gallagher and Desjardins, 2006).

Concentrate sample

5. Pool all the PCR product required from one sample into a 1.5-ml centrifuge tube.

6. Add 1 vol isopropanol and 0.1 vol 3 M sodium acetate, pH 5.2. Place in a –80°C freezer for 10 min. Centrifuge 15 min at 16,100 × *g*, room temperature.

The PCR product should be in a tight white pellet.

7. Remove the isopropanol by decanting or aspirating with a pipet. Wash the pellet with 70% ethanol by adding ~500 μl to the tube.

8. Centrifuge 3 min at 16,100 × *g*, room temperature. Remove the ethanol with a pipet. Repeat wash (steps 7 and 8).

The pellet may be loose and easily lost in decanting. The pellet should be nearly colorless now.

9. Allow the pellet to air dry or place in a vacuum centrifuge to dry any remaining ethanol.

10. Resuspend the pellet in 10 μl TE if preparing sample for one gel and in 20 μl TE if preparing sample for two gels. Store the resuspended PCR product up to 3 months at –20°C.

It is very difficult to load more than 40 μl into a DGGE well. Loading dye should be mixed with PCR product in a 1:1 ratio (see Basic Protocol). Therefore, precipitated PCR product should be resuspended in a very small amount of TE (10 to 15 μl).

SONICATION OF FIELD SAMPLES AND EXTRACTION OF DNA

SUPPORT PROTOCOL 2

Field experiments offer the opportunity to examine microbial communities for biofilm growth under conditions of natural selection. For example, this protocol describes procedures that have been used in studies of aquatic biofilm formation on dialysis tubing

(McLean et al., 2005) and wastewater biofilms (A.K. Welsh and R.J.C. McLean, unpub. observ.). DNA extraction methods may need to be modified for biofilms in other environments. To this end, one strategy employed for technique development is to add known quantities of a test microorganism to an environmental sample and then use different methods to extract and amplify 16S rRNA from the test microorganism. Ideally, the test organism should not occur naturally in the particular environment being tested. In this context, the organism will not be detected in negative control samples and will be detected in positive control samples.

Pipets, dilution tubes, and media are used in large quantities during a field experiment. The authors recommend preparing agar plates and tubes for dilutions at least 1 to 2 days in advance, and having ~5% extra materials available in the event of unforeseen circumstances. In this manner, any plates or tubes that become contaminated can be identified and discarded. Types of substrata used in biofilm field studies are widely variable and can be adapted to each unique environmental biofilm studied.

Materials

Biofilm sample (from the field)
95% or 100% ethanol
Sterile deionized H_2O
R2A agar medium (Difco): prepare agar plates according to manufacturer's instructions
TE buffer (*APPENDIX 2A*)
DNeasy tissue kit (Qiagen)
Enzymatic lysis buffer: 20 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)/2 mM EDTA (*APPENDIX 2A*)/1.2% Triton X-100
Lysozyme (Fisher Scientific)

Writing paper
Petri dishes, sterile
Scalpel, sterile
Glass scintillation vials: Fisher brand 20-ml borosilicate vials with polypropylene caps recommended, sterile
Bath sonicator (e.g., Branson Ultrasonic Cleaner Model 1510MT): fill to a depth of ~1 cm prior to use; drain and clean after use
50-ml centrifuge tubes
Vacuum filter unit with 0.2-μm filter

1. *Optional:* To cut a sample (e.g., a leaf) into a section prior to analysis, trace a 1-cm square (or desired area) on a piece of writing paper. Lay a sterile petri dish on top of the paper. Place the sample to be trimmed onto the petri dish and cut with a sterile scalpel.

   In this fashion one has an accurately measured area, yet can maintain aseptic technique.

2. Sterilize a pair of forceps by dipping in 95% to 100% ethanol and passing through a flame. Use the sterile forceps to aseptically place the sample into a sterile glass scintillation vial with enough sterile deionized water to completely submerge the biofilm material.

   Process biofilm samples from the field for molecular analysis as soon as possible (typically within one week of collection).

   The recommended glass vials are particularly useful for small objects because they are inexpensive and can be readily autoclaved. Other similar type vials are perfectly suitable. For larger objects, glass beakers covered with aluminum foil or bottles can be substituted.

The use of plastic containers is strongly discouraged because the elastic walls dampen the shear forces generated by the sonicator, which drastically reduces biofilm cell yield.

The containers used for sonication should be partially filled with a desired volume of dilution medium (e.g., 10 ml water or physiological buffered saline in scintillation vials) and autoclaved prior to use.

3. Place vials with biofilm material into a bath sonicator filled with water to just above the level of liquid in the vials. Close sonicator lid tightly and sonicate for the optimal time.

In the authors' experience 10 to 15 min is optimal for most samples; however, optimizing sonication conditions for the colonization substrata that are to be used is recommended. For this purpose, perform a preliminary experiment by growing biofilms on a surface, and then subjecting that particular surface to varying periods of sonication while periodically removing aliquots of liquid for dilution plating (McLean et al., 1999). As the plate counts are plotted against sonication time, the time giving the maximum counts is to be selected for the samples. Shorter times will not disrupt bacterial clumps (each of which will plate as a single colony), whereas longer times may result in cell damage and loss of viability, both conditions resulting in lower plate counts.

Some samples, notably limestone rock or plant leaves, will become cloudy or discolored during this process. This cloudiness or discoloration should not cause any problems in subsequent steps.

4. Decant the liquid containing the released biofilm bacteria from the scintillation vials into 50-ml centrifuge tubes. Use the sonicated samples to perform plate counts (step 5) and to extract DNA (step 7).

Ideally, the researcher should immediately proceed with DNA extraction. If necessary, samples may be stored overnight at −20°C before proceeding with extraction.

Perform plate counts

5. Serially dilute an aliquot of the sonicated material 10^{-2} to 10^{-5} in sterile water, and surface plate the dilutions on R2A agar.

For many freshwater heterotrophs, the authors have found sterile water to represent a suitable dilution buffer. R2A agar is an excellent general purpose medium that will grow a wide variety of heterotrophic bacteria commonly found in freshwater environments.

6. Incubate for the appropriate time and at the appropriate temperature for the particular environmental sample. Count colony forming units (cfus).

Time and temperature of incubation for these plates greatly depends upon the environment from which the biofilm sample is obtained. Freshwater heterotrophs typically require incubation for 72 hr at 25°C.

The number of cfu can give an overall indication of the concentration of heterotrophic bacteria present in the biofilm. The data can be used to compare replicate samples or samples with different treatments, in terms of the overall numbers of bacteria present. DGGE can then be used to describe the overall diversity of bacteria present.

Extract DNA

7. Centrifuge the sonicated samples containing the bacteria 10 min at 5900 × *g*, room temperature. Decant or pipet off the supernatant.

8. Suspend the sample in 1 ml TE buffer to preserve nucleic acids during storage.

9. Extract the bacterial community DNA using 250 µl of this sample and the DNeasy Tissue kit following the manufacturer's instructions for extracting Gram-positive bacterial DNA, which includes an enzymatic lysis step using enzymatic lysis buffer with 20 mg/ml lysozyme (see Internet Resources). Store the remaining sample at 4°C.

The Qiagen kit uses an enzymatic lysis protocol, which will target active bacterial cells (not dormant cells or spores) in the biofilm samples. The Gram-positive protocol will readily lyse both Gram-positive and Gram-negative bacteria.

The authors have found the DNeasy Tissue kit to be a straightforward and reliable DNA extraction kit. Other DNA extraction methods such as a freeze-thaw protocol (Gillan et al., 1998) can certainly be used to extract bacterial DNA for DGGE analysis.

The authors have found that substances present in biofilm samples may interfere with PCR. A DNA extraction and purification method is recommended, e.g., a Qiagen kit, that captures DNA on a column and removes it from the biofilm debris.

SUPPORT PROTOCOL 3

PREPARATION OF DGGE STANDARDS

Unlike normal gels, commercially available standards are not available for DGGE. Standards may be prepared from a mixture of PCR products from several organisms such as *Escherichia coli* MG1655, *Pseudomonas aeruginosa* ATCC 10145, and *Chromobacterium violaceum* ATCC 12472. Any organisms can be used to create a DGGE standard. Standard will need to be prepared in large quantities, because it will be included in every DGGE gel.

Additional Materials *(also see Support Protocol 1)*

Bacterial strains for use in the standard—e.g., *Escherichia coli* MG1655 (ATTC #47076), *Pseudomonas aeruginosa* (ATCC #10145), and *Chromobacterium violaceum* (ATCC #12472)
Appropriate medium for bacteria used (*APPENDIX 2C*)
DNeasy tissue kit (Qiagen)

CAUTION: *E. coli, P. aeruginosa, and C. violaceum are* Biosafety Level 2 (BSL-2) pathogens. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

1. Extract DNA from an overnight broth culture of each of the bacterial cultures for the standard using the DNeasy Tissue kit.
2. Carry out PCR, isopropanol precipitation, and sample concentration on the extracted bacterial cultures as described in Support Protocol 1, with the following modifications.
   a. Because these are pure cultures, use a concentration of 100 to 200 ng per well.
   b. Prepare enough of each culture for at least 20 DGGE gels.
   c. Rehydrate dried PCR product from the pure cultures in TE such that the final volume of the mixture of organisms is not more than 15 µl per DGGE well.
3. Electrophorese each pure culture PCR product in individual wells of a DGGE gel using the same denaturant concentration, time, and voltage as optimized for the environmental biofilm samples to determine the melting point of each. Adjust the concentration as required.

   The amount of each pure culture added per well will need to be optimized for each strain. For example, Escherichia coli MG1655 will make one nice bright band and three other weak bands due to multiple copies of its 16S rRNA gene. Reducing the amount of E. coli PCR product added will reveal only one primary band.

4. Mix the appropriate concentrations of PCR product for each of the strains in the standard for use in 20 DGGE gels. Divide into ~60-µl aliquots (for four gels) and store up to 1 year at –20°C.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acrylamide solution (6%) containing denaturant (30% or 50%)

15.0 ml 40% (37.5:1) acrylamide/bisacrylamide
2.0 ml 50× TAE buffer (*APPENDIX 2A*)
12.0 ml (for 30% denaturant) *or* 20.0 ml (for 50% denaturant) formamide, molecular-biology grade
12.6 g (for 30% denaturant) *or* 21.0 g (for 50% denaturant) urea
Adjust volume to 100 ml with water
Store in a dark bottle up to 3 months at 4°C

CAUTION: *Wear gloves because unpolymerized acrylamide is a neurotoxin. It is very helpful to cover lab benches with an absorbent paper in order to contain any spills.*

The authors typically use a 6% polyacrylamide (ratio of acrylamide to bisacrylamide, 37.5:1) gel with a 30% to 50% denaturant concentration where 100% denaturant contains 7M urea and 40% formamide. See (Muyzer et al., 1993) for more information.

DGGE gel loading dye, 2×

Add 0.25 ml 2% bromophenol blue and 0.25 ml xylene cyanol to 7.0 ml 100% glycerol. Add 2.5 ml water. Mix well. Sterilize by passing through a 0.2-μm filter. Divide into 1-ml aliquots. Store up to 5 years at room temperature.

100% glycerol is very difficult to move with a pipet. The authors typically pour the glycerol into a 10-ml graduated cylinder then add all the other ingredients into the cylinder. Cover the graduated cylinder with Parafilm and invert several times to mix. Pour the dye mixture into a sterile petri dish and draw it up into a 10-ml Luer-Lok syringe. Attach a 0.2 um filter by screwing it onto the Luer-Lok syringe with dye in it. Push the dye mix through the filter into a sterile 10-ml centrifuge tube. Dispense aliquots into ten 1.5-ml sterile tubes.

Ethidium bromide gel staining solution, 3μg/ml

Prepare 500 ml of 0.5× TAE by combining 495 ml water and 5 ml 50× TAE buffer (*APPENDIX 2A*) in a plastic tub. Add 3 drops (~50 μl per drop) concentrated (10 mg/ml) stock solution of ethidium bromide (Bio-Rad) using the dropper provided, to obtain a final working concentration of 3 μg/ml. Mix by rocking tub gently. Place cover on tub. Store dilute stain in the dark and use within 1 week.

COMMENTARY

Background Information

Denaturing gradient gel electrophoresis (DGGE), originally developed to identify point mutations, has now been successfully used for evaluating microbial diversity in a number of environments (Muyzer and Smalla, 1998). The banding patterns revealed by DGGE for each biofilm sample yields two kinds of information about the sample. First, the banding pattern from DGGE can be used as a community fingerprint which can be compared to other samples with similar or different treatments to evaluate overall community structure (Emtiazi et al., 2004; Sigler and Zeyer, 2004; Webster et al., 2004). Unlike other popular community fingerprinting techniques, bands can be extracted directly from the DGGE gel and sequenced to reveal the identity of dominant bacterial community members in the biofilm sample (Emtiazi et al., 2004; Webster et al., 2004).

Interpretation of DGGE community fingerprints and identification of community members from excised bands from DGGE gels have several possible limitations, e.g., PCR products with similar GC content can migrate to similar places in the gel, one organism can have generated more than one band due to multiple copies of the 16S rRNA gene, and DGGE has been shown to reveal only organisms that are >1% of the population, (reviewed in Muyzer and Smalla, 1998). In spite of its limitations, DGGE is an excellent tool for disclosing microbial diversity in complex

environments like biofilms (Emtiazi et al., 2004; Webster et al., 2004).

Critical Parameters and Troubleshooting

The procedures in this unit have been successfully carried out using the Bio-Rad DGGE system; the photographs in the DCode manual showing the different steps are very helpful. The only problems encountered have been with the gradient former, which is prone to rust and inaccuracy in the gradient delivery volume. Although there are other DGGE system manufacturers (e.g., C.B.S. Scientific), the authors have no experience with their equipment.

Lack of DGGE bands in a gel

The major critical issue that will compromise DGGE success is insufficient DNA loaded onto a gel. Typically 700 to 1000 ng of PCR product is required from environmental samples (Lyautey et al., 2005).

Time of electrophoresis and voltage will also affect the clarity of bands revealed in the DGGE. First, decide on a time of electrophoresis and a voltage. This has as much to do with scheduling as it does the resolution required. For the GC 357F and 907R primer set, the authors use 180 V for 7 hr. Roughly 1000 to 1200 volt hr should be sufficient and can be achieved with short high voltage runs or long low voltage runs (Diez et al., 2001). Time of electrophoresis should not exceed 16 to 18 hr because the denaturant dissolves into the buffer and can affect banding patterns (Sigler and Zeyer, 2004). Additionally, Bio-Rad recommends not exceeding 200 V with the DCode system. To determine whether gels are running long enough, carry out a time trial DGGE in which samples are loaded every hour for 7 or 8 hr, and examine the banding patterns. The time trial DGGE should show smears at the first time points as well as the migration progression and eventual melting points of the samples. Ideally, the samples should have melted and ceased migrating fully in the last two time points. If not, then the time of electrophoresis should be increased or decreased to match this pattern of migration (see Muyzer et al., 1993).

Another cause of lack of clear bands is an improper gradient. The most challenging aspect of applying DGGE for environmental samples, particularly with species-specific primers, is optimization of the appropriate denaturing gradient. An incorrect gradient will reveal smears, one tight band at the very top of the gel, or no bands at all. Bio-Rad sells a program, WinMelt or MacMelt, which will predict the optimal gradient for a sequence of interest, but this is of little use in biofilms from the environment where there is probably no sequence information.

Bio-Rad also recommends running a perpendicular gel to determine the ideal gradient for new, unknown samples (Fig. 1E.1.1A). The direction of electrophoresis (top to bottom) is perpendicular to the direction of the gradient (right to left). However,

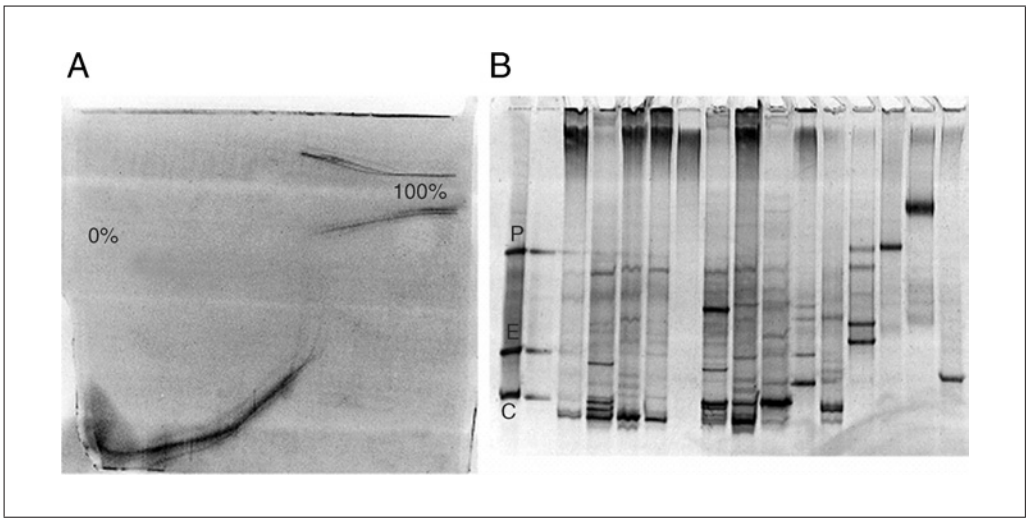

Figure 1E.1.1 Representative DGGE gels. (**A**) Perpendicular DGGE gel of seven wastewater biofilm organisms used to establish gradient range for further analysis. Here changes in band migration occurred between 45% and 60% concentration of urea/formamide. **(B)** A parallel DGGE gel analysis of mixed aquatic biofilm communities. PCR product from three organisms: *Pseudomonas aeruginosa* (P), *Escherichia coli* (E), and *Chromobacterium violaceum* (C) was used as standards. The number of bands approximates the number of different organisms in each environment.

perpendicular gels are extremely hard to cast because the sandwich assembly is filled from the side rather than the top. Instead of running perpendicular gels, it is more advisable to run a parallel gel (Basic Protocol) with a broad gradient of 30% to 70% and then adjust the gradient by 10% to find the appropriate one. For example, in aquatic biofilm samples with the GC 357F and 907R primer set, 20% to 40% denaturant resulted in a few smears and maybe one band, 30% to 50% denaturant gave a beautiful display (Fig. 1E.1.1B) and, 40% to 60% denaturant resulted in smears.

Poor gel polymerization

Replacing the necessary reagents, TEMED and ammonium persulfate, can rectify poor or slow gel polymerization. The authors replace DGGE reagents after one year.

Casting DGGE gels

This procedure must be done quickly yet safely as the reagents will polymerize within 5 to 10 min once the catalysts have been added. Typically the authors use two syringes that are labeled "HI" or "LO" (reflecting a high or low concentration of urea/formamide), labeled with two different colors of tape. Other containers used for mixing the acrylamide should be labeled with the same color tape. Often working with a second individual greatly helps here. One person will actually cast the gel, the second will quickly rinse the syringes and tubing used for casting with water, so that they can be reused.

Staining

Both 1% ethidium bromide and various SYBR stains produced by Molecular Probes (now Invitrogen), have been used for DGGE imaging. While any of these stains will work, the authors prefer ethidium bromide. The SYBR stains may be too sensitive and will also stain single-stranded DNA and generate other smears. (On a precautionary note, it is best to assume that any chemical that stains DNA is a potential mutagen and presents a significant health hazard; see *UNIT 1A.3*.) It is recommended that staining solutions be prepared on a weekly basis, and destaining solutions fresh before each gel.

Imaging

There are a number of protocols used to image gels, ranging from Polaroid pictures to electronic imaging and documentation. Typically, the authors acquire electronic images of all gels and then optimize contrast with a computer program (e.g., Adobe Photoshop). In the authors' experience, producing negative images of DGGE gels (using the Invert Image command of Photoshop) increases resolution.

Removal of bands for subsequent sequencing

Speed is important. The DGGE gel should be imaged quickly and then bands cut out and processed. The ultraviolet light from the transilluminator will interfere with DNA structure through the generation of thymine dimers.

Heteroduplex formation and multiple bands upon reamplification of DGGE bands

Heteroduplexes have been a chronic problem with the DGGE technique, particularly when using universal primer pairs (Muyzer and Smalla, 1998). Heteroduplex formation is caused during PCR when two heterologous strands form a duplex at the primer initiation sites. Following band excision and reamplification, heteroduplexes result in multiple bands upon DGGE electrophoresis of this re-amplified band. If heteroduplexes are a problem, try decreasing the annealing temperature of the PCR reaction, increasing the $MgCl_2$ concentration, and increasing the primer concentration (Muyzer and Smalla, 1998). More than one band in a DGGE gel from one reamplified band may also result from an improper gradient or not running the gel long enough. What may appear to be one band can actually still be a mixture of sequences. Resolving individual bands on DGGE upon reamplification may require changing the gradient, e.g., from a 30% to 50% gradient to a 35% to 40% gradient.

Anticipated Results

Figure 1E.1.1 shows the two types of gels that are commonly used with DGGE: a perpendicular gel (Fig. 1E.1.1A) in which the urea-formamide gradient is perpendicular to the direction of electrophoresis, and the more commonly seen parallel gel (Fig. 1E.1.1B). Although perpendicular gels are sometimes used for identifying suitable gradients for analyzing a particular community, the authors have found it to be more practical to use a parallel gel with a wide gradient range (e.g., 30% to 70%) for range-finding, and a smaller gradient range (e.g., a 35% to 45% gradient) to enhance resolution of DNA fragments of similar G+C content.

Time Considerations

Certainly transportation and other issues will affect the time needed for field work. Table 1E.1.2 provides a general guide for time

Table 1E.1.2 Time Considerations for Field Sampling and DGGE Analysis of Field-Grown Biofilms

Procedure	Time required
Preparation of all supplies and samples needed for experiment and analysis	1-2 days
Transportation to the field site and back to lab	varies with location
Sonication of sample	30 min[a]
DNA extraction and purification	1 hr
PCR	2-3 hr
Agarose Gel analysis of PCR product	1-2 hr
DGGE setup and specimen loading	1-2 hr
DGGE run	4-16 hr[b]
Gel staining and photography	1 hr

[a]Sample can be stored overnight under suitable conditions (e.g., in appropriate buffer at −20°C).
[b]Specimens can be run at lower voltage for longer times (e.g., 16 hr at 80 volts, 60°C) or higher voltages for shorter times (e.g., 7 hr at 180 volts, 60°C).

requirements in obtaining biofilm growth on a glass microscope slide and its subsequent analysis by DGGE. The most time-consuming aspect of applying DGGE for biofilm samples from the environment is optimizing the DGGE conditions. The conditions described in this unit should work well for biofilms from typical aerobic sites using the GC357F and 907R universal bacterial primer set. However, field sites conducive to growing high GC-containing Gram-positive bacteria or a specific primer set targeting sulfate-reducing bacteria, for example, will require careful optimization of the DGGE conditions to reveal the overall bacterial diversity. Optimization of the DGGE conditions should be done prior to the final assay with, if possible, biofilm samples from the same or a similar field site.

Acknowledgments

This research in R.J.C.M.'s laboratory was sponsored by the U.S. Environmental Protection Agency (EPA) under grant application GR825503-01-0, NIH grant R15 AI050638, and a subcontract from the U.S. Air Force. The authors thank M.B. Barnes and M.K. Windham for their help in developing DGGE protocols.

Biological Sand Filters: Low-Cost Bioremediation Technique for Production of Clean Drinking Water

Michael Lea[1]

[1]Clearinghouse: Low-cost Water Treatment Technologies for Developing Countries, Ottawa, Ontario, Canada

ABSTRACT

Approximately 1.1 billion people in rural and peri-urban communities of developing countries do not have access to safe drinking water. The mortality from diarrheal-related diseases amounts to ~2.2 million people each year from the consumption of unsafe water. Most of them are children under 5 years of age—250 deaths an hour from microbiologically contaminated water. There is conclusive evidence that one low-cost household bioremediation intervention, biological sand filters, are capable of dramatically improving the microbiological quality of drinking water. This unit will describe this relatively new and proven bioremediation technology's ability to empower at-risk populations to use naturally occurring biology and readily available materials as a sustainable way to achieve the health benefits of safe drinking water. *Curr. Protoc. Microbiol.* 9:1G.1.1-1G.1.28. © 2008 by John Wiley & Sons, Inc.

Keywords: biofiltration • bioremediation • biosand filter • water treatment • microbiological contamination • water quality • developing countries

INTRODUCTION

The burden of microbiologically contaminated water is borne most heavily by the rural (largest, 80%) and peri-urban (fastest-growing) populations without access to safe water in developing countries—all need microbiologically clean water to sustain their lives and secure their livelihoods.

There is conclusive evidence that biological sand (biosand) filters are capable of dramatically improving the microbiological quality of drinking water. Biosand filters are based on a centuries-old bioremediation concept: water percolates slowly through a layer of filter medium (sand), and microorganisms form a bacteriological purification zone atop and within the sand to efficiently filter harmful pathogens from microbiologically contaminated water. Household-scaled biosand filters are a small adaptation of traditional large, slow sand filters such that they can uniquely be operated intermittently.

To use the simple, yet effective, on-demand biofiltration intervention, a person simply pours contaminated water into the household biosand filter and immediately collects treated water.

The purpose of the following comprehensive protocols is to facilitate knowledge transfer with the goal to empower vulnerable, poorest-of-poor populations in rural and peri-urban communities of developing countries, and to also promote using naturally occurring biology and readily available materials that they already possess as a cost-effective practical approach to combat poverty and inequality and achieve the health benefits of safe water by developing their own household water security solutions.

DOI: 10.1002/9780471729259.mc01g01s9

CAUTION: Under ideal circumstances, a biosand filter can produce drinking water of high quality. However, this cannot always be assured or guaranteed due to variations in the construction and installation of the filter. This also applies to the consumption of water from the biofilter. It should be noted that a biosand filter cannot be relied upon to remove certain or all forms of water contamination.

CAUTION: If it is suspected that the community water source is contaminated with organic and inorganic industrial and agricultural toxicants, or in regions where the ambient air reaches freezing temperatures, biosand filtration should not be recommended as an appropriate water treatment technology.

STRATEGIC PLANNING

The performance efficiency of the biosand filter is limited by excessive turbidity, especially during the monsoon or rainy season where the performance of the filter will be compromised with excessive clogging, requiring frequent recovery of flow rate (see Basic Protocol 8). It is essential to obtain turbidity readings (see Basic Protocol 1) on the raw water source where biofiltration is being proposed as a potable water solution.

When working in partnership with village health workers among the rural poor with the challenge of providing affordable safe drinking water in every household using biosand filters, it is recommended to implement a comprehensive community-based multiple barrier approach (Nath et al., 2006). Education and training, emphasizing environmental awareness, hygiene, and sanitation are thus first necessities. Reduction of excessive turbidity and particulates by settlement or prefiltration or flocculation establishes a second barrier (Basic Protocol 2). Removal of parasites, protozoal cysts, bacterial pathogens, and in some situations removal of chemical contaminants (e.g., arsenic) by biosand filtration is the third barrier (Basic Protocol 3). The fourth and final barrier, safe storage in a closed, spigotted container and providing a disinfectant residual (see Basic Protocol 9) are all key aspects to strengthen local capacity to carry out sustainable community-based primary health care to prevent preventable illnesses and deaths caused by microbiologically contaminated water.

Selecting the Type of Biosand Filter

The three most common biological sand filters, as illustrated in Figure 1G.1.1, are based on the 60 liter (15 gallons) "BioSand" design developed by Dr. David Manz at the University of Calgary, Canada, in the 1990s.

As long as adaptations do not contravene the principles and protocols put forth that safeguard the bioremediation processes and functions of the filter, it may also be suggested that highly effective 15 to 20 gallon (60 to 80 liters) volume per day biological sand filters can be constructed by the household using readily available materials in their own community.

As illustrated in Figures 1G.1.1 and 1G.1.2, there are various materials that biosand filters can be constructed from, ranging from concrete, plastic, metal, or indigenous containers—each with its own benefits and drawbacks.

Strategically, the local availability of appropriate media (sand and gravel), parts, tools, and their respective costs will be critical predetermining factors in making decisions on the choice of construction method and corresponding materials used; therefore, stepwise one-fits-all construction protocols cannot be standardized. This flexibility of construction choice based on locally available resources will also provide the lowest cost—an important parameter for community acceptability and to ensure sustainability.

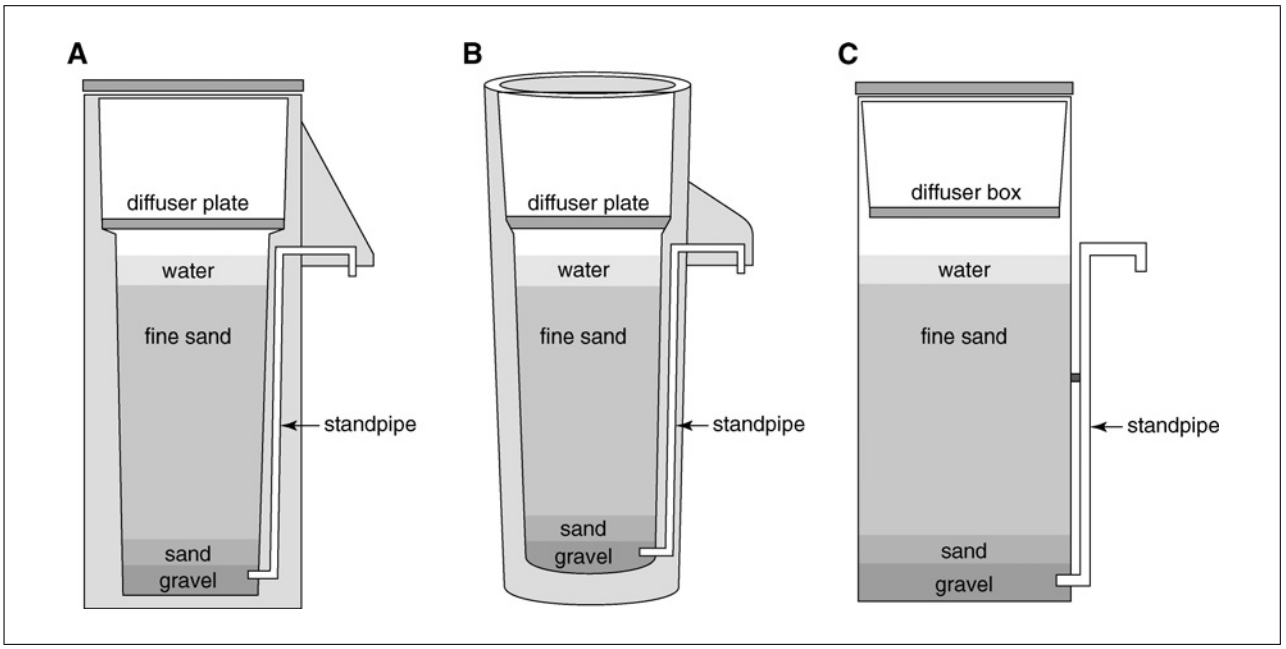

Figure 1G.1.1 Schematic diagrams of three common filters. (**A**) CAWST's concrete (BioSand) filter—high rates of user acceptance (over 300,000 filters worldwide). (**B**) BushProof's Concrete (BioSand) Filter—round shape provides additional strength and requires less materials. (**C**) Barrel Filter—locally built biosand filters made from plastic barrels or metal drums.

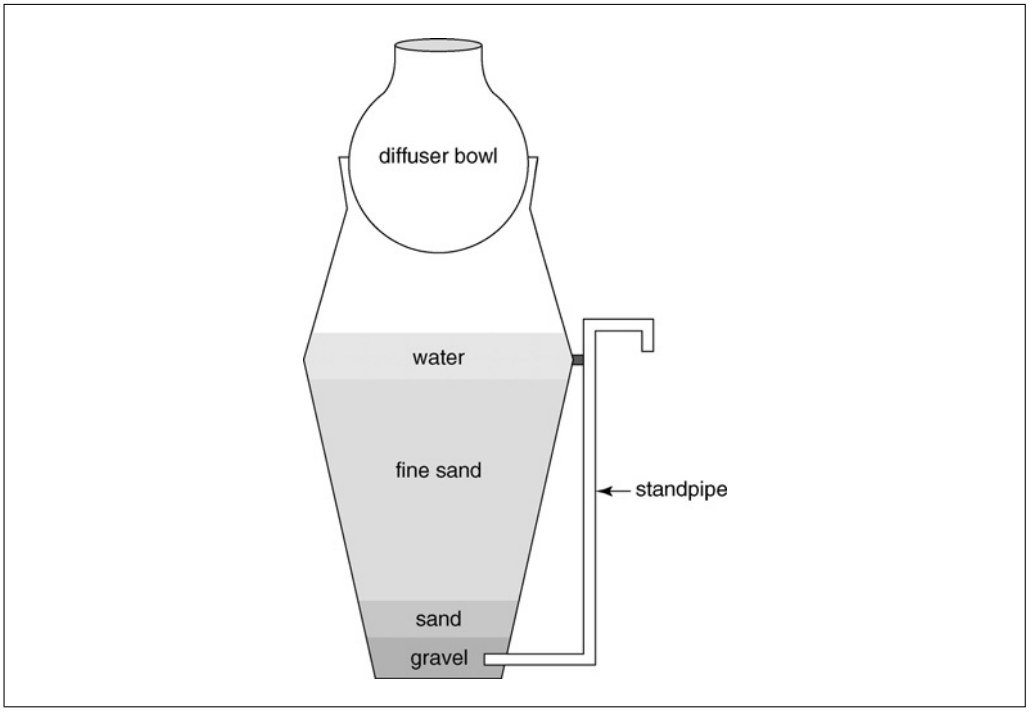

Figure 1G.1.2 Illustration featuring an indigenous biofilter constructed of clay jars.

Constructing the Biofilter

In an attempt to demystify biosand engineering to the essential principles, all on-demand household-scaled biological filters share five simple but critical design parameter commonalities featured in Figure 1G.1.3:

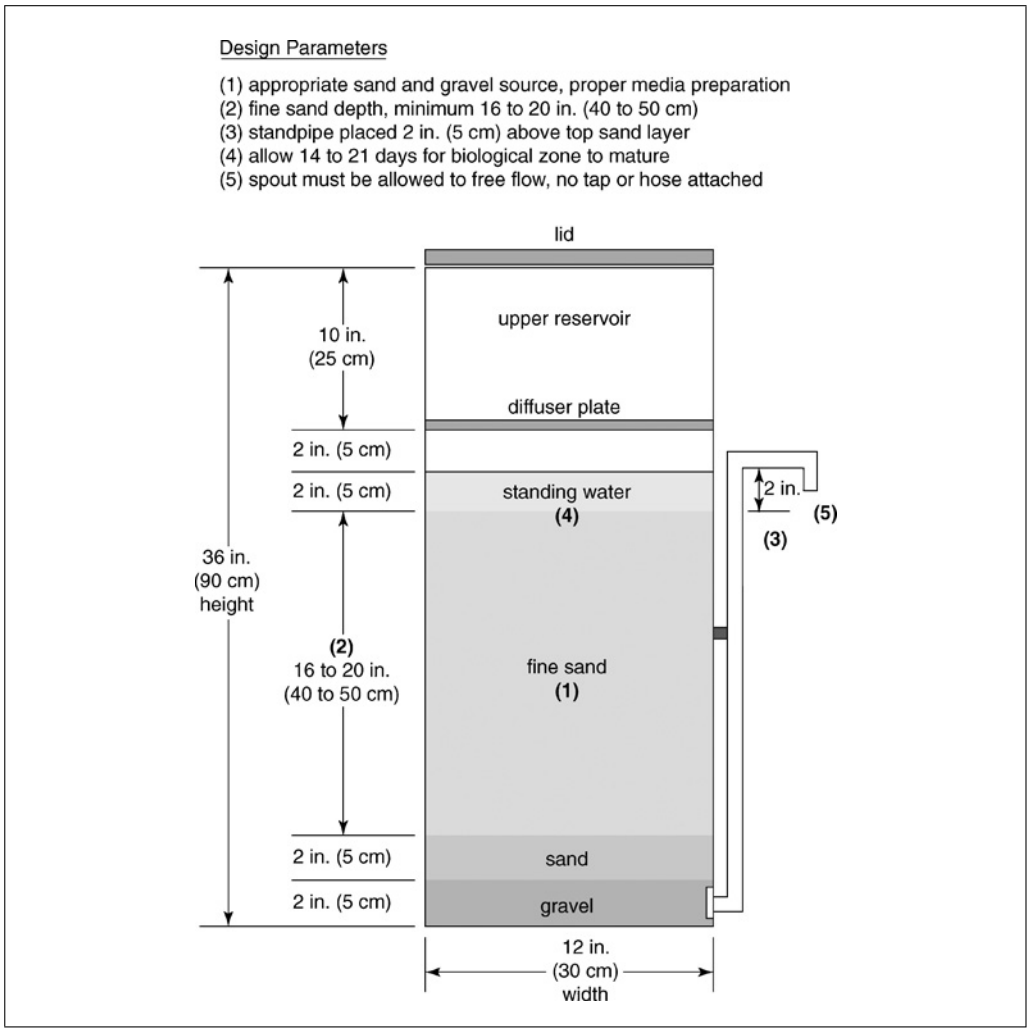

Figure 1G.1.3 Illustration highlighting major principles and generic size dimensions.

1. Biosand filters can be built wherever there is a good source of sand and gravel and where proper media preparation is undertaken (see Basic Protocol 4).

2. The most widely used version of the biosand filter is a concrete container filled with ~16 to 20 in. (40 to 50 cm) of fine sand. This is the absolute minimum fine sand requirement to ensure the best quality of water possible.

3. A layer of static standing water (the supernatant) is automatically maintained by placing the outlet pipe 2 in. (5 cm) above the level of the top sand layer.

4. Allow 14 to 21 days for the biological zone to mature.

5. Water must be allowed to flow freely from the filter—never plug or put a hose or tap on the outlet spout.

Further discussion of specific detailed methods of construction are not required as there are numerous methods and associated protocols readily available from various organizations for constructing the various featured configurations of biosand filters (see Key References).

Major Components of Biological Filters

Container

Durable water-tight "water safe" containers can typically be purchased or constructed in various shapes (square or round) and materials (e.g., concrete, metal, plastic, ferrocement, brick, or clay jars). The key is to find an appropriate-sized container that is readily available or can be constructed at a reasonable price in your area.

Lid

The lid can be made out of any material, but it must be clean and ideally fit tightly onto the container. A filter lid is essential to prevent excess biofilm growth by blocking sunlight and guarding against insects and other contaminants entering the filter.

Diffuser plate

The diffuser plate can also be made out of various common materials, such as plastic or metal. If made from sheet metal, ensure it is constructed out of good quality galvanized metal, or it will rust, either prematurely plugging the diffuser holes with rust or gradually increasing the diffuser hole size. A larger hole will result in disturbance of the schmutzdecke—a word derived from the German schmutz (dirt) and decke (covering)—or sand media.

Avoid wood, as it will attract mold growth and tend to shrink or warp, ultimately not fitting tightly inside the filter container, allowing potential disruption of the top sand layer.

A drip grid is a required feature of all diffusers to evenly distribut the water without disturbance of the schmutzdecke or sand media. On the bottom of the diffuser plate, measure and mark a 1-in. × 1-in. (2.5 cm × 2.5 cm) grid. At each intersection on the grid, pound a $^1/_8$-in. (3 mm) diameter hole through the diffuser material, using a hammer and nail. Smaller holes will restrict the flow through the filter; larger holes will result in disturbance of the schmutzdecke or sand media.

The primary functions of the diffuser plate are: (1) protecting the surface zoogleal biofilm—the schmutzdecke—and top layer of sand by dispersing the energy of water as it enters the filter, and (2) facilitating the addition of critical oxygen to the supernatant water through aeration process.

Filtrate standpipe and the standing water level (supernatant)

The standpipe is the essential component in all biosand filters. This simple but key design component automatically maintains the standing water level (the supernatant) to a constant depth when installed 2 in. (5 cm) above the top of the filtering sand. As illustrated, see Figure 1G.1.1, household-scaled biological filters can be made in various ways, but each configuration share this one simple but important design commonality.

The standpipe can be made out of $^1/_4$-in. (6 mm) i.d. tubing 3 feet (1 meter) long. The materials can vary from plastic or metal, such as copper, PVC pipe fittings, polyethylene, or vinyl tubing. The primary function of the supernatant, as set by the standpipe placed 2 in. (5 cm) above the filtering stand, is to keep the biological layer alive during pause periods. The schmutzedecke requires an aquatic environment and a constant influx of food and oxygen. If the static water level rises above 2 in. (5 cm), oxygen will not diffuse, creating a thinner biological zone. If the static water level drops below 2 in. (5 cm), then the inflowing water will disturb the sand and the biolayer may dry out due to excessive evaporation in high ambient temperatures.

Media (sand and gravel) bed

The media bed is composed of the following matrix of sand and gravel. Also refer to the discussion below: Media Selection and Preparation.

Filtering layer (fine sand)

Upper fine sand (filtering) layer—$^1/_8$ in. (3.15 mm) or less diameter sand. The depth of the filtering sand bed is 16 to 20 in. (40 to 50 cm). This is the absolute minimum fine sand requirement to ensure the best quality of water possible.

The actual volume of fine sand required is 25 quarts (~25 liters). The upper fine sand (filtering) layer is responsible for removal of pathogens and the establishment of the biological zone, including the schmutzdecke.

Support layer (coarse sand)

Support layer—$^1/_8$- to $^1/_4$-in. (3.125 to 6.25 mm) diameter sand, depth 2 in. (5 cm). Coarse sand volume required is 3 quarts (~3 liters). The purpose of the middle support layer is to prevent the sand mixing with the underdrain layer.

Underdrain layer (fine gravel)

Underdrain layer—$^1/_4$- to $^1/_2$-in. (6.25 to 12.5 mm) diameter gravel, depth should cover standpipe inlet [may be a depth of 2 in. (5 cm) or more]. Gravel volume required is 3 quarts (~3 liters). The purpose of the lower gravel layer is to allow unrestricted water flow out of the filter via the standpipe.

Adapting Biosand Construction for Available Materials and Community Needs

Again, as long as adaptations do not contravene basic construction parameters for the major components of biological filters, it is advocated that highly effective biosand filters can be constructed by the household using readily available materials in their own community.

Locating a source of appropriate sand and gravel

The effectiveness and efficiency of the filters is dependent on the community locating a source of uncontaminated sand and gravel.

Media Selection and Preparation

All biosand filters share a common feature, correct media (sand and gravel) selection and preparation.

Good sources of sand and gravel

Clean crushed rock from a quarry or gravel pit is the material of choice. The sand grains will have more surface area and the rough edges provide different ionically charged surfaces causing contaminants to be attracted to the sand grains.

If crushed rock is absolutely not available, the next choice would be sand from high on the banks of a river (that have not been submerged in water).

Poor sources for sand and gravel

Avoid riverbed sand and gravel. The grains are too smooth, round, and uniform in size. River sand is often contaminated with bacteria and organic material.

Sand and gravel should never come from a beach area. The grains are also too smooth, round, and uniform in size. It may also contain salts that dissolve into the filtered water.

Indicators the sand is appropriate for use in a biofilter

When you pick up a handful of the sand, the grains should be of different sizes and shapes and you should be able to feel the coarseness of the grains.

When you squeeze a handful of dry sand, the sand should all pour smoothly out of your hand.

Indicators the sand is NOT appropriate for use in a biofilter

When you squeeze a handful of dry sand, it should not ball up in your hand. If it does, it probably contains dirt or clay.

It should also not contain any very fine sand, silt, or organic material (e.g., leaves, grass, sticks, loam, clay, or dirt).

It should not contain microbiological contamination (avoid areas that have been used frequently by people or animals).

Selection criteria for appropriate sand and gravel

Grain size and quality of the sand are crucial to the effectiveness of a filter's performance. Grain size is important since larger or nonuniform sizes result in removal of less contaminants from the water. Alternatively, a finer grain size, by filling in the voids between larger grains, may render the media bed to be so compact as to offer an unacceptable flow rate due to high resistance. Quality of sand refers to the absence of fine silt or clay, which causes turbidity in the effluent.

As a last resort, a filter can be installed with contaminated river or beach sand. Initially, this will create a situation where the supposedly treated water will contain a greater density of indicator pathogens than the source water originally poured into the filter. Over time (up to 3 months), this situation will stabilize when all the food on the contaminated media has been consumed by the filter's normal biological processes. During this time period, it is highly recommended that filtered water from the biofilter be treated by an additional process such as household chlorination or SODIS (see Basic Protocols 9 and 10).

The Importance of the Schmutzdecke Layer

While locating and preparing proper sand and gravel are of great importance, the formation of the biological zone is perhaps the single most important component within the filter. Newly installed or recently cleaned filters do not effectively remove pathogens.

The biologically active zoogleal film develops on the surface of the sand filter and helps water purification by breaking down pathogens into inorganic compounds through chemical, microbiological oxidation, and predatory activity. The effectiveness of the biofilm relies on the following critical points: (1) a constant aquatic environment; (2) the biological zone needs food, therefore raw water should be intermittently fed within a consistent daily regimen [at least one 5-gallon (20 liter) bucket of water every day with minimum of 1 hr and maximum of 48 hr pause periods, a recommended pause period of 6 to 12 hr in-between feeding is suggested (CAWST, 2008)]; (3) oxygen is required for the metabolism process, and (4) sufficient water temperature are all essential to keep the biofilm microorganisms alive.

The schmutzdecke merges with the deeper distinct biological zone, a continuation of the area of biological action where microorganisms living below the schmutzdecke also help to consume and trap other microorganisms. The bacterial activity is most pronounced in the upper part of the filter bed and gradually decreases with depth as oxygen and food becomes scarcer to sustain life.

The biofilm and biological zone typically develop within two to three weeks (it may take up to 30 days) depending on the temperature and the biological content of the raw water. The water from the filter can be used during the first few weeks while the schmutzdecke is being established if a safer water source is not available, but chlorination is recommended at least during this time period. Over time the filter flow rate may decrease when the schmutzdecke becomes too thick and dense, requiring periodical maintenance (see Basic Protocol 8).

Guidelines for Operating a Biosand Filter

The combined use of the following recommended guidelines for operating a biosand filter will ensure the best quality of treated water.

1. Use a designated dirty container for collecting raw water from source.

2. Use the best sources of water (least contaminated) available: the better the source of water is, the better the treated water will be. A biosand filter can use any water source such as rain water, shallow wells, rivers, lakes, or surface water, but it should be taken from the same source consistently. Using the same source of water every day will improve the filter effectiveness. The water source should be the cleanest available since biosand filters cannot remove 100% of biological contaminants.

3. Over time, the microorganisms in the biological zone adapt to the "food" available in the untreated water source. If different water sources are used for each pour, that may result in an increased level of a contaminant that the microorganisms of the schmutzdecke are unable to consume or destroy. Several days may be required for the schmutzdecke to adapt to a new water source.

4. The diffuser plate must always be in place when pouring water into the filter: **never pour water directly into the filter without using the diffuser plate.**

5. The filter lid should always be kept on the filter.

6. Water must always be allowed to flow freely from the filter—never plug or put a hose or tap on the outlet spout. Plugging the outlet pipe could increase the water level in the filter, which could kill the biolayer due to lower oxygen diffusion into the standing water layer (supernatant) and/or resulting in a thinner biological zone that becomes anaerobic. Putting a hose on the outlet spout can drain (siphon) the water in the filter, dropping the water level below the sand layer, also, killing the biolayer.

7. Use a separate designated safe storage container container to safely store the filtered water. (See below for considerations when storing filtered water.)

8. Food should never be stored in the filter. It will attract insects. Since the water in the top of the filter is contaminated, it will in turn contaminate the food.

9. The treated water should be chlorinated after it passes through the filter to ensure the highest quality of water and to prevent recontamination. See Basic Protocol 9.

10. An ideal flow rate is 0.6 liters per min.

11. Having a pause period between filter usages is important. The in-between time when the filter is not actively filtering contaminated water is the pause period. A pause period of 6 to 12 hr is a suggested time, which allows the biological zone to remain vibrant by consuming the pathogens that have been introduced daily. The percentage removal of biological contaminants is inversely proportional to the flow rate through the filter because the greater biological removal of contaminants takes more time. However, if the pause period is extended for too long, the microorganisms will eventually consume all of the food supply and then die off. This will reduce the filter's treatment efficiency when it is used again.

12. One 5-gallon (20 liter) bucket of water should be poured into the filter every day to maintain the schmutzdecke and the biological zone. A biofilter is most efficient when operated consistently. The maximum volume of daily water that can be treated amounts to a total of 15 to 20 gallons or 60 to 80 liters (CAWST, 2008) depending on the schedule of the household, for instance, filter feeding can occur once in the morning, noon, evening, and later with 6 hr pause periods in-between each feeding.

Storing Filtered Water Safely

It is important to remember that water collected and stored from a filter can be recontaminated before being consumed by the household. To prevent water from becoming contaminated again, follow these recommendations.

1. Use a designated safe storage container for collecting and storing treated water. A safe container has a lid and a narrow opening to prevent recontamination due to dipping with dirty cups or hands. A container with a tap or spigot to access the water is ideal.

2. Keep the container off the ground and away from insects and animals.

3. If possible, do not treat more water than required for daily use.

4. At regular intervals (only when dirty), clean the outside of the storage container.

READING SOURCE WATER TURBIDITY

Biological filters have limits to the amount of turbidity of the raw water source being poured into the filter. High amounts of suspended particles present in the turbid water settle in the top sand layer, leading to rapidly diminishing flow rates. In turn, requiring the filter to be cleaned frequently involves disturbing the biological layer, leading to diminished filter performance for several days thereafter. The preferred turbidity rate is <50 NTU (Nephelometric Turbidity Units). Higher turbidity levels (>50 NTU) will require prefiltration (CAWST, 2008).

Quantitative Estimate of Turbidity

BASIC PROTOCOL 1

The following straightforward procedure provides a reasonably accurate quantitative estimate of turbidity.

Materials

Turbidity gauge (see Support Protocol)

Additional reagents and equipment for turbidity treatment (Basic Protocols 2 and 10)

1. Fill the tube with water until the black and white disk on the bottom of the newly constructed gauge is no longer visible.

2. Read the gauge at the nearest marked water level.

   A simpler alternative test to measure the turbidity is to use a 2-liter clear plastic soft drink bottle filled with water. Place this on top of a black and white disk. Look down through the bottle from the top, if you can see the black and white disk the water probably has a turbidity of <50 NTU.

3. Perform the appropriate treatment based on the following turbidity guidelines:

   a. *If the turbidity reading is 50 NTU or greater before filtration*: Perform turbidity pretreatment as recommended (see Basic Protocol 2) to eliminate the inconvenience of frequent declogging of top layer of fine sand.

   b. *If the turbidity reading is >5 after filtration*: Use a disinfection process such as chlorine addition or solar disinfection (SODIS) in conjunction with the sand biofilter (see Basic Protocol 10).

   No health-based guideline value for turbidity has been proposed within WHO Drinking Water Guidelines *(http://www.who.int/water_sanitation_health/dwq/gdwq3rev/en/index.html)*. Generally, water with a turbidity of <5 NTU is usually acceptable in households, although this may vary with local circumstances.

SUPPORT PROTOCOL

Building a Simple Turbidity Gauge

The following simple do-it-yourself turbidity gauge can be easily constructed at a low-cost.

Materials

1-in (2.5 cm) diameter PVC end cap
Waterproof marking pen
Glass or clear plastic tubing, 1-in (2.5 cm) diameter, 28-in. (70 cm) length
PVC cement (glue)
Measuring tape

1. On the inside of the PVC end cap, draw a secchi disk using the waterproof marking pen by splitting the PVC circle into 4 equal quadrants using the marking pen (Catherman, 2006) as illustrated in Figure 1G.1.4.

2. Close one end of glass or plastic tube with the PVC end cap and cement in place.

   This end should be leakproof.

3. With the marking pen and measuring tape, mark the levels of turbidity, as illustrated in Figure 1G.1.4 (Rau, 2003).

OPTIONS FOR PRETREATING SOURCE WATER

Highly turbid water (>50 NTU) will require pre-filtration procedures to ensure the best quality of water possible. If the raw water source exceeds the previously stated design parameter for turbidity (50 NTU), the filter will clog up rapidly and may produce filtrate (outlet water) exceeding the intended filter performance values for turbidity (1 NTU), see Anticipated Results.

BASIC PROTOCOL 2

Alleviating High Turbidity

A particular challenge for most household-based water treatment technologies is high turbidity, i.e., >150 NTU. The efficiency of the filter is limited by the turbidity of the water source, especially during monsoon season where performance of the filter will be compromised. You can make a pretreatment filter out of old sari cloth, linen, or other fabrics.

Materials

Collected water
Filter container
Sari cloth or other fabrics

1. Let collected water settle (sedimentation) in the container so that solids sink to the bottom

   In some situations, this may be all that is necessary, especially if water is allowed to sit overnight. If so, settled water can be poured directly in the filter. If not, proceed with fabric straining.

2. Remove the lid from the filter container.

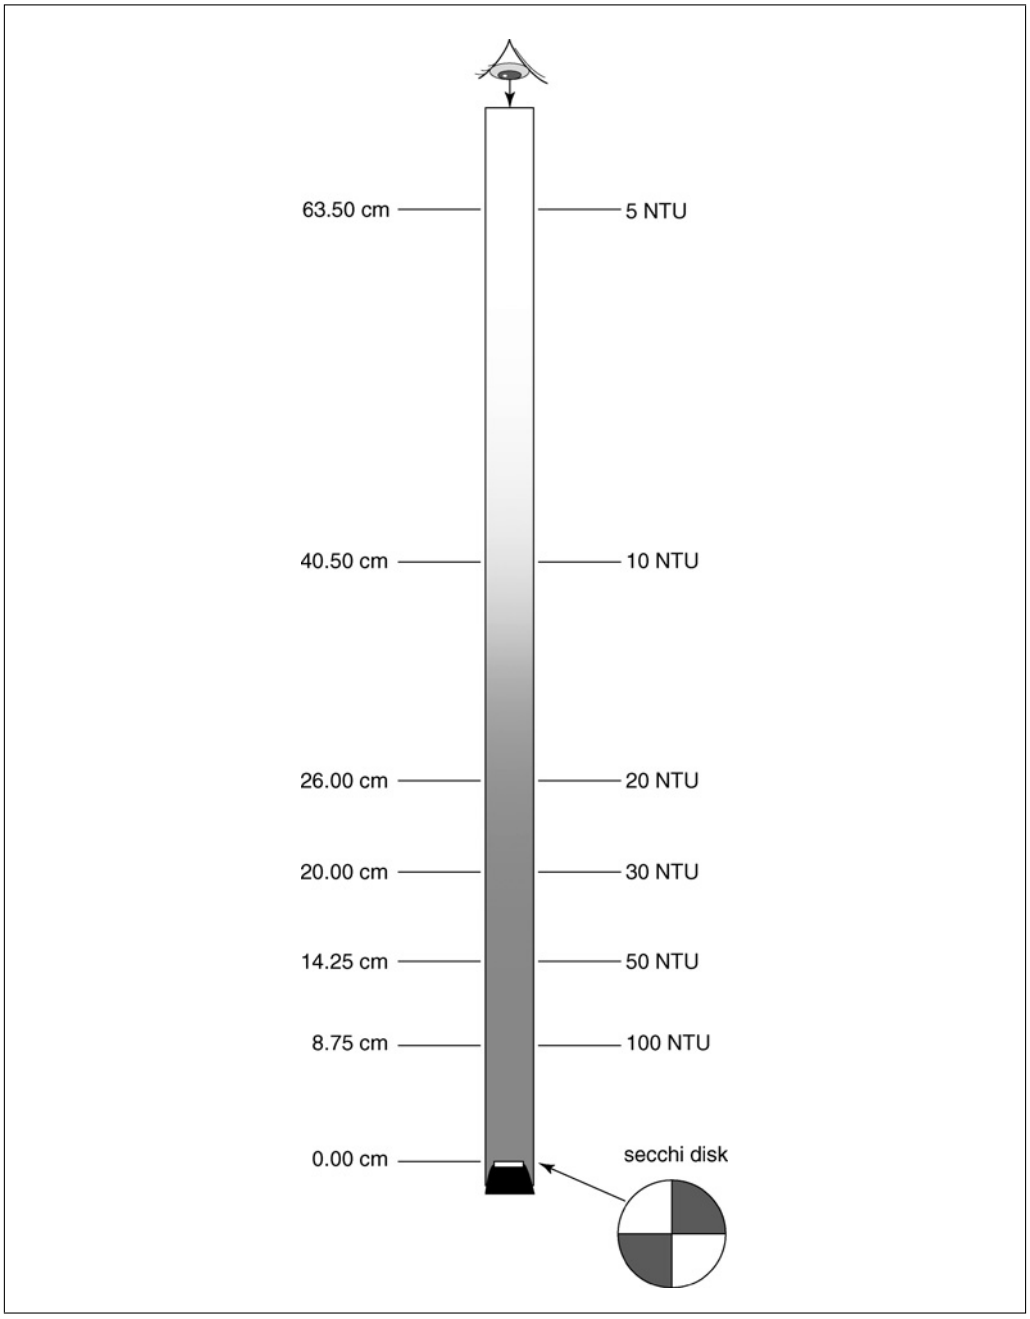

Figure 1G.1.4 Diagram of a home-brew turbidity gauge.

3. Fold the old sari cloth or other fabric four times and tie it over the mouth of the filter container.

   Old cloth is more effective because the worn fibers make the pores smaller and better for filtering.

4. Slowly pour the high turbidity water through the cloth and into the filter.

5. When finished pouring the untreated water through the cloth, remove by untying the folded cloth from the filter, wash the cloth, and expose to sunlight to dry.

   Alternatively, in many countries, there are also indigenous coagulation solutions using native plants, such as moringa seeds, known as drumstick or horseradish tree in India, or benzolive tree in Haiti and the Dominican Republic, or malunggay in the Philippines.

BASIC PROTOCOL 3

Adapting the Biosand Filter for Arsenic Removal

Arsenic is a natural element found in groundwater and is an important public health concern; fecal-contaminated drinking water poses immediate risks to human health for the majority. In countries such as Bangladesh, India, Vietnam, and many others, biosand technology can be modified to reduce both waterborne pathogens and certain toxic chemicals, such as arsenic, to acceptable concentrations with very little additional cost and a simple modification.

The simple modification of adding nails to a sand biofilter affects arsenic removal, as illustrated in Figure 1G.1.5. The nails, when exposed to air and water, rust very quickly, producing iron oxide (common red rust) which is an excellent adsorbent for effectively filtering out arsenic contaminants. The arsenic-loaded iron particles are flushed through the diffuser plate and trapped on top of the fine sand. The purpose of the stones and brick chips is to disperse the water over the nails to promote further absorption.

This ingenious arsenic depletion solution was developed by researchers at Massachusetts Institute of Technology (MIT), Environment and Public Health Organization (ENPHO)

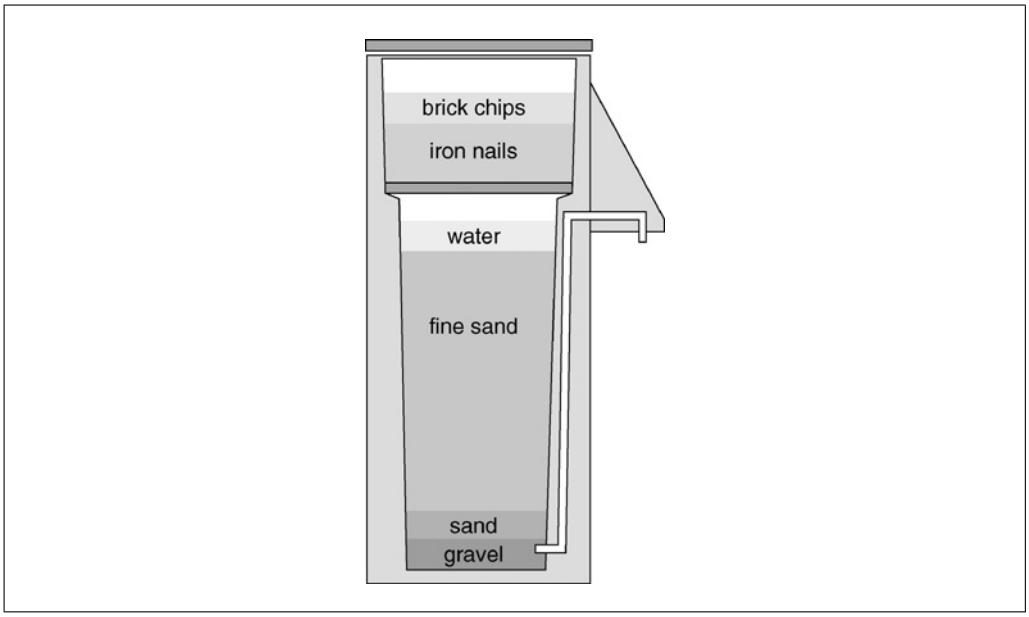

Figure 1G.1.5 Arsenic filter—a simple adaptation for removing both pathogens and arsenic based on biosand remediation and iron hydroxide adsorption principles.

of Nepal, and Rural Water Supply and Sanitation Support Programme (RWSSSP) of Nepal, based on slow sand filtration and iron hydroxide adsorption principles.

Anticipated results for the modified biosand filter are best summarized in the Centre for Affordable Water and Sanitation Technology (CAWST) document entitled: A complete summary of field and laboratory testing for the biosand filter is available for download at the following link: *http://www.cawst.org/assets/File/BSF_Literature_Brief.pdf.*

Materials

Water (from the best source possible)
11 lb (5 kg) of nongalvanized iron nails, length $<^3/_4$ in. (20 mm)
Filter containing diffuser box (see Strategic Planning)
Small broken brick chips or stones, 2- to 4-in. (5 to 10 cm) diameter

1. Wash the nongalvanized iron nails.
2. Place all nongalvanized iron nails in the diffuser box that should already be in place.

   It's important that the iron nails are evenly distributed and cover the diffuser.
3. Wash brick chips or stones with the best available water.
4. Add brick chips or stones on top of iron nails.

   The purpose of the brick chips is to protect the underlying nails from dispersing due to the force of incoming source water to be treated.
5. The filter is now ready to remove arsenic from source water poured into the filter.

   Over time the holes in the diffuser may clog due to exfoliated rust. If so, make the diffuser holes bigger using a $^1/_4$-in. (0.6 mm) nail.
6. Once a year, remove the iron nails, break apart, wash thoroughly, and return the nails back into the diffuser basin, covering again with the brick chips or stones.

   The nails' arsenic adsorption capacity will last years before new nails will need to be added. The hypothesis is that as the iron nails get rusted, the rusted iron particles become exfoliated and fall into the fine sand layer. This exfoliation exposes new iron surface, allowing more arsenic to be adsorbed. Annual washing of the iron nails can help to expose additional iron surface for improved adsorption capacity (Ngai et al., 2006).

CONSTRUCTING THE SAND BIOFILTER

Preparing Media for Use in a Biosand Filter

BASIC PROTOCOL 4

The following protocol describes the steps in preparing sand and gravel for use in a sand biofilter. As the first step, mixed sand and gravel must be separated into its different-sized grain sizes by passing through a series of constructed sieves. *The rate of filtration is influenced by grain size, so this is an important protocol for the operation of a biofilter.*

Next the sand and gravel will be washed to remove fine silt, clay, and other impurities that the media may contain.

Refer to Strategic Planning for factors important in selecting a source of sand and gravel. As a last resort, if biologically contaminated water has been used to wash the sand and gravel, place the media in the sun to dry—the solar radiation will inactivate any possible attached pathogens. If this is not possible, remember that pathogens within the water or attached to sand grains will be consumed by the filter's normal biological processes or, when exposed to an anaerobic environment within the filter, will not survive.

Materials

Mixed sand and gravel
Water (from the best source possible)

Materials for building three wooden sieves including:
- 1-in. × 4-in. (2.5 cm × 10.00 cm) lumber to construct three sieves, three 8 foot (2.4 m) lengths
- 1-in. × 1-in. (2.5 cm × 2.5 cm) wood strapping, three 8 foot (2.4 m) lengths
- $\frac{1}{2}$-in. (12 mm) screen, $\frac{1}{4}$-in. (6 mm) screen, and $\frac{1}{16}$-in. (~1.5 mm) mosquito screen, screens must be metal, not nylon or fiberglass
- Tape measure
- Hammer
- Nails
- Saw

Shovels
Tarp
5-gallon (20 liter) buckets

Sieve the mixed sand and gravel media

1. If sand and gravel is wet, dry in sun.

   The solar radiation will inactivate many possible attached pathogens. Also, sieving is a lot easier if the media is dry.

2. Construct three sieves, using the lumber and the $\frac{1}{2}$-in. (12 mm), $\frac{1}{4}$-in. (6 mm) screen, and the $\frac{1}{16}$-in. (~1.5 mm) mosquito screen (see Fig. 1G.1.6).

   The suggested size is ~16-in. (40 cm) × 22-in. (56 cm) for the three sieves. For the mosquito screen it is necessary to add a piece of $\frac{1}{2}$-in. (12 mm) screen under the finer screen for additional support. The 1-in. × 1-in. (2.5 cm × 2.5 cm) strapping is measured and cut to the same lengths as sieve frames. The strapping will be used to cover the screen edges where the screens were nailed to the frames.

3. Using a shovel, pass the mixed sand and gravel through the constructed $\frac{1}{2}$-in. (12 mm) sieve. Discard the media that doesn't pass through.

   For a simplified understanding of size grading that is going to take place using the screens, please reference Figure 1G.1.7.

4. Using a shovel, pass the mixed sand and gravel that passed through the $\frac{1}{2}$-in. (12 mm) sieve through the $\frac{1}{4}$-in. (6 mm) sieve. Keep the media that doesn't pass through the $\frac{1}{4}$-in. (6 mm) sieve.

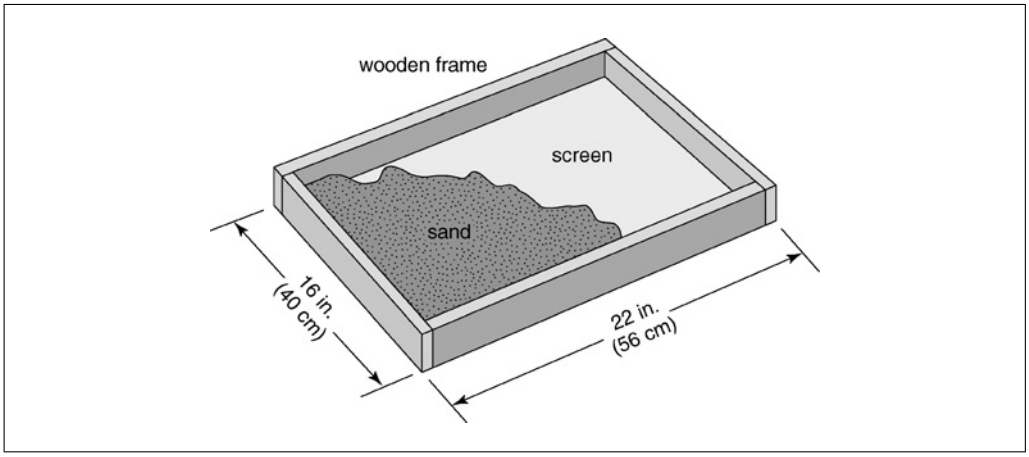

Figure 1G.1.6 Diagram of constructed wooden sieve.

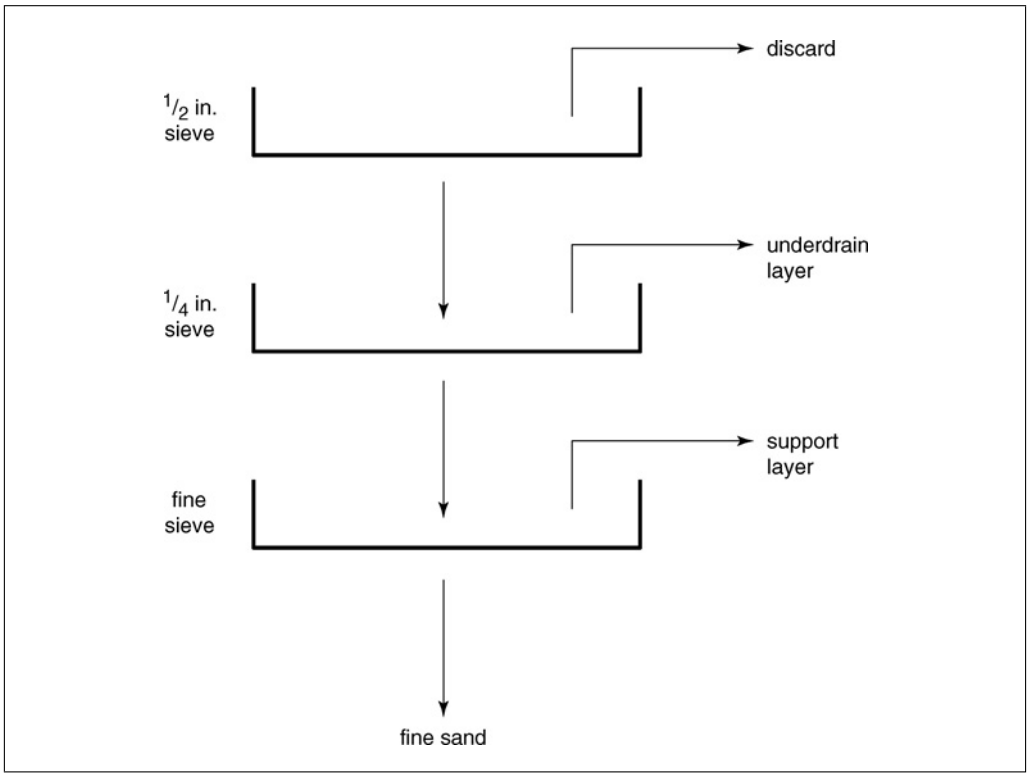

Figure 1G.1.7 Steps needed to sieve the three different grades of media.

The underdrain (gravel) media layer is composed of gravel that passed through the ½-in. (12 mm) sieve but was held back by the ¼-in. (6 mm) sieve. The purpose of this media layer is to allow the treated (effluent) water unrestricted flow out of the filter container and into the standpipe.

5. Using a shovel, pass the mixed sand and gravel that passed through the ¼-in. (6 mm) sieve through the mosquito sieve. Keep the media that doesn't pass through the mosquito sieve (fine gravel), as well as the sand that passed through the mosquito sieve.

   The support (fine gravel) media layer is composed of sand particles that passed through the ¼-in. (6mm) sieve but were held back by the mosquito screen sieve. The purpose of this media layer is to prevent the fine filtering sand from mixing with the underdrain layer.

   The filtering media layer is composed of fine sand that has been sieved through the fly or mosquito mesh. It is this layer that is responsible for removal of pathogens and the establishment of the biological zone, including the schmutzdecke. Please note that it takes substantial sieving to reach the required volume of fine sand as this is the deepest layer of the filter.

6. Store the sand and gravel in a protected dry area away from possible human or animal contamination.

7. Cover the sieved sand and gravel with the tarp until needed.

Wash the underdrain gravel

8. Place a small amount (½-in., or 12 mm) underdrain gravel in a bucket.

9. Place double the amount of water in the same bucket.

10. Using your hand, swirl the underdrain gravel a few times around the bucket.

11. Pour the dirty water out of the bucket. To help conserve water, pour into a waste water container and allow the water to settle for reuse.

12. Repeat steps 8 to 11 until the water in the bucket remains clear and contains no fine particles.
13. Clean the remaining underdrain gravel using steps 8 to 12.

Wash the support gravel

14. Place a small amount of $^1/_4$-in. (6 mm) middle support gravel in a bucket.
15. Place double the amount of water in the same bucket.
16. Using your hand, swirl the middle support gravel a few times around the bucket.
17. Pour the dirty water out of the bucket. To help conserve water pour into a waste water container and allow the water to settle for reuse.
18. Repeat steps 14 to 17 until the water in the bucket remains clear and contains no fine particles.
19. Clean the remaining middle support gravel using steps 14 to 18.

Wash the upper filtering sand

20. Now place an even smaller amount of upper filtering sand in a bucket.
21. Place double the amount of water in the same bucket.
22. Using your hand, swirl the upper filtering sand ~10 times around the bucket.

    This time, do not wash the fine sand until the water is clear; the residual water should be mildly dirty in the bucket.

23. Quickly decant the mildly dirty water out of the bucket.

    As you wash, count the number of times that you decant the bucket. It takes time and practice with the following flow rate test (see Basic Protocol 5) to determine how much the fine sand has to be washed.

24. Repeat steps 20 to 23 until all the remaining fine sand has been washed.

    Once you have initially determined how much the fine sand has to be washed, this will be used as a guideline for future media washes. The filtering sand is washed to ensure an effective size (ES) of 0.10 to 0.25 mm and uniformity coefficient (UC) of 1.5 to 2.5 (CAWST, 2008).

Dry the media

25. If biologically contaminated water has been used to wash the sand and gravel, place the media in the sun to dry.

    The solar radiation will inactivate many possible attached pathogens. If this is not possible, remember that pathogens within the water or attached to sand grains will be consumed by the filter's normal biological processes or when exposed to an anaerobic environment within the filter and will not survive.

26. Once dried, store the sand and gravel in a protected dry area away from possible human or animal contamination. Cover the sieved sand and gravel with the tarp until needed.

BASIC PROTOCOL 5

Installing the Media

Incorrect sand media installation can result in flow rates that are too low or too high, with subsequent problems developing.

Materials

Water
Household chlorine bleach solution (see Basic Protocol 9)

Filter (see Strategic Planning)
Materials for correct media installation including:
2 in. (5 cm), 3 quarts (~3 liters) of washed $^1/_2$-in. (12 mm) gravel
2 in. (5 cm), 3 quarts (~3 liters) of washed $^1/_4$-in. (6 mm) gravel
20 in. (50 cm), 25 quarts (~25 liters) of washed fine sand
Stick, 40 in. (100 cm) long
Measuring tape
Black magic marker pen
Diffuser plate or box (see Strategic Planning)
Materials for testing filter flow rate including:
Measured container (1 liter pop bottle is adequate)
Stop watch
Materials to disinfect the standpipe including:
3-foot (1 meter) garden hose
Hose clamps
Funnel
Bleach-soaked cloth

Place the media in the filter container

1. First, place the empty filter inside the home in an appropriate place (i.e., its final location).
2. Make sure the drain hole, standpipe, or outlet pipe is clear and unobstructed.
3. Place a stick inside the filter.
4. Using a black magic marker, draw a mark across the stick where it meets the top edge of the filter.
5. Measure and mark a second line 2 in. (5 cm) down from the first. Remove the stick.
6. Fill the filter container half full of water.

   The water doesn't need to be uncontaminated; it can be from a raw water source that eventually will be treated. Water is required to be inside the filter before adding sand media to prevent pockets of air from being trapped within the media. If air pockets do develop while placing media, this has the potential to slow the flow rate results.

7. Pour or place the lower underdrain gravel into the filter, level out the surface.
8. Place the stick back into the filter, placing the bottom of the stick on the newly placed lower underdrain gravel.

   When the second line matches up with the top edge of the filter container, enough gravel has been added.

9. Measure and mark a third line 2 in. (5 cm) down from the second line.
10. Pour or place the middle support gravel into the filter, level out the surface.
11. Place the stick back into the filter, placing the bottom of the stick on the newly placed middle support gravel.

    When the third line matches up with the top edge of the filter container, enough middle support gravel has been added.

12. Place a bucket under the standpipe.

13. Ensuring that there is always water above the sand surface, quickly pour the majority of washed upper filtering sand into the filter. Continue adding sand until water starts pouring out of the standpipe.

    A random distribution of different sand grain sizes is critical to the proper operation of the filter. Adding sand quickly maintains the random distribution by not allowing the different sizes of grains to settle into layers.

14. Wait until the water stops pouring out of the standpipe.

    When the water stops pouring out of the spout, the water level is equalized.

    The water level in the filter is determined by the spout. Due to a siphoning effect, the water will stop coming out of the filter when the water is at the same level as the bottom of the spout.

15. Level out the surface of the upper filtering sand.

16. Measure the depth of the water above the upper filtering sand.

17. If the water depth is <2 in. (5 cm), remove sand until the water depth equals 2 in. (5 cm).

18. If the water depth is >2 in. (5 cm), continue to add washed upper filter sand into the filter until the water depth is 2 in. (5 cm).

19. When the water depth equals 2 in. (5 cm), once again level out the surface of the sand.

    This 2 in. (5 cm) of standing water will be the supernatant. Any changes in the water depth above the sand surface will cause a change in the biological zone disrupting the efficiency of the filter. A water depth of >5 cm results in lower oxygen diffusion and consequently a thinner biological zone. A high water level can be caused by a blocked outlet spout or by an insufficient amount of sand media. As the water depth increases, the oxidation and metabolism of the microorganisms within the biological zone decrease. Eventually the layer dies off and the filter becomes ineffective.

Flushing the filter

When all three layers of media have been installed, and the supernatant water depth equals 2 in. (5 cm) perform the following steps.

20. Place the diffuser plate into the filter container.

    The diffuser plate must be above but not touching the surface of the water at its resting level. That would greatly reduce the amount of oxygen in the standing water layer, affecting the survival of the schmutzdecke.

21. Place a waste water container (bucket) under the outlet pipe or standpipe.

    The waste water captured can be reused.

22. Start pouring the cleanest water available into the filter (<50 NTU), continue pouring water until the water starts running clear out of the outlet or standpipe.

    This may take 10 to 20 gallons (40 to 80 liters).

    If the water doesn't run clear after 25 gallons (100 liters), the gravel or sand was too dirty to start with. It is probably easiest to take the media out, wash in pails, and then place back in.

Testing filter flow rate

The amount of water that flows through the biosand filter is controlled by the size of sand media contained within the filter. If the rate is too fast, the efficiency of bacterial removal may be reduced. If the flow rate is too slow, there will be an insufficient amount of treated water available from the filter to meet the needs of the users. The flow rates of

a biofilter are found from measuring the time it takes to fill up a container of a known volume with water.

23. Place the measured 1-liter container under the outlet or drainpipe spout.

24. Fill the filter container completely to the top with water.

    The flow rate through the filter decreases as the height of the water added into the influent reservoir drops.

25. With the stopwatch, time how long it takes the 1 liter container to be filled completely with filtered water—ideally, it should be 0.6 liter per min (or 100 sec per liter).

    Experimentation may be necessary to achieve the desired flow rate.

    If the flow takes a longer time (>100 sec) to fill the 1 liter container, the flow rate is too slow. The filter is still functional, but it will require more maintenance than normally required due to frequent clogging. Since flow rates are controlled by the screening and washing of sand, the sand should be washed more to achieve the desired flow rate. The slow flow rate can sometimes be improved by disturbing the upper sand layer with your fingers and scooping out the dirty water. If this doesn't work, scoop out a few inches of upper filtering sand which contains too many fine particles and rewash, and replace back into the filter.

    If the flow takes a shorter time (<100 sec), the flow rate is too fast, and the efficiency of treatment will be compromised. Since flow rates are controlled by the screening and washing of sand, the sand should be washed less to achieve a slower flow rate. In this instance, the fine media should be taken out and replaced with finer media (less washed).

    It can take up to 45 min for the 5 gallons (20 liters) of poured water to completely pass through the filter. The flow rate of 0.6 liters per min is based on the top reservoir being full of water. The actual flow of water will drop off as the water level (hydraulic head) drops.

Disinfecting the standpipe

The following steps are required to disinfect the underdrain gravel and standpipe of any possible contamination. This procedure is only to be implemented during the initial commissioning of the filter.

26. Fit and clamp the garden hose over the spout.

27. Fit the funnel at the free end of the garden hose.

28. Hold the funnel higher than the spout, and pour ~1 quart (1 liter) of bleach solution into the funnel.

    The bleach solution equals 3 drops per quart (liter)—see Basic Protocol 9.

29. Hold the funnel higher than the spout for 2 min.

30. Remove the garden hose from the biofilter and drain the bleach solution from the hose.

31. Wipe the spout with a bleach-soaked cloth.

32. Add 5 gallons (~20 liters) of water to the top of the filter.

    Never pour chlorine bleach solution into the top of the filter as chlorine will kill important, purifying organisms.

33. Wait 30 min for the bleach to be flushed out.

    The flushed water containing chlorine is not suitable for drinking or cooking.

34. Place the lid on the filter.

OPERATING THE BIOSAND FILTER

Educate all of the filter users, including children on the correct operation for daily use of the filter.

Materials

Raw (untreated) water
Biosand filter including a diffuser plate (see Strategic Planning)
Buckets

1. Use a dedicated "dirty" bucket for fetching raw source water.
2. Place a dedicated "safe" storage container under the spout.

   Place the container as close to the spout as possible to reduce dripping noise and prevent recontamination.

3. Remove the lid on the filter.
4. Make sure the diffuser plate is installed.

   The diffuser must always be in place when pouring water into the filter never pour water directly onto the sand layer.

5. Slowly pour raw (untreated) water into the filter daily, at least 5 gallons (20 liters), twice per day to assist in the establishment of the biolayer [first 14 to 21 days (may take up to 30 days)].

   Based on the recommended flow rate of 0.6 liters per min and the time required for pause periods, the biosand filter can effectively treat 15 to 20 gallons (60 to 80 liters) per day (CAWST, 2008).

   Thereafter, the family can establish a rate of usage that fulfills the family's daily water needs. For example, the filter can be used in the morning, noon, and evening with 6 hr pause periods in between each 5 gallon (20 liter) raw source water input.

   The pause periods are very important because they allow time for the microorganisms in the biological layer to consume the pathogens contained in the water, thereby increasing the hydraulic conductivity of the filter. Consequently, the biosand filter is most effective and efficient when operated intermittently.

   Use the best source of water (least contaminated) available—the better the raw water, the better the treated water will be. Using the same source of water every day will establish a constant biolayer and improve the filter's effectiveness.

6. Replace the filter lid onto the filter.

   Water must be allowed to flow freely out of the standpipe—never plug the spout or connect a hose to end of spout. Doing so will alter the standing water level in the filter, thus potentially harming the biolayer.

   During the first few weeks while the schmutzdecke (biolayer) is being established, the filtrate water can be used if a safer water source is not available, but chlorination is recommended (see Basic Protocol 9) at least during this time.

MAINTAINING THE SAND BIOFILTER

Once the household biological filter has been installed and is operational, periodically the following two primary maintenance protocols will be required. These are periodical disinfection of filter container and cleaning the biolayer when the flow rate is insufficient.

Periodic Disinfection (Cleaning) of Filter Container

BASIC PROTOCOL 7

Clean the spout regularly (every day) with soap and clean water or a chlorine cleaning solution. Regular cleaning of the filter spout will be required due to exposure to insects, animals, and dirty hands of children and other family members.

Clean the entire outside surface of the filter regularly (only when dirty) with soap and water or a chlorine cleaning solution.

IMPORTANT NOTE: Never pour chlorine cleaning solution into the top of the filter.

Recovering the Flow Rate

BASIC PROTOCOL 8

Over time the flow rate of the filter will decrease with usage because of increased accumulation of inorganic and organic material on the filter bed surface. This is a naturally occurring process and recovery of the flow rate can easily be restored with the following simple cleaning protocol.

Better water quality is actually produced at a reduced flow rate due to increased contact time with the ripened biological zone. Thus, this cleaning procedure should only be undertaken when the flow rate has become inconvenient to the family's daily needs.

Materials

Soap
Water
BioSand filter with a diffuser plate (see Strategic Planning)

1. Remove the lid, making sure that the diffuser plate is in place.
2. Pour enough water into the influent reservoir to the half-full mark, then remove the diffuser plate.
3. Gently disturb the surface of the upper filtering sand layer with fingers, ever mindful not to disturb the surface any deeper than 1 cm.
4. Remove suspended turbid water.

   The water in the influent reservoir will now be holding inorganic and organic materials in suspension that can be easily removed with a small container or cup.
5. Discard the turbid contaminated water in an appropriate location.
6. Return the diffuser plate and lid onto the filter.
7. Pour one 5-gallon (20 liter) bucket filled with water.
8. If the recovery of the flow rate is unsuccessful upon first attempt, repeat steps 1 to 7 as many times as necessary to regain the desired flow rate.

   Be mindful that after disturbing the surface, the removal efficiency declines somewhat, but increases very quickly (may take up to 1 week) to its previous level as the biofilm is re-established.
9. Wash hands with soap.

DISINFECTING EFFLUENT WATER

It is recommended that a disinfection process such as chlorine addition or solar disinfection (SODIS) be used in conjunction with the biosand filter as a post barrier.

There are limitations to SODIS and chlorine disinfection. SODIS limitation is the need to have numerous bottles for each household. Chlorination is ineffective against pathogens

such as the zoonotic (referring to pathogens of animal origin that also infect humans) protozoan Cryptosporidium. Furthermore, both SODIS and chlorination disinfection are ineffective with higher turbidity in the water. A benefit of the SODIS method is that it's relatively inexpensive. Alternatively, chlorination requires the household to incur additional costs. The following techniques can be used for effluent disinfection. If the disinfection protocols are done properly, the filtered water will be of the highest quality. Investigators will have to determine the most appropriate method consistent with their purpose and needs and with the availability of resources.

BASIC PROTOCOL 9

Bleach (Free Chlorine) Disinfection of Effluent Water

Residual "free chlorine" disinfection is used to provide a safeguard against recontamination of treated water within the safe storage container. Household bleach is the most common affordable form of free chlorine. The following protocol will demonstrate how to disinfect water with household bleach.

Materials

Household bleach
Clean water
Clean empty container

1. Add 1 cup (240 ml) of household bleach to a clean empty container.

   Household bleach can contain different amounts of chlorine, 3.5% and 5% being the most common. To get the correct measure of chlorine needed to disinfect water, a 1% (final) stock solution is prepared (Conant, 2005).

2. Fill the container with the clean water.
3. Cover the top and shake for ~30 sec.
4. Let the container sit for 30 min. The stock solution is now ready.

   Add the following amounts of stock solution to the water that has been filtered through the sand biofilter:

   3 drops stock solution to 1 quart (~1 liter)
   12 drops to 1 gallon (4 liters)
   1 teaspoon (5 ml) to 5 gallons (20 liters)

   It is important to add enough stock solution to not only kill pathogens in the water, but, to have some chlorine still available in the water as a last barrier to ensure water quality until the time of consumption. The excess chlorine is called "free chlorine" and can easily be identified by the slight chlorine smell and taste of the disinfected water which is still safe to consume.

   If the filtered water is cloudy, twice as much of the stock solution will be required.

   Highlighting an additional benefit of biosand intervention—filtration reduces organic carbon in the water; thus, the filters also reduce the formation of chemical by-products. WHO states that "... the risks to health from these by-products are extremely small," posing no significant health risk.

   Instead, post-chlorine disinfection has to be recognized as potentially being a deterrent towards household acceptance due to lack of product accessibility or the unpleasant odor, taste, and the additional costs that will need to be incurred by the household.

Solar Disinfection (SODIS) of Effluent Water

SODIS is a low-cost, effective way to improve the microbiological quality of drinking water using solar radiation (sunlight) to destroy pathogenic microorganisms. The mechanism of disinfection is heat plus UV-A (wavelength 320 to 400 nm) radiation.

Recent laboratory and field experiments indicate that a number of low-cost additives are capable of accelerating the SODIS process in both sunny and cloudy weather. These additives included 100 to 1000 mM hydrogen peroxide (both at room temperature and at elevated temperatures), 0.5% to 1% lemon or lime juice, and copper metal or aqueous copper plus ascorbate (with or without hydrogen peroxide; Fisher et al., 2008).

Materials

Biosand filtered water
1- to 2-liter clear bottles (e.g., soda bottles)

1. Obtain 1- to 2-liter clear bottle(s).

   1- to 2-liter soda bottles have a better surface/volume ratio.

2. Wash the bottles well if it's the first time using the bottles.

3. Fill one or many 1- to 2-liter clear plastic bottles ¾ full with biosand filtered water.

   Over time replace old or scratched bottles. Do not use green- or brown-colored plastic bottles—they do not transmit UV-A radiation. Use transparent bottles only.

4. Shake the bottle(s) for 20 sec.

   Shaking adds air bubbles to the water, which will assist in disinfecting the water faster.

5. Lay the bottle(s) horizontally in the sun.

   Pick a location where the bottles will not be disturbed by shade, people, or animals.

6. Leave the bottle(s) in the sun for at least 6 hr; 2 days if the sky is cloudy. If the water temperatures rises >50°C, the disinfection process is 3× faster.

7. Consume the water.

   The UV radiation intensity is reduced by turbidity and water depth in the containers. Water should have a low turbidity (<30 NTU) and the water depth in containers should not exceed 10 cm (EAWAG, undated).

   Solar disinfection is most effective in countries close to the equator.

   Alternatively, in many countries, using UV lamp disinfection may be another option where a source of electricity is available (see Internet Resources).

COMMENTARY

Background Information

Household-sized biological filters are simple in design; what is surprising are the complex purification processes that combine and take place inside the filter to provide water treatment. The principle processes are sedimentation, mechanical straining (filtering), adsorption (electrostatic), and most interestingly, a biological process (NSFC, 1997).

Biological filtration

The bioremediation process starts when raw turbid water is poured onto the filter's porous sand bed. Suspended particles and organic colloidal (viscous, gelatinizing) substances are deposited and absorbed (Ellms, 1928) within the top 400 mm of sand (Muhammad et al., 1996). The more organic matter (e.g., algae, diatoms, bacteria, protozoa, and worms) contained in the raw water, the quicker the sand grains become gelatinously coated, in turn decreasing the pore size between sand grains.

As the jelly-like density gradually increases over a 2- to 3-week period, the greatest density forms on top [2 to 4 in. (5 to 10 cm)] of

the sand layer. The filter matures or "ripens" with the creation of a surface zoogleal film (schmutzdecke) at the $\frac{1}{2}$-in. (1.5 cm) sand-water interface, while the bottom level of the media is a particularly hostile environment starved of oxygen, nutrients, and temperature required to sustain life for bacteria such as intestinal bacteria (i.e., *Escherichia coli*) and other disease-causing pathogens.

The fundamental importance of the self-purifying power of the biological ecosystem is illustrated by the living microorganisms naturally contained within the biological zone. Algae and diatoms use photosynthesis to take in carbon dioxide and release oxygen which becomes available for oxidizing organic particles and for beneficial bacterial predation activities (Ellms, 1928). In turn, protozoa and worms feed on pathogenic bacteria and other disease-causing pathogens.

A filter's microbiological ecosystem is aerobic and requires oxygen to thrive (Buzanis, 1995). The increased presence of dead cell material further decreases the pore sizes which increases filtration efficiency, but, also requires additional oxygen to thwart the possibility of anaerobic conditions (Smethurst, 1992). Depending on increased oxygen solely through photosynthesis is limited by: (1) the turbidity (cloudiness) of the filtrate water, and; (2) the secondary function of the filter lid, which is to inhibit clogging (maintenance) caused by possible exponential schmutzdecke growth by the naturally occurring photosynthesis process. Instead, the additional critical oxygen is acquired through oxygen diffusion between the influent reservoir and the intermittently refreshed standing water (supernatant) layer. The finely balanced equilibrium between consistent oxygen and nutrient influx and microorganisms' metamorphosis results in a living system providing extremely efficient pathogen (disease-causing organisms) removal from filtrate water.

Emerging biosand technology

The HydraAid Filter—International Aid recently introduced a plastic biosand water filter (Fig. 1G.1.8). The HydraAid Filter will provide clean, safe drinking water at the rapid rate of up to 12 gallons (48 liters) per hr.

The JAL Filter—Mr. Brett Gresham created a unique biofiltration pathogen removal design (Fig. 1G.1.9) while serving in Afghanistan during the early 1990s. This filter produces the same controlled environment based on biosand principles using just one layer of fine sand, and no standpipe is required.

Importance of bioremediation dissemination

Biosand filters have gained acceptance by the World Health Organization (WHO) as a viable household water treatment (HWT) technology. The WHO is presently "developing guidelines that will establish microbial reduction benchmarks and propose minimum criteria for protocols to verify HWT system performance (WHO, 2007)." In the meantime, "There is now conclusive evidence that simple, acceptable, low-cost interventions at the household and community level are capable of dramatically improving the microbial quality of household stored water" and will reduce the attendant risks of "diarrheal and other enteric diseases by 6 to 50% (Sobsey, 2002)." "A preliminary health impact study (to be published in 2008) estimates a 30% to 40% reduction in diarrhea (CAWST, 2008)" within at-risk populations. The real challenge now is to facilitate the rapid dissemination of this proven bioremediation technology to developing countries.

Critical Parameters

Multiple indicator tools required

"Between 1972 and 1999, 35 new agents of disease were discovered (WHO, 2003)." Waterborne pathogens of importance, such as *E. coli* O157:H7 and Cryptosporidium are amongst this group. A single traditional microbial indicator (i.e., *Escherichia coli*) primarily used for water quality monitoring is inadequate to determine Cryptosporidium cysts, Giardia, and additional emerging water-related diseases of unknown etiology. There is a need for accurate, low-cost multiple indicator tools that can be applied in remote areas of developing countries to extend the multiple barrier approach to the potential risks of emerging water-related microbial pathogens.

Further research

Two groups amongst the major causes of diarrhea worldwide and a significant cause of mortality amongst children are small round-structured waterborne viruses (caliciviruses) and rotaviruses. Presently, there is concern that biosand filters may have a low rate of virus inactivation, therefore further research is required.

Affordability

Variations in regional conditions and availability of local materials contribute to the variability of trying to provide construction cost estimates which are beyond the scope of the provided protocols. As a general guideline, concrete biosand water filters range from $12

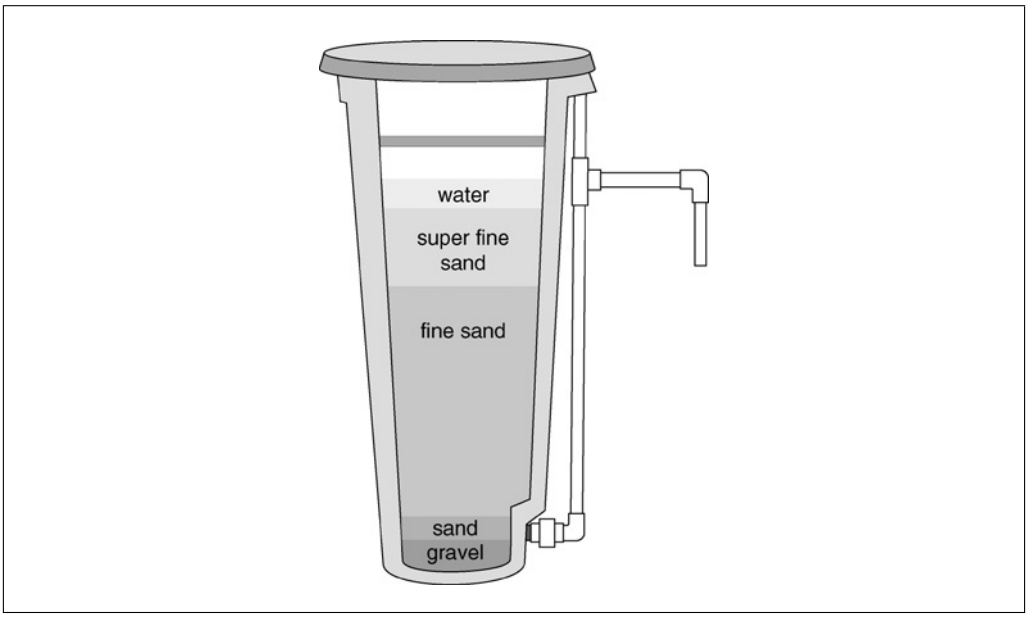

Figure 1G.1.8 International Aid's plastic HydraAid (BioSand) filter—lighter weight, stores and filters up to 47 liters (15 gallons) per hour.

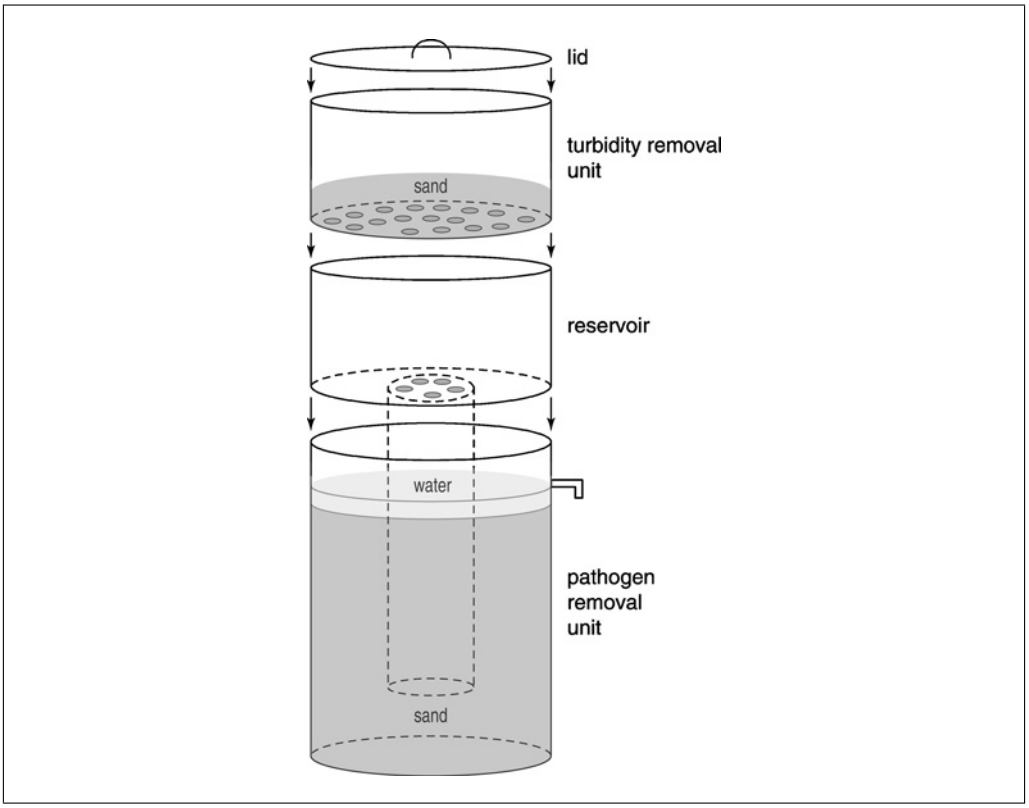

Figure 1G.1.9 Schematic diagram of the JAL filter. No standpipe and only one layer of sand required; lightweight and inexpensive to build.

to $30 US. A multibarrier approach as described increases costs and may limit use by some of the world's poorest people.

Drawbacks

There is no one-size-fits-all biosand filter. Each has its own drawbacks, for example, concrete-made filters require a welding shop to construct a steel mold. Plastic drums of consistent size are hard to locate. Metal filters require a tin smith. Ceramic containers tend to break easily. Industrial produced plastic filters may experience challenging logistics.

Table 1G.1.1 Troubleshooting Guide for Biofilter Implementation

Problems	Solutions
Preparing sand and gravel media	
Unsieved material was mixed with pile of sieved media	Prepare the media by re-sieving mixed pile
Uncertain whether the sand has been washed clean	Place a small amount of sand, and stir in a clear glass of water, allow to settle—if you can't see the sand surface within 3-5 sec, the sand needs to be washed further
Suspicion that dissolved salts exist in filtered water	Ensure that media is not beach sand
Uncertain of gauge size for sieving screens.	Ensure that screen sizes are 2, 4, and 14 gauge
Assembling the biofilter	
The diffuser plate or box floats when water is poured into the filter	Placing a rock or other weight on top of diffuser will stop it from floating
Metal diffuser plate or box is rusting	Ensure that sheet metal is of good quality galvanizing
Uncertain whether to build diffuser plate or box	A diffuser box is will be required for arsenic treatment
Using the biofilter	
Water isn't running clear after filter flush	Ensure that media is taken out of filter and rewashed
The diffuser plate is touching the standing water during pause period	Ensure that the diffuser plate is positioned at least 2 in. (5 cm) above the standing water level
Experiencing problems with air pockets in the filter media	Re-installation of sand and gravel will be necessary. The schmutzdecke and biological zone will need to be re-established with a ripening time of 14 to 21 days.
The top layer of sand is uneven	Ensure that the diffuser plate fits snuggly against the container walls
The flow rate slows down when water in the influent reservoir drops	This is a normal occurrence due to drop in hydraulic head
The flow rate is too low	Most likely caused by top layer of sand being clogged, flow rate recovery maintenance required or check to make sure diffuser plate holes are not too small or are plugged
Chlorine bleach was accidentally poured into the top of the filter	Re-installation of sand and gravel will be necessary after being thoroughly washed and dried in the sun to ensure sand is clear of chlorine. The schmutzdecke and biological zone will need to be re-established with a ripening time of 14 to 21 days.
The standing water depth is no longer 2 in. (5 cm)	Add or remove sand. Initially the sand may settle over time and require more sand to be added.
Maintaining the filter	
Water inside the filter has drained away	Ensure that a hose hasn't been attached to spout that initiated siphon action
Noticed higher turbidity during rainy season	Ensure a turbidity pretreatment process is initiated
There is an irritating dripping noise from the spout	Ensure that the safe storage container has a small opening and is positioned as close as possible to the spout
Removal of arsenic	
The holes in the arsenic diffuser box are plugged with iron rust	Make the holes bigger (~3/16 in.)
Purchased nails for arsenic treatment seem to be oily	Ensure that nails are uncontaminated and nongalvanized

Greatest obstacle

In most countries the greatest obstacle is procuring sand and gravel to meet the media specifications for the filter, and to a lesser degree the availability of components from local suppliers (see Strategic Planning).

Troubleshooting

Table 1G.1.1 outlines some of the more common problems that may be experienced in performing the basic and supportive protocols from this unit. This is not an exhaustive list; others may be encountered.

Anticipated Results

A fully established (ripe) schmutzdecke will perform at 90% to 99% efficiency (CAWST, 2008), removing biological pathogens, but, it will take ~14 to 21 days (ripening period) of daily use to establish the bioremediation zone and the schmutzdecke (may take up to 30 days), depending on the temperature and turbidity (biological content) of the source water. Until the development of the schmutzdecke, the filter will only be performing between 30% to 70% efficiency (CAWST, 2008). The water from the filter can be used during the 14 to 21 day start-up period, but, effluent disinfection (Basic Protocols 9 and 10) is highly recommended during this time period to ensure pathogen free water quality.

Anticipated results under field conditions with fully established schmutzdecke should be: (1) *E. coli* bacteria removal of >97%; (2) protozoa and helminths removal of >99%; (3) removal of 50% to 90% of organic and inorganic toxicants; (4) removal of 90% to 95% of iron; and (5) removal of 85% to 90% arsenic with design modification known as Kanchan Arsenic Filter (see Basic Protocol 3).

Under field conditions, the biosand filter limitations are: (1) cannot remove some dissolved contaminants (e.g., hardness, salt, calcium, and magnesium); (2) cannot remove some organic chemicals (e.g., pesticides and fertilizers or color); and (3) cannot guarantee 100% pathogen-free water—it is recommended to disinfect the water after it has passed through the biosand filter (see Basic Protocols 9 and 10).

Additional laboratory and field testing results are best summarized in the Centre for Affordable Water and Sanitation Technology (CAWST) document entitled: A complete summary of field and laboratory testing for the biosand filter (see Key References).

Time Considerations

The simple design facilitates procedures in the unit to be completed in a timely manner. In a developing country context, the longest period required will be invested in procuring uncontaminated sand and gravel and in finding local suppliers for specific filter components to ensure sustainability.

Proper Alignment and Adjustment of the Light Microscope

Optical microscopes can be powerful tools in biomedical research and diagnosis if properly aligned and adjusted. This is essential for optimal image quality and accurate quantitative measurements. Video cameras, digital cameras, and electronic image processing can improve visibility of structural detail resolved by the microscope optics in comparison to viewing by eye. However, the quality and accuracy of the image still depends critically on proper microscope alignment and adjustment.

This unit presents protocols for alignment and adjustment of a typical research compound light microscope for transillumination and epi-illumination imaging modes typically used today in microbiology research. The transillumination light modes include bright field, phase contrast, dark field, and differential interference contrast (DIC). The primary epi-illumination mode is fluorescence microscopy (*UNIT 2A.2*).

The described procedures are for alignment of a research upright microscope (Fig. 2A.1.1). The procedures are also applicable to inverted microscopes which have similar imaging and illumination light paths to the upright microscope. In either case, the specimen image is produced by an objective lens and the image is projected either to the eye with an eyepiece or to a camera with (and sometimes without) a projection lens. One lamp attached to the back of the microscope provides light for transillumination of the specimen through a condenser lens (Fig. 2A.1.2 and Fig. 2A.1.3). Another lamp attached to the back of the microscope provides light for epi-illumination of the specimen through the objective using a mirror in a filter cube to bring the illuminating light into the objective light path (Fig. 2A.1.5). For both the transillumination and epi-illumination paths, there are field diaphragms for controlling the specimen region illuminated and condenser diaphragms for controlling illumination from the condenser. The lamps, the field diaphragm, and the condenser diaphragm, as well as the condenser and the objective, must be properly focused and centered for the best image formation. In addition, each mode of image formation has special optical components that also require alignment and adjustment for optimal performance.

The first section in this unit (see Major Components of the Light Microscope) describes the location and basic functions of the most important features of the upright compound microscope. The second section (see Basic Imaging and Köhler Illumination Light Paths for Bright-Field, Fluorescence, and Dark-Field Microscopy) introduces the imaging and illumination light paths of the microscope, and describes the principles of Köhler illumination, which is the alignment used typically for both transillumination and epi-illumination in the light microscope. Basic Protocol 1 lists steps in microscope alignment for transmitted-light Köhler illumination. Basic Protocol 2 discusses alignment of the eyepieces. Basic Protocol 3 lists steps in microscope alignment for epifluorescence Köhler illumination. Basic Protocols 4 and 5 provide brief descriptions of the principles of image formation and microscope alignment for phase-contrast and differential interference contrast (DIC) microscopy; these optical modes produce contrast of transparent specimens using transmitted-light illumination. The section entitled Alignment for Dark-Field Microscopy provides a brief description of the principles of dark-field microscopy and details how a bright-field microscope can be easily converted for dark-field microscopy at low- (see Basic Protocol 5) or high- (see Basic Protocol 6) power magnification. Support Protocol 1 deals with mating cameras to the microscope and Support

Contributed by Edward D. Salmon, Kate von Lackum, and Julie C. Canman
Current Protocols in Microbiology (2005) 2A.1.1-2A.1.31

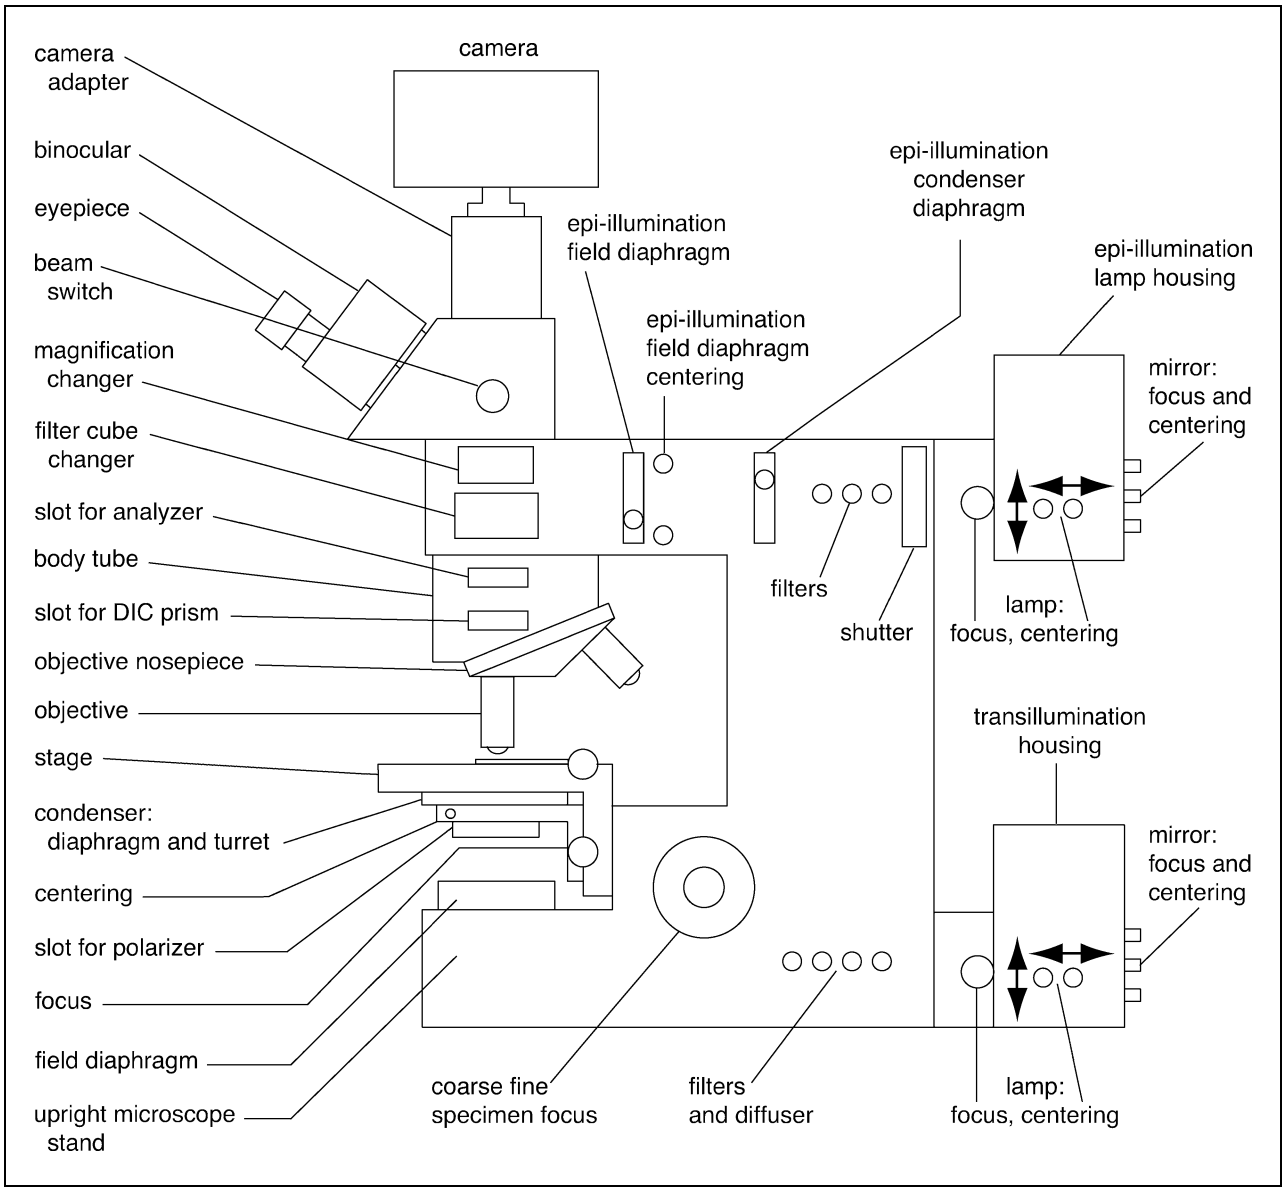

Figure 2A.1.1 Diagram of the major component parts and centering screws for a research upright light microscope.

Protocol 2 deals with calibrating image magnification. Several procedures (see Support Protocols 3, 4, and 5) are given for testing the optical performance of the microscope; these also describe test specimens for microscope performance and their sources. Finally, Support Protocol 6 deals with the care and cleaning of microscope optics. The Commentary refers the reader to references that provide more comprehensive treatments of the basic modes and methods of light microscopy as well as advanced microscope imaging methods like multiwavelength, confocal, or multiphoton imaging, and electronic imaging techniques, including video and digital microscopy.

MAJOR COMPONENTS OF THE LIGHT MICROSCOPE

Proper Alignment and Adjustment of the Light Microscope

Familiarizing oneself with the components of the light microscope is best done using the manual for the microscope as reference. Figure 2A.1.1 provides a diagram of an upright research compound light microscope equipped for both transmitted light and epifluorescence microscopy. Locate the following components on the microscope, identify their

adjustment screws (if applicable) and movements (e.g., condenser focus), and ascertain that they appear correctly mounted. In this and the following sections, *z* is a direction along the microscope axis; *x* and *y* are perpendicular directions.

Image-Forming Components

Specimen stage and focus

A mechanical carrier on the stage holds the specimen slide. Knobs control movement in the *x*–*y* direction. Look for the vernier scales that mark the *x* and *y* positions. Rotatable stages are typically used for DIC microscopy. The objective is usually fixed and the specimen is focused by moving the stage along the *z* axis using coarse- and fine-focus knobs on the microscope body. Check the scale on the fine focus; on research microscopes, this is usually is 1 μm/unit.

Objectives and revolving nosepiece

Examine the different objectives on the nosepiece. Each objective is usually labeled with the following designations: magnification (e.g., 60×); the degree of optical correction (Apochromat is better than Fluor which is better than an Achromat); the label Plan (if both the center and edges of the field are in focus); numerical aperture (NA), which measures the half-angle of the cone of light from the specimen accepted by the objective (Fig. 2A.1.3); immersion medium to be used (e.g., air, oil, water, or glycerin between the objective front lens and the specimen); coverslip thickness; optical tube length (previously 160 mm, currently infinity); and other special features like phase contrast, DIC, or long working distance. Working distance refers to the distance from the front element of the objective to the specimen, and usually decreases with increasing objective magnification and NA. Check that the objectives are mounted in series from the objective of the lowest magnification to the objective of the highest magnification. It is usually best to find the specimen or region of a specimen with a low-magnification objective, and then swing in objectives with higher magnifications and shorter working distances. The high-NA, short-working distance oil-immersion objectives often have the ability to lock up the nosepiece when changing objectives. This prevents running the front element of the objective into the mounting medium on the edges of the coverslip. Check that the nosepiece is down for imaging.

Specimen slides and coverslips

Microscope condenser lenses are usually corrected optically for 1-mm-thick glass slides. The objectives are corrected optically for coverslips with a thickness of 0.17 mm; no. 1.5 coverslips are on average this thick. The image quality decreases for thinner (e.g., no. 1) or thicker (e.g., no. 2) coverslips, particularly for non–oil immersion ("dry") objectives with high NA. For oil-immersion objectives, this problem is not critical when the refractive index of the oil and coverslip (∼1.515 to 1.52) match. Coverslips thinner than no. 1.5 are often used with oil immersion, to allow a greater range of focus.

Body tube

In the modern research light microscope, the imaging light leaving the objective and nosepiece is unfocused and the image is projected to "infinity" (Fig. 2A.1.2, left). This infinity space above the objective allows insertion of filters without changing the focal position of the image at the intermediate image plane. A positive focusing lens, the tube lens, above the infinity space, is used to bring the imaging light into focus for the eyepieces or camera.

Check for the following possible inserts in the infinity space of the microscope.

1. DIC prisms for the DIC objectives. These are usually located right above the objective.
2. Analyzer. This is used for DIC microscopy and should be removed from the light path for bright field, phase-contrast, and fluorescence microscopy.
3. Epi-illuminator filter-cube changer. These devices usually hold two to four filter cubes for fluorescence microscopy, each of which contains an excitation filter, an emission filter, and a dichroic mirror (Fig. 2A.1.5) designed specifically for different fluorophores. Check the numbers on the filter cubes and mark the corresponding positions on the outside of the filter changer to identify the proper cube position for a given fluorophore.
4. Magnification changer and Bertrand lens. Body tube magnifications are selected from a turret, and possible values are 1.0×, 1.25×, 1.5×, and 2.0×. Often one position of the turret contains a Bertrand lens. This lens is used in combination with the eyepieces to produce a telescope view of the objective back focal plane (Fig. 2A.1.2, far right). This is an important device for checking that the lamp image is centered and in focus during alignment for Köhler illumination, and for adjustment of the condenser diaphragm (see Transillumination Components, below).

Beam switch

This device switches the light between the binocular and the camera port. Check for the percentage of light in each direction. For fluorescence microscopy, it is important to be able to send 100% of the imaging light either to the eye or to the camera.

Eyepieces

Eyepiece magnification to the eye is marked on the barrel (e.g., 10×). Note that there are two and maybe three adjustments. The interpupillary distance for the eyes is adjusted by grasping the bases of the eyepiece tubes and moving them closer or further apart. At least one of the eyepieces is adjustable so that the eyes are parfocal.

Camera adapters

Check the type of camera adapter and whether it matches the detector. There are several different types of camera adapters. One type uses an eyepiece tube (not the binocular tube) and a projection eyepiece combined with a camera lens to project an image onto the camera detector. This method is common in photographic film cameras (which use ≥35-mm film) and for some video cameras with large-size detectors (e.g., 1 in., equivalent to 2.54 cm). The recent video and cooled slow and progressive scan charge-coupled device (CCD) cameras have small detectors (≤ $\frac{2}{3}$ in., equivalent to 1.7 cm). These cameras require smaller projection magnifications or none—in the latter case the detector is mounted at the intermediate image plane, the focal plane of the objective (Fig. 2A.1.2), and no eyepiece or projection lens is used.

Transillumination Components

Lamp and housing

The lamp is typically a low-voltage 100-W quartz halogen bulb with a tungsten-filament light source and variable control. Some lamp housings have no adjustments for centering the bulb; the socket is prefixed. Most lamp housings have *x*–*y* adjustments for the bulb

socket, while an advanced lamp housing also has a mirror in the back for reflecting an image of the lamp back along the microscope axis. This mirror usually has adjustments for *x*, *y*, and *z* positions of the mirror image of the lamp. There is usually a knob on the side of the lamp housing for moving the collector lens back and forth along the *z* axis to focus the tungsten-filament image onto the condenser diaphragm plane.

Diffuser and filters

A diffuser and other filters are often inserted in slots in the base of the microscope. The diffuser helps spread the image of the source at the condenser diaphragm plane in order to uniformly fill the condenser aperture. This is important for achieving high resolution. A heat-reflecting filter (e.g., BG 58) blocks infrared light: video cameras, but not the eye, are often sensitive to this wavelength of light. A green filter is frequently preferred for illuminating living cells. High-efficiency interference filters with a 40-nm bandwidth around 540 nm are often best. Various neutral-density (ND) filters, which are not wavelength selective, are useful for attenuating light to cameras.

Field diaphragm

This is usually located just above or beneath the mirror that deflects the light up to the condenser lens. It controls the specimen area illuminated by the condenser (Fig. 2A.1.2, left).

Polarizer

This is inserted below the condenser diaphragm for polarization and DIC microscopy. Otherwise, it is removed from the light path.

Condenser focus knob

This translator moves the condenser along the microscope *z* axis to focus an image of the field diaphragm on the specimen.

Condenser centering screws

There are usually two screws on the condenser carrier which move the condenser in an *x*–*y* plane. These screws are used to center the image of the field diaphragm on the *z* axis.

Condenser diaphragm

The condenser diaphragm is located on the bottom of the condenser. It controls the angle (NA) of the condenser cone of illumination of the specimen (Fig. 2A.1.3).

Condenser turret

Condensers have turrets with inserts for special image-contrast techniques such as phase-contrast, DIC, and dark-field microscopy. Each insert matches certain objectives. In phase-contrast microscopy, the inserts are annuli of different diameters designed to match the phase ring in phase-contrast objectives (Fig. 2A.1.6). For DIC, the inserts are typically DIC prisms designed for certain objectives (Fig. 2A.1.8). For dark-field microscopy, the NA of the condenser must exceed that of the objective. To see these inserts, as well as the opening and closing of the condenser diaphragm, remove the condenser from the condenser carrier by loosening the locking screen and turning it upside down.

Condenser lens

The condenser's main function is to provide bright, uniform illumination of both the specimen field (Fig. 2A.1.2, right) and objective aperture (Fig. 2A.1.3) for objectives with different NAs. Check the markings on the condenser to see if it is designed for air (dry) or oil immersion with the glass slide. Dry (no oil-immersion) condensers have NA values of $\leq$0.9 and should not be used with immersion oil. Oil-immersion condensers usually have NA values of 1.0 to 1.4 when using immersion oil.

Epi-illumination Components

Lamp and housing

The light source for the epifluorescence illumination is typically an HBO 50-W or HBO 100-W mercury arc lamp, or a xenon lamp of similar wattage. These lamps need to be handled with care because they can blow up if mistreated. Their glass envelopes should be carefully cleaned with 70% ethanol before installation to prevent fingerprints or other materials from inducing hot points that may result in fracturing of the bulbs. Look for the adjustment screws to adjust the *x*–*y* position of the lamp. Look also for the rear mirror and its *x*, *y*, and *z* adjustment screws. Identify the focusing knob for the lamp collector lens. Do not turn the lamp on until the bulb has been installed according to the manufacturer's instructions, the collector lens has been inserted properly, and the lamp housing has been installed on the back of the microscope. These lamps produce intense light, and the mercury bulbs have large peaks in the UV range. Therefore, UV-protective glasses should always be worn when handling and installing these lamps. The light intensity decreases and the probability of explosion increases with the number of hours of operation and lamp starts. Check the timer on the lamp power supply to see that the recommended limits are not exceeded.

Shutter

Photobleaching is a major problem in fluorescence microscopy. A shutter is used to block the light from the specimen when not taking exposures on a camera or viewing by eye.

Filters

A heat-reflecting filter is used to prevent infrared illumination of the specimen and to keep infrared scattered light from reaching the camera. Neutral-density (ND) filters are used to reduce the light intensity of fluorescence illumination by the amount indicated on each filter.

Epi-illumination condenser diaphragm

This diaphragm provides variable adjustment of the illumination intensity. Some microscopes lack this diaphragm.

Epi-illumination field diaphragm

This diaphragm controls the area of the specimen illuminated. Look for the centering screws that control the *x*–*y* position of the field diaphragm.

Filter cubes

See Transillumination Components, above.

Dark-Field Illumination Components

Turret condenser with dark-field stop included

A bright-field microscope can be converted for dark-field illumination by adding a special dark-ground condenser or a multifunction condenser with dark-ground facilities. Dark-field stops are included in specially designed dark-ground condensers such that the stops can block the light on its way to or through the condenser. Make sure to fully open the aperture diaphragm of the condenser. A turret condenser (Fig. 2A.1.4) is optimal because the dark-field stop is positioned in exactly the same location as the condenser aperture. If one can outfit their microscope with a turret condenser with a dark-field stop included, then dark-field studies can begin at once. The most sophisticated means of dark-field microscopy configuration makes use of a dark-field condenser/objective pair called a cardioid dark-field condenser. Mirrored surfaces in the cardioid condenser concentrate light onto the specimen as depicted in (Fig. 2A.1.4B).

Multifunctional condenser fitted with patch stops

Alternatively, any condenser can be used and artificial patch stops can be created out of opaque material. The stop is placed below the substage condenser where it blocks out the center of the beam of light coming from the base of the microscope forming the hollow cone of light needed for dark-field illumination. Each lens will have its own stop size requirement based on its NA. For a 10× objective of NA 0.25, the diameter of the patch stop should be ~16 to 18 mm and ~22 to 24 mm for 20× and 40× objectives of NA near 0.65.

BASIC IMAGING AND KÖHLER ILLUMINATION LIGHT PATHS FOR BRIGHT-FIELD, FLUORESCENCE, AND DARK-FIELD MICROSCOPY

The second major step in learning proper alignment of the light microscope is to understand the basic image-forming and Köhler illumination light paths and the functions of the key optical components and diaphragms. These are outlined in Figure 2A.1.2, Figure 2A.1.3, and Figure 2A.1.5.

Imaging-Ray Paths

The upper left section of Figure 2A.1.2 shows ray paths for the image-forming light from the objective. The objective, in combination with the tube lens, produces a real, magnified image of the specimen at the intermediate image plane. The eyepiece provides a second stage of magnification to the eye. The magnification to the eye is the product of objective magnification and eyepiece magnification multiplied by any magnification provided by additional lenses in the body tube of the microscope between the objective and the eyepieces.

When a camera detector—film, video, or charge coupled device (CCD)—is mounted at the intermediate image plane, the magnification to the camera is the magnification produced by the objective and body tube. When a camera is mounted above an eyepiece, the unfocused light leaving the eyepiece must be focused onto the camera detector by a camera lens, which modifies the total magnification to the detector. Special adapters (see Image-Forming Components, Camera Adapters) are also available for projecting the objective image onto a camera detector with magnification, but without the need for an eyepiece.

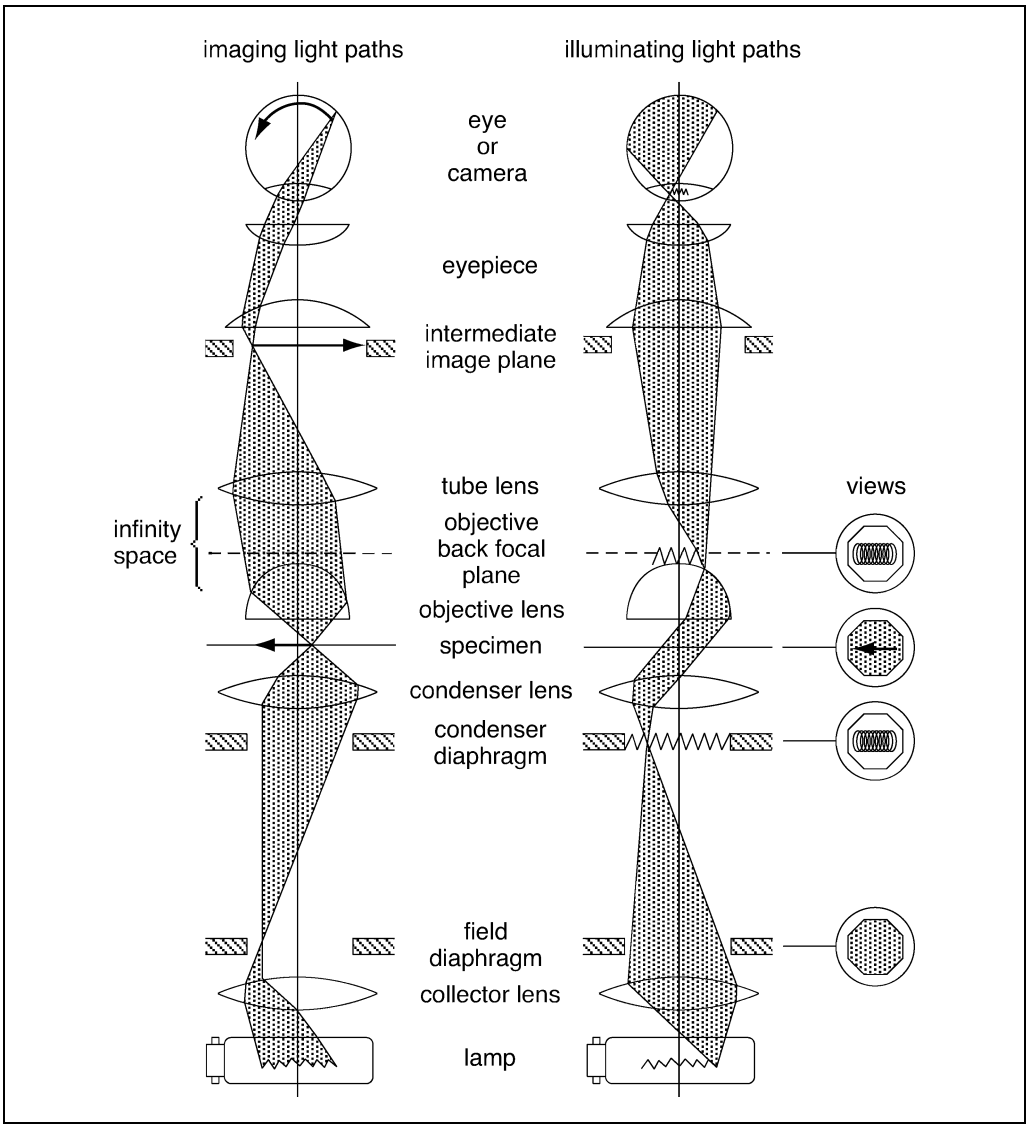

Figure 2A.1.2 The imaging and illuminating light paths for a bright-field microscope aligned for transmitted light Köhler illumination. Modified from Keller (1998).

Transillumination Ray Paths

In the illustration of the standard Köhler method (Fig. 2A.1.2), trace the illumination ray paths for a bright-field microscope aligned for Köhler transillumination (right side). A point on the light source is focused by the lamp collector lens onto the front focal plane of the condenser lens, where the condenser diaphragm is located. This light is projected, out of focus, through the specimen by the condenser lens, producing uniform illumination of the specimen. The objective collects the unfocused illumination light and brings an image of the light source into focus at its back focal plane, which is at the back aperture of the objective (Fig. 2A.1.3). The light source is again out of focus at the intermediate image plane and at the retina of the eye or the detector of the camera. In between these two points, the light source is in focus at the exit pupil of the eyepiece, at a position ~15 mm above the eyepiece. This position is also called the eyepoint, the position of eye placement above the eyepiece (Fig. 2A.1.2, right).

The condenser diaphragm controls the NA (cone angle) of specimen illumination by the condenser lens (Fig. 2A.1.3). Opening the diaphragm increases the aperture of illumination, which increases both the light intensity and resolution in bright-field light

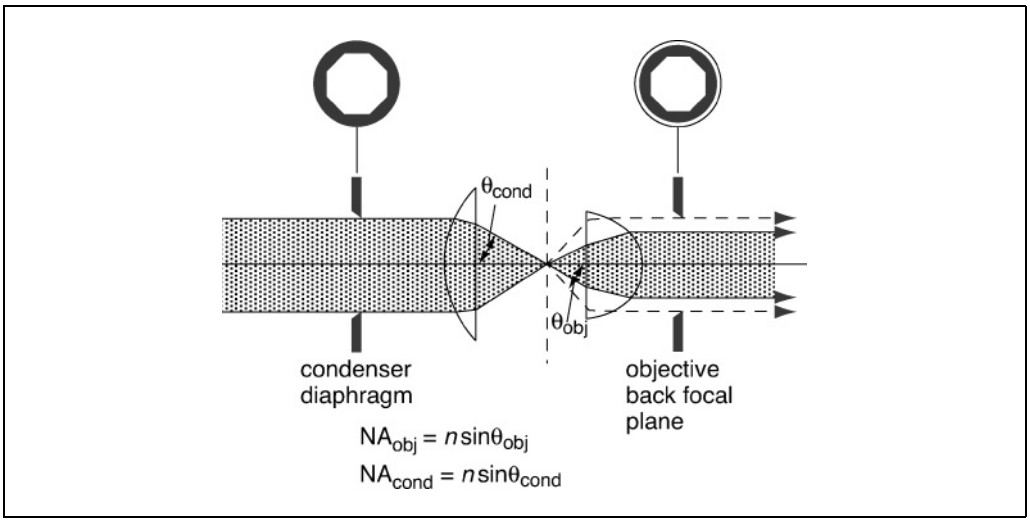

Figure 2A.1.3 Numerical aperture (NA) of objective light collection and condenser illumination. The objective numerical aperture (NA_{obj}) depends on the angle of the cone of light from the specimen, which is accepted by the objective aperture while the numerical aperture of condenser illumination (NA_{cond}) is controlled by the condenser diaphragm and limited by the maximum NA of the condenser when the condenser diaphragm is wide open.

microscopy (see Support Protocol 3). Note on the right side of Figure 2A.1.2 that the image of the condenser diaphragm is in focus where the lamp image is in focus along the microscope axis, at the objective back focal plane, and the exit pupil of the eyepiece.

Trace the imaging light rays from the field diaphragm through the microscope (Fig. 2A.1.2, left). Note that the field diaphragm controls the specimen area illuminated by the condenser. Note also that the field diaphragm is placed between the lamp collector lens and the condenser lens in a plane where the lamp image is out of focus (compare Fig. 2A.1.2, left and right). When the condenser lens has focused the image of the field diaphragm onto the specimen, then the field diaphragm will be in focus with the specimen at the intermediate image plane and at the eye or detector.

Epi-illumination Ray Paths

Figure 2A.1.5 shows the optical alignment for an epi-illuminator and Köhler illumination through the objective. As in transillumination (Fig. 2A.1.2), the light source is focused by a collector lens onto the condenser diaphragm of a condenser lens in the light path. The condenser lens illuminates a field diaphragm. Another lens collects this light and projects it off a reflective mirror into the objective. The image of the light source is focused at the back focal plane of the objective so that it is out of focus at the specimen plane. In epifluorescence microscopy, filter cubes containing dichroic mirrors are used in combination with excitation and emission filters to efficiently reflect the excitation light into the objective and transmit to the eyepiece or camera only the longer-wavelength fluorescent light emitted from the specimen (Taylor and Salmon, 1989; Herman, 2002).

BASIC IMAGING FOR DARK-FIELD MICROSCOPY

Dark-Field Ray Paths

Figure 2A.1.4 shows the optical alignment for a dark-field microscope. The light source is focused by the collector lens onto the condenser diaphragm of the condenser lens as in both transillumination and epi-illumination. Similarly, the condenser lens illuminates the field diaphragm. The majority of the light passing through the condenser aperture is blocked by a dark-field stop within the plane of the condenser aperture. The dark-field

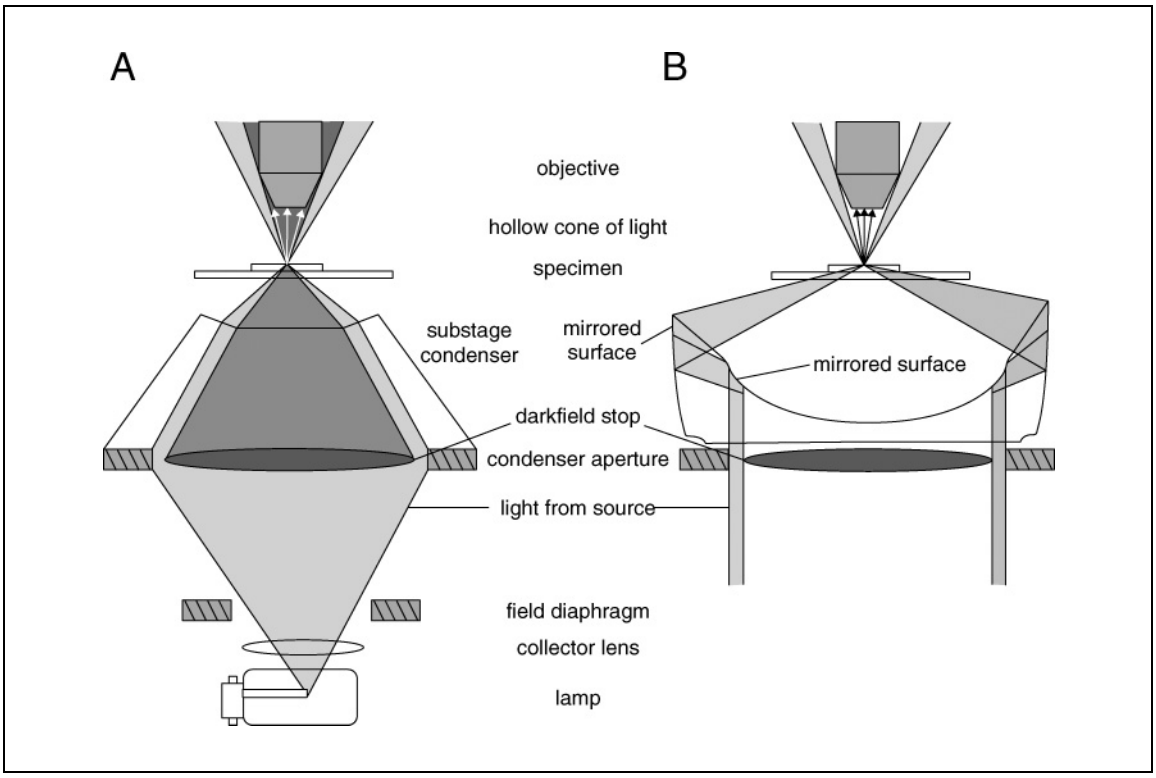

Figure 2A.1.4 The illuminating light paths for dark-field microscopy using (**A**) a multifunctional condenser fitted with a dark-field stop or (**B**) a cardioid condenser.

stop must be of a specific diameter to block the direct light, but it is designed to be open around the outer perimeter, letting light pass around the dark-field stop's circumference. The aperture diaphragm of the condenser must be fully opened so that some light can pass through the dark-field stop. These rays are refracted in the condenser at an oblique angle such that they form a hollow cone of light that passes just outside the objective lens. Compare this to the illuminating light path for a bright-field microscope in Fig. 2A.1.2, in which all of the direct light passes through the specimen and up into the objective lens.

When a mounted specimen is placed on the stage, it is located at the apex of the hollow, inverted cone of light. As the light passes through the specimen it is scattered in all directions. Some of the light is reflected or refracted up into the objective lens, so the specimen appears as a luminous object against a dark background. Only the rays of light reflected, refracted or diffracted by the specimen will enter the objective. The remaining light forms a hollow cone of light that passes outside the objective (Fig. 2A.1.4).

BASIC PROTOCOL 1

ALIGNMENT FOR KÖHLER ILLUMINATION IN BRIGHT-FIELD, TRANSMITTED LIGHT MICROSCOPY

The following procedures assume that the positions of the quartz-halogen tungsten filament and collector lens are adjustable. Inexpensive, nonresearch, compound microscopes may have the illuminator built into the stand, with no adjustment for the lamp. Such microscopes depend on a ground-glass filter for even illumination. For these microscope stands, skip steps 2, 3, 4, and 8.

Focus the light source

Proper Alignment and Adjustment of the Light Microscope

1. If possible, remove the diffusion filter in the transillumination pathway during alignment so that a crisp image of the light source can be viewed at the condenser diaphragm plane and at the objective back focal plane. When alignment is complete, reinsert the diffusion filter.

2. Center and focus the lamp filament near the condenser diaphragm plane. Remove the condenser lens. Place a sheet of lens paper on the microscope stage. Close down the field diaphragm and adjust the intensity of the lamp so that the lens paper is moderately illuminated. Use the lamp-focusing knob to move the condenser lens (or lamp) along the *z* axis until an image of the filament is in focus on the lens paper. Roughly center the lamp on the microscope axis with the adjustment screws on the lamp housing, then adjust the mirror image (if there is a mirror) using its adjustment screws on the lamp housing.

3. Place the lens paper on the condenser carrier and raise the condenser carrier until it is ~20 mm from the top of the stage.

   This is the approximate position of the condenser diaphragm when a condenser is installed and in focus.

4. Refocus the lamp and mirror images at this position of the lens paper.

   If there is no mirror image, center the lamp image. If there is a mirror image, then position the images so that they sit side by side to fill the condenser aperture. Remove the lens paper and replace the condenser.

Focus for low-power viewing

5. Obtain an in-focus image of a specimen with the low-power objective (10× or 16×) by placing a test specimen that absorbs light on the stage (e.g., stained muscle section; see Table 2A.1.1).

   The focus position can be estimated from the working distance of the objective lens. For a standard 10× lens, this is −4 mm. So, use the coarse focus to bring the specimen to ~16 mm from the coverslip by viewing the objective position from the side of the microscope.

6. Move the condenser lens up close to the lower surface of the slide and open the field and condenser diaphragms all the way. Look down the eyepieces, and use the coarse- and fine-focus knobs to bring the specimen into sharp focus.

7. Focus the image of the field diaphragm centered on the specimen by adjusting the condenser *x*–*y* screws and the condenser focus. Initially, close down the field diaphragm until an edge of the image can be focused by the condenser, then close the field diaphragm further as the image is centered, using the *x*–*y* translation screws.

   Usually, the field diaphragm is opened just enough to match the field of view in the eyepiece or the camera. However, the best image contrast is obtained if the field diaphragm is opened just enough to illuminate the region of interest. This eliminates the presence of scattered light from outside the region of interest.

8. Center an in-focus image of the lamp and mirror images at the objective back focal plane using the focus and adjustment screws on the lamp housing. View the objective back aperture (the position of the back focal plane; Fig. 2A.1.3) by using the Bertrand lens in the magnification changer in combination with the eyepieces, by replacing one eyepiece with a telescope, or by simply removing one eyepiece and peering down the body tube. Open the condenser diaphragm all the way. Readjust the collector lens and the mirror so that the lamp images are in focus and sit side by side to fill the objective aperture.

   This is a rough adjustment with the low-power objective and will need to be fine-tuned using the objective with the highest NA.

9. Adjust the opening of the condenser diaphragm so that the diameter of its image at the objective back focal plane (see far right of Fig. 2A.1.2; also see Fig. 2A.1.3) is slightly less than the diameter of the objective back aperture.

   Some research condensers also have centering adjustments for the condenser diaphragms. The image of the condenser diaphragm should be centered in the objective back aperture.

10. Adjust the light intensity for comfortable viewing of the specimen by adjustment of the light-source intensity, either using the power-supply rheostat or by inserting neutral-density filters in the illumination light path.

    The microscope is now adjusted properly for the low-power objective.

Adjust for 40× viewing

11. Switch the turret to the 40× high-dry objective.

    Note that because of parfocal objective design, the specimen is almost in focus. Focus on the specimen with the fine focus.

12. Focus and center the field diaphragm with the condenser focus and the condenser-carrier *x*–*y* adjustment screws.

13. View the objective back aperture (Fig. 2A.1.3).

    Notice that the image of the condenser diaphragm adjusted for the low-power objective is only about half the diameter of the 40× back aperture. The ratio of the diameter of this image to the diameter of the objective back aperture is equal to the ratio of the NA of the condenser illumination to the NA of the objective (Fig. 2A.1.3). When the condenser illumination NA equals the objective NA, the aperture of the objective is filled with light and maximum resolution will be achieved for the objective NA (see Commentary).

14. Adjust the condenser diaphragm so that the condenser illumination NA just about matches the objective NA.

    Each time objectives are changed, these procedures should be repeated.

Adjust for high-power viewing

15. Rotate the nosepiece so that the high power (60× to 100×, NA 1.25 to 1.4) oil-immersion lens is coming into place, but stop before it clicks into place. Place a small drop (~2 mm diameter) of immersion oil directly onto the coverslip above the point upon which the condenser beam is focused.

    This oil drop must be free of air bubbles and dirt. The refractive index of the immersion oil should be close to that of the glass coverslip.

16. Complete the rotation of the nosepiece so that the oil-immersion objective clicks into place. Lower the objective nosepiece if appropriate.

    IMPORTANT NOTE: *Use only the fine adjustment knob when working with the oil-immersion lenses.*

    The space between its front lens and the coverslip is now filled with immersion oil.

17. Remove the eyepiece (or use the telescope or Bertrand lens) and inspect the back aperture of the objective. Open the condenser diaphragm as much as possible to try and match its image with the objective aperture (Fig. 2A.1.3).

    This will be impossible if the condenser is dry and not designed for oil immersion, since dry condensers have NA ≤ 0.9 and the relative size of the image of the condenser aperture or condenser diaphragm seen in the objective back focal plane is given by the following ratio (see Fig. 2A.1.3).

$$\frac{NA_{cond}}{NA_{obj}}$$

18. View the objective back aperture, and tune up the focus and position of the lamp images so that they fill the objective aperture with light as uniformly as possible.

19. Replace the eyepiece (or remove the Bertrand lens) and examine the specimen. Adjust the field diaphragm until its margins just match the field of view.

    With inexpensive condensers, the image of the edge of the field diaphragm will not be in good focus, even at the optimum position. If a condenser designed for oil immersion is being used, enormous improvement in the field iris image can be achieved by oil immersion.

20. Oil the condenser (if possible) to achieve the highest resolution and image quality using the following procedure:

    a. Rotate the objective out of the way and remove the slide.

    b. Oil the condenser.

    c. Replace the slide and refocus the objective.

    Before oiling the condenser, make sure it is not designed to be a "dry" condenser by checking that it is marked with an NA > 0.9. It takes much more air-bubble-free oil than the objective.

    The image of the field diaphragm should now be much sharper when in focus and centered.

    Before oiling the condenser, make sure it is not designed to be a "dry" condenser by checking that it is marked with an NA >0.9.

    The image of the field diaphragm should now be much sharper when in focus and centered.

21. Look at the objective back aperture. Again, tune up the focus and position of the lamp images so that they fill the objective aperture with light as uniformly as possible.

    After oiling, the aperture should be filled by the condenser illumination when the condenser diaphragm is wide open.

    Notice also that viewing the objective back aperture is the best way to see if air bubbles have become trapped in the oil. If so, carefully wipe off the oil with lens paper and repeat steps 15 through 21.

22. Reinsert the diffusion glass in the illumination light path.

    This will reduce light intensity, but make the illumination of the objective aperture more uniform.

23. When finished for the day, use lens paper to remove excess oil from the objective and condenser lens surfaces to prevent dripping on specimens.

    It is not necessary, however, to completely clean oil from the optics after every use (see Support Protocol 6).

ALIGNMENT OF THE EYEPIECES

BASIC PROTOCOL 2

The binocular usually has adjustments for the inter-eyepiece distance and visual acuity in each eye. The goal is for the image to be in focus for each eye without any eyestrain or discomfort. Only the left eyepiece tube or eyepiece is adjustable on a typical microscope. However, if the microscope has a target reticle in the microscope stand that can be rotated into view, then usually both eyepieces are adjustable.

1. With a low-power objective (10× or 16×), focus on a stained specimen placed on the stage of the microscope (e.g., stained muscle section, see Table 2A.1.1) and align the microscope for Köhler illumination.

2. Move the bases of the eyepiece tubes together or apart to set the proper interpupillary distance for your eyes.

3a. *If the microscope has a target reticle:* Rotate the reticle into the field of view. Close the left eye and use the diopter-adjustment ring on the right eyepiece until the target is in sharp focus for the right eye. Then close the right eye and use the diopter-adjustment ring on the left eyepiece until the target is in sharp focus for the left eye. Remove the target to view the specimen.

3b. *If the microscope has no target reticle:* Set the right eyepiece tube to the inter-eyepiece setting (if possible). Close the left eye and bring into sharp focus a structural detail near the center of the field of view with the right eye. Close the right eye and use the diopter-adjustment ring on the left eyepiece tube to bring the specimen detail into sharp focus for the left eye. With both eyes open, fine tune the focus of the left eyepiece tube.

BASIC PROTOCOL 3

ALIGNMENT FOR KÖHLER ILLUMINATION IN EPIFLUORESCENCE MICROSCOPY

The eye is most sensitive to green light. Hence, the following protocol is best done using a filter cube that produces green excitation light (e.g., a filter cube for rhodamine).

Focus the lamp

1. Remove one objective, and rotate the nosepiece so the open position is centered on the microscope axis. Place a white card on the microscope stage, on top of supports that position the card at ~2 to 3 cm from the nosepiece.

   This is approximately the position of the objective back focal plane, where the images of the light source should be in focus and centered after alignment (Fig. 2A.1.5).

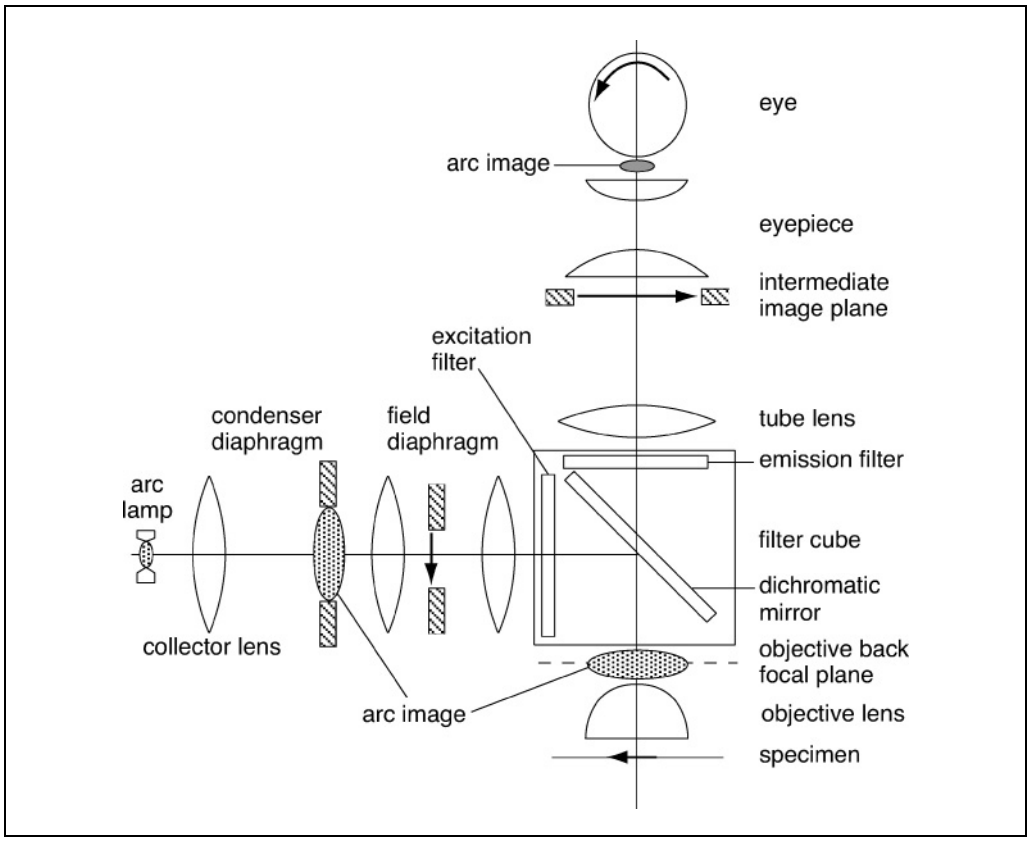

Figure 2A.1.5 Microscope alignment for epifluorescence Köhler illumination.

Some microscopes have a special device for lamp alignment. It screws into the objective nosepiece and projects an image of the epi-illumination arc and electrodes onto a small diffusion screen within the barrel of the device.

2. Install the mercury bulb in the lamp housing and attach the lamp housing on the back of the microscope according to the manufacturer's instructions.

3. Turn on the power source and ignite the lamp.

   CAUTION: *It is usually a good idea to make sure computers in the vicinity are turned off before starting the lamp because the high voltage pulse used to ignite the arc plasma may damage the electronics. Laboratory personnel should protect their eyes against UV light from the lamp.*

   It takes ~10 min for the arc to brighten.

4. Close down the field diaphragm and open the condenser diaphragm (if there is one) all the way.

5. On the diffusion glass screen or on the white card on the stage, the image of the arc between the tips of the two electrodes should be visible. Use the lamp focusing knob to obtain an in-focus image of the lamp arc and electrodes. Use the lamp *x–y* adjustment screws to approximately center the image of the arc and electrode tips (see Figure 2A.1.2).

6. If there is a lamp mirror, use its adjustment screws to focus the mirror image of the arc and electrode tips, centered on the target.

   Often the primary image and the mirror image of the arc are adjusted side-by-side and slightly overlapping, but centered on the microscope axis.

Focus the field diaphragm

7. Place a test fluorescent specimen (see Table 2A.1.1) on the stage and rotate the objective nosepiece to a low-power objective. Select the appropriate filter cube for the fluorescent specimen. Open up the epi-illuminator field diaphragm all the way. Open the shutter and view the specimen.

8. Focus the specimen, then close down the field diaphragm until an edge comes into the field of view. Use the *x–y* adjustment screws for the field diaphragm to center the field diaphragm image within the field of view.

9. Close down the field diaphragm until only the region of interest is illuminated.

   This prevents photobleaching of areas outside the region of interest and reduces the amount of scattered fluorescent light in the image from outside the region of interest.

10. Switch to a high-power objective. For an oil-immersion objective, place a small drop (~2 mm diameter) of immersion oil directly onto the coverslip above the region of

interest. Carefully swing in the objective. Open the shutter and focus on the specimen. Readjust the size and centration of the field diaphragm.

This oil drop must be free of air bubbles and dirt.

11. To prevent photobleaching, be sure to close the epi-illumination shutter when not viewing or taking camera exposures.

BASIC PROTOCOL 4

ALIGNMENT FOR PHASE-CONTRAST MICROSCOPY

Phase-contrast microscopy is often used to produce contrast for transparent, non-light-absorbing, biological specimens. The technique was discovered by Zernike in 1942, who received the Nobel prize for his achievement (Zernike, 1942, 1955, 1958). The last of these references describes the principles of phase contrast and provides an excellent introduction to the wave optics of image formation, resolution, and contrast in the microscope.

The phase-contrast microscope is a bright-field light microscope with the addition of special phase-contrast objectives (Fig. 2A.1.6) containing a phase plate or ring and a condenser annulus instead of a diaphragm; the annulus is usually located on a condenser turret because it has to be selected for different objectives. The microscope optics are usually aligned for bright-field specimen illumination by the standard Köhler method. However, there is no condenser diaphragm to adjust. Instead, the phase annulus must be selected and adjusted properly. Modern phase-contrast objectives have a phase plate containing a ring in the back focal plane within the barrel of the objective. This ring absorbs and advances the phase of the light passing through it by $\frac{1}{4}$ wavelength in comparison to light passing through the rest of the objective aperture. For each phase objective, there is a corresponding annulus in the condenser turret that has about the same relative size as the phase ring in the objective. Light passing through this annulus

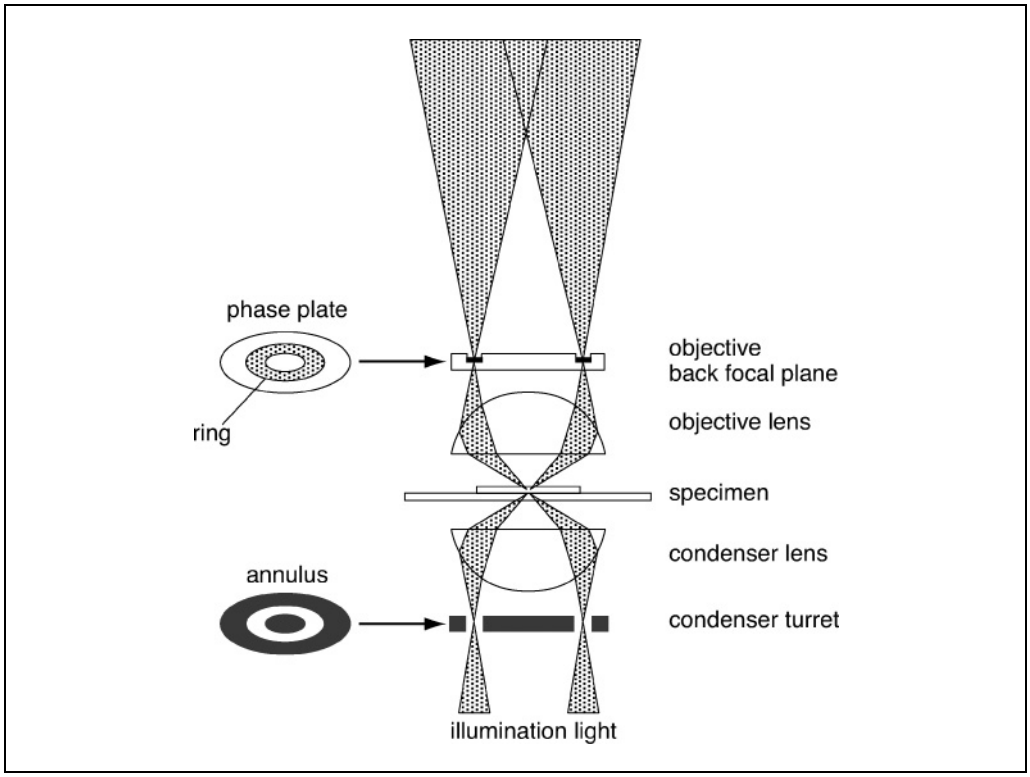

Figure 2A.1.6 Illumination light path through the condenser annulus and objective phase ring in a microscope aligned for phase-contrast microscopy.

passes through the phase ring in the objective when the annulus is selected and aligned properly. Light scattered by the specimen mainly passes through the objective aperture outside the phase ring. Light scattered from a thin transparent specimen is $-\frac{1}{4}$ wavelength retarded from the unscattered illumination light. The additional $\frac{1}{4}$ wavelength retardation between the scattered and illumination light produced by the objective phase ring makes the scattered and illumination light 180° out of phase. They destructively interfere with each other at the image plane to produce the "dark" contrast of structural detail typical of phase contrast images of biological specimens.

Because the phase annulus and the phase ring reduce the intensity of the background light, a bright illuminator—e.g., a 100-W quartz-halogen illuminator—is necessary at high magnifications (because image intensity decreases as 1/magnification^2). For living cells, heat reflection and green illumination filters should be used.

To examine the objective phase ring and matching condenser phase annulus, remove the low- and medium-power phase objectives and the phase condenser from the microscope. View the phase ring (phase plate) within the objective by looking in the back end. The phase ring is located at the position of the objective back focal plane; its diameter is usually $\sim\frac{2}{3}$ that of the objective aperture. Note that it is situated within the objective body and is visible because it absorbs light. Locate the annulus for each objective in the condenser turret. The annulus is located at the condenser diaphragm plane, which is situated at the condenser front focal plane. Notice that as the objective NA increases, the diameter of the corresponding annulus in the condenser turret increases. The NA of condenser illumination from an annulus is designed to match that of the phase ring in the corresponding objective.

Replace the condenser on the microscope and illuminate with white light. Hold a piece of tissue paper near the top of the condenser and examine the illumination cone. Notice that it is an annular cone of illumination. Change the annulus from the setting for the low-power objective to the 40× setting. Note that the NA or angle of illumination increases. Points of illumination further from the central axis in the condenser diaphragm plane produce higher-aperture rays passing through the specimen.

Perform alignment using the following steps.

1. Align the microscope for bright-field Köhler illumination using the low-power phase objective (10× or 16×) and a cheek cell preparation for the specimen (see Support Protocol 4).

   The cheek cell specimen is an excellent transparent test specimen for alignment of the microscope for phase contrast, dark field, and DIC. The cheek cells are transparent and only barely visible by bright-field illumination. To find the plane of focus in bright field, initially close down the condenser diaphragm and look for the edges of air bubbles in the preparation. These edges scatter much light and appear dark in the image. When using dark-field configuration, the cheek cells will appear white against a dark background.

2. Align the condenser annulus with the phase ring by rotating the condenser turret to the position where an annulus matches the phase ring in the objective; use the telescope, your eye, or the Bertrand lens to view the objective back aperture.

   As the condenser turret is rotated, notice in the objective back focal plane the images of the different-diameter annuli designed for the different numerical aperture objectives. The correct annulus may not be properly aligned with the objective phase ring.

3. Use the adjustment screws in the condenser (and the special tools if necessary) to move the annulus in the *x*–*y* plane to achieve alignment with the phase ring in the objective.

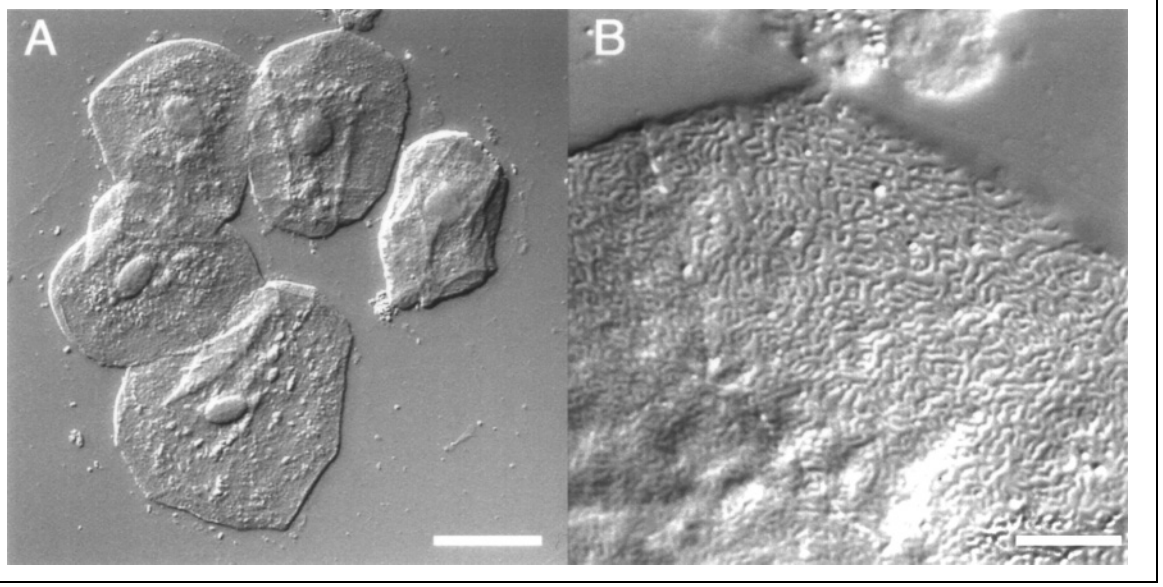

Figure 2A.1.7 DIC images of a human cheek cell test specimen. (**A**) Low magnification of cheek cell preparation with a 20× objective. Bar = 20 μm. (**B**) High-resolution image of the surface of the cell at the top of (A) using a 60×/(NA = 1.4) Plan Apochromat objective and matching condenser ilumination. The ridges on the cell surface are often diffraction limited in width. Bar = 5 μm. From Salmon and Tran (1998), reprinted with permission from Academic Press.

Note that the phase ring is slightly wider than the image of the correct annulus. It is critical that the image of the annulus be within the phase ring, but it is not critical if it is very slightly off center.

4. When the objective phase ring and condenser annulus are aligned, view the specimen and properly adjust the focus and centration of the field diaphragm.

   Notice that if the phase ring and annulus are slightly misaligned (rotate the turret slightly), the background light intensity goes up. This is because the phase ring is designed to absorb much of the illumination light. The unscattered illumination light becomes closer to the intensity of the light scattered by the specimen, which passes through the objective aperture outside of the phase ring. Minimizing the background light intensity while viewing the specimen image can also be used to align the annulus with its phase ring or to touch up the alignment done by viewing down the body tube.

5. Switch to the 40× phase objective and then the high-power 60× or 100× phase objective (NA 1.25 to 1.4) and repeat steps 1 to 4.

   It is necessary to increase light intensity at the higher magnifications. It should be possible to see the ridges on the cell surface (see Fig. 2A.1.7 for a DIC image of the ridges). Notice the "phase halos" at discrete edges, a problem that limits conventional phase contrast in high-resolution imaging.

BASIC PROTOCOL 5

ALIGNMENT FOR DIC MICROSCOPY

Since its introduction in the late 1960s (e.g., Allen et al., 1969), DIC microscopy has been popular in biomedical research because it highlights edges of specimen structural detail, provides high-resolution optical sections of thick specimens—including tissue cells, eggs, and embryos—and does not suffer from the "phase halos" typical of phase-contrast images. See Salmon and Tran (1998) for details of image formation and video-contrast enhancement.

Proper Alignment and Adjustment of the Light Microscope

The DIC microscope is a bright-field light microscope with the addition of the following elements (Fig. 2A.1.8, middle): a polarizer beneath the condenser; a DIC beam-splitting

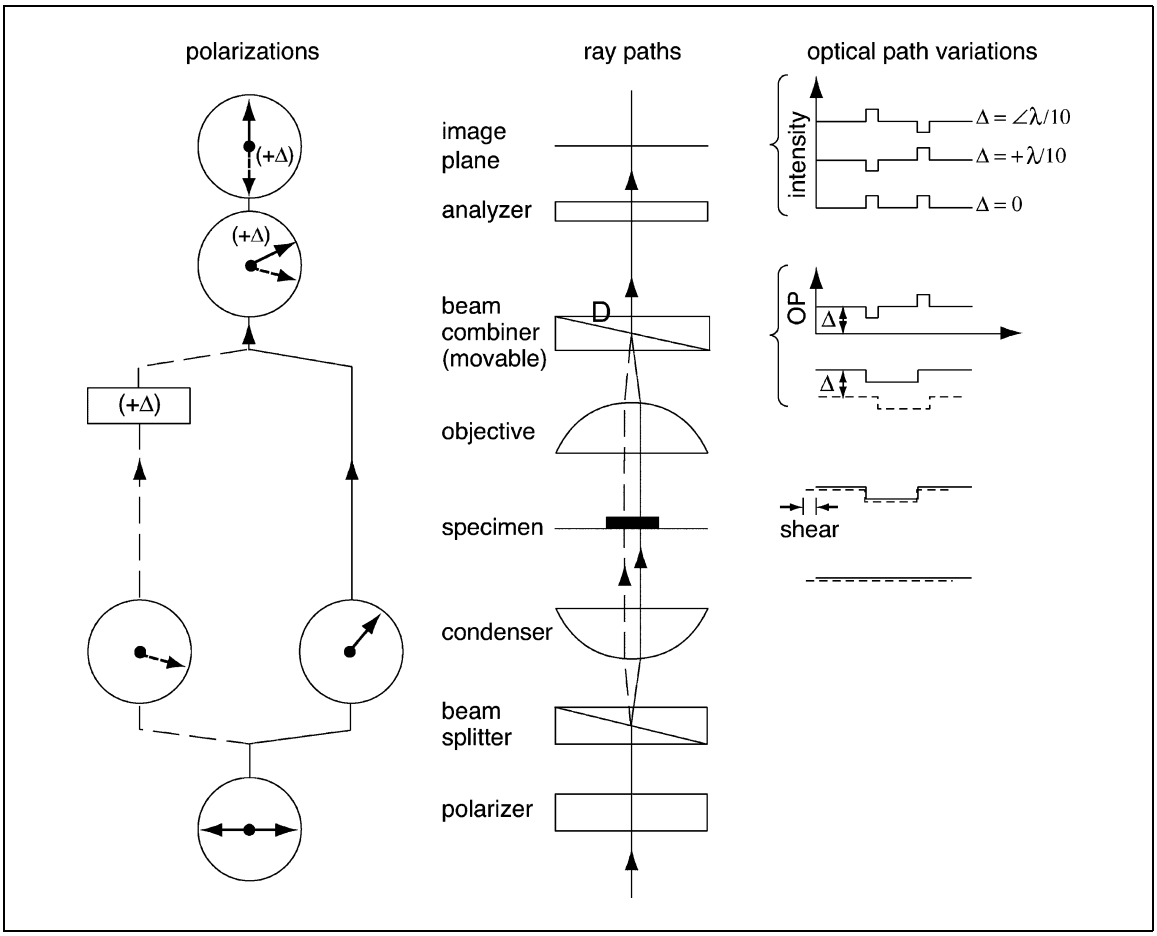

Figure 2A.1.8 The optical system for DIC microscopy. From Salmon and Tran (1998), reprinted with permission from Academic Press.

prism (Nomarski or Wollaston) in the condenser turret; a DIC beam-combining prism (Nomarski) just above the objective; an analyzer above the objective prism in the infinity body tube space; a compensator after the polarizer or before the analyzer in some microscopes (not shown in Fig. 2A.1.8); and a rotatable stage. The microscope optics are usually aligned for bright-field specimen illumination by the standard Köhler method.

The polarizer, which produces plane-polarized light (Fig. 2A.1.8, left), is typically oriented with its transmission azimuth in an east-west direction facing the front of the microscope. Polarizers with high transmission efficiency are preferred. Polarizers are usually high-quality polaroid material held between thin optical glass flats. Another polarizer is used as an analyzer. The transmission azimuth of the analyzer is oriented north-south at 90° with respect to the polarizer azimuth to produce extinction of the illumination light in the absence of the DIC prisms.

The specimen is held on a rotating stage. Contrast depends on orientation and frequently specimens must be reoriented to achieve maximum contrast of the structures of interest. Either the stage or the objective and condenser must be centerable.

For the highest sensitivity, the objective and condenser lenses should be selected free of birefringence (Inoué and Spring, 1997). Rectifiers can be used to correct for the rotation of the plane of polarization of light which occurs at the periphery of lens surfaces (Inoué and Spring, 1997).

Figure 2A.1.8 outlines the principles of DIC image formation and contrast. The DIC beam-splitting prisms are located at the condenser diaphragm plane, just above the polarizer in the condenser turret. Objectives of different magnification and/or NA usually require condenser prisms of different optical characteristics.

The condenser prism splits the light coming from the polarizer into divergent polarized light wavefronts whose planes of polarization are orthogonal to each other and at 45° with respect to the initial plane of polarization (Fig. 2A.1.8, left). The divergent beams are converted by the condenser into two wavefronts, which pass through the specimen separated laterally from each other in the direction of the prism wedge (the shear direction, Fig. 2A.1.8, middle) by a tiny amount that is usually less than the resolution limit of the condenser-objective lens combination (Fig. 2A.1.8, right). These two wavefronts are recombined just above the objective by a beam-combining prism. Often, each objective has its own prism so that it accurately matches the action of the condenser prism. In some microscopes, there is one beam-combining prism for all objectives and a different condenser prism for each objective. Check which is the case for your microscope.

DIC image contrast depends on the "compensation" or "bias retardation" (Δ) between the two wavefronts along the microscope axis (Fig. 2A.1.8, right). When the objective beam-combining prism is perfectly aligned with the condenser beam-splitting prism and there is no compensation ($\Delta = 0$), the background light is extinguished and the edges of objects are bright against a black background (Fig. 2A.1.8, upper right). When one wavefront is retarded relative to the other by Δ, this increases the optical path (OP) between the wavefronts (Fig. 2A.1.8, middle right) and brightens the background light. One edge of an object becomes brighter than the background while the opposite edge becomes darker (Fig. 2A.1.8, upper right). This produces the "shadow cast" appearance of DIC images. Reversing the sign of retardation reverses the contrast of the specimen edges.

In some microscopes, the objective beam-combining prism (Fig. 2A.1.8, middle) is used as a compensator by translating the prism in the direction of prism wedge away from the position of background light extinction. One direction produces positive while the other produces negative retardation (Δ). In other microscopes, both the objective and condenser prisms are fixed at positions that produce background light extinction, and typically a deSenarmont compensator (a birefringent quarter-wave retarder in combination with a rotatable polarizer or analyzer; Inoué and Spring, 1997) is inserted just above the polarizer or beneath the analyzer.

Bright illumination sources are required for high magnification because of the crossed polarizer and analyzer; at least the 100-W quartz-halogen illuminator is usually needed.

To examine the DIC prisms, remove the objective prisms and the DIC condenser from the microscope. Examine the objective prism. Notice that it is very thin and wide enough to cover the objective aperture. Also notice if there is a screw that can be used to translate the prism back and forth in one direction across the objective aperture. Examine the prisms in the condenser turret. Notice that there are different prisms for low- and high-NA objectives. The highest-resolution (NA) objectives often have special prisms designed only for the optical properties of that objective. In aligning the microscope for DIC, be careful to use the condenser Wollaston prism that matches the objective in use. Reinstall the condenser.

Proper Alignment and Adjustment of the Light Microscope

Steps 1 to 6 in the following procedure are for the initial alignment of the microscope. Once this is done, begin at step 7 for routine use.

Perform initial alignment

1. Align the microscope initially for Köhler illumination using the low-power objective and the cheek cell preparation. Again look for the bright air-bubbles in the preparation to find the specimen plane.

2. Check that the polarizer is oriented with its transmission azimuth in an east-west direction as determined facing the front of the microscope (look for the line or double-headed arrow on the polarizer mount). Rotate the deSenarmount compensator (if there is one) so that it is at its zero position (no compensation).

3. Remove the objective prism and rotate the condenser turret to an open position. Make sure that the analyzer transmission azimuth is crossed to the polarizer by checking that the background light is at extinction.

   This exercise is best done with the brightest light position of a 100-W quartz-halogen illuminator.

4. Insert the objective DIC prism (observe caution as the image will be very bright). Observe the extinction fringe in the middle of the prism (you must use the telescope, remove an eyepiece, or insert the Bertrand lens to focus on the objective focal plane). Make a drawing of your view of the fringe in the back aperture.

   The fringe should be at 45° with respect to the analyzer-polarizer transmission azimuths.

5. Remove the objective DIC prism and rotate into place the condenser prism that matches the objective. Observe the objective back focal plane.

   The orientation of the fringe should match the orientation of the extinction fringe for the objective prism in your drawing.

6. Insert the objective prism and observe the objective back focal plane. Rotate in the other condenser prisms and notice that the extinction fringe is no longer spread across the objective aperture. Rotate in the correct condenser prism.

   If the condenser and objective prisms are properly matched and oriented in the same direction, the fringe should become spread across the objective aperture (a dark cross will still occur in high-power, unrectified objectives; Inoué and Spring, 1997).

Align for specimen viewing

7. View the specimen with the correct objective and condenser prisms in place. Translate the objective prism (or rotate the deSenarmount compensator if the objective prism is fixed) to induce a retardation (Δ) between the two wavefronts to brighten the background light and make the edges of the cell appear shaded. If possible, rotate the specimen and observe that contrast is directional—45° with respect to the analyzer-polarizer orientations.

   As the upper prism is translated (or the deSenarmount compensator is rotated) to compensation of opposite sign, the initially bright edges become darker and the initially dark edges become brighter than the background.

8. Adjust for proper bright-field, transmitted-light Köhler illumination.

   The quality of the DIC image depends critically on the field diaphragm being sharply focused on the specimen (Fig. 2A.1.2, left), since this puts the condenser prism in the proper place. The highest possible resolution is achieved when the condenser diaphragm is adjusted to match the diameter of the objective aperture (view the objective back focal plane during this adjustment).

   Optimum edge contrast is produced when the retardation between the wavefronts is adjusted to extinguish the light coming from one set of edges in the specimen. Further retardation increases light intensity, but not contrast to the eye. When using video cameras, it is often important to view the specimen by eye and adjust the compensation for best

contrast, then change illumination intensity to provide the camera with enough light for good image quality.

9. Repeat steps 2 to 8 for the other objectives.

Once you are sure of the correct prisms and their orientation, then only steps 7 and 8 are necessary for each objective.

ALIGNMENT FOR DARK-FIELD MICROSCOPY

Dark-field microscopy, also referred to as dark-ground illumination, is a special optical technique used to observe subjects that have a refractive index similar to that of the medium in which they are mounted and that are difficult to image using conventional bright-field illumination. A major advantage of this technique is that low-power objectives can be used to produce good observation of a specimen that would require higher power magnification using bright-field illumination. Dark-field microscopy does not provide the best resolution, but it can resolve objects clearly against a dark background. The technique was developed by Dupouy to examine bacterial flagella (Dupouy et al., 1969) and bacterial cell walls (Dupouy, 1973). Ideal candidates for dark-field microscopy include living aquatic organisms, diatoms, unstained bacteria, and cells in tissue culture. It is recommended that the specimen be a thin, homogeneous preparation in order to eliminate diffraction artifacts that can interfere with image formation. For this reason, the standard method for observation of such biomedically important bacterial species as *Borrelia burgdorferi* (Fig. 2A.1.9), *Leptospira interogans*, *Treponema denticola*, and *Treponema pallidum*, among others, is dark-field microscopy. Dark-field microscopy detection of spirochetes from patient samples is often critical for diagnosis.

Dark-field conditions are created by blocking bright-field light that normally passes through the specimen and into the objective. The light path is blocked by the application of dark-field stops to the plane of the condenser aperture (Fig. 2A.1.4). To examine this plane, remove an ocular from the microscope and look down the tube. The condenser aperture can be seen at the point of the back objective focal plane. To aid in locating this plane, close and open the condenser aperture while looking down the tube. The diaphragm can be seen moving. The diameter of the stop must be sufficient in size to block the majority of the light passing through the condenser, but open at the perimeter of the condenser diaphragm to allow some light outside the edges of the stop. The apex of the inverted cone of light is centered in the specimen plane, the result of which is a bright image of the specimen seen against a black background. The hollow, inverted cone of light can be visualized using a demonstration created by Faine (1961). This simple but informative experiment involves placing a dish of agar on the stage of the microscope set up for dark-field configuration using a low-power dark-field condenser. As the light source is turned on, the observer can visually reproduce the two inverted cones of light that can be seen from a side view of the agar.

When a mounted specimen is placed on the stage, the specimen is aligned at the apex of the hollow cone of light. All of the light that escapes the dark-field stop is passed through the specimen. The light is then scattered in every direction, such that some of the light is reflected into the objective lens. The result is a bright image of the specimen against a dark background (Fig. 2A.1.9).

Due to the blockage of the majority of the light passing through the condenser of a microscope configured for dark-field microscopy, a 100-W tungsten-halogen bulb is required as a minimum for both low- and high-power magnification. Microscope slides must be $\sim 1 \pm 0.1$ mm thick, and slides used for preparation of specimens for dark-field illumination should not be reused. All slides and optical surfaces in the microscope

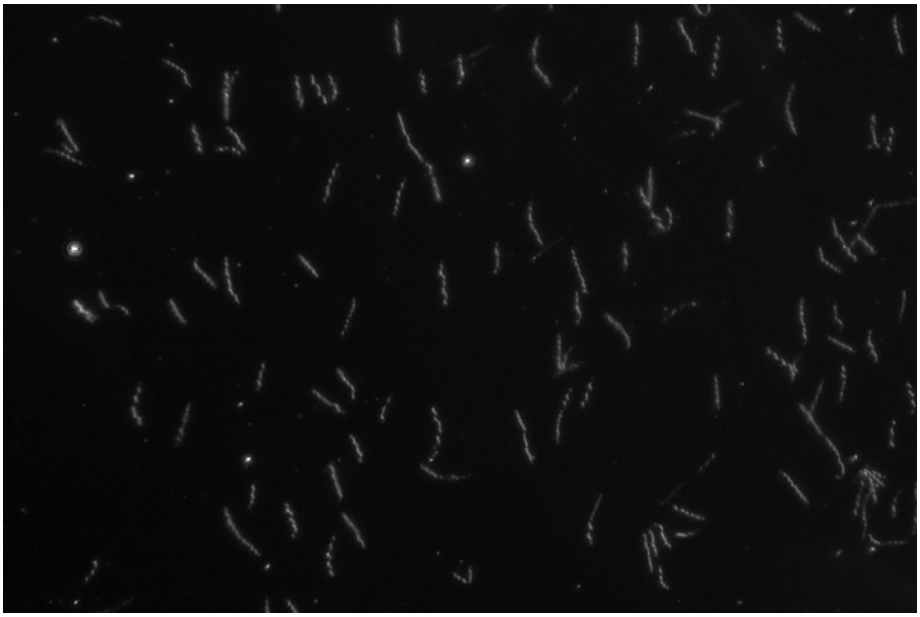

Figure 2A.1.9 Dark-field image of the Lyme disease spirochete, *Borrelia burgdorferi* with a 20× objective and a turret condenser with dark-field stop included.

must be spotlessly clean since dark-field microscopy will detect every speck of dust and particulate matter. Dilute particulate preparations if necessary.

A bright-field microscope can easily be converted for use in dark-field microscopy with the addition a turret condenser with a dark-field stop included. If a turret is not available, any multifunction condenser will work. Dark-field stops can be purchased or handmade. Hayden (2002) provides an excellent resource for instructions on how to devise dark-field patch stops.

ALIGNMENT FOR LOW-POWER MAGNIFICATION DARK-FIELD MICROSCOPY

BASIC PROTOCOL 6

1. Align the microscope as for bright-field Köhler illumination using the lower-power phase objective, but ignore the step used to optimize the opening of the condenser aperture.

   Dark-field conditions require that the condenser aperture be fully opened to its maximum setting to let in as much light as possible. Köhler illumination provides a default position for the user to reference and return to while changing the optics for optimal dark-field settings.

2. Align the condenser turret for dark-field settings using the default dark-field stop. If the turret does not include a dark-field stop, insert the appropriate diameter patch stop (16 to 18 mm stop for use with the 10× objective) by either positioning it into the substage condenser filter holder or by taping it onto the underside of the condenser.

   The turrets usually possess five or six openings, one opening for bright-field, one opening has a dark-field stop (labeled DF), and the remaining openings house several phase stops.

3. Open both the field and the substage condenser aperture iris diaphragms fully to their maximal setting.

   This allows the condenser to operate at its highest NA.

4. Check the dark-field stop diameter by removing the eyepiece and looking down into the focal plane of the objective.

   The dark-field stop diameter should eclipse the bright disk of light that can be normally viewed at the objective rear focal plane under bright-field conditions. If the dark-field stop does not completely mask the bright disk, use the substage screws to center the condenser until the bright disk is fully blocked by the stop. Replace the eyepiece.

5. Place a low-contrast specimen that is suitable for dark-field illumination on the stage.

   The specimen image should be bright against a black background view. Dust and small contaminants on the slide may create artifacts that could obscure the object. Be sure to use premium quality microscope slides and clean them thoroughly with ethanol and Kimwipes Delicate Task Wipers before observing specimens under dark-field illumination. If the specimen image is too dark, increase the light source to its maximum voltage.

6. Focus the condenser by adjusting up or down until a single bright ring of light is central in the field of view.

   When using the condenser dry, the top of the lens should almost come into contact with the bottom of the microscope slide. If a small dark region lies within the bright ring of light, then the condenser is too low. The bright ring of light will appear off-center in the field of view if the microscope is not properly aligned for Köhler illumination.

7. When the condenser is properly adjusted, view the specimen and properly adjust the focus.

   If the field of view has a dark spot in the center obscuring the image, but objects in the periphery appear normal, then the substage condenser may need to be re-positioned or the inappropriate diameter stop is being used or the NA of the objective. Re-establish alignment for Köhler illumination (see Basic Protocol 1) and repeat the steps for dark-field illumination.

BASIC PROTOCOL 7

ALIGNMENT FOR HIGH-POWER MAGNIFICATION DARK-FIELD ILLUMINATION

1. Repeat step 1 of Basic Protocol 6 for low magnification dark-field illumination.
2. Insert a high NA condenser into the substage holder and secure into place.

   Both dry and immersion dark-field condensers are commercially available, but the best results can be obtained with an immersion dark-field condenser due to its internal mirrored surfaces that eliminate chromatic aberration. Use of an oil immersion condenser will also produce the blackest background. The dry dark-field condenser is ideal for objectives with an NA below 0.75. Paraboloid and cardioid immersion condensers are designed for use with objectives with NA up to 1.4.

3. Adjust the condenser until it is <2 mm from the bottom of the specimen slide.
4. Place a low-contrast specimen that is suitable for dark-field illumination on the stage.
5. Use the $10\times$ objective to center the high NA dark-field condensers.

   While viewing the specimen with the $10\times$ objective, focus the condenser as described in step 6 for low magnification dark-field illumination.

6. If using a high NA immersion condenser, apply oil to the lens of the condenser by first lowering the condenser below the mechanical stage and placing a drop of oil on the lens. Next, slowly raise the condenser until it makes contact with the underside of the specimen slide. Make sure to eliminate any air bubbles trapped between the slide and the condenser top lens.

   Note that when an oil immersion condenser is used without oil, regardless of the magnification of the objective used, light will not emerge from the condenser.

7. Switch to the 40× DF objective and then the higher power 100× objective. Position the objective to be used for viewing the specimen.

   Some objectives can be used dry or with oil immersion. For oil immersion–only objectives, place a drop of oil on the specimen slide's cover slip before positioning the objective. Observe the back focal plane of the objective to check for air bubbles. If bubbles are detected, move the objective to the next detent stop on the microscope and remove the oil with lens paper. Then re-apply oil again and re-position the objective.

8. View the specimen and properly adjust the focus.

MATCHING MICROSCOPE MAGNIFICATION TO DETECTOR RESOLUTION

SUPPORT PROTOCOL 1

This procedure uses the diatom test slide (see Table 2A.1.1 for supplier information). For more details on matching a camera to the microscope see Hinsch (1998) or Inoué and Spring (1997).

1. Look down the eyepieces and obtain an in-focus image of the frustrule pores of the diatom *Pleurosigma angulatum* (Fig. 2A.1.10, number 6 in panel A) using 40×/(NA −0.7) phase-contrast or DIC and proper Köhler illumination.

   The pores should be clearly visible by eye.

2. Project the diatom image onto the faceplate of a video or CCD camera.

3. Adjust the gain and contrast camera controls for optimum image brightness and contrast.

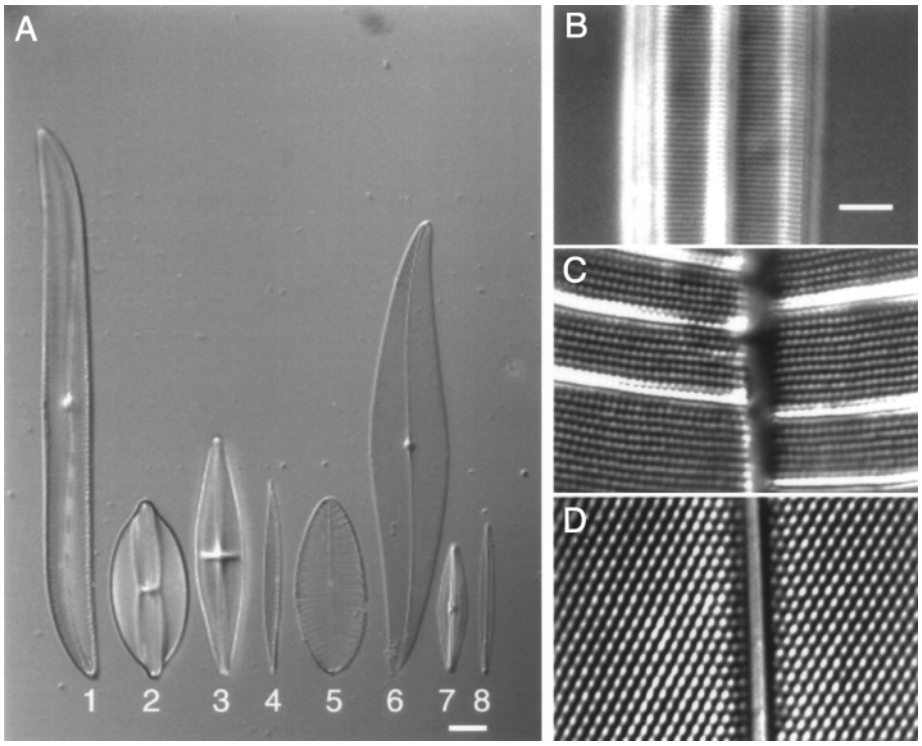

Figure 2A.1.10 (**A**) The diatom test plate. The rows of pores are spaced in the silica shell by ~0.25 μm in *Amphipleura pellucida* (panel **B**; also number 8 on panel A), 0.41 μm in *Surrella gemma* (panel **C**; also number 5 on panel A), and 0.62 μm in *Pleurasigma angulatum* (panel **D**; also number 6 on panel A). Bar: panel A, 10 μm; panels B, C, and D, 2.5 μm. From Salmon and Tran (1998), reprinted with permission from Academic Press.

As you increase contrast, you will need either more camera gain or brighter illumination. Usually, a better signal-to-noise ratio is achieved by leaving the gain control in the middle of its adjustment and increasing illumination intensity.

If the projection magnification to the detector is too small, the frustrule pore lattice will be invisible in the video image, although it will be clearly visible when viewing the image by eye.

4. Increase the magnification to the camera as much as possible.

   As magnification increases, resolution in the image becomes less limited by the resolution of the camera. However, the size of the field of view decreases inversely with magnification. In addition, the intensity of light in the image decreases as magnification^{-2}. The image will become noisy at low light intensities. It will be necessary to increase illumination intensity as much as possible at high magnification or increase the integration period for the camera exposure.

SUPPORT PROTOCOL 2

CALIBRATING IMAGE MAGNIFICATION WITH A STAGE MICROMETER

1. Insert the stage micrometer (see Table 2A.1.1) on the microscope stage.
2. With the low-power objective, find the region of the micrometer with 10-μm scale intervals.

   The larger intervals are 100 μm.

3. Use the 100- or 10-μm scales to calibrate distance in images taken with your objectives.

   The magnifications on the objective barrel and projection lenses are only approximations; accurate measurements of distances in images require a calibration scale.

4. Acquire images of the scale in both the horizontal and vertical directions to check if the camera has square pixels.

TESTS FOR THE OPTICAL PERFORMANCE OF THE MICROSCOPE

Test slides are used to evaluate the performance of the microscope under different conditions.

SUPPORT PROTOCOL 3

Testing Phase-Contrast and DIC Using Diatom Testing Slide

Diatoms have silica shells shaped like pillboxes. There are pores in the shell arranged in a lattice pattern specific for each diatom species. Figure 2A.1.10 shows a low-magnification view of the eight diatoms on the test slide (panel A) plus higher-magnification views of the lattices of three diatoms most useful in testing the resolution performance of microscope optics using phase-contrast or DIC. Number 6 in panel A of Figure 2A.1.10, *Pleurosigma angulatum*, has a triangular pore lattice with spacing of ~0.61 μm between rows (illustrated in Fig. 2A.1.10, panel D). Number 5, *Surrella gemma*, has rows of pores where the rows are separated by ~0.41 μm (illustrated in Fig. 2A.1.10, panel C). Number 8 is *Amphipleura pellucida*, which has horizontal rows of pores separated by ~0.25 μm (illustrated in Fig. 2A.1.10, panel B). In transmitted light, the diffraction limit to lateral resolution, r, is given by (Inoué, 1989):

$$r = \frac{\lambda}{(NA_{obj} + NA_{cond})}$$

where λ is the wavelength of light, NA_{obj} is the objective NA, and NA_{cond} is the condenser NA (see Fig. 2A.1.3). The lateral resolution, r, is equal to 0.195 μm for the highest objective NA, which is equal to 1.4, with $NA_{cond} = NA_{obj}$ and 546 nm green light. As

seen in Figure 2A.1.10B, this objective is capable of resolving the rows of pores in the shell of *Amphipleura*, but not the individual pores, which are slightly <0.19 μm apart.

Use the above equation to calculate the diffraction limit of resolution for your other objectives and use the diatoms to test whether they achieve their theoretical limits.

Testing Phase-Contrast, Dark-Field, and DIC Microscopes Using a Squamous Cheek Cell Test Slide

SUPPORT PROTOCOL 4

Cheek cells are a convenient specimen for testing the performance of phase-contrast, DIC, and dark-field microscopes. As seen in the low-magnification view (Fig. 2A.1.7A) they are large and flat, ≤3 μm thick except near the cell center which contains the nucleus. The upper and lower surfaces have fine ridges which swirl around much like fingerprints. Many of the ridges are <0.2 μm in width and separated by <0.5 to 1.0 μm.

To prepare the cheek cells, gently scrape the inside of your mouth with the tip of a plastic pipet or similar soft tool and spread the cells and saliva on the center of a clean no. 1.5 coverslip. Invert the coverslip quickly onto a clean slide and press down to spread the cell preparation into a thin layer. Seal the edges with a thin layer of nail polish.

Testing Fluorescence Using a Red, Green, and Blue Fluorescent Tissue Culture Cell Test Slide

SUPPORT PROTOCOL 5

The cells in Figure 2A.1.11 are triple labeled: DAPI stained nuclei and chromosomes (blue fluorescence; Fig. 2A.1.11A); Alexa 488-phalloidin labeled actin filaments (green fluorescence; Fig. 2A.1.11B); and X-Rhodamine immunofluorescently labeled microtubules (red fluorescence; Fig. 2A.1.11C). The microtubules and fine actin filamentous arrays are <100 nm in width, but they should appear sharp and in high contrast in the microscope. There should be no "bleed-through" from one fluorescence channel to another if the filters are chosen properly (Taylor and Salmon, 1989).

In fluorescence microscopy, the diffraction-limited lateral resolution is given by (Inoué 1989; Inoué and Spring, 1997):

$$r = \frac{0.61\lambda}{NA_{obj}}$$

and the intensity of the image, I_{image}, is given approximately by:

$$I_{image} \approx \frac{I_{ex} NA_{obj}^4}{M_p^2}$$

where I_{ex} is the excitation light intensity entering the objective and M_p is the projection magnification from the objective to the eye or camera. The rate of photobleaching, R_p, of a specimen depends on:

$$R_p \approx \frac{I_{ex} NA_{obj}^2}{M_{obj}^2}$$

where M_{obj}^2 is the magnification of the objective.

Note from these equations that resolution depends inversely on NA_{obj} (r = 0.24 μm for NA_{obj} = 1.4 and 546 nm green light), image intensity depends on the fourth power of NA_{obj}, while loss of intensity by photobleaching of the fluorophore increases with the

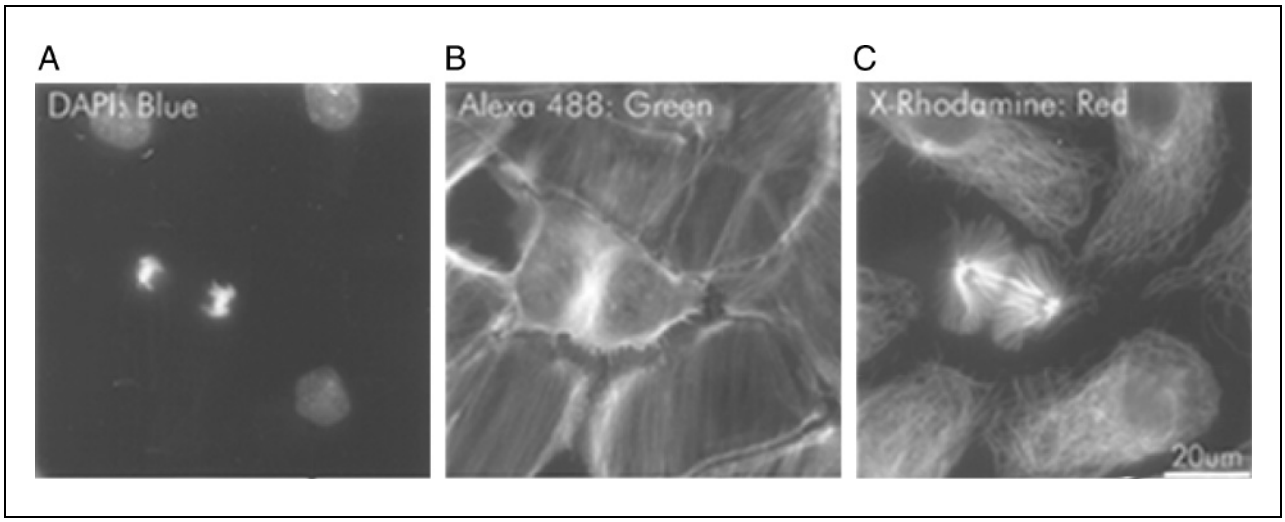

Figure 2A.1.11 Epifluorescent images of fixed tissue culture cells stained with (**A**) DAPI, making DNA fluorescent blue; (**B**) Alexa 488 bound to phalloidin to label actin filaments fluorescent green; and (**C**) X-rhodamine labeled antibodies against tubulin to label microtubules fluorescent red. Bar = 20 μm. Images recorded with a 40×/(NA = 1.4) Plan Fluor objective, 1.5 magnification, to a cooled CCD camera and the multi-modem multiwavelength microscope described by Salmon et al. (1998).

square of objective NA (a measure of the excitation light collected by the objective) and magnification (which concentrates the excitation light on the specimen).

Verify these equations by imaging the fluorescent specimen (the microtubules in the spread cells are a good choice) for objectives with different magnifications and numerical apertures. It will quickly be seen why in fluorescence one wants to use the minimum total magnification necessary to resolve the structures of interest in the detector, as well as use the maximum NA_{obj} in order to maximize light intensity for the least amount of excitation light (and the least amount of photobleaching).

SUPPORT PROTOCOL 6

CARE AND CLEANING OF MICROSCOPE OPTICS

Keeping the microscope optics clean is important for high-quality imaging. Dust, fingerprints, excess immersion oil, or mounting medium on or in a microscope causes reduction in contrast and resolution. DIC is especially sensitive to contamination and scratches on the lens surfaces. Below are steps for keeping the microscope clean.

1. Always keep microscopes covered when not in use.
2. Make sure that all ports, tubes, and unoccupied positions on the lens turrets are plugged.

   Plastic plugs are usually supplied with the microscope.

3. Store objectives in screw-top containers when not on the microscope. Keep accessories—e.g., condensers and compensators—in plastic bags or boxes. Keep slides and coverslips covered.
4. Be careful with salt water, corrosive liquids, and all solvents.
5. When cleaning lens surfaces, avoid touching the lens surface with anything (even lens paper if possible).

   IMPORTANT NOTE: *Never use Kimwipes or commercial facial tissue, because they may contain a filler that is part diatomaceous material (glass). One pass of a Kleenex could ruin an objective.*

6. Remove dust by gently brushing with an oil-free (ether-washed) camel's hair brush or by using a low-velocity stream of purified air.

7. Remove water-soluble contamination using distilled water with a small amount of detergent, such as Kodak Photoflow solution.

   Much (modern) immersion oil can also be removed by washing with detergent.

8. Remove most immersion oil by passing a high-quality lens tissue over the objective or condenser front element.

   IMPORTANT NOTE: *Do not rub. No area on the tissue should come in contact with the lens twice. This prevents dust and dirt removed from the lens from coming back and possibly scratching it. This is easily accomplished by passing the tissue over the lens in a "Z" pattern or by making parallel passes.*

9. Clean objective lenses by holding a piece of doubled lens paper over the objective and placing a few drops of solvent on the paper. Draw the paper across the lens surface so that the solvent flows rapidly in a circular pattern over the recessed lens surface (see Inoué and Spring, 1997). Finish the stroke with a dry portion of the paper. Repeat as necessary.

   In this way, the solvent contacts the lens but the paper does not, because the lens is recessed. For solvent, first use a 1% solution of Kodak Photoflow in distilled water to remove much of the oil and water-soluble material. Then use a small amount of oil solvent like ethyl ether or xylene to clean all the oil from the surface. Avoid soaking a lens with solvent, to prevent damage to lens cements.

10. To clean recessed front elements of dry objective lenses or to remove stubborn dirt, use a cotton-tipped applicator that has been soaked in cleaning solution and then shaken to remove excess fluid. Rotate the cotton tip over the lens surface to clean. Again, first use a 1% solution of Kodak Photoflow in distilled water to remove much of the oil and water-soluble material. Then use a small amount of oil solvent like ethyl ether or xylene to clean all the oil from the surface.

11. Use a detergent solution or ethanol to clean the surfaces of the eyepiece lenses.

    Do not use xylene as it may solubilize enamel surfaces.

COMMENTARY

The development of lasers, electronic cameras, digital image analysis, and specific fluorescent molecular probes have recently made light microscopy an enormously powerful tool in the biomedical sciences. There are a number of excellent books and review articles about these applications, as well as the optical principles of light microscope design and image formation. Listing of all these references is beyond the scope of this unit; only a few of these books and reviews are given here, and these can be used to find other useful references.

Spencer (1982), Zernike (1958), and Keller (1995, 1997, 1998) provide excellent introductions to the principles of image formation and contrast in the light microscope for beginners, while Pluta (1988, 1989) provides a more comprehensive treatment. Inoué and Oldenbourg (1995) also review the basic concepts and principles of microscope design and different methods of image formation. The abovementioned references describe the many modes of transmitted-light imaging in the microscope, including bright-field, phase-contrast, and DIC, which are described in this unit, as well as dark-field, polarization, interference contrast, Hoffman modulation, and reflection interference contrast methods. Taylor and Salmon (1989) and Herman (2002) give clear introductions to fluorescence microscopy. *Video Microscopy* by Inoué and Spring (1997) is a comprehensive introduction to the principles and practical aspects of light microscopy, video, and digital imaging. The *Video Microscopy* volume of *Methods in Cell Biology* edited by Sluder and Wolf (1998) also has contributions that cover many basic concepts and practical aspects of light

microscopy in the biomedical sciences; it also includes chapters on multiwavelength, multimode digital imaging methods, camera selection, ion ratio imaging, and specimen chambers. Salmon and Tran (1998) review the principles of video-enhanced DIC methods used to image macromolecular complexes invisible in the microscope when viewed by eye.

Photography with a Microscope by Rost and Oldfield (2000) provides a detailed overview of dark-field illumination and devising patch stops. Hayden (2002) provides an excellent introduction into the creation and use of dark-field illumination using a bright-field microscope. This reference also points out a comprehensive dark-field microscopy primer located online at *http://www.microscopy.fsu.edu/primer/techniques*. This website is an excellent source for dark-field information, microscope configuration, and troubleshooting. Taylor et al. (1992), Salmon et al. (1998), and Rizzuto et al. (1998) review microscope design for multiwavelength, multimode digital imaging of fluorescent specimens, and four-dimensional microscopy. Advanced quantitative fluorescence methods like ratio imaging, photobleaching, photoactivation, resonance energy transfer, chromophore-assisted laser ablation, and fluorescence lifetime imaging are also reviewed in the *Methods in Cell Biology* volumes edited by Taylor and Wang (1989), and Sluder and Wolf (1998), as well as in Herman and Jacobson (1990), and Inoué and Spring (1997). Reviews on imaging cells containing expressed protein coupled to green fluorescent protein (GFP) include Heim and Tsien (1996), and Sullivan and Kay (1999). Agard et al. (1989), Carrington et al. (1995), and Rizzuto et al. (1998) review how deconvolution of three-dimensional image stacks can produce super resolution in the light microscope. The recent edition of *Handbook of Biological Confocal Microscopy* edited by Pawley (1995) is an excellent reference on this important method for imaging fluorescent structures in thick specimens (Smith, 1997). The new technique of multiphoton laser scanning microscopy is described by Denk et al. (1994), while biological applications of optical traps to manipulate organelles and measure molecular forces is reviewed by Svoboda and Block (1994).

ABSTRACT

Total internal reflection fluorescence (TIRF) microscopy represents a method of exciting and visualizing fluorophores present in the near-membrane region of live or fixed cells grown on coverslips. TIRF microscopy is based on the total internal reflection phenomenon that occurs when light passes from a high-refractive medium (e.g., glass) into a low-refractive medium (e.g., cell, water). The evanescent field produced by total internally reflected light excites the fluorescent molecules at the cell-substrate interface and is accompanied by minimal exposure of the remaining cell volume. This technique provides high-contrast fluorescence images, with very low background and virtually no out-of-focus light, ideal for visualization and spectroscopy of single-molecule fluorescence near a surface. This unit presents, in a concise manner, the principle of operation, instrument diversity, and TIRF microscopy applications for the study of biological samples. *Curr. Protoc. Microbiol.* 10:2A.2.1-2A.2.22. © 2008 by John Wiley & Sons, Inc.

Keywords: total internal reflection fluorescence microscopy

INTRODUCTION

Over the past 25 years, researchers from physics and biology have shown significant interest in developing optical techniques for investigating nanostructures (e.g., single molecules) beyond the diffraction limit of light. Total internal reflection fluorescence (TIRF) microscopy is such a technique. TIRF was introduced in 1965 by Hirschfeld (1965) as a technique for selective surface illumination at a solid/liquid interface. This microscopy technique was further developed and refined by Axelrod (see Axelrod et al., 1983, 1984), with later theoretical contributions from Reichert, Truskey (see Reichert, 1989; Reichert and Truskey, 1990), and Burmeister (see Burmeister et al., 1998).

TIRF microscopy represents a method of exciting and visualizing fluorophores present in the near-membrane region of live or fixed cells grown on coverslips. If the microscope is thoroughly calibrated, the separation distance between cell membrane and substrate can be measured (Reichert, 1989; Truskey et al., 1992). In addition, any movement of fluorescent-tagged proteins in focal adhesion contacts, at the membrane level or in its immediate proximity, can be monitored quantitatively in real time.

TIRF microscopy is based on the total internal reflection phenomenon that occurs when light passes from a high-refractive index medium (e.g., glass) into one with a lower refractive index (e.g., water, cell; see Table 2A.2.1). Due to the difference between the refractive indices at the interface, only a short-range electromagnetic disturbance, called the evanescent field, will pass into the low-refractive medium. This type of excitation can be used to obtain high-contrast fluorescence images, with very low background and virtually no out-of-focus light. While resolution in optical microscopy is usually diffraction limited (see Table 2A.2.1) by the wavelength of light, the TIRF optical imaging technique allows imaging of cellular structures at the coverslip-cell interface with a higher z-resolution ($<$100 nm) than confocal microscopy ($\sim$300 nm) in a wide-field approach (see *UNIT 2C.1* for more on confocal microscopy).

This unit presents, in a concise manner, the principle of operation, instrument diversity, and TIRF microscopy applications for the study of biological samples.

PRINCIPLE OF OPERATION

TIRF microscopy is based on the total internal reflection phenomenon that occurs when

Table 2A.2.1 Glossary of Optical Terms

Reflection	The return of light by a surface, in the same medium, without a change of wavelength (the angle of incidence equals the angle of reflection)
Refraction	The bending of oblique incident light as it passes an interface between media of different refractive indices, which implies a change of speed (Snell's law; see Equation 2A.2.1)
Refractive index	A characteristic of a material (medium) that represents the ratio of the velocity of light in vacuum to the velocity of light in that medium
Diffraction	Refers to various phenomena associated with the bending of waves when they interact with obstacles in their path
Diffraction limit	The effect in an optical microscope where a beam of light of a finite size undergoes diffraction and spreads in diameter, limiting the minimum diameter d (i.e., the diffraction limit) of the spot of light formed at the focus of a lens: $d = 1.22 \times \lambda \times f/a$, where λ is the wavelength of light, f is the focal length of the lens, and a is the diameter of the beam of light, or (if the beam is filling the lens) the diameter of the lens

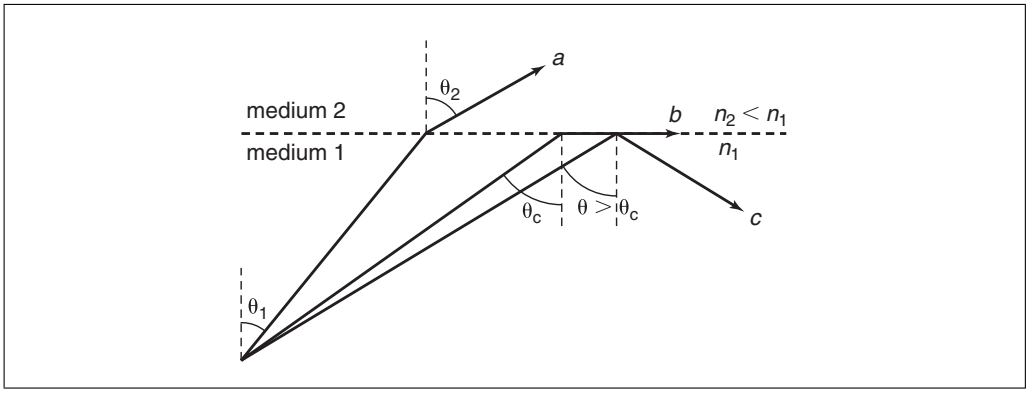

Figure 2A.2.1 Light path at the interface between two media. (***a***) Refracted light at an angle of incidence smaller than the critical angle; (***b***) light at an angle of incidence equal to the critical angle of light, traveling along the interface between the two media ($\theta_2 = 90^\circ$); and (***c***) total internal reflection occurring at incident angles higher than the critical angle. θ_1, incident angle; θ_2, refractive angle; θ_c, critical angle; n_1 and n_2, refractive indices of the two media.

light passes from a medium with a high refractive index into a medium with a low refractive index (n_1 and n_2, respectively, in Fig. 2A.2.1). At the interface, the light will bend and travel along the interface if the incident angle is equal to the critical angle. If the incident angle is higher than the critical angle, the light will turn back into the high refractive medium and only a short-range electromagnetic disturbance called the evanescent field will pass into the low refractive medium. The evanescent field intensity decreases exponentially with distance from the interface (Fig. 2A.2.2), confining the eventual fluorescence excitation to the near-field region (excitation decays over ~λ/4 to λ/5; Axelrod, 2001a). This imaging method provides high-contrast images of the near-membrane area, with a useful maximum depth of penetration of 100 to 200 nm. Due to minimal exposure of cells to light in any other planes in the sample, TIRF images have very low background, with virtually no out-of-focus fluorescence (Fig. 2A.2.3) and low phototoxicity.

TIRF Parameters

To better understand the characteristics and the usefulness of this microscopy technique, we will briefly discuss the theoretical TIRF parameters. See Table 2A.2.1 for definitions of terminology related to optics.

The relationship between the angles of incidence (θ_1) and refraction (θ_2) and the indices of refraction of the two media—n_1 and n_2 are the indices of refraction of the incident and refractive medium, respectively—is known as Snell's Law. This law will apply to the refraction of light in any situation, regardless of what

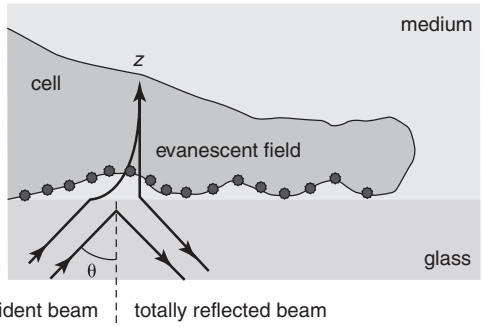

Figure 2A.2.2 Schematic representation of the TIRF effect. The evanescent field produces selective excitation of the fluorophores at the cell-coverslip interface. θ, angle of incidence; *z*, distance from the interface.

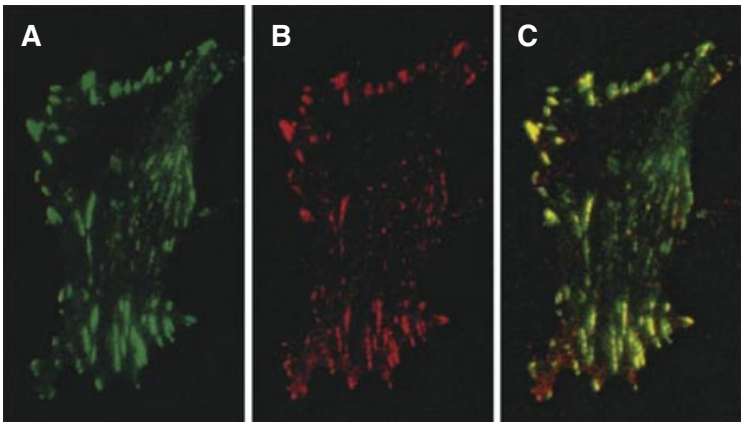

Figure 2A.2.3 A fixed vascular smooth muscle cell labeled with vinculin-Alexa 488 was imaged by epifluorescence (**A**) and TIRF (**B**; pseudo-colored red). The TIRF image was overlapped with the epifluorescence image (**C**) to emphasize the differences between the two imaging modes (yellow represents good overlap between the two images). The discrete pixilation of vinculin-Alexa 488 in the TIRF image (B) is due to the fact that it was obtained by optically sectioning only the very bottom of the cell at a maximum depth of 100 nm, compared to the epifluorescence image which was obtained by collecting the fluorescence through the whole cell volume. Image size is 150 × 110 μm. For the color version of this figure go *to http://www.currentprotocols.com.*

the two media are.

$$n_1 \sin\theta_1 = n_2 \sin\theta_2$$

Equation 2A.2.1

The critical angle of incidence (θ_c in Fig. 2A.2.1) represents the incident angle at which the light travels along the interface between the two different media:

$$\theta_2 = 90^\circ \rightarrow \sin\theta_{critical} = \frac{n_2}{n_1}$$

Equation 2A.2.2

For incidence angles higher than the critical angle, the light will turn back into the high-refractive medium, and only a short-range electromagnetic disturbance called the evanescent field will pass into the low-refractive medium. The total internal reflection (TIR) effect is obtained for a ratio $n_2/n_1 < 1$, with the maximum incident angle (Axelrod, 2001a):

$$\sin\theta_{max} = \frac{NA}{n_1}$$

Equation 2A.2.3

where NA represents the numerical aperture of the microscope objective.

The evanescent field intensity $I(z)$ decreases exponentially with the distance z from the interface of the two media, depending on both

the incident angle and the polarization of the incident light (Fig. 2A.2.4):

$$I(z) = I_o \exp\left(-\frac{z}{d}\right)$$

Equation 2A.2.4

with the depth of penetration given by:

$$d = \frac{\lambda}{4\pi} \frac{1}{\sqrt{n_1^2 \sin\theta_1^2 - n_2^2}}$$

Equation 2A.2.5

This depth of penetration d is independent of the polarization of light and represents the depth of field at which the intensity of evanescent light is $1/e$ of the boundary intensity I_o. The sensitivity of the method is directly related to fluorescence intensity, which is maximal at the interface and decreases exponentially with increasing distance from the interface.

In a simple way, one can consider the ideal case of an interface between two optically transparent media, where no light is reflected back and the fluorophores are homogeneously distributed and randomly oriented in a thin layer (Mathur et al., 2000). The fluorescence intensity in TIRF illumination is proportional to the local electric field energy, which means that it exponentially decreases with the relative separation distance (z) from the interface of the two media. These assumptions allow determination of the distance z from the logarithmic transformation of the fluorescence intensity (Fig. 2A.2.5).

In actual experiments, the interface may be stratified, being approximated with a thin multilayer system rather than an interface between two media (Burmeister et al., 1998; Axelrod, 2001b). The presence of an intermediate layer of dielectric material with a mismatched refractive index deposited on the glass coverslip will affect the evanescent field intensity and depth of penetration. A detailed presentation of the expressions for the evanescent intensities of stratified interfaces is presented in Gingell et al. (1987).

Diversity of TIRF Experimental Configurations

There are different optical configurations for carrying out TIRF in an optical microscope. In the early 1980s, Axelrod described TIRF experimental configurations for use on the stage of an inverted (Axelrod et al., 1983) or an upright (Axelrod et al., 1984) microscope. This optical instrumentation was based on the use of a glass prism placed in optical contact with the coverslip of the cell culture dish (Axelrod, 2001b). Figure 2A.2.6 presents schematic drawings for prism-based TIRF configurations for an inverted microscope.

In the early 2000s, very high–NA objectives became commercially available. The new 1.45- to 1.65-NA objectives are more suitable for live cell work than the former prism configurations. In the "prismless" or "through-the-lens" TIRF (Axelrod, 2001c) the total internal reflection condition is achieved in the microscope with off-center illumination from the periphery of the back focal plane of the objective. Figure 2A.2.7 shows schematic optical paths for through-the-lens TIRF

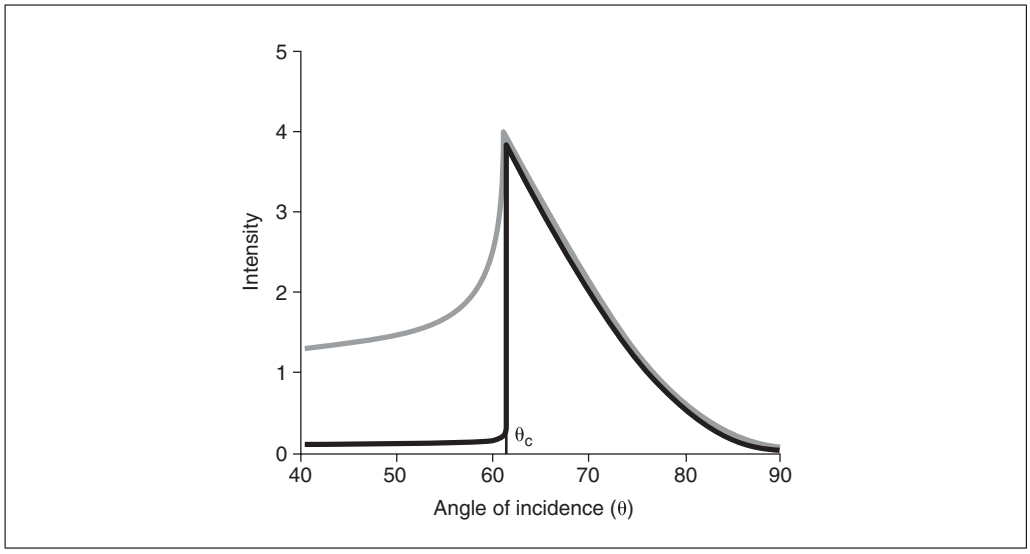

Figure 2A.2.4 Evanescent field intensities of the two planes of polarization parallel (gray line) and perpendicular (black line) to the sample plane as a function of the incident angle.

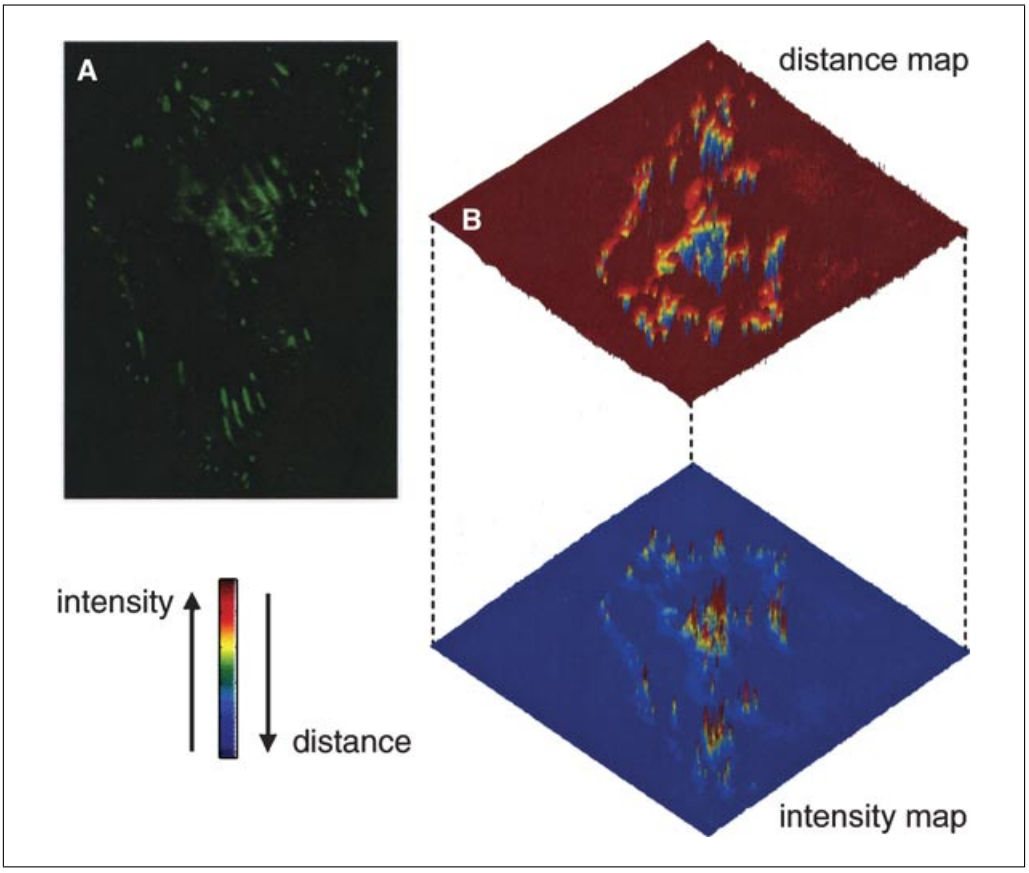

Figure 2A.2.5 (**A**) A vascular smooth muscle cell transiently transfected with GFP-vinculin was imaged in TIRF mode. (**B**) A three-dimensional representation of the fluorescence intensity and the corresponding linear logarithmic transformation of the intensity that generates the separation coverslip-cell distance map. In the distance map, blue indicates a position close to the coverslip and red indicates a position distant from the coverslip. In the intensity map, blue indicates low intensity and red indicates high intensity. The rainbow scale in the lower left shows the colors associated with intermediate levels of distance or intensity. Image size is 70 × 110 μm. For the color version of this figure go to *http://www.currentprotocols.com*.

configurations in an inverted microscope, using side or rear microscope ports for introducing the laser light or conventional arc lamp illumination. Table 2A.2.2 lists the present manufacturers of TIRF modules as turn-key systems.

Introduction of the laser illumination through the side port requires a special dichroic mirror cube facing the side, which is available for the Olympus IX-70 microscope. The beam is focused at the back focal plane (BFP) of the objective at a radial position sufficient to lead to supercritical angle propagation into the coverslip. Moving the lens (L) transversely changes the angle of incidence at the sample and allows switching between subcritical (epi) and supercritical (TIR) illumination (Fig. 2A.2.7a).

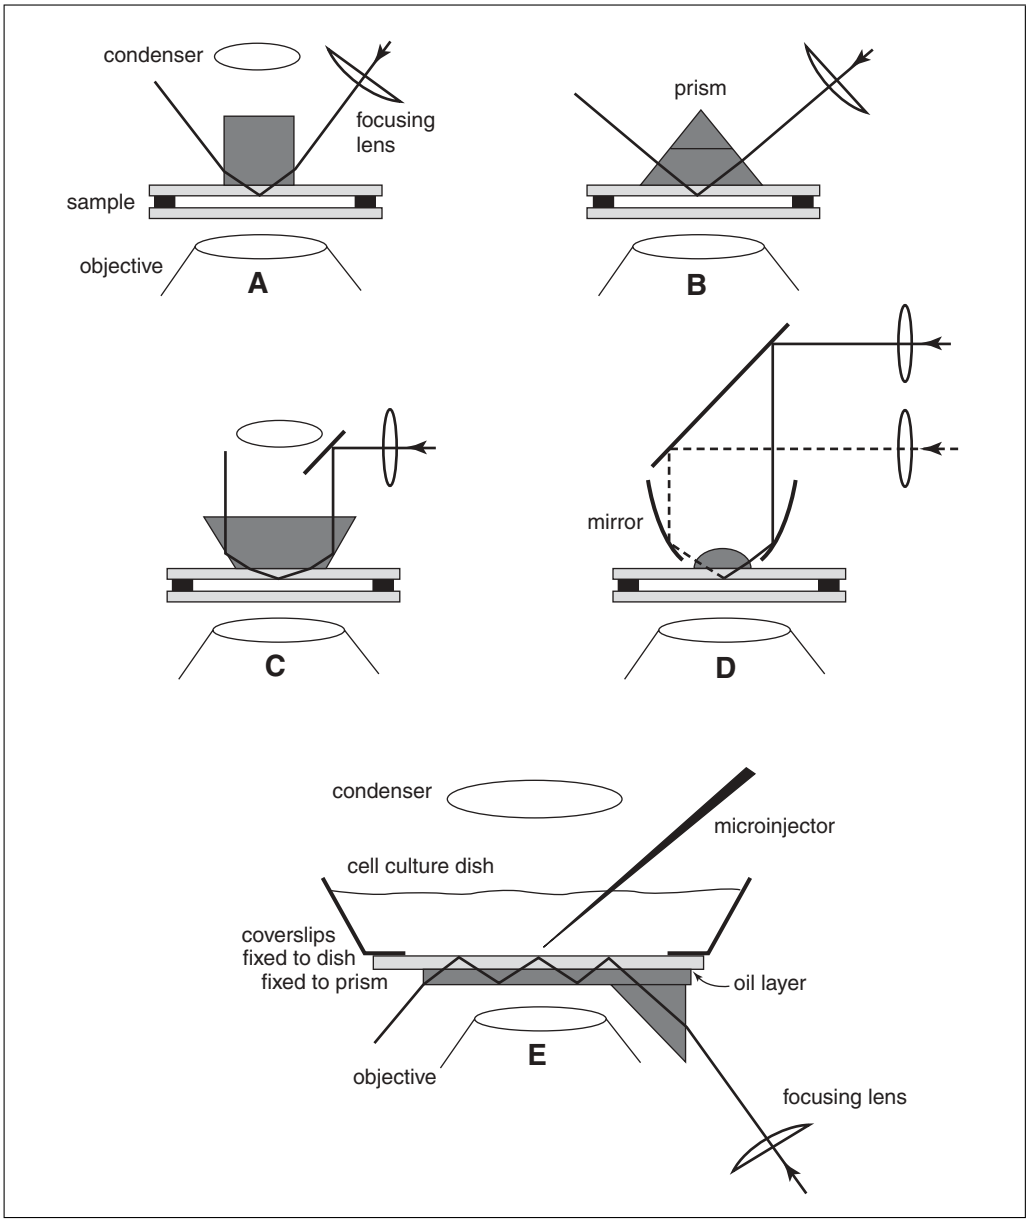

Figure 2A.2.6 Schematic drawings for prism-based TIRF in an inverted microscope (laser illumination). Configurations **A** to **D** use a TIR prism above the sample. In these configurations, the buffer-filled sample chamber consists of a lower bare glass coverslip, a spacer ring (Teflon) and the fluid cell coverslip inverted so the cells face down. The upper surface of the fluid cell coverslip is put in optical contact with the prism by a layer of immersion oil or glycerol. The lateral position of the prism is fixed but the sample can be translated while still maintaining optical contact. In configuration D, two incident beams split from the same laser and intersect at the TIR surface, thereby setting up a striped interference pattern on the sample which is useful in studying surface diffusion. Configuration **E** places the prism below the sample and TIR effect depends on multiple internal reflections in the substrate. This configuration thereby allows complete access to the sample from above for solution changing and/or electrophysiology studies. However, only air or water immersion objectives may be used because oil at the substrate lower surface will thwart the internal reflections. The vertical distances are exaggerated for clarity. Reproduced from Axelrod (2001b) with permission from Blackwell Publishing.

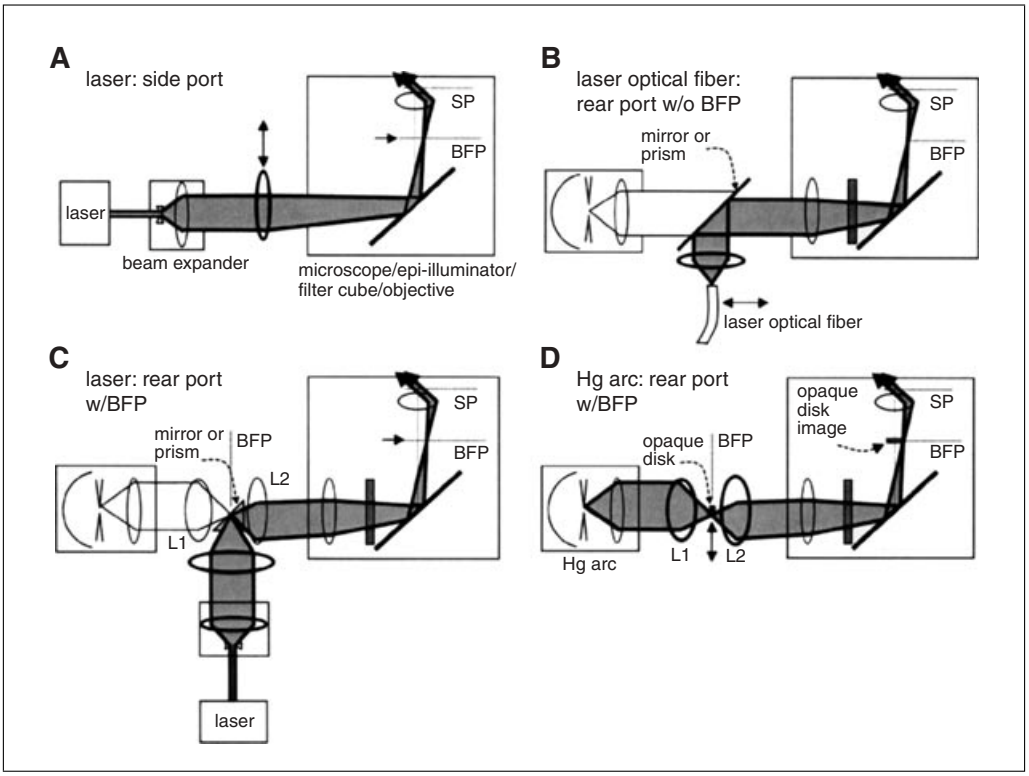

Figure 2A.2.7 Schematic drawings for prismless TIRF in an inverted microscope. (**A**) Laser illumination through a side port. (**B**) Laser illumination introduced by an optical fiber through the rear port normally used by the arc lamp. (**C**) Laser illumination in microscope systems containing an equivalent back focal plane (BFP) in the rear path normally used by an arc lamp. (**D**) Arc lamp TIR illumination. If (as in the Olympus IX-70) an aperture plane does not exist in the indicated position, it can be created with a pair of lenses L1 and L2 (C and D). The illumination at the BFP is a circular annulus; it is shown as a point on one side of the optical axis for pictorial clarity only. In all these configurations. SP refers to sample plane and BFP refers to the objective back focal plane or its equivalent planes (i.e., aperture planes). Components drawn with thick lines need to be installed; components in thin lines are possibly preexisting in the standard microscope. The BFP "aperture plane" (L1 and L2) in panels C and D is also provided by the Nikon TE 2000-U microscope. Reproduced from Axelrod (2001b) with permission from Blackwell Publishing.

Laser illumination introduced by an optical fiber through the rear port of the microscope shares the same port used by the arc lamp. This scheme is employed by the commercial Olympus TIRF device (Fig. 2A.2.7b). Laser illumination in microscope systems containing an equivalent BFP in the rear path normally used by an arc lamp will require that the laser beam be focused at BFP where the arc lamp would normally be imaged. The Zeiss Axiovert 200 provides this BFP "aperture plane" (Fig. 2A.2.7C).

In arc lamp TIR illumination, the goal is to produce a sharp-edged image of an opaque circular disk at BFP such that only supercritical light passes through the objective (Fig. 2A.2.7D). The actual physical disk (aluminized coating on glass) must be positioned at an equivalent upbeam BFP, which in Kohler illumination also contains a real image of the arc. The Zeiss Axiovert 200 provides this BFP, marked as an "aperture plane." The through-the-lens arc-lamp TIRF configuration (Fig. 2A.2.7D) can be easily switched to the laser TIRF configuration (Fig. 2A.2.7C) by insertion of the reflecting mirror into the arc-lamp path.

TIRF Objective Lenses

There are two types of high-NA objectives for TIRF applications currently available on the market: Olympus, Nikon, and Zeiss offer 1.45-NA oil immersion objectives, and Olympus offers a 1.65-NA. The 1.45-NA objectives require glass coverslips (n = 1.51) and standard immersion oil and are the objectives of choice for versatile TIRF microscopy. For special applications that use arc lamp illumination (Stout and Axelrod, 1989) or very dim samples, the 1.65-NA

Table 2A.2.3 TIRF Parameters

NA	$\theta_{critical}$[a]	θ_{max}[a]	*d* (nm)[a]
1.45	~61°	~72°	<100
1.49	~61°	~80	<100
1.65	~48°	~67°	<220

[a]Theoretical values calculated for $\lambda = 488$ nm, $n_1 = 1.516$ (or 1.788 for the 1.65-NA lense), $n_2 = 1.333$.

Table 2A.2.4 TIRF Objectives

Manufacturer	Objective	Numerical aperture (NA)
Olympus	APO 60×	1.45
	PLAN APO 100×	1.45
	APO 100×	1.65[a]
	U APO 150×	1.45
Zeiss	Plan Fluor 100×	1.45
Nikon	Plan APO 60×	1.45
	APO 60×	1.49
	Plan APO 100×	1.45
	APO 100×	1.49
Leica	HCX PL Apo 100×	1.46

[a]Requires high refractive–index coverslips (see Axelrod, 2001c): Sapphire (birefringent) or Schott glass LAF21 and SF11 (*http://www.us.schott.com*) and high refractive index oil ($n = 1.78$) from Cargille Laboratories (*http://www.cargille.com/immeroil.shtml*).

objective might be a better choice. This particular objective requires higher refractive–index coverslips and immersion oil ($n = 1.78$; Cargille Laboratories). The high refractive–index oil is volatile and leaves a crystalline residue in a short period of time. There are several choices for the high refractive–index coverslip, but all are expensive, and they cannot be easily cleaned (Axelrod, 2001c). Figure 2A.2.8 and Tables 2A.2.3 and 2A.2.4 present generic characteristics for these objectives.

PRACTICAL GUIDELINES

Control of the Angle of Incidence

Figure 2A.2.9 presents, in detail, the optical path for a through-the-lens TIRF configuration in an inverted microscope. The laser beam used for excitation is collimated, and then focused at the back focal plane of the objective at a chosen angle of incidence θ with respect to the optical axis of the microscope. The point of focus in the back focal plane is off-axis (black solid line). There is a one-to-one correspondence between the off-axis radial distance (δ), which is dictated by the distance between the optical axis of the microscope and the fiber position at the entrance of the TIRF illuminator (*d*), and the angle of incidence θ. By moving the micrometer that changes the fiber position with respect to the optical axis, the axial radial distance (δ) will increase, and the critical angle of incidence can be exceeded to allow supercritical angles to be reached in a reproducible manner. This adjustment reaches its limit when the laser light is damped into the edge of the objective (Axelrod, 2001c).

Microscope Stability

For obtaining reproducible TIRF images, the microscope focus should be as stable as possible. For quantitative or time-lapse measurements, the focus stability is of great importance. The microscope room should be kept at a constant temperature, and the microscope might require a warm-up time that allows for thermal equilibrium to be achieved (see *UNIT 2C.5*). The new autofocus lock-in systems commercially available from Olympus, Applied Scientific Instrumentation, and Nikon, may improve the focus stability performance.

Sample Preparation

Best TIRF images are obtained on cells cultured on good quality glass coverslips. Due to the small penetration depth of the evanescent field, the quality and thickness of the coverslip are important. Usual TIRF images are obtained by fluorescent labeling of the molecules at the cell level. In this case, TIRF microscopy will provide high-intensity fluorescence images of the labeled molecules on a dark background (Fig. 2A.2.3 and Fig. 2A.2.5). The contact

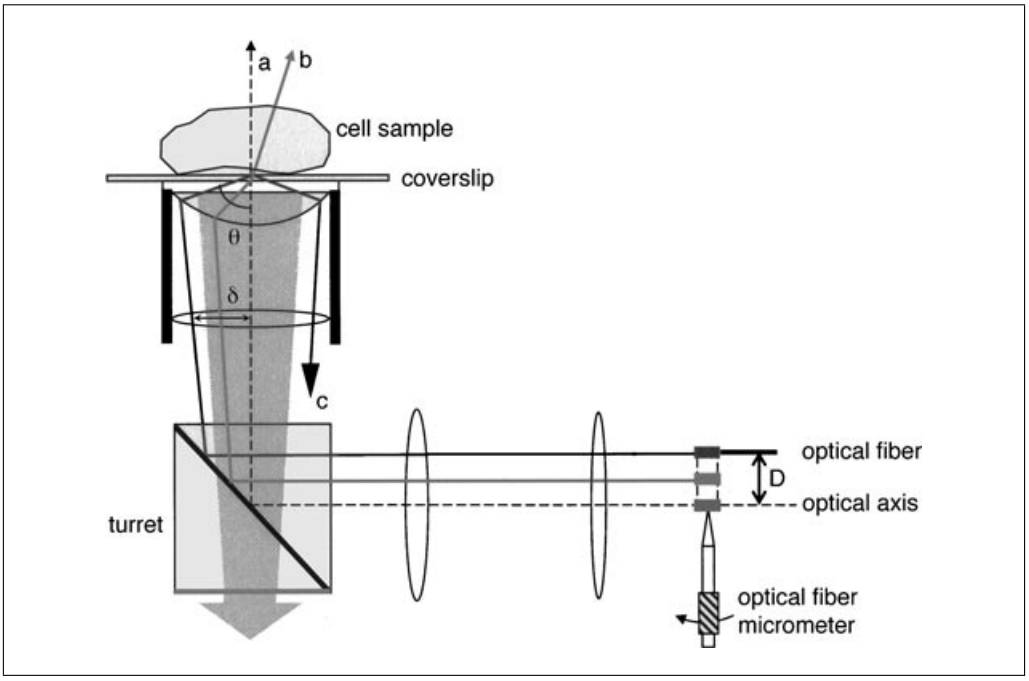

Figure 2A.2.9 Schematic representation of the TIRF optical path in a through-the-lens microscope configuration. The TIRF illuminator provides a micrometer that allows the controlled movement of the optical fiber off-axis to achieve the total internal reflection (TIR) condition at the sample level. Ray a is obtained with the fiber optic centered on the optical axis. Ray b is obtained for an incident angle at the sample plane smaller than the critical angle. Ray c is obtained when TIR effect takes place. The fluorescence light reflected from the sample plane is collected through the same microscope objective and is further sent to the camera where the image is recorded. θ, angle of incidence at the sample; *d*, distance between the optical axis and the fiber position; δ, off-axis distance of the laser beam in the back focal plane of the objective.

regions between cell and substrate could also be investigated by "negative" TIRF. In this case, the cells are not labeled, but a membrane-impermeant dye is added to the medium outside of the cells. The contact regions will appear as dark areas on a fluorescent background.

For some TIRF experiments, it is useful to biofunctionalize the substrate (Fulbright and Axelrod, 1993; Burmeister et al., 1994). This involves pretreatment of the glass substrate before culturing the cells. One should take into consideration the thickness of any pretreatment when coating the glass substrate. If the coating is too thick, it will prevent the evanescent light from reaching the cell membrane and its close proximity.

Artifacts

The oil used between the objective and the coverslip is another important aspect in obtaining good TIRF images. Air bubbles or contaminants in the oil will introduce a mismatch into the refractive indices, producing scattered light. If the oil does not form a film of uniform thickness between the two glass elements, a nonuniform illumination of the sample plane could cause a random striped pattern of light and dark bands (Temple, 1981), and the stripes will move when the stage moves. Dust on the microscope objective will produce similar light and dark stripes in the field of view, but the stripes will not follow the stage movement. Dust on the optics inside the turret could produce a concentric interference fringe pattern. The best way to clean these optical elements is to blow dust away, avoiding wiping the optical surfaces.

TIRF Applications

The unique features of TIRF make this microscopy technique an invaluable tool for biological studies that is finding increasing applications. TIRF can be further combined with other techniques to cover a much larger range of applications, for instance: visualization and spectroscopy of single-molecule fluorescence near a surface by combining TIRF with fluorescence correlation spectroscopy (FCS; Lieto et al., 2003); measurement of the kinetic rates of binding of extracellular and intracellular proteins to cell surface receptors and artificial membranes by combining TIRF with fluorescence recovery after photobleaching (FRAP; Axelrod et al., 1986); measurements of intermolecular distances between fluorescent surface-bound molecules by combining TIRF and Förster resonance energy transfer (FRET, also known as fluorescence resonance energy transfer; Seong and Almers, 2004); observation of turnover of the cytoskeleton and remodeling of focal adhesions in real time by combining TIRF with fluorescence speckle microscopy (FSM; Adams et al., 2004); study of Ca^{2+} channels activity by patch-clamp technique combined with TIRF (Demuro and Parker, 2004); single-molecule force and fluorescence measurements by a combined optical trap and TIRF (Wallace et al., 2003; Lang et al., 2004); monitoring of modifications in the micromorphological structures and dynamics of live cells by combining AFM with TIRF (Sund et al., 1999; Mathur et al., 2000; Wallace et al., 2003; Trache and Meininger, 2005); and making long-term fluorescence movies of cells during development in culture under TIRF illumination (Wang and Axelrod, 1994).

TIRF Applications to Microbiology

Single molecule detection using TIRF imaging

DNA mapping is an important tool in genomic sequence assembly, medical diagnostics, and microbial pathogen identification (van Belkum, 1994; Ried et al., 1997; Wong et al., 1997). A novel method for optical DNA mapping has been developed by Xiao et al. (2007), using TIRF imaging. Direct imaging

Figure 2A.2.10 *(at right)* Direct imaging of DNA molecules and localization of multiple sequence motifs of lambda phage DNA. (**A**) The predicted Nb.BbvC I map of lambda DNA. Positions of the nicking sites are indicated by arrows. Nicking sites 2 to 4 and 5 to 6 are closely clustered and are not resolvable due to the limits of optical diffraction. (**B**) In the intensity-scaled composite image of linear lambda DNA, the Nb.BbvC I sites (labeled with Tamra-ddUTP) are shown as green spots, and the DNA backbone (labeled with YOYO) is shown as blue lines. Due to the diffraction limits of the microscope, only four labels can be fully resolved. In this field, two DNA fragments (a and b) are fully labeled while one fragment (**c**) has three labels. Red arrows point to clustered sites; some of them are brighter than others because of the presence of multiple labels. (**C**) The sequence motif map in the bottom graph was obtained by analyzing 61 single molecular fluorescence images. The solid line is the Gaussian curve fit, and the peaks correspond well to the predicted locations of the sequence motifs. Figure 2A.2.10 *(legend at left)*

of individual DNA molecules and localization of multiple sequence motifs is possible by fluorescently labeling DNA molecules at specific sequence motifs by the action of nicking endonuclease, followed by the incorporation of dye terminators with DNA polymerase (Sanger and Coulson, 1975). After labeling, the DNA molecules were stretched into linear form on a modified glass surface and individually imaged using multicolor TIRF microscopy with nanometer accuracy (Yildiz et al., 2003). This approach has been applied to the construction of sequence motif maps of lambda-phage (Fig. 2A.2.10), a strain of human adenovirus (Fig. 2A.2.11), and human rhinovirus (Fig. 2A.2.12).

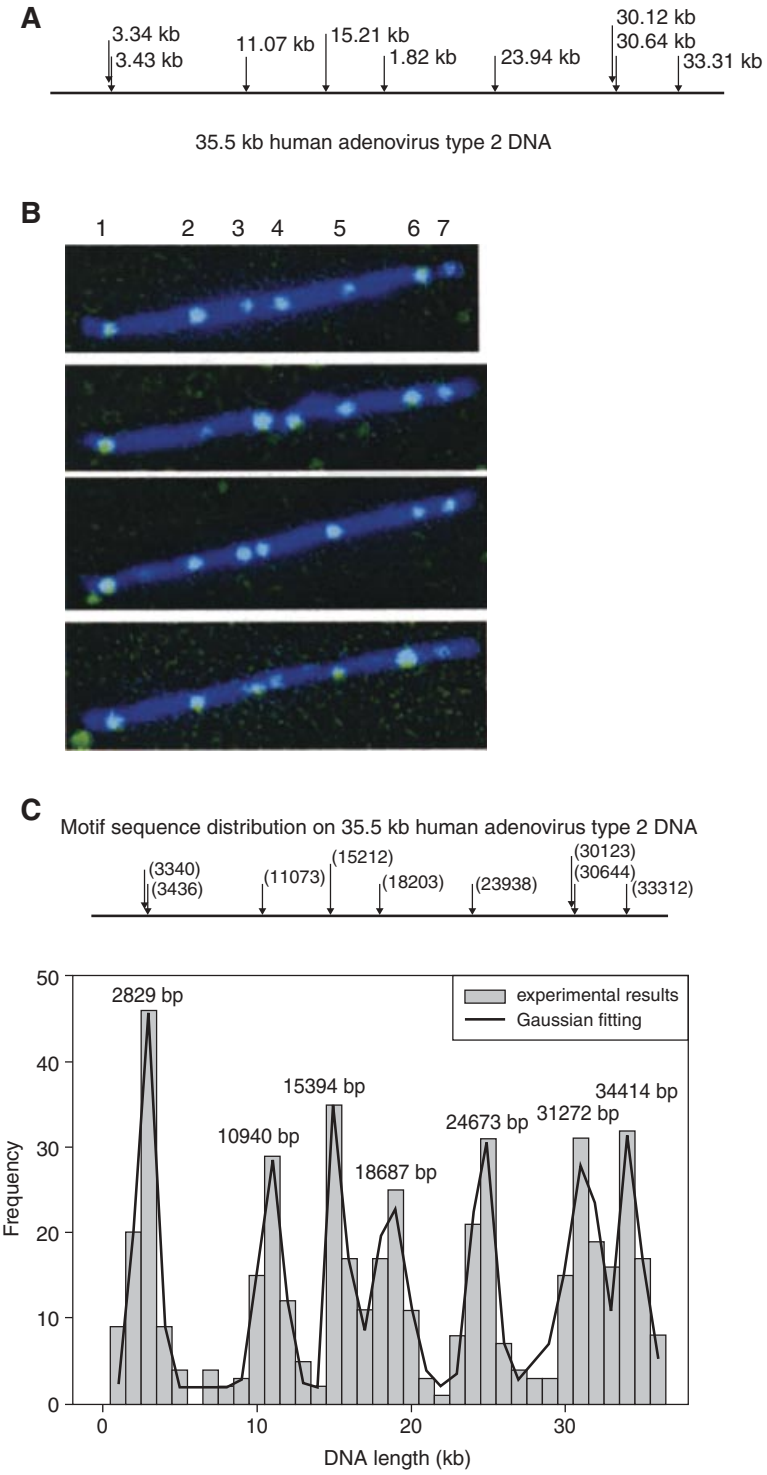

Figure 2A.2.11 Direct imaging of DNA molecules and localization of multiple sequence motifs of human adenovirus type 2. (**A**) Predicted Nb.BbvC I map of human adenovirus type 2. Nine sites are found on the 35.5-kb viral DNA with two sets of clustered sites (1 to 2 and 7 to 8), leading to seven resolvable labels. (**B**) In the intensity-scaled composite images of four fully labeled human adenovirus type 2 DNA, the Nb.Bbvc I sites (labeled with Tamra-ddUTP) are shown as green spots, and the DNA backbone (labeled with YOYO) is shown as blue lines. Due to the diffraction limits of the microscope, only seven labels can be fully resolved. Labels 1 and 6 are generally brighter than the other labels due to clustering. (**C**) The sequence motif map in the graph was obtained by analyzing 63 single molecule fluorescence images. The solid line is the Gaussian curve fitting and the peaks correspond well to the predicted locations of the sequence motif. Reproduced from Xiao et al. (2007) with permission from Oxford University Press.

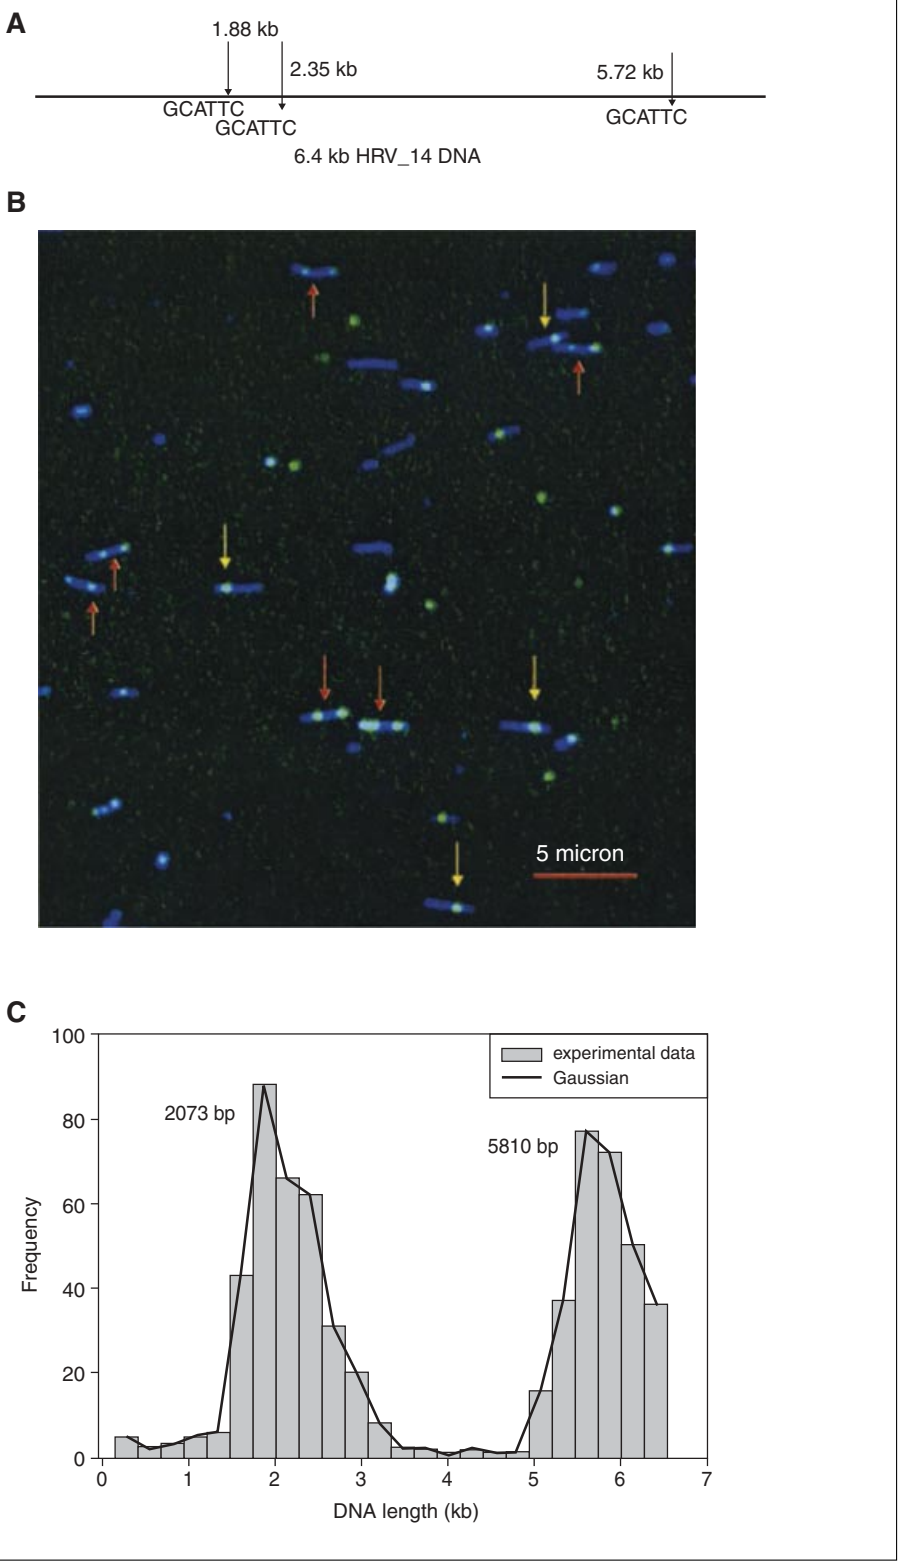

Figure 2A.2.12 Direct imaging of DNA molecules and localization of sequence motifs of human rhinovirus 14 DNA. (**A**) The predicted Nb.Bsm I (GCATTC) map of human rhinovirus 14 DNA. Only two sites are present in this small RNA virus. (**B**) In the large field of the intensity-scaled composite image, numerous molecules are found. Some molecules have two green labels (red arrows) and some have only one green label (yellow arrows). (**C**) The sequence motif map in the graph was obtained by analyzing 56 single molecule fluorescence images. The solid line is the Gaussian curve fitting and the peaks correspond well to the predicted locations of the sequence motif. Reproduced from Xiao et al. Membrane-trafficking perturbations induced by the dynamic interaction of HIV-1 Nef with the clathrin-mediated endocytic pathway

The *nef* gene product of HIV-1 associates with cell membranes, being essential for maximal viral replication in vivo, and markedly contributes to the pathogenesis of AIDS. The positive influence of Nef on viral replication and infectivity is a multifactorial process that affects trafficking of membrane proteins within the endocytic pathway. Endocytosis internalizes plasma membrane–associated proteins through membrane-bound vesicles, supporting various cellular functions (Conner and Schmid, 2003). One of the best characterized endocytosis pathways relies on the protein clathrin (Bonifacino and Traub, 2003). Clathrin adaptors link clathrin to cytoplasmic determinants of endocytic cargo during the formation of plasma membrane invaginations known as clathrin-coated pits, which then bud into the cell to form a coated vesicle in the cell cytoplasm. A dynamic analysis of Nef behavior was necessary to clarify the action of Nef at the plasma membrane, in a model in which Nef uses the clathrin-dependent endocytic pathway to induce internalization of some membrane proteins from the surface of HIV-1 infected T cells (Burtey et al., 2007).

The dynamic behavior of Nef has been observed and analyzed in transiently transfected HeLa cells expressing both Nef-GFP (wild-type HIV-1 Nef fused to GFP green-fluorescing protein) and dsRed-Clathirin (clathrin light chain fused to DsRed) by both epifluorescence (Fig. 2A.2.13) and TIRF microscopy (Fig. 2A.2.14). The epifluorescence image shows that Nef-GFP spots were barely distinguishable from background fluorescence, which precluded the use of this method to follow the dynamics of Nef at the

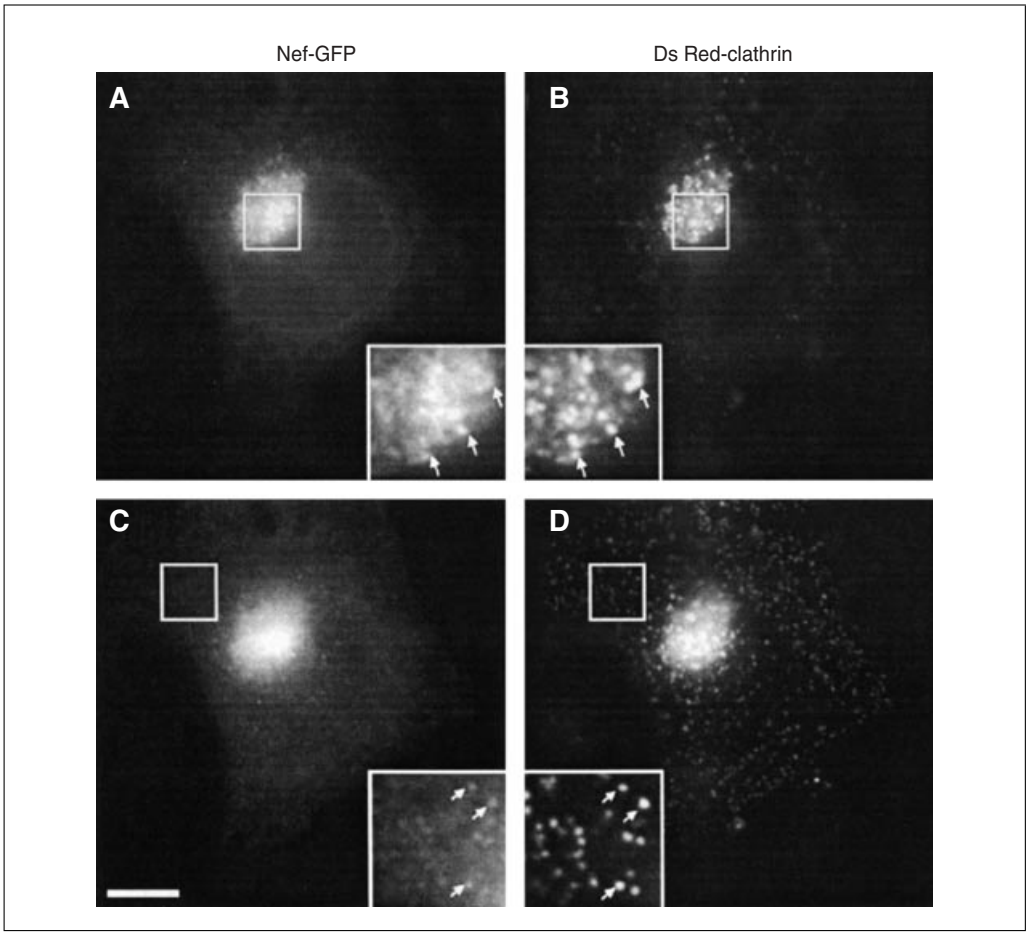

Figure 2A.2.13 Distribution of HIV-1 Nef protein in HeLa cells observed by epifluorescence. HeLa cells were transfected with plasmids encoding wild-type HIV-1 Nef fused to green-fluorescing protein (Nef-GFP, **A** and **C**) and clathrin light chain fused to DsRed (**B** and **D**). Cells were then fixed and observed by epifluorescence. The focus was made on a medial region (**A** and **B**) and on the adherent surface (**C** and **D**) of the same cells. Insets show higher magnification (2.5×) of representative areas. Arrows point out colocalization of both markers. Scale bar, 10 μm. Reproduced from Burtey et al. (2007) with permission from Blackwell Publishing.

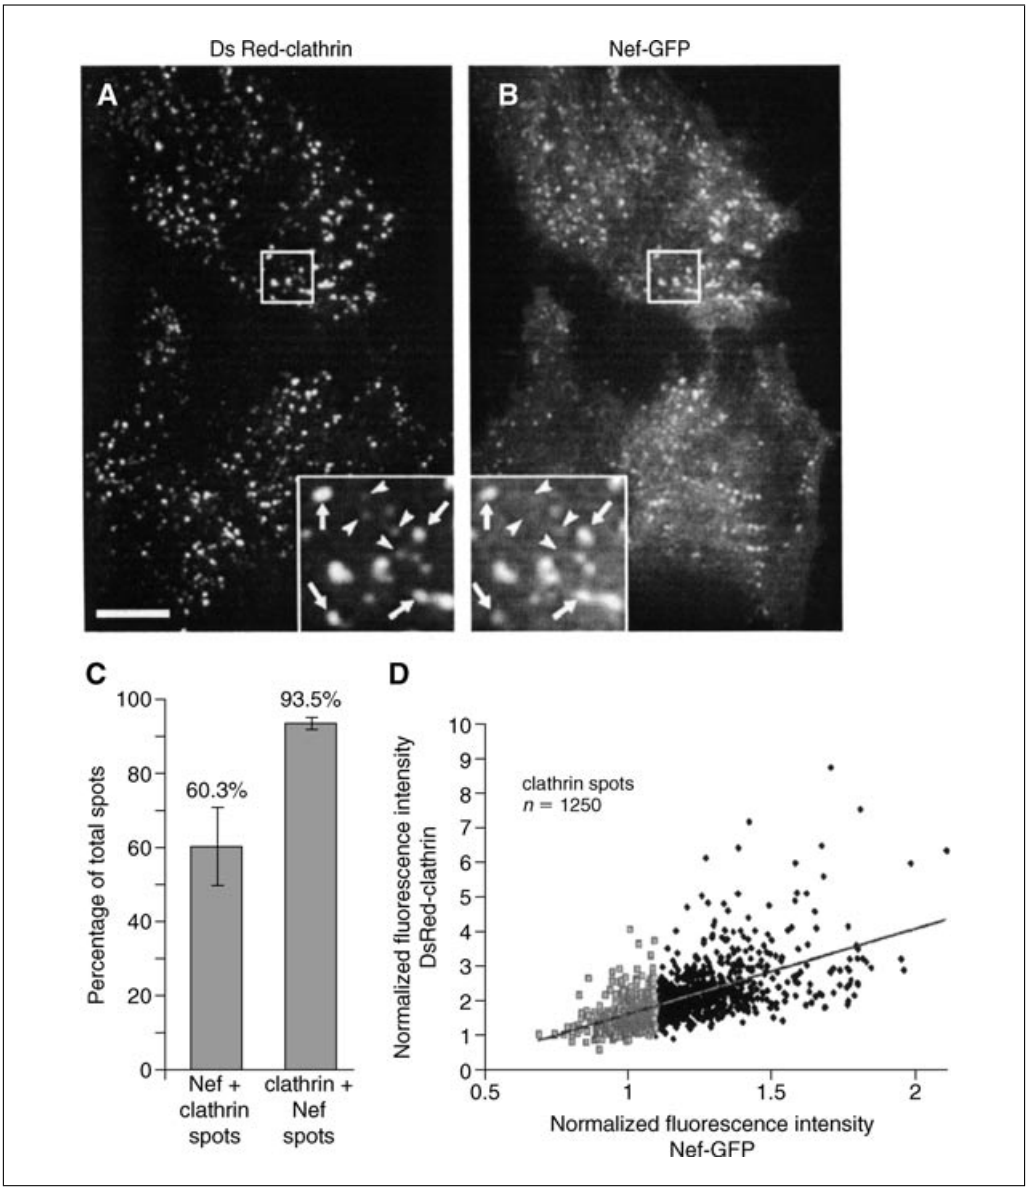

Figure 2A.2.14 Colocalization of Nef with clathrin at the plasma membrane revealed by TIRF microscopy. Live HeLa cells expressing DsRed-clathrin (**A**) and Nef-GFP (**B**) were imaged by TIRF microscopy. Insets show higher magnification (3×) of a representative area. Arrows point out colocalizing spots, and arrowheads show clathrin spots (CS) in which Nef is not concentrated. Scale bar, 10 μm. (**C**) Colocalization of Nef-GFP within CS was quantified in more than seven cells. One thousand spots were quantified and GFP- and DsRed-associated fluorescence intensities were measured and normalized to the local background. The presence of Nef within CS was then quantified by selecting Nef spots with a normalized fluorescence intensity above 1.1, a value corresponding to a detectable increased fluorescence relative to background (a "spot") by direct observation (data not shown). Conversely, the presence of clathrin with Nef spots was similarly quantified. (**D**) Spots analyzed in **C** were plotted as function of their normalized fluorescence for both clathrin and Nef. Spots with a normalized fluorescence below 1.1 appear in gray. Reproduced from Burtey et al. (2007) with permission from Blackwell Publishing.

plasma membrane. In contrast, TIRF imaging shows very clearly that Nef is concentrated within the majority of the clathrin spots (CS) observable at the plasma membrane.

CS at plasma membrane can be categorized into three different populations over a 1 min observation: 80% remain static, 15% disappear from the surface, and 5% move laterally. In the analysis performed on 40 spots from each CS category (Fig. 2A.2.15), Nef was detected in the large majority of static CS (91.5%), in approximately half of the disappearing CS (50.6%), and in a minority of laterally mobile CS (22.1%). Altogether,

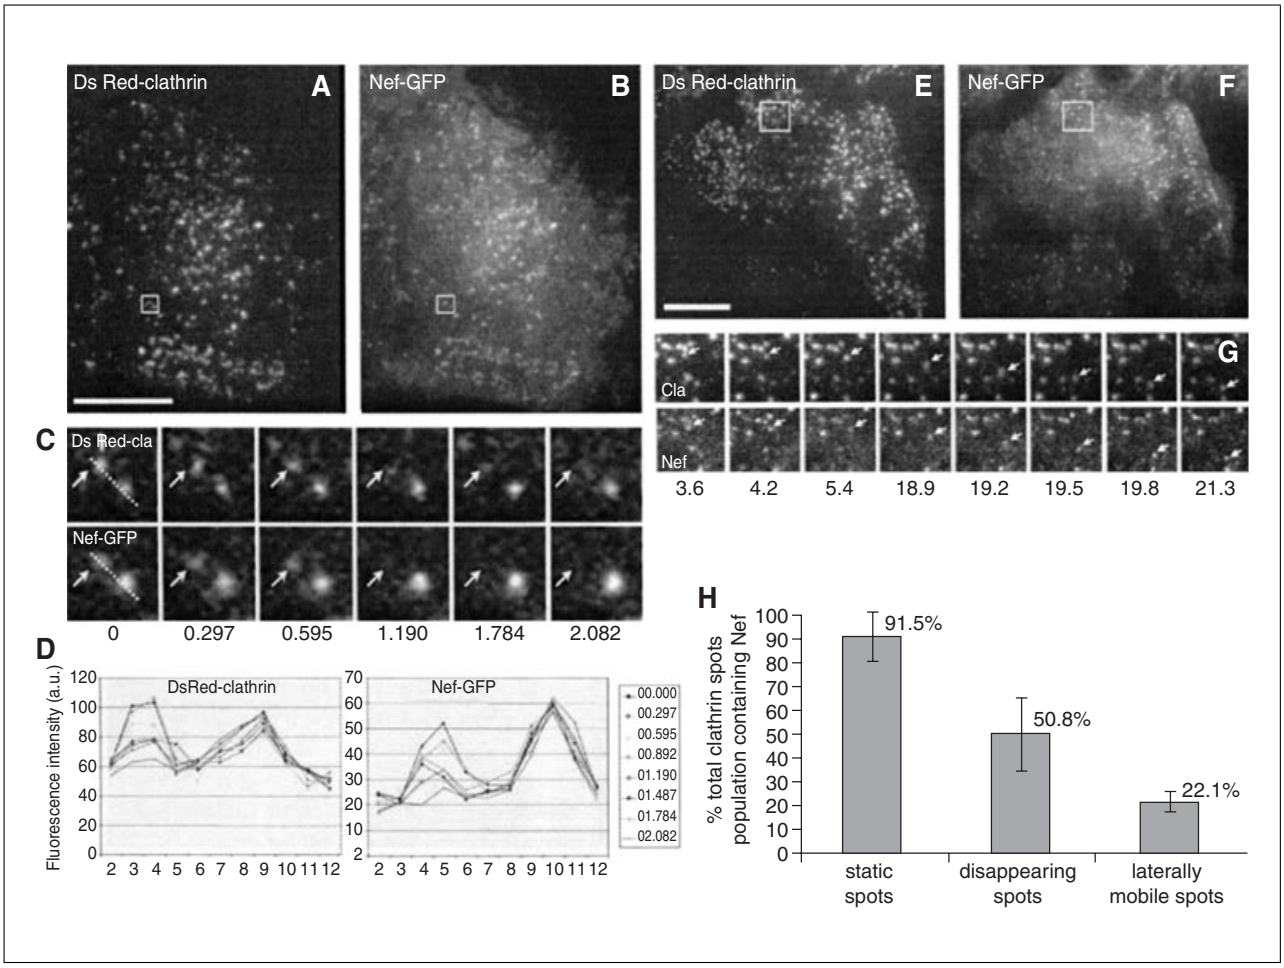

Figure 2A.2.15 Distribution of Nef in dynamic clathrin spot (CS) populations. Live HeLa cells expressing DsRed-clathrin (**A** and **E**) and Nef-GFP (**B** and **F**) were imaged using TIRF microscopy acquired at ∼300 msec/frame for 30 sec. (**A** to **D**) Distribution of Nef in disappearing CS. A disappearing spot was identified on the clathrin frame, green and red images were separated, and the corresponding regions were magnified (5×). (**C**) The fluorescence intensity of each marker was analyzed over time along a line drawn between two spots, a disappearing spot (arrow in C) and a static spot (D). The Nef- and clathrin-associated fluorescence decreased with the same kinetics in the disappearing spot while remaining stable in the neighboring static spot. (**E** to **G**) Distribution of Nef in laterally mobile CS. A laterally mobile spot was identified on the clathrin frame, then green (F) and red images (E) were separated, and the corresponding region was magnified (5×, G). The upper panel in G corresponds to the clathrin images where a laterally mobile CS containing Nef-GFP (lower panel) was identified (arrows). Scale bars 10 μm. (**H**) The presence of Nef-GFP inside 40 CS (from more than five cells) from each CS population (static, disappearing and laterally mobile) was determined. Results are expressed as the percentage of CS of each population that contain Nef-GFP (normalized fluorescence >1.1). Reproduced from Burtey et al. (2007) with permission from Blackwell Publishing.

these results indicate that HIV-1 Nef is present in the clathrin-coated pits (static spots) and in the developing clathrin-coated vesicles (disappearing spots) because it disappeared from the evanescent field together with some CS.

Single particle tracking of murine polyoma virus-like particles in live cells

Murine polyoma virus (Py) is a nonenveloped DNA tumor virus (Stehle et al., 1994) that uses gangliosides GD1a and GD1b as receptors (Tsai et al., 2003) and relies on clathrin-independent, cholesterol-dependent endocytosis to deliver its genome into the cell for replication (Gilbert and Benjamin, 2004). The virus-like particles (VLP) that resemble the virus structurally but do not contain the DNA genome (Gleiter and Lilie, 2001), were labeled with Alexa 568 or fluorescein isothiocyanate (FITC). Their lateral mobility was studied by single fluorescent particle tracking using TIRF microscopy (Ewers et al., 2005). The particle trajectories analyzed in terms of diffusion rates and modes of motion on 3T6 mouse fibroblasts revealed three distinct modes of mobility: rapid random motion, confined movement in small

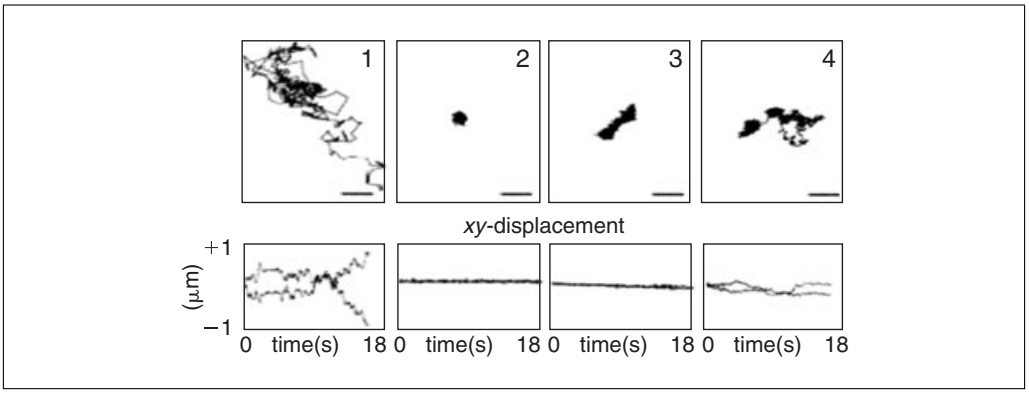

Figure 2A.2.16 Analysis of VLP trajectories at the bottom surface of live cells. All harvested trajectories are plotted irrespective of the recorded length and whether the particles were bound or free at the start of the recording. Every point represents one trajectory, and every trajectory is at least 100 steps (5 sec) long. The longest trajectories are 2000 steps (100 sec) long. Representative trajectories (numbered 1, 2, and 3) and one typical outlier (trajectory 4) represent rapid and random movement (trajectory 1), confinement (trajectory 2), and confinement with a slow drift (trajectory 3). Trajectory 4 represents a VLP that changes its mode of motion during the acquisition time. Below each of these trajectories are the respective analytical plots for absolute displacement in μm for *x* and *y* direction versus time. (Adapted from Ewers, H., Smith, A.E., Sbalzarini, I.F., Lilie, H., Koumouysakos, P., and Helenius, A. Copyright 2005. Single-particle tracking of murine polyoma virus–like particles on live cells and artificial membranes. *Proc. Natl. Acad. Sci. U.S.A.* 102:15110-15115 with permission from the National Academy of Sciences, U.S.A.).

zones (30 to 60 nm in diameter), and confined movement in zones with slow drift. The confinement zones (CZ) fell into a size range of 500 to 3000 nm^2.

For particle tracking, live cells with several VLP already bound were imaged in TIRF at 20 frames/sec for a total of 50 to 100 sec. Trajectories of particle were extracted from digital images by linking particle positions from frame-to-frame using an algorithm developed by the authors (Sbalzarini and Koumoutsakos, 2005) and were classified by computational analysis (Fig. 2A.2.16).

TIRF imaging of constitutive exocytosis

Constitutive secretion, the process that delivers newly synthesized proteins to the plasma membrane and external medium, occurs in all eukaryotic cells. The final stage of secretion is fusion of a Golgi transport vesicle with the plasma membrane. Schmoranzer et al. (2000) applied TIRF microscopy to imaging the fusion of single post-Golgi carriers with the plasma membrane. Quantitative analysis with a time resolution of 30 frames/sec allowed measurements of diffusion constants for the spread of vesicular stomatitis virus glycoprotein (VSVG, Wehland et al., 1982) into the plasma membrane. For easy tracking in TIRF, COS-1 cells were transiently transfected with VSVG fused to its cytoplasmic tail with GFP (Presley et al., 1997; Toomre et al., 1999).

Each carrier (i.e., discrete VSVG-GFP single particle visible in TIRF in proximity to cell membrane) was characterized by its movement, total fluorescence intensity, peak intensity, and the width of its intensity profile. They were classified into three groups: (1) docked carriers that stopped moving and remain stationary adjacent to the membrane, without fusing during the 1 min observation time; (2) carriers that exhibited a synchronous increase and decrease in the total peak intensity due to their movement in and out of the evanescent field, without fusing to the membrane; and (3) carriers that showed a synchronous increase in the total peak and width of the fluorescence and, finally, fusion with the plasma membrane (Fig. 2A.2.17).

When a carrier fuses with the plasma membrane, the total fluorescence intensity will increase as the vesicle flattens to the membrane, whereas the peak intensity will transiently increase and then decrease as VSVG-GFP diffuses laterally into the plasma membrane. In addition, the width will increase as a result of this diffusion. Figure 2A.2.17B shows the parameters of the fusion event plotted over time. Table 2A.2.5 shows a qualitative summary of the kinetic behavior of the characteristic parameters for a fusing carrier. Thus, three temporal phases can be distinguished along this process: (1) stationary (movement of the carrier towards the plasma membrane before

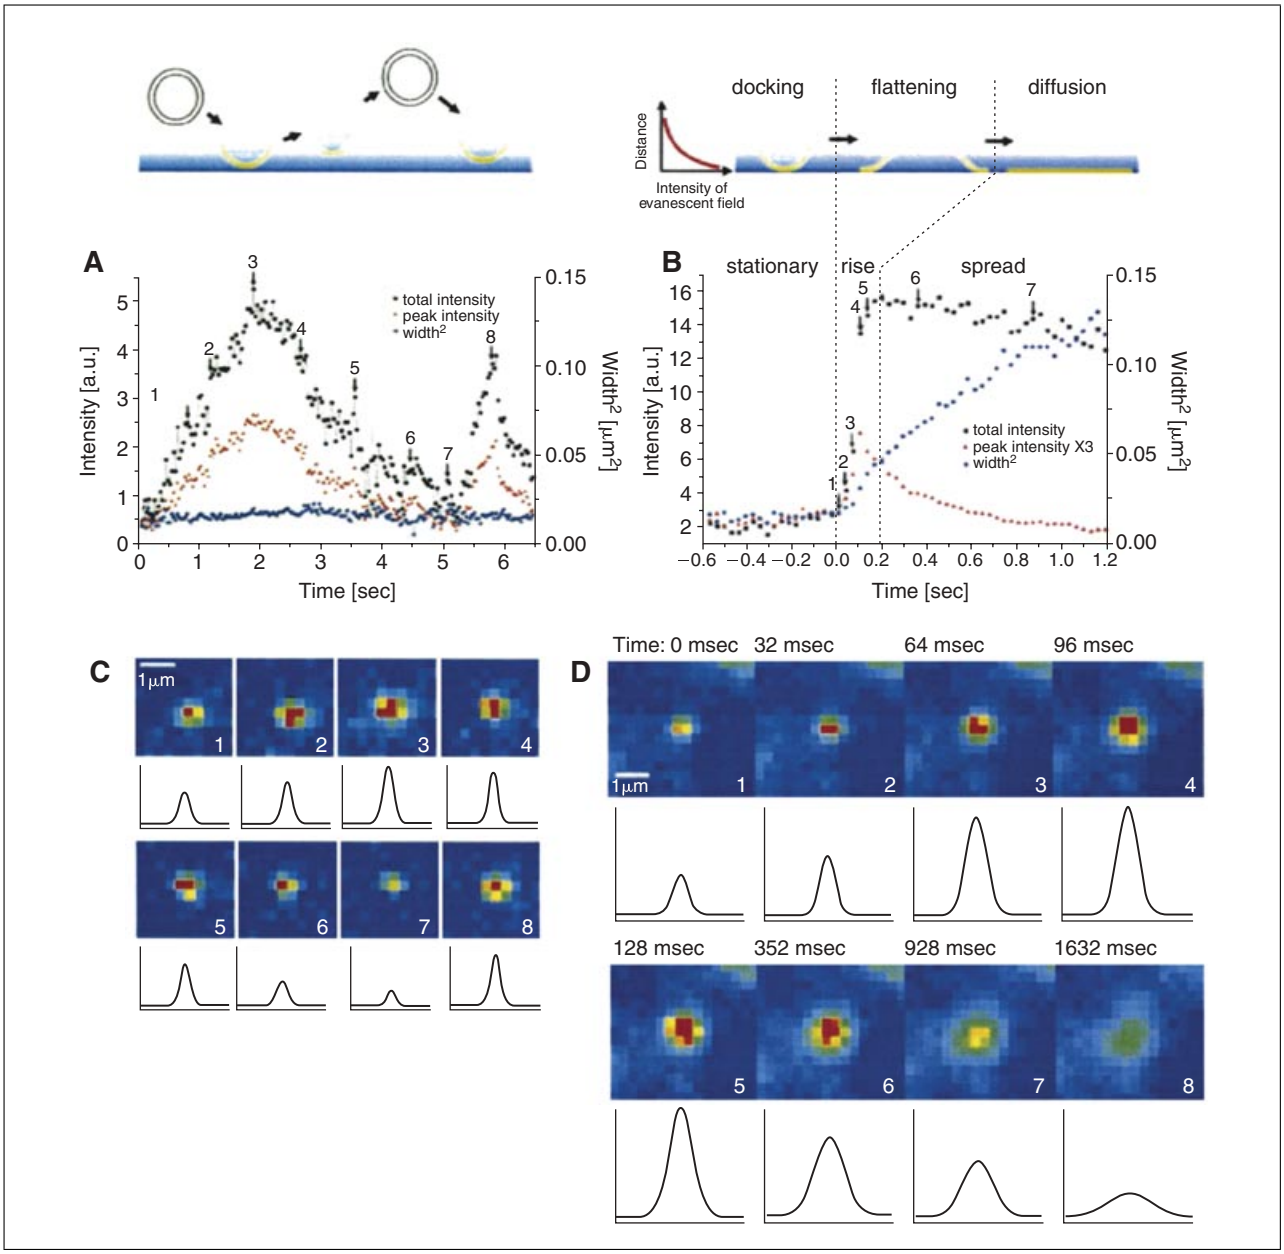

Figure 2A.2.17 Analysis of carriers. The vesicular stomatitis virus glycoprotein/green fluorescent protein (VSVG-GFP) fluorescence was imaged for carriers close to the plasma membrane. The total intensity, peak intensity, and square of the Gaussian width were plotted over time in panels **A** and **B** for the carriers shown in **C** and **D**, respectively. Selected frames are shown from a sequence in panel C for a carrier that moved perpendicular to the coverslip, without fusing to the plasma membrane and in panel D for a carrier which fused to plasma membrane. The intensity of the VSVG-GFP in frames C and D is shown in pseudo-color. Each sequence was processed with a running average in time of ±1 frame, and thresholded separately to aid visualization. The radically symmetric Gaussian fit of the carrier fluorescence is shown below each frame. The numbered arrows refer to the frames from sequences C and D. In panel B the three phases (stationary, rise, and spread) are separated by dotted lines. Times are marked relative to the start of the rise phase. (Reproduced from Schmoranzer et al., *The Journal of Cell Biology*, 149:23-31. Copyright 2000 The Rockefeller University Press. Table 2A.2.5 Qualitative Summary of the Kinetic Behavior of the Characteristic Values for a Fusing Carrier

Phase	Stationary	Rise	Spread
Total intensity	Constant	↑↑	Relatively constant
Peak intensity	Constant	↑↑	↓↓
Width	Constant	↑	↑

fusion), (2) rise (carrier was diffusing into the plasma membrane), and (3) spread (carriers were neither moving closer to or further away from the plasma membrane). This study shows that in constitutive exocytosis, there are vesicles that fully fuse and integrate with the plasma membrane.

Toomre et al. (2000) observed the fusion of single carriers with the plasma membrane, and they were able to isolate a distinct analytical signature in fluorescence spectra over time. TIRF and epifluorescence microscopy were used to visualize the exocytic pathway of vesicular stomatitis virus glycoprotein tagged with yellow florescent protein (VSVG3-SP-YFP) from Golgi exit to plasma membrane fusion (Fig. 2A.2.18). The time-lapse microscopy allowed for monitoring the carrier exit from the Golgi and its approach to the cell surface. Figure 2A.2.18C shows a red carrier that exited the Golgi turned yellow as it approached the surface, where it paused for 45 sec before becoming partially fused. In Figure 2A.2.18D another carrier is shown entering the field, approaching the surface, pausing, and completely fusing with the plasma membrane. At fusion, the signal observed by epifluorescence dropped as the carrier diffused into the membrane (Fig. 2A.2.18E, red trace). In contrast, the corresponding TIRF signal rapidly increased at fusion as the carrier was more excited near the coverslip (Fig. 2A.2.18E, green trace).

ADVANTAGES OF TIRF

The prism-based TIRF configurations are inexpensive and offer a variety of prism shapes that can be coupled with the coverslip. In addition, the prism-based TIRF excitation produces less scattered light than through-the-lense TIRF (Axelrod, 2001b). The drawback of the prism setup is that it restricts sample access, and the entire TIRF path must be custom assembled in the laboratory.

The through-the-lens TIRF configuration represents the simplest method for TIRF excitation. The sample is fully accessible, does not require any customized items, and the angle of incidence adjustment is controlled through a micrometer.

The main advantages of TIRF are:

1. It is a wide-field approach (as opposed to sectioning methods) in the sample plane and is compatible with other microscopy techniques (see Chapter 2, section 2A), e.g., epifluorescence, differential interference contrast (DIC), and interference reflection microscopy (IRM). Switching among these microscopy techniques is straightforward, accomplished simply by sliding different optical components and objectives in and out of the optical path, without moving the sample.

2. Compared to IRM, which is used for the visualization of attachment sites of unstained cells due to the contrast obtained from interference of monochromatic polarized light, TIRF is able to offer biochemical specificity when coupled with fluorescence labeling of specific molecules.

3. In some applications (e.g., photosensitive samples, time-lapse recordings, and FRAP), TIRF offers the advantage of illuminating only a thin section at the bottom of the sample, while the rest of the sample is not affected.

4. Considering that TIRF is an optical sectioning technique in a thin plane parallel with the sample, it is comparable to confocal microscopy *(see UNIT 2C.1)*. As mentioned earlier, TIRF has a higher z-resolution ($<$100 nm) than confocal microscopy ($\sim$300 nm).

The main limitation of TIRF microscopy is its specific localization; TIR effect occurs only at an interface between two media with different refractive indices. Compared to confocal microscopy, where optical sectioning is possible at any plane of the sample, TIRF is effective only at the cell-substrate interface.

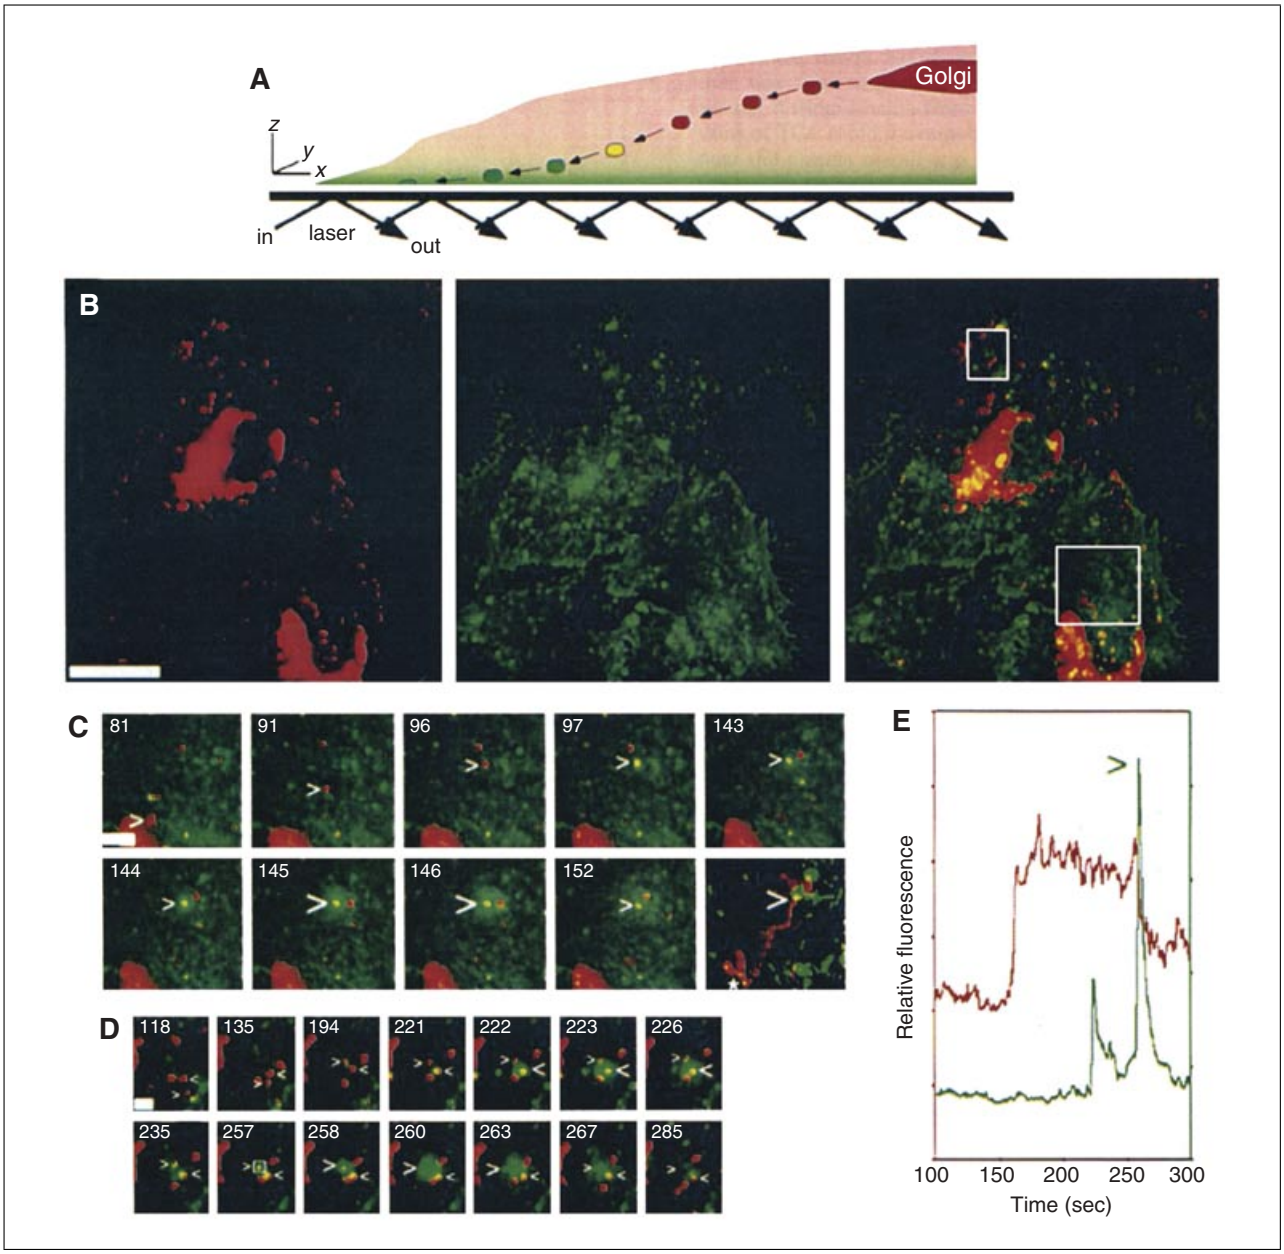

Figure 2A.2.18 Live cell visualization of the late exocytic pathway by combined epifluorescence and TIRF. (**A**) Organelles and carriers distant from the plasma membrane (>100 nm) are visible only by epifluorescence (red). Once carriers approach the plasma membrane, they also become visible by TIRF (green). In an overlay of the two channels, originally red carriers turn yellow and subsequently green as they approach the plasma membrane and later fuse. (**B**) Two live cells imaged by epifluorescence (left) and TIRF (center) as individual channels are merged on the right, where boxes indicate areas enlarged in subsequent images. (**C**) A carrier exits the Golgi complex and moves to the plasma membrane (small >), where it docks and partially fuses (large >). A running subtraction of successive frames tracks the movement of the carrier from the Golgi complex to the apparent docking site (last frame). (**D**) Two carriers that undergo successive fusion in close proximity. Only the second one (>) undergoes complete fusion. The time is indicated in seconds. (**E**) Plot of the relative fluorescence intensity of the second fusion event boxed in panel D. Note that the decrease in epifluorescence (red) is accompanied by a large, sharp increase in TIRF signal (green) when fusion occurs (>). The small TIRF peak is due to an earlier (222 sec) nearby fusion event. Bars: (B) 20 μm; (C) 4 μm; (D) 2 μm. (Reproduced from Toomre et al., *The Journal of Cell Biology*, 149:33-40. Molecular Expressions Microscopy Primer. Excellent presentation of optical microscopy.

Transmission Electron Microscopy

Transmission electron microscopy (TEM) has long been an important tool in the expanding field of microbiology. A major virtue of TEM is the potential resolution provided by electron beams accelerated at high voltage with effective wavelengths that are shorter by a factor of 10^5 than visible light. In principle, electron microscopes are capable of molecular resolution if only the wavelength (diffraction) limitation is considered; in practice, however, other factors limit the achievable resolution, including the sample itself. Other limitations of electron microscopy result from the fact that samples must be thin, dry, and capable of scattering electrons in a vacuum. Typically, this necessitates fixation or stabilization of the sample, and the introduction of electron-scattering heavy metal stains to generate contrast for imaging.

This unit describes two types of TEM preparation techniques for examining particulate samples as well as samples presenting more complex ultrastructural considerations that require analysis in thin sections. Negative staining is a simple but valuable technique that is useful for routine examination of particulate samples in suspension ranging from bacteria to viruses to purified macromolecules. Strategies are presented for delivering sample and stain sequentially onto a grid for TEM analysis (Basic Protocol 1), the direct deposition of sample and stain together onto the grid (Alternate Protocol 1), the delivery of spray droplets of sample and stain to the grid (Alternate Protocol 2), and the preparation of grids for negative staining (see Support Protocol 1). Combination of negative staining with immunolocalization of antigens using protein A– and/or protein G–gold is presented in Basic Protocol 2, along with the alternative procedure using gold-conjugated secondary antibodies in place of protein A/G–gold (Alternative Protocol 3). In order to investigate the relationships between microbes and the environments with which they interface, more complex specimen preparation methods are required. Viruses and bacteria on or in various substrates, including cells and tissues, can be identified by imaging in fixed samples prepared for analysis in sections of 60- to 90-nm thickness. Due to the many steps in sample preparation for ultrastructural analysis of thin-sectioned samples, the major steps in the process are divided into Basic Protocols 3 and Alternate Protocols 4, 5, 6, and 7. In Basic Protocol 3, the fixation and initial processing of solid tissue or biopsy samples is considered; Alternate Protocol 4 describes the variant procedure for pelleted cells, Alternate Protocol 5 describes the procedure for bacterial suspensions, Alternate Protocol 6 describes the procedure for cell monolayers; and Alternate Protocol 7 describes the fixation and initial processing of samples to be subjected to immunogold labeling. Basic Protocol 4 then addresses the process of embedding tissues and cell pellets into plastic resin for sectioning, while Alternate Protocol 8 deals with embedding procedures for monolayers grown on glass slides and Alternate Protocol 9 considers embedding procedures for thin-section immunogold labeling. Once tissues are embedded, the cutting (using an ultramicrotome) of uniform thin sections, free from defects, that adhere to each other as straight ribbons, is an extremely challenging manual skill requiring a high level of dexterity. Ultramicrotomy is not a technique that can be effectively communicated or learned using a protocols manual, and therefore only an overview is presented in this unit (Basic Protocol 5). It is assumed that the reader has access to ultramicrotomy support service or hands-on training in this key element of specimen preparation for analysis of thin sections. Once thin sections are obtained and collected onto a TEM grid, the sample is usually stained with heavy metals as a final step before examination in the electron microscope (Basic Protocol 6). This can be preceded by immunolocalization of antigens in thin sections as discussed in Alternate Protocol 10.

Current Protocols in Microbiology (2006) 2B.1.1-2B.1.39

SAFETY

Aside from the biohazards posed by handling and disposing of pathogenic microbes (refer to *UNIT 1A.1*), many of the chemicals used in the processing of samples for electron microscopy are either volatile, inflammatory, toxic, carcinogenic, and/or radioactive. It is important to understand the nature of health and environmental hazards posed by these chemicals and to handle and dispose of them according to appropriate safety regulations (see *UNITS 1A.1, 1A.3 & 1A.4*). Expose electron microscopy grids containing negatively stained pathogenic specimens to UV radiation or chemical fixation before examination and store in a suitable container for safe temporary storage. Discard grids into a small wide-based container with appropriate decontamination reagents upon completion of the analysis. Rinse forceps used to handle grids with pathogenic samples in alcohol and flame before and after use. Specimens processed for embedding and thin sectioning are typically chemically stabilized in a fresh aldehyde-containing fixative, which will inactivate/kill the majority of viruses and bacteria. Autoclave other disposable preparative materials that come into contact with pathogens (e.g., Parafilm, filter paper) in appropriate containers prior to disposal.

BASIC PROTOCOL 1

NEGATIVE STAINING FOR TEM USING THE DROP APPLICATION METHOD

The following protocols describe the basic steps necessary for the setup and execution of the negative staining procedure. The goal of these procedures is to deliver a suspension of dispersed particles onto a grid coated with a support film such that particle density is sufficiently high and adequately dispersed in order to detect individual particles whose structure can be discerned using TEM. The negative stain surrounds particles, forming an opaque background so that the particles appear translucent. The ideal sample for negative staining is one of high concentration and purity that poses no biohazard, and which is suspended and well dispersed in a solute that can be easily replaced by the negative staining solution during processing. Since few samples meet these ideal criteria, the procedures and protocols necessary to produce adequately stained samples require a considerable amount of flexibility. Ideally, virus samples should contain about 10^9 particles/ml and bacterial samples derived from the desired growth phase should contain at least 10^6 cfu/ml. Highly fragile and/or pathogenic microbes may require chemical fixation (e.g., using 2.5% buffered glutaraldehyde) and washing prior to staining.

In general, a reasonable starting point for the negative staining of viruses and/or bacteria is the use of the versatile neutral 2% phosphotungstic acid, due to the compatibility of the stain with a wide variety of samples. The method chosen for the delivery of the sample onto the grid can affect the population of particles to be viewed. In the following basic negative staining protocol, the drop method is described. This method is used to deposit a population of the sample onto a grid; adsorption of the sample is affected by both the concentration and the affinity of the sample for the coated grid. A similar procedure, described in Alternate Protocol 1, involves direct application of both sample and stain onto the grid. When components within a particulate sample have different affinities for the coated grid surface, there is a need to employ Alternate Protocol 2, the spray droplet (nebulizer) method. The latter technique should result in the deposition of a more representative sample onto the grid surface for analysis.

Each of the negative stains (see Reagents and Solutions) can be prepared with 1% (w/v) carbohydrate (glucose or trehalose) to protect samples that are sensitive to air drying. However, inclusion of carbohydrate involves additional considerations, as it reduces the overall density of the stain, requiring higher stain concentration; also, the electron-beam instability of the carbohydrates necessitates use of lower beam intensities and/or specimen cooling if possible. Lower concentrations of these stains can be prepared from stock solutions if reduced specimen contrast is needed for any particular application.

Negative staining can be at times a relatively dirty procedure with respect to microscope vacuum, due to the generation of a corrosive sublimate, and in some cases can degrade the sample itself. It is always best to limit contamination by using appropriate anticontamination devices such as ion-getter pumps and liquid nitrogen cold traps, if they are available on the TEM instrument.

Materials

Samples: bacterial or viral suspensions
Negative staining solution: phosphotungstic acid staining solution (see recipe), uranyl acetate staining solution (see recipe), or ammonium molybdate staining solution (see recipe)
37% formaldehyde (optional)
Desiccant

Several sets of self-locking fine-point forceps
Formvar- or carbon-coated Formvar hexagonal 300- or 400- mesh copper grids (see Support Protocol 1)
Whatman no. 4 filter paper
E-Series Germicidal Ultraviolet lamp (Spectroline) or equivalent, with UV monitor and UV goggles (optional)
35-mm petri dish (optional)
Grid box (Electron Microscopy Sciences or Ted Pella)

1. Cut a piece of Parafilm from a roll (~6 to 8 cm in length) along with its paper overlay and place wax-side-down on a clean bench top. Prior to removal of the paper overlay, score corners of the Parafilm or score parallel lines into the Parafilm with a blunt object to loosely attach the Parafilm to the bench top.

   This will provide the surface upon which to place individual droplets of sample, wash, and staining solution in rows for sequential transfer of grids during the staining process.

2. Pipet in a row, with a spacing of ~1.5 cm, a 15- to 25-µl droplet of sample, two or three droplets of Milli-Q-purified water (or equivalent) and one droplet of the negative staining solution onto the wax surface of the Parafilm.

   Several rows of these solutions can be prepared to process several grids at one time. The number of water droplets needed depends on the concentration of solute to be removed from the sample, as the presence of salt crystals will degrade and/or obscure the sample. Optimization of the sample is largely by trial and error. If the sample is too concentrated, it can be diluted in solvent and deposited on the Parafilm for further processing.

3. Using several pairs of self-locking forceps, place a Formvar-coated or carbon-coated Formvar grid onto the sample droplet (coated side towards the sample) for a period of time ranging from 5 to 60 sec. Remove the grid from the sample surface and carefully remove the excess liquid by allowing the grid to touch the edge of a wedge of Whatman no. 4 filter paper. Do not let the grid dry completely (Fig. 2B.1.1B and E).

   Grids with support films tend to be hydrophobic; in order to increase the hydrophilicity of the support film, a brief glow discharge treatment can be applied to increase sample adhesion and stain distribution. This involves placing grids into a vacuum evaporator with a glow discharge unit (Emitech Products, Inc.; http://www.emitech.co.uk), under reduced pressure (~0.1 Torr) in air, thereby exposing the grids to a plasma of gas electrons moving toward an electrode through the gas, resulting in deposition of a negative charge on the surface of the grid which lasts about half a day. Alternatively, the inclusion of surfactants such as 0.01% to 0.1% poly-L-lysine, 0.05% bacitracin, or 0.01% bovine serum albumin in the negative stain solution, or floatation of grids on a solution of one of the abovementioned surfactants for a few seconds prior to the addition of the sample, may improve sample spreading on grid.

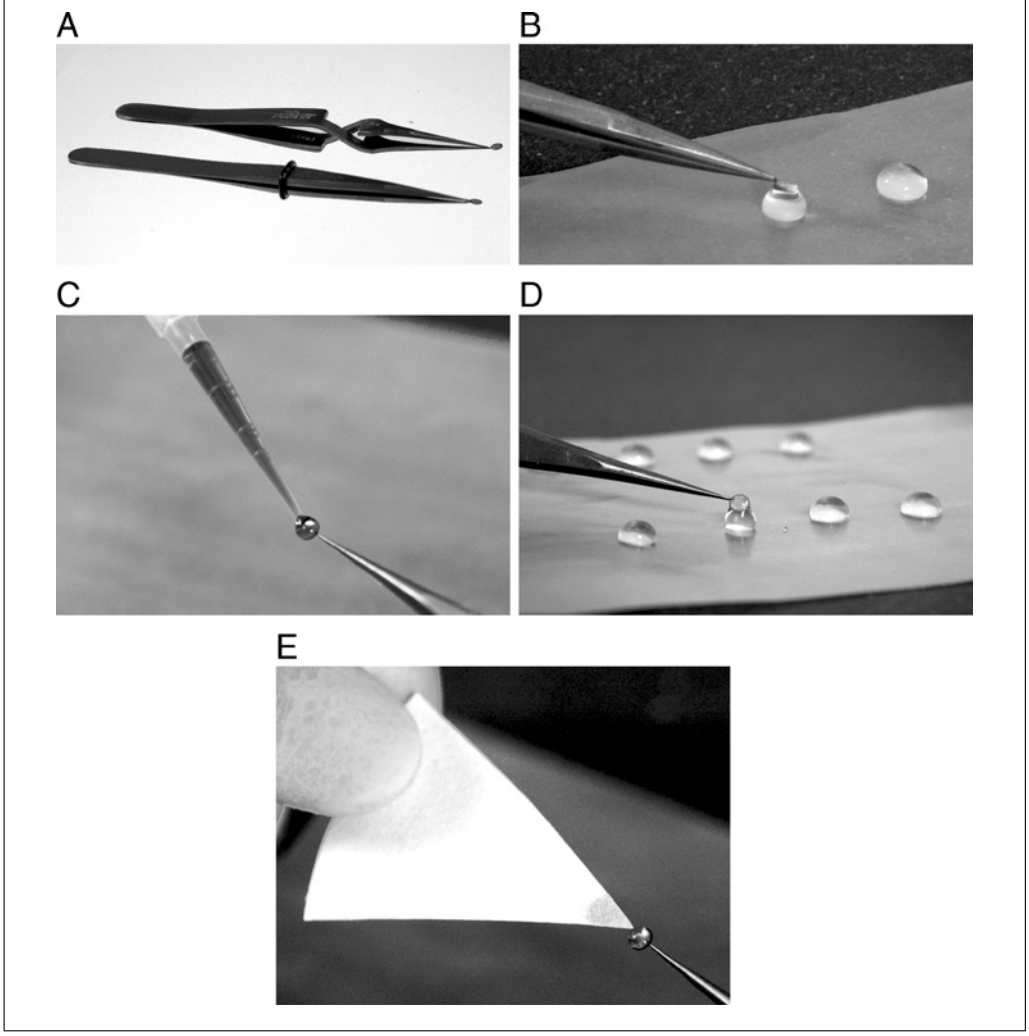

Figure 2B.1.1 Aspects of the negative staining procedure. (**A**) Grids can be conveniently handled using either self-closing forceps (top) or conventional fine-tipped forceps with a rubber O-ring to keep the jaws closed (bottom). Specimen to be examined can be applied either by (**B**) floating grid on a drop of the specimen or by (**C**) direct application to the grid. Stain can be applied as illustrated in B or C. Washing (**D**) and fluid removal (**E**) are performed in subsequent steps of the procedure.

4. Before the sample has air dried on the grid, transfer the grid to the surface of the water droplets sequentially, carefully removing the excess water between each transfer using the edge of a wedge of filter paper.

   This step is necessary if the sample has high concentrations of buffer salts or other solutes which may interfere with uniform deposition of stain. If the sample is suspended in water, the number of washing steps can be reduced or washing can be eliminated.

5. Transfer the grid to the surface of the negative stain solution for 5 to 30 sec, then remove the grid and remove the excess staining solution by again allowing the grid to touch the edge of a filter paper wedge.

   The rate of removal of stain can be adjusted by changing the orientation of the filter paper wedge, since the pointed edge adsorbs less liquid than the broader edges. Thereby, it is possible to increase or decrease the amount of stain removed if stain density requires modification.

6. Allow the grid to air dry completely before TEM analysis to avoid damage to sample and contamination of the microscope.

   The grid with the sample can be placed in a container with a desiccant to accelerate drying.

   Several iterations of this basic procedure are usually required to optimize the concentration and distribution of the sample particles on the grid (see Critical Parameters and Troubleshooting).

7. *Optional:* When dealing with pathogenic microbes, inactivate in one of the following ways:

   a. Expose the grids to UV irradiation (900 μW/cm^2) at 15 to 20 cm for at least 10 min.

   b. Expose grids to 37% formaldehyde fumes in a 35-mm petri dish for at least 30 min.

      The formaldehyde can be placed in the lid from a screw-top fixation vial and the grids can be distributed on filter paper surrounding the lid and exposed to the fumes for at least 30 min.

8. Store grids in a grid box with desiccant at room temperature until ready for further processing or TEM analysis.

NEGATIVE STAINING FOR TEM USING DIRECT DEPOSITION OF SAMPLE AND STAIN ONTO GRIDS

ALTERNATE PROTOCOL 1

Excessive handling of coated grids can be eliminated by the use of the direct deposition technique whereby both the sample and stain are dropped onto the coated grid. This reduces grid manipulation and can speed up the staining procedure once an optimal ratio of sample to stain is determined. When examining pathogenic organisms, it is often necessary to inactivate them with glutaraldehyde prior to staining. If this is the case, it is possible to directly add the negative stain to the sample and drop the mixture in a one-step procedure similar to that outlined below.

For materials, see Basic Protocol 1.

1. Using several sets of self-locking forceps, pick up grids by their edges and place them with support film facing upward in a row on top of plastic-backed bench protectors (“diapers”).

2. Deposit a 10-μl sample droplet on top of the first grid with a pipet, let sample adhere to the grid for 30 to 60 sec, then add a 10-μl droplet of negative stain directly to the grid with a pipet.

   This adsorption step should distribute the sample and stain uniformly over the surface of the grid (Figure 2B.1.1C).

   When dealing with large volumes of sample, it is possible to combine samples, stain together in a microcentrifuge tube, and apply them to the grid simultaneously. Several dilutions of stain and sample can be prepared and run at the same time.

3. Briefly touch the edge of the grid to a wedge of filter paper to remove excess sample.

4. In the case of samples containing high salt concentration, wash twice, each time by placing a 10- to 15-μl drop of distilled water on the grid for a few seconds and then removing it with a clean wedge of filter paper.

   In some instances this extra washing step may cause inadequate sample contrast and will require another brief application of the negative stain solution.

5. Allow the grid to air dry. Inactivate biohazardous organisms as in Basic Protocol 1, step 7, if necessary. Store grids in a grid box with desiccant at room temperature until ready for further processing or TEM analysis.

ALTERNATE PROTOCOL 2

NEGATIVE STAINING FOR TEM USING SPRAY DROPLET APPLICATION

The spray droplet technique is useful for examining specimens or constituents of heterogeneous samples that adsorb poorly to the support film, and/or if there is a need to for a more representative analysis of the sample constituents. Very small droplets of sample and negative stain can be atomized and distributed onto the coated grid with a hand-held nebulizer.

CAUTION: Spray application is not suitable for highly pathogenic organisms even when using an appropriate laminar flow hood. In those instances, one of the drop-staining methodologies (Basic Protocol 1 or Alternate Protocol 1) should be used.

Additional Materials *(also see Basic Protocol 1)*

Hand-held glass nebulizer (Electron Microscopy Sciences or Ted Pella, Inc.)
Stand that can support self-locking forceps holding grid while sample spray is applied

1. Mix appropriate volumes of sample and negative stain in a hand-held glass nebulizer.

   An equal mixture of sample and negative stain is a reasonable starting point, although the ratio of sample and negative stain can be adjusted to yield suitable results.

2. Hold grid in front of the nebulizer using a set of locking forceps inserted into a suitable stand so that the grid projects into the path of the spray.

3. Apply small droplets of sample onto the grid by atomizing the sample.

   CAUTION: *If potentially pathogenic organisms are being examined, appropriate safety precautions must be taken (see UNIT 1A.1). These can include fixation of the sample with glutaraldehyde before use of the nebulizer, spraying the sample onto the grid in a biological safety hood, and/or spraying the sample onto a grid secured in front of a disinfectant-coated towel.*

   The size of droplets can be adjusted by the pressure applied to the nebulizer bulb. The density of sample on the grid can be regulated by varying the distance of the grid from the nebulizer.

4. Allow sample to air dry without washing.

   This prevents differential removal of sample with lower affinity to the substrate.

SUPPORT PROTOCOL 1

PREPARATION OF GRIDS FOR NEGATIVE STAINING

Negative staining requires the use of grids coated with a support film. The preparation of grids with support films is a technique that requires some experience and some specialized equipment (e.g., vacuum evaporator and glow discharge unit), and involves more than following a stated protocol. There are a variety of materials used for support films, which can be cast using a variety of methods. A thorough description of the different materials used for the preparation of support films, their formulations, and casting procedures is given in Hayat (2000). Due to the number of procedural details and considerations in preparing support films, grid preparation is presented here as an overview rather than a step-by-step protocol in this unit. If the laboratory itself does not prepare coated grids on a regular basis, uniform-quality coated grids can be purchased from electron microscopy supply vendors such as Ted Pella, Inc., Electron Microscopy Sciences, Structure Probe, Inc./SPI Supplies (see ***SUPPLIERS APPENDIX*** for these first three suppliers), Canemco Inc.,

and Marivac Inc. (the last two suppliers are accessible through a common Web site at *http://www.canemco.com*). If commercial suppliers are used, it is recommended that freshly prepared support films be purchased in relatively small lots, as the films lose stability under the electron beam when stored for several months.

Support films are commonly prepared from Collodion (nitrocellulose), Formvar, and carbon due to their relatively high transparency to electrons and strength under electron irradiation. Collodion or Formvar can be cast on glass slides or a water surface. Collodion is soluble in ethyl or amyl acetate and acetone, and films are prepared from solutions ranging from 0.5% to 2% (w/v). Formvar is soluble in ethylene dichloride or chloroform and can be prepared from solutions that range in concentration from 0.1% to 0.5% (w/v). A film can be deposited by dipping slides into Coplin jars containing these solutions at a depth of ~10 cm. Once the slide is dipped, the edge is drained onto filter paper and the slide dried in a dust-free area. The dried film is then floated off of the slide by dipping it into a bowl of water at a 30° to 40° angle after the edges of the slide are scraped with a razor blade to allow the hydrophobic film to float off. Once the rectangular film floats on the water surface, a number of grids that are precleaned in acetone can be carefully distributed over the surface of the floating film. A strip of Parafilm slightly larger than the area of the floating support film is then gently laid on top of the grid-containing support film and immediately lifted off of the water surface. The Parafilm with grids on the upper surface is then placed in a covered petri dish or desiccator where the grids remain until needed. Plastic films can be strengthened/stabilized by depositing a thin film of carbon in a vacuum evaporator.

Carbon films are strong and very stable under the electron beam and are useful for high-resolution electron imaging. Preparation of carbon films is a relatively laborious procedure requiring a vacuum evaporation device with appropriately sharpened carbon electrodes. Preparation of carbon support films as well as carbon deposition on plastic films are described in detail in Hayat (2000).

PROTEIN A–GOLD STAINING AND NEGATIVE STAINING FOR IMMUNOELECTRON MICROSCOPY

BASIC PROTOCOL 2

The following protocol describes basic steps necessary for immunolocalization of antigens in negatively stained preparations utilizing colloidal gold preparations conjugated to either secondary antibodies or to protein A–gold, protein G–gold, or protein A plus protein G (protein A/G)–gold, which are used as electron-opaque reporters of primary antibodies that bind to surface antigens on viruses or bacteria. The conjugates interact with mammalian immunoglobulins; however, their individual affinity for immunoglobulins is not equivalent for all species or for all antibody subclasses. There are many alternatives and variations on immunoelectron microscopy approaches, only two of which are outlined below. In these examples, it is assumed that the sample is stable without fixation and that optimal conditions for sample concentration and delivery onto a grid, as well as for negative staining of the sample, have already been determined. If it is suspected that the stability of the sample will be jeopardized by the number of steps and duration of the protocol, the samples can be fixed in appropriately buffered, freshly prepared, 1% paraformaldehyde. This is followed by washing in a glycine-containing buffer to remove residual free aldehydes resulting from fixation prior to immunolocalization of antigens and negative staining.

Materials

Samples: bacterial or viral suspensions
Primary antibody against antigen of interest and irrelevant primary antibody of same species/class as control
Immunogold antibody dilution buffer (see recipe)

Protein A–gold or protein A plus protein G–gold solution: e.g., Structure Probe/SPI Supplies or Nanoprobes (see ***SUPPLIERS APPENDIX***) or Aurion (*http://www.aurion.nl*)

96-well microtiter plate

Humidified chamber: e.g., Tupperware or Rubbermaid plastic container with sealable lid, containing water-saturated paper towels

Several sets of self-locking fine-point forceps

Formvar-coated 300- or 400-mesh nickel grids.

Additional reagents and equipment for negative staining (see Basic Protocol 1)

1. In a well of a microtiter plate, mix 25 µl sample suspension with an equal volume of a suitable dilution of primary antibody in immunogold antibody dilution buffer. Incubate 1 hr at 25° to 37°C in a humidified chamber.

   The antibody dilution needs to be empirically determined. Initial tests should include a serial dilution of antibody that increases by factors of 10. This will help determine optimum conditions for labeling with minimum background. A 1/100 and 1/1000 dilution provide a reasonable starting point.

   To streamline the process, controls can be processed at the same time and should include an irrelevant primary antibody of the same species and/or class, and another preparation without primary antibody.

2. Add 25 µl/well of protein A–, protein G–, or protein A/G–gold solution, depending on the primary antibody subclass and species used to generate the primary antibody, and incubate for another 30 min to 1 hr at 25° to 37°C in a humidified chamber.

   The dilution of the protein complex should be based upon recommendations of the vendor. Note that the size of the gold particles can affect the affinity of the protein A–gold complex for the primary antibody (see Critical Parameters, below). Typically, ≥10-nm-sized gold particles are used with negative staining preparations.

   There are a number of commercial suppliers of colloidal gold products in useful size ranges from 5 to 20 nm and larger (e.g., Structure Probe, Inc./SPI Supplies or Nanoprobes in the U.S. or Aurion in the Netherlands).

3. Using several sets of self-locking forceps, pick up grids by their edges and place them with support film facing upward in a row on top of plastic-backed bench protectors (“diapers”).

4. Deposit a 10- to 15-µl droplet of the mixture from step 2 directly onto the grid with a pipet and allow to stand 5 min.

5. Cut a piece of Parafilm from a roll (~6 to 8 cm in length) along with its paper overlay and place wax-side-down on a clean bench top. Prior to removal of the paper overlay, score corners of the Parafilm or score parallel lines into the Parafilm with a blunt object to loosely attach the Parafilm to the bench top.

6. Pipet, in a row, with a spacing of ~1.5 cm, two drops of immunogold antibody dilution buffer and one drop of distilled water onto the wax surface of the Parafilm. Before the sample dries on the grid, wash by sequential immersion in the two drops buffer and the drop of distilled water. Carefully remove the excess liquid between transfers by allowing the grid to touch the edge of a wedge of Whatman no. 4 filter paper.

7. Perform negative staining as in Basic Protocol 1, using 2% phosphotungstic acid and bringing the sample-containing grid into contact with staining solution for 30 sec.

STAINING FOR IMMUNOELECTRON MICROSCOPY USING GOLD-CONJUGATED SECONDARY ANTIBODIES

There are many variations on immunogold labeling of negatively stained particulate samples. Secondary antibodies generated in a different species against the Fc fragment of the primary antibody can be used to indirectly label the primary antibody, in lieu of the protein A and/or G employed in Basic Protocol 2. The following protocol describes the use of commercially available secondary antibodies conjugated with colloidal gold particles of different sizes.

Additional Materials *(also see Basic Protocols 1 and 2)*

Colloidal gold-conjugated secondary antibody directed against primary antibody

1. Deposit sample onto grids either by floating the Formvar-coated grid on a drop of sample (see Basic Protocol 1) or by direct deposition of the sample onto a grid (see Alternate Protocol 1).
2. Float grid on a drop of the immunogold antibody dilution buffer using the technique described in Basic Protocol 1.
3. Blot excess fluid from grid with Whatman no. 4 filter paper, but do not allow sample to dry completely onto the grid. Immediately transfer grids to a drop of primary antibody diluted in immunogold antibody dilution buffer for 30 min to 1 hr. Cover with a petri dish lid to prevent evaporation.
4. Rinse grids by transferring them to four successive drops of immunogold antibody dilution buffer using the technique described in Basic Protocol 1.
5. Transfer grid to a drop of colloidal gold–conjugated secondary antibody diluted in immunogold antibody dilution buffer.

   The working antibody solution is prepared by diluting the stock with immunogold antibody dilution buffer to yield a solution in which the color of the colloidal gold solution is barely perceptible. Cover and incubate 30 min at room temperature.
6. Rinse grids by sequentially transferring them through four successive drops of immunogold antibody dilution buffer followed by one drop of distilled water using the technique described in Basic Protocol 1. Use a clean wedge of filter paper at the edge of the grid to wick off the water.
7. Perform negative staining as described in Basic Protocol 1.

FIXATION AND INITIAL PROCESSING OF SAMPLES FOR THIN SECTIONING

Biological materials processed for TEM examination of thin sections afford the greatest potential for exploiting the resolving power inherent in the wavelengths of electron beams accelerated at high voltage. Assessment of ultrastructural information within microorganisms, as well as the relationships between microbes and the environments with which they interface, can be analyzed in samples that are chemically stabilized and embedded in a plastic resin. This permits the cutting of sections on the order of 50- to 90-nm in thickness. Such samples are for examination by TEM following deposition of heavy metals on macromolecules to scatter electrons and generate contrast in the sample (see Basic Protocol 6).

The materials to be processed may be particulates such as viral or bacterial suspensions (Alternate Protocol 5), bacterial or cultured cell samples concentrated by centrifugation into pellets (Alternate Protocol 4), monolayer cell cultures (Alternate Protocol 6), or tissue pieces (e.g., biopsies or autopsy tissue samples; Basic Protocol 3). The processing

of these preparations may involve a variety of different strategies. The following protocols describe the basic steps necessary for the chemical fixation and initial processing of tissue pieces, cell pellets, bacterial suspensions, cells in monolayer culture, and samples that are to be immunolabeled in thin sections, each outlined separately.

CAUTION: Due to the volatility and toxicity of the fixatives used in the following protocols (i.e., glutaraldehyde, paraformaldehyde, and osmium tetroxide), these items should be handled in a fume hood using latex or nitrile gloves. Protective eyeware should also be worn.

BASIC PROTOCOL 3

Fixation and Initial Processing of Tissue Samples

Biopsy or autopsy samples are often used to diagnose viral diseases and to study bacterial invasion of epithelial tissues or phagocytosis by macrophages. The following protocol provides the basic steps for processing small pieces of tissue for thin sectioning and electron microscopy. The critical consideration is the size of the tissue sample, which must be reduced to 1 mm^3 or smaller. This critical dimension must not be exceeded, in order to ensure adequate penetration of fixative during the initial processing, post-fixation, en bloc staining, and subsequent infiltration steps that involve incorporation of liquid plastic resin into tissues polymerized into a hardened plastic necessary to permit the cutting of thin sections with glass or diamond knives.

Materials

Tissue sample
TEM primary fixative 1 (see recipe)
Phosphate/sucrose rinse buffer (see recipe), 4°C
Osmium tetroxide post-fixative (see recipe)
Uranyl acetate staining solution (see recipe)
Graded ethanol series: 50% and 75% ethanol (4°C) and 95% and 100% ethanol (room temperature)
Acetone or propylene oxide

Polypropylene cutting board
Single-edged razor blades
Fixation vials: dram vials with caps
Platform rocker or orbital shaker (optional)

Additional reagents and equipment for embedment (Basic Protocol 4)

Fix tissue

1. Obtain a fresh piece of tissue and, as quickly as possible, slice tissue on a polypropylene cutting board with a razor blade into pieces <1 mm in thickness (or smaller than 1 mm^3).

   It is preferable to cover the tissue with a small amount of TEM primary fixative 1 during slicing.

2. Place several small pieces of tissue in a fixation vial containing freshly prepared TEM primary fixative 1 at a volume at least 20 times greater than that of the tissue pieces.

3. Incubate tissue at room temperature for 60 min, them move to a 4°C ice bath for an additional 60 min. Alternatively, fix tissues overnight at 4°C.

4. Decant fixative from vials and replace with phosphate/sucrose rinse buffer at 4°C. Replace the buffer with fresh phosphate/sucrose rinse buffer several times over a 30-min interval to wash the tissue.

Perform post-fixation and en bloc staining

5. Post-fix tissue pieces in osmium tetroxide post-fixative for 90 min at 4°C. Rock tissue pieces frequently during post-fixation or place vials on a platform rocker operating at low speed to facilitate penetration of osmium into the tissue.

6. After post-fixation, decant osmium solution into a waste container in a fume hood. Using the technique described in step 4, rinse tissue pieces twice in chilled phosphate/sucrose rinse buffer, then six times in cold distilled water to remove phosphate buffer residue.

7. Stain tissue en bloc in uranyl acetate staining solution for 90 to 120 min at 4°C with periodic agitation. Alternatively stain in 0.5% aqueous uranyl acetate overnight at 4°C.

   Heavy metal stains are most often deposited after fixation and sectioning. En bloc staining is a supplemental or alternative method for depositing uranyl ions onto subcellular structures in pieces of tissue or tissue pellets after fixation and prior to embedding and section.

   One disadvantage of en bloc staining with uranyl acetate is that glycogen is either extracted or rendered unstainable. If preservation of glycogen in the tissue is of importance, this step may be bypassed. Alternatively, see de Bruijn, (1973)

8. Using the technique described in step 4, wash tissue three times in cold distilled water to remove uranyl acetate.

Dehydrate and embed tissue

9. Dehydrate through ethanol series by sequentially replacing the solution in the vial with the following solutions for 10 min each:

   50% ethanol, 4°C
   75% ethanol, 4°C
   95% ethanol, room temperature
   100% ethanol, room temperature.

10. Rinse tissue three times, each time for 10 min, in acetone or propylene oxide.

11. Embed in epoxy resin (see Basic Protocol 4).

Fixation and Initial Processing of Cell Pellets

ALTERNATE PROTOCOL 4

The following alternate protocol provides a general approach for the preparation and analysis of samples presented as individual cells in a suspension that must be concentrated by centrifugation into pellets. Samples can range from cell cultures used for the isolation and propagation of viruses to pure bacterial cultures in growth medium. The quantity of cells and the type of sample tube will determine the type of pellet to be fixed and subjected to initial sample processing. There are numerous methods to prepare cells in culture for electron microscopy ranging from scraping monolayers with a cell scraper to generating monodispersed populations by trypsinization. These cells are then concentrated by centrifugation and fixed. Once the initial stabilization of the sample is accomplished, the pelleted material must be removed from the centrifuge tube and, depending on the size and stability of the pellet, it can be processed as a solid piece of tissue or it can be encased in agar to ensure its integrity during subsequent steps of the sample preparation process.

Additional Materials *(also see Basic Protocol 3)*

Cell suspension in buffered saline or serum-free culture medium
2.5% molten agar, between 40°C and 60°C

Obtain pellet

1. Harvest bacteria or cultured cells in buffered saline or serum-free culture medium and centrifuge in either hard- or soft-walled microcentrifuge tubes.

   A variety of microcentrifuge tubes can be used for pelleting samples. When using hard-walled tubes such as polypropylene microcentrifuge tubes, pellets can be overlaid with a glutaraldehyde-based fixative for stabilization of cells. Polyethylene microcentrifuge tubes have soft walls and the tips of these tubes containing the pellet can be cut off with a razor blade and dropped directly into fixative for initial tissue processing.

Fix cells

2a. *If the sample is collected in a hard-walled microcentrifuge tube:* Carefully remove supernatant from pellet. In a fume hood, slowly add freshly prepared TEM primary fixative 1 using a volume at least 20 times greater than that of the pellet. Fix for 1 hr at 4°C.

2b. *If the sample is collected in a soft-walled microcentrifuge tube:* Cut off the tip of the microcentrifuge tube containing the sample pellet and drop the pellet along with the end of the tube into a fixation vial containing freshly prepared TEM primary fixative 1 at a volume at least 20 times greater than that of the pellet. Fix for 1 hr at 4°C.

3. Replace fixative with phosphate/sucrose rinse buffer and carefully remove the pellet from the microcentrifuge tube or cut tip of tube.

Encase cells in agar and fix again

4a. *If pellet is <1 mm in thickness:* Carefully transfer pellet to 2.5% molten agar (maintained at 40° to 60°C) deposited on Parafilm, and keep suspended in the agar until solidified.

4b. *If pellet is >1 mm in thickness:* Slice the pellet, from top to bottom, into ~1-mm-thick slices. To maintain pellet integrity, carefully transfer slices of the pellet to a droplet of molten agar deposited on Parafilm and keep slice suspended in the agar until it solidifies.

5. Remove excess solidified agar with a razor blade to enhance fixative and solvent exchange.

6. Transfer pellet or slices to fixation vials containing fresh fixative and incubate an additional 90 min at 4°C.

7. Following fixation, decant fixative from pellet and replace with phosphate/sucrose rinse buffer at 4°C. Incubate 10 min at 4°C, then replace with fresh phosphate/sucrose rinse buffer and incubate an additional 10 min at 4°C.

Perform post-fixation and en bloc staining

8. Remove phosphate/sucrose rinse buffer, replace with osmium tetroxide post-fixative, and incubate 90 min at 4°C. Rock pellet frequently during post-fixation, or place vials on a platform rocker operating at low speed to facilitate penetration of osmium into the tissue.

9. After post-fixation, decant osmium solution into a waste container in a fume hood. Using the technique described in step 7, rinse pellet twice in chilled phosphate/sucrose rinse buffer, then six times in cold distilled water to remove phosphate buffer residue.

10. Stain tissue en bloc in 1% aqueous uranyl acetate for 90 to 120 min at 4°C with periodic agitation.

    Alternatively stain in 0.5% aqueous uranyl acetate overnight at 4°C.

11. Using the technique described in step 7, rinse pellets three times in cold distilled water to remove uranyl acetate.

Dehydrate and embed pellet

12. Dehydrate through ethanol series by sequentially replacing the solution in the vial with the following solutions for 10 min each:

    50% ethanol, 4°C
    75% ethanol, 4°C
    95% ethanol, room temperature
    100% ethanol, room temperature.

13. Rinse tissue three times, each time for 10 min, in acetone or propylene oxide.

14. Embed in epoxy resin (see Basic Protocol 4).

Direct Fixation and Initial Processing of Bacteria in Suspension

ALTERNATE PROTOCOL 5

When organisms, whether in pure or mixed culture, are prepared in growth medium and presented in suspension for preservation, it is frequently easier and more beneficial to add fixative directly to cells in medium, instead of to pelleted preparations. The objective of this procedure is to preserve the ultrastructure of the organisms while concentrating them sufficiently for embedding and sectioning to prepare a representative sample. The use of direct fixation eliminates potential centrifugation artifacts that may be encountered during initial centrifugation of unfixed preparations and helps to ensure that all constituents of the suspension will uniformly fixed and concentrated.

Additional Materials *(also see Basic Protocol 3)*

TEM primary fixative 2 (see recipe)
Bacteria in suspension
2.5% molten agar, between 40° and 60°C
15-ml conical centrifuge tubes
Horizontal mixer (e.g., Adams Nutator Single Speed Orbital Mixer)
Tabletop centrifuge
Polyethylene microcentrifuge tubes

Fix cells

1. In a fume hood, add an equal volume of TEM primary fixative 2 to bacterial cells suspended in culture medium or buffer in a 15-ml conical centrifuge tube.

   This will result in a final fixative concentration of 2% glutaraldehyde.

2. Immediately invert mixture and place on a horizontal mixer 60 min at room temperature.

3. After initial room temperature fixation, transfer cell suspension to a 4°C ice bath for an additional 1 hr of fixation.

4. Centrifuge cell suspension 10 min at 1000 × *g*, 4°C, and discard supernatant.

5. Resuspend cells in phosphate/sucrose rinse buffer and incubate at 4°C for 10 min.

6. Centrifuge cells 10 min at 1000 × *g*, 4°C, and discard supernatant.

Encase cells in agar and fix again

7. Resuspend cells in enough 2.5% molten agar to cover pellet, mix with a warmed transfer pipet, and transfer to polyethylene microcentrifuge tubes.

8. Centrifuge the agar and cell suspension 5 min at 5000 × *g*, room temperature, to pellet cells.
9. Chill tubes briefly on ice to solidify agar.
10. Using a single-edged razor blade, cut through the microcentrifuge tube just above the cell pellet in the agar to remove the pellet. Slice the removed agar encased pellet into thin slices, ~0.5 mm wide, and place in fixation vials containing chilled phosphate/sucrose rinse buffer.

Perform post-fixation and en bloc staining

11. Replace buffer with osmium tetroxide post-fixative and incubate 90 min at 4°C. Rock pellets frequently during post-fixation or place vials on a platform rocker and rock at low speed to facilitate penetration of osmium into the tissue.
12. Rinse pellets twice in chilled phosphate/sucrose rinse buffer.
13. Rinse pellets six times over the course of 1 hr with chilled distilled water to remove phosphate buffer residue.
14. Stain pellets en bloc in uranyl acetate staining solution for 90 to 120 min at 4°C with periodic agitation.

    Alternatively, stain in 0.5% aqueous uranyl acetate overnight at 4°C.

15. Wash three times in cold distilled water to remove uranyl acetate.

Dehydrate and embed pellet

16. Dehydrate through ethanol series by immersing successively for 10 min each in the following solutions:

    50% ethanol, 4°C
    75% ethanol, 4°C
    95% ethanol, room temperature.

Transfer to 100% ethanol.

17. Rinse tissue three times, each time for 10 min, in acetone or propylene oxide.
18. Embed in epoxy resin (see Basic Protocol 4).

ALTERNATE PROTOCOL 6

Fixation and Initial Processing of Monolayer Cells in Culture

Tissue culture cell preparations are frequently used for studying the propagation of viruses, the evaluation of viral cytopathic effect, and the evaluation of bacterial attachment and cell invasion. There are numerous methods that can be used to prepare cells in culture for electron microscopy, ranging from scraping monolayers with a cell scraper followed by centrifugation into a pellet to methods that permit evaluation of the monolayer in situ. In the following alternate protocol, a useful method for preserving and embedding cell monolayers by TEM is presented. The method involves use of cells cultured in Nunc Lab-Tek Chamber Slides. These slides consist of a plastic culture chamber that is attached to a glass microscope slide and sealed by means of a silicone gasket. The chamber is available in various configurations, ranging from a single chamber up to eight separate chambers on one slide. The protocol outlined below should produce embedded cell monolayers that can be sectioned either en face or in cross sections.

Additional Materials *(also see Basic Protocol 3)*

Cultured cells grown in Nunc Lab-Tek chamber slides
TEM primary fixative 2 (see recipe)

1. In a fume hood, slowly remove medium from the cultured cells and add TEM primary fixative 2 to the chamber so as to cover the monolayer with ~3 to 5 mm of fixative (~6 ml fixative per slide). Cover, and incubate cells in fixative for 30 min at room temperature followed by an additional 30 min at 4°C.

   The plastic chamber should not removed until after the fixation and uranyl acetate staining are completed.

2. Remove fixative and replace with an equal volume of cold phosphate/sucrose rinse buffer. Cover and incubate 10 min.
3. Remove phosphate/sucrose rinse buffer and replace with an equal volume of osmium tetroxide post-fixative. Incubate at 4°C for 60 min.
4. Remove post-fixative solution and rinse once in phosphate/sucrose rinse buffer.
5. Rinse chambers with cold distilled water six times over the course of 1 hr.
6. Add 1 ml uranyl acetate staining solution to the chamber and incubate 1 hr at 4°C.
7. Rinse chambers twice with cold distilled water.
8. Dehydrate and embed cells on the chamber slide (see Alternate Protocol 8).

Fixation and Initial Processing of Samples for Immunogold Labeling of Thin Sections

ALTERNATE PROTOCOL 7

The fixation and processing of samples that will permit labeling of antigens in thin-sectioned materials pose substantial challenges. Methods commonly used for optimal ultrastructural morphology must usually be modified to ensure that antigens are not only retained but available for labeling. This often involves optimization, with compromises between the fixation, processing, and embedding steps; however, careful selection of preparation methods can yield high-quality combinations of structural detail and immunochemical labeling.

Additional Materials *(also see Basic Protocol 3)*

Tissue or cell sample
TEM primary fixative 3 (see recipe)
Aldehyde quenching solution (see recipe)

1a. *For tissue specimens:* In a fume hood, fix tissue specimens by incubating with TEM primary fixative 3 for 12 to 24 hr at 4°C.

1b. *For free cells or cell suspension:* In a fume hood, fix cells or pellet by incubating with TEM primary fixative 3 for 2 to 4 hr at 4°C.

2. Rinse in phosphate/sucrose rinse buffer three times for at least 10 min each at 4°C.
3. Incubate in aldehyde quenching solution for 30 min at 4°C to remove residual free aldehydes.
4. Wash in phosphate/sucrose rinse buffer two times for 15 min each at 4°C.
5. Dehydrate through ethanol series by immersing successively in the following solutions for the indicated amounts of time:

50% ethanol, 4°C	10 min
75% ethanol, 4°C	10 min
95% ethanol, room temperature	10 min
100% ethanol, room temperature	30 min
100% ethanol, room temperature	30 min.

6. Directly embed in resin (see Alternate Protocol 9).

   Note that this procedure omits the acetone or propylene oxide infiltration step included in the previous tissue fixation and processing protocols.

BASIC PROTOCOL 4

EMBEDDING OF TISSUES AND CELL PELLETS FOR THIN SECTIONING

The following basic protocol is a continuation of Basic Protocol 3 and Alternate Protocols 4 and 5. All material to be thin sectioned for TEM examination must be embedded in a hardened plastic matrix. The unpolymerized plastic matrix must be fluid enough to completely infiltrate the specimen. Once polymerized, the plastic must not alter the ultrastructure of the specimen (i.e., as a result of specimen shrinkage, swelling, or extraction of cellular components) while being able to withstand the stress of thin sectioning. The resulting sections should remain stable in the electron beam and impart adequate contrast to the sample to allow for the visualization of ultrastructural detail. An additional consideration is the preservation of antigenicity in the case of thin-section immunogold labeling; a separate procedure is provided to deal with this issue (see Alternate Protocol 9).

In general, the goal is to introduce a plastic resin into the sample over time by the gradual replacement of dehydrating agent and resin solvent (usually ethanol and acetone, or ethanol and propylene oxide) with increasing concentrations of resin and solvent over time. Tissue pieces and cell pellets are eventually transferred to resin-filled embedding molds for polymerization. Cells in polymerized resin can then be prepared for thin sectioning.

CAUTION: Some resin components are possible carcinogens and others can produce allergic reactions in certain individual. Their preparation may therefore require a fume hood, a suitably vented oven, and other adequate measures for personal protection (also see *UNIT 1A.3*).

Materials

Fixed and processed tissue (Basic Protocol 3), cell pellet (Alternate Protocol 4), or bacterial sample (Alternate Protocol 5)
Luft's epoxy mixture (see recipe)
Acetone or propylene oxide
Orbital shaker
Transfer forceps or applicator stick
Embedding molds or capsules (available from Ted Pella; BEEM flat embedding molds, cat. no. 111-2, PTFE flat embedding molds, cat. no. 10509, or BEEM embedding capsules, size 00, cat. no. 13)
60°C oven

1. Pipet out the last rinse of acetone or propylene oxide from the fixation vial and replace with a mixture of 50% (v/v) Luft's epoxy mixture and 50% acetone or propylene oxide. Place the vial on an orbital shaker and rotate sufficiently to suspend the tissue pieces or pellet in the resin.

   Upon initial introduction of the resin, the tissue pieces or pellets will float to the top. With time, they will sink as they become infiltrated.

2. Incubate at room temperature for 30 min with rotation on the orbital shaker to aid infiltration.

3. Remove all of the 50-50 resin mixture and replace with a mixture of 75% (v/v) Luft's epoxy mixture and 25% acetone or propylene oxide. Incubate at room temperature for 30 min with rotation to aid infiltration.

   The pellets will again float to the top of the suspension and will slowly sink as the resin infiltrates the pellets.

4. Remove the resin from step 3 and replace it with 100% Luft's epoxy mixture. Rotate on an orbital shaker for 1 hr at room temperature, then remove the epoxy mixture and replace with freshly prepared 100% Luft's epoxy mixture.

5. Remove the resin and, using transfer forceps or an applicator stick, carefully transfer pellets to suitable embedding molds containing freshly prepared 100% Luft's epoxy mixture. Transfer molds to a vented 60°C oven and incubate overnight.

   A variety of embedding molds and capsules are commercially available that allow tissue to be optimally positioned for sectioning once released from the mold. For pelleted material, polyethylene caps for snap-cap sample vials (Electron Microscopy Sciences #64257-30) work well for this purpose. They come in a variety of sizes, allow for easy placement of the sample, have plenty of surface area for outgassing of residual solvent if necessary, and are reusable; in addition, the polymerized resin is easily removed. Pellets or tissue can be excised from the resin using a jeweler's saw or a single-edged razor blade if the resin is slightly heated and mounted on a blank BEEM capsule or Plexiglas pegs (Ladd Research #21830) using superglue. Small pieces of tissue can be directly placed in resin-filled BEEM capsules for polymerization. However, when BEEM capsules are used for direct embedding of tissue, it is often advantageous to employ flat embedding molds for embedding extra pieces of tissue if the need arises.

RESIN EMBEDDING OF MONOLAYER CELLS ON GLASS CHAMBERED SLIDES

ALTERNATE PROTOCOL 8

The following is a continuation of Alternate Protocol 6, describing the dehydration, resin infiltration, and polymerization steps for cultured monolayer cells.

Materials

Fixed and processed monolayer cells in chamber slides (Alternate Protocol 6)
50%, 75%, 95%, and 100% ethanol
Mollenhauer's no. 2 resin mixture (see recipe)
Single-edged razor blade

1. Dehydrate the cell monolayer in the chamber slide by sequentially adding the following solutions at room temperature to the chamber, leaving for the indicated length of time, and then draining and filling with the next solution:

50% ethanol	5 min
50% ethanol	5 min
75% ethanol	5 min
75% ethanol	5 min
95% ethanol	5 min
95% ethanol	5 min
100% ethanol	5 min
100% ethanol	5 min
100% ethanol	5 min.

   Each dehydration step is performed multiple times to insure adequate exchange of fluid around the corners of the chambers.

2. Remove the last change of ethanol and then quickly invert chamber onto an absorbent paper towel to remove excess ethanol, being careful not to allow cells to dry out or touch the paper towel. Quickly refill chambers with a mixture of 50% (v/v) Mollenhauer's no. 2 resin mixture/50% ethanol.

3. Rotate the chamber slide gently to mix contents and decant mixture. Invert over a fresh paper towel and then refill the chamber with fresh resin mixture of the same composition that was used in step 2. Cover and incubate for 30 min, rotating the slide occasionally.

4. Repeat the procedure used in steps 2 and 3 with a mixture of 75% Mollenhauer's no. 2 resin mixture/25% ethanol, then again with 100% Mollenhauer's no. 2 resin mixture. Replace the 100% resin with fresh resin after an initial 30 min incubation, for a total incubation time of 60 min in 100% resin.

5. Using a pair of forceps, carefully pull up the plastic chamber from the slide, leaving the silicone gasket intact on the glass. Carefully refill each gasket-outlined chamber with fresh 100% resin to just below the top of the gasket surface. Place in a level 60°C oven to polymerize.

6. After resin polymerization, remove the gasket from the slide and then remove the embedded cells from the slide using a single-edged razor blade.

   The application of heat to the slide may be necessary for the removal of the embedded chambers. If that is the case, set the slide on an 80°C hot plate for 30 to 45 sec.

   Pieces of the embedded monolayer can be cut out and mounted on plastic pegs so that they are sectioned either en face or in cross-section. When sectioning across the monolayer, the use of grids with Formvar support will provide stability to the section.

ALTERNATE PROTOCOL 9

RESIN EMBEDDING FOR THIN SECTION IMMUNOGOLD LABELING

Preservation of sample antigenicity is of paramount importance when choosing an embedding resin for thin section immunogold labeling. Dehydration and embedding protocols must minimize loss of potential antigenic sites. This generally requires the use of ethanol alone as the dehydrating agent, an altered infiltration schedule, and the use of a more hydrophilic embedding resin coupled with room-temperature or cold polymerization. Several specific resins are available, all acrylic based, that offer good antigen protection, although some require elaborate cooling chambers in order to optimize their superior antigenic preservation qualities during polymerization. The resin protocol described below utilizes a one-part resin, which only needs an accelerator for room temperature polymerization and yields consistent results.

Materials

Fixed and processed tissue or cell sample (Alternate Protocol 7)
LR White resin (Polysciences)
LR White accelerator (Polysciences)
Embedding molds (available from Ted Pella; BEEM flat embedding molds, cat. no. 111-2, PTFE flat embedding molds, cat. no. 10509, or BEEM embedding capsules, size 00, cat. no. 13)
Cooled water bath or cooling block (optional)
Jeweler's saw
Plexiglas pegs (Ladd Research, cat. no. 21830; *http://www.laddresearch.com/*)
Cyanoacrylate glue (e.g., Superglue, Krazy Glue)

1. Following the last two washes of tissue in 100% ethanol described Alternate Protocol 7, infiltrate the sample with LR White resin as follows. Remove the ethanol and replace with 100% LR White resin, incubate 1 hr at room temperature, then replace with fresh 100% LR White resin and incubate an additional 1 hr at room temperature. Finally, replace again with fresh 100% LR White resin and incubate an additional 1 hr to overnight at room temperature.

   See technical data sheet for LR White resins at http://www.polysciences.com/shop/assets/datasheets/305A.pdf.

2. To 10 ml LR White resin, add 20 µl LR White accelerator and mix well. Partially fill embedding mold(s) with the resin/accelerator mixture. Remove LR White resin–infiltrated tissue pieces or pellets from their vials using fine-tipped forceps

or a wooden stick with a fine tip. Deposit the tissue pieces into the resin-containing embedding mold(s). Allow molds to polymerize for 48 hr at room temperature.

If flat embedding molds are used, it may be necessary to exclude air from the surface of the resin and overlay the mold with a piece of ACLAR film (Ted Pella, cat. no. 10501-10) to exclude as much air as possible from the surface of the mold. Embedding in BEEM or gelatin capsules is preferred over the use of flat embedding molds, as the surface area exposed to air is minimized and the capsules do not require the film overlay.

3. Remove polymerized block(s) from embedding mold(s) or capsule(s). If the tissue has been flat-embedded, cut out the desired area with a jeweler's saw and mount on Plexiglas specimen-mounting pegs (that fit into the specimen chucks of the ultramicrotome) using cyanoacrylate glue.

OVERVIEW OF ULTRAMICROTOMY

BASIC PROTOCOL 5

As noted previously, the goal of ultramicrotomy is to prepare thin sections between 50 and 90 nm thick. The generation of sections that adhere to one another as straight ribbons using an ultramicrotome is an extremely challenging manual skill that requires a high level of dexterity. Ultramicrotomy is not a technique that can be effectively learned using a protocols manual and is therefore given as an overview rather than a method in this unit.

While it is assumed that the reader has access to ultramicrotomy support service or hands-on training in this key element of specimen preparation for analysis of thin sections, a brief description of ultramicrotomy follows. In order to thin-section embedded tissue that has been placed in an embedding mold, it must be mounted in a holder for trimming. Some ultramicrotomes have different types of holders that can grip flat embedded tissue or hold a cylinder of plastic with a tapered end (pyramid shape) containing the tissue. The tapered end must be trimmed further to form a small trapezoid of ~200 μm^2. This is usually done by hand with a single-edged razor blade under a stereo microscope and requires considerable dexterity and practice. Some microtomes have specimen holders, which permit rapid trimming of the block to form the trapezoid with a highly polished face.

Thin sections are cut with either a glass or diamond knife. Glass knives are normally made freshly with a knife-maker instrument, which breaks ~1-in. (~2.5-cm) squares of glass from high-quality glass strips. The squares of glass are scored diagonally and carefully broken to form triangular pieces, one edge of which contains the knife edge. A commercially made plastic trough is sealed with dental wax. Alternatively, a trough or "boat" is fashioned around the knife edge with Mylar or other tape that will provide a distilled water–filled reservoir that reaches the edge of the knife and that will allow sections to float away from the edge of the knife from the block during the cutting stroke of the microtome arm. The wide side of the trapezoid-shaped block face makes first contact with the knife edge during the cutting stroke of the microtome. Prior to collecting sections, the block face must be "polished" in preparation for thin sectioning by cutting initial sections until the block face appears to have a mirrored surface. Thin sections are then cut, and individual trapezoid-shaped sections adhere to the knife edge until the subsequent section displaces the previous section during the cutting stroke of the microtome arm. With each consecutive section, a ribbon resembling the shape of a tapeworm floats into the boat (Fig. 2B.1.2). These ribbons are typically manipulated into parallel rows with a fine eyelash attached to the end of a small applicator stick just prior to picking up the sections on a 3-mm-diameter electron microscope grid. Sections are adhered to the grid by lowering it with a pair of forceps above the sections, gently touching the grid to the surface of the water, and then lifting the grid off the water surface in a smooth motion. Residual water is removed from the edge of the grid with a wedge of filter paper as is done for negative staining.

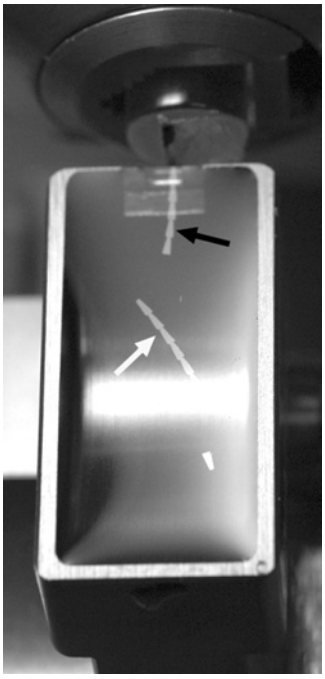

Figure 2B.1.2 Thin sections (~70 to 80 nm) prepared on a diamond knife as seen through a stereo microscope. Trapezoid-shaped sections are cut sequentially, adhering to the knife edge and forming ribbons during sectioning (black arrow). They are visible as the result of reflected light from above, which generates an interference pattern that can be used to estimate section thickness. As sections accumulate, they can be separated into smaller ribbons, which float on the water surface and can be aligned for collection onto a grid. The width of the trough of the diamond knife shown is ~10 mm.

Copper grids are routinely used for most biological samples; nickel grids are usually used with samples prepared for immunogold electron microscopy. The 50- to 90-nm thickness of each section can be estimated by adjusting the microtome stereomicroscope viewing and illumination system to detect interference colors reflecting from the sections. Generally, gray sections indicate a thickness of less than 60 nm, while silver sections range from 60 to 90 nm (the typical section thickness for most biological samples), and gold sections range from about 90 to 150 nm. The diamond knife, which contains a high-quality diamond with a cleaved knife edge mounted in an aluminum holder fashioned into a trough for floating sections, is a considerably more expensive and longer-lasting alternative to disposable, freshly made glass knives.

BASIC PROTOCOL 6

HEAVY METAL (AND IMMUNOGOLD) STAINING OF THIN SECTIONS

Heavy metal staining of thin sections is normally required to impart contrast in thin-sectioned biological materials. Two of the most widely used heavy metal post-staining solutions (i.e., uranyl acetate and lead citrate) are described. It is also possible to immunolocalize antigens in thin sections using colloidal gold particles of various sizes (5 to 20 nm) that effectively scatter electrons, which can be easily seen even when sections are post-stained with uranyl acetate and lead citrate.

Materials

Thin sections collected on copper grids (Basic Protocol 5)
Uranyl acetate staining solution (see recipe)
Lead citrate staining solution (see recipe)

Whatman no. 4 filter paper
Spray bottle with distilled H_2O
Grid box

1. Place 50-µl drops of uranyl acetate staining solution onto a clean Parafilm surface using the technique described in Basic Protocol 1.
2. Using forceps, place grids containing sections face-down onto uranyl acetate drops using the technique described in Basic Protocol 1, and incubate for 3 to 10 min at room temperature.
3. Remove grids from uranyl acetate drops and carefully direct a gentle stream of Milli-Q or deionized distilled water from a spray bottle onto the section side of the grid for 10 to 15 sec, slowly wetting the back side of the grid (i.e., the side without the section).
4. Remove excess water with a wedge of Whatman no. 4 filter paper (see Basic Protocol 1); do not let section dry.
5. Place 50-µl drops of lead citrate staining solution onto a clean sheet of Parafilm and deposit the grid, section-side-up, into the drop. Incubate 2 to 5 min at room temperature. Use a new drop of stain for each grid.
6. Remove grids and gently run a stream of Milli-Q or deionized distilled water from a spray bottle down the tips of the forceps onto the grid to remove residual stain.
7. Remove excess water with a filter paper wedge and ensure that no water remains between the tips of the forceps by sliding a piece of filter paper down between them while releasing the grid from the forceps onto a clean piece of filter paper.
8. Ensure that grids are completely dry and place them into a grid box. Store in a desiccator until ready to image in the electron microscope.
9. Place lead and uranyl waste in appropriate containers for disposal.

IMMUNOGOLD POST-EMBEDDING STAINING OF THIN SECTIONS

ALTERNATE PROTOCOL 10

Localization of antigens in thin sectioned material usually requires special fixation procedures to limit the extent of macromolecular cross-linking, as well as embedment in a plastic resin which preserves antigenic sites. The following is one of many alternative procedures that can be used to localize antigens with immunogold reagents.

Materials

Thin sections on 300-mesh Formvar-coated nickel grids (Basic Protocol 5)
Immunogold blocking buffer (see recipe)
Primary antibody against antigen of interest and control (irrelevant) primary antibody of same Ig class
TBS-Tween (see recipe)
Reagents for colloidal gold labeling—one of the following:
  Colloidal gold-labeled secondary antibody against species from which primary antibody was obtained
  Biotinylated secondary antibody against species from which primary antibody was raised, and streptavidin-conjugated colloidal gold
  Colloidal gold-labeled protein A and/or protein G
TEM primary fixative 2 (optional; see recipe)
Whatman no. 4 filter paper
Spray bottle
Grid box

Additional reagents and equipment for etching of epoxy embedding resin (optional; see Support Protocol 2) and uranyl acetate/lead citrate staining of thin sections (see Basic Protocol 6)

1. If the sample is not embedded in LR White resin, perform Support Protocol 2.

Block sample

2. Place an ~50-µl drop of immunogold blocking buffer onto Parafilm and float sample-containing grid on top of it for 30 min as a blocking step.

Treat with primary antibody

3. Prepare appropriate dilution of primary antibody in TBS-Tween, place 50-µl droplets of the diluted antibody onto Parafilm, then place grids on droplets and incubate at room temperature for 2 hr.

   Controls can be processed at the same time and should include both an irrelevant primary antibody of the same class and another preparation without primary antibody.

4. Remove grid and draw off excess solution with a filter paper wedge (see Basic Protocol 1) and gently rinse with a stream of TBS-Tween from a spray bottle.

Label with colloidal gold

5a. *To use colloidal gold–conjugated secondary antibody:* Place appropriate dilution of colloidal gold-conjugated secondary antibody onto Parafilm in 50-µl droplets, then transfer grids onto droplets and incubate at room temperature for 60 min.

5b. *To use biotinylated secondary antibody:* Place appropriate dilution of biotinylated secondary antibody onto Parafilm in 50-µl droplets, then transfer grids onto droplets and incubate at room temperature for 1 hr. Wash grids briefly in 50-µl droplets of distilled water, then transfer to 50-µl droplets of streptavidin-conjugated colloidal gold and incubate at room temperature 60 min.

5c. *To use protein A and/or protein G:* Place appropriate dilution of colloidal gold–conjugated protein A, protein G, or protein A/G onto Parafilm in 50-µl droplets, then transfer grids onto droplets and incubate at room temperature for 60 min.

6. Rinse grids 1 min in a succession of four or five 50-µl droplets of TBS-Tween on Parafilm.

Post-fix (optional) and stain with heavy metals

7. *Optional:* Post-fix by transferring grid to a 50-µl droplet of TEM primary fixative 2 for 10 min, then rinse in a 50-µl droplet of TBS-Tween for 1 min.

8. Wash grid with a stream of Milli-Q or deionized distilled water from a spray bottle.

9. Stain grids with uranyl acetate and lead citrate as described in Basic Protocol 6.

10. Rinse grids in a gentle stream of distilled water and remove excess water with a filter paper wedge.

11. Ensure that grids are completely dry and place them into a grid box. Store in a desiccator until ready to image in the electron microscope.

ETCHING OF EPOXY EMBEDDING RESIN TO INCREASE IMMUNOGOLD STAINING

The following steps may precede Alternate Protocol 10 if the tissue is not embedded in LR White resin. Tissues subjected to optimal fixation for immunolocalization with colloidal gold reagents embedded in an epoxy resin may be etched to increase access of primary antibody to antigenic sites in the sectioned tissue.

Materials

Plastic etching solution: 5% (w/v) sodium metaperiodate (prepare fresh)
Thin sections on 300-mesh Formvar-coated nickel grids (Basic Protocol 5)
TBS-Tween (see recipe)
Spray bottle

1. Place 50-µl drops of plastic etching solution onto clean Parafilm.
2. Place grids section-side-down on etching solution for 10 min at room temperature.
3. Gently run a stream of TBS-Tween from a spray bottle down the tips of the forceps onto the grid to wash off etching solution.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified or deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Aldehyde quenching solution

Prepare 100 mM glycine by dissolving 0.75 g in 100 ml phosphate/sucrose rinse buffer (see recipe). Alternatively, prepare 100 mM ammonium chloride by dissolving 0.53 g ammonium chloride in 100 ml phosphate/sucrose rinse buffer. Store up to 1 month at 4°C.

Ammonium molybdate staining solution

Prepare a 1% to 4% (w/v) solution of ammonium molybdate tetrahydrate (e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies) in water. Adjust with 1 M KOH or NaOH to pH 7.5. Store up to several months at 2° to 8°C.

Ammonium molybdate is slightly more hydrophilic than phosphotungstic acid and may result in a more even distribution of sample and stain for some specimens.

Immunogold antibody dilution buffer

To 180 ml Milli-Q-purified water or distilled H_2O add:
1.04 g sodium phosphate, monobasic ($Na_2PO_4 \cdot H_2O$)
8.70 g sodium phosphate, dibasic, heptahydrate ($Na_2HPO_4 \cdot 7H_2O$)
4 g bovine serum albumin (BSA), fraction V
0.6 ml Tween 20
Milli-Q-purified or deionized distilled water to 200 ml
Store up to 2 months at 4°C

Final concentrations 1 mM PBS containing 2% BSA and 0.3% Tween 20.

Immunogold blocking buffer

To 100 ml TBS-Tween (see recipe) add:
1 g bovine serum albumin (BSA), fraction V
3 ml normal serum from species in which secondary antibody was generated
Stir to dissolve
Store up to 6 months at 4°C

Final concentrations: 1% (w/v) BSA, 3% (v/v) serum in TBS-Tween.

Lead citrate solution

Add the following items to 30 ml distilled H_2O in the following order:
1.33 g lead nitrate
1.76 g sodium citrate, dihydrate
5 ml of 1 N NaOH
Stir 10 min to dissolve
Add an additional 15 ml H_2O
Store solution for 3 to 6 months at 4°C

The solution becomes cloudy when sodium citrate is added and then clear when NaOH is added.

Luft's epoxy mixture

Combine the following components in a plastic disposable beaker and mix thoroughly while avoiding the generation of bubbles in the resin:
12 g Epon 812 (e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies)
7.0 g nadic methyl anhydride (NMA; e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies)
6.0 g dodecenyl succinic anhydride (DDSA; e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies)
0.5 g 2,4,6-tri-dimethylaminomethyl phenol (DMP-30; e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies)
Prepare fresh

Mollenhauer's no. 2 resin mixture

Combine the following components in a plastic disposable beaker and mix thoroughly while avoiding the generation of bubbles in the resin:
6.2 g Epon 812 (e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies)
8.1 g Araldite 506 (e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies)
10.0 g dodecenyl succinic anhydride (DDSA; e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies)
0.5 g 2,4,6-tri-dimethylaminomethyl phenol (DMP-30; e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies)
Prepare fresh

Osmium tetroxide post-fixative

In a fume hood and wearing nitrile gloves, combine the following in a 25-ml graduated cylinder:
2.5 ml of 4% aqueous osmium tetroxide stock from sealed ampule (see recipe for TEM fixative stock solutions)
5 ml phosphate/sucrose buffer stock (see recipe)
2.5 ml Milli-Q-purified or distilled water
Mix and keep on ice for immediate use
Prepare fresh each time

Final concentrations: 1% (w/v) osmium tetroxide in 100 mM phosphate buffer containing 100 mM sucrose, pH 7.4.

Phosphate/sucrose buffer stock solution

To 150 ml of Milli-Q-purified water or distilled water add:
1.04 g sodium phosphate monobasic ($Na_2PO_4 \cdot H_2O$)
8.70 g sodium phosphate dibasic heptahydrate ($Na_2HPO_4 \cdot 7H_2O$)
13.68 g sucrose
Milli-Q-purified or deionized distilled water to 200 ml
Store up to 2 months at 4°C

Final concentrations: 200 mM sodium phosphate plus 200 mM sucrose, pH 7.4.

Phosphate/sucrose rinse buffer

Combine 50 ml phosphate/sucrose buffer stock solution (see recipe) with 50 ml Milli-Q-purified or deionized distilled water. Store up to 2 months at 4°C.

Final concentrations: 100 mM sodium phosphate plus 100 mM sucrose, pH 7.4.

Phosphotungstic acid staining solution

Prepare 1% to 2% (w/v) solution of phosphotungstic acid (e.g., Electron Microscopy Sciences, Ted Pella, or SPI Supplies) in water. Stable for months (pH 7.0) at 2° to 8°C.

Solution is acidic and should be adjusted to a pH ranging from 5.0 to 7.0 with 1 M KOH or NaOH. A pH of 7.0 is most often used.

This is a versatile stain for viruses, bacteria, subcellular structures, and macromolecules.

TBS-Tween

To 1 liter of distilled water add:
6.1 g Trizma base
9 g NaCl
Mix to dissolve
Adjust pH to 7.6 using 1 N HCl
Add 0.5 ml Tween 20
Store up to 6 months at 4°C

Final concentrations: 0.5 M Tris-buffered saline, 0.05% Tween 20.

TEM fixative stock solutions

The most convenient source for EM-grade fixative stocks is from commercial electron microcopy suppliers (e.g., Electron Microscopy Sciences, Energy Beam Sciences, Structure Probe/SPI Supplies, or Ted Pella). For example, stock solutions of 16% paraformaldehyde, 8% or 25% glutaraldehyde, and 4% aqueous osmium tetroxide can be purchased in 10-ml quantities in sealed ampules individually or in boxes of 10 or more units. These stocks typically have a shelf life of 12 months if unopened, but once opened must be used in fixative solutions on the same day, preferably within hours of preparation.

Uranyl acetate staining solution

Dissolve 1 g uranyl acetate (Polysciences, cat. no. 21447) in 100 ml Milli-Q-purified or distilled water by stirring overnight at room temperature. Stable for months at 2° to 8°C in the dark.

Uranyl acetate can produce an image with higher contrast than phosphotungstic acid. Because uranyl acetate has smaller grain size than phosphotungstic acid, it has the potential for producing an image with higher resolution. Uranyl acetate is a useful stain for viruses, (especially since it tends to inactivate them) and macromolecules; however, structures sensitive to low pH may be damaged. Specimens stained with uranyl acetate may exhibit both positive and negative staining. Uranyl acetate should not be used with samples prepared in phosphate buffer unless they are first rinsed either in distilled water, or, in the case of unfixed biologically sensitive organisms, HEPES buffer, as uranyl ions form an insoluble uranyl phosphate.

COMMENTARY

Background Information

Negative staining TEM

Negative staining is one of the simplest yet most useful methods for imaging small particles in suspension. Introduced in the late 1950s for the study of viruses, it has been widely used for diagnostics in infectious diseases and for structural analysis of particulates ranging from bacteria to viruses to macromolecules. Because of the simplicity of the technique,

it is also a very practical method for rapid screening and quality assessment of fractionated cellular constituents and protein preparations and for screening contaminants of cell cultures. In recent years, bioterrorism threats have increased awareness of the utility of negative staining for identifying infectious disease agents, e.g., for assisting in poxvirus diagnosis and/or ruling out other causes of illness involving rash. Electron microscopy techniques, including negative staining, can provide relevant information in conjunction with other investigative techniques to identify and/or further the understanding of infectious diseases. Useful information regarding sample collection and preparation, and particle enrichment in the application of electron microscopy for identification of infectious disease agents has been reviewed by Hazelton and Gelderblom (2003). Other considerations for application of negative staining in the ultrastructural analysis of proteins and macromolecular complexes have been reviewed by Ohi et al. (2004).

By embedding particulate samples in an air-dried heavy metal solution, which is thought to occupy the hydrated sample surface and associated structures, the transparent (i.e., electron translucent) sample is surrounded by a dark halo of stain that scatters electrons, resulting in a negative image of the sample. Quite a range of different negative-staining salts are available (see Bremer et al., 1992), each exhibiting a variety of interactions with the sample due to properties of the stain (e.g., size of the metal salt crystals affecting resolution, as well as pH of the stain and other considerations) that can affect sample-stain interactions. These interactions can damage some fragile structures and are an important consideration when choosing a suitable negative stain. While there are numerous negative stains, those listed for use in Basic Protocol 1 are widely used and considered reliable for a wide variety of applications. Phosphotungstic acid and ammonium molybdate yield negatively charged metal oxide ions and have the advantage that the pH of the stains can be adjusted. Uranyl acetate is a positively charged stain that produces high contrast and has fixative properties; however, the staining solution is acidic (pH ~4.5) and pH adjustment without precipitation of the stain is limited. The above-referenced stains have been selected as general-purpose negative stains; however, other formulations may be advantageous for specific applications (see Hayat and Miller, 1990). For example, uranyl formate, despite its relative instability, is the highest-density uranyl salt with smallest grain size, and is often required for structural analysis of macromolecules, particularly those of smaller size (Ohi et al., 2004).

It is important to note that the utility of negative staining can be significantly enhanced in conjunction with immunoelectron microscopy methods to improve sensitivity of sample (usually virus) detection, for enrichment of specific sample components, for rapid detection and diagnosis of infectious agents, and/or for localization or structural identification of antigens within a sample. For example, rapid immunologic methods such as solid-phase immunoelectron microscopy, which involves attachment of antibodies or protein A plus antibodies to the grid (Pegg-Feige and Doane, 1983) and the serum-in-agar method, which employs pooled human immunoglobulins or specific antibodies in agar (Anderson and Doane, 1973), are both used to concentrate antigens by immune capture and are useful to search for specific and/or unknown infectious agents prior to negative staining. Many of these applications are described in Doane and Anderson (1987).

Immunoelectron microscopy

In general, immunoelectron microscopy applications involve the direct electron microscopy imaging of antigen-antibody complexes. A wide range of applications have been developed to improve the sensitivity of microbe detection and to reveal the ultrastructure of elusive organisms. When used to increase detection sensitivity, antibodies serve to aggregate viruses or bacteria in solution or onto a grid for negative staining. Immunogold staining can be combined with negative staining to provide a sensitive technique that enables the identification and visualization of individual antigens by TEM, and which can be useful in the identification of the biologic agent itself.

Fixation techniques for TEM

Ultrathin sections of samples provide insights regarding the internal structure of chemically stabilized samples. Individual sections that are used to provide images in the TEM represent two-dimensional views of three-dimensional objects; therefore, considerable efforts must be made to understand the three-dimensional ultrastructure of a sample. It is also important to appreciate that the appearance of the thin-sectioned sample is the result of the multiple steps in the protocol, including isolation of the sample, one or more chemical fixation steps, dehydration and embedding, sectioning, and staining.

Embedding techniques for TEM

The term epoxy resin, as used in electron microscopy, usually denotes a mixture of at least three and sometimes four components: resin, hardener (frequently a mixture of two hardeners to yield polymerized resin with the correct characteristics), accelerator, and sometimes a resin modifier. The resin formulations provided herein yield reproducible results for the preparations mentioned in this unit.

The component Epon 812 is used in two of the formulations outlined above and come from their original citations (Luft, 1961; Mollenhauer, 1964). This particular component is no longer produced by the original manufacturer, but suitable substitutes are available. These include Poly/Bed 812 from Polysciences, EMbed 812 from Electron Microscopy Sciences, SPI-Pon 812 from SPI Supplies, LX-112 from Ladd Research, and Eponate 812 from Ted Pella.

TEM of thin sections

Contrast in thin-sectioned biological materials is generated in the electron microscope as the result of scattering of electrons by macromolecular constituents of the sample that have bound heavy metal stains. In several of the tissue-processing protocols given above, both osmium tetroxide and uranyl acetate were used because of their combined properties as postfixatives and heavy metal stains. Additional electron-scattering stain is usually deposited on thin-sectioned samples shortly after collecting sections onto a grid and is usually the last step of sample preparation prior to viewing sections on the TEM.

Commercially available colloidal gold conjugated to protein A/G, secondary antibodies, or streptavidin can also be used as an electron-scattering agent for immunolocalization of antigens in thin sections. Many of the suppliers of these products have recommended protocols and specific reagents for use with their products, although the protocol provided here is fairly generic.

Critical Parameters and Troubleshooting

Negative staining TEM

Several iterations of this basic procedure are usually required to optimize the concentration and distribution of the sample particles on the grid. The sample dilution is usually determined empirically. Stain density can be varied by adjusting the amount of excess stain during removal with the filter paper wedge, by additional washing steps, and/or by reducing the concentration of the staining solution. As with any technique, technical problems can arise with the sample itself (e.g., concentration, purity, stability, and solute composition), the substrate used to support the sample (stability of support film under the electron beam, hydrophilicity of the support film affecting sample distribution, etc.), and the stain selected (stability of sample in stain, grain size, etc.). A list of some of the technical problems that can occur with negative stain preparations, some of their causes, and possible solutions are summarized in Table 2B.1.1.

Immunoelectron microscopy

Adequate controls must be incorporated into the procedure for the proper analysis of experimental results. Controls should include a grid in which the primary antibody incubation is omitted and a grid incubated with a nonspecific IgG of the same species as the primary antibody to identify nonspecific binding. Adjustments to increase labeling and decrease nonspecific binding may include, for example, use of different or additional blocking agents and/or concentrations and blocking times, changing concentration or incubation time of primary antibody, or addition of more rinses (see Table 2B.1.2).

When considering the use of the protein A–, protein G–, or protein A/G–gold procedure, it is important to understand that, while these conjugates interact with mammalian immunoglobulins, their individual affinity for immunoglobulins is not equivalent for all species or for all antibody subclasses. For example, in the case of polyclonal antibodies, protein A or protein G can be used for human, pig, rabbit, or mouse. Horse and cow immunoglobulins have relatively high affinity for protein G, while sheep, goat, chicken, hamster and rat antibodies will bind protein G weakly. Guinea pig immunoglobulins will bind protein A. For use with monoclonal antibodies, human isotypes IgG_1, IgG_2, and IgG_4 have good affinity for protein A or protein G, while human IgG_3 has good affinity for protein G only. Protein G is used with rat isotypes, whereas mouse isotypes $IgG_{1,}$ $IgG_{2a,}$ $IgG_{2b,}$ and IgG_3 all bind protein G, and mouse IgG_{2a} and IgG_{2b} also bind protein A. The use of protein A/G can therefore be useful if the antibody isotype is unknown.

Another important consideration is size and affinity of the conjugated gold particles for the primary antibody. In general, the smaller the gold particle, the lower the steric hindrance to

Table 2B.1.1 Troubleshooting Guide for Negative Staining

Problem	Possible cause	Solution
Sample not uniformly dispersed on grid	Grids with support films tend to be hydrophobic	Grids with support films can be glow discharged shortly before staining.
		Wetting agents can be used make grids more hydrophobic. Incubate grids for 30-60 sec on a drop of bacitracin (50 μg/ml), poly-L-lysine (1 μg/ml), or BSA (0.05% to 0.005% w/v).
		Alternatively, wetting agents can be added directly to the sample to aid spreading.
Stain not uniformly dispersed on grid	Grids with support films tend to be hydrophobic	Can add wetting agents at lower concentrations than those mentioned above directly to the stain
		If using phosphotungstic acid, switch to a more hydrophilic stain such as ammonium molybdate
Stain density too dense to discern structural details	Too much stain retained on the grid	Allow more stain to absorb onto the filter paper before removing grid during staining
	Stain concentration too high	Reduce stain concentration
	Adjust accelerating voltage on TEM	Increasing acceleration voltage can result in the reduction of image contrast
Structural details of sample surface are not resolved	Grain size of negative stain may be too large	Phosphotungstic acid grain size is ~0.9 nm whereas uranyl salts are approximately half of this. Molecular dimensions of the negative stain must be smaller than dimensions of structures in the hydrated sample surface.
Stain precipitate	Buffer containing phosphate forms insoluble salts with uranyl salts	Wash sample with additional distilled water to remove phosphate
		Resuspend sample in a non–phosphate containing buffer such as HEPES or PIPES
		Change stain
Unstable coating during examination in the electron microscope	Heating of the film due to interaction of the electron beam with the film and the specimen	If using Formvar-coated grids, switch to those with a carbon coating
		Stabilize the film by slowly increasing the intensity of the electron beam over time as it crosses the grid
		Coat grid with an additional layer of indirect carbon using a vacuum evaporator

Table 2B.1.2 Troubleshooting Guide for Negative Stain Immunoelectron Microscopy

Problem	Possible cause	Solution
No gold labeling	The antigen may be present in very low amounts	Use longer incubation times and more concentrated primary antibody
	The primary antibody may be bad, e.g., due to poor titer, age, improper storage, improper dilution, or excessive freezing and thawing	If available, run a positive control to check
	The pH of solutions may be excessively acidic or alkaline	Adjust the pH
	Heavy negative staining may mask gold particles	Reduce the concentration of negative stain and/or use larger gold particles. Use higher magnification to visualize gold particles (e.g., 200,000× for 5 nm; 100,000× for 10 nm; 80,000 for 15 nm; 50,000 for 20 nm).
	The section may not have been exposed to solutions (as a result of being wrong-side-up) if on a plastic film	Be careful when transferring and washing grids that the side of the grid containing the sample is kept facing up
	The antigen may be destroyed by preparative procedures	Use a different procedure. Consider brief fixation in 1% paraformaldehyde.
Excessive background gold particles	Ionic concentration of solutions may be too low	Use increased salt concentration (up to 2.5%). Add ovalbumin, BSA, or normal goat serum (not for protein A) to ~1% in incubation solutions.
	Sections may have been inadequately washed between incubations	Increase washing steps
	Nonspecific charge attraction of antibody can cause background	Use 1% detergent (e.g., Tween 20) in all solutions. Include normal goat serum (not for protein A) in all solutions. Increase concentration of normal goat serum before primary antibody incubation.
	Free aldehyde groups in fixed tissue may be a source of background	Reduce by exposing sections to 0.5 M ammonium chloride for 1 hr before incubations.
	The primary antibody concentration may be too high	Dilute by orders of magnitude
	The gold conjugate concentration may be too high	Dilute further
Clustering of gold particles	Clumped primary antibody.	Use fresh antiserum
	Clustering can be caused by the natural amplification factor of the gold conjugate. For IgG–gold conjugates, up to 10 conjugated gold particles may attach to the Fc component of the primary antibody, producing the appearance of clusters on the section. This does not occur with protein A conjugates.	Use higher dilution of gold conjugates if desired
Gold particles over surface of support film	Nonspecific binding	Incorporate additional blocking steps prior to delivery of primary antibody

antigen detection; however, a confounding consideration is that the smaller the gold particle, the fewer the molecules of protein A bound per gold particle. For example, it has been estimated that a 5-nm gold particle can bind about four protein A molecules, whereas a 20-nm particle can bind ~48 protein A molecules. Similarly, a 5-nm gold particle can bind about three secondary antibody molecules, while 10-nm gold particles can bind ~12 antibody molecules and 20-nm gold particles can bind ~48 antibody molecules. Therefore, the affinity of the gold particle can increase with increasing size. An additional consideration when immunogold staining is combined with negative staining is that the smallest gold particles (e.g., 5 nm) are much more difficult to detect in negatively stained preparations; therefore, the recommended range of gold particle sizes is from 10 to 30 nm.

The use of colloidal gold-tagged secondary antibodies described above is an alternative to protein A/G and involves a secondary antibody generated in a different species against the Fc fragment of the primary antibody. A third alternative involves the use of biotinylated secondary antibodies that are subsequently rendered visible in the TEM by binding of colloidal gold–conjugated streptavidin. Immunolocalization of two antigens in the same preparation is also possible if compatible primary antibodies are available (e.g., primary antibodies generated in different species). This procedure involves the sequential indirect labeling of two primary antibodies with secondary antibodies conjugated to gold particles of different size.

Fixation techniques for TEM

Preparation of the sample and the choice of fixative, stains, and plastic resin can affect the quality of the preparation. Unfortunately, there is no optimal fixative for all biological samples, although freshly prepared fixatives containing glutaraldehyde are considered among the best primary fixatives currently available. The useful property of glutaraldehyde, a five-carbon dialdehyde, is its ability to cross-link proteins. Freshly prepared glutaraldehyde at neutral pH will also polymerize into longer chain dialdehydes, which provide cross-links of variable size that efficiently stabilize protein structure. Paraformaldehyde is commonly combined with glutaraldehyde to better stabilize biological samples. In general, when fixatives are identified as containing paraformaldehyde, it usually means that they contain formaldehyde generated from the paraformaldehyde polymer of formaldehyde. The advantages of this freshly prepared one-carbon monoaldehyde, formaldehyde, which reacts in an aqueous solution as methylene glycol, are its rapid penetration properties and ability to polymerize and cross-link proteins and nucleic acids, and also modify the chemical properties of lipids. While not included here, acrolein is another highly reactive fixative that is often used in combination with other aldehydes such as glutaraldehyde and/or paraformaldehyde for fixing very dense specimens.

The primary aldehyde-fixation step is frequently combined with a post-fixation step involving osmium tetroxide, which acts as a fixative and electron stain and also as a mordant to enhance staining of the sections with lead. The primary fixatives and post-fixatives described in these protocols are generally considered to be good starting points for the preservation of solid tissues and cells in either suspension or pellets. More specific protocols are available in the literature that address specific fixation requirements of specific organisms and cells (Fassel et al., 1997; Karlyshev et al., 2001). Variations on fixative concentrations, fixation times, buffer types and osmolarity are all important considerations for optimal preservation of any particular sample.

The preparation of individual cells or aggregates of cells poses special challenges. Generating a sample of adequate size for processing usually requires concentration of cells by centrifugation into pellets. Maintenance of pellet integrity is also an important consideration during primary fixation, post-fixation, post-staining, dehydration, and embedding. If cells are not sufficiently concentrated during centrifugation before addition of fixative, as described in Alternate Protocol 5, there can be a tendency for the pellet to disintegrate during subsequent processing. If the pellet is of sufficient size to yield multiple slices for processing, some cell loss can be tolerated. If not, then it is important to encase the slices of pellet in a thin layer of agar to preserve the integrity of the pellet. Proper temperature management of the agar used to encase suspension fixed cells is also important during the preparative procedure. The agar must be warm enough to remain molten when the cells are introduced while at the same time not being hot enough to damage tissue and/or to allow the cells to effectively spin out of the agar during centrifugation. It is advisable, if the sample size permits, to subdivide the sample and perform multiple runs to ensure preservation of the pellet.

Preparation of tissues and cells for immunogold labeling requires a balance between preservation of tissue/cell ultrastructure and the preservation of antigens. The goal is to optimize these compromises in order to combine adequate structural detail and adequate immunochemical labeling. Concentrations of glutaraldehyde that are normally used for ultrastructure most often destroy or cross-link antigens. Therefore paraformaldehyde alone or in combination with dilute glutaraldehyde (0.1% to 1%) is a useful starting point for fixation. Tissues processed for immunolabeling in thin sections require special embedding procedures, as discussed below.

The protocols presented in this section can be classified as representing classical approaches to the preservation of tissue for examination by thin-section electron microscopy. Other techniques are available that offer the advantages of potentially better preservation of specimen ultrastructure and possibly shorter processing times at the expense of having specialized processing equipment, additional safety concerns, and special modifications of the electron microscope itself. Freeze substitution, accomplished by the formation of vitreous ice within the sample by either plunging the sample into cooled liquid propane or ethane or exposing samples to a jet of liquid propane or to high-pressure freezing, offers the advantage of better preservation of ultrastructure, and usually better antigen preservation as well. Microwave processing techniques offer the advantage of rapid specimen fixation and embedding times. All of these techniques require specialized preparation protocols adapted to suit the specific equipment on hand, and are beyond the scope of this chapter.

Embedding techniques for TEM

By their nature, epoxy resins and their components are viscous, and this viscosity tends to increase with time after the individual components of the resin are mixed. Because of this, it is advisable to prepare resins in small batches just prior to use. Dilutions of complete resin mixtures in dehydration agents are prepared by dispensing the resin components into new disposable beakers. Preparations of resin and dehydration agent are kept capped to prevent evaporation of the agent over time, an especially important consideration when working in a fume hood. In the case of epoxy resin, accurate weighing of all components and dilution of resins is of critical importance in their preparation to ensure a resin mixture that will give the proper characteristics. It is also important that the individual components of the resin be completely mixed. Inadequate mixing of resin components can result in poorly infiltrated samples that section poorly, that have poor specimen contrast, and that do not hold up in the electron beam. Shaking or vigorous stirring results in well mixed resin. Any resulting entrapped air is liberated upon standing or can be removed by use of a vacuum chamber for 5 to 10 min or until the generation of gas bubbles stops (the vacuum provided by a one-stage rotary pump is sufficient). Caution must be used when degassing the resin mixture, as it can boil out of the disposable beaker; careful monitoring of the mixture in the vacuum chamber is necessary. Furthermore, the ability to introduce air into the chamber to minimize initial boiling of the resin during degassing is also necessary.

The decision to process cultured cells as pellets or as intact monolayers warrants additional comment. While scraping and pelleting monolayers provides a useful approach for collecting and concentrating a sufficient number of cells for processing, the disadvantage of this approach is that scraping of monolayers can damage some cells and disrupt the cell-substrate interactions, and often cell-cell interactions as well. Figure 2B.1.3 shows an example of virus-infected cultured chicken spleen cells prepared as a pellet.

When there is a need to evaluate the polarity of cells and/or cell-cell and cell-substrate interactions, processing of monolayers in chambered slides is a useful, albeit more complicated alternative that poses some special challenges. Figure 2B.1.4 shows an example of HeLa cells prepared as a monolayer in chamber slides along with the appearance of the sample at different stages of the processing steps, ending with the embedment of the entire monolayer for thin sectioning.

The individual epoxy resin–filled chambers with embedded cells, outlined by the silicone gasket, should come free cleanly from the glass microscope slide surface. Each individual chamber can be further subdivided and mounted for sectioning purposes. It is important when processing monolayers to ensure that there is an adequate exchange of fluids during dehydration and resin infiltration. Areas of the monolayers near the edges of the gasket on chambered slides tend to retain fluid during exchanges, which can inhibit uniform dehydration and infiltration of the monolayer. If the monolayer being prepared is not confluent, identification of the areas of embedded chambers where cells are located can be aided

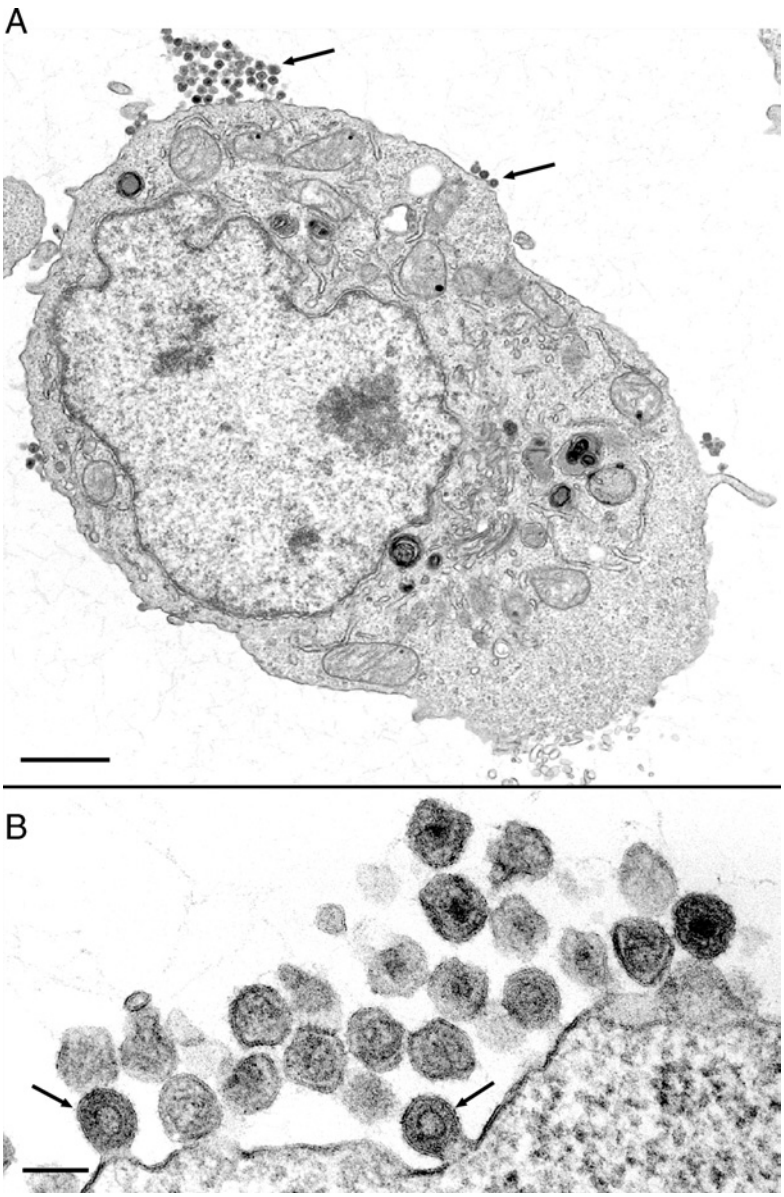

Figure 2B.1.3 Transmission electron micrograph of cultured chicken spleen cells infected with avian reticuloendotheliosis virus, embedded using Basic Protocol 4. (**A**) Clusters of virus particles (arrows) are seen adjacent to the plasma membrane of an individual spleen cell. (**B**) Higher magnification of an area of plasma membrane with shedding virus (arrows) similar to that shown in A. Bars = 1.0 μm (A) and 0.1 μm (B).

by the addition of a staining step just prior to the initiation of dehydration. A stain composed of toluidine blue (0.365 g) and basic fuchsin (0.135 g) in 50 ml of 30% ethanol can be used to stain cells just prior to the first step in the dehydration sequence. The stain is diluted 1:10 in distilled water and the cells are stained for 10 min. The cells will destain to some degree during the subsequent steps of the dehydration process, but there will be enough residual stain in the cells after resin polymerization to enable areas of high cell density to be easily visualized. En face sectioning of the embedded monolayers allows for the observation of cells from the attachment surface of the cells up through the cells to the apical surface of the cell. While positioning the attachment surface of the monolayer parallel to the knife edge while sectioning will allow one to serially section through the cells, sectioning on an axis slightly off parallel will enable both the apical and basal surfaces of the monolayer to be visualized simultaneously as the block is sectioned. If cross-sections of the monolayer are

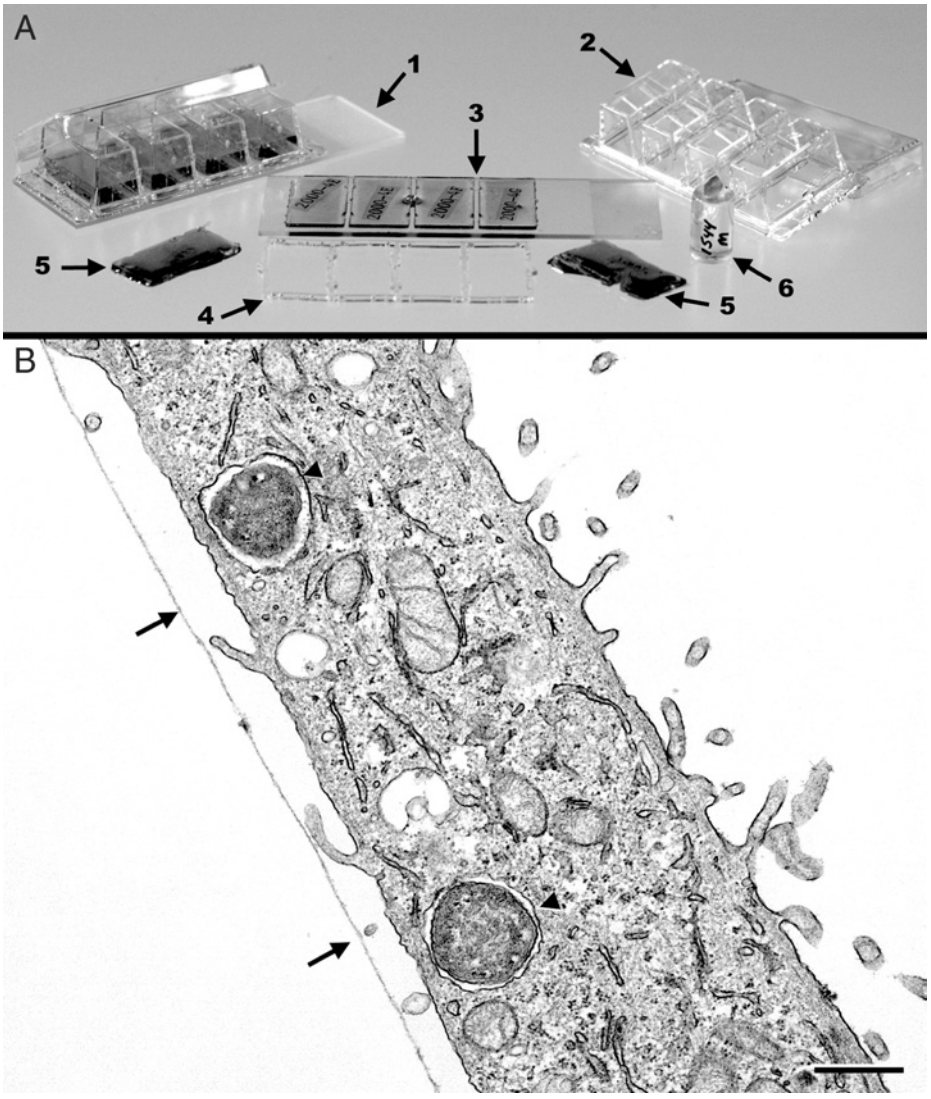

Figure 2B.1.4 Monolayer processing in chambered slides. (**A**) The 4-well chambered slide consists of plastic wells mounted onto a glass slide (1) with a silicone gasket. When the plastic chamber is removed (2), a thin layer of unpolymerized epoxy resin is added (3) at the thickness of the silicone gasket (4). Embedded wells containing cells are removed from the glass slide (5) and pieces of the resin embedded wells are mounted onto plastic pegs for sectioning (6). (**B**) Transmission electron micrograph of a HeLa cell monolayer grown and processed for electron microscopy on a 4-well chambered slide. In this preparation, a cross-section of the monolayer was prepared following removal of the embedded monolayer from the glass slide, and an additional layer of fresh resin (5 in panel A) was added to the substrate side. A piece of the monolayer was then cut with a jeweler's saw and mounded on plastic pegs (6 in panel A) for sectioning. Bar = 0.5 μm.

desired, the side of the embedded monolayer in contact with glass, upon removal of the slide, can be coated with epoxy resin which is then allowed to polymerize. This additional layer of resin material should support the edge of the monolayer for cutting cross-sections.

The cells of embedded monolayers frequently display less contrast than similar cells that have been fixed, scraped off the tissue culture vessel, pelleted, and embedded. This reduced contrast is thought to result from a more complete infiltration of the resin components compared to what is achieved when embedding larger pieces of tissue (Mollenhauer and Droleskey, 1997).

Embedding molds are available from commercial electron microscopy suppliers in a variety of shapes and sizes. In selecting embedding molds, consideration should be given to the relative size of the tissue piece or cell

pellet, the number of tissue pieces, the tissue orientation, and the tissue's ability to be easily mounted in the specimen holder of the ultramicrotome. In general, use of flat embedding molds offers the most options for sectioning of tissues or cell pellets, as they allow for specific portions of the pellet to be excised for subsequent mounting and sectioning. These embedded portions can be removed by gently heating the polymerized resin and cutting it with a single-edged razor blade or by sawing the selected area out using a jeweler's saw.

For embedding of material in LR White resin, it is important to remember that dehydration in acetone is omitted along with dilution of the resin in a solvent. For optimal antigen preservation, it is advisable to cool this resin during polymerization to dissipate the heat generated. It is possible to polymerize LR White resin using heat alone, without the accelerator, but this can be detrimental to antigen preservation and can lead to incomplete curing of the block unless additional steps are taken.

TEM of thin sections

Staining with uranyl acetate and lead are relatively straightforward procedures. Occasionally, electron-dense precipitates occur that are the result of a staining problem. Care is taken with lead citrate to minimize the exposure to CO_2, which can come from one's breath and result in the precipitation of insoluble lead carbonate. Precipitates can be formed from contaminants in glutaraldehyde and osmium tetroxide, and, as noted previously, uranyl phosphate forms an insoluble precipitate. For valuable samples, post-staining precipitates can sometimes be removed by using the plastic etching solution for 10 min, washing in a stream of distilled water, and then restaining (see Aldrich and Mollenhauer, 1986).

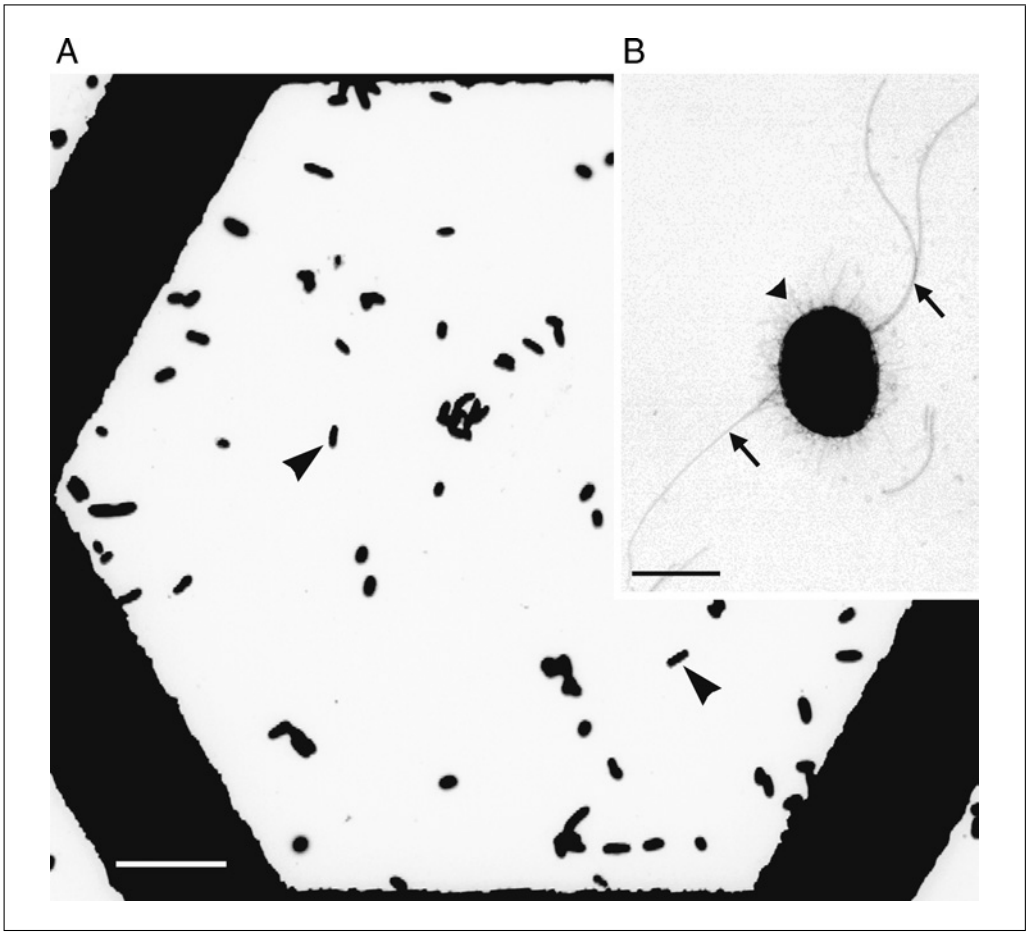

Figure 2B.1.5 Transmission electron micrographs of *Salmonella typhimurium* negatively stained using the direct deposition of sample and stain procedure (Alternate Protocol 1). (**A**) An example of an even distribution of bacteria (arrowheads) over the surface of a 300-mesh Formvar-coated hexagonal grid. Grid stained with 0.25% ammonium molybdate. (**B**) Higher magnification of a bacterium from the same grid. Peritrichous flagella are visible radiating from the cell (arrows) while individual fimbrae are barely evident around the bacterium (arrowhead) at this magnification. Bars = 10 μm (A) and 0.5 μm (B).

Troubleshooting suggestions for immunogold staining of negatively stained preparations are summarized in Table 2B.1.2 and are generally relevant to immunogold staining of thin sections. It is important that a suitable nonspecific binding control be included for all samples. This should at least consist of a section blocked according to the standard procedure described above and then incubated on the colloidal gold suspension, eliminating the primary antibody incubation step. The addition of a grid incubated with a purified IgG from the same species as that in which the specific primary antibody was raised and used at the same concentration as the primary antibody is also appropriate. Before any meaningful assessment of labeling is performed, these controls must be evaluated for labeling. In addition, the degree of labeling in the portions of the grid containing only support film and, if present, plastic without sample, provides an index of background labeling. While it is not absolutely necessary to use Formvar-coated grids in this procedure, they greatly aid the retention of sections on the grid, as the numerous wash steps in this procedure increase the chances of losing sections from uncoated grid surfaces.

LR White embedding resin was chosen for the above-referenced protocol due to its good antigen-preservation characteristics. Tissues embedded in epoxy resins may need to be etched to expose antigenic sites. Etching involves basic attack on the end-linked epoxide rings. Some proteins and peptides and many amino acids have been successfully deplasticized by etching methods to restore immunoreactivity lost in the embedding process.

Anticipated Results

Negative staining TEM

A successful negatively stained preparation has sample distributed on all Formvar-coated grid squares; aggregates of sample and stain can be easily detected at low magnification in the electron microscope. Figures 2B.1.5A and B show low and higher magnification view of a grid in which a relatively uniform distribution of sample and stain. Figures 2B.1.6A and B provide representative examples of negatively stained bacteria and bacteriophage.

Immunoelectron microscopy

When successfully labeled and stained, the negatively stained organisms should be dispersed onto the grid with colloidal gold

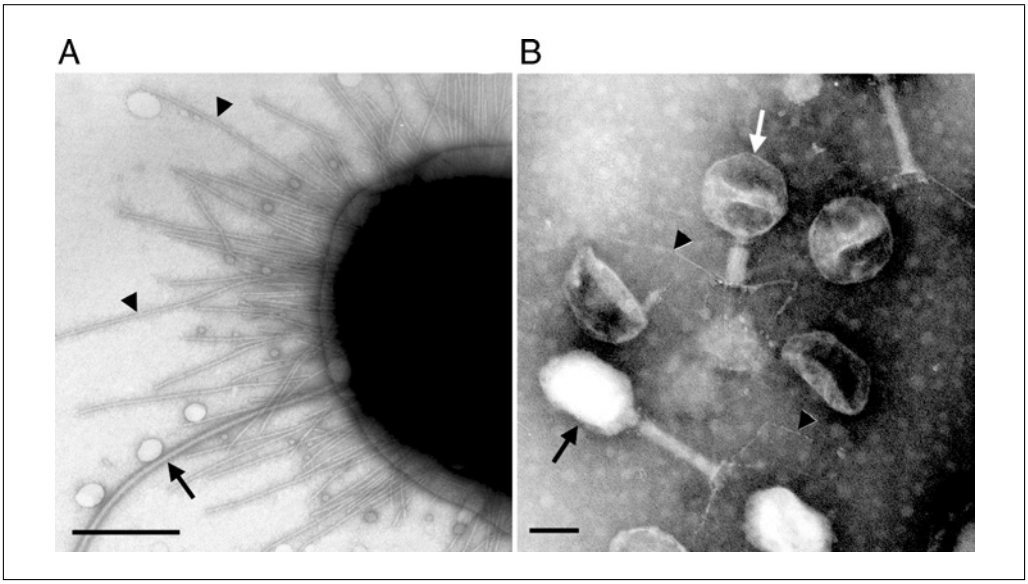

Figure 2B.1.6 Higher-magnification transmission micrographs of negatively stained organisms showing structural detail obtainable with negative stain. (**A**) *Salmonella typhimurium* stained with 0.5% ammonium molybdate by direct deposition of sample and stain showing type 1 fimbrae (arrowheads) and a single flagellum in the field of view. Stain is evenly distributed around the cell, which allows these structures to be easily discernible. (**B**) Bacteriophage (T-even type) isolated from the intestinal contents of a sheep stained with 0.2% phosphotungstic acid. Stain is distributed to allow for the recognition of tail fibers (arrowheads). Phage with intact (black arrows) and empty heads (white arrows) are present in the preparation. In the background of the preparation are globular aggregates of protein from the growth medium used to culture the phage and its host bacterium. Bars = 250 nm (A), 50 nm (B).

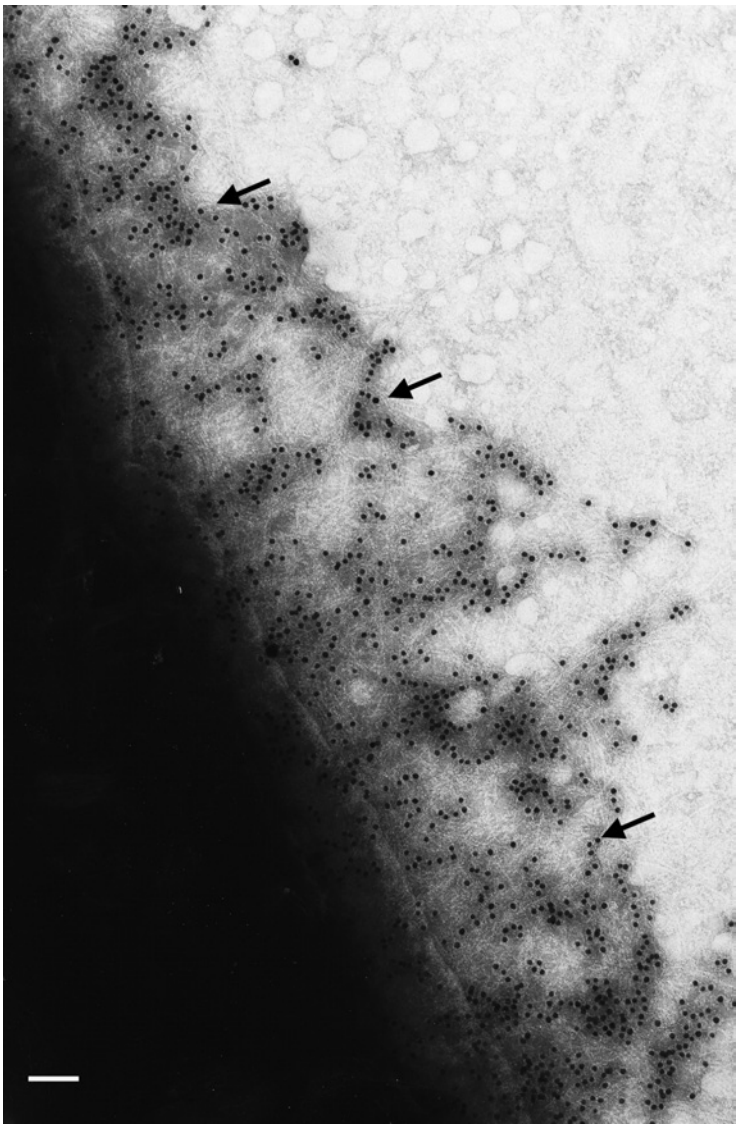

Figure 2B.1.7 Immunogold-labeled and negatively stained preparation of *Salmonella typhimurium* prepared using Basic Protocol 2. Bacteria were deposited on the grid and incubated with an anti-fimbrial primary antibody; this was followed by incubation with protein G–gold and negative staining with 1% ammonium molybdate. The 10-nm gold particles (arrows) decorate the fimbrial structures as seen in Figure 2B.1.5 A.

particles bound to antigenic sites located on the surface of the sample. The support film lacking any organisms should be free of gold particles.

Figure 2B.1.7 is an example of an immunogold labeled, negatively stained preparation of *Salmonella typhimurium*. Table 2B.1.2 lists some common problems with immunoelectron microscopy on negatively stained samples and some possible solutions.

Fixation techniques for TEM

At the conclusion of the fixation and initial processing of samples for thin-sectioning procedures, samples sufficiently stabilized to preserve ultrastructural organization are now ready for the step of embedding in plastic. This step is necessary to stabilize tissues in a matrix that is uniformly hardened to allow ultrathin sectioning with glass or diamond knives.

Embedding techniques for TEM

At the conclusion of the embedding process, tissues are infiltrated with a hardened matrix which is able to withstand the stress of ultrathin sectioning (i.e., ultramicrotomy) with glass or diamond knives.

Time Considerations

Negative staining TEM

The protocol for negative staining is relatively simple, and, when dealing with an ideal sample (i.e., high concentration of particulates in an easily diluted solvent, with a relatively stable structure in the negative staining solution), grids can be ready for viewing in a TEM within 30 min to 1 hr. Similarly, when viewing grids with the TEM, recording of sample images can begin relatively soon after initial evaluation of the preparation. It is usually necessary to survey the grid at low magnification to assess the quality of the preparation and to select areas for higher-magnification examination. Typically, areas with moderate stain that outlines aggregated sample and/or sometimes debris should be carefully screened. Suitable specimens for image acquisition can usually be found within minutes at higher magnification. Prior to image acquisition, it is sometimes necessary to stabilize the area of the grid to be photographed with the electron beam to reduce movement of the Formvar-coated film. Sample dilution and stain density can be adjusted empirically; technical problems (e.g., poor spreading of the negative stain, structural damage to sensitive samples caused by low pH in samples stained with aqueous uranyl acetate, or unstable support films) require thoughtful adjustment with subsequent preparations, which can significantly extend the duration of the specimen preparation and examination process.

TEM of thin sections

Successful heavy metal staining of thin sections results in sections that are relatively easy to visualize on the phosphor screen of the electron microscope. The deposition of sufficient stain is required to record images, as identification of optimal focus in a TEM is another procedure that requires considerable care and practice. Figure 2B.1.3 and Figure 2B.1.4 show examples of samples suitably stained with uranyl acetate and lead. Figure 2B.1.8 provides an example of the use of immunogold

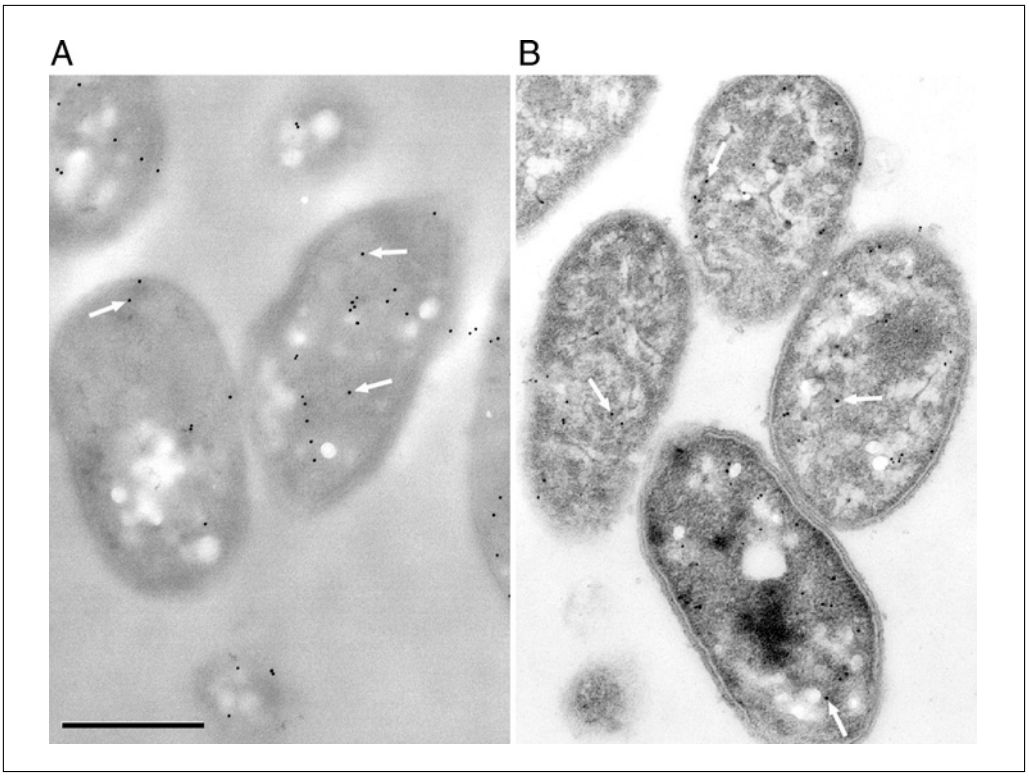

Figure 2B.1.8 *Propionibacterium* fixed and initially processed for immunogold labeling and embedded in LR White resin. In panels (**A**) and (**B**) shown at the same magnification, the LR White–embedded sections were labeled first with a primary monoclonal antibody specific for this particular isolate of *Propionibacterium*; this was followed by secondary labeling with 10-nm protein G–gold (white arrows). Panel A shows inherent specimen contrast without staining uranyl acetate and lead staining of the section, whereas panel B shows the added contrast obtained by employing those stains. Note that while the ultrastructural detail of cells is improved with heavy metal staining, the visualization of gold particles can be more difficult and may require examination of sections at higher magnification.

localization of antigens followed by heavy metal staining. In this figure, differences between the electron scattering of 10-nm gold particles and heavy metal stains that generate contrast in the TEM can be appreciated.

Immunoelectron microscopy

These procedures require extensive manipulation of grids and several incubations, which will require several hours to complete. It is therefore desirable to process several girds simultaneously, not only to speed up the process of evaluating samples, but to ensure that a sufficient number of samples are observed along with appropriate controls. It is also possible to run several dilutions of antibody and gold conjugate simultaneously to expedite the procedure.

Fixation techniques for TEM

Preservation of cells for examination by thin sections is an extensive protocol that requires multiple steps to accomplish. If a sample is presented early in the work day, it is possible to have the infiltrated sample polymerizing in the oven by the end of the day. However, it is more likely that these procedures will be performed over several days. Fortunately, there are several points at which the processing can be arrested until such time that it can be resumed without doing damage to the sample, all of which involve storage at 4°C. Some potential points at which it is possible to halt the procedure include the primary fixative stage (if the tissue is being fixed overnight at 4°C), after the first buffer rinse following primary fixation, after the buffer rinse following post-fixation, or when the sample is in the 100% resin mixture.

Embedding techniques for TEM

In the embedding process, it typically takes several hours to replace the resin/solvent mixture with unpolymerized resin, which is then usually hardened in an oven overnight. On the following day, blocks are removed from the oven and either trimmed in preparation for ultramicrotomy or stored in appropriate containers until samples are needed for preparation of thin sections. Embedded tissue will last many years when kept at normal room temperature and humidity.

TEM of thin sections

Staining with uranyl acetate and lead usually takes about 30 min. Immunogold staining of antigens on thin sections typically takes 4 to 6 hr to complete.

Basic Confocal Microscopy

INTRODUCTION

Confocal microscopy is a powerful tool for visualizing fluorescent specimens. The principal advantage of confocal microscopy over conventional wide-field microscopy is that it can reveal the three-dimensional structure of the specimen. Fluorescent specimens viewed with a conventional wide-field fluorescent microscope appear blurry and lack contrast because fluorophores throughout the entire depth of the specimen are illuminated, and fluorescence signals are collected not only from the plane of focus but also from areas above and below. A confocal microscope selectively collects light from a thin (<1 μm) optical section at the plane of focus in the specimen (Fig. 2C.1.1). Structures within the focal plane appear more sharply defined than with a conventional microscope because there is essentially no flare of light from out-of-focus areas. A three-dimensional view of the specimen can be reconstructed from a series of optical sections at different depths (Fig. 2C.1.2).

Several types of confocal microscopes are available. The most common type is the laser scanning confocal microscope (LSCM), which captures images by scanning the specimen with a focused beam of light from a laser and collecting the emitted fluorescence signals with a photodetector. LSCMs sometimes are referred to as "spot-scanning" confocal microscopes, to distinguish them from microscopes that scan the specimen with a slit of light (slit-scanning) or multiple spots of light (spinning-disk or Nipkow disk). Spot-scanning LSCMs have slower image acquisition rates than slit-scanning or spinning-disk microscopes (<1 frame/sec versus 30 frames/sec or higher). However they are more versatile in a number of ways. They can accommodate lasers with a wide range of wavelengths (from the UV to the infrared) and can be configured to image multiple fluorophores either simultaneously or sequentially. Some include spectral detectors that can capture the entire spectrum of the fluorescence emitted at each pixel in the image. The most sophisticated LSCMs allow the user to control the illumination wavelength and intensity on a microsecond time scale. This feature makes it possible to perform experiments that require selectively illuminating fluorophores in a defined region of interest in order to photobleach (Fig. 2C.1.1D) or photoactivate them. Measurement of fluorescence recovery after photobleach (FRAP) or fluorescence loss in photobleach (FLIP) can provide information about molecular mobility and binding (Cole et al., 1996; McNally and Smith, 2002; Lippincott-Schwartz et al., 2003; Sprague and McNally, 2005). Photosensitive molecules include certain fluorescent proteins (for example, see Patterson and Lippincott-Schwartz, 2002, for the fluorescent protein PaGFP and see Ando et al., 2002, for the photosensitive protein Kaede), "caged" molecules such as caged Ca^{2+} chelators, neurotransmitters, and second messengers (Nerbonne, 1996). Confocal microscopy also can be used to measure fluorescence resonance energy transfer (FRET; Wouters and Bastiaens, 2000).

In microbial research, confocal microscopy is widely used for applications that require visualizing microorganisms within their hosts (Roux et al., 2004; Fig. 2C.1.3A,B). Topics that have been addressed include the mechanisms of microbial adhesion and entry into host cells (Elphick et al., 2004; Ferrari et al., 2003), mechanisms of intracellular motility (Satpute-Krishnan et al., 2003; Viachou et al., 2004; Forest et al., 2005), and the reactions of host cells to infection (Perrin et al., 2004; Shaner et al., 2004). Confocal microscopy also has been used to characterize the growth and physical properties of biofilms (Drenkard and Ausubel, 2002; Rani et al., 2005; Daims et al., 2006; Fig. 2C.1.3C,D). The current generation of confocal microscopes, particularly those that utilize charge-coupled devices (CCDs) as photon detectors, are sufficiently sensitive to detect weak fluorescence signals and potentially could be used for imaging structures within individual microorganisms.

The purpose of this unit is to provide background information and practical tips for optimizing confocal imaging. The first section (Basis of Optical Sectioning) explains the basic principle of confocal imaging as implemented in a LSCM. The second section (Configuration of an LSCM) describes the components and light path in a typical LSCM and compares this with the light paths of spot-scanning microscopes and a new type of slit-scanning confocal microscope. The third

section (Practical Guidelines) provides guidelines for preparing specimens and configuring the critical parameters for confocal imaging. The Commentary provides references to sources of additional information.

BASIS OF OPTICAL SECTIONING

Confocal microscopes accomplish optical sectioning by scanning the specimen with a focused beam of light and collecting the fluorescence signals emitted by the specimen via a pinhole aperture. The pinhole aperture blocks signals from out-of-focus areas of the specimen whereas light from the focal plane passes through the pinhole to reach the detector. The physical basis of optical sectioning is illustrated in Figure 2C.1.4. The microscope objective focuses light from a point source (a laser) to a diffraction-limited spot in the specimen. The irradiation is most intense at the focal spot, but areas of the specimen above and below the focal spot are also illuminated. Fluorescent molecules excited by the incident light

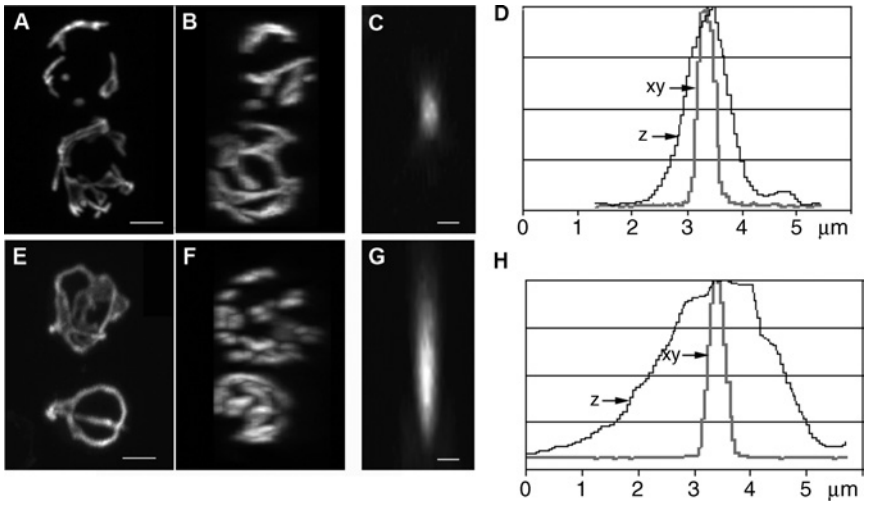

Figure 2C.1.2 3-D Imaging in living specimens. Comparison of water- and oil-immersion objectives. (**A,B,E,F**) Living yeast cells expressing a GFP construct that targets to the mitochondrial matrix were visualized with C-APO 63× 1.2 NA (water) objective (**A,B**) or a Planapochromat 100 × 1.4 NA (oil) objective (**E,F**). The images show *xy* and *yz* projections of stacks of 40 images collected at 0.2-µm intervals along the optical axis. The *xy* projections appear sharper than the *yz* projections because the resolution is higher in the focal plane of the objective than along the optical axis. The yeast were embedded in an aqueous solution with 0.2% agarose. Panels C and G are *yz* projections of images of 0.19-µm fluorescent beads captured with a 63× (water; **C**) or 100× (oil; **G**) objective. The beads were embedded in an aqueous solution with 2% agarose. **D** and **H** are intensity profiles along the horizontal and vertical axes of the beads. A 63× 1.2 NA (water) objective provides better axial resolution than an 100× 1.4 NA objective (oil) in specimens in an aqueous solution. Scale bars = 5 µm (**A,B,E,F**); 0.5 µm (**C,G**). Images were captured with a LSM510 (Carl Zeiss, Inc.).

emit fluorescence in all directions. The objective captures a portion of the emitted light. The objective projects light from the focal spot in the specimen to a conjugate spot in an "image" plane. The pinhole aperture is positioned in the image plane so as to be centered on this spot. The light that passes through the aperture is detected by a photomultiplier tube (PMT). Light from out-of-focus areas of the specimen is spread out at the image plane and is largely blocked by the pinhole aperture.

The diameter of the pinhole determines how much of the fluorescence emitted by the illuminated cone in the specimen is detected, as well as the thickness of the optical section. From wave optics, it is known that a point light source in the plane of focus of an objective produces a three-dimensional diffraction pattern in the image plane. The cross-section at the image plane is an Airy disk, a circular diffraction pattern with a bright central region. The radius of the bright central region of the Airy disk in the reference frame of the specimen is given by $R_{\text{Airy}} = 0.61\lambda/\text{NA}$ where λ is the emission wavelength and NA is the numerical aperture of the objective (Inoué and Spring, 2002). At the image plane, the radius of the central region is R_{Airy} multiplied by the magnification at that plane (Wilson, 1995).

Adjustment of the pinhole to a diameter slightly less than the diameter of the central region of the Airy disk allows most of the light from the focal point to reach the detector and reduces the background from out-of-focus areas by ~1000-fold relative to wide-field microscopy (Sandison et al., 1995). The separation of the in-focus signal from the out-of-focus background achieved by a properly adjusted pinhole is the principal advantage of confocal microscopy for examination of thick specimens.

Point illumination and the presence of a pinhole in the detection light path also produce improved lateral and axial resolution relative to conventional microscopy (Table 2C.1.1). The actual extent of improvement depends on the size of the pinhole. Near-maximal axial resolution is obtained with a pinhole radius of $\sim 0.7 \times R_{\text{Airy}}$, whereas optimal lateral resolution is obtained with a pinhole smaller than $0.3 \times R_{\text{Airy}}$ (Wilson, 1995). However, a pinhole smaller than $\sim 0.7 \times R_{\text{Airy}}$ significantly

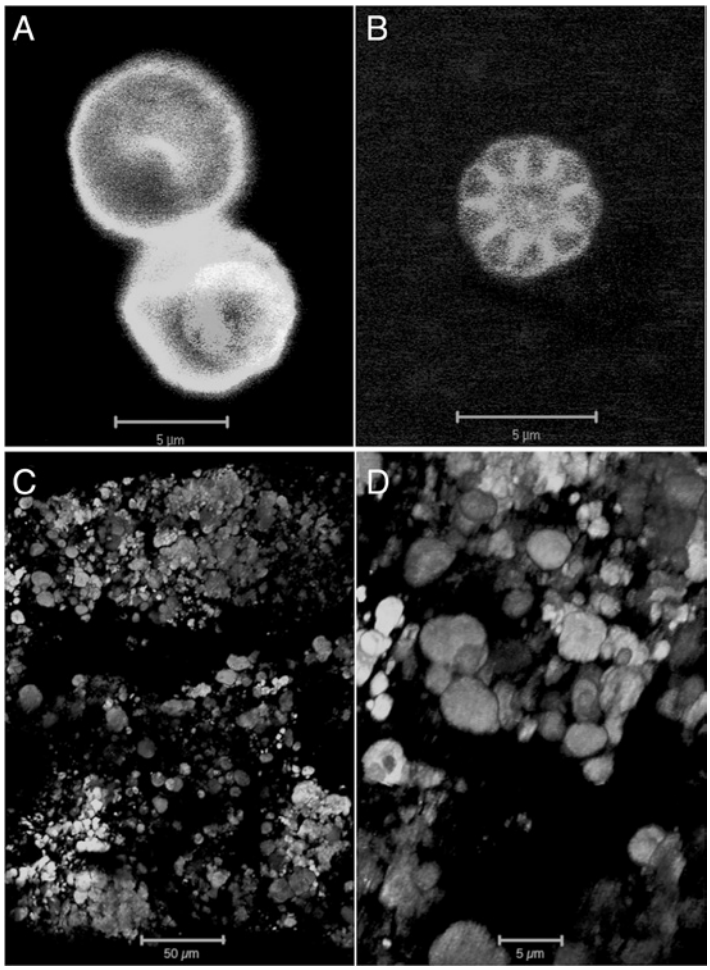

Figure 2C.1.3 Applications of confocal microscopy in microbial research. (**A, B**). Human red blood cells (RBC) infected with malaria parasites (*Plasmodium falciparum*; 3D7 strain). Biotinylated human RBC were labeled with streptavidin-conjugated Quantum Dots 525 (CA; green color; *http://www.qdots.com*) and 0.5- to 4-μM FM-64 (Molecular Probes, red color). The cells were injected into chambers (HybriWell HBW20 from Grace Bio-Labs) and were examined with an LSM 510 confocal microscope (Carl Zeiss, Inc.) with a 100× 1.4-NA oil objective. Panel A shows two RBC, one containing a parasite at the trophozoite stage; panel B shows a parasite at the schizont stage. The schizont was extruded from the RBC for better imaging of individual parasites (red). The green signal in the center of the schizont represents autofluorescence from hemazoin in the digestive vacuole. Images were provided by Dr. Svetlana Glushakova (National Institutes of Health, Bethesda, Md.; methods described in Glushakova et al., 2005). (**C, D**) Biofilm composed of microcolonies of nitrifying bacteria (ammonia oxidizers; *Nitrosomonas sp.*) and nitrite oxidizers (*Nitrospira sp.*). Both populations were labeled by fluorescence in situ hybridization (FISH) with 16S rRNA-targeted oligonucleotide probes. *Nitrosomonas* colonies are green; *Nitrospira* colonies are red. Images are 3-D reconstructions created using the *Daime* imaging program (see Daims et al., 2006, and Internet Resources) from stacks of optical sections collected with an LSM 510 (Carl Zeiss, Inc). Panel C shows an overview of the projected image of the biofilm, while panel D shows a smaller region at higher zoom. Images were provided by Dr. Holger Daims (Universität Wien, Vienna, Austria). For the color version of this figure go to *http://www.currentprotocols.com*.

reduces the total signal, a sacrifice that may not be worth the gain in resolution, especially when imaging dim samples. In fluorescence imaging, resolution is also influenced by the emission and excitation wavelengths (Table 2C.1.1).

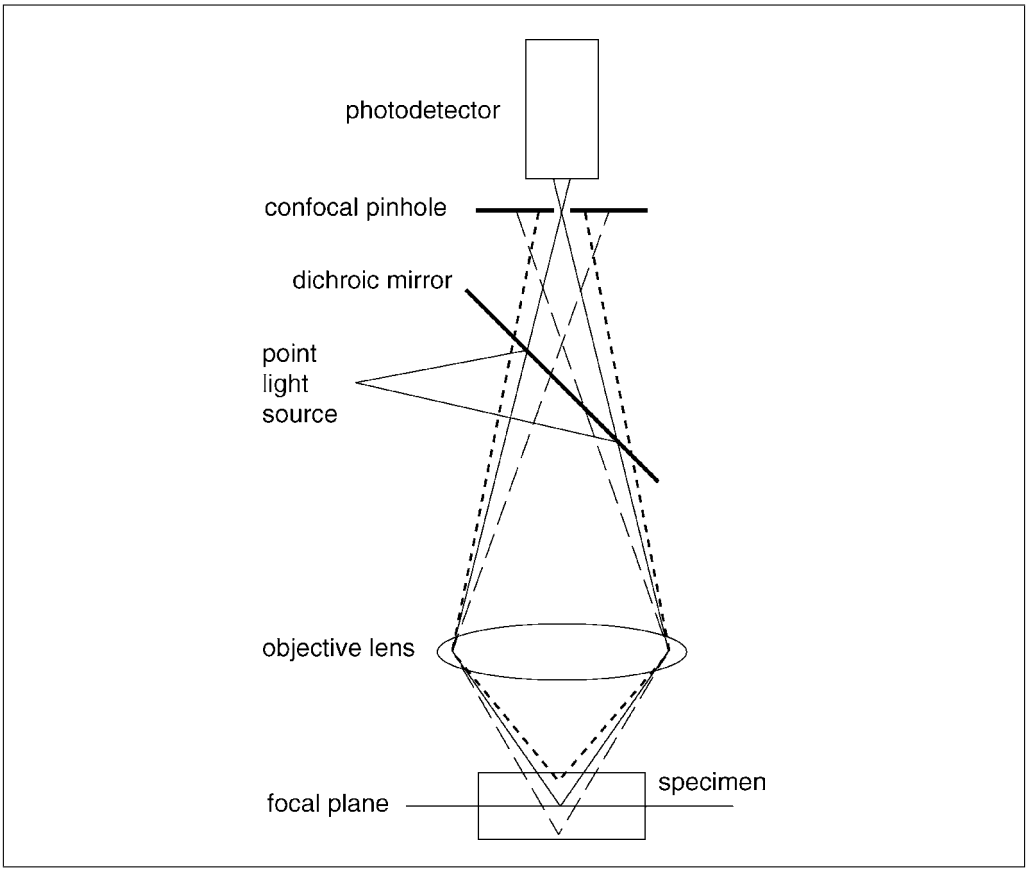

Figure 2C.1.4 The basis of optical sectioning. Illumination from a point light source is reflected by a dichroic mirror into the back aperture of a microscope objective. The objective lens focuses the light to a diffraction-limited spot within the specimen. Fluorophores at the focal spot and within the cones of illumination above and below it are excited, emitting fluorescence in all directions. The fluorescence captured by the objective passes through the dichroic mirror because the fluorescence is at a longer wavelength than the excitation. The confocal pinhole allows fluorescence from the focal spot to reach the photodetector and blocks fluorescence from out-of-focus areas. Redrawn from Shotton (1993).

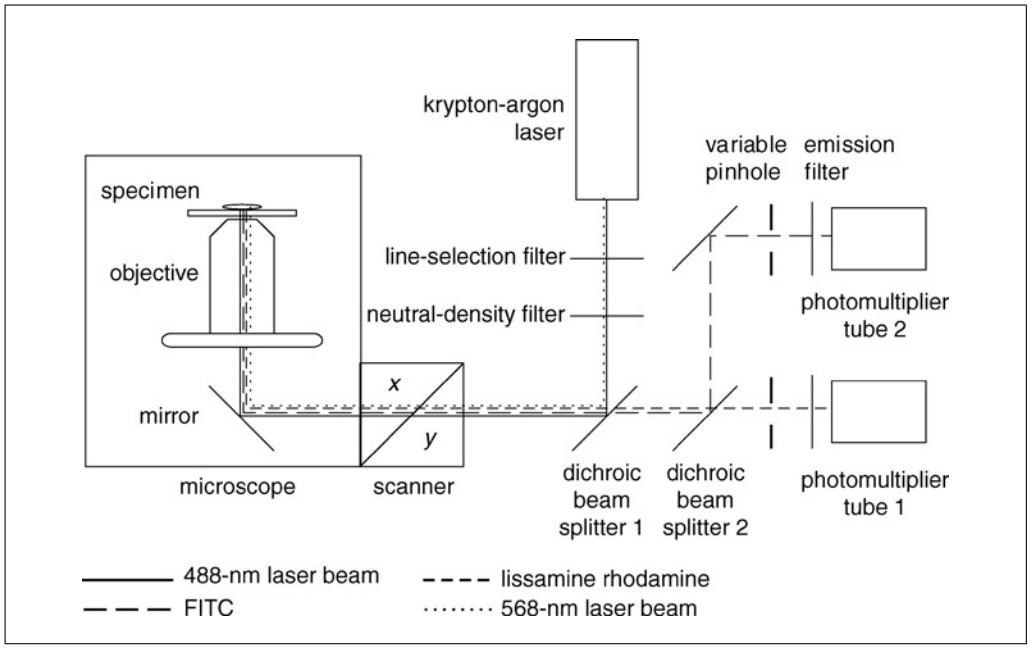

Figure 2C.1.5 The light path of a laser-scanning confocal microscope. The diagram illustrates the light path of a LSCM set up for simultaneous imaging of FITC and lissamine rhodamine. The 488- and 568-nm lines of a krypton-argon laser are reflected by dichroic beam splitter 1 into the optical axis of the microscope. The beam is reflected by a mirror into the microscope objective, which focuses the beam to a diffraction-limited spot in the specimen. The scanner consists of a pair of galvanometer mirrors that deflect the laser beams so as to scan the spot across the specimen in a raster pattern. Fluorescence emitted as each point is illuminated travels the reverse path through the scanning system. The FITC fluorescence (peak at 520 nm) and lissamine rhodamine fluorescence (peak at 590 nm) pass through dichroic beam splitter 1 to dichroic beam splitter 2, which transmits the lissamine rhodamine fluorescence to photomultiplier tube 1 and reflects the FITC fluorescence to photomultiplier tube 2. A variable pinhole in front of each photodetector blocks light from out-of-focus areas of the specimen while allowing light from the focal plane to reach the detector.

CONFIGURATION OF AN LSCM

Confocal microscopes use lasers for illumination because they provide intense excitation within a narrow range of wavelengths. Mixed krypton-argon gas lasers are popular for multicolor confocal microscopy because they emit at three wavelengths (488, 568, and 647 nm) that excite many commonly-used fluorophores—e.g., FITC, rhodamine, Cy3, Cy5, Alexa 488/555/568/647, green fluorescent protein (GFP), and red fluorescent protein (mRFP or DsRed). The disadvantage of krypton-argon lasers is that their life spans are short (~2000 hr). Another way to achieve multiwavelength excitation is to combine the outputs of multiple lasers. Many of the confocal microscopes currently on the market combine an argon laser (488 nm) with a green helium-neon (HeNe) laser (543 or 594 nm) and a red HeNe laser (633 nm). The argon laser also may provide 458 and 514 nm lines, which can be used to excite the cyan and yellow variants of GFP (CFP and YFP). Some confocal microscopes can accommodate a 405-nm diode laser. The 405-nm laser is more optimal for excitation of CFP than the 458 line of the argon laser and also excites photosensitive GFP (PaGFP). It can even be used to visualize some UV fluorophores such as DAPI and Hoechst DNA dyes, although 405 nm is not the optimal excitation wavelength for these dyes. UV argon lasers (351/364 nm) also are available. Inclusion of a 405 nm or UV argon laser adds considerably to the cost of the confocal microscope system due to the requirement for additional optical components to handle these wavelengths.

The light path in a simple confocal microscope is illustrated in Figure 2C.1.5. The output of the laser (or the combined output of multiple lasers) is reflected into the optical axis of the microscope by the primary dichroic beam splitter (splitter 1 in Fig. 2C.1.5). Wavelength-selection filters are inserted into the light path to block specific laser lines, and neutral-density filters may be inserted to attenuate the illumination. In current, high-end confocal

systems, the line selection and neutral-density filters have been replaced with an electronically controlled acousto-optical tunable filter (AOTF). An AOTF can alter its transmission characteristics so as to pass selected wavelengths, while completely blocking others. An AOTF also provides precise control over the attenuation of the individual laser beams.

The scanner deflects the laser beam into the objective at varying angles in order to scan the laser beam across the specimen. Several different technologies for scanning have been devised. The most common method employs a pair of galvanometer mirrors. One mirror oscillates rapidly to excite sequential spots along the *x*-axis of the specimen, and the second mirror oscillates more slowly to move the illumination from line to line in the *y*-axis.

The fluorescence emissions that are collected by the objective follow the reverse path through the scanner to the primary dichroic beam splitter, and thereby are "descanned" (Fig. 2C.1.5). The fluorescence signals (which are at a longer wavelength than the excitation due to the Stokes shift; are transmitted through the beam splitter. To simultaneously image fluorescence from multiple fluorophores requires selection of a primary dichroic beam splitter that reflects each of the required excitation wavelengths and transmits the emissions of all of the fluorophores. Secondary dichroic mirrors split the fluorescence emissions from different fluorophores for detection by separate detectors. Emission filters are inserted in the light path to the detectors (Fig. 2C.1.5) to block backscattered excitation light and to reduce bleedthrough of signals between channels. Current high-end confocal microscopes use more sophisticated technology for emission discrimination; descriptions of the designs of specific systems are available from the vendors (see *SUPPLIERS APPENDIX*).

The fluorescence captured by the objective focuses to a stationary spot (Airy disk) in the image plane (Fig. 2C.1.4). The pinhole aperture is positioned in the image plane so as to be centered on the Airy disk. The diameter of the pinhole aperture can be adjusted to allow optimization for different Airy-disk sizes, which vary with the objective's numerical aperture and the emission wavelength. Adjustment of the diameter of the pinhole to a value of 0.7 to 1.0 Airy Unit allows most of the in focus light to reach the detector and blocks most of the out-of-focus light. In systems with a separate pinhole aperture for each detector, the pinhole apertures are located immediately in front of the detectors. Incorporation of a separate pinhole for each detector allows the user to optimize the pinhole settings for different wavelengths.

The photodetectors in LSCMs are photomultiplier tubes (PMTs), which generate electrons at a rate proportional to the intensity of the incoming fluorescence signal (Art, 1995). The PMT output is converted to a digital image that can be displayed on a computer monitor and stored as a digital file for later analysis. Digitization may be at 8-bit (256 gray levels), 10-bit (1024 gray levels) or 12-bit resolution (4096 gray levels). Confocal microscopes typically have two to four PMTs for reflected light/epifluorescence imaging and may have, in addition, a photodetector for transmitted light.

In spinning disk confocal microscopes, the illumination from a laser or white light source passes through pinholes in the Nipkow disk so as to excite fluorescence at multiple (~1000) sites within the specimen. The disk revolves rapidly (1000 to 5000 rpm) causing the illuminating spots to sweep across the specimen as uniformly-spaced scan lines (Inoué and Inoué, 2002). Fluorescence emitted by the specimen that is collected by the objective returns through the same pinholes in the Nipkow disk that provided the excitation light before it is detected by a full-field CCD camera. In this way, point light sources and detector pinholes to block out-of-focus fluorescence are provided, with the advantage of higher collection speeds than a spot scanner. Drawbacks of this approach include decreased illumination to the specimen from light loss through the pinholes and the inability to change the pinhole diameter. This means that, unlike the case with a spot scanner, optimal confocality is achieved only for one objective magnification, and the thickness of the optical section cannot be changed. Although the reduced specimen illumination generates a smaller fluorescent signal, scientific-grade CCD cameras have significantly higher quantum efficiencies than the PMTs used for fluorescence detection in LSCMs and are able to more than adequately detect these levels of fluorescence. Fluorescent specimens have been reported to undergo less photobleaching during examination with a spinning disk confocal microscope than with a LSCM. The lower rate of photobleaching is thought to be due to the lower illumination levels (Inoué and Inoué, 2002).

A new type of slit-scanning confocal microscope (LSM 5 Live; Carl Zeiss, Inc.) that allows images to be acquired at rates as fast

as or faster than can be achieved with a spinning disk confocal microscope and with as low or lower rates of photobleaching has recently been introduced. The system adopts principles from both the spot scanner and the spinning disk in that it uses a single scanning galvanometer to move an illumination line that is combined with a sensitive single-line CCD detector. The point source of light from the laser is optically converted to a narrow line, which is reflected onto the specimen by a novel beam splitter consisting of a mirrored line on transparent glass. The line illumination is scanned across the specimen. The emitted fluorescence from the specimen that is collected by the objective passes through the beam splitter and is detected by a linear CCD detector. A slit aperture in front of the detector blocks out-of-focus light, analogous to the pinhole aperture in an LSCM. The LSM 5 Live has somewhat poorer resolution than a spot-scanning LSCM, and the initial version is less versatile but can capture images much more rapidly.

PRACTICAL GUIDELINES

Sample Preparation

The preeminent goal in preparing samples for imaging with a confocal microscope is to maximize the fluorescence signals while preserving the three-dimensional structure of the specimen. Ideally, the sample should be less than ~50 μm in thickness, although thicker samples can be visualized. Guidelines for preparing fixed and living samples are described below.

Fixation

A standard fixative for fluorescence microscopy is 2% to 4% formaldehyde in PBS. Formaldehyde penetrates cells rapidly and preserves the antigen-recognition sites for many antibodies. However, formaldehyde cross-links proteins slowly and may cause vesiculation of membranes. Some commercial preparations of formaldehyde (formalin) contain methanol, which shrinks cells. Techniques for optimizing formaldehyde fixation are described by Bacallao et al. (1995). Fixatives containing a small amount of glutaraldehyde (0.125% to 0.25%) in addition to formaldehyde preserve cellular morphology better, but glutaraldehyde destroys the epitopes for some antibodies. Glutaraldehyde fixation induces autofluorescence but autofluorescence can be reduced by treating the sample after fixation with $NaBH_4$ (1 mg/ml in PBS, pH 8.0, using two treatments of 5 min each for dissociated cells, longer for thicker samples). An alternative procedure for preparing specimens for immunocytochemistry is to immerse them in cold (−20°C) methanol or acetone but fixation by this method causes severe shrinkage.

Choices of fluorophores

The choice of fluorophores should take into account the available laser lines and the detector channels of the confocal microscope. Excitation is most efficient at wavelengths near the peak of the excitation spectrum of the fluorophore, but a precise match is not required. For experiments that require imaging multiple fluorophores with standard photodetectors (PMTs), it is best to select fluorophores that are excited by different laser lines, in order to minimize spectral crossover (bleed-through) between the channels (Fig. 2C.1.6). Excitation and emission spectra for many fluorophores are available via the Internet (see Internet Resources). A recommended combination of fluorophores for excitation at 405 nm, 488 nm, 543/561 nm, and 633 nm would comprise Marina Blue, Alexa 488, Alexa 555, and Alexa 647 (all available from Molecular Probes/Invitrogen). The nucleic acid stain DAPI can be excited by illumination at 405 nm, although ultraviolet excitation (350 nm) is more optimal. The cyanine dyes Cy2, Cy3, and Cy5 (available from Jackson ImmunoResearch Laboratories) are also suitable for confocal microscopy. For multiwavelength imaging with a spectral detector and spectral unmixing, it is important to select fluorophores that have distinct emission spectra, but there is no advantage in using fluorophores that have differing excitation spectra. Indeed, it is best to use fluorophores that have similar excitation maxima, so that they can be excited with a single laser line reflected into the microscope with a single-wavelength dichroic mirror. Other important criteria to consider in selecting fluorophores for confocal microscopy are the quantum efficiencies and rates of photobleaching. In addition, the staining protocol should be designed so as to produce similar signal intensities in each channel. More information about selecting fluorophores for confocal imaging is available at the Molecular Expressions Web site (see Internet Resources).

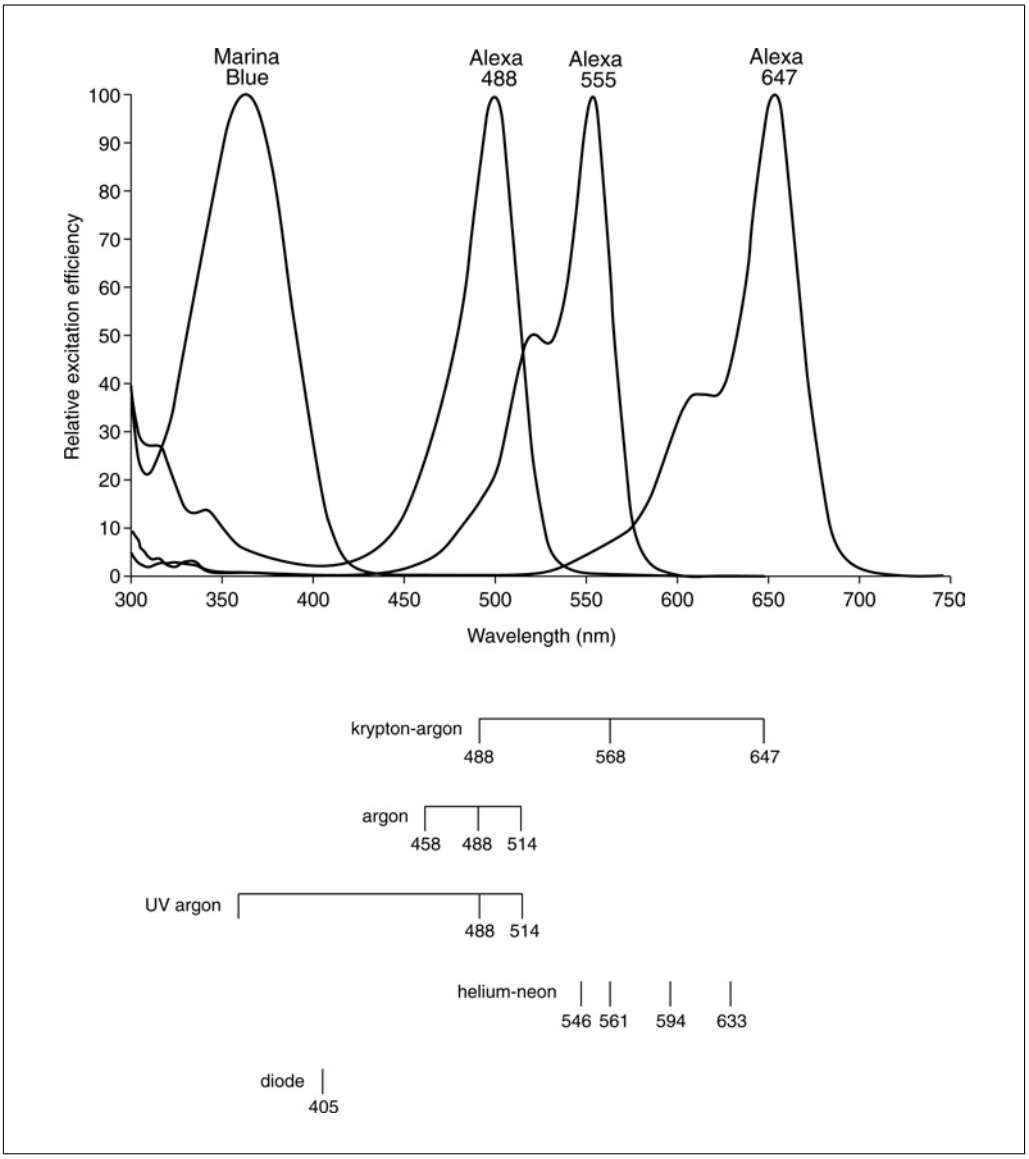

Figure 2C.1.6 Excitation spectra of representative fluorophores and emission wavelengths of lasers for confocal microscopy. The graph at the top shows the excitation spectra of Marina Blue, Alexa 488, Alexa 555, and Alexa 647 (Molecular Probes). The emission wavelengths of lasers commonly used for confocal microscopy are shown below. Data for the excitation spectra are from Molecular Probes.

Control samples

Confocal microscopes rely on electronic image enhancement techniques that can make even dim autofluorescence signals or non-specific background staining look bright. In order to distinguish a real signal from background, it is essential to prepare and examine appropriate control samples. For immunofluorescence experiments with one primary antibody, the appropriate control samples are unstained specimens and specimens treated with the secondary antibody but no primary antibody. Other control experiments may be required to verify the specificity of labeling. Experiments with two primary and secondary antibodies require additional controls to test whether the secondary antibodies cross-react with the "wrong" primary antibody. Singly stained samples also should be prepared and imaged to determine the extent of spectral cross-over between the channels.

Mounting the specimen

Selection of a mounting medium should take into account the type of microscope objective that will be used to observe the specimen (see section on Microscope Objectives). In order for an objective to perform optimally, the mounting medium should have the same refractive index as the objective immersion

Table 2C.1.2 Refractive Indexes of Common Immersion and Mounting Media

Medium	RI
Immersion media	
Air	1.00
Water	1.338
Glycerol	1.47
Immersion oil	1.518
Mounting media	
50% glycerol/PBS/DABCO	1.416[a]
5% *n*-propyl gallate/0.0025% *p*-phenylene diamine (PPD) in glycerol	1.474[a]
0.25% PPD/0.0025% DABCO/5% *n*-propyl gallate in glycerol	1.473[a]
VectaShield (Vector Labs)	1.458[a]
Slow Fade (Molecular Probes)	1.415[b]
ProLong (Molecular Probes)	1.3865[b,c]

[a]Data from Bacallao et al. (1995).
[b]Data from Molecular Probes.
[c]Refractive index (RI) for liquid medium. (RI for solidified medium will be higher.)

medium. Mismatches in the refractive indices produce spherical aberration leading to loss of light at the detector, as well as decreased *z*-axis resolution and incorrect depth discrimination. Image deterioration caused by spherical aberration increases with depth into the specimen; therefore, matching the immersion and mounting medium refractive indices is particularly important for thick specimens. The refractive indices of some commonly used mounting media are listed in Table 2C.1.2.

Mounting media that have refractive indices close to that of immersion oil (RI = 1.51) include DPX (RI = 1.5; ProSciTech) and Permount (RI = 1.52; ProSciTech). However, specimens must be dehydrated prior to mounting in these media, and dehydration causes shrinkage and distortion. Moreover, some fluorophores cannot withstand dehydration. Cells retain their three dimensional shapes when they are kept in physiological saline (PBS) or a mixture of PBS and glycerol (Bacallao et al., 1995). If the specimen is to be mounted under a coverglass, it may be necessary to support the coverglass to avoid damaging the specimen.

Addition of an antioxidant (antifade agent) to the mounting medium helps to alleviate photobleaching of synthetic fluorophores such as those used for immunocytochemistry. One of the best antifade agents is 100 mg/ml 1,4-diazabicyclo[2,2,2]octane (DABCO; Sigma; Bacallao et al., 1995). *n*-propyl gallate (Giloh and Sedat, 1982) and *p*-phenylenediamine (PPD; Johnson et al., 1982) are also effective antifade agents, but the former may cause dimming of the fluorescence while the latter may damage the specimen (Bacallao et al., 1995). A wide variety of mounting media are available from commercial sources (Biomeda, Electron Microscopy Sciences, ProSciTech, Molecular Probes, Vector Laboratories) and many of these contain antifade agents. It is wise to check a the fluorophore provider for recommendations about which mounting medium and antifade agents to use. Antioxidants do not reduce photobleaching of fluorescent proteins.

Living specimens

Microscopy on living specimens grown in vitro is most conveniently performed with an inverted microscope, because the specimens can be viewed through the bottom of the culture chamber and the top can be opened for access. To allow imaging with an oil- or water-immersion objective, the culture chamber substrate should be a coverglass. The glass coverslip can be coated with poly-L-lysine (using a 1 mg/ml solution; Sigma) to promote adhesion of the specimens (either eukaryotic cells or microorganisms). Nonadherent specimens can be immobilized by embedding them in a thin layer of low-melting-point agar (0.2% for eukaryotic cells, up to 2% for smaller organisms). Motile specimens

such as *Paramecium* can be attached to the substrate with CellTak (BD Biosciences; W. Bell, pers. comm.). Culture chambers with coverglass substrates can be made from standard plastic petri dishes by boring holes in their bottoms and affixing coverglasses to the holes with Silgard (Dow-Corning). Culture chambers with coverglass substrates are also available from commercial sources (Labtek coverglass chamber, Fisher Scientific; MatTek glass-bottom culture dish, MakTek Corp). Alternatively, cells may be grown on a coverglass that can be mounted in a chamber for observation on a microscope. A simple chamber can be constructed from a gasket cut from a sheet of silicon rubber or a soft plastic ruler and affixed to a glass microscope slide with silicon grease. The well formed by the gasket is filled with medium, and then the coverglass with cells attached is sealed onto the well. More elaborate chambers, some having built-in heaters and/or ports for perfusion, are available from commercial sources (see Internet Resources for a list of suppliers).

Specimens that need to be kept warm during observation pose a particular challenge because temperature transients can make it difficult to maintain focus. Probably the best way to keep specimens warm is to place the entire microscope in a temperature-controlled enclosure. Alternative strategies include warming the microscope stage with heated air (using an air stream incubator or hair dryer) or infrared lamps, or using a temperature-controlled specimen chamber (Terasaki and Dailey, 1995). If an oil or water immersion objective is used, heating the objective helps to maintain the specimen at the desired temperature. Microscope enclosures, stage warmers, temperature-controlled chambers, and objective heaters are available from suppliers of microscopes and microscope accessories.

Living specimens should be kept in a medium that is buffered to maintain the correct pH. Many commonly used culture media are buffered with bicarbonate and require an atmosphere with 5% to 10% CO_2 to maintain the correct pH. For microscopy, it is more convenient to use a buffer that maintains the correct pH in air. Many types of cells can be maintained for several hours in a balanced saline solution or culture medium that is buffered with HEPES (10 to 20 mM). Use of a medium that contains phenol red should be avoided because phenol red adds background fluorescence and can produce oxygen radicals when exposed to intense illumination. Addition of 0.3 U/ml Oxyrase (Oxyrase, Inc.) to the medium can help to alleviate photobleaching of synthetic fluorophores (Waterman-Storer et al., 1993).

Optimizing Imaging Parameters

Microscope objectives

High-NA objectives are optimal for fluorescence microscopy because they collect more light than low-NA objectives (brightness is proportional to NA^4). Oil-immersion objectives have the highest numerical apertures (NA = 1.4 or 1.45). However, oil-immersion objectives have short working distances (100 to 200 μm). Moreover, they work optimally only with specimens mounted in a medium with a refractive index the same as that of immersion oil ($n = 1.51$). Mismatch of the refractive indices leads to a deterioration of image quality that becomes increasing severe with depth into the specimen. When a high-NA oil objective is used to image a specimen mounted in an aqueous medium, image quality and signal brightness decline noticeably at distances of 5 to 10 μm from the coverglass. Mismatch of the refractive indices also leads to spatial distortion in the *z*-axis. The actual movement of the focal plane in the specimen (d_s) produced by a movement of the objective (d_{obj}) depends on the ratio of the refractive indexes: $d_s/d_{obj} = \eta_s/\eta_{obj}$ (Majlof and Forsgren, 2002).

A water-immersion objective is useful for imaging living specimens that are more than a few microns thick. Water-immersion objectives with numerical apertures of 1.2 are available. These objectives are designed for viewing specimens mounted under a coverglass (0.17 μm; no. 1.5) and have fairly short working distances (130 to 220 μm). "Dipping" objectives, which are intended for use without a coverglass, have lower numerical apertures (NA = 0.9) and longer working distances (1 to 2 mm).

Objectives differ in their transmission efficiency and degree of correction for spherical and chromatic aberration and flatness of field. Plan Apochromat objectives provide the flattest fields of view and color correction for three wavelengths. Plan Apocromat objectives generally transmit efficiently throughout the visible spectrum (400 nm to 700 nm), but may transmit poorly in the UV (<400 nm) or infrared (>700 nm; Keller, 1995). Some objectives that are less highly corrected (Fluar, Plan NeoFluar, Plan Fluor) provide higher transmission at visible, UV, and infrared wavelengths. For additional information about objectives for confocal microscopy see

the *UNIT 2A.1*, Keller (1995), Benham (2002), and the Molecular Expressions Web site (see Internet Resources).

Pinhole size

As explained in the section on the Basis of Optical Sectioning, the size of the detector pinhole has a critical influence on image quality. A pinhole with a diameter slightly less than or equal to the diameter of the bright central region of the Airy disk will let most of the light from the plane of focus reach the detector, while blocking most of the out-of-focus flare. The lateral resolution will be ~10% better than that obtainable by conventional microscopy with the same optics (Centonze and Pawley, 1995), although not as good as can be achieved with a smaller pinhole. Lateral resolution continues to improve as pinhole radius is decreased down to a pinhole size of ~0.2 × Airy disk radius, but a pinhole this small excludes ~95% of the signal (Wilson, 1995). Axial resolution improves as pinhole size decreases, down to ~0.7× Airy disk radius, then levels off. The best trade-off between signal intensity and resolution will depend on the characteristics of the sample and the required resolution.

Scan zoom

The scan zoom determines the dimensions of the area in the specimen that is scanned. Increasing the zoom reduces the dimensions of the scan area. The pixel number remains the same; consequently, individual pixels represent a smaller area. For example, the scan area at zoom 2 is one quarter the scan area at zoom 1 and the pixel dimensions are half as large in each dimension. That is, if the pixel dimensions represent 0.25 μm × 0.25 μm at zoom 1, then dimensions are 0.125 × 0.125 μm at zoom 2.

For each objective, there is an optimal zoom setting that yields pixel dimensions sufficiently small to take advantage of the full resolution of the objective but large enough to avoid oversampling. In order for the minimum resolvable entity to be visible on the display monitor, the pixel dimension needs to be smaller than (less than one-half) the optical resolution. However, if the pixel size is made too small by using a higher-than-optimal zoom factor, the specimen is subjected to more irradiation than necessary, with an increased risk of photobleaching. The rate of photobleaching increases proportionally to the square of the zoom factor (Centonze and Pawley, 1995). A guideline for selecting an appropriate zoom factor derived from information theory (the Nyquist Sampling Theorem) states that the pixel dimensions should be equal to the optical resolution divided by 2.3 (see Webb and Dorey, 1995). The optical resolution in confocal imaging depends on the numerical aperture of the objective, the refractive index of the immersion medium, the excitation and emission wavelengths, and the diameter of the pinhole aperture. Values calculated for different objectives and wavelengths using the point-spread functions (PSF) for wide-field and confocal microscopy are given in Table 2C.1.1. The lateral resolution for confocal microscopy can be approximated by: $\text{Resel}_{x,y\ \text{confocal}} = 0.4\lambda/\text{NA}$, where λ is the wavelength of the illumination and NA the numerical aperture of the objective (see Webb and Dorey, 1995). The above equation assumes the use of an infinitesimal pinhole; $\text{Resel}_{x,y}$ will be larger with a pinhole of 0.7 to 1 Airy unit.

z-axis sectioning interval

In order to study the three-dimensional structure of a specimen, a series of images are captured at fixed intervals throughout the entire depth of the specimen. The interval between focal planes needed to achieve optimal resolution in the *z*-axis is not as small as the *x,y* pixel dimensions because the axial resolution is poorer than the lateral resolution (see Table 2C.1.1). The optimal interval (according to the Nyquist Sampling Theorem) is equal to the axial resolution divided by 2.3. The axial resolution for an objective in confocal imaging can be approximated by: $\text{Resel}_{z\ \text{confocal}} = 1.4\lambda\eta/\text{NA}^2$ where n is the refractive index (see Webb and Dorey, 1995). Collecting images at shorter intervals results in oversampling, with an increased risk of photobleaching.

Illumination intensity

Fluorescence emission increases linearly with illumination intensity up to a level at which emission saturates. Optimal signal-to-background and signal-to-noise ratios are obtained with illumination levels well below saturation (Tsien and Waggoner, 1995). The illumination intensity on a laser-scanning microscope can be adjusted by operating the laser at submaximal power and by inserting neutral-density filters into the light path or varying the transmission through the AOTF. In general, the best images are obtained with illumination levels that are as high as possible without producing unacceptable rates of photobleaching.

PMT black level and gain

The contrast and background of confocal images are determined by the gain and black-level settings of the photomultiplier tube (PMT) amplifiers. To obtain maximal information, the black level and gain should be adjusted to take advantage of the full dynamic range of the PMTs. The appropriate black-level setting can be found by scanning while the light path to the PMT is blocked. The image that appears on the display monitor should be just barely brighter than the background, which is black (gray level = 0). To set the gain, scan the specimen and adjust the gain so that the brightest pixel in the image is slightly below white (gray level = 255, for 8-bit images). Ensuring that all signals fall within the dynamic range of the PMT is especially important for quantitative imaging experiments. Confocal imaging software typically includes a pseudocolor image display mode ("range indicator") that facilitates selection of appropriate black level and gain settings by highlighting pixels with intensity values near 0 or 255.

Averaging

Confocal images of dimly fluorescent specimens captured at the fastest scan rate on a typical LSCM (~0.5 sec/frame) appear noisy because of the small numbers of photons collected from each spot. Improved signal-to-noise can be attained by scanning the specimen at a slower rate or by scanning multiple times and averaging the signals. Current LSCMs allow individual lines in the image to be repeatedly scanned and averaged. Line averaging generally produces sharper images than frame averaging (which averages full frames) because there is less risk of blurring due to movements or changes in the specimen.

Imaging multiple fluorophores

Confocal microscopes can typically be configured to capture images of two or more fluorophores simultaneously or sequentially. Each approach has advantages and disadvantages. For simultaneous imaging, the specimen is scanned with all of the required excitation wavelengths and the emissions of the different fluorophores are split for detection by separate photodetectors (Fig. 2C.1.5). The drawback of this approach is that spectral cross-over between channels may occur if the emission spectra of the fluorophores overlap. If each fluorophore is excited by only one laser line, then exciting them sequentially will avoid spectral cross-over. The disadvantage of sequential excitation is that there may be misalignment of the signals in different channels, particularly if the specimen is alive and moving. A third way of imaging multiple fluorophores is available in confocal systems in which the laser excitation is controlled with an AOTF; such systems can scan each line of the specimen sequentially with different excitation wavelengths with a time delay between scan lines of less than a millisecond. Line-by-line wavelength switching provides rapid acquisition of fluorescence signals from each spot in the specimen while avoiding the spectral cross-over between channels that may occur when the fluorophores are excited simultaneously.

Image display

Confocal images are typically displayed as 8-bit grayscale or 24-bit RGB (red/green/blue) color images. Each channel of an RGB image can represent a different fluorophore (Fig. 2C.1.1A to C). Color mixtures indicate colocalization of fluorophores within a pixel. A RGB fluorescence image can be merged with a grayscale transmitted light image by adding the transmitted light image to each channel of the RGB image (Fig. 2C.1.1D; fluorescence in green channel merged with DIC image).

The three-dimensional dataset obtained by capturing a series of optical sections through the specimen can be used to compute views of the specimen from different viewing angles. Commercial confocal microscopes typically include the capability to generate orthogonal views of the specimen (*xy*, *xz*, and *yz*) and may permit views from arbitrary angles. An *xy* projection or "*z*-series projection" is a two-dimensional display formed by merging multiple image planes (Fig. 2C.1.1B,C, Fig. 2C.1.2A,E). The most common type of projection is a "maximum" projection in which each pixel represents the intensity of the brightest pixel in the *z*-axis. Another type of projection, referred to as "surface render," displays the most superficial pixels with intensities above a defined threshold. Projections also can be created for different viewing angles (Fig. 2C.1.2B, F). Projections of the specimen from different viewing angles can be combined to create an animation in which the specimen appears to rotate in space. Such animations give the viewer a striking impression of the three-dimensional geometry of the specimen. Generating two projections at azimuths differing by 4° to 10° creates stereo pairs that can be visualized with a stereo viewer or color-coded and merged to form a stereo anaglyph. Volume-rendering

imaging software is available that provides additional options for three-dimensional visualization and measurements (see Internet Resources).

COMMENTARY

Effective use of a confocal microscope requires understanding of the principles of image formation and knowledge of how to set up and use a microscope. The unit on Proper Alignment and Adjustment of the Light Microscope (*UNIT 2A.1*) describes the components of a light microscope and provides protocols for setting up a microscope for transmitted light and epifluorescence imaging. This unit also lists references to literature on light microscopy. *The Handbook of Biological Confocal Microscopy* (edited by V. Centonze and J. Pawley, 1995, new edition planned for March 2006) is a comprehensive reference book on confocal microscopy. It includes chapters on the fundamental principles, instrumentation, image acquisition and display, sample preparation, and much more. *Confocal Microscopy* (Wilson, 1990) provides a thorough discussion of the principles behind confocal imaging. *Cell Biological Applications of Confocal Microscopy* (edited by B. Matsumoto, 2002) discusses the performance of different types of confocal microscopes and contains practical information about common applications such as imaging immunofluorescence and calcium ion indicators. Additional applications are described in *Confocal and Two Photon Microscopy: Foundations, Applications and Advances* (Diaspro, 2002). The Molecular Expressions Web site also is an excellent source of information about light microscopy, including confocal microscopy (see Internet Resources).

Confocal microscopy is only one of several available techniques for capturing optical sections in fluorescent specimens. An alternative to confocal microscopy is computational "deconvolution" of images captured by wide-field epifluorescence microscopy (McNally et al., 1999; Boccacci and Bertero, 2002). Computational deconvolution makes use of all of the fluorescence captured by the objective, in contrast to confocal microscopy, which discards fluorescence from out-of-focus areas. In addition, wide-field microscopy can employ CCD cameras that have higher quantum efficiencies than the photodetectors used for confocal microscopy. For these reasons, wide-field microscopy and deconvolution can be superior to confocal microscopy for imaging dim specimens or specimens that are susceptible to photobleaching or photodamage. However, computational deconvolution of images is time-consuming and does not work well in specimens with high levels of dispersed fluorescence. Confocal microscopy allows direct visualization of optical sections and is applicable to a wider range of specimens.

Another technique for confocal imaging takes advantage of the optical phenomenon known as multiphoton excitation. Multiphoton microscopy allows deeper penetration into tissue than either wide-field microscopy or conventional (single-photon) microscopy, and is particularly useful for imaging in thick specimens such as tissue slices or multicellular organisms. However, this method suffers loss of resolution due to the longer illumination wavelength and absence of a detector pinhole.

Troubleshooting

Test samples are useful for monitoring the performance of a confocal microscope. A micrometer slide should be used to check the spatial calibration of each objective. Fluorescent microspheres with mixtures of fluorophores (FluoSpheres; Molecular Probes) are useful for checking the *x,y* and axial alignment of images acquired at different excitation wavelengths. Misalignment of the images in the *xy* plane may indicate that the pinholes are not centered or that the lasers need to be aligned; misalignment in the *z* axis may be due to incorrect setting of a collimating lens, misalignment of pinholes, or chromatic aberration in the objective. The optical resolution of the microscope can be measured by capturing images of submicroscopic (<0.2 nm) fluorescent microspheres (Fig. 2C.1.2C,G). The images of the microspheres should be radially symmetrical in the *xy* plane and elliptical in the *z*-axis (Fig. 2C.1.2C). Horizontal and axial resolutions are defined by the full width at half maximal intensity (FWHM) of intensity profiles along the horizontal and vertical axes of the beads (Fig. 2C.1.2D,H).

Anticipated Results

Confocal microscopy provides sharp images of fluorescent structures in thick specimens (Fig. 2C.1.1, Fig. 2C.1.2, Fig. 2C.1.3C, D). The maximum depth at which adequate images can be obtained depends on the objective and the optical properties of the specimen. With a high-NA immersion objective, it may be possible to capture images at depths of >100 μm in a specimen that is transparent and not heavily stained (Centoze and Pawley, 1995). However, if the specimen scatters light, both the illumination intensity and the proportion

of the emitted fluorescence that is captured by the objective decline with increasing focal depth. Mismatch of the refractive indexes of the immersion medium and specimen will further reduce the depth at which adequate signal can be obtained. A low-NA objective can capture images at greater depths but provides much poorer axial resolution.

A three-dimensional reconstruction of the specimen can be generated from a series of optical sections at appropriately spaced intervals along the optical axis. The reconstruction can be viewed from any angle, but the view along the optical axis of the objective will appear sharper than off-axial views, because the lateral resolution of the objective is better than the axial resolution (Fig. 2C.1.2). The axial distortion can be corrected by computational deconvolution (Wouterlood, 2005).

Confocal imaging in living specimens is feasible although care must be taken to avoid phototoxicity and photodamage. Robust fluorophores such as the fluorescent proteins EGFP and EYFP can be imaged hundreds of times with minimal photobleaching and no apparent phototoxicity, provided that the illumination is kept at a low level. Synthetic fluorophores, such as organelle-specific dyes (Molecular Probes), generally are more photosensitive, although in some applications the rate of bleaching can be reduced by the addition of Oxyrase. The maximum rate at which images can be collected will depend on the scan speed, resolution, and area. Typical scan times for a 512 × 512 image are 1 to 4 sec/frame.

A common application of confocal microscopy is to determine the relative distributions and extent of colocalization of the molecules tagged with different fluorophores (Brelje et al., 2002). As many as four different fluorophores can be discriminated on a confocal microscope with laser excitation at 350/405, 488, 546/568, and 633/647 nm, and standard photodetectors, provided that the excitation spectra of the fluorophores are well separated and matched to the laser lines. Confocal microscopes with spectral detectors can discriminate larger combinations of fluorophores on the basis of their emission spectra. Spectral detection and linear unmixing allows discrimination of fluorophores with highly overlapping emission spectra, such as GFP and YFP (Dickinson, et al., 2001).

Confocal microscopy also is well suited for visualizing variants of the green fluorescent protein. CFP and YFP can be visualized with minimal cross-talk between channels on a confocal microscope with 405 nm and 514 nm excitation. The overlap of the excitation and emission spectra of CFP and GFP or GFP and DsRed may result in cross-talk between channels in experiments with these combinations of fluorophores. New fluorescent proteins have been developed that potentially could provide more optimal combinations for multi-color imaging (Shaner et al., 2004). Fluorescent proteins have also been incorporated into biochemical reporters for measuring intracellular calcium, kinase activity, and other signaling molecules (Zhang et al., 2002).

Photosensitive fluorescent proteins are available that undergo a change in spectral properties upon photoactivation. Photactivatable GFP (PaGFP; Patterson and Lippincott-Schwartz, 2002) exhibits little fluorescence under 488 nm illumination prior to activation but undergoes a 100-fold increase in fluorescence after photoactivation at 400 to 430 nm. An LSCM with a 405- or 413-nm laser can be used to photoactivate PaGFP within a user-defined region of interest within the specimen and thereby selectively "highlight" GFP fluorescence within that region. The activated GFP retains its fluorescence indefinitely and, importantly, manifests these properties even when fused to another protein. PaGFP fusion proteins provide a useful tool for studying the intracellular dynamics of proteins and organelles (Karbowski et al., 2004).

LSCMs that incorporate an AOTF to control the illumination wavelength and intensity can be configured to perform various types of photobleach experiments. Measurement of fluorescence recovery after photobleach (FRAP) or fluorescence loss in photobleach (FLIP) can provide information about molecular mobility and binding (Cole et al., 1996; McNally and Smith, 2002; Lippincott-Schwartz et al., 2003). In FRAP, fluorescence in a small region of the specimen is photobleached by scanning with high-intensity illumination, and recovery of fluorescence into the bleached area is then monitored by scanning with low-intensity illumination. The rate of return of fluorescent molecules into the bleached area may be governed by diffusion, binding interactions with other molecules, or a combination of both, and appropriate mathematical models have been developed to analyze these responses (Sprague and McNally, 2005). In FLIP, a region of the specimen is photobleached several times with a delay between the bleach scans and images are collected during this process to monitor the distributions of bleached and nonbleached fluorescent molecules. Observation of FLIP can

show whether there is exchange of fluorescent molecules between two compartments of a cell or whether a fluorescent structure is a single organelle or a network of contiguous but independent organelles (Cole et al., 1996).

The spatial precision by which two fluorophores can be said to colocalize on the basis of light microscopy is limited by the optical resolution (~0.2 μm in the *xy* plane and 0.6 μm in the *z*-axis). The phenomenon of fluorescence resonance energy transfer (FRET) can potentially reveal whether two fluorophores are within <10 nm proximity. FRET (Wouters and Bastiaens, 2000) is the nonradiative transfer of energy from a fluorescent donor molecule to an acceptor molecule. Energy transfer occurs only if the molecules are within a distance of less than ~10 nm, and only if the emission spectrum of the donor overlaps the excitation spectrum of the acceptor. One application of FRET is to determine whether two populations of molecules undergo binding interactions. One population is labeled with donor fluorophores (e.g., CFP) and the second is labeled with acceptor fluorophores (e.g., YFP). Several techniques for measuring FRET have been devised (Jares-Erijman and Jovin, 2003) and many of these can be carried out with current LSCMs.

Current LSCMs are much superior to their predecessors in sensitivity, speed of image acquisition and versatility. Although they are expensive ($200,000 to $600,000) and require costly service contracts to ensure optimal performance, their many benefits justify these costs.

Acknowledgements

The author wishes to thank Dr. Albert Neuztner (National Institutes of Health, Bethesda, Md.) for providing the cells illustrated in Fig. 2C.1.3 and Dr. James Galbraith (also of the National Institutes of Health) for helpful comments on the manuscript. ABSTRACT

The atomic force microscope (AFM) is an important tool for studying biological samples due to its ability to image surfaces under liquids. The AFM operates by physical interaction of a cantilever tip with the molecules on the cell surface. Adhesion forces between the tip and cell surface molecules are detected as cantilever deflections. Thus, the cantilever tip can be used to image live cells with atomic resolution and to probe single molecular events in living cells under physiological conditions. Currently, this is the only technique available that directly provides structural, mechanical, and functional information at high resolution. This unit presents the basic AFM components, modes of operation, useful tips for sample preparation, and a short review of AFM applications in microbiology. *Curr. Protoc. Microbiol.* 8:2C.2.1-2C.2.17. © 2008 by John Wiley & Sons, Inc.

INTRODUCTION

Understanding the function of microbial cell surfaces requires knowledge of their structural and physical properties. Most of the classical methods used to investigate these structures (e.g., electron microscopy, X rays) require cell drying, which may compromise the accuracy of the analysis by denaturing the surfaces (Dufrêne, 2002, 2003). Because of microorganisms' small size, the information is generally obtained from a large number of cells and not at the individual cell level. Thus, there is a need for new, nondestructive technologies capable of probing single cell surfaces at high resolution. The atomic force microscope (AFM) has emerged as a nondestructive technique, offering resolution comparable to electron microscopy but allowing the study of biological material in its native environment. AFM was invented in 1986 by Binnig et al. (1986) as a novel technique that allows imaging of surfaces and force measurements at the atomic scale, whether the sample is in air or under fluid. This last property makes it very attractive as a tool for biological applications for live cell imaging (Radmacher et al., 1992; Lal and John, 1994) and single molecule force spectroscopy (Willemsen et al., 2000; Wojcikiewicz et al., 2004; Trache et al., 2005), providing structural, mechanical, and functional information with high resolution under physiological conditions. Biologists are using the AFM in an increasing number of creative ways, and the referenced literature is vast (see Key References). This unit presents the basic AFM components and modes of operation, gives useful tips for sample preparation, and provides a short review of AFM applications in microbiology.

PRINCIPLE OF OPERATION

The principle of operation of the AFM is very similar to that of a stylus profilometer: a sharp cantilever tip interacts with the sample surface, sensing the local forces between the molecules of the tip and sample surface (Fig. 2C.2.1). This instrument is not a conventional microscope that collects and focuses light. The word microscope has been

DOI: 10.1002/9780471729259.mc02c02s8

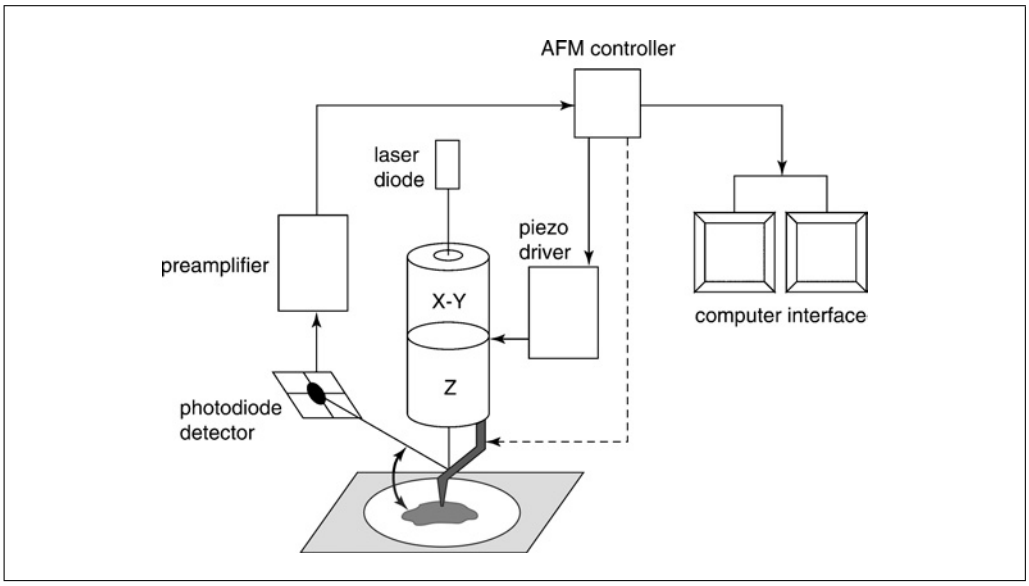

Figure 2C.2.1 Schematic illustration of the AFM system. A flexible cantilever with a tip at the end is rigidly connected to an *xyz* piezoelectric element. The optical lever consists of a laser diode beam that is focused on the back of the cantilever and bounces off, reaching the quadrant photodetector. In contact mode the *xyz* position of the cantilever is given by recording the corresponding position of the piezoelectric element, and the detector reading is proportional to the cantilever deflection. In tapping mode the AFM cantilever is vibrated at its resonant frequency under an external electrical excitation (dashed line).

associated with this instrument because it is able to measure microscopic features of the sample. The most characteristic property of the AFM is that the images are acquired by "feeling" the sample surface without using light. A common analogy is to imagine a blindfolded person who perceives the characteristics of a surface just by touching it. In this way, not only the sample topography can be recorded with atomic resolution, but also material characteristics and the eventual strength of the interaction between the sample surface and the AFM tip. Due to the fact that no light is involved in acquiring the sample properties, the resolution achieved by the AFM is not limited by the wavelength of the radiation that investigates the sample, as in classical light microscopy. Thus, the AFM reaches a resolution far below the diffraction limit offered by light microscopy, being limited only by the tip radius and the spring constant of the cantilever.

The main components of an AFM (Gad and Ikai, 2001) consist of the AFM probe (a sharp tip mounted on a soft cantilever), the optical lever that allows for measuring the cantilever deflections, the feedback loop that allows for monitoring the interaction forces between the molecules on the tip with the ones on the cell surface, the piezoelectric scanner that moves the tip in respect with the sample in a 3D pattern, and a conversion system from raw data acquired by the instrument into an image or other useful display. A short overview of the system components is presented below.

The most sensitive part of an AFM is the tip that interacts directly with the sample surface. The most common probes are constructed from silicon or silicon nitride using microfabrication techniques (Binnig et al., 1987). Each probe can have multiple integrated cantilevers (Fig. 2C.2.2). The properties and dimensions of the cantilever and tip play a major role in determining the sensitivity and resolution of the AFM (Morris et al., 1999). For special applications the pyramidal tip can be replaced with glass or polystyrene beads with a diameter of 1 to 5 μm. The AFM tip must be chosen carefully depending on the specific application. In general, the cantilever should be soft enough to be deflected at

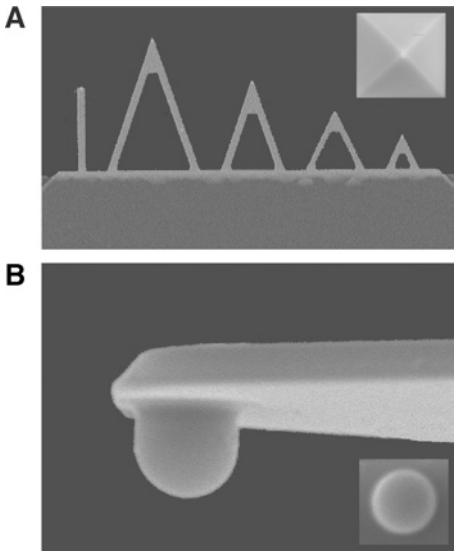

Figure 2C.2.2 Scanning electron microscope images of AFM cantilevers. (**A**) Typical AFM probe for force measurements (magnification 45×). At the very end of the cantilever is a pyramid-shaped tip with a 4-μm base, 35° half angle of the tip, and a radius of 50 nm (inset, magnification 16,000×). (**B**) Typical AFM probe for mechanical stimulation measurements (magnification 10,000×). The cantilever is V-shaped, with a spring constant of ∼0.06 N/m and a 2-μm glass bead attached at its end (inset, magnification 10,000×). Images were taken at the Microscopy & Imaging Center of TAMU, College Station, Texas. Reproduced from Trache and Meininger (2005) with permission of the International Society for Optical Engineering.

Table 2C.2.1 Most Common Cantilever Parameters

Cantilever material	Silicon nitride[a]		Silicon[a]
Spring constant (k)	0.58, 0.32, 0.12, 0.06		20-100 N/m
Resonant frequency			200-400 kHz
Cantilever configuration	V-shaped		Single beam
Reflective coating	gold		Uncoated, aluminum
Tip shape	Pyramid	Sphere[b] glass/polystyrene	Pyramid
Tip radius of curvature/diameter	20-60 nm	0.6-45 μm[b]	5-10 nm
Sidewall angles	35° on all four sides	NA	35° on all four sides

Abbreviation: NA, not applicable.

very small forces, and the tip radius should be comparable with the features of interest. Table 2C.2.1 presents the properties of the most common cantilevers.

Use of the optical lever is the most common technique for detecting the cantilever deflection. A laser beam coming from a laser diode is reflected off the back of the cantilever onto a photodetector. The photodetector consists of a split photodiode that senses the change in light intensity from the reflected beam due to changes in the deflection of the cantilever following tip-sample interaction. The sensitivity of such a system is in the range of 0.1 nm (Meyer and Amer, 1990).

The AFM scanners are made from piezoelectric material, which expands or contracts proportionally with an applied voltage. The piezoelectric scanner can move very precisely with very good reproducibility for small displacements, but for displacements >70% of the full-scale displacement, the piezoelectric response is nonlinear. The commercially available AFM featuring closed-loop feedback systems independently monitors the scanner movement and corrects its motion for nonlinearity. There are two types of scanner configurations: scanned tip AFM (where the piezoelectric scanner is rigidly attached to the probe and is moved over the sample surface, which stands still) and scanned sample AFM (where the scanner is attached to the sample and is moved under the tip). Both designs could be integrated with optical microscopes or used as stand-alone AFM systems.

A dual monitor computer interface allows for display of data (images or force curves) on the display monitor and the parameters of the system on the control monitor.

OPERATION MODES OF AFM

Contact Mode Imaging

The most common imaging mode is the constant force mode. In this case, the AFM tip is brought in contact with the sample surface and set to scan the sample in an *xy* raster pattern. The feedback loop maintains a constant deflection (force) of the cantilever with respect to the sample surface by moving the *z* scanner for each *xy* coordinate. This change in *z* axis corresponds to the topographical height of the sample at each given point. The height image preserves the true height information of the sample. Also, a "deflection" image can be recorded by monitoring the cantilever deflection from a straight line. This image is not recorded at constant force, the tall features in the image representing regions of higher force (i.e., higher degree of cantilever bending). This type of imaging loses the true height information, but it presents more fine details of the sample than the height image because the feedback loop response is faster for correcting the position of the small cantilever, in comparison with correcting the position of the piezoelectric element.

Tapping Mode Imaging

For very soft samples, contact mode might not be the best choice due to the friction between the AFM tip and the sample surface. In tapping mode, the cantilever vibrates at its resonant frequency (bounces up and down) under an external electrical excitation. While rastering the sample in *xy* the AFM tip briefly touches the sample at the bottom of each swing, producing a decrease in the oscillation amplitude. Similar to the constant force in contact mode, the feedback loop keeps this decrease in oscillation amplitude at a constant value by moving the piezoelectric tube, and a height image can be recorded (Putman et al., 1994). In addition, a "phase" image can be recorded in tapping mode. When the tip touches the sample at the bottom of its swing, the phase of oscillation is disturbed, inducing a phase difference between the tip and the electrical oscillator that is driving it (Morris et al., 1999). The contrast of a phase image is directly dependent on the elastic properties of the sample. This is not a preferred mode for imaging cells because the elastic properties of the cell surface do not vary enough from point-to-point to offer a good phase-contrast image.

Dynamic Force Spectroscopy Mode

For force measurements the AFM is operated in force mode. The piezoelectric scanner is set to drive the cantilever to touch and retract over a predefined distance in the *z* axis at a fixed *xy* position, in such a way that the *z* axis movement of the piezoelectric element and the deflection signal from the cantilever are recorded in a force curve. In this way,

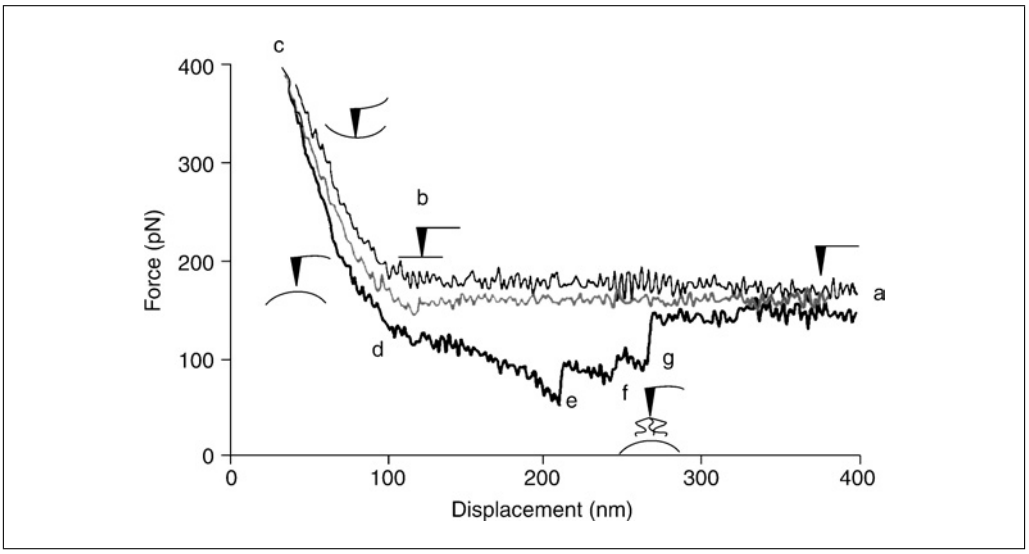

Figure 2C.2.3 Diagram of generic force curves. Approach (black thin line) and retraction force curves with (black thick line) and without (middle line) adhesions are presented. The *x* axis represents the piezoelectric element displacement, and the *y* axis represents the force (see text for details).

measurements of the relative stiffness of the cell surface (approach curve) and adhesion force measurements between the biologically functionalized AFM tip and the cell surface (retraction curve) are acquired (Fig. 2C.2.3). When the probe is extended towards the cell surface (a), a contact point is established with the cell (b), and thereafter the cell surface is indented. Due to cell stiffness, further probe extension causes an opposing force of increasing magnitude to be generated along with increasing indentation in the cell membrane (b to c). The upward deflection of the cantilever as it bends in response to this force, results in an increasing deflection signal. When the probe retracts from the sample (c to d), the force between probe and sample gradually decreases until the cantilever returns to the original position, at which time the deflection signal returns to the original value (a). However, if adhesions occurred between the probe and sample surface, the force causes the cantilever to bend downward, and the deflection signal will be lower than the original value (e to g). When all adhesions are broken, the cantilever returns to the original position (a), and the deflections (unbinding of adhesion events) are recorded on the retraction force curve. The adhesion force is calculated as the product of the deflection height associated with the unbinding event and the spring constant of the cantilever.

On soft samples such as cells, the force application results in an indentation of the cell that is a measure of the local elastic properties of the cell membrane. Due to this elasticity of the cell membrane, only a portion of the piezoelectric element movement causes deflection of the probe; the remainder results in indentation of the cell membrane. The membrane indentation part of the approach curve could be analyzed using different models (Sneddon, 1965; Costa and Yin, 1999) in order to determine the local values of the Young modulus of elasticity as a measure of the local apparent elasticity of the cell membrane.

PRACTICAL GUIDELINES

Although AFM has great potential in microbiological studies, it is important to understand that accurate data collection is sometimes difficult due to the technical limitations associated with the technique itself. Images produced by AFM always represent a convolution of the tip shape with the sample features. It is important to correlate the tip geometrical

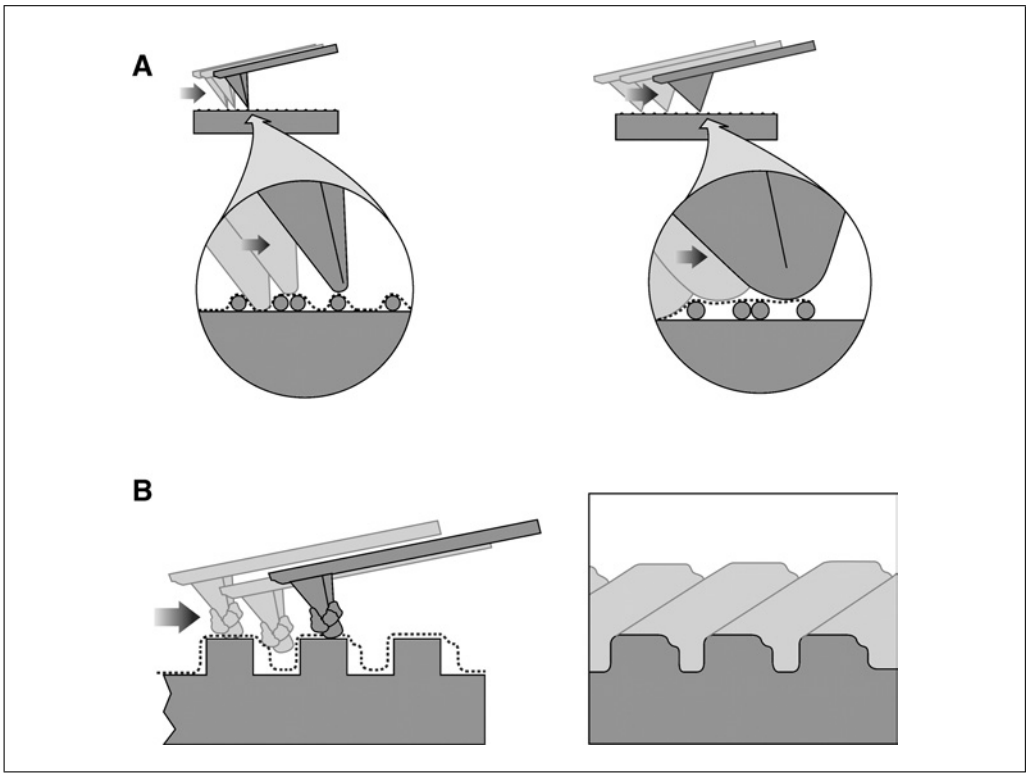

Figure 2C.2.4 Schematics of tip artifacts. (**A**) The smaller the tip radius of curvature, the smaller the sample feature that can be resolved. A dull or dirty (**B**) tip will affect the image profile. Adapted from SPM Training Notebook (2003) with permission of Veeco Instruments.

features with the expected features of the sample to obtain the best images. A tip that is too large will not be able to record features in the sample smaller than the tip parameters (Fig. 2.C2.4A). Also, a contaminated, broken, or blunt tip will introduce distortions into an image, affecting its sharpness or even introducing noise, with the geometry of the tip dominating the geometry of the sample (Figure 2.C2.4B). A detailed description of AFM artifacts is presented at *http://www.pacificnanotech.com/afm-artifacts_single.html*.

Sample Immobilization

One of the most important aspects of imaging live cells under physiological conditions using the AFM is sample immobilization. If the sample is not firmly attached to the bottom of cell culture dish, the AFM tip can easy lift the sample. In this case the tip will break or get contaminated in the process, and no measurements can be performed. Most live cells (e.g., smooth muscle cells, endothelial cells, fibroblasts) attach well to classical substrates like polystyrene or glass. Some cells (e.g., myocytes) can be problematic for AFM measurements due to their intrinsic movement or poor attachment to the substrate. Coating the cell culture dish with gelatin or an extracellular matrix protein (e.g., fibronectin, laminin) can considerably enhance the cell attachment. Live cell imaging can be performed at room temperature or 37°C depending on the experimental requirements. For imaging single bacteria, yeast, or fungal cells under physiological conditions, a concentrated cell suspension is absorbed through an isopore polycarbonate membrane with a pore size comparable to the cell size (Kasas and Ikai, 1995; Dufrêne et al., 1999). Imaging of reconstituted microbial layers or DNA is performed by absorbing the layers of interest on a flat substrate, i.e., fresh cleaved mica or glass (Müller et al., 1997; Colton et al., 1998). Other immobilization methods involve air-drying the sample (a droplet of a concentrated cell suspension is placed on a mica or glass substrate and

allowed to dry in air; Amro et al., 2000) or covalently bonding bacteria to silanized glass slides (Camesano et al., 2000).

Labeling AFM Tips

For force spectroscopy measurements, the AFM tips are typically biofunctionalized with ligands of interest to allow the study of ligand-receptor or protein-protein interaction. This process consists of cross-linking a protein of interest on the AFM tip that has the role of ligand, while its specific receptor is situated on the cell surface. The conjugation can be performed in-laboratory or by using specialized services for more complicated conjugation processes. Two simple ways of cross-linking fibronectin on the AFM tip are presented here. These methods can be applied for other proteins as well.

Coating silicon nitride cantilever probes with fibronectin

For adhesion force measurements, the silicon nitride cantilevers probes (ThermoMicroscope) can be coated (Lehenkari and Horton, 1999) with 1 mg/ml fibronectin (FN). Polyethylene glycol (Sigma) at 10 mg/ml is used to cross-link fibronectin onto probes at room temperature (Hinterdorfer et al., 2000). After the tip is mounted on the glass holder and washed, it is incubated 5 min with polyethylene glycol, washed five times with deionized water, and then incubated 1 min with fibronectin. The tip is then washed again five times with phosphate-buffered saline (*APPENDIX 2A*) and mounted on the AFM scanner.

Coating modified silicon nitride cantilevers with avidin-biotin/fibronectin

A more robust coating that can be used for mechanical cell stimulation consists of avidin (Sigma) cross-linked with biotin/fibronectin (Pierce) onto functionalized glass beads attached to silicon nitride cantilevers (Novascan Technologies). The cantilevers are customized by Novascan Technologies, such that glass beads are glued to the cantilever and then prefunctionalized with biotin. The probes are first incubated 5 min with avidin (1 mg/ml), washed with phosphate-buffered saline five times, and then incubated 5 min with biotin/fibronectin. The tip is washed again with phosphate-buffered saline five times.

The coating should be performed only at the very end of the cantilever to avoid altering its spring constant that is assumed to be unchanged after protein labeling.

AFM APPLICATIONS SPECIFIC TO MICROBIOLOGY

AFM is the only technique available that directly provides structural, mechanical, and functional information at high resolution of cells under physiological conditions. In comparison to electron microscopy, which requires cell fixation and drying, AFM offers the possibility of acquiring high-resolution data in living specimens in real time. Tables 2C.2.2 and 2C.2.3 provide examples of AFM studies relevant to microbiology, focusing on imaging cell surface layers using different immobilization procedures and imaging living cells under physiological conditions (Dufrêne, 2002), respectively. To avoid air-drying techniques that may induce protein or cellular surface denaturing, the physiological imaging techniques are preferred when appropriate. Table 2C.2.4 shows a list of microorganisms for which molecular interactions or local elasticity measurements have been performed. Combining force measurements with high-resolution imaging of cells will be an important challenge, as this will make possible to correlate molecular interactions with structural changes. The examples presented here are just a few of many applications that can be developed in applying AFM to microbiology.

Table 2C.2.2 Imaging the Ultrastructure of Cell Surface Layers[a]

Organism	Sample	Immobilization procedure	Observations[b]	Reference
Bacillus coagulans	S-layer	Covalent linkage to glass/mica	Oblique lattice; $r \approx 10$ nm (study of antibody binding)	Ohnesorge et al. (1992)
		Recrystallization on silanized silicon	Oblique lattice; $r = 1$-2 nm (agreement with electron microscopy)	Pum and Sleytr (1996)
Bacillus sphaericus	S-layer	Covalent linkage to glass/mica	Square lattice; $r \approx 12$ nm (agreement with electron microscopy)	Ohnesorge et al. (1992)
		Recrystallization on silanized silicon	Square lattice; $r = 1$-2 nm (agreement with electron microscopy)	Pum and Sleytr (1996)
		Recrystallization on supported lipid bilayers	Square lattice; $r = 1$-2 nm (novel S-layer/lipid bilayer structure)	Wetzer et al. (1997)
Bacillus stearothermophilus	S-layer	Recrystallization on various silicon surfaces	Oblique lattice; $r \approx 1.5$ nm (study of recrystallization process)	Pum and Sleytr (1995)

Investigating *Actinomyces* Species

Tang et al. (2004) used AFM to image and directly detect interactive forces between the AFM tip and *Actinomyces* species that are predominant early colonizers of the oral cavity and prime mediators of interbacterial adhesion. Figure 2C.2.5 shows the two-dimensional and three-dimensional reconstruction of a height image of *A. naeslundii genospecies 1* adherent to mica substrate. In their paper, several sets of experiments were performed in which the interaction forces between the AFM tip and different locations on the same or different *Actinomyces* species were measured. This study was the first to quantitatively evaluate interactive forces at cell surfaces of *Actinomyces* species at the nanoNewton (nN) force range.

Imaging Tipula Iridescent Virus

The largest virus investigated by AFM is the insect virus tipula iridescent virus (TIV). Figure 2C.2.6 shows such a virus, dried from water onto a mica substrate, forming hexagonal arrays that have some degree of crystalline order. Although not properly crystalline, the constraints introduced by association into an array make it possible to measure center-to-center distances that agree well with height measurements and dimensions determined by other methods (Williams, 1998; Kuznetsov et al., 2001).

Imaging Paramecium Bursaria Chlorella Virus Type 1 (PBCV-1)

Paramecium bursaria chlorella virus type 1 (PBCV-1) is a member of a large group of viruses that infect certain unicellular, eukaryotic, chlorella-like green algae and is common in fresh water bodies worldwide (Van Etten, 2000). Kuznetsov et al. (2005) performed an AFM study to complement the electron microscopy data for this type of virus. AFM can reveal structural anomalies and individual defects of single particles.

Table 2C.2.4 Probing Cell Surface Properties, Molecular Interactions, and Elasticity[a]

Organism	Method	Results	References

Figure 2C.2.7 shows high-magnification images of individual virions that exhibit a surface appearing to be an open network with large spaces of almost hexagonal shape.

Visualizing Dynamic Events of *Saccharomyces cerevisiae*

Figure 2C.2.8 represents a three-dimensional reconstruction of an AFM height image under fluid from a *Saccharomyces cerevisiae* cell trapped in a porous membrane (Dufrêne, 2002). The cell surface is smooth and shows a circular protrusion attributed to a bud scar. The main advantage of using AFM at low resolution (as done here) is that dynamic events such as the cell growth and budding process (Gad and Ikai, 1995; Kasas and Ikai, 1995) and the change in cell surface morphology resulting from treatment with external agents (e.g., enzymes or antibiotics) can be explored in real time.

Force Spectroscopy Measurements on *S. cerevisiae* at the NanoNewton Level

As mentioned earlier, AFM can also be used in the force spectroscopy mode to measure molecular interactions and physical properties by functionalizing the AFM tip with chemical coatings (Ahimou et al., 2002; Dufrêne, 2003). Such an example is shown in Figure 2C.2.9 where the AFM tip functionalized with carboxyl groups maps the electrostatic properties of *S. cerevisiae* at the nanometer level. Changes in adhesion forces were measured as a function of pH, providing information on local isoelectric points.

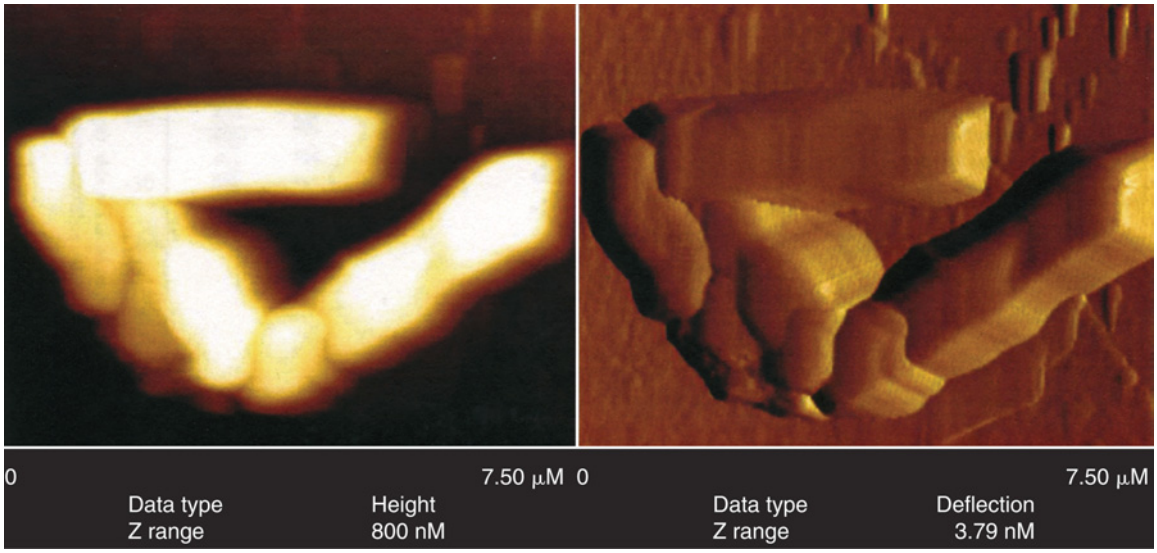

Figure 2C.2.5 Height and deflection images of *A. naeslundii genospecies 1* (ATCC #12104) adherent to the mica substrate after a 5-day period of anaerobic growth. The shape of the outer bacterial surface and the typical diptheroidal arrangements (V, Y, or T forms and palisades) of *Actinomyces* species are seen in these images. Reprinted from *Archives of Oral Biology*, vol. 49. Tang, G., Yip, H.K., Samaranayake, L.P., Chan, K.Y., Luo, G., and Fang, H.H.P. Direct detection of cell surface interactive forces of sessile, fimbriated, and nonfimbriated *Actinomyces* spp. using atomic force microscopy. pp. 727-738. Copyright 2004, with permission from Elsevier.

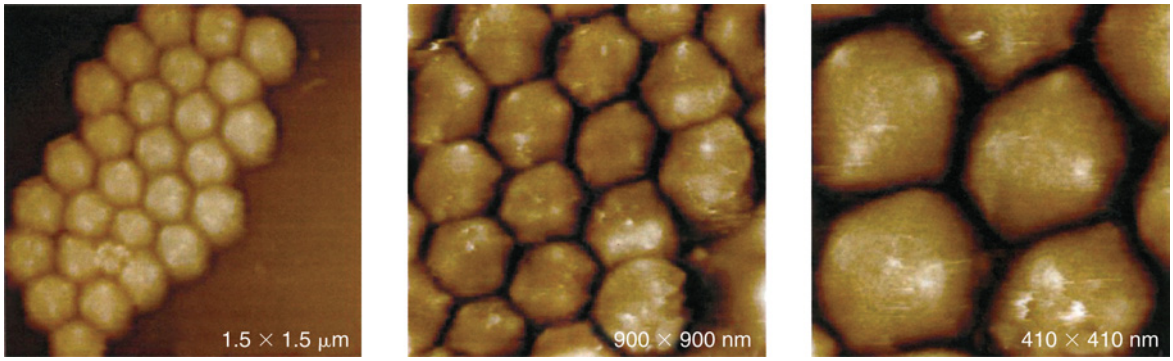

Figure 2C.2.6 When virus particles are clustered into two-dimensional arrays on the mica substrate, they are more firmly immobilized and, therefore, yield better AFM images. The progressively magnified hexagonal arrangement seen here is of the insect tipula iridescent virus (TIV). The little capsid structure is visible, and the polygonal structure of the capsid is evident. Reproduced from Kuznetsov et al. (2001) with permission of the Society for General Microbiology.

Effect of BMS Biosurfactant on Dental Plaque Interactive Forces

Dental plaque can develop and maintain its position on the tooth surface only if the interactive forces between the organism and the tooth surface are sufficiently strong to withstand oral shear forces. Using an adhesion force spectroscopy approach, van Hoogmoed et al. (2006) showed that *Streptococcus mitis* BMS biosurfactant changes the interactive forces between mutant streptococci and enamel, explaining the effects of biosurfactant on adhesion. This study showed for the first time direct measurements of interactive forces between enamel and oral bacteria. The AFM probes were functionalized by gluing enamel particles onto silicon nitride cantilevers. Upon approach of the enamel particles toward each of the mutant streptococci strains trapped in an isopore polycarbonate membrane filter, force-distance curves were acquired, and the data are presented in Table 2C.2.5.

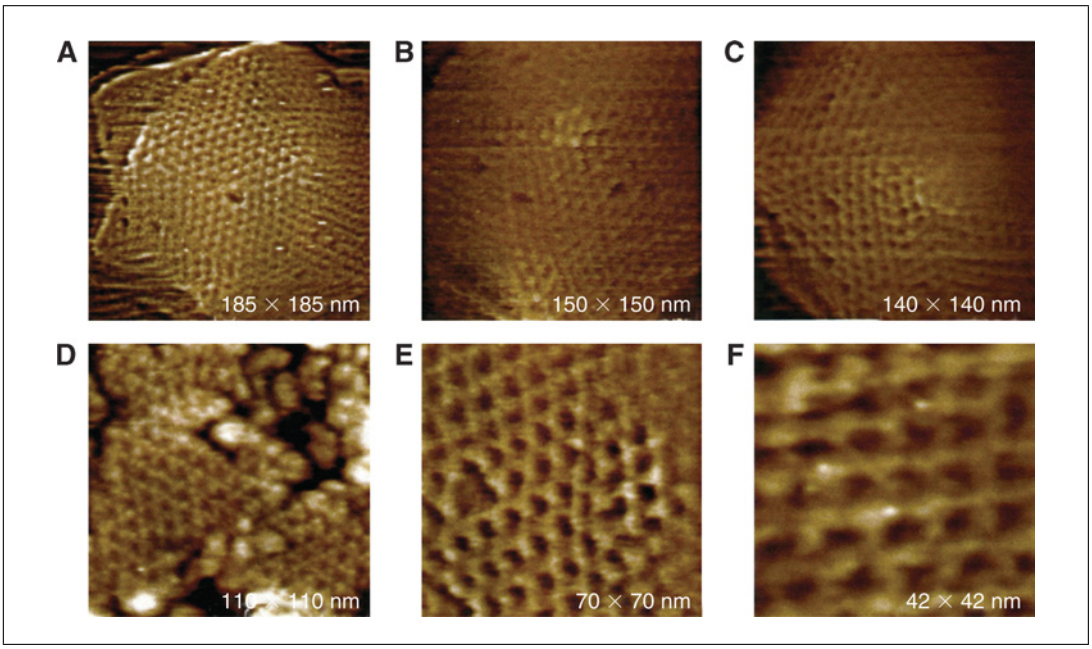

Figure 2C.2.7 At higher magnification, the honeycomb appearance of the surface lattice of Paramecium bursaria chlorella virus type 1 (PBCV-1) is evident. Scars and defects are common on the virion faces, and the unique pentagonal clusters at the vertices can be seen in some cases. In panel **D** a large fragment of a trisymmetronis flattened on the mica substrate, thereby allowing high-resolution imaging. In panels **E** and **F** are two higher-magnification images of the network of trimeric proteins making up the honeycomb arrangement. Reprinted from *Journal of Structural Biology*, vol. 149, Kuznetsov, Y.G., Gurnon, J.R., Van Etten, J.L., and McPherson, A. Atomic force microscopy investigation of a chlorella virus, PBCV-1. pp. 256-263. Copyright 2005, with permission from Elsevier.

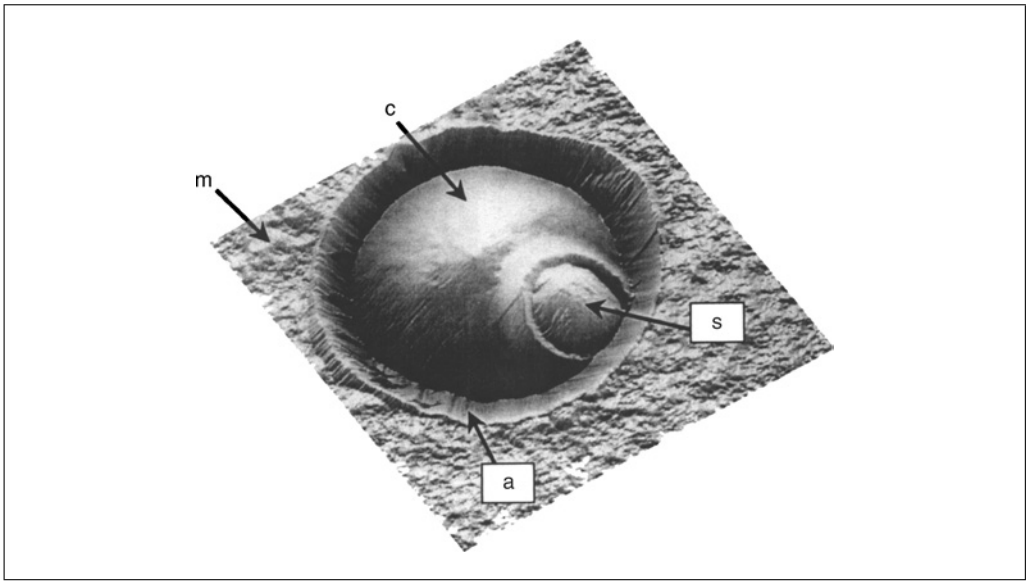

Figure 2C.2.8 AFM height image (6 × 6 μm, *z* range 1.5 μm), in aqueous solution, of a single *Saccharomyces cerevisiae* cell trapped in a porous membrane. The cell (c) is located at the center of the image, while the surrounding flat area represents the polymer membrane (m). The ~1 μm circular protrusion is attributed to a bud scar. Note that the cell is surrounded by an artifactual structure (a) resulting from the contact between the AFM probe and the pore edges Reproduced from Dufrêne (2002) with permission from the American Society for Microbiology.

Investigating the Elastic Modulus of the *Methanospirillum hungatei* GP1 sheath

For the first time, AFM force spectroscopy measurements have allowed for probing mechanical properties of microbial cell-surface layers on a local scale. In a pioneering investigation, Xu et al. (1996) measured the elastic modulus of the sheath of the archeon *Methanospirillum hungatei* GP1. The large values obtained for the Young modulus of elasticity showed that this layer of unusual strength could withstand an internal pressure of 400 atmospheres. Other investigators applied AFM to measure the local elasticity of various cell-wall layers (Dufrêne, 2002). Touhami et al. (2003) used force mapping to demonstrate that the cell wall elasticity of the *S. cerevisiae* varies significantly across the cell surface. A 10-fold increase in the Young modulus of elasticity was measured for the bud scar, in agreement with the accumulation of chitin in this region of the cell wall.

CONCLUSION

The AFM is the only instrument capable of nondestructively imaging specific molecules in real time with a resolution comparable to electron microcopy. The exploration of biological applications of the AFM, although technically challenging, are destined to be of great importance. The new approaches that integrate AFM with classical optical methods lead towards a deeper understanding of the dynamics of biological processes, allowing a wide range of experiments, from discerning single molecule interactions to monitoring the live cell responses. In this respect, AFM can be further combined with optical methods to cover a much larger range of applications, including Forster

Table 2C.2.5 Characteristics of Force-Distance Curves Measured by AFM between Two Strains of Mutants Streptococci and Enamel Particles with and without a Salivary Pellicle in the Absence and Presence of a Biosurfactant Coating[a,b]

[a]Results are means of 50 force-distance curves, taken over five different organisms on ten randomly selected locations per organism, and including four different enamel particles standard ± deviations.

[b]Reproduced from van Hoogmoed et al. (2006) with permission of the International and American Associations for Dental Research.

[c]F_0 the repulsive force of zero separation distance.

[d]Λ, the decay length of the repulsive force upon approach.

[e]Percentage of the force-distance curves showing adhesion.

[f]D_{max}, average maximum distance at which a local maximum in adhesion forces occurred upon retraction.

[g]F_{max}, average local maximum in adhesion forces upon retraction.

resonance energy transfer (FRET; Ebenstein et al., 2004), surface plasmon resonance (SPR) measurements (Chen et al., 1996), total internal reflection fluorescence (TIRF) microscopy and/or internal reflection microscopy (IRM; Hugel et al., 2002; Trache and Meininger, 2005), or confocal microscopy (Horton et al., 2000; Noy and Huser, 2003; *UNIT 2C.1*).

The future should bring advances to the challenging aspects of the present technology, most importantly the development of instrumentation for increasing acquisition speed to allow for real time imaging of fast biological processes, an improved sample preparation and immobilization technology, and better technology for preparing AFM functionalized bioprobes.

Laboratory Maintenance of *Ehrlichia chaffeensis* and *Ehrlichia canis* and Recovery of Organisms for Molecular Biology and Proteomics Studies

Chuanmin Cheng[1] and Roman R. Ganta[1]

[1]Department of Diagnostic Medicine/Pathobiology, College of Veterinary Medicine, Kansas State University, Manhattan, Kansas

ABSTRACT

Tick-borne illnesses are emerging as a major concern for human health in recent years. These include the human monocytic ehrlichiosis caused by the *Amblyomma americanum* tick-transmitted bacterium, *Ehrlichia chaffeensis*; human ewingii ehrlichiosis caused by *Ehrlichia ewingii* (also transmitted by *A. americanum* ticks); and human granulocytic anaplasmosis caused by the *Ixodes scapularis* tick-transmitted pathogen, *Anaplasma phagocytophilum*. Likewise, tick-borne rickettsial pathogens are also a major concern to the health of various vertebrates including dogs, cattle, and several wild animals. In vitro–cultured pathogens grown in a vertebrate host cell and a tick cell culture system will be useful in studies to understand the pathogenic differences as well as to perform experimental infection studies and to generate large quantities of purified antigens. In this unit, methods for culturing *E. chaffeensis* and *Ehrlichia canis* (a canine monocytic ehrlichiosis pathogen) in cell lines to represent vertebrate and tick hosts are described. The unit also includes methods useful in purifying bacteria from the host cells and to evaluate proteins by 2-D gel electrophoresis and western blotting. *Curr. Protoc. Microbiol.* 9:3A.1.1-3A.1.21. © 2008 by John Wiley & Sons, Inc.

Keywords: *Ehrlichia* • culture • macrophage • tick cell • 2-D gel electrophoresis • IFA • polychromatic staining • cell-free *Ehrlichia*

INTRODUCTION

Several emerging tick-borne rickettsial infections have been reported in recent years and have been shown to significantly impact the health of humans and other vertebrates (Paddock et al., 1993; De Silva et al., 1996). These include infections by *Ehrlichia chaffeensis*, a human monocytic agent; *E. ewingii*, a granulocytic ehrlichiosis agent; and *Anaplasma phagocytophilum*, a human granulocytic anaplasmosis agent (*UNIT 3A.2*; Dawson et al., 1991; Chen et al., 1994; De Silva et al., 1996; Caspersen et al., 2002). *Ehrlichia canis* has been identified as the major cause of tick-borne infections in dogs in nearly all parts of the world for several decades (Haas and Meyer, 1986). *E. chaffeensis* and *E. canis* may have evolved common strategies in host-pathogen adaptation based on the fact that they share extensive genetic similarity, contain several immunogenic antigens with shared epitopes, and are macrophage-tropic pathogens (Dawson et al., 1991; Palmer et al., 2000). Understanding the biology of parasitism and host-pathogen interactions requires the growth of these organisms under in vitro conditions.

This unit presents protocols for culturing the *Ehrlichia* species *E. chaffeensis* and *E. canis*. In addition, it includes methods for identifying *Ehrlichia* organisms in culture or tissue samples through the use of polychromatic staining and IFA methods. Protocols are also included for purifying bacteria from host cells from in vitro cultures in support of isolating

Current Protocols in Microbiology 3A.1.1-3A.1.21, May 2008
Published online May 2008 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/9780471729259.mc03a01s9

Ehrlichia genomic DNA, RNA, and total protein. Proteome analysis protocols, such as 2-D gel electrophoresis and western blotting, are also discussed.

CAUTION: E. chaffeensis and *E. canis* are Biosafety Level 2 (BSL-2) pathogens. Follow all appropriate guidelines and regulations for the use and handling of these pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

CAUTION: The protocols described in this unit involve the use of human and/or other animal blood or tissue samples that may also be infected with *Ehrlichia* species or other potential pathogens. Follow all appropriate guidelines and regulations for the use and handling of human- and animal-derived materials. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

NOTE: When preparing solutions, use deionized or double distilled water and all of the highest quality reagents that are available from a vendor. Sterilization by filtration through a 0.22-μm filter or by autoclaving is recommended for most solutions and is essential for cell culture media. Discard any reagent that shows evidence of contamination, precipitation, or discoloration.

BASIC PROTOCOL 1

CULTURING *EHRLICHIA* SPECIES IN A MACROPHAGE CELL LINE

This protocol outlines the culturing of *Ehrlichia* species in the canine macrophage cell line, DH82 (Dawson et al., 1991). The step-by-step protocol described here is intended to help users in culturing *Ehrlichia* isolates currently available at ATCC or at various research laboratories to sufficient quantities for use in experimental infection studies as well as to isolate nucleic acids and proteins for molecular characterization.

Materials

E. chaffeensis and *E. canis* strains of interest (ATCC)
Complete MEM medium (see recipe)
Canine macrophage cell line, DH82 (ATCC # CRL-10389), grown to ~60% confluence in 25-cm^2 tissue culture flask (see Support Protocol 1)
Minimum essential medium with Earle's salt (MEM; Mediatech cat. no. 15-010-CV)

25-cm^2 sterile tissue culture flasks
37°C, 5% CO_2 humidified incubator

1. Obtain frozen stocks of *E. chaffeensis* or *E. canis* from ATCC or from a laboratory stock stored in a liquid nitrogen tank.
2. Thaw a vial of frozen culture by warming to 37°C in a water bath until culture is thawed. Transfer the contents of the vial into a 15-ml centrifuge tube containing 10 ml complete MEM medium using a sterile 1-ml pipet. Centrifuge 10 min at 200 × *g*, 4°C.
3. Discard the medium and resuspend the culture pellet in 1 ml complete MEM medium. Transfer into a 25-cm^2 tissue culture flask containing at least ~60% confluent monolayer DH82 cells (prepared as in Support Protocol 1).
4. Transfer the flask to a 37°C, 5% CO_2 humidified incubator.
5. Check the infectivity two times a week by making a Cytospin slide and evaluating under a light microscope as described in Basic Protocol 5.
6. If the infectivity is less than 50% (as estimated by calculating the ratio of infected cells to total cells counted under a microscope), change half of the medium (see Fig. 3A.1.1 for identification of *Ehrlichia*).

7. When the infectivity reaches 80% to 90%, subculture by inoculating 10% to 20% of the infected culture into a new 25-cm^2 tissue culture flask having at least 60% confluence of DH82 cultures. Alternatively, harvest the cultures for protein preparations (as described in Basic Protocol 7) or for nucleic acid isolation as described in UNIT 3A.3.

   This culture procedure can also be used to inoculate a specimen (such as a blood or a tissue sample) suspected to be positive for Ehrlichia in an effort to recover an isolate. For recovering Ehrlichia species from a specimen, refer to UNIT 3A.3.

MAINTAINING HEALTHY DH82 CELL CULTURES

SUPPORT PROTOCOL 1

Healthy DH82 (macrophage) culture is the prerequisite for growing *Ehrlichia* species. The DH82 cell line is established from neoplastic progenitor cells from a dog with malignant histiocytosis (Wellman et al., 1998). This cell line is widely used for growing *E. chaffeensis* and *E. canis* and to serve as an in vitro model system representing a vertebrate host (Singu et al., 2006).

Materials

70% (v/v) ethanol
Complete MEM medium (see recipe)
Fetal bovine serum (FBS; Atlanta Biologicals cat. no. S11550)
L-Glutamine (Mediatech cat. no. 25005CI)
Canine macrophage cell line, DH82 (ATCC # CRL-10389 or a previously stored frozen stock)

Biosafety Class II (Type B2) cabinet
37°C water bath
15-ml centrifuge tubes (Falcon)
25- and 75-cm^2 tissue culture flasks
37°C, 5% CO_2 humidified incubator
Inverted microscope
4-mm glass beads (Fisher Scientific cat. no. 11-312 A), sterile

1. Sterilize the biosafety cabinet by turning on the UV light for at least 30 min prior to initiating the culture work.
2. Disinfect the work surface area inside the biological safety cabinet with 70% ethanol.
3. Prepare complete MEM medium inside the biosafety cabinet by mixing 500 ml MEM, 6 ml L-glutamine, and 35 ml heat-inactivated FBS (heat inactivate 30 min at 56°C).
4. Thaw a vial of frozen DH82 culture by warming to 37°C in a water bath until cultures are thawed, transfer the contents of the vial into a 15-ml centrifuge tube containing 10 ml complete MEM medium, and centrifuge 10 min at 200 × *g*, 4°C.
5. Discard the medium and resuspend the culture pellet in 5 ml of complete MEM medium.
6. Transfer the contents into a 25-cm^2 tissue culture flask and incubate in a 37°C, 5% CO_2 humidified incubator.
7. Change 50% to 100% of the medium every 3 to 4 days. Replace 50% of the medium if the cell confluence is ≤50% (as assessed by viewing under inverted microscope at 40× magnification) and replace the entire medium if the confluence is ≥50%.
8. When the cells reach 90% to 100% confluence, replace the entire volume of medium and detach the cultures by gently rocking the culture flask by hand after adding ~15 sterile 4-mm glass beads (typically takes ~15 to 30 sec).

9. Dilute the culture in complete MEM medium two- to ten-fold depending on the need to expand the cultures, then transfer 5 or 15 ml each to new 25- or 75-cm^2 tissue culture flasks, respectively, and continue growing the cultures in a 37°C, 5% CO_2 humidified incubator.

BASIC PROTOCOL 2

PREPARATION OF UNINFECTED AND *EHRLICHIA*-INFECTED DH82 CELL LIQUID NITROGEN STOCKS

Preparation of frozen stocks of cultures on a regular basis (preferably once every month) should be done to prevent the loss of cell lines due to accidental contamination or other incidents. Always store stocks in two separate liquid nitrogen tanks. Both the uninfected and *Ehrlichia*-infected cultures should be stored by following a slow freezing protocol done overnight to reach −80°C (described below). Culture vials should then be transferred to a liquid nitrogen tank for long-term storage.

Materials

70% ethanol
E. chaffeensis- or *E. canis*-infected DH82 cultures (see Basic Protocol 1) or healthy DH82 cultures (from a 25-cm^2 tissue culture flask; see Support Protocol 1)
DH82 culture freezing medium (see recipe)
Liquid nitrogen tank

Biosafety Class II (Type B2) cabinet
15-ml sterile polypropylene centrifuge tubes (Falcon)
Refrigerated tabletop centrifuge
Alcohol-resistant marker pen
2-ml screw-cap cryovials
Nalgene Cryo 1°C freezing container (Fisher Scientific cat. no. 5100-0001)

1. Sterilize a biosafety cabinet by turning on UV light for at least 30 min prior to initiating the culture work.
2. Disinfect the work surface area of the biological safety cabinet with 70% ethanol.
3. Transfer *E. chaffeensis*- or *E. canis*-infected DH82 cultures (see Basic Protocol 1) or 5 ml (∼1×10^7 cells) healthy DH82 cultures (from a 25-cm^2 tissue culture flask; see Support Protocol 1) to a 15-ml sterile centrifuge tube.

   CAUTION: *This step and subsequent handling of cultures must be performed inside the biosafety cabinet.*

4. Centrifuge cultures 10 min at 200 × *g*, 4°C.
5. Discard the supernatant and resuspend the culture pellet in 1 ml DH82 culture freezing medium.
6. Transfer the culture to a properly labeled (with alcohol-resistant marker pen) 2-ml cryovial. Freeze the vials by transferring to a −80°C freezer in a Nalgene Cryo 1°C freezing container.

   The Nalgene Cryo 1°C freezing container is designed to provide a 1°C per min drop of temperature.

7. After ∼24 hr of incubation at −80°C, transfer the vials to a liquid nitrogen tank for long-term storage.

   NOTE: *It is important to avoid defrosting the frozen vials during the transfer from a −80°C freezer to a liquid nitrogen tank. The transfer must be performed very rapidly.*

CULTURING *EHRLICHIA* SPECIES IN A TICK CELL LINE

BASIC PROTOCOL 3

General protocols for growing *Ehrlichia* in tick cell lines (e.g., ISE6, IDE8, or AAE2) are very similar to those for *Ehrlichia* grown in the DH82 cell line (as described in Basic Protocol 1). Major differences include the following: tick cells require a specialized medium and are usually incubated at 34°C in the absence of CO_2 (see Support Protocol 2). *Ehrlichia*-infected tick cells also require a slightly different medium than that used for uninfected tick cells. Both uninfected and infection tick cell media must include several minerals, vitamins, and other supplements. One of the important considerations for growing tick cells and *Ehrlichia* cultured in tick cells is that all the reagents and glassware used for culture work must be free of any endotoxins and should be of the highest quality available (see Support Protocol 3).

Materials

E. chaffeensis and *E. canis* (ATCC or from laboratory stock)
Complete *Ehrlichia*-infected tick cell culture medium (see recipe)

Glassware (see Support Protocol 3)
25-cm^2 tissue culture flasks
34°C humidified incubator

1. Prepare glassware for tick cell culture (see Support Protocol 3).
2. Obtain frozen stocks of *E. chaffeensis* and *E. canis*.
3. Thaw a vial of frozen tick cell stock by following Support Protocol 2, steps 2 to 9, but using complete *Ehrlichia*-infected tick cell culture medium.
4. Inoculate the culture pellet from the frozen stock into a 25-cm^2 tissue culture flask containing tick cells having at least ~80% confluent monolayer (prepared as described in Support Protocol 2).
5. Transfer the flask to a 34°C humidified incubator.
6. Check the infectivity two times a week by making a Cytospin slide and evaluating under a light microscope as described in Basic Protocol 5.
7. If the infectivity is <50%, change half of the medium.

8a. When the infectivity reaches 80% to 90%, subculture by inoculating 10% to 20% of the infected culture into a new 25-cm^2 culture flask having at least 80% confluence of tick cells.

8b. Alternatively, harvest the cultures for nucleic acid or protein preparations (*UNIT 3A.3*).

MAINTAINING UNINFECTED TICK CELL CULTURE

SUPPORT PROTOCOL 2

Two *Ixodes scapularis* embryonic cell lines (ISE6 and IDE8) and an *Amblyomma americanum* embryonic cell line (AAE2) have been used (Munderloh et al., 1994; Singu et al., 2006) to support the growth of *Ehrlichia* and *Anaplasma* species and are useful to serve as in vitro model systems to represent tick hosts (Singu et al., 2006). The tick cell line supports the growth of *E. chaffeensis*, *E. canis*, *Ehrlichia ruminantium*, *A. phagocytophilum*, and *A. marginale* (Munderloh et al., 1996, 1999, 2003; Bell-Sakyi et al., 2000; Singu et al., 2005, 2006). Tick cell lines have also proven to be valuable in understanding host-specific differences in the tick-transmitted rickettsiales, *E. chaffeensis*, *E. canis*, *A. marginale*, and *A. phagocytophilum* (Rurangirwa et al., 1999; Jauron et al., 2001; Lohr et al., 2002; Singu et al., 2005, 2006). The protocols (see Basic Protocol 3 and Support Protocol 2) described are adapted from those described in Kurtti et al. (1988), Munderloh

and Kurtti (1989), and Munderloh et al. (1994). All three tick cell lines are cultured using exactly the same procedures.

Materials

70% ethanol
Complete tick cell culture medium (see recipe)
Frozen uninfected tick cell culture

Glassware for tick cell culture (see Support Protocol 3)
Biosafety Class II (Type B2) cabinet
37°C water bath
15-ml centrifuge tubes
1- and 5-ml sterile serological pipets
25- and 75-cm^2 tissue culture flask
34°C humidified incubator

1. Prepare glassware for tick cell culture (see Support Protocol 3).
2. Sterilize the biosafety cabinet by turning on UV light for at least 30 min prior to initiating the culture work.
3. Disinfect the work surface area of the biological safety cabinet with 70% ethanol.
4. Prepare complete tick cell culture medium (see Reagents and Solutions) inside the biosafety cabinet using the base medium, L15B 300.
5. Obtain a vial of uninfected tick cell culture from a frozen stock and defrost rapidly by incubating for few minutes in a 37°C water bath.
6. When the cell suspension is defrosted completely, wipe the culture vial with a 70% ethanol-soaked paper towel.
7. Carefully transfer the entire contents of culture into a sterile 15-ml centrifuge tube and centrifuge 10 min at 400 × *g*, 4°C.
8. Discard the supernatant and add 1 ml of complete tick cell culture medium to the pellet and gently mix using a 1 ml pipet.
9. Transfer the contents to a 25-cm^2 tissue culture flask containing 5 ml of complete tick cell culture medium and incubate the flask in a 34°C humidified incubator.
10. Replace the entire medium the next day and from then once every week until the desired growth of culture is achieved.
11. Monitor the growth of the culture by following Basic Protocol 5.
12. When the cells reach 90% to 100% confluence, replace the entire medium and detach the cultures by pipetting the medium up and down using a 5-ml sterile pipet to create a stream of medium at the cell layer.
13. Dilute the culture in complete tick cell culture medium (two- to ten-fold depending on the need to expand the cultures) and transfer 5 or 15 ml of the diluted cultures to a new 25- or 75-cm^2 tissue culture flask, respectively.

Splitting tick cell cultures too soon may result in the complete loss of cultures. Enzymatic treatment, such as trypsin, or the glass bead method to separate the cells are not recommended, as these procedures can damage the tick cells.

PREPARING GLASSWARE FOR TICK CELL CULTURE

SUPPORT PROTOCOL 3

All glassware used for tick cell culture must be prepared by following strict standards of a cleaning procedure as outlined here. This protocol is intended for the removal of any endotoxins or other contaminants that stick to glassware.

Materials

Glassware detergent
Glassware for cell culture
Autoclave
Aluminum foil
180°C oven

1. Wash glassware once with a detergent designed for laboratory glassware washing.
2. Rinse several times with tap water and then several times with deionized water.
3. Fill the glassware completely with deionized water and autoclave 15 min at 121°C.
4. Discard water, cover with two layers of aluminum foil, and bake glassware 2 hr in a 180°C oven.

PREPARING UNINFECTED AND *EHRLICHIA*-INFECTED TICK CELL LIQUID NITROGEN STOCKS

BASIC PROTOCOL 4

The procedure of making tick cell stocks is slightly different from that described for preparing DH82 culture stocks. Medium for freezing tick cells (both infected and uninfected) is composed of the complete medium (infected or uninfected), but with an FBS concentration raised to 20% and also by including 10% dimethyl sulfoxide (DMSO).

Materials

Ehrlichia-infected tick cells (Basic Protocol 3)
Freezing medium for uninfected tick cell culture (see recipe)
Freezing medium for infected tick cell culture (see recipe)
Liquid nitrogen tank

2-ml cryovials
Nalgene Cryo 1°C freezing container

1. Check the appearance of healthy cells and infectivity of *Ehrlichia*-infected tick cells by evaluating cultures using the polychromatic staining method (see Basic Protocol 5).

   For preparing infected tick cell culture stocks, select cultures having infectivity ranging from 50% to 70%.

2. Remove the growth medium from the culture flasks.
3. Add 5 ml freezing medium and detach the adhering cells by following Support Protocol 2, step 12.
4. Transfer 1 ml to each properly labeled cryovial.
5. Freeze the vials by transferring to a −80°C freezer in a Nalgene Cryo 1°C freezing container.
6. After ∼24 hr, transfer the frozen vials to a liquid nitrogen tank for long-term storage.

   It is important to avoid defrosting the frozen vials during the transfer from a −80°C freezer to a liquid nitrogen tank. The transfer must be performed very rapidly.

EXAMINATION OF CULTURED HOST CELLS FOR *EHRLICHIA* INFECTION USING POLYCHROMATIC STAINING

It is important to monitor infectivity to ensure that *Ehrlichia* does not outgrow macrophage or tick cell cultures or lyse all of the host cells. Aliquots of infected cultures can be transferred onto glass slides using a Cytospin centrifuge and examined for the presence of morulae (*Ehrlichia* infection in a phagosome) in the cytoplasm of host cells using a polychromatic staining method or an indirect fluorescent antibody (IFA) assay (Fig. 3A.1.1). IFA is a useful tool in identifying *Ehrlichia*-infected in vitro cultures (Ristic et al., 1972) and is particularly useful to monitor infections in host cells having low infection rates.

Materials

Uninfected or *Ehrlichia*-infected host cells
Hema staining kit (Fisher Scientific cat. no. 23-122929, 23-122937, 23-122952) containing:
Hema-3 fixative solution
Hema-3 solution I
Hema-3 solution II

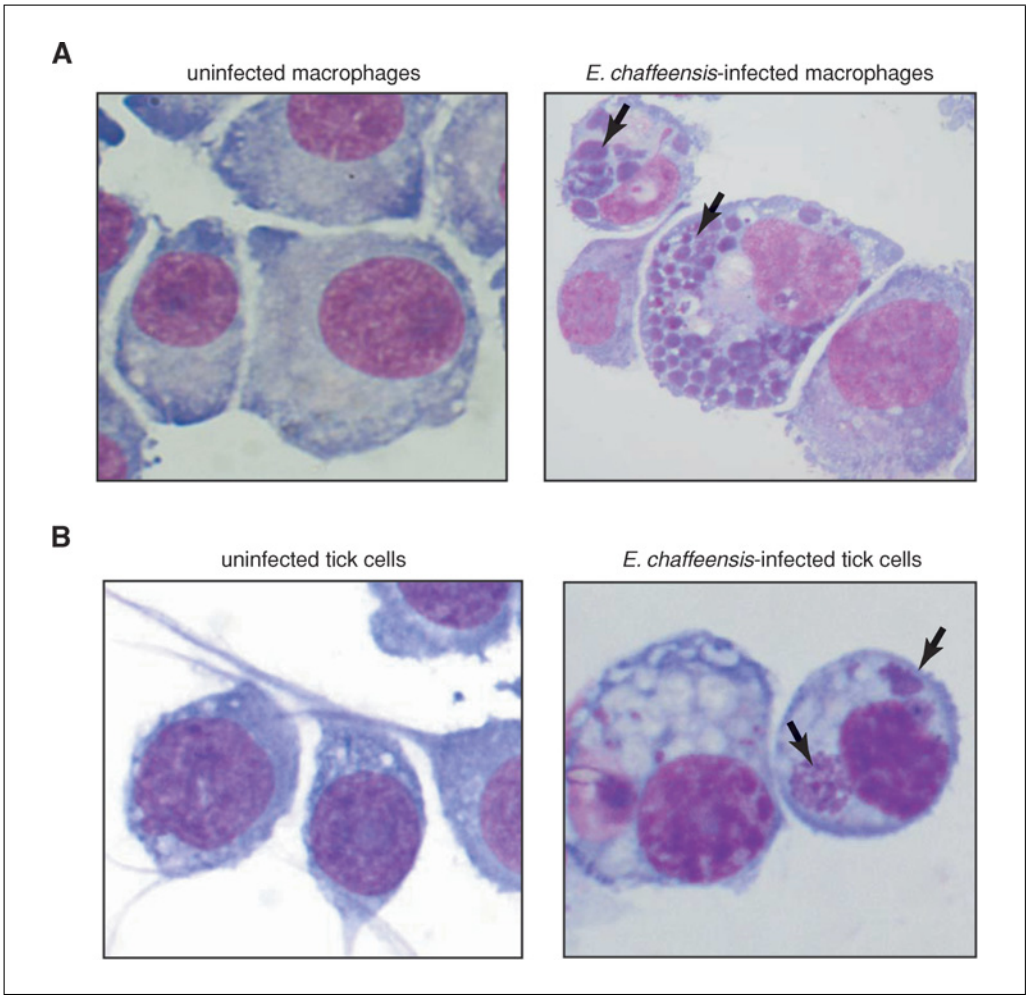

Figure 3A.1.1 Polychromatic staining of healthy and *E. chaffeensis*–infected in vitro cultures of (**A**) macrophage cell line (DH82) and (**B**) tick cells (ISE6). Hema-3 staining kit (Fisher Diagnostics) is used in staining cultures transferred onto a glass slide. *Ehrlichia* organisms are visible in the phagosomes within cytoplasm of infected macrophage and tick cells (identified with arrows). For a color version of this figure, see *http://www.currentprotocols.com*.

Glass microscope slides with frosted ends
Cytospin centrifuge and accessories (Thermo Fisher cat. no. A78300002)
Glass staining jars
Light microscope with 10× and 40× standard objectives and 100× oil immersion objective

1. Label the frosted portion of glass slides with a pencil and assemble for Cytospin analysis.
2. Use 75 to 150 µl of culture suspension (uninfected or *Ehrlichia*-infected host cells) per slide and perform Cytospin as per the manufacturer's instructions by centrifuging culture suspensions 4 min at 400 × *g*.
3. Air dry slides at room temperature until completely dry.
4. Immerse the slides in glass staining jars containing Hema-3 fixative solution for 20 sec, then in Hema-3 solution I for 7 sec, followed by Hema-3 solution II for 4 sec.
5. Rinse the slides in a gentle flow of tap water until excess staining solution is washed off.
6. Air dry slides at room temperature until completely dry.
7. Examine the slides under a light microscope (*UNIT 2A.1*), initially using a 10× or 40× objective to identify the appropriate field containing evenly distributed culture.
8. Use an oil immersion 100× objective to look for the presence of morulae (Fig. 3A.1.1).

INDIRECT FLUORESCENT ANTIBODY ANALYSIS (IFA)

ALTERNATE PROTOCOL

For the most part, polychromatic staining is sufficient for assessing *Ehrlichia* infection. However, IFA may be used to further confirm the presence of *Ehrlichia* in infected cultures. IFA can also be more sensitive in detecting early infections.

Following this procedure, uninfected culture cells will be visible under a microscope with no prominent fluorescence detected, while *Ehrlichia* in morulae will appear as bright green dots (Fig. 3A.1.2).

Materials

Cytospin slides (see Basic Protocol 5)
Acetone
Phosphate-buffered saline (PBS), pH 7.4 (see recipe) containing 1% (v/v) BSA
Polyclonal *E. chaffeensis* or *E. canis* antiserum (obtained from a commercial vendor, e.g., VMRD, cat. no. 211-P-EC, or from infected vertebrate host blood)
1× FA rinse buffer (see recipe)
Fluorescein isothiocyanate (FITC)-conjugated host-specific secondary antibody
Antifade gel mounting medium

Glass staining jars
37°C incubator
Slide box
Paper towels
Aluminum foil
Coverslips
Fluorescence microscope with filters for detecting FITC

1. Prepare Cytospin slides as described for polychromatic staining (see Basic Protocol 5, steps 1 to 3).

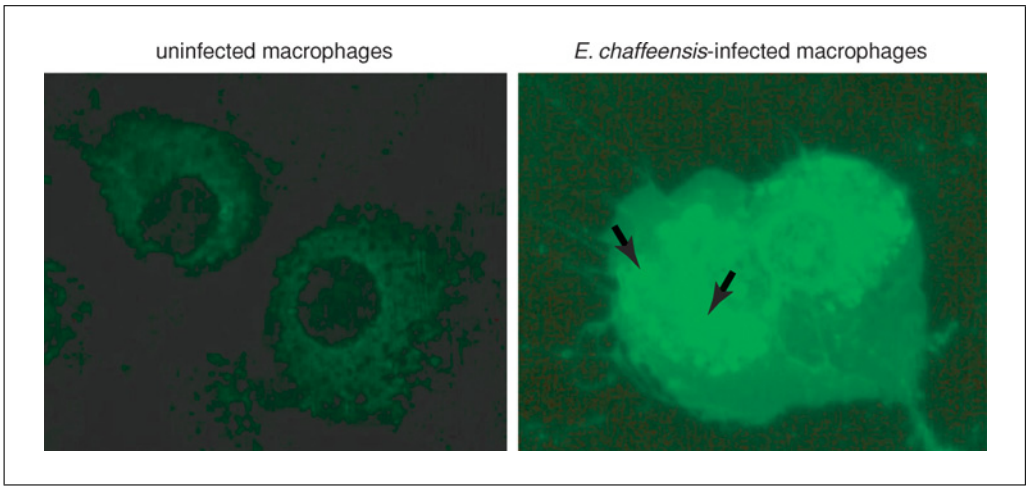

Figure 3A.1.2 Indirect fluorescent antibody (IFA) staining of in vitro cultured *E. chaffeensis*-infected macrophage cell line, DH82. Uninfected DH82 cells are used as a control to demonstrate specific staining only in *E. chaffeensis*–infected cells. *Ehrlichia* organisms in the phagosomes of cytoplasmic compartment of infected macrophages retain strong green fluorescence (identified with arrows). For a color version of this figure, see *http://www.currentprotocols.com.*

2. Immerse slides in a glass jar containing acetone for 1 min.
3. Incubate slides in 1× PBS containing 1% BSA solution for 45 min at 37°C to reduce nonspecific signals.
4. On a flat surface, add 10 μl of prediluted antiserum onto the slides.

   The dilution of antisera can range from 1:64 to 1:4096 depending on the antibody titer.
5. Incubate slides 30 min in a 37°C moist chamber.

   A moist chamber typically consists of a slide box containing water-soaked paper towels.
6. Soak the slides for 10 min with 1× FA rinse buffer in a glass staining jar.
7. Place slides in a moist chamber and add 10 μl of FITC-conjugated host-specific secondary antibodies.
8. Incubate slides 30 min in a dark moist chamber at 37°C (cover slide box with a piece of aluminum foil).
9. Soak slides 10 min with 1× FA rinse buffer in a glass staining jar protected from exposure to light.
10. Add one drop of antifade gel mounting medium and place a coverslip over a slide to allow the medium to spread along the surface of the slide viewing area.
11. Gently press the surface of the coverslip to remove any air bubbles.
12. Examine the slides under a fluorescence microscope initially using a 10× or 40× objective and then using a 100× oil immersion objective.

EHRLICHIA PURIFICATION

BASIC PROTOCOL 6

Recently, methods for purifying host cell-free *Ehrlichia* for use in proteome analysis have been described (Singu et al., 2005, 2006). The protocols have been proven to be useful for isolating different *E. chaffeensis* isolates and *E. canis* cultured organisms. This method can also be used to recover cell-free *Ehrlichia f*or use in antigen analysis or for infection studies using cell-free *Ehrlichia*, or possibly any other molecular biology experiments.

Materials

Uninfected and *Ehrlichia*-infected (Basic Protocol 1) canine macrophage cell line (DH82) or tick cells in a 75-cm^2 confluent flask
SPK buffer (see recipe)

Sonic Dismembrator (Fisher Scientific or equivalent)
3- and 5-μm sterile isopore membrane filters (Millipore)

1. Harvest 15 ml of macrophage or tick cell culture from a 75-cm^2 confluent flask having 80% to 100% *Ehrlichia* infection and centrifuge 15 min at 15,560 × *g*, 4°C, to recover infected host cells and cell-free *Ehrlichia*.

   This protocol can be scaled up or down depending on the volume of purified Ehrlichia needed.

2. Resuspend the resulting culture pellet in 10 ml of SPK buffer and sonicate two times for 30 sec, each time at a setting of 6.5 in a Sonic Dismembrator to release *Ehrlichia* organisms from host cells.

   The sonication setting may vary from instrument to instrument and minor standardization may be required.

3. Centrifuge lysates 5 min at 100 × *g*, 4°C, to pellet host nucleus and other host cell debris.

4. Filter the supernatant sequentially by passing it through 5- and 3-μm sterile isopore membrane filters.

5. Centrifuge *Ehrlichia* organisms from filtrates 15 min at 15,560 × *g*, 4°C and wash pellets two times with 10 ml SPK buffer.

   Avoid disrupting the pellets during this wash protocol. Alternatively, centrifuge cells 5 min at 15,560 × g, 4°C, after each wash.

6. Check the purity of cell-free *Ehrlichia* by preparing a smear on a glass slide stained with a polychromatic stain and examined under a light microscope (see Basic Protocol 5).

PREPARATION OF *EHRLICHIA* PROTEIN EXTRACT

BASIC PROTOCOL 7

The method described here aids in the preparation of total *Ehrlichia* proteins useful for 1-D and 2-D gel analysis.

Materials

Ehrlichia organisms (Basic Protocol 6)
Protein lysis buffer (see recipe)
4:1 (v/v) acetone/trichloroacetic acid, ice cold
Protein sample buffer (see recipe)
RC DC protein assay kit (BioRad)

1. Lyse *Ehrlichia* by adding 0.5 ml of protein lysis buffer to the pelleted organisms obtained in Basic Protocol 6, and incubating 1 hr at room temperature.

2. Precipitate *Ehrlichia* proteins by adding 2 vol of ice-cold 4:1 acetone/trichloroacetic acid and store overnight at −20°C.

3. Centrifuge precipitated protein 15 min at 15,000 × *g*, 4°C, dissolve the final protein pellet in 100 μl sample buffer.

4. Estimate the protein concentration using the RC DC protein assay kit and following the manufacturer's step-by-step protocol.

TWO-DIMENSIONAL (2-D) GEL ELECTROPHORESIS AND WESTERN BLOT ANALYSIS

Proteins resolved on a polyacrylamide gel will be useful for identifying pathogen-specific proteins and proteins that are immunogenic. One- and two-dimensional gel electrophoresis–resolved proteins can also be used for establishing the identity of a protein by mass-spectrometry methods (Singu et al., 2005, 2006).

Materials

Ehrlichia proteins (Basic Protocol 7)
Equilibration buffer I (see recipe)
Equilibration buffer II (see recipe)
4% to 20% gradient polyacrylamide gels (BioRad cat. no. 3450104)
Tris-glycine electrophoresis buffer (see recipe)
Silver-staining kit (BioRad)
Blocking solution: 5% nonfat dairy milk in PBS
Primary antibodies (polyclonal sera against *E. chaffeensis* or *E. canis* raised in mouse, dog, or human)
PBS containing 0.1% Tween 20 (PBS-T; see recipe for PBS)
Anti-mouse and anti-dog horseradish peroxidase (HRPO)–conjugated secondary antibodies
ECL western blotting detection reagents (Amersham)

Multiphor II electrophoresis system (Amersham)
Immobiline dry strips (11-cm, pH 3 to 10; Amersham)
Criterion cell apparatus (BioRad cat. no. 165-6001) or equivalent
Hybond-N nitrocellulose membrane (Amersham cat. no. RPN303D)
Protean Trans-blot cell (BioRad) or equivalent
X-ray film (Amersham)

1. Resolve 100 μg *Ehrlichia* proteins in a Multiphor II electrophoresis system using Immobiline 11-cm dry strips, pH 3 to 10.

   The IEF parameters are 300 V, 2 mA, and 5 W for 1 min, followed by 3500 V, 2 mA, and 5 W for 245 min.

2. Equilibrate the strips sequentially for 15 min each in 1 ml of equilibration buffer I and equilibration buffer II.

3. Perform the second dimension (SDS-polyacrylamide gel electrophoresis analysis) on the 1-D resolved strips in a Criterion Cell apparatus using 4% to 20% gradient polyacrylamide gels for 2 hr at 74 V at room temperature using Tris-glycine electrophoresis buffer.

4. Stain the gels using a silver-staining kit per the manufacturer's protocol to identify a pathogen-specific resolved proteome map (Fig. 3A.1.3).

5. Transfer the 2-D-resolved proteins from unstained gel after step 3 (skip step 4) to a nitrocellulose membrane using Protean Trans-blot cell or equivalent as per the manufacturer's instructions.

6. Soak the membrane in 50 ml blocking solution for 1 hr at room temperature.

7. Transfer the membrane to 10 ml of blocking solution containing 1:250 diluted primary antibody (polyclonal sera against *E. chaffeensis* or *E. canis* raised in mouse, dog, or human) and incubate 2 hr at room temperature.

   Polyclonal sera are obtained from wild-type mice (C57BL6 mice) 21 to 24 days after infection with either macrophage-grown or tick cell-grown E. chaffeensis or E. canis

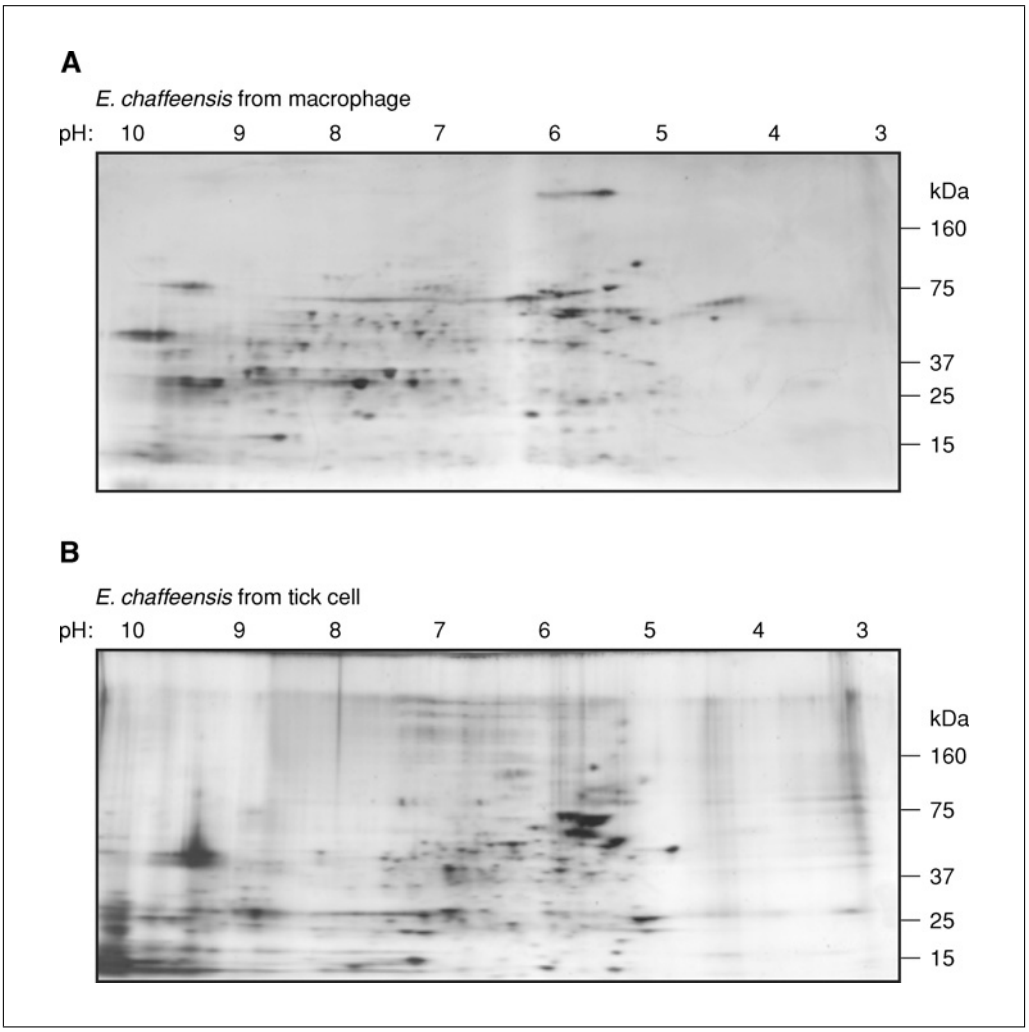

Figure 3A.1.3 Proteome maps of *E. chaffeensis* grown in (**A**) macrophage and (**B**) tick cells (Singu et al., 2005). Scanned images of silver-stained 2-D gels of *E. chaffeensis* proteomes are presented. The approximate location of the pI values of the protein migration and the protein molecular weight standards are shown on the top and right side of the gel images, respectively.

(Ganta et al., 2002, 2004). More details about infection are provided in Ganta et al. (2002, 2004, 2007).

8. Wash the membrane three times, 10 min each time, at room temperature in saturating volumes of PBS-T.
9. Incubate the membrane with appropriately diluted HRPO-conjugated anti-mouse or anti-dog secondary antibody for 1 hr at room temperature.
10. Wash the membrane with PBS-T three times as described in step 8.
11. Detect the antigen-antibody complexes by exposing an X-ray film for 2 to 5 min using the ECL western blotting detection reagents.

Silver-stained gels and X-ray film having western blot data may be digitalized using a scanner and the images may be analyzed with the aid of image analysis software to perform comparisons of 2-D gels.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Complete Ehrlichia-infected tick cell culture medium

412 ml L15B300 medium (see recipe)
25 ml heat-inactivated FBS (Invitrogen cat. no. 26140079)
25 ml TPB medium (see recipe)
25 ml 5% $NaHCO_3$
12.5 ml 1M HEPES (see recipe)
0.5 ml concentrated lipoprotein (ICN Biomedicals cat. no. 0219147680)

Adjust pH to 7.5 to 7.8 with 1 N NaOH and filter sterilize using a 0.22-μm filter unit. Cover the bottle with aluminum foil to protect from light and store up to 2 months at 4°C.

FBS from Invitrogen works well. FBS is shipped with dry ice, upon arrival, thaw in a 37°C water bath, dispense into 25-ml aliquots, and store at −20°C for future use. Before use, heat-inactivate FBS by incubating 30 min in a 56°C water bath.

Complete MEM medium

500 ml minimum essential medium with Earle's salt (MEM medium: Mediatech cat. no. 15-010-CV)
35 ml heated-inactivated FBS (Invitrogen cat. no. 26140079)
6 ml 100 mM L-glutamine
Mix by inverting bottle several times, filter sterilize using a 0.22-μm filter unit, and store up to 2 months at 4°C.
MEM is used for both uninfected cells and Ehrlichia-infected culture.

Complete tick cell culture medium

449.5 ml L15B300 medium (see recipe)
25 ml heat-inactivated FBS (Invitrogen cat. no. 26140079)
25 ml TPB medium (see recipe)
0.5 ml concentrated lipoprotein (ICN Biomedicals cat. no. 0219147680)

Adjust pH to 7.20 with 1 N NaOH and filter sterilize using a 0.22-μm filter unit. Cover the bottle with aluminum foil to protect from light damage and store up to 2 months at 4°C.

DH82 culture freezing medium

0.5 ml MEM medium (Mediatech cat. no. 15-010-CV)
0.45 ml FBS (Invitrogen cat. no. 26140079)
50 μl DMSO
Prepare fresh

Equilibration buffer I

375 mM Tris·Cl, pH 8.8
6 M urea
2% sodium dodecyl sulfate (SDS)
2% DTT

To prepare 100 ml, mix 37.5 ml of 1 M Tris·Cl, pH 8.8, 36.04 g urea, 2 g SDS, and 2 g DTT. Bring volume up to 100 ml with deionized water, dispense into 2-ml aliquots, and store up to 1 year at −20°C.

This buffer is commercially available from BioRad.

Equilibration buffer II

375 mM Tris·Cl, pH 8.8 (*APPENDIX 2A*)
6 M urea
2% SDS
2.72 mg iodoacetamide/ml
0.01% bromophenol blue

To prepare 100 ml, mix 37.5 ml of 1 M Tris·Cl, pH 8.8, 36.04 g urea, 2 g SDS, 272 mg iodoacetamide, and 10 mg bromophenol blue. Bring volume up to 100 ml with deionized water, dispense into 2-ml aliquots, and store up to 1 year at −20°C.

This buffer is commercially available from BioRad.

FA rinse buffer, 1×

2.85 g Na_2CO_3
8.4 g $NaHCO_3$
2.125 g NaCl
Add distilled deionized water to 1000 ml
Adjust pH to 9 to 9.5 with 1 N NaOH
Store up to 1 year at room temperature

Freezing medium for uninfected tick cell culture

7 ml complete tick cell culture medium (see recipe)
2 ml FBS (Invitrogen cat. no. 26140079)
1 ml DMSO
Prepare fresh

Freezing medium for infected tick cell culture

7 ml complete *Ehrlichia*-infected tick cell culture medium (see recipe)
2 ml FBS (Invitrogen cat. no. 26140079)
1 ml DMSO
Prepare fresh

HEPES, 1 M

23.83 g HEPES (Sigma-Aldrich cat. no. H-3375)
Add cell culture–grade water to 100 ml, filter sterilize using a 0.22-μm filter unit, and store up to 6 months at 4°C.

L15B medium

1 packet of L15B medium powder (Invitrogen cat. no. 41300-039)
0.299 g L-aspartic acid (Sigma-Aldrich cat. no. A-4534)
0.299 g α-ketoglutaric acid (Sigma-Aldrich cat. no. K-1128)
0.292 g L-glutamine (Sigma-Aldrich cat. no. G-6392)
0.3 g proline (Sigma-Aldrich cat. no. P-5607)
0.5 g L-glutamic acid (Sigma-Aldrich cat. no. G-8415)
14.41 g D-glucose (Sigma-Aldrich cat. no. G-7021)
1 ml mineral stock D (see recipe)
1 ml vitamin stock (see recipe)

Add the above ingredients to a 1000-ml volumetric flask, make up the volume to 1000 ml with cell culture–grade water, adjust pH to 6.4 to 6.6 with 10 N NaOH, filter sterilize using a 0.22-μm filter unit, and store up to 6 months at 4°C, covering with aluminum foil to protect from light damage.

L15B300 medium

1000 ml L15B medium (see recipe)
333 ml cell culture–grade water
Store up to 2 months at 4°C

Mineral stock solution A

20 mg $CoCl_2 \cdot 6H_2O$ (Sigma-Aldrich cat. no. C-8661)
20 mg $CuSO_4 \cdot 5H_2O$ (Sigma-Aldrich cat. no. C8027)
160 mg $MnSO_4 \cdot H_2O$ (Sigma-Aldrich cat. no. M1144)
200 mg $ZnSO_4 \cdot 7H_2O$ (Sigma-Aldrich cat. no. Z0251)

Prepare the mineral stock solution by weighing the desired weights in 100 ml cell culture–grade water (Invitrogen cat. no. 15230-162), filter sterilize using a 0.22-μm filter unit, dispense into 1-ml aliquots into sterile microcentrifuge tubes, and store up to 2 years at −20°C for future use.

Mineral stock solution B

Prepare 20 mg $Na_2MoO_4 \cdot 2H_2O$ (Sigma-Aldrich cat. no. M1003) in 100 ml of cell culture–grade water, filter sterilize using a 0.22-μm filter unit, and store as 1-ml aliquots up to 2 years at −20°C for future use.

Mineral stock solution C

Prepare 20 mg Na_2SeO_3 (Sigma-Aldrich cat. no. S5261) in 100 ml of cell culture–grade water, filter sterilize using a 0.22-μm filter unit, and store as 1-ml aliquots up to 2 years at −20°C for future use.

Mineral stock solution D

1 g glutathione (reduced) (Sigma-Aldrich cat. no. G-6013)
1 g ascorbic acid (Sigma-Aldrich cat. no. A-4544)
50 mg $FeSO_4 \cdot 7H_2O$ (Sigma-Aldrich cat. no. F-8633)
1 ml mineral stock A (see recipe)
1 ml mineral stock B (see recipe)
1 ml mineral stock C (see recipe)

Add the above ingredients and make up the volume to 100 ml with cell culture–grade water, filter sterilize using a 0.22-μm filter unit, and store as 1-ml aliquots up to 2 years at −20°C.

$NaHCO_3$, 5%

Add 5 g of $NaHCO_3$ in 100 ml of cell culture–grade water, filter sterilize using a 0.22-μm filter unit, and store up to 2 months at 4°C.

NaOH, 1 N

Add 4 g of NaOH in 100 ml culture grade–water, filter sterilize using a 0.22-μm filter unit, and store up to 6 months at 4°C.

PBS buffer, pH 7.4

8 g NaCl
0.2 g KH_2PO_4
0.2 g KCl
Plus one of the following:
2.17 g $Na_2HPO_4 \cdot 7H_2O$

continued

2.9 g $Na_2HPO_4 \cdot 12H_2O$
1.15 g Na_2HPO_4 (anhydrous)
Make up the volume to 1 liter with deionized distilled water.

Protein lysis buffer

9 M urea
2% Triton X-100
3.24 mM dithiothreitol (DTT)
8 mM phenylmethylsulfonyl fluoride (PMSF)
0.2% ampholyte, pH 3 to 10 (Amersham Pharmacia Biotech)

To prepare 100 ml, add 54.05 g urea, 2 g Triton X-100, 50 mg DTT, 139.3 mg PMSF, and 0.2 ml ampholyte and make up the volume to 100 ml with deionized water and store up to 1 year at −20°C.

Protein sample buffer

9 M urea
0.2% ampholyte, pH 3 to 10 (Amersham Pharmacia Biotech)
2% 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS; Sigma)
65 mM DTT
0.52% Triton X-100
0.001% bromophenol blue

Mix 54.05 g urea, 0.2 ml ampholyte, 2 g CHAPS, 1.003 g DTT, 0.52 g Triton X-100, and 1 mg bromophenol blue with deionized water to a total volume of 100 ml and store up to 1 year at −20°C.

SDS-PAGE gel transfer buffer, pH 8.3

39 mM glycine
48 mM Tris base
0.037% SDS (electrophoresis grade)
20% methanol

To prepare 1 liter of transfer buffer, weigh 2.9 g glycine, 5.8 g Tris base, 0.37 g SDS, add 200 ml methanol, and make up the volume to 1000 ml with deionized water. Store up to 1 year at room temperature.

SPK buffer, pH 7.4

0.05 M potassium phosphate
0.2 M sucrose

To make 1 liter of SPK buffer, measure 80.2 ml of 0.5 M K_2HPO_4, 19.8 ml of 0.5 M KH_2PO_4, 68.46 g sucrose, dissolve in deionized distilled water, and make up volume to 1000 ml with deionized distilled water. Store up to 1 year at 4°C.

TPB medium

Add 29.59 g tryptose phosphate broth (TPB; Difco cat. no. 260300) to culture grade–water and make up volume to 1000 ml, dispense into 100-ml aliquots, and autoclave with loose caps for 15 min at 121°C. Store up to 1 year at 4°C.

The color should be pale yellow; if it darkens, the TPB should be discarded as it will be toxic to the tick cells.

Tris-glycine electrophoresis buffer

25 mM Tris base
250 mM glycine
0.1% SDS

Weigh out 15.1 g Tris·Cl and 94 g glycine, dissolve compounds in 900 ml deionized water, and add 50 ml of 10% SDS. Make up the final volume to 1000 ml with deionized water (5× stock). Dilute 1:5 to make 1× working buffer. Store up to 1 year at room temperature.

Vitamin stock

100 mg 4-aminobenzoic acid (PABA; Sigma-Aldrich cat. no. A-9878)
50 mg cyanocobalamine (B12; Sigma-Aldrich cat. no. V2876)
10 mg D-biotin (Sigma-Aldrich cat. no. B-4639)

Prepare the vitamin stock by weighing these ingredients and transferring to 100 ml cell culture–grade water, filter sterilize using a 0.22-μm filter unit, and store as 1-ml aliquots up to 1 year at −20°C for use.

COMMENTARY

Background Information

Ehrlichia culture protocols described in this unit require particular care and attention to details. Two important precautions must always be followed: (1) Monitor the availability of uninfected macrophage and tick cell cultures in sufficient quantities to maintain the *Ehrlichia*-infected cultures. This is especially important for tick cell culture since the doubling time of tick cells is longer than macrophage cultures by about two fold. Typically, three to five times more flasks of uninfected tick cultures to one flask of *Ehrlichia*-infected culture are needed. (2) Care must be taken to avoid culture contaminations, as all the cultures must be maintained in the absence of any added antibiotics. During the initial stages of culture establishment, it may be worthwhile to maintain one or two uninfected host cell culture flasks in the presence of antibiotics, such as gentamycin (50 μg/ml final concentration), or a mixture of penicillin and streptomycin (50 to 100 IU/ml and 50 to 100 μg/ml, respectively) and fungizone (0.125 to 0.25 μg/ml) by following the protocols described by a manufacturer (Sigma-Aldrich).

Polychromatic staining and indirect immunofluorescence assay (IFA) are commonly used for detecting *Ehrlichia* infection in in vitro cell culture as well as in infected animal blood or tissue samples. IFA is a more sensitive method and it is useful to assess low level infection in culture or tissue samples.

Cryopreservation of uninfected and *Ehrlichia*-infected cultures at a regular interval (once every 1 to 2 months) is recommended to facilitate rapid recovery in the event of culture contamination. Host cell–free *Ehrlichia* is needed for use in pathogen-specific protein analysis. Host cell–free *Ehrlichia* can be purified by sonication, differential centrifugation followed by fractionation using small pore size isopore membrane filters. This method aids in the preparation of pure *Ehrlichia* useful in protein analysis and molecular biology experiments.

Critical Parameters

Culturing Ehrlichia in canine macrophage cell line, DH82, and tick cell lines

Sterile culture techniques are a very critical step for *Ehrlichia* culture as all the cultures must be maintained in the absence of any antibiotics to insure bacterial growth. Always keep infected cultures separate from uninfected cultures. Also, maintaining duplicate sets of infected and uninfected cultures by independently prepared media and reagents is preferred.

Tick cells seem to be more sensitive to minor changes of pH and cell density. Cell density of tick cell culture should be between 20% and 80% for optimal growth. Tick cell culture can also be affected due to impurities that may be introduced from glassware and other culture supplies. Thus, it is recommended to use the culture supplies from the same vendor when one finds a product(s) useful in growing *Ehrlichia* in tick cell culture.

Preparing cell culture stocks

One must prepare liquid nitrogen culture stocks on a regular basis to prevent the loss of cell lines due to accidental contamination

or other incidents. It is also recommended to store stocks in two separate liquid nitrogen tanks. Both the uninfected and *Ehrlichia*-infected cultures should be stored by following the slow freezing protocol to reach −80°C overnight and then transferred to a liquid nitrogen tank for long-term storage.

Checking the infectivity by polychromatic staining and IFA methods

It is important to maintain a proper cell density (by assessing under an inverted microscope) so that the culture does not overgrow. It is also critical to check the infectivity of *Ehrlichia*-infected DH82 or tick cells by examining a slide using polychromatic staining or the IFA method. When the infectivity of a flask reaches 70% to 90%, the infected cells need to be harvested and 1/10 to 1/5 of the infected cells can be used to infect a new flask having a confluent monolayer of healthy cells for continued maintenance of the cell culture.

Troubleshooting

Table 3A.1.1 presents some of the common problems associated with the protocols in this unit.

Anticipated Results

Growth of Ehrlichia in DH82 and tick cell culture

DH82 cell culture is easier to maintain as compared to tick cell culture. When recovering a frozen healthy DH82 culture stock, the culture growth should be visible within 2 to 3 days. By 5 to 7 days, a 25-cm^2 tissue culture flask should be confluent and ready to be split. The doubling time for tick cells is longer, and it will take 7 to 10 days for a flask to reach confluency.

When an *Ehrlichia* culture has 70% to 90% infectivity, it is subcultured by inoculating 5% to 10% into a flask containing a confluent monolayer. Infections should reach 80% to 90% within 3 to 5 days after inoculation.

Detection of Ehrlichia-infected cells by polychromatic staining and IFA methods

When examining a Cytospin slide stained with a polychromatic stain, the morulae (cytoplasmic inclusions of *Ehrlichia*) stain purple, while the host cell nucleus stains pink. Morulae in tick cells are more loosely packed compared to those in DH82 cells.

Table 3A.1.1 Troubleshooting Guide for Laboratory Maintenance of *Ehrlichia*

Problem	Possible cause	Solution
Medium color changed to yellow	Bacterial or fungal contamination, or pH may be too low	If contamination was confirmed, discard the medium. If pH too low, adjust pH with NaOH.
Poor culture growth	Cultures were split too fast or diluted too much during subculture	Monitor cell density during growth and subculture
Most of the host cells of an infected culture are lysed	Overgrowth of *Ehrlichia*	Add more healthy cells or re-infect a new flask containing confluent monolayer of host cells
Fewer or no cells detected on a stained Cytospin culture slide	Poor fixation of the cell culture prior to staining	Fix slides in the Hema-3 fixative for a longer period of time
All cellular contents are purple on a stained Cytospin culture slide	Slide incubated too long in Hema-3 solution II	Reduce incubation time in Hema-3 solution II
High background fluorescence on IFA slide	Poor blocking	Increase the length of blocking to >1 hr using BSA or non-fat dairy milk
Low yield of host cell–free *Ehrlichia*	Started with low volume of infected culture or infectivity is low or poor lysis of host cells	Check for infectivity and confluence before use and start with at least 15 ml of 80%–90% infected culture. Sonicate for longer time intervals.

Morulae are visualized as fluorescent green clusters in the IFA slides when examined under a fluorescence microscope.

Purifying host cell–free Ehrlichia

The purified *Ehrlichia* pellet is typically much smaller than the original culture pellet and looks creamy white.

Laboratory Maintenance of *Anaplasma phagocytophilum*

Anaplasma phagocytophilum is the etiologic agent of human granulocytic anaplasmosis (HGA; formerly human granulocytic ehrlichiosis). This unique bacterium resides within salivary glands of its *Ixodes* tick vector or within the intracytoplasmic confines of neutrophils in its mammalian hosts. Because of its obligate intracellular nature, *A. phagocytophilum* is maintained in the laboratory in eukaryotic cell culture or within murine hosts. The human-derived promyelocytic leukemia cell line HL-60 is routinely used for in vitro cultivation of *A. phagocytophilum*. The susceptibility of these cells to *A. phagocytophilum* infection, like that of human neutrophils, is attributable to the expression of P-selectin glycoprotein ligand-1 (PSGL-1) on the cell surface. The rapid rate at which HL-60 cells grow and their permissiveness with respect to *A. phagocytophilum* infection allows one to obtain high yields of in vitro–cultured bacteria. However, the ability of *A. phagocytophilum* to successfully establish in vivo infection declines considerably when continually maintained in cell culture. It is therefore important that the bacterium also be maintained in vivo. Laboratory mice are excellent in vivo models, as infection in these mice partially mimics many of the hematological parameters and histopathological lesions associated with HGA. Peripheral blood infection of immunocompetent mice resolves by the third or fourth week post-inoculation. Moreover, *A. phagocytophilum* pathogenicity wanes with repeated passage through immunocompetent mice. SCID mice are unable to clear *A. phagocytophilum* infection, and are therefore used for continual maintenance of the pathogen in vivo. This unit describes the inoculation and maintenance of *A. phagocytophilum* in vivo using a murine model of infection (see Basic Protocol 1) and in vitro using HL-60 cells (see Basic Protocol 2). Methods for identifying *A. phagocytophilum*–infected cells in a peripheral blood sample (see Support Protocol 1) or infected HL-60 cells (see Support Protocol 2) using either cytological staining (see Support Protocol 3) or immunofluorescent microscopy (see Support Protocol 4) are also discussed. Additionally, cryopreservation of *A. phagocytophilum*–infected HL-60 cell lines (see Support Protocol 3) is described. Furthermore, this unit describes the recovery of semipure preparations of viable *A. phagocytophilum* from infected HL-60 cells (see Basic Protocol 2). Techniques for further purifying these bacterial preparations by density gradient centrifugation (see Support Protocol 6) or for fluorescently labeling them to track infection (see Support Protocol 7) are also provided. Figure 3A.2.1 demonstrates how these protocols are interrelated.

CAUTION: *Anaplasma phagocytophilum* is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

CAUTION: The protocols described in this unit involve the use of human and/or murine blood that is infected with *A. phagocytophilum.* Syringe lysis of *A. phagocytophilum*–infected HL-60 cells is also involved. Follow all appropriate guidelines and regulations for the use and handling of human-derived materials and blood-borne pathogens, as well as storage and disposal of "sharps." See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

CAUTION: These experiments require Animal Biosafety Level 2 (ABSL-2) conditions. Follow all appropriate guidelines for the use and handling of infected animals. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information. Protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

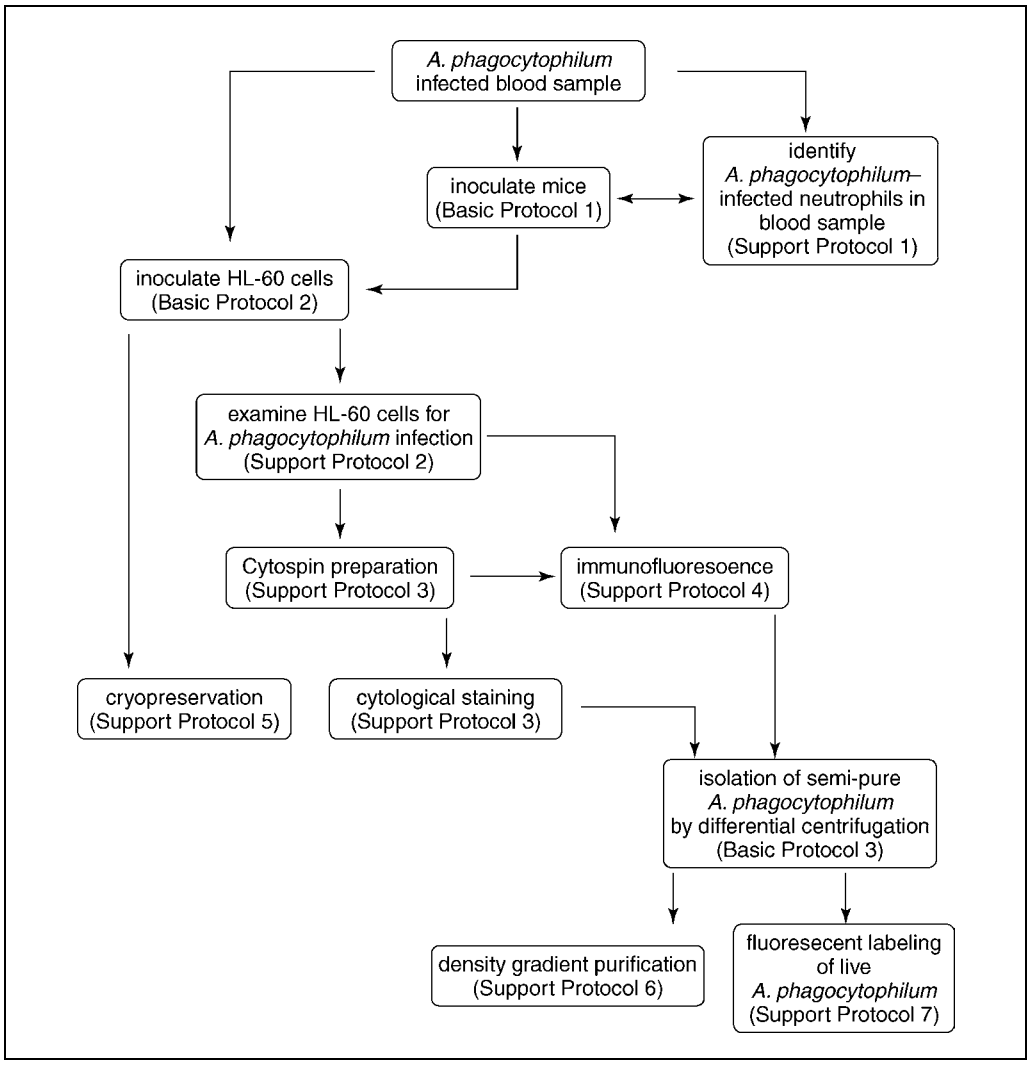

Figure 3A.2.1 Flowchart of protocols described in this unit.

BASIC PROTOCOL 1

INOCULATION OF *A. PHAGOCYTOPHILUM* INTO LABORATORY MICE

Prolonged culture of *A. phagocytophilum* in HL-60 cells results in attenuation of infectivity and pathogenicity of the bacterium. *A. phagocytophilum* infectivity can be maintained by mouse passage. Although it has been demonstrated that blood from infected immunocompetent mice can remain infectious for up to 60 days, the bacterial load in peripheral blood declines significantly by day 30. It is therefore recommended that an immunocompetent mouse remain infected for no longer than 30 days before passing an aliquot of its blood to a naive mouse. Pathogenicity, however, declines with continual passage in immunocompetent mice, but can be restored and successfully maintained by passage in SCID mice. Blood, either from an *A. phagocytophilum*–infected mouse or a patient suspected of having HGA that has yet to be treated with antibiotics, is inoculated into SCID mice. The bacterium is maintained in vivo by passage through SCID mice. *A. phagocytophilum* infection may be maintained in an individual SCID mouse for up to 2 months before being passed to naive SCID mice. For studies of *A. phagocytophilum* in an immunocompetent animal, *A. phagocytophilum*–infected SCID mouse blood is inoculated into C3H/HeN mice. Following inoculation of either SCID or immunocompetent mice, intracytoplasmic colonies of *A. phagocytophilum* are detectable in peripheral blood neutrophils by day 2. Infection is monitored by examination of peripheral blood smears.

While the protocol below calls for C3H/Smn.CicrHsd/*scid* or C3H/HeN mice, C3H/HeJ and their congenic C3H-scid counterparts may also be used. There is no observable difference in bacterial loads between the C3H/ HeN and C3H/ HeJ strains.

Materials

5% (v/v) Lysol
70% (v/v) ethanol
Mouse: C3H/Smn.CicrHsd/*scid* (SCID; 3 to 5 weeks old; Harlan Sprague-Dawley) *or* C3H/HeN (3 to 5 weeks old; National Cancer Institute Animal Production Program, Frederick Cancer Research Center)
Ketamine/xylazine anesthetic cocktail (see recipe) or other anesthetic agent as outlined in approved institutional protocol
Anticoagulant-treated, *A. phagocytophilum*–infected peripheral blood (either from an *A. phagocytophilum*–infected mouse or a HGA patient that has not yet received antibiotic therapy)
Class II, Type B2, vertical flow biological safety cabinet
1-cc syringes with 28-G, $\frac{1}{2}$-in. (12.7-mm) needles
1-cc tuberculin syringes with 26-G, $\frac{1}{2}$-in. (12.7-mm) needles
Gauze
Additional reagents and equipment for anesthesia (Donovan and Brown, 1998) and intraperitoneal injection (Donovan and Brown, 1995a) of mice

NOTE: The total blood volume of a mouse is ~5.5 ml per 100 g body weight. Do not collect more than 20% of total volume at one time. Do not collect more than this volume weekly. There is no limit to the number of times a mouse may be bled, provided that the aforementioned parameters are observed. For repeated blood collection via the retro-orbital route, alternate eyes should be used.

Anesthetize mice

1. Disinfect the work surfaces of a Class II, Type B2, vertical flow biological safety cabinet with 5% Lysol followed by 70% ethanol. Place a paper towel on the work surface of the biological safety cabinet.
2. Anesthetize the mouse (Donovan and Brown, 1998) by injecting 0.1 ml/20 g body weight of ketamine/xylazine anesthetic cocktail intramuscularly using a 1-cc tuberculin syringe with a 28-G, $\frac{1}{2}$-in. needle.

   This dosage should provide effective anesthesia for ~30 to 40 min.

   Once the mouse becomes unresponsive to a toe pinch, the procedure may be continued. If the mouse flinches or otherwise responds to the pinch, wait 5 min and check again. If the mouse still responds, administer an additional dose of 0.1 ml anesthetic cocktail/20 g body weight.
3. Transfer the anesthetized mouse to the biological safety cabinet, placing it on the paper towel covering the flat work surface.

Inoculate mice

4. In the biological safety cabinet, fill a 1-cc tuberculin syringe fitted with a 26-G, $\frac{1}{2}$-in. needle with 100 µl of *A. phagocytophilum*–infected blood.
5. While holding a mouse against the flat surface, slowly inject the 100 µl blood sample into the peritoneal cavity (Donovan and Brown, 1995a).
6. Carefully withdraw the needle and use gauze to apply digital pressure at the injection site to maintain hemostasis.

7. Place the injected mouse in a spare cage and continue injections with additional mice. When injections are finished, check the animals for normal behavior and return them to their normal housing location.

8. Remove unused materials from the biological safety cabinet. Disinfect the interior of the biosafety cabinet with 5% Lysol followed by 70% ethanol.

SUPPORT PROTOCOL 1

PREPARATION OF BLOOD SMEAR FOR IDENTIFYING *A. PHAGOCYTOPHILUM*–INFECTED NEUTROPHILS

Within neutrophils, *A. phagocytophilum* replicates in the confines of intracytoplasmic inclusions to form a cluster of organisms termed a morula. In the following protocol for the identification of *A. phagocytophilum*–infected neutrophils, blood from an infected mouse or HGA patient is smeared onto a glass slide and fixed. Morulae are subsequently identified using either light or immunofluorescent microscopy as discussed in Support Protocols 3 and 4, respectively. The day post-inoculation at which the blood sample is obtained will have bearing on one's ability to detect morulae-positive neutrophils. Following intraperitoneal inoculation of immunocompetent mice with *A. phagocytophilum*, morulae are evident in 2% to 4% of peripheral blood neutrophils on day 2. By days 7 to 8, which typically represent peak infection, morulae are detectable in 7% to 13% of neutrophils. By day 14, the peripheral blood infection wanes considerably, with the percentage of neutrophils with detectable morulae dropping to <2%. Often, morulae are no longer evident in peripheral blood smears by days 28 to 30. The kinetics of infection observed for immunocompetent mice are similar to those observed in human patients with HGA. The kinetics of infection for SCID mice are similar to those observed for immunocompetent mice for the first 7 to 8 days of infection, after which the percentage of infected peripheral blood neutrophils usually remains at 5% to 13% (for up to several weeks) until the mice are euthanized.

Materials

A. phagocytophilum–infected mice (see Basic Protocol 1)
Glass tubes coated with anticoagulant (e.g., EDTA, heparin)
Glass microscope slides with frosted ends
Additional reagents and equipment for blood collection from mice (Donovan and Brown, 1995b)

NOTE: A blood sample from a human patient suspected of having HGA who has yet to receive antibiotic therapy is processed in a manner identical to that described in steps 2 through 6.

1. Collect blood from *A. phagocytophilum*–infected mice (Donovan and Brown, 1995b) via retro-orbital bleed, saphenous vein puncture, or other approved technique and transfer to anticoagulant-treated glass tubes.

2. Place 1 to 2 μl of the anticoagulant-treated blood sample onto one end of a glass slide with frosted end.

3. Holding the slide steady with one hand, touch the end of another slide held at a 45° angle to the drop of blood.

   The blood will spread along the interface of the two slides.

4. Drag the angled slide along the surface of the held slide in a single sweeping motion. Repeat this process to generate at least 3 slides per blood sample.

   The desired result is to achieve a tongue-shaped smear of blood along the slide's surface. The vast majority of neutrophils and other leukocytes are present in the arch-shaped periphery ("tongue") of the smear.

5. Allow slides to air dry for at least 30 min at room temperature.
6. Stain and observe the slides for *A. phagocytophilum*–infected neutrophils as described in Support Protocol 3 or 4.

INOCULATION AND PASSAGING OF *A. PHAGOCYTOPHILUM* INFECTION IN HL-60 CELL CULTURE

BASIC PROTOCOL 2

The human-derived promyelocytic leukemia cell line HL-60 is the predominant choice for in vitro cultivation of *A. phagocytophilum*. Blood from either an *A. phagocytophilum*–infected mouse or a human patient suspected of having HGA that has yet to be treated with antibiotics is inoculated into HL-60 cells to generate a primary in vitro culture of *A. phagocytophilum*. The infected HL-60 cells are subsequently passaged to maintain proper cell density and supplemented with uninfected HL-60 cells to prevent lysis of the entire host cell population.

Materials

5% (v/v) Lysol
70% (v/v) ethanol
HL-60 cells (ATCC #CCL240) growing in culture
IMDM-10: Iscove's modified Dulbecco's medium (Invitrogen 12440-053) supplemented with 10% (v/v) heat-inactivated FBS
A. phagocytophilum–infected blood sample(s) collected in glass tubes coated with anticoagulant (e.g., EDTA, heparin)
Class II, Type B2, vertical flow biological safety cabinet
15-ml polypropylene conical centrifuge tubes with screw caps (BD Falcon)
25-cm^2 tissue culture flasks with vented caps (BD Falcon)
Additional reagents and equipment for counting cells using a hemacytometer (Strober, 1997a) and determining cell viability by trypan blue exclusion (Strober, 1997b)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Inoculate A. phagocytophilum–infected blood into HL-60 cell culture

1. Disinfect the work surfaces of a Class II, Type B2, vertical flow biological safety cabinet with 5% Lysol followed by 70% ethanol. Organize all materials to be used in the biological safety cabinet.

   CAUTION: *Steps 1 to 3 must be performed in the biological safety cabinet. When removing aliquots of uninfected or A. phagocytophilum–infected HL-60 cells from culture flasks in later steps, this must also be done in the biological safety cabinet.*

2. Aliquot 3 ml of HL-60 cells in IMDM-10 at a density of 500,000 per ml into a 15-ml conical polypropylene centrifuge tube. Perform this for each inoculum.

   HL-60 cells are nonadherent.

   RPMI 1640 medium supplemented with 10% FBS (RPMI-10) is equally suitable.

3. Add 100 µl of *A. phagocytophilum*–infected blood, pipet up and down to mix, and transfer the entire volume to a 25-cm^2 culture flask with a vented cap. Perform this for each inoculum.

   At least one flask of HL-60 cells should receive no inoculum, to serve as an uninfected control.

4. Incubate. Bi-weekly, examine the cultures as follows.

   a. Determine the culture densities by examining aliquots using a hemacytometer (Strober, 1997a) and light microscope. Maintain a density of 2–5 $\times$ 10^5 cells/ml by supplementing with fresh medium as needed.

   b. Determine the viability of the cells based on their ability to exclude trypan blue (Strober, 1997b).

      When visualized in the presence of trypan blue under light microscopy, uninfected HL-60 cells are typically round and have smooth borders. The membranes of infected cells, however, become more compromised as the infection progresses. They become permeable to trypan blue, and, as a result, are darker than uninfected cells. Also, their borders are rougher in appearance.

   c. Monitor cultures for infection load to make sure that the bacteria do not outgrow and completely lyse the HL-60 cells, by cytological or immunofluorescence staining as described in Support Protocols 2, 3, and/or 4.

      Morulae, or intracellular inclusions of A. phagocytophilum, should be apparent by ~5 days post-inoculation. The percentage of infected HL-60 cells will depend on the bacterial load of the inoculum.

Maintain A. phagocytophilum–infected HL-60 cells

5. After confirming the presence of *A. phagocytophilum*–infected HL-60 cells, expand the culture to a volume of 10 ml by adding fresh IMDM-10 medium to the flask.

6. Continue incubating. Bi-weekly, determine the cell density by examining aliquots using a hemacytometer. Feed cells by removing 6 to 8 ml of spent medium and supplementing with fresh IMDM-10 to achieve a density of 2 to 5 $\times$ 10^5 cells per ml, and add 0.5 to 1.0 $\times$ 10^6 uninfected HL-60 cells in 1 ml of medium. Determine the percentage of infected cells bi-weekly as described in Support Protocols 2, 3, and/or 4; if percentage of infected cells is <50%, do not add uninfected HL-60 cells.

   For example, if it is determined that the culture density has expanded to 1 $\times$ 10^6 cells/ml, one should remove and discard 9 ml of culture, corresponding to 9 $\times$ 10^6 cells. Remaining in the 25-cm^2 flasks will be 1 ml of A. phagocytophilium–infected culture, corresponding to 1 $\times$ 10^6 cells. It will then be necessary to add 1 $\times$ 10^6 uninfected HL-60 cells (as enumerated using a hemacytometer), suspended in medium, followed by the addition of fresh medium to a final volume of 10 ml, for a final culture density of 2–3 $\times$ 10^5 cells/ml.

SUPPORT PROTOCOL 2 EXAMINATION OF TISSUE CULTURE CELLS FOR *A. PHAGOCYTOPHILUM* INFECTION

Monitoring the percentage of infected HL-60 cells and determining the relative bacterial burden per cell is requisite for ensuring that the bacterial density is neither diluted too greatly by uninfected HL-60 cells nor outgrows and lyses the entire host cell population. Additionally, it is important to gauge the bacterial burden of a given culture prior to lysing it for recovering host cell–free *A. phagocytophilum*. Aliquots of infected HL-60 cells are centrifuged onto glass slides using a Cytospin cytocentrifuge (Thermo Electron). The slides can be examined for the presence of morulae (intracytoplasmic inclusions of *A. phagocytophilum*) using either cytological staining (see Support Protocol 3) or immunofluorescence (see Support Protocol 4).

Peripheral blood, either from an *A. phagocytophilum*–infected mouse or a patient suspected of having HGA that has yet to receive antibiotic therapy may be used in place of *A. phagocytophilum*–infected HL-60 cells in the protocol below. However, examination of peripheral blood using the smear method (Support Protocol 1) is preferable because of the rapidity and ease with which it can be performed.

Materials

5×10^5 cell/ml suspension of *A. phagocytophilum*–infected HL-60 cells in IMDM-10 (see Basic Protocol 2)
5×10^5 cell/ml suspension of uninfected HL-60 cells in IMDM-10 (control)
0.5% (v/v) sodium hypochlorite
Glass microscope slides with frosted ends
Cytocentrifuge setup (Thermo Electron Corp.) including:
Shandon Stainless Steel Cytoclip
Shandon TPX Filter Cards
Shandon TPX Sample Chamber
Shandon Cytospin 4 Cytocentrifuge
Absorbent bench paper with plastic backing

Prepare slides

1. Label the frosted portion of each slide with the appropriate sample designation. Use a Shandon Stainless Steel Cytoclip to secure a TPX Filter Card and TPX Sample Chamber to each slide, situating the filter card between the sample chamber and slide with the holes of the sample chamber and filter card aligned. Place the assemblies in the cytocentrifuge and balance the rotor properly.

   The use of a cytocentrifuge is recommended because the nuclei of HL-60 cells are quite large and can obscure detection of morulae. Centrifugation of HL-60 cells flattens them, which greatly facilitates viewing of their cytoplasmic contents.

2. Pipet 200 µl of a 5×10^5 cell/ml suspension of *A. phagocytophilum*–infected or uninfected (control) HL-60 cells in IMDM-10 into each sample chamber.

   Alternatively, 100 µl of peripheral blood to be examined for A. phagocytophilum may be added to the sample chamber.

3. Centrifuge the suspensions onto the slides for 2 min at $70 \times g$, using a Shandon Cytospin 4 Centrifuge.

4. Unclip the assembly, remove the sample chambers, and soak them in 0.5% sodium hypochlorite for ≥30 min. Afterwards, rinse the sample chambers in deionized water. Dispose of the filter cards into a biohazard-labeled trash receptacle.

   Disposable cytospin funnels are also available from Thermo Electron.

5. Place the slides at a 45° angle on a level surface covered with a sheet of absorbent bench paper with plastic backing. Allow to air dry at room temperature for at least 20 to 30 min, until completely dry.

Stain and examine slides for the presence of A. phagocytophilum

6. Stain and observe the slides for *A. phagocytophilum*–infected HL-60 cells as described in Support Protocol 3 or 4. Perform a minimum of three independent counts of at least 100 cells each, and determine the percentage of infected cells.

CYTOLOGICAL STAINING OF *A. PHAGOCYTOPHILUM*–INFECTED CELLS

SUPPORT PROTOCOL 3

Slides of *A. phagocytophilum*–infected and uninfected control cells are stained using the Protocol Hema-3 staining solutions, which are comparable to Wright and Giemsa stains. Peripheral blood smears (see Support Protocol 1) or cytospins of peripheral blood or HL-60 cells (see Support Protocol 2) may be used. Morulae, or intracytoplasmic colonies of *A. phagocytophilum*, are visualized by light microscopy as stippled vacuolar inclusions that stain more darkly than host cell nuclei. An advantage of this technique is the rapidity with which it can be performed. If a Cytospin cytocentrifuge is unavailable, then immunofluorescent screening (see Support Protocol 4) may be performed.

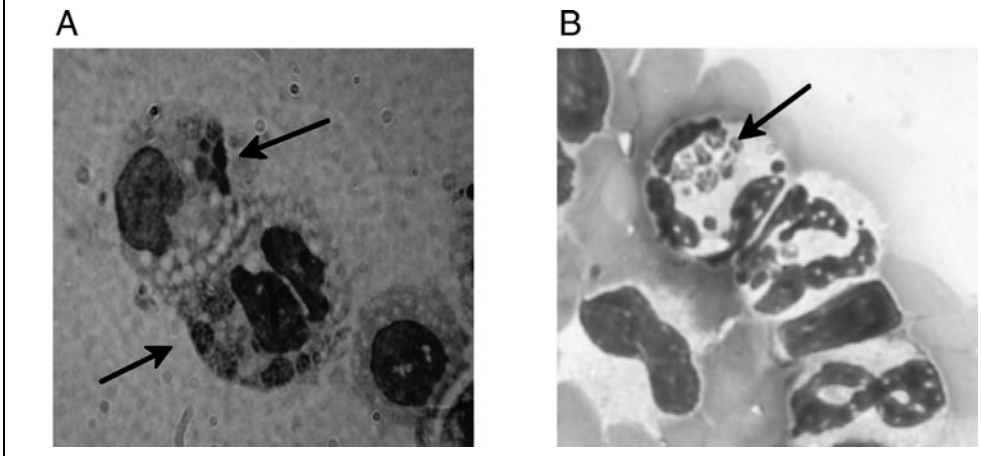

Figure 3A.2.2 Hema-3-stained *A. phagocytophilum*–infected cells visualized by light microscopy. (**A**) Retinoic acid–differentiated HL-60 cells. (**B**) Murine neutrophils. Morulae are denoted by arrows. Photo courtesy of Dr. Venetta Thomas, Yale University; modified from Carlyon and Fikrig (2004), with permission. This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to *http://www.interscience.wiley.com/c_p/colorfigures.htm*.

Materials

Protocol Hema-3 staining solutions (Fisher):
  Protocol Hema-3 fixative
  Protocol Hema-3 solution I
  Protocol Hema-3 solution II
Microscope slides with blood smear (see Support Protocol 1 or 2) or HL-60 cells (see Support Protocol 2)
Four glass staining dishes with removable racks (Wheaton model 900200)
Absorbent bench paper with plastic backing
Light microscope (*UNIT 2A.1*)

Stain slides

1. Fill three staining dishes, respectively, with Protocol Hema-3 fixative, staining solution I, and staining solution II, to a depth that will completely immerse the slides when placed in the dishes. Similarly fill a fourth staining dish with deionized water.
2. Place the slides in the staining rack. Immerse the staining rack in the fixative for 60 sec. Remove and allow for drainage of residual fixative.
3. Immerse the staining rack in solution I for 45 sec. Remove and allow for drainage of residual stain. Immerse briefly in deionized water, remove, and allow for drainage of residual water.
4. Immerse the staining rack in Solution II for 45 sec. Remove and allow for drainage of residual stain. Immerse briefly in deionized water, remove, and allow for drainage of residual water.
5. Place the slides on a sheet of absorbent bench paper placed on a level surface at a 45° angle to facilitate drainage of residual water. Allow the slides to air dry for 2 hr to overnight.

Examine slides

6. Observe the slides by light microscopy under oil immersion using the 100× objective. Look for neutrophils with the presence of morulae.

   Morulae are stippled in appearance and stain more darkly than the host cell's nucleus (Fig. 3A.2.2).

IMMUNOFLUORESCENT DETECTION OF *A. PHAGOCYTOPHILUM* IN INFECTED CELLS

SUPPORT PROTOCOL 4

This method is useful if one's laboratory does not possess a Cytospin cytocentrifuge, and therefore serves as an alternative to Support Protocol 3. Also, the increased sensitivity of immunofluorescence microscopy allows one to visualize individual organisms. This is an advantage over cytological staining (see Support Protocol 3), which is better suited for detecting clusters of *A. phagocytophilum*. Slides of *A. phagocytophilum*–infected cells are prepared by aliquotting the cells into wells of Teflon-coated immunofluorescence slides. Alternatively, if one so chooses, slides prepared using the Cytospin procedure (see Support Protocol 2) may be used. The slides are incubated with polyclonal antiserum against *A. phagocytophilum*, followed by incubation with fluorescein isothiocyanate (FITC)–conjugated secondary antibody. The slides are subsequently observed using a fluorescence microscope. Prepare antibodies during the blocking step.

Materials

5% (v/v) Lysol
70% (v/v) ethanol
A. phagocytophilum–infected HL-60 cells (see Basic Protocol 2)
Uninfected HL-60 cells (control)
Phosphate-buffered saline, pH 7.4 (PBS; *APPENDIX 2A*)
Acetone
PBS/1% and 5% BSA: phosphate-buffered saline, pH 7.4 (PBS; *APPENDIX 2A*) containing 1% or 5% (v/v) bovine serum albumin (BSA)
Polyclonal *A. phagocytophilum* antiserum (rabbit or murine; see Cooper and Patterson, 1995)
Fluorescein isothiocyanate (FITC)–conjugated secondary antibody: either goat anti-rabbit IgG (Sigma cat. no. F-6005) or goat anti-mouse IgG (Sigma cat. no. F-8264)
PBS-T: phosphate-buffered saline, pH 7.4 (PBS; *APPENDIX 2A*) containing 0.05% (v/v) Tween 20
20 μg/ml propidium iodide (light-sensitive; store up to 6 months at 4°C; optional)
Antifade gel-mounting medium (Biomeda Gelmount BMM-01)
Clear nail polish
12-well (5-mm diameter) Teflon-coated immunofluorescence slides (Carlson Scientific, cat. no. 101205) with coverslips
Class II, Type B2, vertical flow biological safety cabinet
Plastic, light-impermeable container large enough to accommodate slides
1-ml serological pipets
Forceps
Fluorescence microscope with filters for detecting FITC and rhodamine emission
Additional reagents and equipment for counting cells using a hemacytometer (Strober, 1997a)

NOTE: Propidium iodide staining (steps 30 to 31) is optional. Propidium iodide binds DNA, which results in the host cell nuclei staining red. This can facilitate easier identification of host cells though it is not necessary.

Prepare slides and safety cabinet

1. Label frosted ends of 12-well immunofluorescence slides with sample designations.
2. Disinfect the work surfaces of a Class II, Type B2, vertical flow biological safety cabinet with 5% Lysol followed by 70% ethanol.
3. In the biological safety cabinet, remove 100-µl aliquots from the *A. phagocytophilum*–infected HL-60 cultures to be examined and determine the cell density using a hemacytometer (Strober, 1997a).

Pellet and wash cells

4. Transfer 5×10^5 *A. phagocytophilum*–infected cells to a 1.5-ml microcentrifuge tube. Prepare another tube with the same number of uninfected control HL-60 cells.
5. Microcentrifuge cells 5 min at $210 \times g$, room temperature. Remove the supernatant. Gently resuspend the cells using 1 ml PBS. Microcentrifuge again as before, then remove the supernatant and gently resuspend the cells in 250 µl PBS for a final concentration of $\sim 2 \times 10^3$ cells/µl.

Transfer cell suspensions to immunofluorescence slides

6. Pipet 5 µl of the infected HL-60 cell suspension into the leftmost well of the top row (designated as well no. 1) of the immunofluorescence slide. Use the pipet tip to gently spread the suspension over the entire surface of the well.

   This will yield $\sim 1 \times 10^4$ cells in well no. 1.

7. Pipet 5 µl of PBS to the two wells adjacent to well no. 1 (i.e., wells no. 2 and 3).
8. Pipet 5 µl of infected HL-60 cells into well no. 2. Mix by pipetting to yield a two-fold dilution ($\sim 5 \times 10^3$ cells).
9. Transfer 5 µl of the two-fold dilution from well no. 2 to well no. 3 containing PBS. Mix by pipetting to yield a four-fold dilution ($\sim 2.5 \times 10^3$ cells).
10. Repeat steps 7 to 9 for wells nos. 4 to 6 and nos. 7 to 9 (see Fig. 3A.2.3).
11. Repeat steps 6 to 10 to prepare a control slide using uninfected HL-60 cells.
12. Allow the slides to air dry at room temperature for at least 30 min.

Prepare the humidified chamber

13. Place a paper towel in the bottom of a light-impermeable plastic container. Wet the towel with water.
14. Using a razor blade, section 1-ml serological pipet in lengths that will span the bottom of the container.
15. Place three to four pipet sections ~2 cm apart on top of the wetted paper towel in the bottom of the chamber.

    This chamber will be used in steps 20 to 31.

Fix and permeabilize the cells

16. Pour acetone into the staining jar to a depth that will immerse the slides.
17. Place the slides in the staining rack and immerse the rack in the acetone for 8 min at room temperature.

    If cytospin preparations are used, these must also be fixed with acetone.

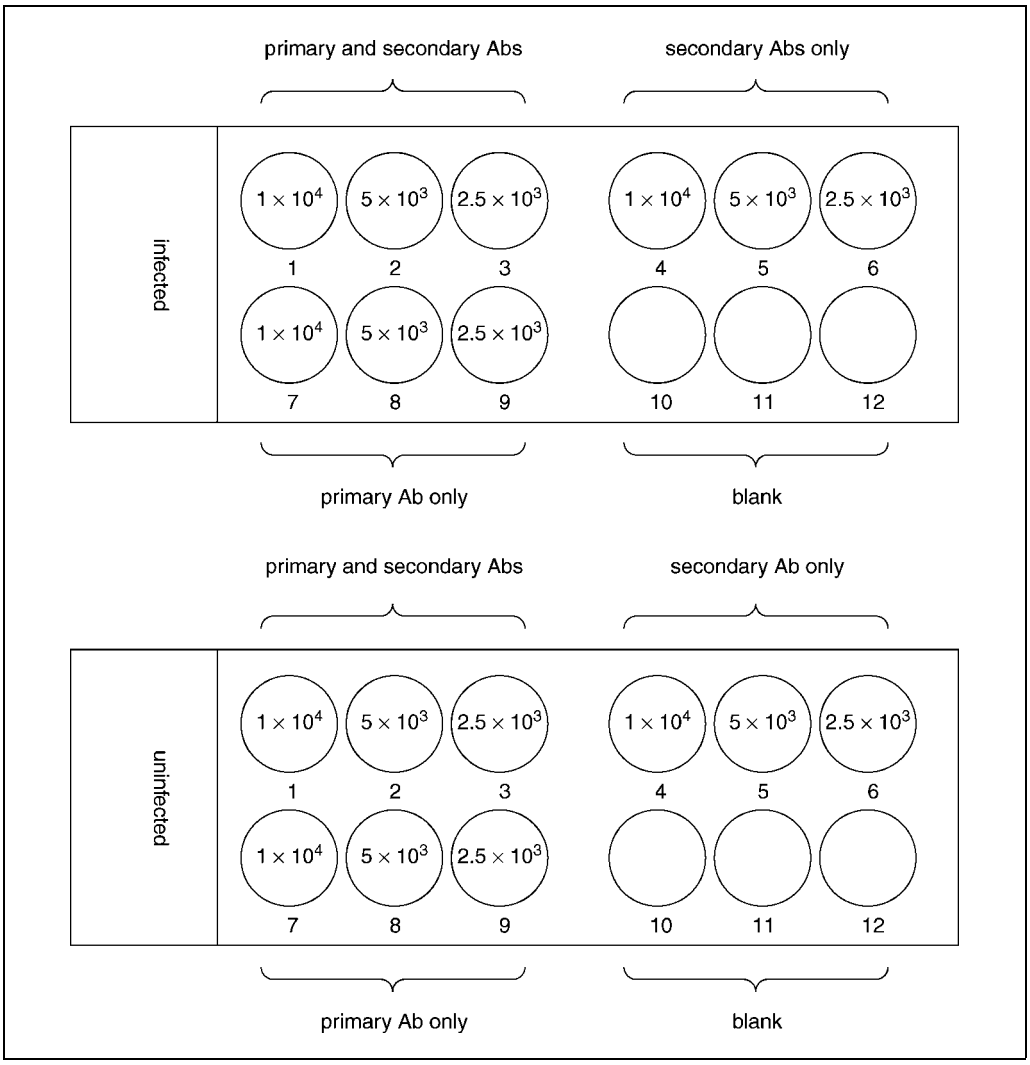

Figure 3A.2.3 Preparation of slides for immunofluorescent detection of *A. phagocytophilum*–infected HL-60 cells.

18. Using forceps, remove the slides and allow excess acetone to drain into the staining jar. Allow residual acetone to evaporate from the slides.

    This will take only a few seconds.

19a. *If slides are not to be screened immediately:* Place pairs of slides back-to-back and wrap in a Kimwipe. Wrap once more using aluminum foil. Label the foil with the sample designations and store up to 6 months (or possibly longer) at –20°C.

19b. *If slides are to be screened immediately:* Proceed to step 20.

Block nonspecific binding sites

20. If the slides were stored at –20°C, unwrap and allow them to sit at room temperature for 10 min. Place the slides on top of the rack of pipet sections in the humidified chamber (see step 15).

21. Add 5 µl PBS to each cell-containing well. Allow the cells to rehydrate for 5 min at room temperature.

    If screening Cytospin preparations, draw a circle around the border of the fixed cell sample using a Pap Pen (e.g., Electron Microscopy Sciences). This will create a barrier that will keep any solution pipetted onto the cells confined to that sample area, in a manner similar to the Teflon-coated wells of the immunofluorescence slides.

22. Remove PBS by aspiration. Add 5 µl PBS/5% BSA to each sample-containing well. Close the humidified chamber and incubate 1 hr at room temperature.

    This blocking step will reduce nonspecific binding of antibodies.

Prepare working stocks of antibodies

Because of the presence of BSA in the antibody solution, the antibodies should be diluted freshly at the time of the experiment and used the same day. However, if sodium azide is added to the solution to a final concentration of 0.1% (w/v), the antibodies can be stored up to 6 months at 4°C.

23. Dilute the polyclonal *A. phagocytophilum* antiserum to an appropriate working concentration in PBS/1% BSA.

    Usually, a 1:500 dilution will suffice. The titer of the antiserum will need to be determined beforehand.

24. Dilute the FITC-conjugated secondary antibody to 1:1000 in PBS/1% BSA. Store at 4°C protected from light until use.

Incubate slides with antibodies

25. Remove the PBS/5% BSA from each well (see step 22) by aspiration.

26. Add 5 µl of the working stock of polyclonal *A. phagocytophilum* antiserum (see step 23) to each sample-containing well. Close the humidified chamber and incubate at room temperature for ≥30 min.

27. Remove the primary antiserum by aspiration. Wash each well by adding 20 µl of PBS-T, then incubating 2 min at room temperature and removing the PBS-T by aspiration. Repeat this wash using PBS-T two more times.

28. Add 5 µl of the working stock of FITC-conjugated secondary antibody (see step 24) to each sample-containing well. Close the humidified chamber and incubate at room temperature for ≥30 min.

29. Wash each well three times as described in step 27.

Counterstain host-cell nuclei (optional)

30. Add 20 µl propidium iodide solution to each sample-containing well. Close the humidified chamber and incubate at room temperature for 3 min.

    CAUTION: *Propidium iodide is hazardous.*

31. Wash each well three times as described in step 27.

Mount and seal slides

32. Add three small drops of antifade gel-mounting medium along the length of the slide between the rows of wells. Place a coverslip on the slide and allow the medium to spread along the surface of the slide until all wells are covered. Gently press the surface of the coverslip to direct any air bubbles until they are released at the edge.

    Be sure to wear clean gloves for this step to avoid leaving any residue or smudges on the coverslip.

33. Allow the slide to dry at room temperature in the dark for 2 hr to overnight. Once the mounting medium has dried, seal the edges with clear nail polish.

Examine slides using fluorescence microscopy

34. Examine the slides using a fluorescent microscope equipped with a filter for detecting FITC emission and either the 40× or 100× objective to visualize *A. phagocytophilum*.

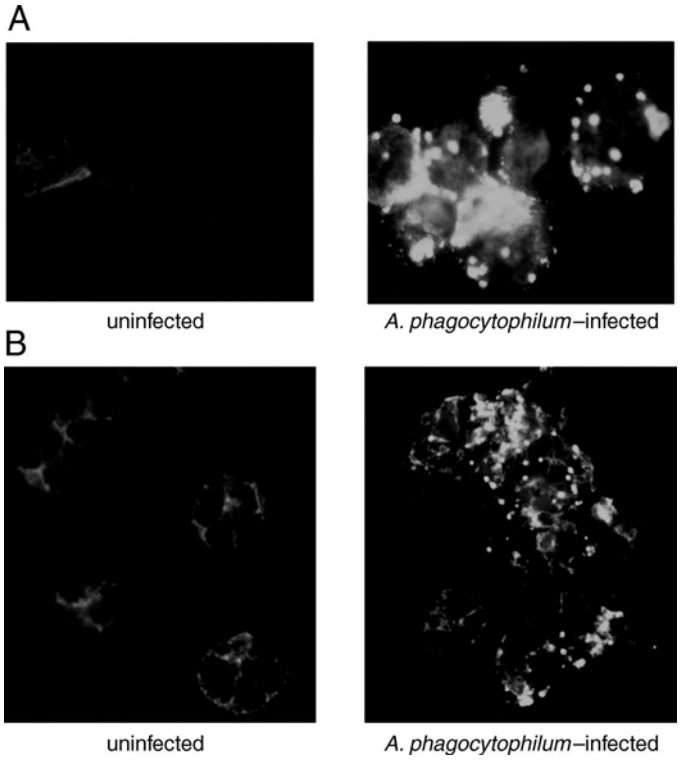

Figure 3A.2.4 *A. phagocytophilum*–infected cells visualized by immunofluorescent microscopy. All samples were incubated with polyclonal rabbit anti–*A. phagocytophilum* serum followed by FITC-conjugated goat anti-rabbit IgG. (**A**) Uninfected and *A. phagocytophilum*–infected HL-60 cells. (**B**) Uninfected and *A. phagocytophilum*–infected human neutrophils. Nuclei were counterstained using propidium iodide. This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to *http://www.interscience.wiley.com/c_p/colorfigures.htm*.

35. Visualize propidium iodide–stained HL-60 nuclei by fluorescence microscopy using a filter for detecting rhodamine emission. Representative slides are presented in Figure 3A.2.4.

CRYOPRESERVATION OF *A. PHAGOCYTOPHILUM*–INFECTED HL-60 CELLS

SUPPORT PROTOCOL 5

It is good practice to maintain frozen stocks of the cell lines. To protect against complete loss of cell lines due to accidental contamination or other incidents, stocks of uninfected and *A. phagocytophilum*–infected HL-60 cells should be stored. The cells are pelleted, resuspended in medium containing DMSO, frozen in an isopropanol bath at −80°C, and transferred to liquid nitrogen for long-term storage.

Materials

5% (v/v) Lysol
70% (v/v) ethanol
A. phagocytophilum–infected HL-60 cells growing in culture (see Basic Protocol 2)
100% isopropanol
IMDM-10 with and without 12% (v/v) dimethylsulfoxide (DMSO)
0.5% (v/v) sodium hypochlorite

Class II, Type B2, vertical flow biological safety cabinet
10- and 1-ml serological pipets

15-ml polypropylene conical centrifuge tubes with screw caps (BD Falcon)
Refrigerated tabletop centrifuge
Alcohol-resistant pen (VWR)
250-ml beaker for waste
2-ml screw-cap cryovials
Nalgene Cryo 1°C freezing container
−80°C freezer
Cryobiological storage vessel containing liquid nitrogen
25-cm^2 tissue culture flasks with vented caps (BD Falcon)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Pellet cells

1. Disinfect the work surfaces of a Class II, Type B2, vertical flow biological safety cabinet with 5% Lysol followed by 70% ethanol.
2. Using a serological pipet, transfer 1×10^7 of *A. phagocytophilum*–infected HL-60 cells to a 15-ml conical centrifuge tube.

   Uninfected HL-60 cells are processed in an identical manner.

3. Place the tube in a refrigerated tabletop centrifuge. Centrifuge cells 10 min at $210 \times g$, 4°C. During the centrifugation, label a screw-cap cryovial with the sample designation using an alcohol-resistant pen. Discard supernatant in a 250-ml beaker designated for waste.

   Be sure that the centrifuge is properly balanced.

Prepare the Cryo 1°C freezing container

4. Remove the polyethylene vial holder and foam insert from the freezing container.

   Do not discard the foam insert.

5. Add 100% isopropanol to the fill line of the container. Replace the foam insert and vial holder.

   This will require a volume of ∼250 ml. Do not overfill.

Freeze cells

6. Using a 1-ml serological pipet, gently resuspend the cells from step 3 in 1 ml IMDM-10 containing 12% DMSO. Immediately transfer the suspension to the corresponding labeled, 2-ml screw-cap cryovial. Close the cap.

   DMSO serves as a cryopreservative, which enables the HL-60 cells to survive the freezing process.

7. Immediately transfer the tube to a hole in the vial holder of a Nalgene the Cryo 1°C freezing container. Place the Cryo 1°C freezing container in a –80°C freezer. Leave undisturbed for a minimum of 4 hr.

   This achieves a controlled cooling rate of −1°C per minute, which is recommended for eukaryotic cell lines.

   Cells should be stored for no more than 1 week at –80°C before transferring to liquid nitrogen. Longer storage at the lower temperature will compromise the viability of the culture upon thawing. A temperature of –130°C or below is necessary for long-term storage.

8. After a period of at least 4 hr, remove the frozen vial from the freezing container and place in a cryobiological storage vessel containing liquid nitrogen for long-term storage.

   The long-term storage vessel should have a temperature of –130°C or below. Cells may be stored indefinitely.

Thaw cells

9. Remove the frozen sample from storage and place on ice to thaw slowly.

10. Using a 1-ml serological pipet, gently resuspend and transfer the tube's contents to a 15-ml conical centrifuge tube.

Wash cells

11. Using a 10-ml serological pipet, immediately add 10 ml of IMDM-10.

    DMSO will cause terminal differentiation of HL-60 cells. It is therefore important to thoroughly wash the cells immediately upon thawing to remove all traces of DMSO.

12. Centrifuge the tube as in step 3, then remove and discard the supernatant in the waste beaker.

13. Repeat steps 11 to 12 two additional times.

14. Resuspend cells in 10 ml IMDM-10 and transfer to a 25-cm^2 tissue culture flask with a vented cap.

15. Place newly resuspended culture in incubator and continue culturing as described in Basic Protocol 2.

Decontaminate and clean up work area

16. Add 10 ml of 0.5% sodium hypochlorite to the beaker containing the pooled supernatants. Wait 10 min, then pour the disinfected solution into a sink and flush with running water for 30 sec.

17. Remove unused materials from the biological safety cabinet. Disinfect the interior of the biosafety cabinet with 5% Lysol followed by 70% ethanol.

OBTAINING HOST CELL–FREE *A. PHAGOCYTOPHILUM* BY DIFFERENTIAL CENTRIFUGATION

BASIC PROTOCOL 3

Preparations of *A. phagocytophilum* that are relatively free from contaminating HL-60 cell components are used for a variety of in vitro applications. *A. phagocytophilum*–infected HL-60 cells are lysed via syringe passage, and a semipure preparation of viable bacteria is recovered by differential centrifugation. These preparations can be used in subsequent in vitro infection assays, inoculated into mice (see Basic Protocol 1), subjected to further purification by density gradient centrifugation (see Support Protocol 6), or fluorescently labeled for tracking infection (Support Protocol 7).

Materials

5% (v/v) Lysol
70% (v/v) ethanol
A. phagocytophilum–infected HL-60 cells growing in culture (see Basic Protocol 2)
Uninfected HL-60 cells (control)
Phosphate-buffered saline, pH 7.4 (PBS; *APPENDIX 2A*), prechilled
0.5% (v/v) sodium hypochlorite

Class II, Type B2, vertical flow biological safety cabinet
25-, 10-, and 5-ml serological pipets

15- and 50-ml polypropylene conical centrifuge tubes with screw caps (BD Falcon)
Refrigerated tabletop centrifuge
500-ml beaker for waste
5-cc tuberculin syringes
27-G, $\frac{1}{2}$-in. (12.7-mm) needles
Additional reagents and equipment for counting cells (Strober, 1997a) and cytological (see Support Protocol 3) or immunofluorescence staining (see Support Protocol 4) of *A. phagocytophilum* cultures

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

Determine the cell density and percentage of A. phagocytophilum–infected HL-60 cells

1. Disinfect the work surfaces of a Class II, Type B2, vertical flow biological safety cabinet with 5% Lysol followed by 70% ethanol. Organize all materials to be used in the cabinet.

   With the exception of the centrifugation steps, all work is performed in the hood.

2. Determine cell density of cultures of interest using a hemacytometer (Strober, 1997a).

3. Determine the percentage of infected cells in the cultures of interest using either cytological staining or immunofluorescence microscopy as described in Support Protocol 3 or Support Protocol 4, respectively.

   The percentage of infected cells should be ≥70%. If the percentage of infected cells is ≤70%, return the culture to the incubator and allow the infection to proceed for an additional 1 to 2 days before reassessing it for infection. If necessary, adjust the density of the culture to 2–5 × 10^5 cells per ml by supplementing with fresh medium as described in Basic Protocol 2, step 6.

Pellet cells

4. Using a 10- or 25-ml serological pipet, transfer the appropriate number of *A. phagocytophilum*–infected cells in culture medium to a 50-ml conical centrifuge tube. Prepare a separate tube in a similar manner using uninfected HL-60 cells and carry through the following steps in parallel as a control.

   The number of infected cells can be scaled according to the purpose of the experiment. For instance, if the resulting semipure preparation of A. phagocytophilum is to be further purified by density gradient centrifugation (see Support Protocol 6), pellet 2.5 × 10^8 cells. If using the A. phagocytophilum preparation in an in vitro infection assay, pellet a number of infected cells equal to 1 to 5 times the number of cells to be infected. If host cell–free A. phagocytophilum recovered from lysed HL-60 cells are to be used in subsequent infection assays, it is imperative that uninfected HL-60 cells be processed in an identical manner and used as a control in the subsequent infection assay. This is essential for determining whether results of the infection assay are influenced by the presence of contaminating HL-60 lysate components present in the A. phagocytophilum preparation.

5. Place the 50-ml tubes in a refrigerated tabletop centrifuge. Centrifuge the cells 10 min at 2300 × *g*, 4°C. Discard supernatant in a 500-ml beaker designated for waste.

   Be sure the tubes are properly balanced.

6. Resuspend the pellet in 4 ml chilled PBS.

7. Place a 50-ml conical centrifuge tube upright in a rack. Remove and place the cap to the side.

Lyse cells

8. Remove the plungers from five 5-cc syringes (designated nos. 1 to 5). Attach a 27-G, $\frac{1}{2}$-in needle to each.

   A set of five syringes should also be prepared for the uninfected HL-60 cells.

9. Using a 5-ml serological pipet, transfer the cell suspension to syringe no. 1.

10. Uncap the needle of syringe no. 1 and, using constant pressure, expel the suspension through the needle into the 50-ml tube (see step 7).

    For maximum recovery of the suspension, hold the syringe at a 45^o angle and place the end of the needle as close to the inner wall of the tube as possible without touching. This will allow the suspension to run down the inner wall to the tube bottom and will minimize the chance of producing an aerosol.

11. Discard syringe no. 1 into a sharps container. Repeat steps 9 and 10 four times.

    This process lyses the HL-60 cells without lysing the bacteria.

Recover semipure preparation of host cell–free A. phagocytophilum

12. Cap the 50-ml tubes containing the lysates of *A. phagocytophilum*–infected and uninfected cells. Centrifuge 5 min at 750 × *g*, 4°C.

    This will pellet the majority of host cellular debris.

13. Transfer the supernatants to new 15-ml centrifuge tubes. Discard the tubes containing the pellets of cellular debris into a biohazard-labeled trash receptacle.

14. Centrifuge the tubes containing the supernatants from step 13 for 5 min at 1000 × *g*, 4°C.

    A pellet of considerably smaller size than that generated in step 12 should be visible.

15. Transfer the supernatants to new 15-ml tubes. Discard the tubes containing the pellets of cellular debris into a biohazard-labeled trash receptacle.

16. Centrifuge the tubes containing the supernatants from step 15 for 10 min at 2300 × *g*, 4°C. Remove and discard the supernatant into the beaker designated for waste.

    A small pellet should be visible. The majority of the pellet is composed of host-cell-free A. phagocytophilum. A minor portion of the pellet consists of HL-60 debris and cellular components that were not removed in steps 12 and 14.

Decontaminate and clean up work area

17. Add 10 ml of 0.5% sodium hypochlorite to the beaker containing the pooled supernatants. Wait 10 min, then pour the disinfected solution into a sink and flush with running water for 30 sec.

18. Remove unused materials from the biological safety cabinet. Disinfect the interior of the biosafety cabinet with 5% Lysol followed by 70% ethanol.

DENSITY GRADIENT PURIFICATION OF HOST CELL–FREE *A. PHAGOCYTOPHILUM*

SUPPORT PROTOCOL 6

This method is useful for generating *A. phagocytophilum* preparations that are more highly purified from contaminating host cell components than those prepared by differential centrifugation. Such preparations are used for inoculating animals with the purpose of obtaining anti–*A. phagocytophilum* antiserum that exhibits little to no recognition of HL-60 cells. Alternatively, such preparations are used for subsequent isolation of *A. phagocytophilum* nucleic acids, proteins, or outer membranes. It is best that contaminating host cellular components be minimized for such procedures. An *A. phagocytophilum*

preparation obtained via differential centrifugation (see Basic Protocol 3) is layered onto a discontinuous Renografin gradient and subjected to ultracentrifugation. This results in the resolution of a band of *A. phagocytophilum* that is free from host cell components, with the exception of host cell organelles of a similar density, such as mitochondria.

Materials

5% (v/v) Lysol
70% (v/v) ethanol
A. phagocytophilum–infected HL-60 cells growing in culture (see Basic Protocol 2)
PBS/glucose (see recipe), ice cold
Complete Protease Inhibitor Cocktail Tablets (Roche, cat. no. 1 697 498)
DNase I (from bovine pancreas; Roche cat. no. 776785)
RNase (from bovine pancreas; Roche cat. no. 1 119 915)
30% Renografin (see recipe)
42% Renografin (see recipe)
SPGN buffer (see recipe)
0.5% (v/v) sodium hypochlorite

Class II, Type B2, vertical flow biological safety cabinet
50-ml polypropylene conical centrifuge tubes with screw caps (BD Falcon)
Refrigerated tabletop centrifuge
1-liter beaker for waste
10-cc tuberculin syringe
Beckman L7-55 ultracentrifuge and Beckman SW 28 swinging-bucket rotor (or equivalent)
38.5-ml ultracentrifuge tubes (Beckman Ultra-Clear)
Harvard trip balance
2.0-ml polypropylene microcentrifuge tubes

Additional reagents and equipment for counting cells (Strober, 1997a), cytological (see Support Protocol 3) or immunofluorescence staining (see Support Protocol 4) of *A. phagocytophilum* cultures, preparing a semipure preparation of *A. phagocytophilum* (see Basic Protocol 3), and protein assay (*APPENDIX 3A*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

Determine the cell density and percentage of A. phagocytophilum–infected HL-60 cells.

1. Disinfect the work surfaces of a Class II, Type B2, vertical flow biological safety cabinet with 5% Lysol followed by 70% ethanol.

   With the exception of the steps involving centrifugation and water bath incubation, this work is to be performed in the biological safety cabinet. This is especially important if the purified A. phagocytophilum is to be injected into animals.

2. Determine cell density of cultures of interest by examining aliquots using a hemacytometer (Strober, 1997a).

3. Determine the percentage of infected cells in the cultures of interest as described in Support Protocol 3 or Support Protocol 4.

   The percentage of infected cells should be ≥70%.

4. For each Renografin prep to be prepared, place 2.5×10^8 infected HL-60 cells in a (depending on the culture density) of 50-ml conical centrifuge tube.

5. Centrifuge the tubes in a refrigerated tabletop centrifuge 10 min at 2300 × *g*, 4°C.

   The number of processed cells can be scaled according to the purpose of the experiment. As a general rule, process 2.5 × 10^8 cells per Renografin prep.

Lyse the cells

6. While the centrifugation in step 5 is proceeding, transfer 25 ml ice-cold PBS-glucose to a 50-ml conical centrifuge tube. Add 1 Complete Protease Inhibitor Cocktail tablet and vortex to mix. Place the solution on ice.

   Other protease inhibitors may be substituted. However, the author has achieved excellent results with the Complete tablets from Roche.

7. Discard supernatant from step 4 into a 1-liter beaker designated for waste.

8. Mechanically lyse the infected cells and recover a semipure preparation of *A. phagocytophilum* as described in Basic Protocol 3, steps 8 to 16, except use 10-cc syringes in the lysis steps.

Digest host cell nucleic acids

9. Resuspend the pellet in 10 ml ice-cold PBS-glucose with added protease inhibitors (prepared at step 6).

10. Add DNase I and RNase to final concentrations of 50 μg/ml each.

11. Place the tube containing the suspension in a water bath set at 37°C. Incubate 45 min.

    This digests host cell nucleic acids, which reduces the viscosity of the solution.

Prechill rotor and ultracentrifuge

12. Chill the SW 28 rotor and swinging buckets at 4°C. Turn the power switch of the ultracentrifuge to ON. Close the rotor chamber door and turn the vacuum switch to ON. Set the temperature to 4°C.

    Any refrigerated ultracentrifuge and swinging-bucket rotor capable of achieving speeds of at least 87,300 × g may be used.

Prepare discontinuous Renografin gradient

13. Place 10 ml of 42% Renografin in a 38.5-ml ultracentrifuge tube.

14. Gently pipet 10 ml of 30% Renografin over the 42% Renografin layer. If not processing an even number of samples, prepare an identical gradient to use as a balance during centrifugation.

    To avoid mixing the Renografin layers, hold the pipet at a 45° angle to the ultracentrifuge tube and position the tip of the pipet at the inner wall of the tube. This allows the 30% Renografin to settle on top of the 42% layer.

15. Following the nucleic acid digestion in step 11, chill the lysate on ice for 10 min.

16. Using a serological pipet, overlay the lysate on the Renografin gradient. If processing an odd number of samples, overlay the gradient in the balance tube with deionized water.

Recover host cell–free A. phagocytophilum

17. Place the experimental and balance tubes in the SW 28 buckets. Make sure that the combined weight of the balance tube and swinging bucket is equal to the combined weight of the swinging bucket and experimental tube using a Harvard trip balance. If not, adjust the amount in the balance tube.

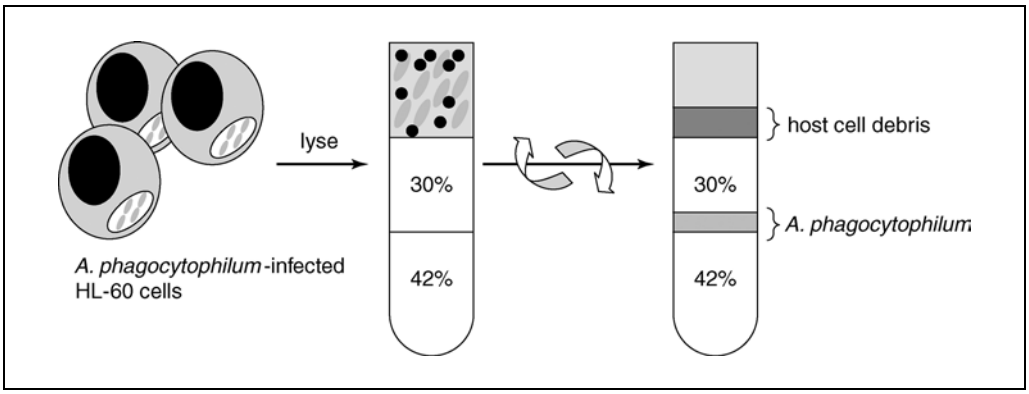

Figure 3A.2.5 Renografin density gradient purification of host cell–free *A. phagocytophilum*.

18. Screw the caps onto all six swinging buckets. Hang each of them at its matched position on the SW 28 rotor.

    CAUTION: *Because of the high speeds at which they are used, ultracentrifuge rotors must be precisely balanced. The SW 28 buckets are numbered 1 through 6. When hanging on the rotor, 1 must lie opposite 4, 2 must lie opposite 5, and 3 must lie opposite 6. Keep this in mind when choosing the swinging buckets.*

19. Turn the vacuum switch to OFF and wait for the rotor chamber to equilibrate. Open the rotor chamber door and place the SW 28 rotor onto the drive spindle. Close the rotor chamber door and turn the vacuum switch to ON. Enter a speed of 22,000 rpm (87,300 × *g*). Enter a run time of 75 min. Leave the temperature setting at 4°C. Set the brake at 800 rpm (115 × *g*).

    The brake switch of the Beckman L7-55 allows either for full dynamic braking until 0 rpm or for full dynamic braking until 800 rpm followed by no braking to a gentle stop. Allowing the rotor to come to a gentle stop allows for minimal disruption of the resulting centrifugation layers. Newer ultracentrifuge models have the option of no brake. Choose this option if using a newer model. However, keep in mind that it will take considerably longer for the rotor to come to a full stop without braking.

20. Press START and allow the centrifugation to proceed.

21. Once the rotor has stopped, turn the vacuum switch to OFF and allow the rotor chamber to equilibrate.

22. Open the chamber door, remove the rotor, and return it to its support stand. Remove the swinging buckets and return them to their rack.

Recover A. phagocytophilum–enriched fraction

23. Unscrew the swinging-bucket caps and remove the ultracentrifuge tubes containing the samples.

    When observing the tubes, three distinct layers of ~10 ml each separated by two distinct bands should be readily apparent (Fig. 3A.2.5). A pellet will also be present at the bottom of the tube.

    The band atop the 30% Renografin layer consists primarily of host cellular debris. The pellet primarily consists of unbroken HL-60 cells. The band between the 30% and 42% Renografin layers is highly enriched for A. phagocytophilum. Likely, host cellular components of similar size and density to that of A. phagocytophilum, such as mitochondria, are present. These, however, constitute a very minor portion.

24. Using a serological pipet, carefully remove the top 18 to 19 ml of the Renografin gradient and discard into the beaker designated for waste. Be sure to leave ~1.5 cm of Renografin above the enriched *A. phagocytophilum* layer.

Wash, pool, and store the A. phagocytophilum–enriched fraction

25. Place several opened 2.0-ml microcentrifuge tubes on ice. Using a serological pipet, remove the entire *A. phagocytophilum*–enriched layer and distribute among the 2.0-ml tubes by pipetting 1 ml into each.

26. Add 1 ml SPGN buffer to each tube. Close the caps. Invert the tubes to mix and to dilute the Renografin.

27. Place the tubes in a prechilled refrigerated microcentrifuge. Microcentrifuge 20 min at 13,000 × *g*, 4°C. Remove and discard the supernatants into the waste beaker. Combine the pellets in a final volume of 500 to 600 μl SPGN buffer.

28. Measure the protein concentration of the enriched *A. phagocytophilum* fraction using the method of choice (*APPENDIX 3A*). Adjust the final concentration to 2 mg/ml by adding SPGN buffer. Store indefinitely at –80°C.

Decontaminate and clean up work area

29. Add 10 ml of 0.5% sodium hypochlorite to the beaker containing the pooled supernatants. Wait 10 min, then pour the disinfected solution into a sink and flush with running water for 30 sec.

30. Remove unused materials from the biological safety cabinet. Disinfect the interior of the biosafety cabinet with 5% Lysol followed by 70% ethanol.

FLUORESCENT LABELING OF LIVE *A. PHAGOCYTOPHILUM*

SUPPORT PROTOCOL 7

This technique enables one to infect and subsequently identify *A. phagocytophilum*–infected cells based on detection of fluorescent bacteria. The difference between this technique and immunofluorescence (see Support Protocol 4), which detects bacteria in fixed host cells, is that this technique utilizes live bacteria and enables one to trace an ongoing infection in live cells. Labeled bacteria will remain fluorescent for up to 4 days. Host cell–free *A. phagocytophilum* preparations obtained via differential centrifugation (see Basic Protocol 3) are incubated with CellTracker Green 5-chloromethylfluorescein diacetate (CMFDA), a vital dye available from Molecular Probes. CellTracker Green CMFDA will not label dead cells or host cell debris.

Materials

Semipure preparation of host cell–free *A. phagocytophilum* (see Basic Protocol 3)
Phosphate-buffered saline, pH, pH 7.4 (PBS; *APPENDIX 2A*), chilled
10 μM CellTracker Green CMFDA (see recipe)
250-ml beaker for waste
Fluorescence microscope with filters for detecting FITC emission

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

Wash host cell–free A. phagocytophilum

1. Resuspend pellet of semipure host cell–free *A. phagocytophilum* in 2 ml chilled PBS.

2. Pellet the bacteria in a refrigerated microcentrifuge 10 min at 2300 × *g*, 4°C.

3. Remove and dispose of the supernatant into a 250-ml beaker designated for waste.

4. Repeat steps 1 to 3.

Thorough washing of the A. phagocytophilum is pertinent because any residual serum remaining from the culture medium will inactivate CellTracker Green CMFDA.

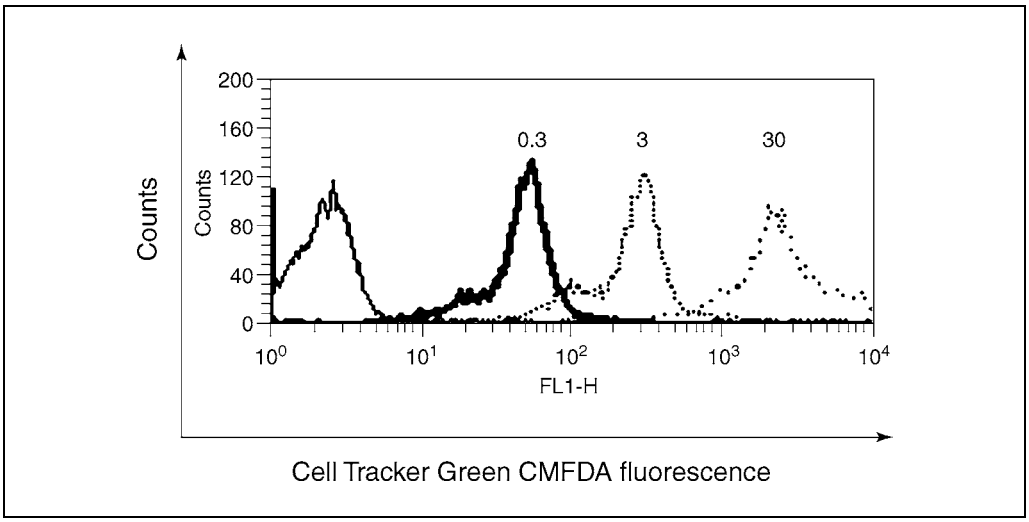

Figure 3A.2.6 Flow cytometric analysis of human neutrophils incubated with CellTracker Green CMFDA–labeled *A. phagocytophilum*. Bacteria were incubated with neutrophils for 60 min at ratios of 0.3 (solid, thick histogram), 3 (dashed histogram), and 30 (dotted histogram) *A. phagocytophilum* organisms per cell. Uninfected neutrophils (solid, thin histogram) served as a negative control.

Label A. phagocytophilum

5. Prewarm the 10 μM working solution of CellTracker Green CMDFA in a 37°C water bath for at least 10 min.

   CellTracker Green CMFDA is light-sensitive; protect the solution from light.

6. Resuspend the *A. phagocytophilum* pellet from step 4 using 1 ml of the prewarmed 10 μM CellTracker Green CMFDA.

7. Close the lid of the tube and seal with Parafilm. Place in the 37°C water bath and incubate 15 min.

Wash labeled A. phagocytophilum

8. Remove the Parafilm. Add 1 ml PBS. Mix by inversion.

9. Pellet the labeled bacteria in a refrigerated microcentrifuge at 2300 × *g* for 10 min at 4°C. Remove and discard the supernatant into the waste beaker.

10. Add 2 ml of PBS and wash the bacteria once more as in steps 8 to 9.

    It is very important to remove any unincorporated CellTracker Green CMDFA, as any remaining dye will label eukaryotic cells when incubated with the A. phagocytophilum preparation.

11. Dilute the labeled bacteria to the desired concentration and incubate with host cells of choice. Infection can be monitored either by flow cytometry (Fig. 3A.2.6) or fluorescent microscopy using a filter equipped for observing FITC fluorescence.

    Labeled bacteria should be incubated with recipient host cells for ≥30 min.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

CellTracker Green CMFDA, 10 μM

Prepare a 10 mM stock of CellTracker Green by resuspending 50 μg lyophilized CellTracker Green 5-chloromethylfluorescein diacetate (CMFDA; Molecular

Probes cat. no. C7025) in 10.8 μl DMSO. Prepare a 10 μM working stock of CellTracker Green CMFDA by adding 1 μl of 10 mM CellTracker Green CMFDA to 1 ml PBS, pH 7.4 (*APPENDIX 2A*), in a sterile microcentrifuge tube.

NOTE: *CellTracker Green CMFDA is sold as a set of twenty individual tubes of 50 μg. Thus, resuspend the entire contents of one tube with 10.8 μl DMSO. CellTracker Green CMFDA is light-sensitive and should therefore be protected from light.*

Ketamine/xylazine anesthetic cocktail

10 ml 100 mg/ml ketamine in sterile 0.9% saline (see *APPENDIX 2A* for saline)
1.5 ml 100 mg/ml xylazine in sterile 0.9% saline (see *APPENDIX 2A* for saline)
After the ketamine and xylazine are combined in a final volume of 11.5 ml, dilute 1:4 in sterile saline (*APPENDIX 2A*) and inject according to body weight as directed in the protocol.

PBS/glucose

0.5 g glucose
250 ml phosphate-buffered saline, pH 7.4 (PBS; *APPENDIX 2A*)
Dissolve glucose in PBS and sterilize using a 0.2-μm filter.
Store up to 2 months at 4°C

Renografin, 30%

125 ml 60% Renografin (Renografin-60; Bracco Diagnostics)
125 ml Renografin buffer (see recipe)
Filter sterilize through a 0.2-μm filter
Store up to 6 months at 4°C

Renografin, 42%

175 ml of 60% Renografin
75 ml Renografin buffer (see recipe)
Filter sterilize through a 0.2-μm filter
Store up to 6 months at 4°C

Renografin buffer

Dissolve the following in 450 ml H_2O
0.163 g KH_2PO_4
0.58 g Na_2HPO_4
3.39 g NaCl
12.5 ml of 200 mM L-glutamine
Adjust pH to 7 using 0.1 N HCl
Bring final volume to 500 ml with H_2O
Filter sterilize through a 0.2-μm filter
Store up to 6 months at 4°C

SPGN buffer

Dissolve the following in 450 ml H_2O
37.3 g sucrose
0.25 g KH_2PO_4
0.80 g K_2HPO_4
12.5 ml of 200 mM L-glutamine
Adjust pH to 7 using 0.1 N HCl
Bring final volume to 500 ml with H_2O
filter sterilize through a 0.2-μm filter
Store for up to 2 months at 4°C

COMMENTARY

Background Information

A. phagocytophilum is the etiologic agent of human granulocytic anaplasmosis (HGA), a potentially fatal disease that is emerging in the United States, Europe, and Asia (for recent reviews see Dumler and Bakken, 1998; Carlyon and Fikrig, 2003; Rikihisa, 2003; Carlyon and Fikrig, 2004). In the U.S., cases of HGA occur primarily in the Northeast, the Upper Midwest, and the West Coast. The incidence of HGA in these areas ranges from ~2 to ≥70 cases per 100,000 persons. *A. phagocytophilum* is a highly unique intracellular bacterium in that it preferentially colonizes neutrophils in mammalian hosts. Within neutrophils, the obligate intracellular bacterium replicates as clusters of organisms, forming intracytoplasmic inclusions termed morulae. In nature, *A. phagocytophilum* cycles between ticks of the *Ixodes persulcatus* complex and its primary mammalian reservoir, *Peromyscus leucopus*, the white-footed mouse. Humans are accidental hosts. Following inoculation via tick feeding, nonspecific symptoms arise, including fever, chills, headache, and myalgia. More distinguishing manifestations follow, including neutropenia, thrombocytopenia, and elevated hepatic transaminases. If left untreated, HGA can be fatal as a result of the patient's increased susceptibility to opportunistic bacterial and fungal pathogens. Chen et al. (1994a) documented the first case of HGA in 1994. Until recently, *A. phagocytophilum* was generically referred to as the agent of human granulocytic ehrlichiosis. Phylogenetic reclassification grouped the HGE agent with *Ehrlichia equi* and *Erhlichia phagocytophila*, which infect horses and sheep, respectively, into the collective designation, *A. phagocytophilum* (Dumler et al., 2001).

Goodman et al. (1996) were the first to demonstrate that *A. phagocytophilum* could infect and be maintained in the human-derived promyelocytic leukemia cell line HL-60. HL-60 cells are highly permissive to *A. phagocytophilum* invasion and intracellular replication, making them an ideal cell line for in vitro propagation. Susceptibility of HL-60 cells to *A. phagocytophilum* infection, like that of human neutrophils, is linked to their surface expression of P-selectin glycoprotein ligand-1 (Goodman et al., 1999; Herron et al., 2000; Carlyon et al., 2003; Yago et al., 2003). Inside HL-60 cells, *A. phagocytophilum* replicates within morulae that are morphologically indistinguishable from those seen within infected neutrophils (Goodman et al., 1996). Successful propagation of *A. phagocytophilum* in the tick embryo cell line IDE8 (ATCC #CRL 11973), isolated from *I. scapularis*, has also been reported (Munderloh et al., 1996, 1999).

Both infectivity and pathogenicity of the bacterium wane considerably with in vitro passage (Hodzic et al., 1998). Thus, *A. phagocytophilum* must also be maintained by passage through inbred mice. As first demonstrated by Barthold, Hodzic, and colleagues, laboratory mice are excellent models, as infection in them partially mimics many of the hematological parameters and histopathological lesions associated with HGA (reviewed in Borjesson and Barthold, 2002). The majority of studies to date have utilized either the C3H/HeN or C3H/HeJ strains and their congenic C3H-*scid* counterparts. However, laboratory propagation of *A. phagocytophilum* in C57BL/6, CD-1, DBA/2, C.B.-17-*scid*, and *Peromyscous leucopus* mice, as well as LVG hamsters, has also been reported.

Unfortunately, peripheral blood infection of immunocompetent mice resolves by the third or fourth week post-inoculation. Additionally, pathogenicity attenuates with successive passage in immunocompetent mice. SCID mice, however, are unable to clear *A. phagocytophilum* infection, and are therefore used for restoring pathogenicity of this organism, as well as for its continual maintenance in vivo (Borjesson and Barthold, 2002; Hodzic et al., 1998).

A. phagocytophilum infection can be assayed using a number of methods (Dumler and Bakken, 1998; Hodzic et al., 1998; Carlyon and Fikrig, 2003, 2004; Dumler and Brouqui, 2004). Direct observation of morulae within neutrophils of a peripheral blood smear or infected HL-60 cells using Romanowsky stains (e.g., Protocol Hema-3) is included here (see Support Protocol 3) because the protocol is relatively simple to perform and requires few materials. It also allows for a determination of the percentage of infected cells. Immunofluorescence microscopy is a more sensitive method in that it can additionally detect individual organisms. This method is quite useful for monitoring *A. phagocytophilum* infection kinetics in an in vitro time course assay. A second means for tracing in vitro infection is the use of CellTracker Green CMFDA to fluorescently label viable *A. phagocytophilum* (see

Support Protocol 7). Herron et al. (2000) first described this technique. Cryopreservation of infected HL-60 cells using standard methods is also presented (see Support Protocol 5). Host cell–free *A. phagocytophilum* is easily recovered from mechanically lysed HL-60 cells by differential centrifugation (see Basic Protocol 3). These preparations can be further purified by Renografin density gradient centrifugation (see Support Protocol 6), which has been utilized for purifying an array of intracellular organisms (McCaul and Williams, 1981; Plano and Winkler, 1989; Weiss et al., 1989; Chen et al., 1994b).

Critical Parameters

Preparing slides and culturing A. phagocytophilum in HL-60 cells

When preparing slides of *A. phagocytophilum*–infected blood to be subsequently screened for morulae-positive neutrophils, it is essential to achieve a good smear. The area of the smear should nearly cover the slide's entire surface and end in a tongue-shaped arc. The vast majority of leukocytes will be present in the periphery of the arc. Confining one's microscopic examination to this region will provide the best opportunity to visualize neutrophils. Once an HL-60 culture is inoculated with *A. phagocytophilum*, it is important to maintain a proper HL-60 cell density such that the culture does not overgrow. Therefore, split the culture bi-weekly to maintain a density of 2–5 $\times$ 10^5 cells/ml. Additionally, it is crucial to determine the percentage of infected cells and add uninfected HL-60 cells as needed to prevent *A. phagocytophilum* from outgrowing and lysing the entire host cell population. For example, if 90% of the cells in a 10-ml culture of HL-60 cells at a density of 1 $\times$ 10^6 cells/ml are infected with *A. phagocytophilum*, discard 8 ml (8 $\times$ 10^6 cells) and add 2 $\times$ 10^6 uninfected HL-60 cells. Bring the final volume to 10 ml with fresh IMDM-10. By day 3, the culture will again contain $\geq$90% infected cells and will need to be split again. Using this example as a guide, cultures can be supplemented while still retaining a high percentage of infected cells.

Lysing infected HL-60 cells

When lysing *A. phagocytophilum*–infected HL-60 cells in preparation for obtaining bacterial preparations that are relatively free from host cellular components, it is crucial to pass the cells through a 27-G, $\frac{1}{2}$-in. (12.7-mm) needle five times to maximize host cell lysis. It is equally important to thoroughly remove the host debris by differential centrifugation. Failure to do so will greatly interfere with density gradient purification of the bacteria. Instead of two distinct bands of host debris and purified *A. phagocytophilum* at the top of the 30% Renografin layer and at the 30% to 42% interface, respectively, excess host cell debris will be distributed throughout the entire gradient.

Bleeding and infecting mice

When obtaining blood from *A. phagocytophilum*–infected mice, do not collect more than 20% of total blood volume at one time. Keep in mind that the total blood volume of a mouse is 5.5 ml per 100 g body weight. For repeated blood collection via the retro-orbital route, alternate eyes should be used. In the event that one eye is damaged, the second eye can be bled. If the second eye becomes damaged, bleeding via the retro-orbital route can no longer be performed. Also, be sure to rapidly transfer collected blood to the anticoagulant-treated tube, as it will otherwise clot. Lastly, do not successively pass *A. phagocytophilum* more than four times through immunocompetent mice, as the bacterium's pathogenicity will become increasingly attenuated with each passage. For in vivo maintenance, it is best to pass the bacterium through SCID mice.

Immunofluorescent microscopy

A critical parameter to keep in mind while preparing slides for examination by immunofluorescence microscopy is that the slides should be left in acetone for 8 min to ensure proper fixation and permeabilization. Also, allow at least 1 hr for the blocking step to prevent nonspecific antibody binding. Additionally, thoroughly resuspend the cells by gently pipetting up and down when transferring cell suspensions into the slide wells. This will minimize clumping and facilitate easier viewing of the cells. When preparing samples for cytological staining, centrifuging the infected HL-60 cells onto the slides results in the host-cell cytoplasm spreading out. This greatly aids in identification of morulae, as they are otherwise often obscured by the large HL-60 cell nuclei. In addition, the Hema-3 solutions can become diluted with repeated use and may require longer incubations for thorough cell staining. If this occurs, it may be necessary to leave the slides in each stain for up to 1 min. If the stains become so dilute that incubations longer than 1 min are required, then discard the old solutions and use fresh stains.

Fluorescent labeling using CellTracker Green CMFDA

When preparing host cell–free *A. phagocytophilum* for fluorescent labeling using CellTracker Green CMFDA, it is crucial to thoroughly wash the bacteria to remove all traces of FBS, as serum components will inactivate the dye. It is equally important to thoroughly wash the labeled bacteria to remove unincorporated label. Otherwise, the entire host cell population will be labeled in the subsequent infection assay, thereby making it impossible to distinguish infected from uninfected cells.

Troubleshooting

Table 3A.2.1 presents some of the common problems associated with the protocols in this unit, as well as their causes and solutions.

Anticipated Results

Inoculation and continual passage of A. phagocytophilum in HL-60 cell culture

Following inoculation of *A. phagocytophilum*–infected blood into HL-60 cell culture, morulae are typically not detectable until day 5 post-inoculation. However, *A. phagocytophilum* has a slow doubling time. Thus, even on day 5, the percentage of HL-60 cells with morulae remains quite low. By days 12 to 14, morulae should be detectable within $\geq$80% of cells.

When viewing HL-60 cells incubated in the presence of trypan blue under light microscopy, uninfected HL-60 cells are typically round and have smooth borders. The membranes of infected cells, however, are rougher in appearance. Moreover, the integrity of the membranes becomes compromised as the infection progresses, and they become permeable with respect to trypan blue. As a result, heavily infected cells and cells that have been lysed upon bacterial exit appear darker than uninfected cells.

Obtaining host cell–free A. phagocytophilum

Following the initial post-lysis spin, a large host cellular debris pellet will be visible at the bottom of the microcentrifuge tube. The pellet obtained after the subsequent centrifugation step is considerably smaller than that obtained after the first spin step. Upon centrifugation at 2300 $\times$ *g*, a small pellet will be visible. This represents *A. phagocytophilum* with minor host cell contaminants.

Inoculation of A. phagocytophilum into laboratory mice

Following intraperitoneal inoculation of immunocompetent mice with *A. phagocytophilum*, morulae are evident in 2% to 4% of peripheral blood neutrophils on day 2. By days 7 to 8, which typically represent peak infection, morulae are detectable in 7% to 13% of neutrophils. By days 14, the peripheral blood infection wanes considerably, and the percentage of neutrophils with detectable morulae drops to <2%. Often, morulae are no longer evident in peripheral blood smears by day 28. With successive passage of *A. phagocytophilum*–infected C3H mouse blood into naive C3H mice, the pathogenicity of the bacterium will rapidly wane. By the sixth or seventh passage, morulae-positive neutrophils will drop to nearly undetectable levels. However, it has been demonstrated that blood from infected C3H mice remains infectious for up to 60 days (Hodzic et al., 1998). Pathogenicity of the bacteria can be restored by inoculation of infected C3H mouse blood into SCID mice. By the third or fourth passage in SCID mice, the percentage of peripheral blood neutrophils with *A. phagocytophilum* infection should rise considerably. The initial kinetics of infection in SCID mice is similar to that observed for immunocompetent mice. However, the maximal level of bacteremia does not subside after day 8, and may be sustained for several weeks. *A. phagocytophilum* should be passaged from infected to naive SCID mice at least every 8 weeks.

Cytological staining of A. phagocytophilum–infected cells

Morula is a Latin term meaning "mulberry." The morphology of the intracytoplasmic inclusions formed by *A. phagocytophilum* makes it an appropriate metaphor. Morulae stain more darkly than the host cell's nucleus and are stippled in appearance (Fig. 3A.2.2). Morulae are most readily distinguishable when present in the cytoplasm and not obstructed by the large HL-60 cell nucleus. For this reason, centrifugation of the cells onto slides using a Thermoshandon Cytospin 4 Cytocentrifuge, which causes the cytoplasm to spread out away from the nucleus, is strongly recommended.

Immunofluorescent detection of A. phagocytophilum in infected HL-60 cells.

Morulae are visualized as fluorescent green clusters of organisms (Fig. 3A.2.4). Because of the enhanced sensitivity of immunofluorescence relative to cytological staining,

Table 3A.2.1 Troubleshooting Guide for Laboratory Maintenance and Staining of *Anaplasma phagocytophilum*

Problem	Possible cause	Solution
Cultivation of A. phagocytophilum in HL-60 cells		
Entire HL-60 cell population lysed	Overgrowth of *A. phagocytophilum*	Add 1×10^6 uninfected HL-60 cells per 2×10^6 infected cells
Obtaining A. phagocytophilum from infected HL-60 cells		
Low yield of host cell–free *A. phagocytophilum*	Low bacterial burden of starting pool of infected HL-60 cells	Determine bacterial load of donor cell population prior to lysing
	Poor lysis of HL-60 cells	Pass infected HL-60 cells through 27-G, 1/2-in. (12.7-mm) needle five times
Inoculation of A. phagocytophilum into mice		
Blood from *A. phagocytophilum*–infected C3H mice has low percentage of morulae-positive neutrophils after third or fourth passage	Pathogenicity of *A. phagocytophilum* has waned with continual passage in immunocompetent mice	Restore pathogenicity by transferring *A. phagocytophilum* to SCID mice
Cytological staining		
Few to no cells present on slide post-staining	Poor fixation; cells washed off	Fix slides in Hema-3 fixative for 1 min
All cellular contents stained purple	Slides incubated too long in Hema-3 Solution II	Reduce incubation time in Hema-3 Solution II
Cellular contents stained too faintly	Staining solutions are too old, diluted	Increase incubation time in each solution or use fresh staining solutions
Immunofluorescence		
Few to no cells present on slide post-staining	Poor fixation; cells washed off	Fix slides in acetone for 8 min
Clumping of cells	Samples not thoroughly resuspended when transferring to slide wells	Pipet samples up and down when transferring to slide wells
High background fluorescence	Poor blocking	Block nonspecific sites by incubating slides with 5% BSA in PBS for $\geq$1 hr
Fluorescence of host cell nuclei is too intense	Propidium iodide staining allowed to proceed for too long	Reduce incubation time to $\leq$3 min and wash slides thoroughly with PBS to remove excess propidium iodide

continued

Table 3A.2.1 Troubleshooting Guide for Laboratory Maintenance and Staining of *Anaplasma phagocytophilum*, *continued*

Problem	Possible cause	Solution
Density gradient purification		
Low yield of host cell–free *A. phagocytophilum*	Low bacterial burden in starting pool of infected HL-60 cells	Determine bacterial load of donor cell population prior to lysis
Host cellular debris present throughout gradient following centrifugation	Ineffective removal of majority of host cellular debris by differential centrifugation	Following syringe lysis, pellet host cell debris by centrifugation as described in Basic Protocol 2
		Dilute host cell–contaminated gradient 4-fold with PBS-glucose and repeat density gradient purification
Fluorescent labeling of A. phagocytophilum		
Poor labeling of *A. phagocytophilum*	Ineffective removal of FBS following lysis	Thoroughly wash host cell–free *A. phagocytophilum* to remove all traces of serum
Fluorescent labeling of entire host cell population in subsequent infection assay	Ineffective removal of unincorporated CellTracker Green CMFDA	Thoroughly wash labeled *A. phagocytophilum* to remove unincorporated dye

individual bacteria can also be discerned. These will be evident in *A. phagocytophilum*–infected HL-60 cells, but will not be detectable in uninfected cells or in cells incubated with only primary or secondary antibody. Host cell nuclei are easily distinguished by their red color when counterstained with propidium iodide.

Cryopreservation of A. phagocytophilum–infected HL-60 cells

The majority of HL-60 cells should survive the cryopreservation procedure. After inoculating a frozen stock culture into fresh medium, the cell density and number of infected cells should begin to increase within 2 to 3 days.

Density gradient purification of host cell–free A. phagocytophilum

Centrifugation of a semipure preparation of *A. phagocytophilum* through the discontinuous gradient (see Basic Protocol 3) will result in three distinct layers of ~10 ml each, separated by two distinct bands (Fig. 3A.2.5). A pellet will also be present at the bottom of the tube. The band on top of the 30% Renografin layer consists primarily of host cellular debris. The pellet primarily consists of unbroken HL-60 cells. The band present at the interface of the 30% and 42% Renografin layers is highly enriched for *A. phagocytophilum*. It is likely that a minor portion will consist of host cellular components that are of similar size and density to that of *A. phagocytophilum*, such as mitochondria.

Fluorescent labeling of live A. phagocytophilum

When cells infected with CellTracker Green CMFDA–labeled *A. phagocytophilum* are viewed using a fluorescent microscope, individual bacteria within or bound to the surfaces of host cells are discernible as bright green dots. When analyzed using flow cytometry, infected cells exhibit a strong rightward shift relative to uninfected cells (Fig. 3A.2.6).

Time Considerations

With the exception of the protocols for establishing *A. phagocytophilum* infection in HL-60 cell culture (see Basic Protocol 2) or in mice (see Basic Protocol 1), each protocol described in this unit can be performed in a single day. Inoculation of HL-60 cells or mice should take <1 hr, depending on the number of inoculations to be performed. Following inoculation of infected blood into HL-60 cell culture, it takes ≥5 days before morulae are evident in even a minor percentage of cells. By days 12 to 14, however, ≥90% of the cells should

be infected. Following inoculation into laboratory mice, *A. phagocytophilum* inclusions are evident in ~2% to 4% of peripheral blood neutrophils by day 2. Maximal bacterial burden, which is represented by infection of 7% to 13% of neutrophils, is achieved by days 7 to 8.

Obtaining host cell–free *A. phagocytophilum* by differential centrifugation will require ~2 hr. Cryopreservation of infected HL-60 cells will require <1 hr to complete, as will the cytological staining procedure. Immunofluorescent staining of samples will take ~4 hr if performed without interruption. However, the protocol can be stopped after acetone fixation and the slides stored indefinitely at –20°C.

In addition, slides can be stored indefinitely at room temperature in the dark after being mounted. Density gradient purification of *A. phagocytophilum* requires ~6 hr and should be performed without interruption. Labeling of host cell–free *A. phagocytophilum* with CellTracker Green CMFDA will require ~3.5 hr and should also be performed without interruption.

Isolation and Molecular Detection of *Ehrlichia* from Vertebrate Animals

Chuanmin Cheng,[1] Kamesh R. Sirigireddy,[1] and Roman R. Ganta[1]

[1]Department of Diagnostic Medicine/Pathobiology, College of Veterinary Medicine, Kansas State University, Manhattan, Kansas

ABSTRACT

Human monocytic ehrlichiosis (HME), caused by *Ehrlichia chaffeensis*, was first recognized in 1986. Infection with this pathogen can be fatal in immune compromised and elderly humans. *E. chaffeensis* can also infect dogs and several wild animals. The clinical symptoms of HME include fever, headache, malaise, myalgia, confusion, rash, lymphadenopathy, and nausea. White-tailed deer serve as the major reservoir host for the natural maintenance of *E. chaffeensis*. *E. canis* is primarily responsible for the canine monocytic ehrlichiosis and is endemic throughout the world. It has a significant impact on the health of dogs. The isolation and growth of *Ehrlichia* species from vertebrate host samples is difficult and time consuming. In this unit, methods to recover *E. chaffeensis* and *E. canis* from infected blood samples collected from dogs, deer, and human patients are described. PCR and RT-PCR methods for sensitive detection of *Ehrlichia* infection are also discussed. *Curr. Protoc. Microbiol.* 9:3A.3.1-3A.3.16. © 2008 by John Wiley & Sons, Inc.

Keywords: *Ehrlichia* isolation • animal blood • PCR • RT-PCR • real-time RT-PCR • DNA isolation • RNA isolation

INTRODUCTION

Human monocytic ehrlichiosis (HME), caused by *Ehrlichia chaffeensis*, was first recognized in 1986 (Dawson et al., 1991a*). E. chaffeensis* can also infect dogs and several wild animals (Dawson et al., 1996; Magnarelli et al., 1997). The clinical symptoms of HME include fever, headache, malaise, myalgia, confusion, rash, lymphadenopathy, and nausea (Rikihisa, 1999). HME can be fatal to the immune compromised and elderly. White-tailed deer are presumed to be the reservoir hosts of *E. chaffeensis* (Dawson et al., 1994; Lockhart et al., 1997). *E. canis* causes canine monocytic ehrlichiosis and was first recognized in Algeria in 1935 (Buhles et al., 1974). Wild and domestic dogs with chronic infection serve as reservoir hosts. During the acute phase of infection, the clinical signs include fever, anorexia, and lymphadenopathy, and, in the chronic phase of infection, the dogs may show emaciation, hemorrhage, and peripheral edema (Buhles et al., 1974).

The first successful culture of *E. canis* was obtained from peripheral blood monocytes obtained from experimentally infected dogs during the acute phase of the disease (Lovering et al., 1980). Similarly, the first isolation and cultivation of *E. chaffeensis* in canine macrophage cell line was reported by Dawson et al. (1991a). The isolation and growth of *Ehrlichia* species is difficult and time consuming. Several laboratories described the isolation of *Ehrlichia* species from vertebrate animals (Dawson et al., 1991a,b; Lockhart et al., 1997; Paddock et al., 1997; Breitschwerdt et al., 1998). Protocols for isolating *E. chaffeensis* from several human blood samples suspected to be positive for *Ehrlichia* are also described (Paddock et al., 1997). Methods of in vitro isolation of *Ehrlichia* from naturally infected deer blood are described in Dawson et al. (1994) and Lockhart et al. (1997). Mice serve as a good model system to understand the host response against *E. chaffeensis* (Winslow et al., 1998; Ganta et al., 2002, 2004). In this unit, methods are

Current Protocols in Microbiology 3A.3.1-3A.3.16, May 2008
Published online May 2008 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/9780471729259.mc03a03s9

described to recover *E. chaffeensis* and *E. canis* from blood samples collected from clinically suspected dogs, deer, and human patients. Methods are also described to recover *Ehrlichia* organisms from tissue samples collected from experimentally infected mice.

Molecular detection methods, such as PCR, RT-PCR, and real-time RT-PCR, are useful in detecting *Ehrlichia* infection, as they are very sensitive and the assays can be performed rapidly. Molecular methods have been described by several laboratories and most of them are targeted to either 16S ribosomal DNA or ribosomal RNA (rRNA). 16S rRNA–based tests are ~100 times more sensitive than PCR because the target is available in multiple copies per bacterium (Felek et al., 2001; Sirigireddy and Ganta, 2005). Single or co-infections with three *Ehrlichia* species, *E. chaffeensis*, *E. canis*, and *E. ewingii*, can occur in animals or humans (Breitschwerdt et al., 1998; Murphy et al., 1998; Paddock and Childs, 2003; Dumler et al., 2007). 16S rRNA-based multiplex real-time RT-PCR is most efficient in detecting the aforementioned three *Ehrlichia* species (Sirigireddy and Ganta, 2005). DNA and RNA isolation and their use in detecting *Ehrlichia* by molecular methods further aid in pathogen diagnosis and are complementary to culture recovery methods.

CAUTION: E. chaffeensis and *E. canis* are Biosafety Level 2 (BSL-2) pathogens. Follow all appropriate guidelines and regulations for the use and handling of these pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

CAUTION: Some of the methods described in this unit also require the use of Animal Biosafety Level 2 (ABSL-2) conditions. Follow all appropriate guidelines for the use and handling of infected animals. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information. Protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

CAUTION: The protocols described in this unit involve the use of human and/or other animal blood or tissue samples that may be infected with *Ehrlichia* species and/or other potential pathogens. Follow all appropriate guidelines and regulations for the use and handling of human- and animal-derived materials. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

CAUTION: Follow strict sterile culture procedures in all steps involving sample processing and during cultivation to minimize contamination.

NOTE: When preparing solutions, use deionized or double distilled water (ddH_2O) and use reagents of the highest quality. Sterilization by filtration through a 0.22-μm filter or by autoclaving is recommended for most solutions; this is critical for all reagents used for cell culture work. Discard any reagent that shows evidence of contamination, precipitation, or discoloration.

BASIC PROTOCOL 1

ISOLATION AND CULTIVATION OF *E. CHAFFEENSIS* FROM HUMAN BLOOD SAMPLES

This protocol outlines step-by-step instructions for the isolation and cultivation of *Ehrlichia* from infected human blood samples. This method is adapted from the protocol described by Paddock et al. (1997).

Materials

Human blood sample in sterile blood collection tube containing EDTA
Hanks' balanced salt solution (HBSS; without $CaCl_2$, $MgCl_2$, $MgSO_4$, or phenol red; *APPENDIX 2A*)
Histopaque-1083 (Sigma-Aldrich)

Complete MEM medium (see recipe)
DH82 monolayer (~60% confluent) in a 25-cm^2 tissue culture flask (*UNIT 3A.1*)

15- and 50-ml centrifuge tubes
Pasteur pipets
37°C, 5% CO_2 incubator

Additional reagents and equipment for DH82 monolayer culture and Cytospin slide preparation (*UNIT 3A.1*)

1. Collect ~5 to 30 ml of blood in a sterile blood collection tube containing EDTA and use immediately or store up to 1 week at 4°C before use.

   It is best to use freshly obtained blood samples to increase the success of culture work for recovering of Ehrlichia organisms.

2. Dilute the blood sample with 2 vol sterile HBSS.
3. Layer the diluted blood onto 3 ml (for every 5 ml of blood) of Histopaque-1083 in a 15-ml centrifuge tube.
4. Centrifuge the blood/Histopaque tube 20 min at 800 × *g*, room temperature.
5. After centrifugation, carefully aspirate and discard the upper plasma layer using a Pasteur pipet (see Fig. 3A.3.1).
6. Carefully transfer the opaque interface containing mononuclear cells to a 50-ml centrifuge tube containing 10 ml of HBSS with a clean Pasteur pipet, gently mix by inverting tube four to five times, and then centrifuge 10 min at 400 × *g*, room temperature.
7. Discard supernatant and resuspend cell pellet in 5 ml of complete MEM medium.
8. Transfer suspension to a 25-cm^2 tissue culture flask containing a DH82 monolayer that is ~60% confluent (described in *UNIT 3A.1*, Support Protocol 1).

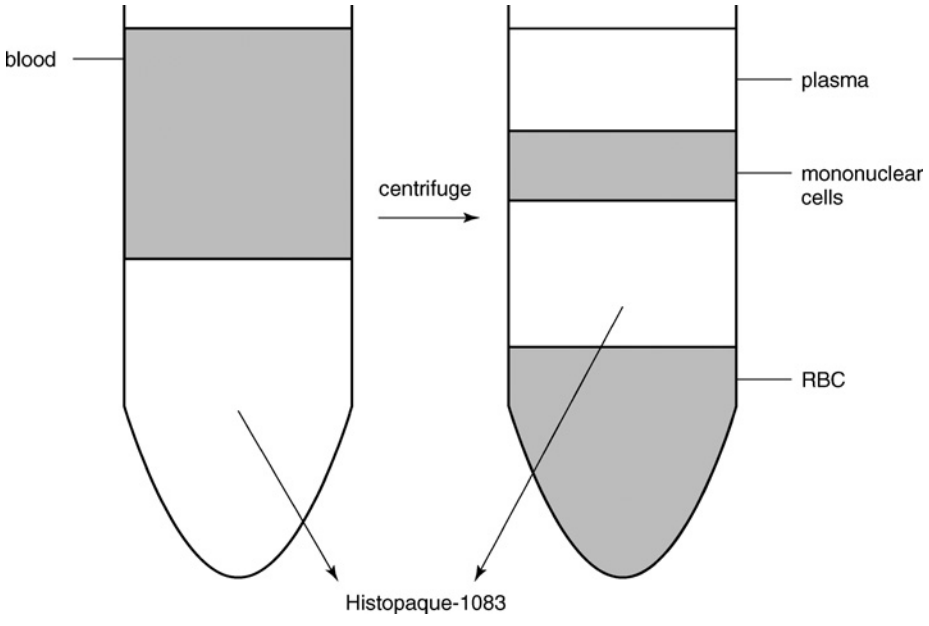

Figure 3A.3.1 Schematic drawing of the different layers of blood sample before and after centrifugation with Histopaque-1083.

9. Transfer flask to a 37°C, 5% CO_2 incubator.

10. Check the infectivity two times a week by preparing a Cytospin slide and evaluating under a light microscope as described in *UNIT 3A.1*, Basic Protocol 5.

    The growth and monitoring should be continued until infection is detected or for up to 10 weeks by changing ~50% of the medium once every 3 to 4 days. If the cells reach 90% to 100% confluence during this incubation period, replace the entire volume of medium, detach the cells by gently rocking the culture flask by hand after adding ~15 4-mm sterile glass beads, discard 50% of the culture using a sterile serological pipet, and replace with an equal volume of fresh culture medium.

BASIC PROTOCOL 2

ISOLATION AND CULTIVATION OF *E. CHAFFEENSIS* FROM DEER BLOOD SAMPLES

This protocol describes a method for the isolation and cultivation of *Ehrlichia* organisms from blood samples collected from naturally or experimentally infected deer. This method is described in two other publications with minor differences to the protocol (Dawson et al., 1994; Lockhart et al., 1997). The protocol described here is adapted from those two publications.

Materials

Heparinized deer blood samples infected with *Ehrlichia chaffeensis*
ACE lysing solution (see recipe)
Complete MEM medium (see recipe)
DH82 cells (~60% confluent) in 25-cm^2 tissue culture flask (*UNIT 3A.1*)

50-ml tubes
37°C, 5% CO_2 incubator

Additional reagents and equipment for DH82 monolayer culture and Cytospin slide preparation (*UNIT 3A.1*)

1. Collect 5 to 7 ml of heparinized deer blood infected with *E. chaffeensis*, transfer to a sterile 50-ml tube containing 25 ml of ACE lysing solution, and mix gently by inverting tube several times to form homogeneous solution.

2. Incubate 5 min at room temperature, centrifuge suspension 5 min at 160 × *g*, room temperature, and discard supernatant.

3. Add 25 ml ACE lysing solution to pellet, mix gently, centrifuge 5 min at 160 × *g*, room temperature, and then discard the supernatant.

4. Repeat step 3 one additional time.

5. Resuspend final pellet in 5 ml complete MEM medium and transfer contents to a 25-cm^2 tissue culture flask containing a ~60% confluent monolayer of DH82 cells.

6. Transfer flask to a 37°C, 5% CO_2 incubator.

7. Check the infectivity two times a week by preparing a Cytospin slide and evaluating under a light microscope as described in *UNIT 3A.1*, Basic Protocol 5. Change ~50% of the medium once every 3 to 4 days.

    Ehrlichia may be first detected in cell culture at ~4 to 5 weeks of evaluation. However, it is advisable to monitor the growth for up to 10 weeks to check for Ehrlichia positives. If the cells reach 90% to 100% confluence during this incubation period, replace the entire volume of medium, detach the cells by gently rocking the culture flask by hand after adding ~15 4-mm sterile glass beads, discard 50% of the culture using a sterile serological pipet, and replace with an equal volume of fresh culture medium.

CULTURE ISOLATION OF *E. CHAFFEENSIS* OR *E. CANIS* FROM CANINE BLOOD

BASIC PROTOCOL 3

This protocol describes a method for isolating *E. chaffeensis* or *E. canis* from the blood of a naturally or experimentally infected dog. This protocol is adapted from Dawson et al. (1991a) with minor modifications. This revised protocol uses a culture medium containing 6.5% FBS rather than 12.5% FBS and the cultures are grown in the presence of 5% CO_2.

Materials

Ehrlichia-infected dog blood in a sterile blood collection tube containing EDTA
Serofuge centrifuge (Becton Dickinson)
37°C, 5% CO_2 incubator

Additional reagents and equipment for DH82 monolayer culture and Cytospin slide preparation (*UNIT 3A.1*)

1. Collect ~6 ml *Ehrlichia*-infected blood from a dog in a sterile blood collection tube containing EDTA (purple tube) and use immediately.

   Blood samples may be stored up to 1 week at 4°C prior to culture isolation. However, it is best to use fresh blood to increase the likelihood of recovering Ehrlichia organisms.

2. Centrifuge blood samples 5 min at 3000 rpm, room temperature, in a Serofuge centrifuge.

3. Transfer 200 µl of the buffy coat to a 25-cm^2 tissue culture flask containing 5 ml (~60% confluent) DH82 culture (see *UNIT 3A.1*, Support Protocol 1 for detailed instructions for DH82 culture growth).

   The buffy coat is a thin fraction in EDTA blood (or in any anticoagulated blood) that is settled between plasma and erythrocyte layers following low-speed centrifugation. It is rich in white blood cells but also contains red and other blood cells.

4. Transfer flask to a 37°C, 5% CO_2 incubator.

5. Check the infectivity two times a week by preparing Cytospin slides of cultures and evaluating under a light microscope as described in *UNIT 3A.1*, Basic Protocol 5.

   If Ehrlichia is not identified within the first week, continue growing until the infection is noted or for up to 8 to 10 weeks. If the cells reach 90% to 100% confluence during this incubation period, replace the entire volume of medium, detach the cells by gently rocking the culture flask by hand after adding ~15 4-mm sterile glass beads, discard 50% of the culture using a sterile serological pipet, and replace with an equal volume of fresh culture medium.

RECOVERY OF *EHRLICHIA* FROM EXPERIMENTALLY INFECTED MOUSE PERITONEAL CELLS

BASIC PROTOCOL 4

This protocol outlines a simple method useful for *Ehrlichia* isolation from experimentally infected mice. The mouse model has been used extensively to understand the pathogenicity and to assess host immune response against *E. chaffeensis* infection (Winslow et al., 1998; Ganta et al., 2002, 2004, 2007).

Materials

E. chaffeensis-infected mice
Sterile PBS (see recipe), ice cold

24-well sterile culture plates
37°C, 5% CO_2 incubator

Additional reagents and equipment for DH82 monolayer culture and Cytospin slide preparation (*UNIT 3A.1*)

1. Aseptically collect peritoneal fluid containing macrophages from an experimentally infected mouse by washing peritoneal cavity, i.e., by injecting 20 ml of ice-cold, sterile PBS using a needle and syringe into the intact mouse.
2. Harvest cells from 5 ml of peritoneal wash solution by centrifuging 10 min at 500 × *g*, 4°C.

   The remaining peritoneal wash solution may be used for other experiments or discarded.
3. Resuspend cell pellet in 1/5 volume of DH82 cells harvested from a 25-cm^2 tissue culture flask having a complete monolayer of cells.
4. Transfer cell suspension to a well of a 24-well sterile culture plate and incubate in a 37°C, 5% CO_2 incubator.
5. Check the infectivity two times a week by preparing a Cytospin slide and evaluating under a light microscope as described in *UNIT 3A.1*, Basic Protocol 5. Change ~50% of the medium once every 3 to 4 days until infection is detected.

   The culture may be monitored for up to 10 weeks if the infection is not observed prior to that. If the cells reach 90% to 100% confluence during this incubation period, replace the entire volume of medium, detach the cells by gently rocking the culture flask by hand after adding ~15 4-mm sterile glass beads, discard 50% of the culture using a sterile serological pipet, and replace with an equal volume of fresh culture medium.

BASIC PROTOCOL 5

DETECT FOR THE PRESENCE OF *EHRLICHIA* BY PCR

The PCR assay described here is useful to confirm infection in host cells. However, it is not necessary to routinely use this method for infection monitoring. In the event that multiple isolates of *Ehrlichia* species are being cultured, it is important to perform a PCR assay to validate the isolate in use. Isolate-specific PCR assays may also be performed using methods described in Cheng et al. (2003).

Materials

PCR kit (Invitrogen cat. no. 10966-034) containing:
  Platinum *Taq* DNA polymerase
  10× PCR buffer
  50 mM $MgCl_2$
PCR/RT-PCR primers for *E. chaffeensis* and *E. canis* (Table 3A.3.1)
10 mM dNTPs
Nuclease-free water
DNA template
1% agarose gel containing 0.1 μg/ml ethidium bromide
1-kb plus DNA ladder (or any other comparable molecular weight DNA standards)

0.2-ml thin-walled PCR/RT-PCR tubes
GenAmp9700 PCR thermal cycler (Applied Biosystems)

1. Prepare PCR master mix by adding the following per reaction (multiply by the number of samples plus one or two extra reactions to compensate for pipetting error):

   2.5 μl 10× PCR buffer
   0.5 μl each of 10 μM forward and reverse primers
   0.5 μl 10 mM dNTPs
   1.5 μl 25 mM $MgCl_2$
   0.2 μl *Taq* DNA polymerase (5 U/μl)
   17.3 μl nuclease-free water
   Mix gently by pipetting up and down.

Table 3A.3.1 Primers and Probes Used in PCR/RT-PCR and Multiplex *Ehrlichia* Real-Time RT-PCR

Primers and probes	Sequence
Primers for PCR/RT-PCR	
E. chaffeensis-forward primer	5′gcatacttggttataaata
E. chaffeensis-reverse primer	5′gtattaccgcggctgctggcac
E. canis-forward primer	5′cctctggctataggaaattg
E. canis-reverse primer	5′gtattaccgcggctgctggcac
Primers and TaqMan probes	
Ehrlichia-common forward primer	5′ctcagaacgaacgctgg
Ehrlichia-common reverse primer	5′catttctaatggctattcc
E. chaffeensis TaqMan probe	5′TET/cttataacctttggttataaataatgttag/TAMRA
E. canis TaqMan probe	5′FAM/tatagcctctggctataggaaattgttag/TAMRA
E. ewingii TaqMan probe	5′ROX/ctaaatagtctctgactatttagatagttgttag/BQH2

For example, if preparing a master mix for ten reactions, add twelve times the suggested volumes of each reagent and then transfer 23-μl aliquots of the homogeneous mixture to each reaction tube.

2. Add 2 μl DNA template or water (to serve as a negative control) to appropriately labeled reaction tubes containing 23 μl of PCR master mix.

   The following precautions must be taken when performing PCR analysis. (1) It is best to set up PCR reactions in a PCR work station (e.g., available from Coy Laboratory Products) to minimize aerosol contamination to PCR reagents and templates. (2) A dedicated set of pipet aids and equipment must be used in setting up PCRs and always use aerosol-barrier tips. (3) All of the PCR reagents should be maintained at 4°C by submerging in a cold chamber or in an ice bucket when setting up PCR reactions (Pollard et al., 2000).

3. Transfer the reaction tubes to a GeneAmp9700 PCR thermal cycler or similar instrument and initiate the PCRs by setting up the machine for the following program:

1 cycle:	4 min	94°C (denaturation)
35 cycles:	30 sec	94°C (denaturation)
	30 sec	55°C (annealing)
	1 min	72°C (extension)
1 cycle:	5 min	72°C (extension).

4. Cool samples to 4°C, either in the PCR machine or by transferring to a refrigerator.

5. Resolve 5 μl of PCR products (along with a 1-kb plus DNA ladder) on a 1.5% agarose gel containing 0.1 μg/ml ethidium bromide (Voytas, 2000).

   Molecular weight markers should also be resolved on agarose gels to aid in the identification of the predicted ~0.4-kb DNA amplicon (Fig. 3A.3.2).

   To prevent contamination with previously made amplicons, DNA isolation and PCR assembly should be performed in one laboratory, while the executing PCRs and product analysis should be done in another laboratory. A positive control (with Ehrlichia-specific DNA as a template) and a negative control (reaction mix lacking a template) should also be included in every PCR experiment.

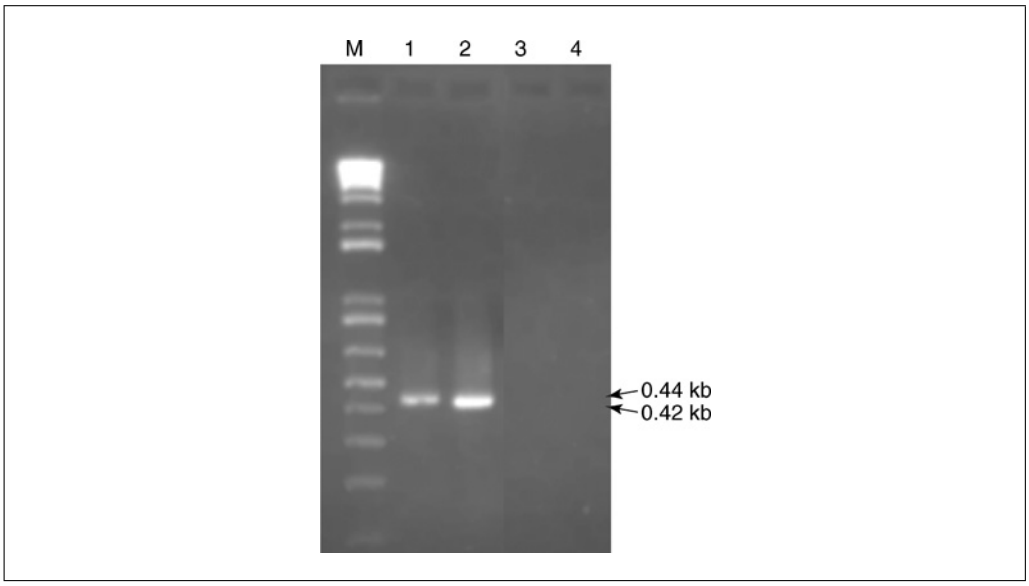

Figure 3A.3.2 PCR product analysis of *E. chaffeensis* and *E. canis.* Lanes 1 and 3 have the PCR products in the reactions containing *E. chaffeensis*-specific PCR primers with and without the templates, respectively. Similarly, lanes 2 and 4 included PCR products with *E. canis* primers with and without the DNA template, respectively. A molecular weight marker (1-kb plus DNA ladder from Promega) is included in lane M. Predicted molecular sizes for the PCR products of *E. chaffeensis* and *E. canis* are 0.44 and 0.42 kb, respectively.

SUPPORT PROTOCOL 1

EHRLICHIA DNA ISOLATION BY SDS/PROTEINASE K METHOD

The DNA isolation method described here is adapted from a previously reported SDS/proteinase K method (Sambrook and Russell, 2001). However, there are also many commercially available kit protocols.

Materials

ACE lysing solution (see recipe)
Whole blood
DNA extraction buffer (see recipe)
20 mg/ml proteinase K in 50 mM Tris·Cl, pH 7.5
Phenol, pH 8.0
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol
24:1 (v/v) chloroform/isoamyl alcohol
70% and 100% ethanol, ice cold
TE buffer (see recipe)

1.7-ml microcentrifuge tubes
Table top high-speed microcentrifuge
65°C water bath

1. Add 1 ml ACE lysing solution to 0.2 ml whole blood in a 1.7-ml microcentrifuge tube, shake gently by inverting tube several times to create a homogenous mixture, and incubate 5 min at room temperature.
2. Centrifuge lysate 5 min at 160 × *g*, room temperature, and discard supernatant.
3. Add 1 ml ACE lysing solution to carefully rinse the white blood cell pellet.

   This procedure aids in the lysis of red blood cells. Steps 1 to 3 are not needed when using this protocol for isolating genomic DNA from a cell culture pellet.

4. Add 0.5 ml DNA extraction buffer containing 12.5 µl proteinase K (20 mg/ml) to the cell pellet, mix gently by pipetting up and down, and incubate 2 hr in a 65°C water bath.

   Incubation may be extended for up to 20 hr.

5. Add 0.5 ml phenol and gently vortex or mix the contents by inverting the tube several times.

   CAUTION: *Phenol is extremely toxic, highly corrosive, and can cause severe burns. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves, goggles, and protective clothing. Always use in a chemical fume hood. Rinse any areas of skin that come in contact with phenol with a large volume of water and wash with soap and water; do not use ethanol. Also see* UNIT 1A.3.

6. Centrifuge 10 min at 10,000 × *g*, 4°C and carefully transfer the aqueous layer to a new tube using a pipet.

7. Add 0.5 ml of 25:24:1 phenol/chloroform/isoamyl alcohol and gently vortex or mix the contents by inverting the tube several times.

8. Repeat step 6.

9. Repeat steps 7 and 8 but using 0.5 ml of 24:1 chloroform/isoamyl alcohol.

10. Add 2.5 vol of 100% ice-cold ethanol and gently vortex or mix the contents by inverting the tube several times.

11. Incubate tube at least 15 min at 4°C, centrifuge 10 min at 10,000 × *g*, 4°C, and discard supernatant.

12. Add 1 ml of 70% ethanol to the tube containing DNA pellet and then carefully discard the supernatant.

13. Air dry the pellet until ethanol is completely evaporated (~10 min) and dissolve DNA in 100 µl TE buffer.

RT-PCR ASSAY FOR DETECTION OF *EHRLICHIA*

BASIC PROTOCOL 6

The RT-PCR assay described here is very similar to the PCR assay outlined above in Basic Protocol 5 with the exception of introducing a reverse transcriptase step. The RT-PCR assay is ~100 times more sensitive than PCR for detecting *Ehrlichia* species (Sirigireddy and Ganta, 2005).

Materials

SuperScript III, one-step RT-PCR system with Platinum *Taq* DNA polymerase and 2× buffer (Invitrogen cat. no. 11732-020)
PCR/RT-PCR primers for *E. chaffeensis* and *E. canis* (Table 3A.3.1)
RNAsin (RNase inhibitor; Promega cat. no. N2515)
Nuclease-free water
RNA template
1.5% agarose gel containing 0.1 µg/ml ethidium bromide (Voytas, 2000)
1-kb plus DNA ladder (or any other comparable molecular weight DNA standards)

0.2-ml thin-walled PCR/RT-PCR tubes
GenAmp9700 PCR thermal cycler (Applied Biosystems)

1. Prepare an RT-PCR master mix by adding the following for a total volume of 23 µl per reaction (multiply each volume with the number of samples plus one or two reactions for pipetting error):

   12.5 µl 2× SuperScript III/*Taq* polymerase buffer
   0.5 µl each of 10 µM forward and reverse primers

1 μl SuperScript III/*Taq* enzyme mixture
0.1 μl RNAsin (40 U/μl)
8.4 μl nuclease-free water.

For example, if preparing a master mix for ten reactions, add 12 times the suggested volumes of each reagent and then transfer 23-μl aliquots of the homogeneous mixture to each reaction tube.

2. Add 2 μl RNA template or water (for negative control) to each reaction tube containing 23 μl of master mix.

3. Transfer reaction tubes to a thermal cycler and initiate RT-PCR by performing the parameters described in Basic Protocol 5, step 3, except add a 1-hr incubation cycle at 48°C at the start of the PCR cycles to aid in synthesizing cDNA.

4. Resolve 5 μl PCR products (along with DNA markers) on a 1.5% agarose gel containing 0.1 μg/ml ethidium bromide (Voytas, 2000).

Molecular weight markers should also be resolved on agarose gels to aid in the identification of the predicted ~0.4-kb DNA amplicon (Fig. 3A.3.2).

BASIC PROTOCOL 7

TRIPLEX REAL-TIME RT-PCR FOR QUANTITATION OF *EHRLICHIA*

Triplex real-time RT-PCR is useful to differentiate *Ehrlichia* species. It is also valuable in quantifying the *Ehrlichia* organisms in culture or in a test sample (Sirigireddy and Ganta, 2005).

Materials

SuperScript III, one step RT-PCR system with Platinum *Taq* DNA polymerase and 2× buffer (Invitrogen cat. no. 11732-020)
10 mM dNTPs
Real-time RT-PCR primers and *Taq*Man probes for *E. chaffeensis*, *E. canis*, and *E. ewingii* (Table 3A.3.1)
Nuclease-free water
RNA (see Support Protocol 2)

1.7-ml microcentrifuge tubes
PCR tubes for Smart Cycler (Cepheid cat. no. 11-400-3)
Smart Cycler real-time PRC machine (Cepheid)

1. Prepare a master mix in a 1.7-ml microcentrifuge tube by adding the following reagents for a total volume of 23 μl per reaction (multiply each volume by the number of samples plus one or two reactions for pipetting errors):

12.5 μl 2× SuperScript III/*Taq* polymerase buffer
0.5 μl 10 mM dNTPs
1.0 μl each of 10 μM forward and reverse primers (Table 3A.3.1)
1.7 μl 50 mM $MgSO_4$
0.5, 1.0, and 1.2 μl of 7.5 μM *Taq*Man probes for *E. canis*, *E. chaffeensis*, and *E. ewingii*, respectively
1 μl SuperScript-III/*Taq* enzyme mix along with 3 units of platinum *Taq* DNA polymerase
Bring up to final volume of 23 μl (per reaction) with nuclease-free water.

For example, if preparing a master mix for ten reactions, add twelve times suggested volume of each reagent and then transfer 23-μl aliquots of the homogeneous mix to each reaction tube.

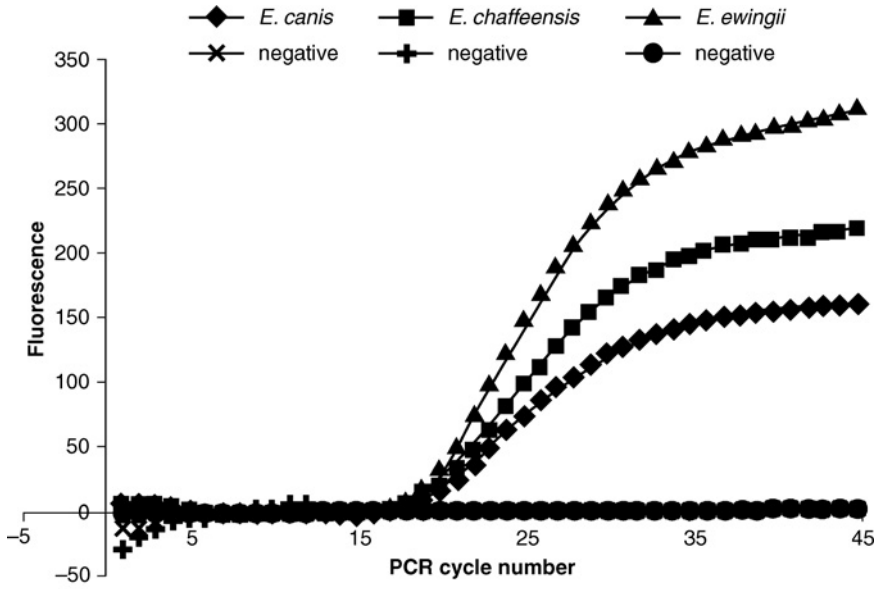
2. Dispense 23 µl of master mix into real-time RT-PCR tubes and add 2 µl of RNA or water (negative control) as templates.

   The experiment should include a positive control (DNA or RNA template from known positives) and a negative control that contains all the reagents except a DNA or RNA template.

3. Perform real-time RT-PCR in a Smart Cycler system (or similar instrument that is designed for use in performing *Taq*Man probe-based real-time RT-PCR assays) using the following parameters:

1 cycle:	30 min	48°C (reverse transcription)
1 cycle:	2 min	94°C (initial denaturation)
45 cycles:	15 sec	94°C (denaturation)
	30 sec	50°C (annealing)
	1 min	60°C (extension)

   The optics of Smart Cycler should be set to turn on during the extension phase of each amplification cycle and, similarly, the threshold fluorescence intensity should be set to 10 U. The dye set should be selected as FTTR (FAM, TET, TAMRA, and ROX). At the completion of the setup cycles, the results are displayed on a computer attached to the machine. If a sample tests positive, a Ct-value (the cycle at which the fluorescence crossed the threshold of 10 U for a specific pathogen probe) will be displayed for the positives (Fig. 3A.3.3). A reaction for which the Ct-value is displayed as ≤39 is considered as positive. If a blood sample has more than one pathogen, real time RT-PCR analysis is expected to yield positive results for more than one pathogen.



Sample	*E. chaffeensis* (TET) Ct (results)	*E. canis* (FAM) Ct (results)	*E. ewingii* (ROX) Ct (results)
DNA	18.4 (positive)	19.12 (positive)	18.00 (positive)
water	0.00 (negative)	0.00 (negative)	0.00 (negative)

Figure 3A.3.3 Real-time data generated for *Ehrlichia* triplex real-time RT-PCR using a Smart Cycler system is presented. Equal molar concentrations of in vitro–synthesized templates of *E. chaffeensis*, *E. canis*, and *E. ewingii* are used to demonstrate the detection by real-time assay (Sirigireddy and Ganta, 2005). Negative controls contained all components of a real-time RT-PCR mixture with the exception of the templates (template volume replaced with water). The Ct values generated by the Smart Cycler are presented as a table format generated by the machine.

EHRLICHIA RNA ISOLATION

The RNA isolation method described here is adapted from the Tri-reagent method kit protocol (Sigma-Aldrich).

Materials

Ehrlichia-infected blood, tissue samples, or culture organisms
Tri-reagent and Tri-reagent BD (Sigma-Aldrich) or similar reagents (available from other manufacturers)
TE buffer (see recipe) or nuclease-free water
RNAsin (RNase inhibitor; Promega cat. no. N2515)

1.7-ml microcentrifuge tubes
Table-top high-speed microcentrifuge

1. Isolate total RNA from *Ehrlichia*-infected blood, tissue samples, or culture organisms using the Tri-reagent or Tri-reagent BD (from blood) method by following the manufacturer's instructions.
2. Dissolve RNA pellet in 100 µl TE buffer or nuclease-free water.
3. Add 40 U RNAsin to purified RNA solution and store up to 2 years at –80°C until use.
4. Use 2 µl of each DNA or RNA in PCR or RT-PCR assays, respectively, to determine the presence of *Ehrlichia*.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ACE lysing solution

150 mM NH_4Cl
0.7 mM KH_2PO_4
3 mM Na_4-EDTA

Weigh 8.012 g NH_4Cl, 0.0952 g KH_2PO4, 1.248 g Na_4-EDTA, and dissolve the compounds in a total volume of 1000 ml water and filter sterilize using a 0.22-µm filter unit. Store up to 6 months at 4°C.

Complete MEM medium

500 ml minimum essential medium with Earle salt (MEM medium; Mediatech cat. no. 150-10-CV)
35 ml heat-inactivated FBS
6 ml 100 mM L-glutamine

Mix by inverting the bottle several times and filter sterilize using a 0.22-µm filter unit and store up to 2 months at 4°C.

DNA extraction buffer

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
100 mM NaCl
50 mM EDTA
0.25% SDS

Add 2.922 g NaCl, 5 g SDS, 50 ml EDTA (0.5 M, pH 8.0), and 50 ml Tris·Cl (0.5 M, pH 7.5), and dissolve compounds in a volume of 500 ml water. Sterilize by passing through a 0.22-µm filter or autoclave. Store up to 1 year at room temperature.

PBS buffer, pH 7.4

8 g NaCl
0.2 g KH_2PO_4
0.2 g KCl
Plus one of the following:
2.17 g $Na_2HPO_4 \cdot 7H_2O$
2.9 g $Na_2HPO_4 \cdot 12H_2O$
1.15g Na_2HPO_4 (anhydrous)
Dissolve the above ingredients in 1 liter water
Sterilize by passing through a 0.22-μm filter or autoclave
Store up to 6 months at 4°C.

TE buffer

10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 mM EDTA

Measure 10 ml of 1 M Tris·Cl, pH 7.5 and 2 ml of 500 mM EDTA, pH 8.0, and bring volume up to 1 liter with water. Sterilize by passing through a 0.22-μm filter or by autoclaving. Store up to 1 year at room temperature.

COMMENTARY

Background Information

Several emerging tick-borne rickettsial infections have been reported in recent years and have shown to significantly impact the health of humans and other vertebrates (Paddock et al., 1993; De Silva et al., 1996; Dumler et al., 2001). These include infections by *E. chaffeensis*, a human monocytic agent, *E. ewingii*, a human ewingii ehrlichiosis agent, and *Anaplasma phagocytophilum*, a human granulocytic anaplasmosis agent (Dawson et al., 1991a; Chen et al., 1994; De Silva et al., 1996; Caspersen et al., 2002; Dumler et al., 2007). *E. canis* has been identified as the major cause of tick-borne infections in dogs in nearly all parts of the world for several decades (Haas and Meyer, 1986).

Culture methods that serve as the gold standard for pathogen diagnosis are also described for recovering *Ehrlichia* species from human, deer, and dog blood and mouse tissue samples (Dawson et al., 1991a,b; Lockhart et al., 1997; Paddock et al., 1997; Breitschwerdt et al., 1998; Ganta et al., 2002, 2004, 2007). Simple step-by-step protocols are described in this unit to aid in isolating *Ehrlichia* species from clinically suspected patient samples.

Accurate diagnosis aids considerably in defining treatment regimes for infections with *Ehrlichia* species in humans or animals. In this unit, various protocols for DNA and RNA isolation and molecular methods for rapid diagnosis are presented. Various laboratories have described similar methods (Felek et al., 2001; Sirigireddy and Ganta, 2005) and the methods most suitable for pathogen diagnosis are adapted and described in this section.

Critical Parameters

Isolation and cultivation of Ehrlichia from infected animal samples

Isolating *Ehrlichia* from human and/or animal blood or tissue samples can be very challenging; thus one should carefully follow all the steps for culture isolation as outlined in this unit.

The volume of blood used is important for culture isolation. Consider using a large volume of blood sample (up to 30 ml) for culture recovery experiments, particularly when a blood sample is obtained from an animal suspected to be having a chronic phase of infection.

If an animal is under antibiotic treatment, the probability of culture recovery of *Ehrlichia* significantly decreases.

Culture must be maintained by following strict sterile culture techniques to avoid bacterial and fungal contamination. Cultures should be monitored for up to 10 weeks before considering a sample to be negative.

Nucleic acid isolation and molecular detection methods

It is important to prevent the introduction of previously amplified products into PCR/RT-PCR reactions to avoid false positives.

It is critical to have two independent laboratories to physically separate the pre-PCR assembly (which includes nucleic acid

Table 3A.3.2 Troubleshooting Guide for *Ehrlichia* Isolation and Its Molecular Application[a]

Problem	Possible cause	Solution
No *Ehrlichia*-positive cells observed despite the identification of morulae-like structure in a blood smear	Blood or tissue samples stored too long before use or a sample may contain a significantly different strain, isolate, or species	Use fresh blood samples or confirm by molecular methods
Color of culture flask changed to yellow	Bacterial or fungal contamination	Discard flask, strictly follow sterile culture procedures when conducting culture experiments
Most of the host cells of an infected culture are lysed	Overgrowth of *Ehrlichia*	Add more healthy cells or re-infect a new flask containing a confluent monolayer of DH82 cells
Positive control DNA/RNA did not show positive	One or more ingredients of PCR/RT-PCR reaction mix are missing	Repeat the experiment and carefully check for proper assembly of reaction setup
Negative control gave a positive signal	One or more of the ingredients of master mix are contaminated with previously amplified products or genomic DNA or RNA templates	Carefully follow the protocols for PCR assembly and analysis as described

[a]For additional troubleshooting information related to culture methods, see Table 3A.1.1.

isolation and PCR reaction setup) from post-amplification analysis. Always include positive and negative controls for nucleic acid isolation and PCR setup. The same precautions should be followed when analyzing samples by RT-PCR methods.

Troubleshooting

Table 3A.3.2 presents some of the common problems associated with the protocols in this unit.

Anticipated Results

Isolating Ehrlichia from infected vertebrate host

If starting with a sufficient volume of fresh blood (which may range from 5 to 30 ml), then the *Ehrlichia* inclusions in macrophage cell culture are expected to be seen within ~7 days to 3 weeks. If the bacterial load is very low, detection of culture positives may take up to 6 to 10 weeks. After 10 weeks of culture monitoring, a sample may be considered negative for *Ehrlichia*.

Molecular methods

Both PCR and RT-PCR methods are extremely sensitive in detecting low levels of infection; however, RT-PCR is ~100 times more sensitive as the 16S rRNA target is present in hundreds of copies per cell. If a sample is positive for *Ehrlichia*, a predicted size amplicon is seen following resolution of PCR/RT-PCR products on an agarose gel. Similarly, positive signal is anticipated in the real-time RT-PCR assay. The results should be carefully interpreted in the content of the outcome for the reaction positive and negative controls. The reaction positive control must yield a positive result and the reaction negative control must yield a negative result before the outcomes of the test samples are judged. A test must be rejected if a negative control yields positive or a positive control yields negative.

Acknowledgments

This study was supported by the National Institutes of Health grants AI055052 and AI070908. The manuscript is published as Kansas Agricultural Experiment Station contribution no. 08-223-B.

Transfection of *Wolbachia pipientis* into *Drosophila* Embryos

Interest in *Wolbachia* has grown exponentially in recent years as increasing numbers of biologists discover symbionts in their experimental systems. Considering the major impact that *Wolbachia* can have on infected hosts, it can be expected that research interest will continue to grow. Recent surveys estimate *Wolbachia* infection rates in insects to range between 16% to 76% (Werren et al., 1995; Jeyaprakash and Hoy, 2000; Werren and Windsor, 2000). Given that there are currently >750,000 known insect species globally (Wilson, 1993), extrapolation using a conservative estimate of 10% infected host species gives 75,000 *Wolbachia*-infected insect species, making *Wolbachia* one of the most abundant and widespread groups of parasitic bacteria (Werren et al., 1995). In addition to infections in insects, *Wolbachia* have also been observed in mites (Johanowicz and Hoy, 1995; Breeuwer, 1997), isopods (Rousset et al., 1992), nematodes (Bandi et al., 1998), and a species of spider (Oh et al., 2000).

Wolbachia exhibit multiple mechanisms for manipulating host reproduction to increase the vertical transmission of infections. Reproductive manipulations include cytoplasmic incompatibility (CI; O'Neill et al., 1992), parthenogenesis (*Wolbachia* induction of asexual reproduction; Stouthamer et al., 1993), the reversal of genetic sex-determination (Rousset et al., 1992), and male killing (Hurst et al., 1999). *Wolbachia* are inherited exclusively through females (i.e., maternal inheritance). Thus, the reproductive manipulations serve to bias females in the host population toward infected individuals (Dobson, 2003). The mechanisms responsible for reproductive manipulations act to alter early embryonic events and development and are therefore of interest as tools for studying these processes (Stouthamer and Kazmer, 1994; Reed and Werren, 1995; Dobson and Tanouye, 1996; Lassy and Karr, 1996; Callaini et al., 1997; Dobson and Tanouye, 1998; Presgraves, 2000). *Wolbachia* reproductive manipulations are also of interest for their role in genetic conflict, host reproductive isolation, and speciation (Laven, 1967a; Breeuwer and Werren, 1990; Werren, 1998; Shoemaker et al., 1999). There is additional applied interest in the potential use of *Wolbachia* to manipulate field populations of medically and economically important invertebrates (Laven, 1967b; Curtis and Sinkins, 1998; Sinkins and O'Neill, 2000; Taylor et al., 2000).

The transfer of *Wolbachia* infection (transfection) is used both for basic research examining the *Wolbachia*-host interaction and for applied strategies that use *Wolbachia* infections to affect harmful insect populations. For example, the interspecific transfer of *Wolbachia* between *Drosophila simulans* and *Drosophila melanogaster* has been used to demonstrate host effects on *Wolbachia* infection density and CI (Boyle et al., 1993; Riegler et al., 2004). Applied population replacement and population suppression strategies (Dobson et al., 2002; Dobson, 2003b) require the ability to generate novel *Wolbachia*-host associations. This unit describes a method for *Wolbachia* transfection via the microinjection of *Drosophila* embryos. As demonstrated by recent work, the methods described here for *Drosophila* can be modified and adapted for transfection of additional insect species (Fuji et al., 2001; Kang et al., 2003; Xi et al., 2005, 2006; Zabalou et al., 2004).

CAUTION: Wolbachia pipientis is a Biosafety Level 1 (BSL-1) organism. Such organisms are not known to consistently cause disease in healthy adult humans, and are of minimal potential hazard to laboratory personnel and the environment. Standard microbiological practices should be followed when working with these organisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

MICROINJECTION OF *DROSOPHILA* EMBRYOS

The technique for *Wolbachia* microinjection is based upon that used to introduce DNA into developing *Drosophila melanogaster* embryos (Karess, 1985). The Drosophila embryo is bounded by two membranes at oviposition: an outer chorion and inner vitelline membrane. The chorion may be removed mechanically by gently rolling the embryo on double-sided tape or by submerging briefly in a bleach solution. Once the chorion is removed, embryos are aligned on a tape-covered glass slide and desiccated to minimize yolk leakage from the embryo upon puncturing the vitelline membrane with the microinjection needle. Following desiccation, embryos are covered with oil for injection. Injection is accomplished using a micromanipulator that holds a finely drawn glass needle attached to a microinjector. Although the injection process can be accomplished by a single person, it can be much less frustrating and more efficient when done by a team of two people: one collecting and preparing embryos and another microinjecting. Following injection, *Drosophila* embryos are allowed to develop on the slide. Hatching larvae are immediately transferred to *Drosophila* media. Since the *Wolbachia* infection status of injected individuals is unknown, *Drosophila* females are isolated as virgins and mated to *Wolbachia* uninfected males to assure that CI does not occur. *Wolbachia* is transmitted exclusively through females. Thus, males resulting from microinjection are not useful for establishing transfected lines and may be discarded.

Materials

Wolbachia-infected and -uninfected *Drosophila* embryos (Support Protocol 1)
Apple juice agar plates (Support Protocol 2; Fig. 3A.4.1)
50% bleach solution (Clorox bleach recommended)
Halocarbon oil 700 (Sigma)
Uninfected *Drosophila* males

Camel hair paint brush (Fig. 3A.4.1) or alternate preferred tool for manipulating embryos
Fine mesh for embryo collection and washing
Filter paper, damp
Double-sided tape (e.g., Scotch, #666)
Glass slides
Microinjector, microinjection needles (Support Protocol 3; Fig. 3A.4.2D,E) and micromanipulator
Dissecting microscope
Compound microscope with movable stage

Prepare Drosophila embryos

1. After female flies oviposit in the yeast paste coating of apple juice agar plates (Fig. 3A.4.1), add 2 µl water and agitate using a soft paint brush to suspend embryos.

   Embryos that are inserted into the agar are relatively difficult to remove and may be ignored since their extraction is not an efficient use of time.

   A fine camel hair brush works well, but brush preference varies between users. Thus, several brush types may be purchased and tested. Metal probes are also useful tools for manipulating embryos.

2. Filter embryos suspended in the yeast through mesh and rinse thoroughly with water to remove yeast.

   Figure 3A.4.1 shows an inexpensive design for embryo collection.

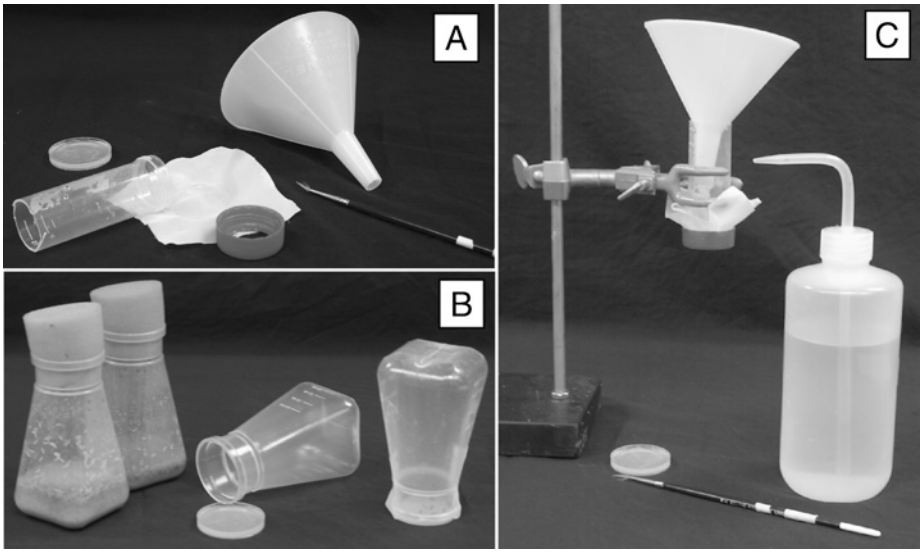

Figure 3A.4.1 Tools for embryo collection. (**A**) Brush for egg manipulation, apple juice plate, funnel, and disassembled mesh sieve. (**B**) *Drosophila* media bottles, a disassembled egg collection chamber, and an assembled egg collection chamber. (**C**) Assembled mesh sieve with water bottle and brush for suspending embryos off the apple juice plates.

3. Dechorionate embryos by submerging briefly in a 50% bleach solution.

   For the authors, 2 min in ~100 ml of 50% bleach is sufficient for dechorionating >90% of embryos. However, results can vary depending upon the bleach used and water quality. Thus, the correct amount of time for dechorionation may need to be determined empirically.

   Care should be taken in the selection of bleach. Many modern brands include fragrances or acids that can significantly reduce embryo survivorship. The label should be examined carefully.

4. Rinse embryos thoroughly with copious amount of distilled water.

5. Use a clean wet brush (or alternate preferred tool) to transfer embryos from the mesh (Fig. 3A.4.2A) onto damp filter paper.

   The filter paper should be saturated but without pools of water. A useful technique is to place the filter paper on a wet sponge.

6. Align embryos on a piece of apple juice agar (Fig. 3A.4.2B) using a wet brush or another preferred tool.

   The anterior of embryos may be recognized by its tapering end and the projecting point of the micropyle (site of sperm entry). Embryos should be oriented in the same anterior/posterior direction, touching laterally and flush along the posterior axis (Fig. 3A.4.2C). Groups of ~30 embryos work well.

7. Place a piece of double-sided tape along the edge of a clean glass slide and invert over the row of embryos on agar. Slowly, lower the tape into contact with the embryos, such that the embryos adhere to the tape.

   Note that the tape may be toxic to embryos. The suggested brand was observed to work well with Drosophila embryos. If it cannot be obtained, alternate brands should be tested empirically for toxicity effects.

8. Lift the tape carefully from the slide so as not to damage the embryos and replace onto the center of the same slide, such that the tape no longer overhangs the slide.

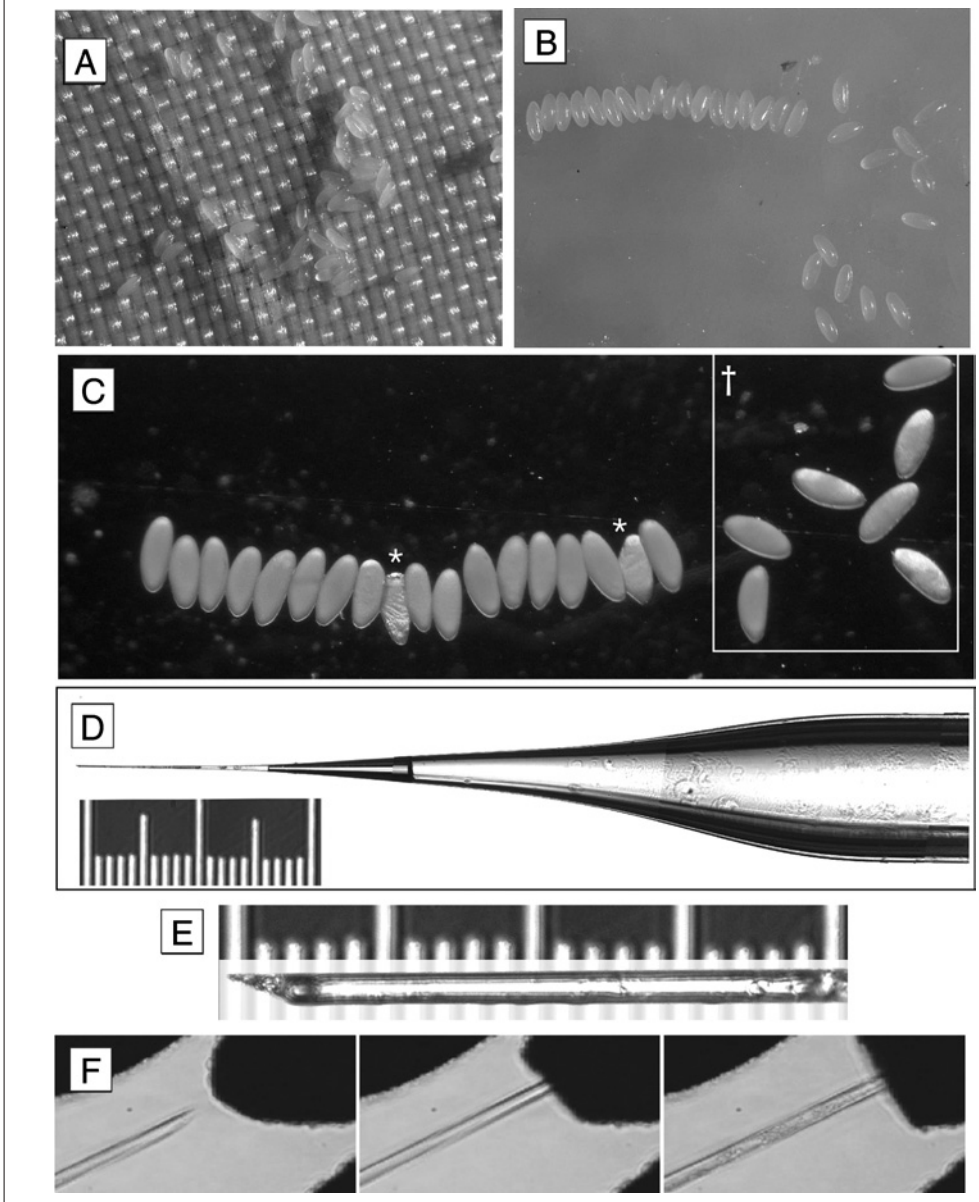

Figure 3A.4.2 Dechorionated embryos on mesh (**A**) are transferred and aligned on agar (**B**). (**C**) Aligned embryos on tape under oil. Note that some embryos are too old (marked with asterisk) or are oriented in the incorrect direction (within box marked with a cross). The latter would be destroyed prior to microinjection. (**D**) Microinjection needle with (**E**) detail of the needle tip. (**F**) A sequence of penetrating and injecting an embryo. The smallest increment of the scale shown in (D) and (E) is 10 μm.

9. Prepare uninfected embryos for injection by desiccating. Do not dessicate donor embryos, which will be used as a source of *Wolbachia*-infected cytoplasm.

   Desiccation is an important step: over-desiccation will reduce survivorship while under-desiccation will result in embryo leaking upon microinjection. As each laboratory differs in its conditions, the desiccation time must be determined empirically for each location. Slides with embryo groups can be desiccated for varying lengths of time and then microinjected. The appropriate time will be based upon observations during injection (e.g., leaking) and observed survivorship. While embryos may be desiccated in ambient room conditions, room conditions may change daily in some locations. Thus, a desiccator may be used to promote uniformity (see http://en.wikipedia.org/wiki/Desiccator for additional information).

10. Cover the embryos with water-saturated halocarbon oil (Fig. 3A.4.2C) and store at 18° to 22°C.

Transfer of cytoplasm from donor to recipient embryos

Temperature during injections is important. The ideal range is 18° to 22°C and should not exceed 25°C. Low temperature slows embryo development and improves survivorship by increasing cytoplasm viscosity.

11. Under a compound microscope, orient the needle such that it is submerged in the oil and parallel with the embryo, with the needle tip pointing at the center of the embryo posterior (Fig. 3A.4.2F).

    To determine the height of the needle relative to the embryo, the needle may be gently pressed against the embryo posterior.

12. Insert the needle into the posterior of a donor embryo and withdraw ~10% of the yolk. Withdraw needle and repeat with an adjacent embryo. Repeat with ten or more embryos to obtain sufficient *Wolbachia*-infected cytoplasm for injections.

    In this step and subsequently, it is important not to expose the needle to air for extended periods, which will allow yolk at the needle tip to dry and clog the needle. Instead, keep the needle tip submerged in oil.

13. Exchange slides, replacing infected donor embryos with uninfected recipient embryos. Orient the needle as described in step 11. Prepare for embryo injection.

    Embryo injection (step 14) should be an abrupt event (Fig. 3A.4.2F). The needle should be quickly plunged into the embryo. If properly desiccated, the embryo should dimple only slightly during injection. Effort should be made to prevent the needle tip from going too deep (>20% of the embryo length).

    If the embryo has not been sufficiently desiccated, cytoplasm can leak from the embryo. Often the leaking cytoplasm can be observed flowing into the needle. If the latter occurs, the needle should be withdrawn from the embryo, and the recipient embryo cytoplasm should be expelled from the needle before proceeding. The cytoplasm may be expelled into the oil away from embryos.

14. Use the microinjector to pump cytoplasm from the needle into the embryo. Withdraw the needle slowly as the embryo is filled.

    The embryo should visibly swell during the injection.

    The pump technique depends upon the type of microinjector. Different needles will also vary in the amount of pressure required. Even using the same needle, the pressure required will change depending upon the amount of cytoplasm remaining in the needle and periodic clogging. Thus, the pressure must be constantly readjusted during injection. A useful strategy permitted by some microinjectors that allow the user to set both the pressure and time of injections is to set the time for a period that is shorter than needed. In this way, the user can adjust for embryo variation by simply adjusting the number of pumps into the recipient embryo.

    Needle clogging is a frequent problem during injections. Many microinjectors include a clearing function that allows for a brief pulse of high pressure to clear clogs. Clearing of clogs should be done away from embryos in the oil.

15. Once finished injecting embryos on the slide, transfer to a dissecting microscope and use a probe to crush or tease away and remove uninjected embryos to simplify the downstream screening of injected lines.

    Killing of embryos should not be done with the injection needle due to the risk of damaging the needle. Instead, while injecting, mentally keep track of the embryos to be killed by their position in the line.

'Problem embryos' occur commonly for several reasons including: (1) embryo overdeveloped, attempting to inject an embryo after cell formation increases the risk of damaging the needle; (2) embryos not attached firmly to tape and move away from the needle when try to inject.

Post-injection care of recipient embryos

16. Maintain glass slides with injected embryos at ~25°C and >90% relative humidity.

    This may be accomplished by placing embryos in an incubator within a sealed Tupperware container with wet paper towels.

17. Observe slides frequently (multiple times per day) for larvae. When observed, gently remove larvae from the oil and transfer onto *Drosophila* media (e.g., Jazz Mix; Applied Scientific).

    If allowed sufficient time, larvae will crawl out of the oil to become lost and die.

    The surface of fly media will dry and develop a skin that is difficult for a single larva to penetrate, resulting in mortality of transferred larvae. Thus, media quality should be examined. The surface of media can be scratched prior to adding larvae and the larvae placed into the resulting groove. Larvae may be gently manipulated on the media to reduce the amount of oil on the larvae.

18. Once pupae are observed (~6 days), monitor frequently to obtain virgin females.

    Injected individuals are often not observed again until pupation, when they migrate to the surface and commonly attach to the container wall.

    Females will not mate for ~8 hr post-eclosion.

    Females and males should be removed when observed and transferred individually into vials with media. The rationale for preventing injected females and males from mating is that their Wolbachia-infection status is unknown.

19. Mate injected females (G_0) with males known to be *Wolbachia* uninfected and then place individually in vials to oviposit. Once sufficient embryos (G_1) are obtained, sacrifice the female and perform PCR to detect *Wolbachia* infection.

    Based upon prior work (Xi and Dobson, 2005), G_0 females that are negative via PCR assay are unlikely to result in transfected lines and may be discarded with their progeny. G_0 females that are positive via PCR assay do not necessarily result in transfected lines. Thus, PCR assays of the G_1 progeny are required for the latter. Isofemale lines with G_1 PCR positive individuals were observed to be stably infected.

    Appropriate PCR primers will depend upon the Wolbachia infection. However, PCR with the general wsp primers (Zhou et al., 1998) have been used by the authors for the general detection of the presence/absence of infections.

SUPPORT PROTOCOL 1

COLLECTION OF *DROSOPHILA* EMBRYOS

An important factor in microinjection is obtaining a sufficient quantity of *Drosophila* embryos that are <1 hr post-oviposition. The requirement of early embryos necessitates a repeated cycle of embryo collection followed by injection. The need for repeated collections of large numbers of young embryos requires access to groups of *Drosophila* females that can oviposit quickly and frequently upon being introduced to the oviposition medium (apple juice plates; Support Protocol 2).

The status of *Drosophila* females (e.g., age, nutrition) is important for obtaining sufficient quantities of early embryos. Protocols for general *Drosophila* care have been previously described in detail (Roberts, 1998). *Drosophila* females begin producing embryos two days after eclosion and can produce up to 100 embryos/female/day for two weeks if treated properly. Females oviposit best in the dark and produce the greatest number of

embryos in the late afternoon or evening. Thus, it may be advantageous to maintain the flies on a shifted light-dark cycle.

To maximize embryo production, it is advantageous to know the age of flies used to generate embryos. Therefore, cohorts of similarly aged flies can be generated by emptying adults from rearing bottles that contain many immatures and recording the date. Adults that are subsequently removed from the same bottles fall within a known time period.

A variety of designs for embryo collecting apparati have been described (Wieschaus and Nüsslein-Volhard, 1986; Santamaria, 1987). An inexpensive version consists of polypropylene *Drosophila* media bottles (AS-355, Fisher Scientific) inverted over apple juice plates with yeast paste (Fig. 3A.4.1B).

Approximately 2 days prior to embryo collection, adults are transferred from culture bottles with fly food media such as Jazz Mix from Applied Scientific ("media bottles"; Fig. 3A.4.1B) into embryo collection chambers to become accustomed to the environment. The flies may remain in the collection chambers for more than a week for continued collections, but the apple juice plates must be exchanged at least once per day. Therefore, if embryo collections are not to be repeated for several days, it may be convenient to return the flies into media bottles when finished with embryo collection.

When collecting embryos, disturbing the flies can reduce oviposition. Therefore, to reduce disturbances, they can be covered with a black cloth. A notation system may be used to identify unproductive collection chambers, which can be replaced with groups of females that are more productive. Ten productive collection chambers should yield a sufficient number of embryos for a two person team. However, if collection is to continue for several hours, additional chambers should be made ready to substitute for exhausted females.

PREPARATION OF APPLE JUICE PLATES

SUPPORT PROTOCOL 2

Apple juice plates are used for collecting embryos from infected and uninfected females (see Support Protocol 1). A thin layer of yeast paste over the agar acts as an oviposition stimulant to the females. If the plates are prepared correctly, a majority of the eggs will be inserted into the yeast paste, not the agar.

Materials

Agar
Sucrose
Apple juice
10% Tegosept (optional, Fisher Scientific)
Live baker's yeast
35 × 10–mm petri plates (BD Falcon)

1. Dissolve 12 g agar and 12.5 g sucrose in 375 ml distilled water by stirring with heat. Stir fast enough to maintain the suspension but do not create bubbles and do not allow to boil over.
2. Once dissolved, remove from heat and continue to stir until the temperature drops to 80°C.
3. While stirring, add 125 ml apple juice followed by 3.5 ml of 10% Tegosept.

   Tegosept (an antifungal agent) is not required, but facilitates long-term storage of plates.

4. Immediately divide into aliquots in small petri plates (35 × 10–mm; BD Falcon; see Fig. 3A.4.1). Add at least enough to cover the bottom of the plate.

   Plating should be done quickly, before the solution solidifies.

   The petri plates work well with the embryo collection chamber that is described above.

5. After solidifying, store the plates at 4°C in a sealed container to prevent desiccation.

6. Immediately prior to use, lightly coat the agar with a yeast paste made by mixing live yeast with distilled water. Spread the paste using a finger or desired tool.

   The consistency of the paste should be similar to that of peanut butter. If plates have been stored at 4°C, they should be allowed to warm prior to use. The yeast acts as an oviposition stimulant for female Drosophila.

SUPPORT PROTOCOL 3

PREPARATION OF MICROINJECTION NEEDLES

The quality of microinjection needles represents a critical consideration for successful transfection. The needle bore must have a diameter large enough to allow the uptake and ejection of the cytoplasm without clogging, however, not so large as to be lethal to the embryos. The parameters below have been used to generate needles appropriate for *Drosophila* transfection.

Materials

Micropipet puller (Sutter Instrument Co., P-87)
Borosilicate glass capillaries (World Precision Instruments, TW100F-4)
Micropipet beveller (Sutter Instrument Co., BV-10)

NOTE: Microinjection needles may be purchased commercially (e.g., Eppendorf). The author does not have experience with purchased needles. Alternatively, needles may be prepared if appropriate equipment is available. The program described here should serve as a starting point only. The parameters will require adjustment depending upon the Puller model, ambient conditions, and the age of the heating element.

1. Using an automated micropipet puller, pull needles to be used for microinjection (Fig. 3A.4.2D,E) from capillaries using the two-step program in Table 3A.4.1.

	Heat	Pull	Velocity	Time	Pressure
Step 1	405	0	10	150	0
Step 2	370	150	40	50	300

2. Bevel needle tips to a 20° angle using the micropipet beveller (Fig. 3A.4.2E).

COMMENTARY

Background Information

Wolbachia is a genus of obligate intracellular alpha proteobacteria represented by the type species *Wolbachia pipientis* (Dumler et al., 2001). *Wolbachia* commonly reside within cytoplasmic vacuoles of arthropods and helminths (Casiraghi et al., 2004; Werren and Windsor, 2000) and are maternally transmitted from mothers to offspring through the embryonic cytoplasm. *Wolbachia* are able to induce a diverse range of phenotypes in their invertebrate hosts, ranging from classical mutualism to reproductive parasitism. Examples of the latter include male killing, host feminization, parthenogenesis, and cytoplasmic incompatibility (reviewed in Dobson, 2003a). Current *Wolbachia* research foci include examining the impact of *Wolbachia* infection on host evolution, characterizing the mechanisms by which *Wolbachia* manipulate invertebrate hosts, and developing applied strategies that employ *Wolbachia* for pest and disease control. Here, a

protocol for the transfer of *Wolbachia* infections (transfection) via embryonic microinjection is described.

Critical Parameters and Troubleshooting

An ability to collect sufficient quantity and appropriate quality of *Drosophila* embryos should be a primary consideration. It is advisable to practice embryo collection, dechorionation, and alignment on tape without the additional steps. Once an acceptable level of survivorship is attained, the additional steps of desiccation and injection can be introduced.

The authors have found the use of a video camera to be helpful in learning to microinject. Embryo injections can be recorded, noting the video time position relative to the slide number. This allows the person injecting to review the injection process once survivorship is known. Comparing lethal and nonlethal injections will help the person injecting to improve his or her technique.

Anticipated Results

Once appropriate technique is developed, >30% hatch rate can be obtained, with ~50% of larvae reaching adulthood (Xi and Dobson, 2005). Transferring from *Wolbachia*-infected *Drosophila simulans* to aposymbiotic *Drosophila simulans*, >60% infection can be detected by PCR of injected individuals surviving to adult (G_0). However, a subset of the G_0 females stably transmit the infection to offspring (Xi and Dobson, 2005).

Time Considerations

With a team of two people and assuming that the flies are laying sufficient eggs, >500 eggs may be injected in a day. Screening slides for survivorship and transferring survivors requires only a few minutes and should be done multiple times per day until the slides are discarded. Once larvae are transferred to media bottles, the development of injected flies may be significantly reduced relative to uninjected flies. Thus, media bottles should be observed for >2 weeks at 27°C.

Laboratory Maintenance of *Brucella abortus*

This unit presents simple methods for growth and maintenance of *Brucella abortus*. *B. abortus* grows more slowly than *E. coli* K-12; therefore, experiments with this organism require advance planning to have it ready and in the correct growth phase. Since brucellosis is one of the most frequent laboratory-acquired infections, avoidance of infection requires careful microbiological technique. All work with *B. abortus* must be performed at Biosafety Level 3 (BSL-3), and experiments with *B. abortus* cultures are performed in a Class II biosafety cabinet (BSC; see *UNIT 1A.1*). In the U.S., laboratories working with this bacterium are required to seek prior approval from the Select Agent Program of either the Department of Agriculture (USDA) or the Center for Disease Control (CDC; see Internet Resources), and individual laboratory personnel must receive security clearance from the CDC's Select Agent Program to access cultures of *B. abortus*. Other countries may have similar regulations. Be sure to check with the appropriate authorities before starting work with *Brucella* (e.g., see *APPENDIX 1B*). Receipt of *Brucella* cultures from interstate sources is also controlled and requires a separate permit from the USDA for transfer of organisms that may be harmful to livestock or poultry.

Basic Protocol 1 describes how to grow *B. abortus* in liquid culture. Many *Brucella* genes have been shown to be regulated by growth phase; therefore, particular attention is given to growth phases to allow reproducibility between experiments. Basic Protocol 2 describes how to generate laboratory stocks of *B. abortus* for long-term frozen storage and discusses regulations pertaining to maintaining a *Brucella* strain collection. The Alternate Protocol describes how to generate stocks for long-term storage by lyophilization. Basic Protocol 3 gives a method for detecting undesirable rough colonies, which result from spontaneous variants appearing after extended in vitro passages without selection in an animal host.

CAUTION: B. abortus is a BSL-3 pathogen. Follow all appropriate guidelines for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

NOTE: B. abortus has been classified as a Select Agent by the United States Government. Refer to the CDC's Select Agent Program for more information (*http://www.cdc.gov/od/sap*). Also refer to *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*).

GROWTH OF *B. ABORTUS* IN LIQUID CULTURE

BASIC PROTOCOL 1

Under the growth conditions specified in this protocol, *B. abortus* 2308 will be in logarithmic growth phase between 8 and 20 hr, in late log/early stationary phase between 20 and 24 hr, and in stationary phase after 24 hr (see Fig. 3B.1.1). If a different *B. abortus* strain is used, then a growth curve should be prepared for each individual strain used.

Materials

B. abortus strain
Agar plates:
- Tryptic soy agar (TSA) plates (see recipe)
- TSA blood agar plates (see recipe)
- *Brucella* agar plates (e.g., BBL, Oxoid, EMD), prepare according to manufacturer's instructions
- Potato infusion agar plates (PIA; see recipe)

Tryptic soy broth (TSB; see recipe)
70% (v/v) ethanol in a spray bottle

Contributed by Yao-Hui Sun, Andreas B. den Hartigh, Renée M. Tsolis, and Thomas A. Ficht
Current Protocols in Microbiology (2005) 3B.1.1-3B.1.11

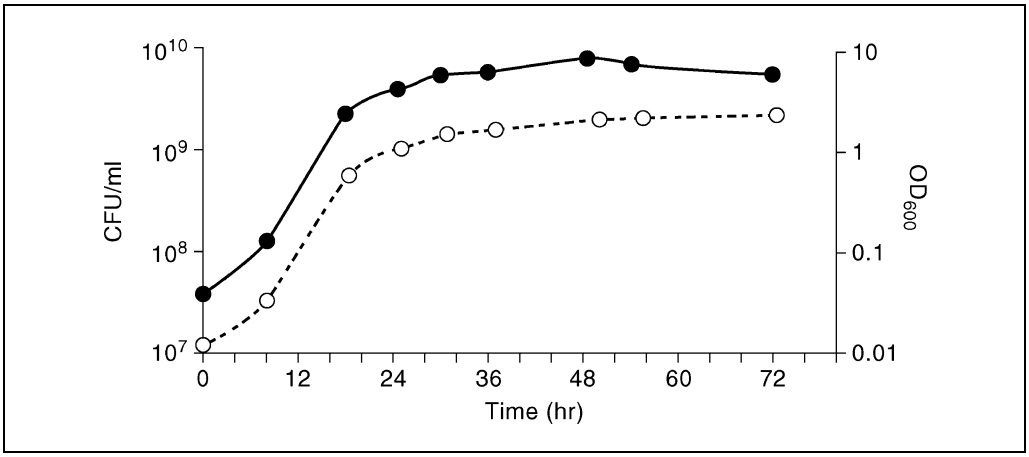

Figure 3B.1.1 Growth of *Brucella abortus* 2308 in tryptic soy broth. Solid circles, CFU/ml; empty circles OD_{600}.

10% (v/v) bleach or 1% (w/v) Virkon S (Dupont) in a spray bottle
Peptone saline maintenance medium (see recipe)
15- and 50-ml disposable polypropylene centrifuge tubes (e.g., Falcon or Sarstedt), sterile
1-µl inoculating loops
10-mm, screw-topped, glass tubes
Closed container (e.g., large plastic box with lid)
Spectrophotometer (e.g., Spectronic 20)
1-liter polypropylene straight-sided jar with screw top (e.g., Nalgene, 2118-0032)
Styrofoam tube racks from 50-ml conical tube package
Shaking incubator

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

1. In a Class II BSC, streak an agar plate with the *B. abortus* strain of interest and incubate 3 to 4 days.

   Colonies will be colorless and dombed (convex), and will reach 1 to 2 mm in diameter. B. abortus is nonhemolytic on TSA blood agar plates. Potato infusion agar (PIA), Brucella agar, or tryptic soy agar (TSA) can also be used, but B. abortus will grow more slowly on TSA.

   Most field isolates of Brucella require CO_2 for growth, while some laboratory strains are CO_2-independent; therefore, the growth requirements for each individual strain should be tested.

2. Aliquot 5 ml sterile tryptic soy broth (TSB) to a sterile, disposable, 15-ml polypropylene centrifuge tube

3. Using a 1-µl inoculating loop, inoculate the tube with a loopful of bacteria from the plate. Close the tube securely, and vortex to suspend the bacteria.

4. To measure the optical density, add 4 ml TSB into a 10-mm, screw-capped, glass tube that will fit into a Spectronic 20 spectrophotometer. Add 5 ml of TSB to an empty tube as a blank for the spectrophotometer. Pipet 1 ml of the *B. abortus* suspension into the tube with 4 ml TSB (1:5 dilution), close the cap securely, and vortex to mix.

   CAUTION: *All work with open B. abortus cultures must be performed within a Class II BSC (see UNIT 1A.1).*

The authors recommend use of a Spectronic 20 spectrophotometer with holder for 10-mm screw-capped glass cuvettes, or a Klett colorimeter (fitted with a 660-nm filter), which will also hold the screw-capped glass tubes. The advantage of these instruments is that the cuvettes can be tightly closed, allowing the instrument to be located outside the BSC. However, any other spectrophotometer that uses plastic cuvettes without lids can also be used within the BSC. This protocol specifies the Spectronic 20, but can be modified to fit another spectrophotometer by scaling the volumes up or down to fit the capacity of the cuvettes used. The Klett colorimeter uses arbitrary units (Klett units) to measure culture density, so a growth curve similar to the one shown in Figure 3B.1.1 can be established for this instrument using the Klett meter.

5. Place the dilution tubes into a rack. Spray the outside of the tubes and the rack with 70% ethanol and place them into a second, closed container (e.g., a large plastic box with lid) for transport to the spectrophotometer.

   CAUTION: *If there has been any leakage or spillage of bacteria on the outside of the tubes, spray them first with 10% bleach or 1% Virkon S, then with 70% ethanol, to decontaminate them.*

6. Wipe the 70% ethanol off the surface of the tubes and measure the optical density at 600 nm (OD_{600}) against the blank tube containing 5 ml TSB. To be accurate, the OD_{600} reading must be between 0.1 and 0.4; if the OD_{600} is outside this range, make a second dilution of the original suspension from step 3 and repeat the OD_{600} measurement.

   While the screw-capped tubes require a large (5-ml) sample volume, compared to plastic cuvettes, they have the advantage that the sample is contained in a closed tube, which allows the spectrophotometer to be located outside the BSC, saving valuable workspace.

7. Calculate the OD_{600} by multiplying the measured OD_{600} by the dilution factor (e.g., measured OD_{600} of 0.2 × 1:5 dilution = OD_{600} of 1.0 in the original suspension).

   An OD_{600} of 1.0 is equivalent to 2 to 4 × 10^9 CFU/ml of B. abortus.

8. Calculate the dilution factor of the original culture needed to generate a culture with an OD_{600} of 0.01, and dilute accordingly into a sterile, disposable 50-ml polypropylene centrifuge tube containing 5 ml TSB.

9. Place the tubes in a 1-liter polypropylene straight-sided jar that has been fitted with styrofoam tube racks (see Fig. 3B.1.2) and close. Place the jar in a shaking incubator and incubate overnight (16 hr) with shaking at 180 rpm.

10. Remove the jar from the shaker and open it in the BSC.

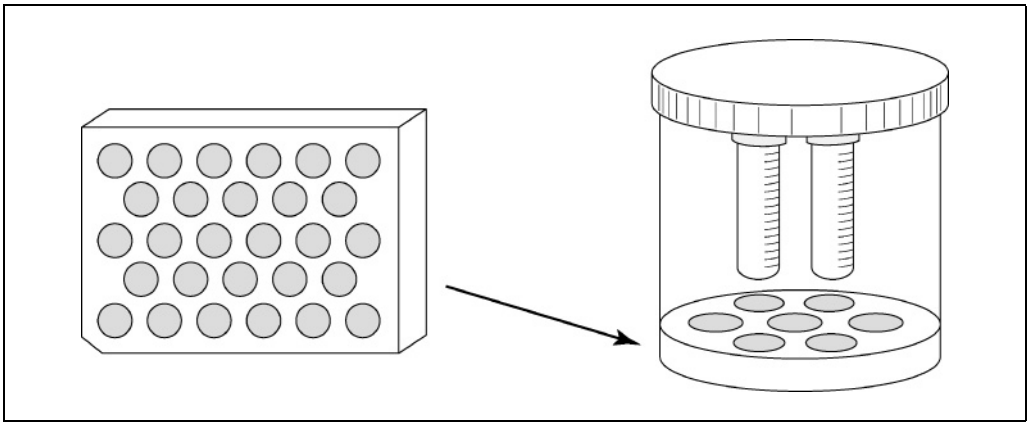

Figure 3B.1.2 Double containment jar for incubating *Brucella* cultures. To construct, cut the styrofoam package insert from the 50-ml conical tubes to fit a 1000-ml straight-sided jar (e.g., Nalgene) and insert. This will secure the 50-ml conical tubes during incubation.

11a. *For immediate use:* Dilute the culture to the required concentration for the application.

11b. *For short-term storage:* Place the culture on ice for 1 to 2 hr.

Liquid cultures of B. abortus will rapidly lose viability if stored at 4°C. Viability can be improved by centrifuging the cells 20 min at 5000 × g, room temperature, and resuspending the pellet in peptone saline maintenance medium before storage.

11c. *For long-term storage:* Proceed to Basic Protocol 2 or the Alternate Protocol.

BASIC PROTOCOL 2

MAINTENANCE OF LABORATORY STOCKS OF *BRUCELLA* BY FREEZING

A consideration for strain collections of *Brucella* maintained in U.S. laboratories is that the Select Agent regulations require close control of strain inventories. Access to the strain collection should be restricted to personnel who have been approved to work with *Brucella*. This can be achieved by locking the freezer, keeping the freezer in a secure location, or a combination of these measures. Note that other countries may have similar regulations. Be sure to check with the proper authorities (e.g., see *APPENDIX 1B*).

Each time a stock is removed from the strain collection, it should be documented in the inventory whether the strain has been destroyed or returned to the freezer. The strain inventory should be checked at regular intervals to ensure that all stocks in the collection are accounted for. The results of the inventory check should be recorded in the inventory documents.

The procedure for long-term storage of *Brucella* cultures at −80°C is similar to that used for many bacterial strains. Stocks prepared in this manner should retain viability for many years. For laboratories without access to a −80°C freezer, a different protocol for preserving stocks by lyophilization is given (see Alternate Protocol).

Materials

B. abortus strain to be stored
TSA blood agar plates (see recipe)
TSB/50% (v/v) glycerol (see recipe)
15-ml disposable polypropylene centrifuge tubes, sterile
1.5-ml freezer vials

1. In a Class II BSC, streak the *Brucella* strain to be stored onto a TSA blood agar plate and incubate 3 to 4 days at 37°C, 5% CO_2, until colonies are visible.

   Colonies will be colorless and domed (convex), and will reach 1 to 2 mm in diameter. B. abortus is nonhemolytic on TSA-blood agar plates. PIA, Brucella agar, or TSA can also be used, but B. abortus will grow more slowly on TSA.

   Not all Brucella strains require CO_2 for growth, so the growth requirements for each individual strain should be tested.

2. Using an inoculating loop, scrape up as many individual colonies as possible from the plate and suspend in 1 ml TSB in a sterile, disposable, 15-ml polypropylene centrifuge tube. Close the tube securely and vortex to suspend the bacteria.

3. Add 1 ml of TSB/50% glycerol to the tube, close the tube securely, and vortex to mix.

4. Aliquot 1 ml of the bacterial suspension to each of two freezer vials. Close the vials securely, spray the outside of the vials with 70% ethanol, and wipe off the ethanol with a paper towel before storing at −80°C.

In the absence of repeated freeze-thaw cycles, the freezer stocks should maintain viability indefinitely. For frequently used strains, it is a good policy to use one of the freezer vials as a working stock to inoculate cultures, as this vial may lose viability over time with repeated thawing and freezing due to removal from the freezer. The second vial should be held in reserve in case the working stock suffers said loss of viability.

Other methods of long-term storage, such as storage in liquid nitrogen or lyophilization (see Alternate Protocol), will also maintain viability of Brucella stocks; however, liquid nitrogen storage of vials has the disadvantage that the vials may explode on removal, creating infectious aerosols.

PRESERVATION OF *BRUCELLA* STOCKS BY LYOPHILIZATION

ALTERNATE PROTOCOL

Lyophilization is used for storage of *Brucella* vaccine stocks. Lyophilization in glass ampules has the disadvantage that it necessitates breaking the ampule, which is a risk to lab workers handling the lyophilized cultures. The handling of sharps, especially glass, should be minimized when working with Brucella, as sharp objects carry the risks of injury and infection. For laboratories without access to a −80°C freezer, a protocol for lyophilization of stocks in glass vials is described below. Lyophilized samples may be maintained at 4°C for up to 2 years without reduction in viability.

CAUTION: This protocol is not the best choice for preservation of virulent *Brucella* stocks, as it requires transport of loosely stoppered vials between the BSC and the lyophilizer. Extra respiratory protection should be used (e.g., a HEPA-filtered respirator) for this step to prevent infection in case of a spill.

Additional Materials *(also see Basic Protocol 2)*

Peptone saline maintenance medium (see recipe)
Bleach
Stabilizing medium (see recipe)

50-ml disposable, polypropylene centrifuge tubes, sterile
Centrifuge with an aerosol-proof rotor
Sterile 10-dram glass vials
Sterile rubber stoppers (autoclaved separately from vials)
Tray
Lyophilizer equipped with an internal stoppering device
Metal crimp closures

1. Grow confluent plates of the strain to be stored by spreading a few colonies from an agar plate or 10 to 50 μl from a frozen stock or liquid culture onto an agar plate in a Class II BSC. Incubate the plates up to 72 hr at 37°C, 5% CO_2, until colonies are visible.

   To avoid accumulation of rough mutants in the stock (see Basic Protocol 3), it is preferable to inoculate from a plate or from frozen stock.

2. Aliquot 10 ml peptone saline maintenance medium into 50-ml sterile, disposable polypropylene centrifuge tubes (one tube per plate).

3. Using an inoculating loop, scrape the confluent lawn gently from the surface of the agar plate and add to the peptone saline maintenance medium by wiping the bacteria onto the inner surface of the tube. Close the tube securely and suspend the material by vortexing.

4. Using an aerosol-proof rotor, pellet the cells 20 min at 5000 × *g*, room temperature. Once the centrifugation is complete, remove the rotor or buckets from the centrifuge and open inside the BSC to remove the tubes (in case of leakage during centrifugation).

CAUTION: *Be sure the tubes are balanced properly, as imbalance can lead to centrifuge accidents, resulting in aerosolization of Brucella.*

5. Carefully pipet off the supernatant and discard into a beaker containing 50 ml undiluted bleach. Resuspend each pellet in 10 ml peptone saline maintenance medium by vortexing.

6. Pellet the cells and resuspend in peptone saline maintenance medium a total of three times, using the same centrifugation conditions as in step 4.

7. After the third wash, resuspend cells in stabilizing medium at a concentration of 10^{10} CFU/ml.

   The concentration can be estimated by measuring in a spectrophotometer (see Basic Protocol, steps 4 to 8).

   The cell suspension may be stored up to 3 days at 4°C before lyophilizing.

8. Aliquot 1 ml of the bacterial suspension aseptically into sterile 10-dram glass vials. Set autoclaved stoppers loosely on top of the vials and place them onto a tray that will fit on a shelf inside the lyophilizer.

   CAUTION: *Use special care when transporting the loosely stoppered vials to the lyophilizer, as potential exists for spilling viable Brucella outside the BSC.*

9. Run the lyophilizer according to the manufacturer's instructions so that the final temperature does not exceed room temperature and the residual moisture content is 1% to 2%.

   The lyophilizer should be located inside the BSL-3 lab.

   The authors routinely employ a temperature range of between −20° and 0°C in the evaporating chamber and −50° to −60°C in the condensing chamber.

10. Use the freeze dryer's internal stoppering device to seal all of the vials at the end of the run and prior to returning the evaporation chamber to atmospheric pressure.

    Failure to properly seal the vials will result in condensation, resuspension of the bacteria, and reduction in viability.

11. Place metal crimp closures on the vials to prevent the rubber stoppers from being removed inadvertently.

12. Check viability of one sample vial by resuspending the contents in 1 ml peptone saline maintenance medium and performing ten-fold serial dilutions. Spread 0.1 ml of each dilution on a TSA plate and incubate for 3 to 4 days at 37°C, 5% CO_2, until individual colonies can be counted.

    Better than 99.9% recovery is expected. Vials may be stored at 4°C for up to 2 years without loss of viability.

BASIC PROTOCOL 3

DETECTION OF ROUGH *BRUCELLA* COLONIES BY CRYSTAL VIOLET STAINING

Brucella may be grown in liquid or on solid medium, but the preferred method for stock culture is growth on solid medium. Choice of media includes PIA, TSA, *Brucella* agar, or TSA blood agar plates. During growth in liquid medium *Brucella* mutants (rough mutants), lacking a complete lipopolysaccharide, may appear spontaneously and can outgrow the smooth wild-type bacteria. Stock cultures can have a large percentage of rough organisms if they have been passaged serially in vitro without selection in an animal host. This is of consequence because rough *Brucella* are attenuated for virulence in animal models of infection. The content of rough *Brucella* may be evaluated by staining

individual colonies on the surface of solid medium with crystal violet, which will stain rough but not smooth colonies.

Materials

B. abortus growing on solid medium
Crystal violet stock solution (see recipe)
Agar plate containing well-spaced individual colonies of *Brucella*
10% (v/v) bleach solution in a beaker

1. Dilute the crystal violet stock solution 1:40 with sterile distilled, deionized water.
2. In a Class II BSC, flood the surface of each plate with 1 ml of diluted crystal violet solution. Allow the plates to stand for 30 sec to 1 min.

   Allowing the liquid to stand too long on the plates may cause the colonies to float off the surface of the agar.
3. Carefully pipet off the crystal violet solution into a beaker of 10% bleach solution.
4. Examine the colonies on the plate. Restreak individual colonies for isolation to make a stock culture.

   Rough colonies are stained dark blue while smooth colonies resist staining and remain white.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Crystal violet stock solution

Dissolve 0.8 g ammonium oxalate in 90 ml water. Dissolve 2 g crystal violet in 20 ml absolute ethanol. Add the ammonium oxalate solution to the crystal violet solution and pass through a sterile filter. Store indefinitely at room temperature.

Peptone saline maintenance medium

1% (w/v) Bacto-Peptone
0.5% (w/v) NaCl
Autoclave and store indefinitely at room temperature

Potato infusion agar (PIA)

Dissolve 49 g dehydrated Bacto Potato Infusion Agar (PIA) powder (Difco) in 1 liter of 2% (v/v) glycerol in a 2-liter Erlenmeyer flask and boil with stirring to dissolve completely. Autoclave 20 min at 121°C with a magnetic stirring bar to sterilize. While the agar is in the autoclave, wipe down the surfaces of a clean bench or tissue culture hood with 70% ethanol. Cool the agar with stirring or by placing in a 50°C water bath. Add any required antibiotics and pour the plates on a clean bench or in a tissue culture hood. Pour 35 to 40 ml agar into each Petri dish to give a thicker plate, which will prevent it from drying out during incubation. Allow the plates to solidify 6 to 8 hr at room temperature, then incubate at 37°C overnight to identify contaminated plates. Remove the plates from the incubator, discard any contaminated plates containing colonies growing on the surface, and allow to cool to room temperature on the bench before storing at 4°C. Store plates up to 1 month at 4°C.

If plates are moved directly from the incubator to the cold room, condensation will occur and the resulting liquid will increase the likelihood of contamination.

Each liter of agar will yield 25 to 30 plates.

Plates are normally opaque at room temperature.

Stabilizing medium

2.5% (w/v) Bacto Casitone (Difco)
5% (w/v) sucrose
1% (w/v) sodium glutamate
Sterilize by passing through a 0.2-μm filter unit
Store indefinitely at 4°C

Tryptic soy agar (TSA)

Dissolve the following in a 2-liter Erlenmeyer flask containing 1 liter H_2O:
15 g pancreatic digest of casein
5 g Bacto Soytone (Difco)
5 g NaCl
15 g agar

Leave the stir bar in the flask and autoclave 20 min at 121°C to sterilize. Prepare and preincubate the plates as described above for PIA (see recipe). Store up to 1 month at 4°C.

TSA is widely used in microbiology, and it may prove more economical to purchase the powdered prepared TSA from Difco or Oxoid than to prepare this medium from scratch.

Tryptic soy broth (TSB)

Dissolve the following in 1 liter H_2O:
17.0 g pancreatic digest of casein
3.0 g Bacto Soytone (Difco)
5.0 g NaCl
2.5 g K_2HPO_4
2.5 g glucose

Aliquot into bottles that can withstand autoclaving. Autoclave for 20 min to sterilize. Store up to 1 month at 4°C.

It is easier and relatively inexpensive to order powdered TSA from a commercial supplier such as Difco or Oxoid.

TSA blood agar plates

Prepare TSA (see recipe), cooling the agar to 50°C after autoclaving. Add 50 ml defibrinated sheep blood (e.g., BBL, Difco) per liter agar and stir to distribute. Add antibiotics as needed and prepare the plates as described above for PIA (see recipe). Store plates up to 1 month at 4°C.

TSA/5% (v/v) blood plates can be ordered relatively inexpensively from microbiology suppliers such as Becton Dickinson. However these plates contain less medium and are prone to drying out during the 3 to 4 day incubation period required to grow Brucella; therefore, it is advisable to incubate them in a humidified incubator.

TSB/50% (v/v) glycerol

Add 50 ml glycerol to 50 ml sterile TSB (see recipe) and stir to dissolve. Filter sterilize by passing through a 0.2-μm filter unit, and store indefinitely at room temperature.

COMMENTARY

Background Information

Brucella abortus is a small, gram-negative coccobacillus. The bacteria are nonmotile and do not form spores. Although many *Brucella* strains can be cultivated aerobically in a bacteriological incubator, some strains require 5% to 10% carbon dioxide for growth. For primary isolation of *Brucella* from clinical specimens, media should be incubated in a 5% to 10% carbon dioxide atmosphere; under these conditions bacteria may take up to 30 days to grow. However, laboratory strains of *B. abortus* will form visible colonies on solid media within 3 to 4 days. *B. abortus* colonies are colorless, 1 to 2 mm in diameter, and have a convex surface. They are nonhemolytic on blood agar. The six species of *Brucella* are designated *B. abortus*, *B. canis*, *B. melitensis*, *B. neotomae*, *B. ovis*, and *B. suis*. In addition, two new species, *B. pinnepediae* and *B. cetaceae*, have been proposed, based on molecular characterization of *Brucella* isolates from dolphins, porpoises, whales, and seals. While it has been proposed that the different *Brucella* species should be considered as biovars of a single species, *Brucella melitensis*, adoption of this proposal has met with resistance from the *Brucella* research community, which is seeking to maintain the species designations. Therefore, in the scientific literature, both the biovar and the species designations are currently in use. For a discussion of the controversy see Moreno et al. (2002).

B. abortus is a pathogen of cattle, in which it causes abortion late during gestation. In addition, *B. abortus* has been found in wildlife species in the U.S., including bison and elk. This has presented a challenge for wildlife management, particularly in areas of the United States such as Wyoming, as the seropositivity rates have been found to be close to 50% for bison and 28% for elk (for more information on this problem, see *http://wyagric.state.wy.us/relatedinfo/wybrucellosisinfo.htm*). Based on these surveillance results, there is some concern about transmission between these wildlife species and cattle, or transmission to hunters handling infected carcasses.

B. suis, which is closely related to *B. abortus*, is a pathogen of swine, while *B. melitensis* infects goats and sheep. *B. melitensis*, *B. suis*, and *B. abortus* can be transmitted to humans via contact with infected animals or their tissues, or by consumption of unpasteurized dairy products. Brucellosis is rare in the U.S. as a result of its eradication in cattle and pasteurization of dairy products, with fewer than 200 (mostly imported) cases reported per year to CDC. Worldwide, however, over 500,000 cases of human brucellosis are reported to the World Health Organization, and the disease is widespread, especially in Africa, South America, the Middle East, and Russia. Humans generally are considered a "dead end" host and do not transmit the infection. During the 1950's, both the U.S. and the former U.S.S.R. developed technology for use of *Brucella* species as a bioweapon, and, for this reason, *B. abortus*, *B. suis*, and *B. melitensis* are regulated as Select Agents in the U.S.

Some individuals infected with *Brucella* may initially be asymptomatic. Within 8 weeks of exposure, acute onset of symptoms including fever, weakness, headache, malaise, fatigue, night sweats, and muscle and back pain may be reported. Other patients may experience a more gradual development of these symptoms over months. If the illness goes untreated, chronic brucellosis, which is characterized by recurring (undulant) fevers, can develop. Since these symptoms are nonspecific, history of possible exposure will aid in the diagnosis. Blood cultures often fail to yield *Brucella*, hence a diagnosis is made by determining serum agglutination titers with *Brucella* antigen. The recommended treatment for brucellosis is a 6-week course of doxycycline, in combination with rifampin. Treatment with a single antibiotic has been associated with a high rate of relapse of brucellosis.

Critical Parameters and Troubleshooting

Although *B. abortus* grows relatively slowly, with an in vitro doubling time of 3 to 3.5 hr, the techniques for its cultivation are straightforward. An important consideration when working with slow-growing bacteria such as *Brucella* is that any contaminants introduced into cultures will rapidly outgrow *Brucella*, so good aseptic technique is essential.

The protocols described here use TSB and TSA as media for growing *B. abortus*. Many laboratories use *Brucella* agar and *Brucella* broth. Since these are considered specialty media, they are generally more expensive than TSA and TSB, which are widely used in microbiology labs. The authors' *B. abortus* laboratory strain 2308 grows at a similar rate in both *Brucella* broth and TSB, so the less

expensive TSB is generally used. One consideration for the choice of medium is the intended application. For experiments such as enumeration of CFU obtained from tissue culture or animal experiments, where the plates will be discarded after counting, TSA is a good choice because of the cost and the large number of plates used. However, serial passage of *Brucella* on this medium can result in attenuation. In fact, serial passage in vitro was originally used to derive the live, attenuated animal vaccines currently in use, and it has been shown that for vaccine production, use of more nutrient-rich media, such as TSA blood agar or PIA, reduces the appearance of spontaneous rough mutants lacking a complete lipopolysaccharide (Alton et al., 1975). Therefore, for construction of strains to be used for virulence studies, or for strains that will be added to the laboratory stock, it is advisable to keep the number of in vitro passages to a minimum and to maintain stocks on the more nutrient-rich PIA or TSA blood agar. Other media, such as chocolate agar and modified Thayer-Martin medium, will also support growth of *B. abortus* and are routinely used in clinical microbiology laboratories.

Brucellosis is the most frequently reported laboratory-acquired infection, so it is important to follow established laboratory protocols for avoidance of contamination and infection. Disinfectants such as 70% ethanol, 1% Virkon S, or 10% bleach should always be within reach while working in the BSC. Aerosols, cuts, needle sticks, or splashes in the eye have been implicated as causes of laboratory-acquired infections. Use of sharps and glass items should be minimized to reduce the risk of infected wounds. In particular, procedures that can generate aerosols, such as homogenization of tissues, vortexing, electroporation, and centrifugation require special care to ensure containment of the aerosols. Many centrifuge manufacturers now offer special rotors that will contain aerosols in case of a spill: these rotors are highly recommended for centrifugation of samples containing *Brucella*, since centrifuge accidents are a frequent cause of laboratory infection (e.g., see Fiori et al., 2000).

When working in the BSL-3 lab, it is a good idea to plan in advance and, before starting the experiment, make a checklist to ensure that all required materials and equipment are present. A frequent cause of lost time is having to change out of the personnel protective equipment, leave the lab, and fetch whatever is missing in the middle of an experiment. An experiment that takes 1 hr at the bench in a BSL-2 lab will take at least 1.5 hr in the BSL-3 lab because of the extra safety precautions involved, so it is important to plan enough time for experiments. A final consideration is that, in equipping a BSL-3 lab, it may be useful to duplicate existing laboratory items, especially instruments such as pipet fillers or electronic equipment that cannot be readily disinfected or autoclaved.

Anticipated Results

B. abortus grows in TSB with a doubling time of ~3 to 3.5 hr. Under these conditions, a culture of *B. abortus* 2308 inoculated as described in Basic Protocol 1 will be in logarithmic growth phase between 8 and 20 hr, at late log/early stationary phase between 20 and 24 hr, and in stationary phase after 24 hr (Fig. 3B.1.1). If a different *B. abortus* strain is used, then a growth curve should be prepared for each individual strain. Unlike *E. coli* or *Salmonella*, which grow to a density of $\sim 5 \times 10^9$ CFU/ml, *B. abortus* can grow to culture densities exceeding 1×10^{10} CFU/ml. For *B. abortus* cultures, an OD_{600} of 1.0 is log phase and is equivalent to $2–4 \times 10^9$ CFU/ml, which is two to four times higher than an *E. coli* culture with the same optical density. This is likely due to the small size of *B. abortus*, which is ~0.5 μm in diameter and 0.6 to 1.5 μm in length.

Time Considerations

Three days in advance of the planned experiment, the *B. abortus* strain should be streaked out from the frozen stock culture. Cultures on blood agar plates, if sealed with Parafilm, can be maintained at 4°C for up to 4 weeks and still maintain viability; however, the bacteria from these plates will grow more slowly initially on inoculation into a liquid culture, and this should be taken into consideration when the bacterial culture is to be harvested at a particular growth phase. Alternatively, one can use a plate that has been stored at 4°C for up to 4 weeks to inoculate an overnight culture (thickly), then use this saturated overnight culture to reinoculate a new starting culture to an OD_{600} of 0.01.

For work in the BSL-3 lab, always plan extra time (at least 30 min.) for disinfection, and BSL-3 entry and exit procedures. It is wise to wipe the outer and inner surfaces of the BSC with 70% ethanol before starting work, and after completing work, all surfaces in the BSC and the lab (e.g., door handles, incubator

handles) should be wiped down with 70% ethanol. In addition, it saves time and increases safety to keep the blower of the BSC in constant operation, as it takes ~20 min after switching on the fan to establish laminar flow in the hood.

Laboratory Maintenance of *Bartonella quintana*

James M. Battisti[1] and Michael F. Minnick[1]

[1]Division of Biological Sciences, The University of Montana, Missoula, Montana

ABSTRACT

Trench fever is the common name for the acute febrile syndrome associated with a *Bartonella quintana* bacterial infection. The focus of this unit is to describe reliable methods for cultivation and cryopreservation of *B. quintana* and can be applied to cultivation and preservation of all *Bartonella.* Detailed recipes for preparation of three types of semisolid media are also included. *Curr. Protoc. Microbiol.* 10:3C.1.1-3C.1.13.

Keywords: *Bartonella,* trench fever • culture • HIB-B • BB-H • chocolate agar • cryopreservation

INTRODUCTION

B. quintana infection has affected millions of people during war and is currently reemerging in inner cities throughout the world and in AIDS patients (Maurin and Raoult, 1996; Ohl and Spach, 2000). Of all bacteria, *B. quintana* has the greatest known requirement for exogenous heme, a large cyclic organic molecule (protoporphyrin) containing an iron atom (Vinson, 1966; Myers et al., 1969, 1972). It is generally accepted that this extraordinary supplement requirement is similar for all *Bartonella* species, as erythrocytes, hemoglobin, or hemin are essential for cultivation (Birtles et al., 1995).

The overall function of this unit is to describe reliable methods for cultivation and preservation of *B. quintana* (previously known as *Rochalimaea quintana*). *Bartonella* species are relatively slow growing and require nutrient-rich media; therefore there is a high risk of contamination. Thus, this unit includes a biosafety cabinet preparation protocol (Support Protocol) that should be followed for all procedures. Procedures for inoculation of semisolid media from three sources are described: glycerol stock (Basic Protocol 1), liquid suspension (Basic Protocol 2), and solid plate culture (Basic Protocol 3). A unique harvesting method (Basic Protocol 4) is used to collect bacteria from the surface of a plate, and long-term storage of *B. quintana* is accomplished by cryopreservation with glycerol (Basic Protocol 5).

CAUTION: B. quintana is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

CAUTION: Follow all appropriate guidelines and regulations for the use and handling of human-derived materials. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

STRATEGIC PLANNING

Culture Media

Although several liquid media have been shown to facilitate replication of *B. quintana* (Huang, 1967; Mason, 1970; Maggi et al., 2005), medium solidified with 1.5% agar

Current Protocols in Microbiology 3C.1.1-3C.1.13, August 2008
Published online August 2008 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/9780471729259.mc03c01s10

Table 3C.1.1 Semisolid Media Commonly Used for Culture of *Bartonella*

Medium	Comments
HIB-B	Heart infusion broth with 4% blood (v/v), 2% serum (v/v), and 1.5% agar. A good general purpose medium for culturing *Bartonella*.
CHOCO	GC agar with 1% hemoglobin (w/v) and IsoVitaleX medium enrichment. Recommended by ATCC for cultivation of *B. quintana.*
BB-H	Brucella broth supplemented with 1.5% agar and a variable amount of hemin chloride. Facilitates analysis of hemin-associated physiology of *B. quintana* by simulation of natural environments.

Table 3C.1.2 Hemin Supplementation of *Brucella* Agar for Growth of *B. quintana*[a]

H_2O[b]	Hemin chloride[c]	Final concentration	Simulated niche
496.8	3.2	0.05 mM	Human bloodstream (low)
490.3	9.7	0.15 mM	In vitro control[d] (normal)
337.7	162.3	2.5 mM	Louse gut (high)

[a]See Background Information.
[b]Milliliters of H_2O used to initially dissolve *Brucella* broth base.
[c]Milliliters of 5% hemin chloride solution to achieve final concentration listed.
[d]Approximate concentration of heme in a standard HIB-B plate.

provides the most reliable growth substrate. Three separate semisolid formulations containing alternate heme sources are provided in this unit (see Table 3C.1.1): (1) heart infusion broth with 4% (v/v) sheep blood (HIB-B), (2) chocolate agar containing 1% (w/v) hemoglobin (Koehler et al., 1992), and (3) *Brucella* broth supplemented with a variable concentration of hemin (BB-H). Both HIB-B and chocolate agar plates can be used for routine passage of *B. quintana.* Alternatively, BB-H plates are used to study the effect of heme concentration on gene expression and physiology of *B. quintana* (see Table 3C.1.2 and Background Information).

Culture Conditions

B. quintana is considered a microaerophile (only a small amount of oxygen is required for growth) and a capnophile (growth is enhanced in the presence of increased CO_2 tension). This atmosphere is typically achieved using a candle extinction jar. Alternatively, a 5% CO_2 incubator (at atmospheric O_2) can be used. The standard incubation temperature for *B. quintana* is 35° to 37°C in a humidified CO_2-rich environment. Alternatively, incubation can be performed at 30°C to simulate conditions experienced by *B. quintana* in the body louse vector (see Background Information).

Isolation of *B. quintana*

Isolation of *B. quintana* from nature is challenging even for an experienced researcher, and a detailed explanation of the methods employed is beyond the scope of this unit. Although cell coculture systems are considered superior, chocolate agar and HIB-B can be used to isolate *B. quintana* from human samples (Koehler et al., 1992; La Scola et al., 1999), as well as decontaminated body lice (La Scola et al., 2001).

INOCULATION OF *B. QUINTANA* FROM A FROZEN STOCK ONTO SEMISOLID MEDIA

There are three procedures depending on the source of inoculum; (1) glycerol stock, (2) liquid suspension, and (3) agar plate culture. The type of media used is based on the particular experiment (see Strategic Planning). Be sure to properly label the plates with a fine-tipped permanent marker on the agar-side of the petri plate.

Materials

B. quintana glycerol stock (Basic Protocol 5)
Petri plates with solidified medium of choice (see Strategic Planning and Reagents and Solutions)
250 ml glass beaker containing ~100 ml 95% ethanol

Ice bucket
Kimwipes, moistened with 70% (v/v) ethanol
Aerosol-barrier pipet tip
Glass culture spreader, sterilized with ethanol
5% CO_2 incubator with a pan of H_2O to maintain humidity

Additional reagents and equipment for preparing a biological safety cabinet (Support Protocol) and using the spread technique (*APPENDIX 4A*)

NOTE: Cultivation of *B. quintana* should be performed in a biosafety cabinet after preparation of workspace and tools (see Support Protocol and *APPENDIX 4D*).

1. Place glycerol freezer stock in ice bucket in a prepared biological safety cabinet (see Support Protocol) and allow contents to thaw completely.

   Thawing can be expedited by warming the tube between the palms. The tube should be gently inverted to resuspend bacteria and ensure a consistent inoculum.

   Keep the frozen stock tube in an ice bucket when not in use.

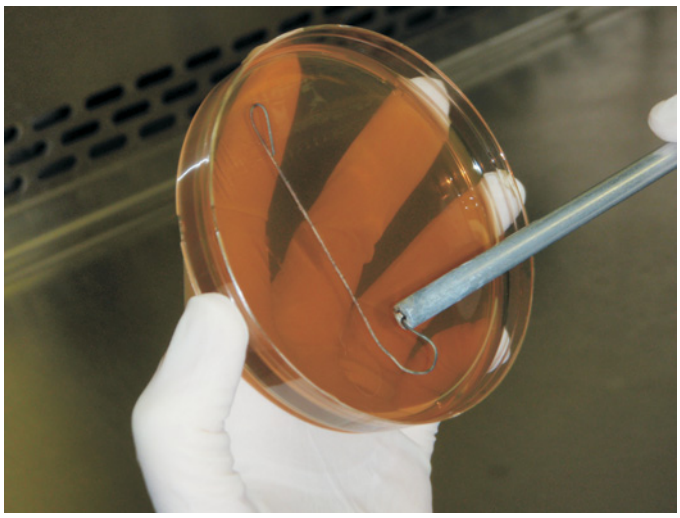

Figure 3C.1.1 Bent inoculation wire. This tool is useful for inoculation of plates from a confluent lawn of a clonal population. A *Brucella* agar plate containing 0.15 mM hemin chloride is shown. For color version of this figure see *http:www/currentprotocols.com.*

2. Sterilize the outside of the screw-capped tube by gently wiping with a 70% (v/v) ethanol-moistened Kimwipe.

   This is to ensure that the freezer stock does not become contaminated. The moistened Kimwipe can also be used to partially unscrew the lid. Do not rub too hard as you are likely to erase the label.

3. Using aseptic technique, remove 10 to 150 µl of thawed freezer stock using an aerosol-barrier pipet tip. Use the spread technique (see *APPENDIX 4A*) to evenly distribute liquid on the surface of the agar-solidified medium using an ethanol-sterilized glass culture spreader.

   Volume used for inoculation is based on empirical determination of the viable density by plating. However, if the volume exceeds 150 µl the plates should be dried agar-side down in the cabinet. Return the glass culture spreader to the ethanol and re-flame prior to spreading each separate plate.

4. Return thawed stock to the freezer.

   The number of freeze-thaw cycles does not seem to have a significant effect on viability.

5. Incubate plates agar-side up in a humidified 5% CO_2 incubator or candle jar at 37°C.

BASIC PROTOCOL 2

INOCULATION OF *B. QUINTANA* FROM A LIQUID SUSPENSION ONTO SEMISOLID MEDIA

The volume used for inoculation is based on the particular experiment. For culturing mammalian blood, larger volumes are often concentrated by centrifugation prior to plating (Koehler et al., 1992; La Scola et al., 1999). For isolation of *B. quintana* from decontaminated body lice (La Scola et al., 2001) a ~1:500 dilution is recommended to allow colony formation in the presence of faster growing bacterial species present. When using a liquid suspension obtained from a harvested plate(s) (see Basic Protocol 4), fragments of solidified media can plug the micropipet tip, resulting in erroneous volume measurements.

Materials

Liquid suspension of *B. quintana* (Basic Protocol 4)
Petri plates with solidified medium of choice (see Strategic Planning and Reagents and solutions)

Aerosol-barrier pipet tip
Glass culture spreader, sterilized with ethanol
5% CO_2 incubator with a pan of H_2O to maintain humidity

Additional reagents and equipment for using the spread technique (*APPENDIX 4A*) and preparing a biological safety cabinet (Support Protocol)

NOTE: Cultivation of *B. quintana* should be performed in a biosafety cabinet after preparation of workspace and tools (see Support Protocol and *APPENDIX 4D*).

1. Using aseptic technique, obtain 10 to 150 µl of the liquid suspension using an aerosol-barrier pipet tip.

2. Use the spread technique (see *APPENDIX 4A*) to evenly distribute the liquid on the surface of the solidified medium using an ethanol-sterilized glass culture spreader.

   Volume used for inoculation is based on empirical determination of the viable density by plating. However, if the volume exceeds 150 µl, the plates should be dried agar-side down in the cabinet. Return the glass culture spreader to the ethanol and re-flame prior to spreading each separate plate.

3. Incubate plates agar-side up in a humidified 5% CO_2 incubator or candle jar at 37°C.

INOCULATION OF *B. QUINTANA* FROM A SOLID PLATE CULTURE ONTO SEMISOLID MEDIA

BASIC PROTOCOL 3

A standard inoculation loop is used to subculture individual colonies of *B. quintana*. A bent inoculation wire (see Fig. 3C.1.1) is a useful tool to inoculate a large number of plates from a confluent lawn of a clonal population.

Materials

B. quintana colony or confluent lawn (from Basic Protocol 1 or 2)
Standard inoculation loop *or* bent inoculation wire (see Fig. 3C.1.1)
Kimwipe, moistened with 70% (v/v) ethanol
Petri plates with solidified medium of choice (see Strategic Planning and Reagents and solutions)
5% CO_2 incubator with a pan of H_2O to maintain humidity

Additional reagents and equipment for sterilizing the inoculation loop or bent wire using a flame (*APPENDIX 4A*)

NOTE: Cultivation of *B. quintana* should be performed in a biosafety cabinet after preparation of workspace and tools (see Support Protocol and *APPENDIX 4D*).

1. Sterilize the handle of an inoculation loop or bent wire with a Kimwipe moistened with 70% (v/v) ethanol.
2. Sterilize the inoculation loop or bent wire using a flame (see *APPENDIX 4A*) and cool it by touching the agar surface of the un-inoculated plate near the outer perimeter.
3. Touch the colony (with a loop) or confluent lawn (with bent wire) and gently streak across the surface of a new agar plate.

   Avoid using too much pressure when streaking as gouges in the surface result in inefficient harvesting (Basic Protocol 4).

4. Incubate plates agar-side up in a humidified 5% CO_2 incubator or candle jar at 37°C.

   The incubation conditions are based on the particular experiment and source of inoculum (see Strategic Planning and Commentary).

HARVESTING *B. QUINTANA* FROM SEMISOLID MEDIA

BASIC PROTOCOL 4

B. quintana harvesting should be performed in a biosafety cabinet after preparation of workspace and tools (see Support Protocol) and inoculation of semisolid media (see Basic Protocols 1 to 3). Harvesting is the collection of large numbers of a clonal population of bacteria from the surface of a plate using a single-edged razor blade and liquid medium.

Materials

Plate(s) containing *B. quintana* clonal populations (Basic Protocols 1, 2, or 3)
Heart infusion broth (HIB; see recipe)

Single-edged razor blades with grooved handle (Smith Brand, cat. no. 67-0238)
Test tube holder (see Fig. 3C.1.2)
250-ml glass beaker containing ~100 ml 95% ethanol
1000-µl micropipettor
Sterile collection tube

Additional reagents and equipment for sterilizing harvesting tool using a flame (*APPENDIX 4A*)

NOTE: Cultivation of *B. quintana* should be performed in a biosafety cabinet after preparation of workspace and tools (see Support Protocol and *APPENDIX 4D*).

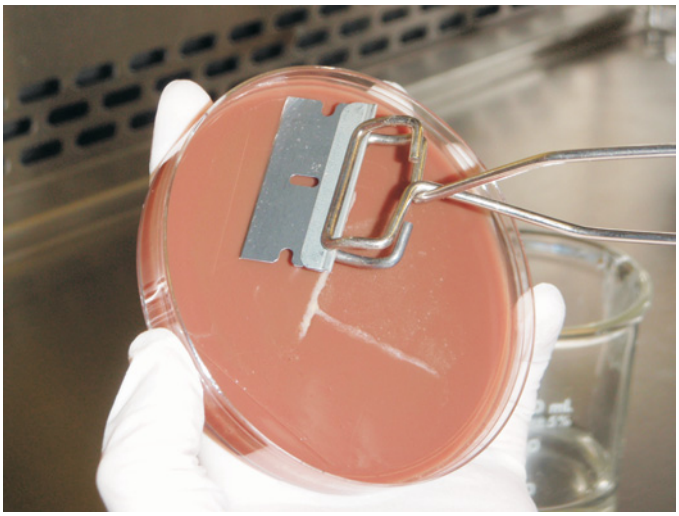

Figure 3C.1.2 Harvesting *B. quintana* from a chocolate agar plate. The harvesting tool, consisting of a single-edged razor blade and a test tube holder, is used to scrape the bacterial lawn toward the outer perimeter of the plate.

1. Carefully analyze plate(s) for contamination in the prepared cabinet.
2. Assemble harvesting tool as shown (Fig. 3C.1.2*)* by clamping the test tube holder along the groove of the razor blade handle.

   Single-edged razor blades with a groove on both sides of the handle provide stability during use. The wire of the test tube holder should firmly clamp the blade.
3. Soak the blade portion of the harvesting tool in a beaker containing 95% ethanol and briefly pass through a flame to sterilize as described for a glass culture spreader (see *APPENDIX 4A*).
4. Hold the plate agar-side-up with one hand, and the sterilized harvesting tool with the other. With the blade slightly angled toward the surface of the agar, gently scrape the bacteria into a single clump close to the outer perimeter of the plate. Return the harvesting tool to the beaker of 95% ethanol.

   CAUTION: *Dispose of the contaminated blade(s) in a sharps biohazard container.*

   Avoid movements of the blade that gouge the surface or create fragments of agar.

   The bacteria have a tendency to stick to each other and the blade. A single blade can be used to harvest >10 plates.
5. Hold the plate agar-side up with one hand, and a 1000-µl micropipettor containing ~300 µl sterile HIB with the other. Slightly tilt the plate such that the clump is facing you and is toward the bottom.
6. Moisten the clump by slowly ejecting this ~300 µl HIB liquid medium directly onto it.

   The liquid decreases the stickiness of the bacteria. The HIB should flow over the clump of bacteria and form a pool in the space between the agar surface and the inner wall of the plate.
7. Holding the pipet tip nearly horizontal to the surface of the plate, moisten the pipet tip in the pool of HIB and push clump of bacteria into this pool.

The goal is not to resuspend the clump, but rather collect it from the surface of the plate such that it can be aspirated and transferred. Avoid movements of the pipet tip that gouge the surface or create fragments of agar.

8. Aspirate and transfer the bacteria to a sterile collection tube.

   The tube size and type is based on the particular experiment. For 1 to 3 plates, use a 1-ml screw-capped vial or 1.5-ml microcentrifuge tube. For >4 plates, 30 ml Oak Ridge-type tubes are useful.

9. Resuspend the bacterial clump by gentle up-and-down pipetting or gentle swirling by hand.

CRYOPRESERVATION OF *B. QUINTANA*

BASIC PROTOCOL 5

Cryopreservation of *B. quintana* should be performed in a biosafety cabinet after preparation of workspace and tools (see Support Protocol). Long-term storage is achieved by freezing at −80°C in a final concentration of 12.5% (v/v) glycerol. Prepare at least two vials of each strain and if possible, store in separate freezers.

Materials

Cryopreservation solution (see recipe)
1-ml screw-capped cryovials (Nunc, cat. no. 375353)
Fine-tipped permanent marker (to label the cryovials)
−80°C freezer

Additional reagents and equipment for growing and harvesting a clonal population of *B. quintana* (Basic Protocol 4)

NOTE: Cultivation of *B. quintana* should be performed in a biosafety cabinet after preparation of workspace and tools (see Support Protocol and *APPENDIX 4D*).

1. Grow a clonal population of *B. quintana* and harvest (see Basic Protocol 4) into liquid HIB.
2. Combine equal volumes of the cryopreservation solution and the liquid suspension in a properly labeled 1-ml screw-capped cryovial.
3. Mix by gentle inversion and store >10 years in −80°C freezer.

PREPARATION OF WORKSPACE AND TOOLS

SUPPORT PROTOCOL

The combination of slow-growing *B. quintana* and nutrient-rich media often leads to contamination. Contamination of cultures is very common but can be reduced when using aseptic technique in a biosafety cabinet. The following procedures are performed to ensure safety for the researcher as well as decrease contamination of bacterial cultures.

Materials

Laminar-flow type biosafety cabinet equipped with germicidal UV bulb
Spray bottle with 70% ethanol (v/v)
Kimwipes
Latex, vinyl, or nitrile protective gloves
Laboratory coat
Touch-O-Matic (Hanau) bunsen burner
10-µl, 100-µl, and 1000-µl micropipettors
Aerosol-barrier micropipet tips, sterile
Biohazard bag

1. Using the spray bottle of 70% ethanol, lightly mist the bench surface of the biosafety cabinet and wipe with a Kimwipe.
2. With the exception of live bacterial cultures, place all items required for a particular procedure in the cabinet, and lightly mist with 70% ethanol paying special attention to the barrels of the micropipettors.
3. Turn on the UV bulb for 10 min to allow ethanol to evaporate and germicidal action to occur.

   Do not sit in front of the cabinet when the UV light is on as damage to skin and eyes can occur.

4. Put on a long-sleeved laboratory coat and protective gloves.

   Ideally, the laboratory coat should have elastic cuffs to reduce exposure of skin.

5. Outside the cabinet, gently mist from the fingertips of gloved hands to elbows with 70% ethanol.

   Use caution when using ethanol spray bottle around open flame and avoid direct contact with eyes or skin. Do not place spray bottle in the cabinet.

6. Turn off the UV germicidal bulb.
7. Begin inoculation/culture (Basic Protocols 1 to 3), harvesting (Basic Protocol 4), or cryopreservation (Basic Protocol 5) procedures.

   To reduce heat generation within the cabinet, bunsen burners equipped with a pilot light (Touch-O-Matic), should be used and ignited only when in use. Outside of the cabinet, periodically mist hands with 70% ethanol throughout the procedures.

8. Remove live bacteria and ensure that gas to the burner is off.

   Live bacterial cultures should be immediately placed in an incubator. Used culture media, micropipet tips, and any other or potentially contaminated material should be discarded in a biohazard bag and autoclaved.

9. Lightly mist micropipet barrels and the surface of the cabinet bench with 70% ethanol.
10. As in step 5 (above), lightly mist hands and arms. Dispose of gloves in biohazard bag.
11. Finally, expose the cabinet to the germicidal bulb for 10 min as in step 3 (above).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

B. quintana cryopreservation solution

Make a 25% glycerol solution (v/v) with water. Sterilize with a 0.22-μm filter or autoclave for 15 min at 121°C. Store up to 1 year at room temperature.

Brucella broth supplemented with a variable concentration of hemin (BB-hemin) agar plates

Dissolve 14 g BBL Brucella Broth (Becton Dickinson, cat. no. 211088) with 496.8 down to 337.7 ml H_2O (see Table 3C.1.2) in a 1000-ml Pyrex flask. Add 7.5 g Difco Agar (Becton Dickinson, cat. no. 214530) and autoclave for 15 min at 121°C. Cool for ~45 min in a 56°C H_2O bath. Lightly mist outside of flask with 70% ethanol

continued

and place in prepared biosafety cabinet. Add 3.2 to 162.3 ml 5% hemin solution (see recipe) to concentration appropriate for specific simulated environment (see Table 3C.1.2). Pour into sterile petri plates in the cabinet, then pass flame over the surface of agar using a standard bunsen burner to remove bubbles. Replace lid. Allow plates to dry overnight (agar-side down) in the cabinet. Re-sleeve, invert, and store up to 1 month at 4°C.

The approximate formula per liter is 10.0 g pancreatic digest of casein, 10.0 g peptic digest of animal tissue, 1.0 g dextrose, 2.0 g yeast extract, 5.0 g sodium chloride, 0.1 g sodium bisulfite, and 15 g agar.

Also see Strategic Planning.

Heart infusion broth with 4% sheep blood (HIB-B) agar plates

Dissolve 12.5 g of Bacto Heart Infusion Broth (Becton Dickinson, cat. no. 238400) with 470 ml H_2O in a 1000-ml Pyrex flask. Add 7.5 g Difco Agar (Becton Dickinson, cat. no. 214530) and autoclave for 15 min at 121°C. Cool for 45 min in a 56°C H_2O bath. Lightly mist outside of flask with 70% ethanol and place in prepared biosafety cabinet, then add 20 ml defibrinated sheep blood (Quad Five, cat. no. 610), 10 ml sheep serum (Quad Five, cat. no. 662), and swirl to mix. Pour into sterile petri plates in the cabinet then pass flame over the surface of agar using a standard bunsen burner to reduce bubbles and replace the lid. Allow plates to dry overnight (agar-side down) in the cabinet. Re-sleeve, invert, and store up to 1 month at 4°C.

Prepare 500 ml batches rather than 1 liter batches as they are easier to pour in the biosafety cabinet. Also see Strategic Planning.

The approximate formula per liter is 10.0 g beef heart infusion, 10.0 g tryptose, 5.0 g sodium chloride, 15.0 g agar (w/v), 40 ml defibrinated sheep blood (v/v), 20 ml sheep serum (v/v).

Heart infusion broth (HIB)

Dissolve 25 g of Bacto Heart Infusion Broth (Becton Dickinson, cat. no. 238400) with 1000 ml H_2O in a 2000-ml beaker. Dispense 100 ml into ten screw-capped 125-ml Pyrex bottles and autoclave for 15 min at 121°C. Store up to 1 year at room temperature.

The approximate formula per liter is 10.0 g beef heart infusion, 10.0 g tryptose, and 5.0 g sodium chloride.

Hemin solution (5 mg/ml)

Dissolve 0.08 g sodium hydroxide with 100 ml H_2O in a 250-ml beaker. Add 0.5 g hemin chloride and stir to mix. Place in a prepared biosafety cabinet and sterilize with a 0.22-μm filter. Store <2 months at 4°C.

Make 100 ml batches rather than 1 liter batches to maintain freshness. Different volumes of this hemin solution are added to Brucella broth (above) to simulate natural hemin concentrations encountered by B. quintana (see Table 3C.1.2 and Strategic Planning).

The approximate formula per liter is 0.8 g sodium hydroxide and 5.0 g hemin chloride.

Koehler's Bartonella chocolate agar plates

Dissolve 7.2 g GC Agar (Acumedia, cat. no. 7104B) with 100 ml H_2O in a 1000-ml Pyrex flask. Dissolve 2.0 g hemoglobin (Acumedia, cat. no. 7195A) with 100 ml H_2O in a 1000-ml Pyrex flask. Autoclave both flasks for 15 min at 121°C, and then cool for ~45 min in a 56°C H_2O bath. In a prepared biosafety cabinet aseptically reconstitute lyophilized IsoVitaleX medium enrichment with 2 ml diluent per manufacturer's instructions (Becton Dickinson, cat. no. 211875). Lightly mist outside

continued

of flasks with 70% ethanol and place in cabinet. Add hemoglobin and IsoVitaleX enrichment to GC Agar. Swirl to mix, and dispense ~28 ml into petri plates with a sterile graduated pipet. Allow plates to dry overnight in the cabinet. Re-sleeve, invert, and store up to 1 month at 4°C.

Prepare 202 ml batches rather than 1010 ml batches as they are easier to dispense in petri plates in the cabinet. Also see Strategic Planning.

The approximate formula per liter is 7.5 g enzymatic digest of casein, 7.5 g enzymatic digest of animal tissue, 1.0 g corn starch, 4.0 g dipotassium phosphate, 1.0 g monopotassium phosphate, 5.0 g sodium chloride, 10.0 g agar, 10.0 g hemoglobin, 0.01 g Vitamin B_{12}, 10.0 g L-glutamine, 1.0 g adenine, 0.03 g guanine hydrochloride, 0.013 g p-aminobenzoic acid, 0.25 g nicotinamide adenine dinucleotide, 0.1 g thiamine pyrophosphate, 0.02 g ferric nitrate, 0.003 g thiamine hydrochloride, 25.9 g L-cysteine hydrochloride, 1.1 g L-cystine, and 100.0 g dextrose.

COMMENTARY

Background Information

The *Bartonellaceae* are members of the order Rhizobiales, a group of Alpha Proteobacteria responsible for a variety of mammalian (e.g., bartonellosis, brucellosis) and plant (e.g., crown gall) diseases. There are currently twenty species in the genus *Bartonella*, nine of which have been associated with human disease (Rolain et al., 2004; Eremeeva et al., 2007). Although the majority of human *Bartonella* infections are considered zoonoses (Breitschwerdt and Kordick, 2000), maintenance of *B. quintana* in nature is thought to be restricted to humans and body lice *(Pediculus humanus corporis*). Two disparate environmental cues experienced by *B. quintana* in these niches are heme concentration (low in human and high in louse; Battisti et al., 2006) and temperature (35°C to 37°C in human and 30°C in louse; Mellanby, 1932; Marsh and Buxton, 1937).

Trench fever is the common name for the acute febrile syndrome associated with *B. quintana* infection. Chronic manifestations of persistent infection include protracted bacteremia, endocarditis, bacillary angiomatosis, and bacillary peliosis (Maurin and Raoult, 1996), which are coincident with its facultative intracellular lifestyle. Transmission to humans occurs when a crushed louse or louse fecal matter containing the bacterium is introduced into the bloodstream by a breach in the skin caused by itching concurrent with louse infestation. PCR is considered the most sensitive method for diagnosis (La Scola and Raoult, 1999), and infections are treated with different antibiotic regimens depending on the acute or chronic nature of the disease (Rolain et al., 2004).

The overall goal of this unit is to convey basic laboratory maintenance procedures for *B. quintana*, which, in general, can be applied to cultivation and preservation of all *Bartonella.* Recent advancements in genetic manipulation (Fournier et al., 2001; Minnick et al., 2003; Battisti et al., 2006), gene regulation (Battisti et al., 2007), proteome analysis (Boonjakuakul et al., 2007), and genome sequencing (Alsmark et al., 2004) have provided a foundation to better understand the molecular aspects of *B. quintana* pathogenesis. Thus, application of the methods provided in this unit can further explain the virulence mechanisms utilized by *Bartonella,* which will certainly lead to more efficient methods of diagnosis, treatment, and prevention of these emerging human pathogens.

Critical Parameters and Troubleshooting

The most critical issue involved in successful completion of the procedures in this unit is proper aseptic technique. For this reason, detailed methods for preparation of workspace and tools are provided (see Support Protocol). In addition to contamination resulting from hands-on manipulation of cultures in the cabinet, improperly prepared medium is another source of unwanted growth. Incubation of an un-inoculated plate is often included to test the sterility of the medium. If the medium is suspect, re-prepare and ensure that all components have been properly autoclaved or filter-sterilized. Finally, condensation often forms within the lid of the plate during extended incubation, and is a vehicle for contamination. The purpose of the overnight drying period (see Reagents and Solutions*)* is to decrease this occurrence. If a considerable amount of moisture is noticed when inspecting a culture, it should be aseptically decanted.

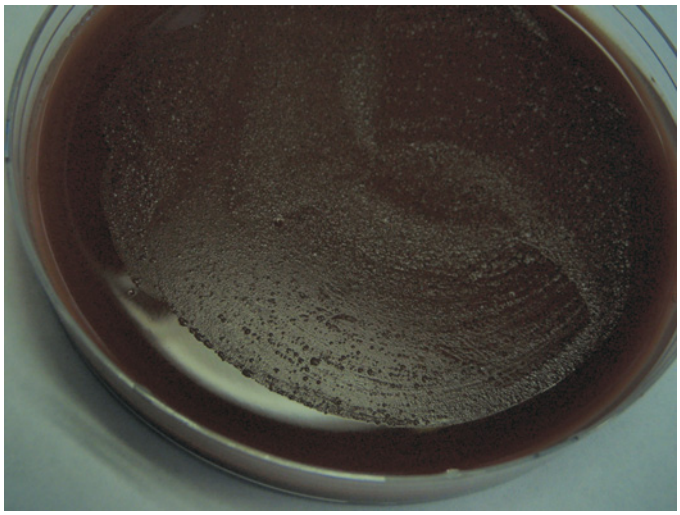

Figure 3C.1.3 Confluent lawn of *B. quintana.* A chocolate agar plate inoculated from a liquid suspension by the spread plate method and incubated in a candle jar for 7 days is shown. Formation of colonies of various sizes within a grainy background sheen is typical. For color version of this figure see *http:www/currentprotocols.com*.

Differentiation of *B. quintana* from other species of bacteria can be achieved at several levels of confidence. First, the colony morphology is described below (see Anticipated Results) and an image is provided (Fig. 3C.1.3). Second, the cellular morphology is best viewed with oil immersion and a phase-contrast microscope at 1000×. The cells are Gram-negative cocco-bacilli, ~0.5-μm wide and 1.5-μm long. Last, PCR and sequence analysis (Koehler et al., 1992; Norman et al., 1995; Minnick and Barbian, 1997) can be employed for genetic identification of the species.

Another challenge in laboratory maintenance of *B. quintana* is variable growth rate, primarily associated with inoculation source and inoculation density. The growth rate of an equal volume of bacteria from freezer stocks can fluctuate, and is often much slower than anticipated. For this reason, it is recommended to inoculate 2 to 3 plates directly from freezer stock, monitor them for growth, and then reinoculate these bacteria onto fresh plates. The second passage of plates is used for the actual experiment, as a more consistent growth rate can be expected. Standard CFU determination and Petroff-Hausser counting chambers (see *APPENDIX 4A*) are routinely used to enumerate cells from a liquid suspension. The BacLight kit (Invitrogen, cat. no., L-7007) can also be used to assist in enumeration and monitor bacterial viability.

Anticipated Results

The growth rate of *B. quintana* can vary greatly depending on the strain, passage number, inoculation source, inoculation density, and culture media. Initial isolation from mammalian blood or decontaminated lice usually requires several weeks of incubation on chocolate agar or HIB-B. Alternatively, colony formation is usually evident in 5 to 7 days from strains that have been grown at least once on HIB-B or chocolate agar.

The colony morphology of *B. quintana* is small (0.2 to 1 mm) and circular, with a convex elevation, even margin, and a translucent-tan color. The color of the colonies can vary with different media. A confluent lawn typically exhibits an opaque sheen with a variety of colony sizes and contains 1×10^7 to 1×10^{10} bacteria (see Fig. 3C.1.3).

Time Considerations

The major portion of hands-on time to complete the basic protocols in this unit is devoted to preparation of growth media. Dissolving the media components (~0.5 hr), autoclaving (~1.0 hr), cooling (~0.75 hr), and dispensing media into plates (~0.25 hr) requires ~2.5 hr. The cooling time can be extended (to ~3 hr) and the overnight drying time can be reduced (to ~3 hr). The major portion of total time for completion of the basic protocols is dedicated to incubation (5 to 21 days; see Anticipated Results). Following preparation of the

workspace and tools (~15 min), the remaining basic protocols listed in this unit (inoculation, harvesting, and cryopreservation) can be completed in <1 hr.

Laboratory Maintenance of *Neisseria gonorrhoeae*

Janice M. Spence,[1] Lori Wright,[1] and Virginia L. Clark[1]

[1]University of Rochester, Rochester, New York

ABSTRACT

Neisseria gonorrhoeae is a human pathogen of mucosal surfaces, thus laboratory manipulations must include appropriate safety measures. The growth requirements and behavior of the gonococcus are significantly different from many bacteria, necessitating modifications of common laboratory techniques. A fastidious organism, *N. gonorrhoeae* requires enriched media in a CO_2 atmosphere at 35° to 37°C for growth. In addition, *N. gonorrhoeae* expresses potent autolysins whose activity increases following glucose depletion during stationary phase, leading to cell death. Long believed to be an obligate aerobe, the gonococcus is capable of anaerobic growth when provided with a suitable electron acceptor. This unit provides information for both aerobic and anaerobic growth, basic long-term and daily maintenance of gonococcal cultures, as well as safety considerations for laboratory studies. *Curr. Protoc. Microbiol.* 8:4A.1.1-4A.1.26. © 2008 by John Wiley & Sons, Inc.

Keywords: *Neisseria gonorrhoeae* • bacterial growth • *Neisseria* media • anaerobic bacterial growth • frozen stock

INTRODUCTION

Neisseria gonorrhoeae ("gonococcus") is an obligate human pathogen, thus all strains are derived from human infections. Best known as the agent of the sexually transmitted disease gonorrhea, this organism readily infects other mucosal surfaces, including the pharynx and eyes, and may cause invasive disease if inoculated into the bloodstream. Thus, appropriate laboratory precautions are needed to prevent laboratory acquired infections following accidental contact with broken skin or procedures that may promote splashes or produce aerosols from gonococcal suspensions. Safety issues specifically related to common laboratory manipulations of gonococci are discussed, including CDC recommendations for *N. gonorrhoeae*.

While *N. gonorrhoeae* can be readily grown in the laboratory, it is a fastidious organism that requires enriched media along with a 3% to 10% CO_2 atmosphere at 37°C for growth, conditions commonly used for clinical isolates. The organism is sensitive to desiccation and cannot survive temperatures <25°C for extended periods of time. In addition, the viability of *N. gonorrhoeae* decreases rapidly in stationary phase, due to enhanced autolysis following the depletion of glucose from the medium. Thus, many techniques used for both long- and short-term growth and storage of most microbes are unsuitable for *N. gonorrhoeae*, such as overnight broth cultures or refrigeration of plate-grown colonies. Detailed protocols are presented for the laboratory growth of *N. gonorrhoeae* under both aerobic and anaerobic conditions. A protocol for a chemically defined medium is also provided for those whose work requires the rigor of exact medium composition.

Neisseria gonorrhoeae is a well-adapted human pathogen, which is demonstrated by the high degree of phase and antigenic variation observed for many surface features of the organism. See *UNIT 4A.3* for detailed information on *N. gonorrhoeae* pilin and Opa variations and their effects on colony morphology.

Current Protocols in Microbiology 4A.1.1-4A.1.26, February 2008
Published online February 2008 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/9780471729259.mc04a01s8

CAUTION: Neisseria gonorrhoeae is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information. Also see Strategic Planning, Biosafety Considerations.

NOTE: N. gonorrhoeae is very fastidious, so it is essential that high-quality distilled and deionized water be used in all recipes and protocol steps.

STRATEGIC PLANNING

Biosafety Considerations

Laboratory associated infections with *N. gonorrhoeae* from contaminated clinical material have been reported in the United States. The primary risk factor centers on the direct or indirect contact of mucous membranes with infectious materials, though the importance of aerosols has not yet been determined. Therefore, the most probable sites of laboratory acquired infections include the pharynx (throat), the conjunctiva (eye surface), and invasive disease acquired through contact with broken skin. *Neisserial* pharyngitis is often asymptomatic, while infection of the conjunctiva rapidly produces a severe, purulent response that can lead to scarring and permanent damage. Infection of the bloodstream, called disseminated gonococcal infection (DGI), initially gives rise to fevers, migratory polyarthralgia (aching joints), and petechial, maculopapular, or pustular rash (skin rash). Without treatment, joints may become infected, leading to septic arthritis often of the elbow or knee. Thus, it is important to seek medical treatment for known accidental exposures or symptoms that may indicate exposure, as gonococcal infections respond readily to standard antibiotic therapy.

In addition, since the risk of aerosols is not yet known, the CDC recommends that production quantities of *N. gonorrhoeae* be handled under BSL-3 containment. The CDC does not qualify what constitutes production level quantities, but does make reference to vaccine production. Thus, the determination for any given set of experiments must be determined through review of the proposed study by the individual Institutional Biosafety Committee.

NOTE: Examples of common laboratory precautions and emergency laboratory procedures for posting in the laboratory are given in Figures 4A.1.1 through 4A.1.3.

Overview of Important Considerations for Laboratory Growth of *N. gonorrhoeae*

Neisseria gonorrhoeae is an obligate human pathogen of mucosal membranes, and is optimized for growth in that moist, nutritionally rich, homogeneous environment with minor temperature and pH variations. Transmission of infection is by direct contact and the gonococcus displays limited ability to survive outside the human host. Thus, the challenge in the laboratory for in vitro growth is to match the conditions of the native environment.

Neisseria gonorrhoeae is characterized as a fastidious organism, requiring enriched media and 3% to 10% CO_2 for initial growth. The CO_2 requirement is not related to anaerobiosis; rather, it is believed to be related to the need for heterotrophs to fix CO_2 to replenish the C_4 dicarboxylic acids for the anaplerotic requirements of the cell.

Many gonococcal clinical isolates are amino acid and/or nucleic acid precursor auxotrophs, traits that are used as epidemiological markers. Due to the known needs of many common laboratory strains of *N. gonorrhoeae*, and the unknown needs of clinical isolates, a rich medium is used for the isolation and growth of gonococci.

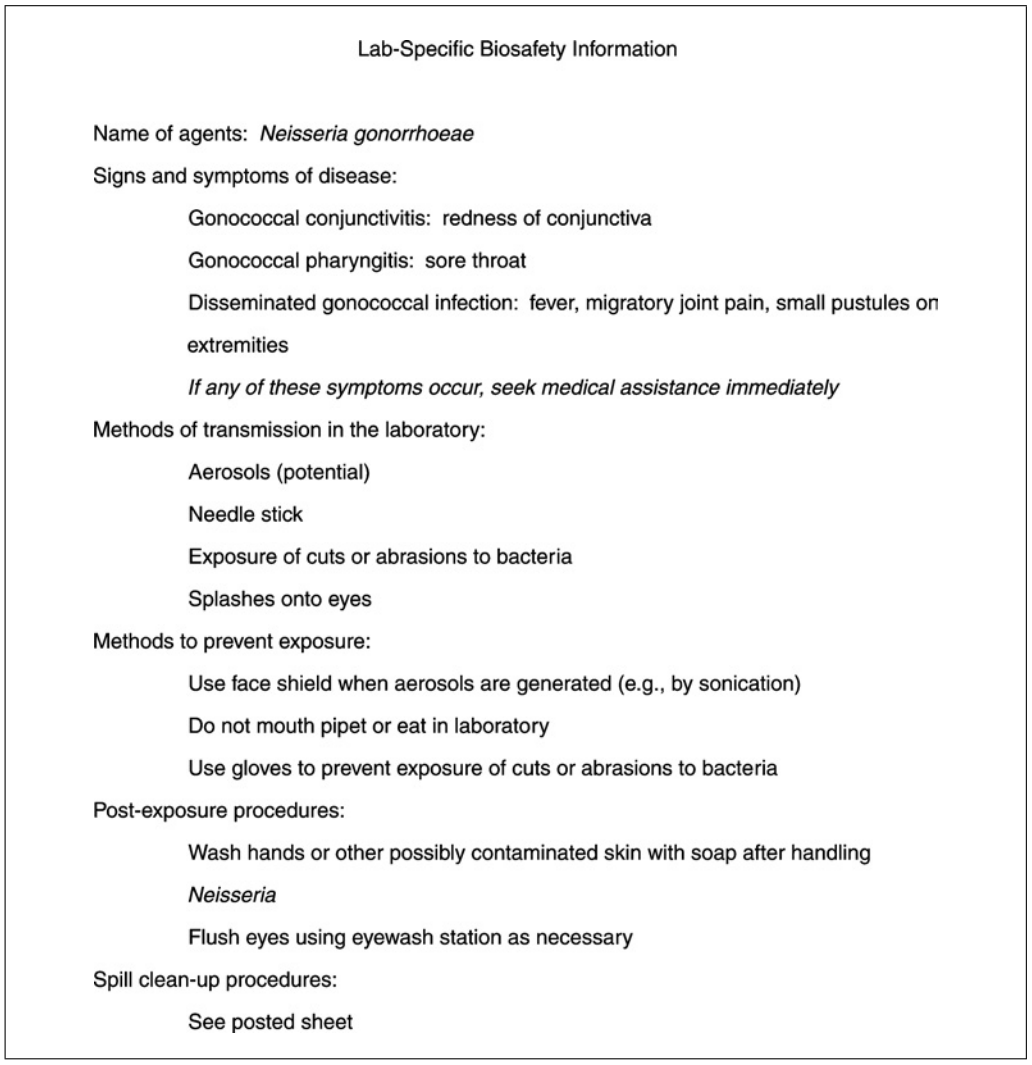
Additional special practices for work with *Neisseria gonorrhoeae* include:

1. A biohazard sign must be posted on the entrance to the laboratory when etiologic agents are in use. Appropriate information to be posted includes the agent(s) in use, the biosafety level, and the investigator's name and telephone number.
2. Biosafety procedures are incorporated into standard operating procedures or in a biosafety manual adopted or prepared specifically for the laboratory by the laboratory director. Personnel are advised of special hazards and are required to read and follow instructions on practices and procedures.
3. The laboratory director ensures that laboratory and support personnel receive appropriate training on the potential hazards associated with the work involved, the necessary precautions to prevent exposures and the exposure evaluation procedures. Personnel receive annual updates or additional training as necessary for procedural or policy changes.
4. A high degree of precaution must always be taken with any contaminated sharp items, including needles and syringes, slides, pipets, capillary tubes, and scalpels. Plasticware should be substituted for glassware whenever possible.
5. The use of needles and syringes or other sharp instruments should be restricted for use only when there is no alternative, such as parenteral injection, phlebotomy, or aspiration of fluids from laboratory animals and diaphragm bottles. Used needle and syringes must be placed in a hard-walled container for transport to a processing area for decontamination, preferably by autoclaving. Needles must not be bent, sheared, broken, recapped, removed from disposable syringes, or otherwise manipulated by hand before disposal.
6. Broken glassware must not be handled directly by hand, but must be removed by mechanical means such as a brush and dustpan, tongs, or forceps. Containers of contaminated needles, sharp equipment, and broken glass must be decontaminated according to any local, state, or federal regulations before disposal.
7. Spills and accidents that result in overt exposures to infectious materials are immediately reported to the laboratory director. Medical evaluation, surveillance, and treatment are provided as appropriate and written records are maintained.

Figure 4A.1.1 An example of a specific biosafety information form required to be posted in the laboratory to comply with the safety requirements of the Institutional Biosafety Committee at the University of Rochester for additional special practices for work with *Neisseria gonorrhoeae*.

CO_2 conditions

The need for enhanced CO_2 to initiate growth of many microbes is well known, especially with the mucosal pathogens. It has been suggested that this mimics the host environment, and is only required initially until the number of microbes in the colony grow sufficiently for their metabolism to generate the needed CO_2. There are several ways to generate the needed $CO_2$to initiate gonococcal growth. Since most liquid cultures are grown in benchtop shaking incubators under room air, a sodium bicarbonate supplement is added to the culture broth to provide the needed CO_2. Pre-incubating the medium in a CO_2 incubator can also provide the needed CO_2; however, this results in more variation than supplementing the medium with sodium bicarbonate. For growth on a solid medium, CO_2 can be provided by the use of a CO_2 incubator, a CO_2-generating GasPak (BBL), or a candle jar. Wheaton Science (*http://www.wheatonsci.com/*) offers a large range of



Lab-Specific Biosafety Information

Name of agents: *Neisseria gonorrhoeae*

Signs and symptoms of disease:

Gonococcal conjunctivitis: redness of conjunctiva

Gonococcal pharyngitis: sore throat

Disseminated gonococcal infection: fever, migratory joint pain, small pustules on extremities

If any of these symptoms occur, seek medical assistance immediately

Methods of transmission in the laboratory:

Aerosols (potential)

Needle stick

Exposure of cuts or abrasions to bacteria

Splashes onto eyes

Methods to prevent exposure:

Use face shield when aerosols are generated (e.g., by sonication)

Do not mouth pipet or eat in laboratory

Use gloves to prevent exposure of cuts or abrasions to bacteria

Post-exposure procedures:

Wash hands or other possibly contaminated skin with soap after handling *Neisseria*

Flush eyes using eyewash station as necessary

Spill clean-up procedures:

See posted sheet

Figure 4A.1.2 An example of a specific biosafety information form required to be posted in the laboratory to comply with the safety requirements of the Institutional Biosafety Committee at the University of Rochester for laboratory specific biosafety information.

suitable, wide-mouth glass jars for use as candle jars. The GasPak system (BBL) is commercially available from BD (*http://www.bd.com/*). It involves the generation of CO_2 from the mixing of sodium bicarbonate with citric acid in a foil-package that is activated by the addition of water. The plates and the CO_2-generating package are placed into an air-tight container (GasPak container). The closed containers are placed into a 37°C incubator overnight to allow gonococcal growth. The candle jar is the precursor to the GasPak. It involves placing the plates into a large, fire-resistant container, traditionally a large glass jar. A small, white, votive candle (unscented) is placed on top of the plates. The candle is lit and the lid tightly closed. The flame will burn until the oxygen in the jar is consumed. At this time, the closed container is placed in a 37°C incubator. The burning candle generates ~3% CO_2, which is sufficient to initiate gonococcal growth.

Starting from frozen stock

If starting the plate culture from frozen stock, it is essential that the stock vial remain frozen. Remove the vial from the freezer and place in an ice-bucket containing crushed dry ice. Use a sterile wooden applicator stick to scrape-up a sample of the frozen stock and place onto a room-temperature GCMB plate. Alternatively, a sterile toothpick can

Emergency Procedures for Spills Involving *Neisseria gonorrhoeae*:
Requires Biosafety Level 2 Containment

1. Alert people in immediate area of spill.
2. Anyone exposed to *N. gonorrhoeae* must clean the affected areas as soon as possible:

   Skin contact/cuts/puncture wounds: wash with soap and water

   Mouth and eyes: flush with water
3. Inform supervisor of exposure.
4. Contact appropriate health service provider for medical attention (name and phone).
5. A properly trained employee must proceed with the clean-up and decontamination of the spill area. Environmental Health and Safety assistance is available by calling Security at (x-xxxx).
6. This person must put on protective equipment (full face shield or mask and safety glasses/goggles, latex gloves, lab coat).
7. Pick out any sharps using tongs or other mechanical means and cover spill with absorbent material such as paper towels.
8. Carefully pour a freshly prepared disinfectant (e.g., 1:5 dilution of bleach in water) around the edges of the spill and then into the spill. Avoid splashing.
9. Allow a 20-min contact period.
10. Use paper towels to wipe up the spill, working from the edges into the center.
11. Clean spill area with fresh paper towels soaked in disinfectant.
12. Place towels into a biohazard bag for disposal.
13. Remove protective equipment and wash hands thoroughly.

Figure 4A.1.3 An example of a specific biosafety information form required to be posted in the laboratory to comply with the safety requirements of the Institutional Biosafety Committee at the University of Rochester for emergency procedures for spills involving *Neisseria gonorrhoeae*.

be used to scrape the frozen stock. Experience has shown that the larger and sturdier applicator stick (i.e., the opposite end of the sterile cotton-tipped swab) does not break as often as toothpicks. The longer applicator stick also appears to minimize contamination of the GCMB plate with *Staphylococci* sp. Therefore, if using toothpicks, wear gloves. Minimize the time the stock vial is held to limit the warming of the vial. The expected viability of gonococcal frozen stocks is not as high as with most other organisms, and the viability decreases with freeze-thaw cycles. This lower viability often necessitates the use of a larger inoculum.

Maintaining anaerobic chamber

Keeping it dry

It is critical to keep the interior of the anaerobe chamber dry. Anaerobic conditions are usually generated by using a palladium catalyst to enhance the reduction of oxygen by hydrogen to form water. The water must be removed from the surface of the catalyst to allow for continued reduction of oxygen. This is often achieved through the use of desiccants. It is very important to maintain the desiccant and catalyst according to manufacturer's directions. Most desiccants have a color indicator that can be used to judge the degree of saturation. Regenerating (usually by baking in an oven or vacuum oven)

the desiccant as soon as the color indicator shows any sign of change is recommended, while the palladium catalyst is dried in a similar manner, at least weekly.

This need for dry conditions means spills in the anaerobe chamber must be cleaned immediately. Spills of media can be as damaging to the functioning of the chamber as spills of cultures. Thus, all chambers should contain disinfectant, either 10% bleach or 70% ethanol in a squeeze bottle, along with towels for blotting and biohazard bags to facilitate removal of contaminated materials through the entry portal.

Measuring function

It is recommended to measure proper functioning of the anaerobe chamber. This can be done by the use of a combined hydrogen and oxygen monitor or anaerobic indicator strips. The use of a dual monitor allows for the assessment of chamber function (oxygen level) as well as monitoring the reducing agent (hydrogen). If sufficient levels of hydrogen are present, the oxygen will be reduced if the palladium catalyst is active. This information aids in troubleshooting of the system if anaerobic conditions are not achieved. Anaerobic indicator strips, which contain methylene blue, are available from BD as part of the GasPak systems. The anaerobic strips become decolorized after 4 to 6 hr in anaerobic conditions.

GCMB Solid Medium

Plate media used for clinical isolation of *N. gonorrhoeae*, including Thayer-Martin, modified Thayer-Martin, Lewis-Martin, and GC-Lect, are chocolate-based media that contain antibiotics to inhibit growth of yeast and bacteria other than gonococci. Most research laboratories use a commercially prepared base media (Difco GC medium–based or BBL GC- or BBL GCII agar–based) for their studies. These recipes are all very similar, using an enzymatic digest of meat proteins or a combination of milk and meat proteins as sources of nitrogen and amino acids. They also include corn starch to bind free fatty acids released by growing gonococci, as these tend to inhibit gonococcal growth at high concentrations. Di- and mono-potassium phosphates are used to buffer the pH of the medium with sodium chloride to maintain osmotic balance. Agar is included in these preparations at a final concentration of 1%, which is a lower concentration than used for most plate media, but empirically determined to enhance the isolation of *N. gonorrhoeae*. See the BD Website (*http://www.bd.com*), maintained by the manufacturer of both Difco and BBL products, for further information on these products.

General considerations

The following is a list of useful tips for preparing GCMB solid medium for culture of *N. gonorrhoeae*.

1. It is important to completely mix GC base media with water prior to autoclaving, as clumps of media stuck to the container tend to burn during the autoclave cycle. Likewise, it is important to remove GCMB from the autoclave at the end of the cycle. Leaving it in the hot autoclave for a prolonged time tends to damage critical components in the media, and the resulting plates will not support gonococcal growth. The soluble corn starch in the media tends to form small flecks. This is not unusual and may be mistaken for contamination. Check by incubating a plate at 37°C to see if the flecks increase in size, as would be expected for microbial contamination.
2. The GC base medium is relatively viscous, so bubbles formed by shaking or vigorous stirring will persist. These bubbles are often the size of the gonococcal colonies and can make it difficult to evaluate growth, especially if performing colony counts. Adding a stir bar to the medium prior to sterilization allows for thorough but gentle

mixing of GC base components prior to pouring plates, as well as mixing supplements added after autoclaving.

3. Supplements are aseptically added after the autoclaved medium has cooled to 55°C. This serves to prevent thermal inactivation of components, as in the case of Kellogg's and certain antibiotics. The Kellogg's supplement, which is stored at 4°C, also needs to be prewarmed so the 4°C solution will not cause localized gelling of the agar.
4. Taping or holding a large stir bar to the outside of the medium container during pouring of the plates will prevent the stir bar in the medium from sliding around in the container, which tends to generate bubbles.

Kellogg's supplement

Douglas S. Kellogg, among others, examined the correlation of colony morphology with virulence. Since colony morphology is dependent on growth media, these studies often included comparisons of media and the effects of different supplementation on *N. gonorrhoeae* growth. One supplement formulation was found to enhance the growth of all tested strains and is now identified as Kellogg's supplement (Kellogg et al., 1963). Often, 500 ml of Kellogg's supplement is made and dispensed into aliquots of multiple bottles during filter sterilization. Kellogg's supplement can be easily contaminated, thus preparing smaller aliquots limits loss due to inadvertent exposure. This 100× solution can be stored at least 6 months at 4°C without loss of activity. The solution is close to saturation for glucose, which makes it somewhat difficult to prepare. It is important to use a large (1-liter) beaker and stir bar to quickly help the glucose into solution and to add the glucose slowly, allowing it to go into solution before adding more. If too much is added at once, the glucose will form a rock-like clump on the bottom of the beaker, which will take a long time to go into solution. Patience is required.

Chemically Defined Medium (CDM)

General considerations

In some cases, it is desirable to determine the exact nutrient requirements of a given strain or to manipulate the type of iron source that can be utilized by a particular strain. The chemically defined medium (CDM) is made from a mixture of several solutions that are prepared and sterilized independently (Morse and Bartenstein, 1980). The CDM stock is often made at 2× concentration, which allows it to be diluted 1:1 with sterile, distilled, deionized water for broth, or 1:1 with sterile 2% to 4% agar for plates. It is recommended to use a high-quality agar to preserve the known concentration of the various components.

While this is a chemically defined medium, it is not a minimal medium and will support the growth of many microbes. Thus, it is advisable to either prepare the exact amount needed, plus allowance for errors, or dispense the 2× CDM into commonly needed volume aliquots during the filter sterilization process.

Iron

Chemically defined medium is often used to test the effect of individual components on bacterial growth. Iron is often a limiting factor in bacterial growth. Thus, testing various types of iron sources addresses the ability of pathogens to utilize iron from the human host.

There are many potential sources of iron that can be used to supplement CDM. Two commonly used iron sources are ferric chloride ($FeCl_3 \cdot 6H_2O$) and ferric nitrate ($Fe(NO_3)_3 \cdot 9H_2O$). Regardless of the source, a 10 mM stock solution, used at a final concentration of 0.01 mM can be tested with 1× CDM. See Reagents and Solutions for recipes.

Solid medium

It is important to use a high-quality agar when preparing solid medium, such as low-EEO agar for IEF immunological assays, or Noble agar, to prevent the introduction of trace chemicals often found in less-purified preparations.

CDM plates may be soft. It is acceptable to increase the final agar concentration to 2% (w/v) and to chill the plates after pouring to enhance gelling. Warm the hardened plate to room temperature before using to plate *N. gonorrhoeae*.

BASIC PROTOCOL 1

AEROBIC GROWTH OF *N. GONORRHOEAE* ON STREAK PLATES

Most laboratory strains of *Neisseria gonorrhoeae* will form colonies between 0.5 and 2.0 mm in diameter on GCMB plates following overnight incubation with 3% to 10% CO_2 at 37°C. However, a high proportion of cells that have reached stationary phase will be dead due to autolysis, which occurs in gonococci at an accelerated rate following the exhaustion of glucose. Thus, there are some factors that aid in the selection of a high proportion of viable cells for additional studies.

Since the viability of the initial inoculum is often low, it usually is not necessary to heat sterilize the loop between spread-quadrants to achieve isolated colonies. It is also very likely that cells in well-isolated colonies that are 1 to 2 mm in diameter are primarily dead. Experience has shown that the highest viability of cells is found in the colonies that are very close together but not confluent (see Fig. 4A.1.4). These cells were not

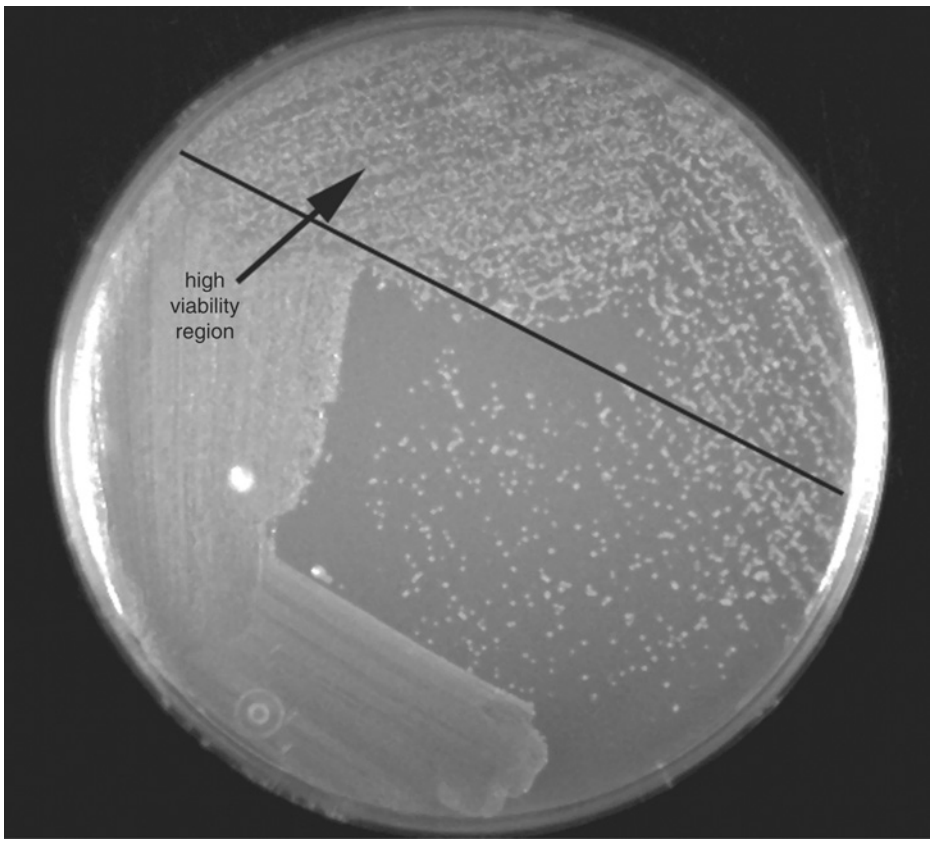


Figure 4A.1.4 Overnight growth of *N.gonorrhoeae* strain F62 on GCMB plate. The ~16-hr culture of F62 shows regions of colony growth that are considered very closely spaced but not confluent. Cells in these colonies tend to have high viability and thus are preferred for use in subsequent experiments.

able to grow as fast as those that produced well-isolated colonies, due to competition for nutrients. Thus, the majority of cells in these small but not confluent colonies have not yet reached stationary phase, and maintain viability. The ability to grow large numbers of viable colonies on plates is critical, as broth cultures of gonococci will not survive an overnight incubation. Thus, scraping cells off plate cultures is the only method to generate large numbers of gonococci for study.

Materials

Gonococci inoculum
GCMB plates (see recipe for GCMB solid medium), at room temperature

Microbiological loop or sterile cotton-tipped applicator
37°C incubator with 3% to 10% CO_2 flow or CO_2-generating GasPak or candle jar (Wheaton cat. no. W216938) with candle
Sterile wooden applicators (opposite end of cotton-tipped swab) or flat tooth-picks, sterilized

1. Using a sterile loop or cotton-tipped applicator, place a small inoculum of gonococci on the edge of the medium. Spread to cover no more than 1/6 of the plate, keeping it near the edge.

2. Without heating the loop, start the second quadrant streak, entering the initial inoculum multiple times. Turn the plate and repeat two times to streak the entire plate. See Figure 4A.1.5.

   Oftentimes, it is not necessary to perform the standard microbiological four-quadrant streak method (see APPENDIX 4A), as there are few colonies found in the fourth quadrant. Thus, depending on the style of the individual, streaking in thirds often generates more viable gonococcal colonies per plate.

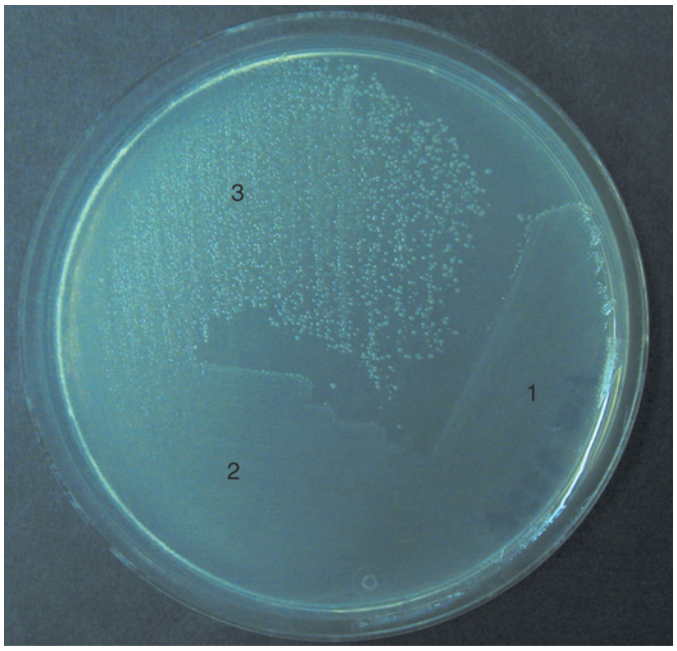

Figure 4A.1.5 Optimal streaking pattern for *N. gonorrhoeae* studies. Standard microbiological plating instructions are designed to provide well-isolated colonies. Since *N. gonorrhoeae* rapidly die following localized depletion of glucose due to rapid growth, streaking patterns are modified to increase the regions of growth constrained colonies to provide a large number of colonies with high viability.

3. If using the cotton-tipped swab, turn the applicator to use a fresh portion of the tip to streak out each of the remaining quadrants.

4. Invert the plates and incubate overnight at 37°C with 3% to 10% CO_2.

   The gonococcal growth will be viable the next day, but the viability will decline rapidly over the next 12 to 24 hr, depending on the strain. It is best to use fresh gonococcal plate cultures for each day.

   A technique to generate large amounts of small but not confluent colonies is to sub-culture late in the afternoon. Spread the initial inoculum, followed by filling the rest of the plate with tightly spaced streaking, each entering the initial inoculum. The majority of these colonies will be small but not confluent if used within 15 to 18 hr of growth. The relatively short incubation time coupled with the close spacing of the cells, to generate competition, will result in a high proportion of the growth with good viability.

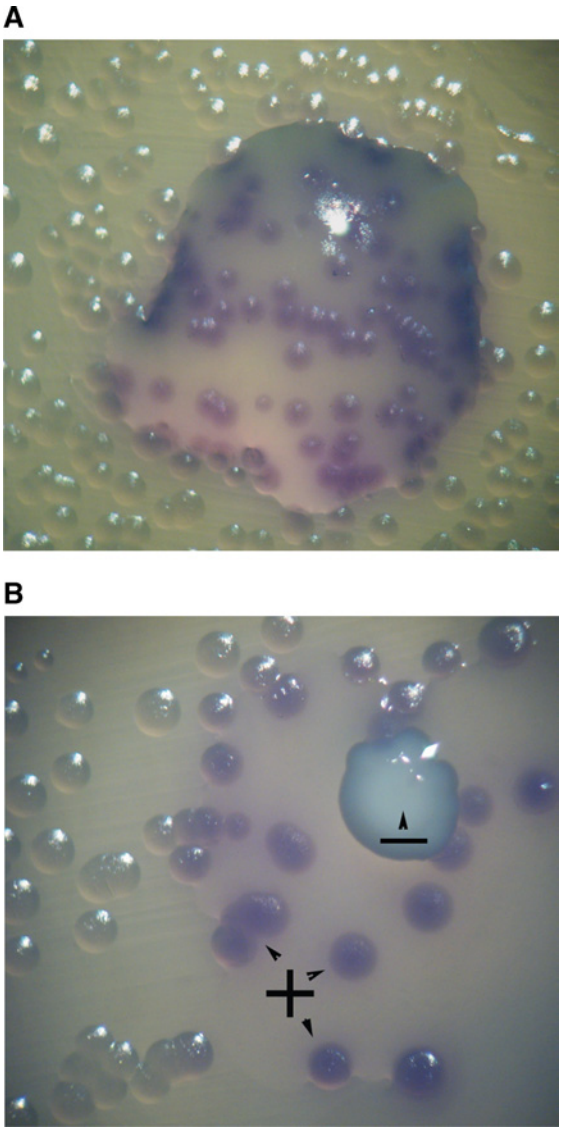

Figure 4A.1.6 Oxidase assay used for presumptive identification of *Neisserial* colonies. **A** shows a GCMB plate of *N. gonorrhoeae* with a small drop of tetramethyl-*p*-phenylenediamine solution. The oxidase-positive colonies rapidly turn pink-purple. **B** shows both oxidase-positive (+) and oxidase-negative (–) colony types. This presumptive assay is used to identify oxidase-positive colony types. Note that tested colonies cannot be used for subculturing or other assays but serve to confirm that a particular colony morphology type has a high probability of being *N. gonorrhoeae*. For a color version of this figure, see *http://www.currentprotocols.com*

OXIDASE TEST

SUPPORT PROTOCOL 1

Colony morphology can vary significantly in *N. gonorrhoeae*, and can be mistaken for contamination by other organisms. A quick method to presumptively identify a colony as *N. gonorrhoeae* is the oxidase test. A freshly prepared 1% di- or tetramethyl-*p*-phenylenediamine solution will react with *Neisseriae*, and turn the colony color pink to purple (see Fig. 4A.1.6). This rapid assay can be performed in a variety of ways. A colony can be picked up onto a swab and then a drop of reagent is applied directly onto the colony on the swab and monitored for color change. Alternatively, a small amount of the reagent can be added directly to the questioned colony type on the culture plate, being careful to limit the spread of the reagent on the plate. Once an oxidase-positive colony type has been identified, the other identical colonies on the plate from non-tested regions can be used with high level of assurance that they are *N. gonorrhoeae*. While some protocols call for a freshly prepared 1% solution, a toothpick full of di- or tetramethyl-*p*-phenylenediamine in 0.5 ml deionized water in a microcentrifuge tube has been found to work well. In addition, some methods require DMSO to solubilize di- or tetramethyl-*p*-phenylenediamine and 2 to 3 days bacterial growth; these protocols are not specific for GC, which are strongly oxidase positive.

CATALASE TEST

SUPPORT PROTOCOL 2

A common contaminant that gives rise to colonies very similar in appearance to GC is *Streptococcal* sp. A rapid method to distinguish these contaminants from GC is the catalase test, as GC are strongly catalase positive while *Streptococcal* sp. are catalase negative. Catalase is a protective enzyme that converts hydrogen peroxide into water and oxygen. In this very simple test, a drop of hydrogen peroxide (3% to 30%) is placed onto a slide and a sample of colony is dragged through this drop, and the immediate formation of bubbles indicates the presence of catalase (see Fig. 4A.1.7). Care must be taken if the colony is obtained from blood or chocolate plates as erythrocytes contain catalase and carryover from medium can give rise to a false-positive test.

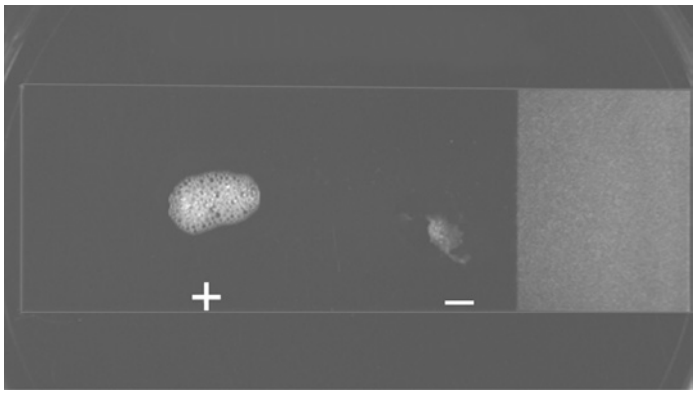

Figure 4A.1.7 Slide catalase assay. Samples of two different colonies were spread on a glass microscope slide. A drop of hydrogen peroxide was placed on each streak. Note the extensive bubbling from the *N. gonorrhoeae* (+) sample.

ESTABLISHING BROTH CULTURES FOR THE AEROBIC GROWTH OF *N. GONORRHOEAE*

BASIC PROTOCOL 2

The growth of *N. gonorrhoeae* in broth requires special consideration. The medium (GCP) is equivalent to GCMB but without agar. Since most shaking incubators are in ambient air, the CO_2 requirement is provided by adding sodium bicarbonate to the broth. *N. gonorrhoeae* may not be well-suited for growth in liquid, as it is a pathogen of mucosal surfaces. This is reflected as poor growth in broth cultures relative to most organisms.

Broth cultures require a relatively high initial inoculum, which may be related to the need for CO_2, as the time in lag-phase is dependent on CO_2 concentration (see Strategic Planning for a discussion of CO_2 conditions). In addition, the growth pattern of different gonococcal strains varies, depending on the expression of pili and other surface adherence factors. Thus, some strains will generate smooth suspensions while others tend to form grainy cultures.

Materials

Supplemented GCP (see recipe)
Overnight plate culture of *N. gonorrhoeae* (see Basic Protocol 1)

3- to 10-ml sterile tubes
Sterile culture flask (volume five times that of broth culture)
Sterile cotton-tipped swab
Spectrophotometer capable of reading at 600 nm and cuvettes
37°C shaking incubator

1. Transfer 1 to 3 ml of supplemented GCP into a 3- to 10-ml sterile tube, and the desired amount into the culture flask.
2. Use a sterile cotton-tipped swab to remove gonococci from the overnight plate(s).

   Be sure to use the small but not confluent colonies from the overnight plate culture to ensure high viability in the inoculum. Some prefer to pre-moisten the swab in the GCP before scraping up the gonococci, as it may make it easier to resuspend the cells from the swab.

3. Vigorously agitate the swab in the tube containing the 1 to 3 ml GCP to create an inoculating suspension of gonococci.

   Do not use a tube that is filled more than 1/3 total height by the GCP, as head-space is needed to allow for vortexing without splashing the gonococcal suspension out of the tube. A capped tube is highly preferred for extra protection.

4. Vortex the suspension at high speed to make a smooth mixture of the gonococci, taking precautions to avoid splashing.
5. Add the inoculating suspension, in small additions, to the GCP in the culture flask until the desired density is reached.

   Many strains of gonococci will not grow if the initial concentration of gonococci, as measured by OD_{600} of the culture, is <0.1, and some may require much higher initial inoculums. Keep the volume of culture to no more than 20% of the flask volume to ensure appropriate aeration of the culture. Successful exponential growth of F62 with initial starting cultures at $OD_{600} = 0.07$ to 0.09 has been obtained, reaching mid-log ($OD_{600} = 0.5$) within 2.5 hr growth.

6. Place the flask on a 37°C shaking incubator at relatively high speed (200 to 250 rpm).
7. Allow the culture to grow until the desired density is reached. Acquire intermediate OD_{600} readings (every hour) to ensure that the culture is growing appropriately, i.e., starting exponential phase within 3 hr of growth.

   The culture will start to lyse if allowed to go into stationary phase for any length of time (often within 1 hr). For the laboratory strain F62, OD_{600} readings of 1 to 1.2 are typical of early stationary phase. The length of time in which it takes a broth culture to reach this level of growth depends both on the strain and on the viability and size of the initial inoculum. Quite often, stationary phase is obtained within 8 to 10 hr of growth from an initial culture OD_{600} of ~0.1. Failure to enter exponential growth may indicate that the initial inoculum was too small, or that its viability was low.

8. Subculture growing broth cultures into fresh complete GCP, however, avoid over-diluting new cultures. Keep the density over $OD_{600} > 0.05$, usually no more than a 1:20 dilution. Grow with shaking at 37°C.

ANAEROBIC GROWTH OF *N. GONORRHOEAE* ON SOLID MEDIUM

BASIC PROTOCOL 3

N. gonorrhoeae was long believed to be an obligate aerobe until it was discovered that nitrite could serve as a terminal electron acceptor, allowing growth under anaerobic conditions (Knapp and Clark, 1984). A technical problem was how to effectively deliver a sub-lethal dose of nitrite. The solution was to place the nitrite on a disc and allow it to diffuse into the medium. This generates a gradient of nitrite in the medium and allows the gonococci to 'select' the preferred concentration for growth. This technique is detailed here.

An effective method to grow *N. gonorrhoeae* anaerobically in broth has not yet been discovered. There have been studies using microaerobic broth, established by either completely filling the culture container with broth (to minimize air space) or capping the culture or by initiating the culture aerobically, then stopping all agitation of the culture (Knapp and Clark, 1984). This loss of motion coupled with the poor solubility of oxygen in liquids will establish an oxygen gradient in the culture. Neither system has been particularly reproducible, therefore, they are not provided in this unit. Contact the authors for more information concerning these techniques (ginny-clark@urmc.rochester.edu).

Materials

GCMB solid medium (see recipe)
Fresh (1-day-old) *N. gonorrhoeae* plate culture
GCP broth (see recipe; non-supplemented GCP is suitable for the temporary resuspension of GC)
70% ethanol
20% sodium nitrite solution, sterilized (see recipe)
100-mm plates
3- to 10-ml sterile tubes with caps
Sterile cotton-tipped swabs
Sterilized glass spreaders (*APPENDIX 4A*)
Tweezers or forceps
Bunsen burner
Paper discs, $\frac{1}{2}$-in. diameter, sterilized (Schleicher and Schuell 740-E)
Anaerobe chamber containing 37°C incubator (highly preferred) or 37°C incubator with H_2/CO_2-generating GasPak (BBL) (BD cat. no. 260678)

1. Pour thick GCMB plates using ~30 ml GCMB solid medium per 100-mm diameter plate (~30 to 36 plates per liter).

   It is important to use fresh (1-day-old), room-temperature, thickly poured GCMB plates, as the anaerobic environments tend to be dehydrating, and normal GCMB plates dry out too much to support gonococcal growth. Allow plates to sit on the benchtop overnight, do not bag or refrigerate.

2. Start a subculture of the gonococci, grow overnight aerobically on GCMB (see Basic Protocol 1).

   Results are more reproducible if the gonococci have been subcultured at least once from frozen stock.

3. Place 1 to 3 ml GCP into a 3- to 10-ml sterile tube, preferably one with a cap.

4. Use a sterile cotton-tipped swab to remove the small but not confluent colonies from the overnight aerobic plate culture of gonococci.

   If the swab is pre-moistened in the GCP before scraping up the gonococci, it may be easier to resuspend the cells from the swab.

5. Vigorously agitate the cotton-tipped swab with gonococci colony in the tube containing the 1 to 3 ml GCP to produce an inoculating suspension of gonococci.

6. Vortex the suspension at high speed to create a smooth mixture of the gonococci, taking precautions to avoid splashing.

   It is desirable to have the concentration at an OD_{600} of ~1.0 to 1.5.

7. Add 100 µl of the gonococci suspension to each plate. Evenly distribute the inoculum by spreading with a sterile glass spreader.

   This method is preferred because spreading the gonococcal suspension with a swab often scratches the medium. These scratches make recovery of the anaerobically prepared gonococci more difficult, as the organisms appear to stick in the scratches.

   Alternatively, heavily inoculate the plates by dipping a fresh, sterile swab into the gonococcal suspension and use it to spread a heavy inoculum evenly across the fresh GCMB plate.

   Spread the inoculum over the plate by streaking the wet swab completely over the plate in one direction, turn the plate 120° and spread again, then turn and spread a third time. This will provide an even suspension of gonococci on the plate. A wet swab is used to limit scratches in the medium and provide a suitable number of gonococci. Allow the plates to dry until the gonococcal suspension is completely absorbed.

8. Dip the tweezer tips into 70% ethanol and flame to sterilize.

9. Use the tweezers to place a sterile $^1/_2$-in. diameter paper disc onto the center of the inoculated GCMB plate.

   Gently tap the disc onto the surface with the tweezers tip to achieve good contact with the medium. This is beneficial if the medium surface is very wet and the disc is sliding on the inoculum. Alternatively, tap the disc onto the plate with a pipet tip used to dispense the nitrite solution.

10. Slowly place 40 µl of 20% sodium nitrite solution onto the paper disc.

    Care must be taken to avoid adding the fluid faster than the disc can absorb it, or the disc will float on the surface of the liquid and shift position on the plate. It is also important to add the nitrite to the disc before it absorbs too much water from the medium, which then limits nitrite absorption. Setting discs onto no more than five to ten plates before adding nitrite is recommended. Allow the nitrite to fully absorb into the disc prior to inverting the plates to prevent the discs from moving.

11. Place all the prepared plates (inverted) into the container for incubation in the anaerobe chamber and load into the entry portal. Alternatively, place the inverted plates into the GasPak container, and activate the H_2/CO_2-generating GasPak.

    In some cases, the gas flow into the entry portal is fast and can move the items in the portal. If the plates are in a container, they are less likely to be tipped. However, make sure the lid is placed on the container in an offset manner, as the lid can become vacuum sealed to the container during the evacuation portion of the cycle. A permanent solution to the vacuum-lock problem is to place a small hole in the lid of the container to allow for gas exchange.

12. Cycle entry portal to switch the atmosphere to 85% N_2, 10% H_2, and 5% CO_2, according to manufacturer's instructions.

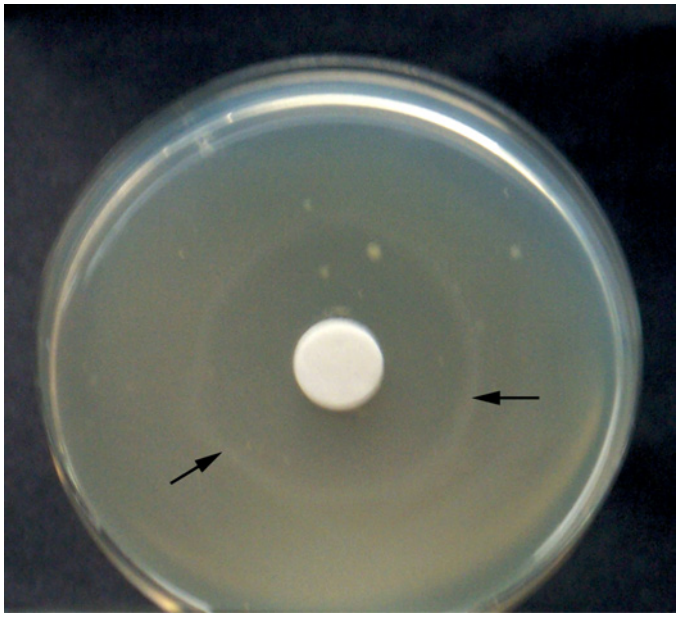

Figure 4A.1.8 Plate of anaerobically grown *N. gonorrhoeae*. A GCMB plate was inoculated with *N. gonorrhoeae* and incubated anaerobically as described in Basic Protocol 3. Arrows indicate the ring of strong *N. gonorrhoeae* growth at the optimal nitrite concentration surrounding the paper disc. Note how the region between the disc and the denoted growth ring is clear and devoid of growth. *N. gonorrhoeae* growth typically extends outward beyond the ring of optimal growth for ~0.5 to 1 in. This is best observed by tipping the plate to find the optimal lighting to show the differences in the medium surface reflectivity due to bacterial growth.

13. Open the internal portal door, remove the plates from the entry portal and place in the 37°C incubator.

    Placing the plates into a container allows easier group handling in the glove box. The container also helps to limit dehydration of the plates during incubation.

14. Check for growth in 24 to 42 hr, depending on the gonococcal strain.

    The anaerobic growth of gonococci does not take the form of colonies, but rather appears as a hazy ring of growth somewhere between the nitrite disc and the outside edge of the plate (Fig. 4A.1.8). This growth is very light and is often discernable as a change in the reflective nature of the medium surface. The nitrite diffuses from the disc and creates a radial concentration gradient in the medium. The area nearest the disc has a lethal concentration of nitrite, so there will be no gonococcal growth near the disc. The gonococci will grow at the optimum nitrite concentration, below toxic levels but yet sufficient to adequately serve as the electron acceptor; see Figure 4A.1.8.

SUBCULTURING ANAEROBIC CULTURES

BASIC PROTOCOL 4

In some cases, it is desirable to regrow the gonococci under anaerobic conditions. Experience has shown that certain measurements of gonococcal physiology are much more consistent when performed on gonococci subcultured anaerobically three times. Thus, it may be important to determine the consistency of the gonococcal behavior as related to anaerobic growth. While it may be preferred to keep gonococci under anaerobic conditions at all times once grown anaerobically, it may be necessary to perform the actual subculture on the benchtop, as would be the case if using the GasPak anaerobic system. Aerobic subculturing of anaerobically grown gonococci often shows no detrimental effect, although this should be tested for any given procedure. It is important to perform the subculture quickly and return the plates to anaerobic conditions. If many plates are involved, the workload should be divided into small units so any given plate is rapidly returned to anaerobic conditions.

Set up the anaerobe chamber so that the instruments and reagents are easily reached. The working space in the anaerobe chamber is often limited, so it is important to maintain a clutter-free area for viewing and manipulating the cultures.

Materials

24- to 42-hr anaerobic gonococcal culture
GCP stock (see recipe)
GCMB plates (see recipe for GCMB solid medium)
20% sodium nitrite solution, sterilized (see recipe)
Squeeze bottle with 70% ethanol or 10% bleach

Anaerobe chamber containing 37°C incubator stocked with:
Pipets and sterile tips
Waste container lined with biohazard bag
Sterile swabs
Paper discs, ½-in. diameter, sterilized (Schleicher and Schuell 740-E)
Tweezers or forceps
Rack to hold tubes, tweezers, marker
Pipet aide
Container for holding inoculated plates
Lab-wipes or paper towels
3- to 5-ml sterile tubes
Mechanical vortexer
Individually wrapped sterile glass spreaders or disposal sterile plastic
Bacteriological loops, optional

1. Remove 24- to 42-hr anaerobic gonococcal plate cultures from the incubator, and identify the ring of gonococcal growth on each plate.
2. Place 1 to 1.5 ml GCP stock broth into a 3- to 5-ml sterile tube.
3. Use a sterile swab to remove the growth ring and resuspend gonococci in the tube containing GCP stock. Agitate swab vigorously and vortex to create a smooth suspension of gonococci, being careful to avoid splashing.
4. Add 100 µl of this GC suspension to a fresh thickly poured GCMB plate.
5. Gently spread with a fresh sterile swab, evenly spreading the suspension in three directions as described in Basic Protocol 3, step 7.

   Alternatively, use autoclaved, individually wrapped glass spreaders or pre-sterilized plastic spreaders. Glass spreaders cannot be sterilized by dipping in ethanol and burning off the alcohol, as the anaerobic environment will not support a flame, therefore, place a sufficient number of sterilized glass spreaders in the chamber for the procedure. One spreader can be used to spread multiple plates inoculated with the same gonococcal suspension if care is taken to avoid contamination.

   An alternative is to use sterile disposable bacteriological loops. These plastic loops can be bent into spreaders by gently pressing the loop end onto the inside of the plate top. This will cause the thinner, ~2 to 3 in. of the loop end to bend at an angle to the handle, which can then be used to evenly spread the inoculum.

6. Prepare the desired number of plates.

   Approximately eight to ten new plates are obtained from every overnight anaerobic culture plate.

   The rate of anaerobic growth is much slower than aerobic growth. To approximate the number of anaerobic plates needed for a given protocol, assume that under anaerobic conditions, 5% to 10% of the gonococci will be obtained as compared to aerobic growth.

7. Use the tweezers to place a sterile paper disc onto the center of the inoculated GCMB plate. Tap to set the disc.

   The tweezers must be sterilized to avoid contaminating the plates. Options include the use of a ceramic incinerator to heat-sterilize the tweezer tips in the anaerobe chamber or to sterilize the tweezers prior to entering the anaerobe chamber, and maintaining sterility by placing them into sterile tube.

   Do not add the discs to too many plates at once, as the paper will absorb water from the inoculated plate. Once the paper is saturated, it cannot absorb the nitrite solution, which will then run out onto the plate.

8. Slowly add 40 μl of 20% sodium nitrite solution onto the paper disc.
9. Let the 20% sodium nitrite solution absorb into the disc before inverting plates so that the disc does not slip from the center of the plate.
10. Invert plates and place into the incubator for 24 to 42 hr.

    A quick and easy way to place inverted plates into the container is to place the container lid on the floor of the anaerobe chamber, top down. Place the plates on the lid, right side (tops) up. Place the bottom of the container over the plates and onto the lid. Slide a hand under the lid and carefully turn the container right-side up. This works best if the plates fill the container. If there are not enough to fill the container, add empty plates to the stack.

LONG-TERM STORAGE OF *N. GONORRHOEAE*

BASIC PROTOCOL 5

In this respect, the maintenance of *N. gonorrhoeae* differs the most from other microbes, as long-term in the *Neisserial* world refers to anything over 2 days. Laboratory stocks of *N. gonorrhoeae* are frozen (−70° to −80°C) in a 25% glycerol solution. Preparing *N. gonorrhoeae* strains for long-term storage is a very easy process, which is advantageous since it needs to be performed quite often. Since *N. gonorrhoeae* modulates its surface features quite frequently through both phase and antigenic variation, it is important to freeze the representative mixture of gonococcal colony types for that particular strain, and to return to this original stock for fresh working material. As the original frozen stock vial is removed and returned to the freezer on a weekly basis, it is important to keep both the original stock vial frozen at all times, and to prepare multiple stock vials from the original stock, taken from an early passage with a representative mixture of colony types.

Variations in piliation and expression of opa proteins give rise to significant differences in colony morphology (see Fig. 4A.1.9). It is often desirable to maintain the complete range of colony types in stock cultures. However, the efficiency of transformation is substantially higher in piliated strains, thus their inclusion in stock cultures is essential if the strain is to be used for genetic experiments. While it is possible to select for non-piliated variants from a predominantly piliated stock, in many strains, the reverse is not feasible, as loss of pili is often due to loss of the pilin expression site (P_E) in the chromosome. See *UNIT 4A.3* for information on discriminating piliated from non-piliated *N. gonorrhoeae*.

Never allow the frozen stock sample to thaw, as the viability of the gonococci will rapidly decline. Always place the frozen stock vial in dry ice when taken out of the freezer, and minimize the time that the vial is held in hand to limit thawing while removing samples to maintain a suitable viability of the stock culture. When the viability appears to be significantly diminished, either switch to a second stock vial or prepare additional stocks from a fresh culture prepared from the original stock.

Materials

GCP stock (see recipe)
18- to 24-hr culture of *N. gonorrhoeae*
50% glycerol (see recipe), autoclaved
Dry ice

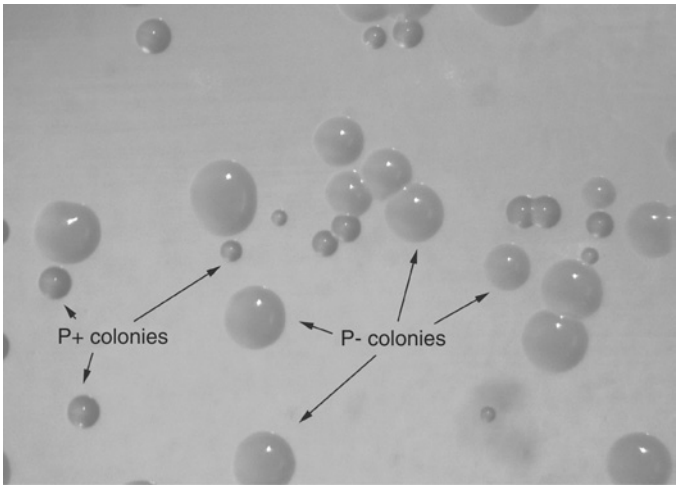

Figure 4A.1.9 Photograph of piliated and non-piliated *N. gonorrhoeae*. Pilin expression can undergo phase variation and is reflected in variation in colony morphology. Piliated (P+) cells form colonies that tend to be smaller, taller, and darker (gumdrop-like) when viewed under a stereoscope while non-piliated (P–) cells form colonies that take a flatter, more wafer-like appearance (Kellogg et al., 1968).

3- to 5-ml sterile tubes
Sterile swab
Spectrophotometer and cuvettes
2-ml cryovials, sterilized
Ice bucket or other suitable container for holding dry ice

1. Place ~2.5 ml of GCP stock broth into a 3- to 5-ml sterile tube.
2. Dip a sterile swab into the GCP stock and rim the swab on the inside edge of the tube to wring out excess broth.
3. Use the wet swab to collect the gonococci colonies from the 18- to 24-hr *N. gonorrhoeae* culture plate, collecting the small but not confluent colonies from the culture.
4. Resuspend the gonococci into the GCP stock broth. Repeat if necessary until the approximate density of the gonococci suspension is equivalent to an $OD_{600} = 1$.
5. Label a cryovial tube using an indelible marking pen.

   It is very difficult to write on frozen tubes, so label first.
6. Add 0.75 ml of sterile 50% glycerol to the cryovial.
7. Add 0.75 ml of gonococcal suspension to the cryovial, cap, and vortex to mix.

   This generates a 25% glycerol suspension of gonococci at an ~OD_{600} of 0.5.
8. Place the cryovial into pulverized dry ice to snap-freeze the sample.

   An ethanol- or acetone-dry-ice mixture can also be used to snap freeze the sample, but the organics tend to remove the ink labeling from the cryovial.
9. Place the frozen sample at –70° to –80°C.

   How long any given stock remains viable varies significantly with the quality of the initial frozen culture, the number of times the frozen stock is accessed, and the degree of thawing that occurred with each handling. Viable N. gonorrhoeae from frozen stocks that were well over 10 years old have been retrieved.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acid-soluble amino acid solution

Dissolve 540 mg L-cystine in 50 ml 1.0 N HCl. Store up to 6 months at −80°C. Discard if precipitates form upon thawing.

Base-soluble essential component solution

To 100 ml of 1.0 N NaOH, add:
750 mg L-hypoxanthine
1065 mg L-tyrosine
1200 mg L-tryptophan
750 mg uracil
Mix until dissolved
Store up to 6 months at −80°C

Calcium chloride, 250 mM

Add 367 mg $CaCl{\cdot}2H_2O$ to 100 ml ddH_2O. Mix to dissolve. Filter sterilize (0.22-μm filter) and store up to 1 year at room temperature.

CDM, 2×

For 1 liter, mix the following:
50 ml CDM stock solution 1 (see recipe)
360 ml CDM stock solution 2 (see recipe)
20 ml CDM stock solution 3 (see recipe)
40 ml CDM stock solution 4 (see recipe)
50 ml 20% (w/v) glucose solution (see recipe)
Add ddH_2O to 800 ml total volume
Adjust pH to 7.4 with 10 N NaOH
Add 2 ml 10 mM ferric chloride ($FeCl_3{\cdot}6H_2O$) or ferric nitrate ($Fe(NO_3)_3{\cdot}9H_2O$) (see recipes)
Add ddH_2O to a final volume of 1 liter
Add 2 ml 250 mM $CaCl_2$ (see recipe; final concentration 0.25 mM)
Sterilize by passing through a 0.2-μm filter sterilization system with sterile storage container
Transfer into appropriate aliquots and store up to 1 week at 4°C

Refer to Table 4A.1.1 for a brief explanation of the component stock solutions.

It is important to add the $CaCl_2$ to diluted CDM as it has a tendency to precipitate. Adding 2 ml to 1000 ml does not significantly alter the concentrations of the final medium.

There are many potential sources of iron that can be used to supplement CDM. Two commonly used iron sources are ferric chloride ($FeCl_3{\cdot}6H_2O$) and ferric nitrate ($Fe(NO_3)_3{\cdot}9H_2O$); see Strategic Planning. Regardless of the source, a 10 mM stock solution, used at a final concentration of 0.01 mM can be tested with 1× CDM.

Table 4A.1.1 CDM Stock Solutions and their Purpose

Stock solution	Purpose
CDM stock solution 1	Salts solution
CDM stock solution 2	Amino acid solution
CDM stock solution 3	Vitamins/biotin solution
CDM stock solution 4	Phosphate solution

CDM, liquid

Dilute 2× CDM 1:1 with sterile ddH_2O and add 1/100 volume 4.2% $NaHCO_3$. Prepare fresh.

CDM, solid

For plates, prepare 3% agar (3 g agar to 100 ml H_2O), autoclave, and cool to 55°C. Mix the agar 1:1 with 2× CDM stock (see recipe; warmed to 55°C), then pour plates.

CDM stock solution 1

To 150 ml ddH_2O, add:
58.45 g NaCl
10 g K_2SO_4
2.18 g $MgCl_2 \cdot 6H_2O$
2.2 g NH_4Cl
30 mg EDTA·Na_2
Stir until dissolved and transfer to 250-ml graduated cylinder
Add ddH_2O to 250 ml total volume
Sterilize by autoclaving at standard conditions
Store up to 6 months at room temperature

CDM stock solution 2

Prepare three intermediate amino acids solutions (acid, base, and neutral soluble essential component/amino acid solutions; see recipes) and mix together to make CDM stock solution 2 to accommodate the different conditions necessary to dissolve the various amino acids and other essential components. This is summarized in Table 4A.1.2.

To combine the acid-, base-, and neutral-soluble amino acid solutions: To 2000 ml neutral-soluble amino acid solution, add 50 ml acid-soluble amino acid solution (L-cystine), and 100 ml base-soluble essential component solution. Add ddH_2O to yield 2700 ml total volume. Filter sterilize. Aliquot into 50-ml tubes. Store up to 6 months frozen at –80°C.

A volume of 40 ml per tube is convenient, as 360 ml is needed per liter of 2× CDM.

Avoid repeat freeze-thaw cycles, as the amino acids tend to precipitate and CDM made with precipitated amino acid solution does not support the growth of gonococci.

CDM stock solution 3

Dissolve the following reagents in 300 ml 95% ethanol:
120 mg thiamine·Cl
28.8 mg Co-carboxylase
180 mg biotin
114 mg D-pantothenic acid
Add ddH_2O to yield 600 ml final volume
Filter sterilize using a 0.22-μm filter
Store up to 1 year at –20°C

Refer to Table 4A.1.3 for component concentrations.

CDM stock solution 4

To 100 ml ddH_2O, dissolve:
13.6 g KH_2PO_4 (1 M)
17.4 g K_2HPO_4 (1 M)
Sterilize by autoclaving and store up to 1 year at room temperature

Table 4A.1.2 Components of CDM Stock Solution 2

Component	Amount	Solvent	Stock concentration (mM)	Final concentration (mM)
Acid-soluble amino acid solution				
L-cystine	540 mg	50 ml 1.0 N HCl	240.3	0.15
Base-soluble essential component solution: add following to 100 ml of 1.0 N NaOH				
L- hypoxanthine	750 mg	100 ml 1.0 N NaOH	136.1	0.37
L-tyrosine	1065 mg	100 ml 1.0 N NaOH	181.2	0.39
L-tryptophan	200 mg	100 ml 1.0 N NaOH	204.3	0.39
Uracil	750 mg	100 ml 1.0 N NaOH	112.1	0.45
Neutral-soluble amino acid solution: add all listed amino acids to 2000 ml ddH_2O				
L-alanine	1500 mg	2000 ml ddH_2O	89.9	1.1
L-arginine·Cl	250 mg	2000 ml ddH_2O	210.8	0.71
L-asparagine·H_2O	385 mg	2000 ml ddH_2O	150.1	0.17
L-aspartic acid (K salt)	9.65 g	2000 ml ddH_2O	171.2	3.8
L-cysteine·Cl	825 mg	2000 ml ddH_2O	157.6	0.35
L-glutamic acid (Na salt)	23.3 g	2000 ml ddH_2O	169.1	8.8
L-glutamine	750 mg	2000 ml ddH_2O	146.1	0.34
Glutathione (reduced)	690 mg	2000 ml ddH_2O	307.3	0.15
Glycine	375 mg	2000 ml ddH_2O	75.1	0.33
DL-histidine·Cl·H_2O	375 mg	2000 ml ddH_2O	209.6	0.12
DL-isoleucine	450 mg	2000 ml ddH_2O	131.2	0.23
DL-leucine	1365 mg	2000 ml ddH_2O	131.2	0.69
DL-lysine·Cl	750 mg	2000 ml ddH_2O	182.0	0.27
DL-methionine	225 mg	2000 ml ddH_2O	149.2	0.1
DL-phenylalanine	375 mg	2000 ml ddH_2O	165.2	0.15
L-proline	750 mg	2000 ml ddH_2O	115.1	0.43
DL-serine	750 mg	2000 ml ddH_2O	105.1	0.48
DL-threonine	750 mg	2000 ml ddH_2O	119.1	0.42
L-valine	900 mg	2000 ml ddH_2O	117.2	0.51

Table 4A.1.3 Concentrations of CDM Stock Solution 3

Component	Stock concentration (mM)	Final concentration (mM)
Thiamine·Cl	0.593	0.59
Co-carboxylase	0.104	0.01
Biotin	1.2	0.12
mg D-Pantothenic acid	0.40	0.004

Ferric chloride, 10 mM

Add 27 to 40 mg $FeCl_3 \cdot 6H_2O$ to a 15-ml conical
Divide the weighed amount by the molecular weight (270.3)
Multiply the result by 100, and add that volume of ddH_2O in milliliters
Mix and filter sterilize (using a 0.2-μm filter)
Store in 1-ml aliquots up to 1 year at 4°C

This iron solution is clear yellow. Discard the solution if the yellow color intensifies or if precipitates form, as that indicates that the iron is oxidized and no longer available for gonococcal growth.

Since the amount of ferric chloride needed to make a 10 mM solution is small, weighing out the reagent first and then adding the appropriate amount of ddH_2O to the reagent is recommended.

Ferric nitrate, 10 mM

Add 40 to 60 mg $Fe(NO_3)_3 \cdot 9H_2O$ to a 15-ml conical tube
Divide the weighed amount by the molecular weight (404.0)
Multiply the result by 100, and add that volume of ddH_2O in milliliters
Mix and filter sterilize (using a 0.2-μm filter)
Store in 1-ml aliquots up to 1 year at 4°C

This iron solution is clear yellow. Discard the solution if the yellow color intensifies or if precipitates form, as that indicates that the iron is oxidized and no longer available for gonococcal growth.

Since the amount of ferric nitrate needed to make a 10 mM solution is small, weighing out the reagent first and then adding the appropriate amount of ddH_2O to the reagent is recommended.

GCMB solid medium

Place 18 g GC base medium (Difco), 500 ml distilled, deionized water, and a stir bar into a 1-liter flask or bottle. Place the flask or bottle onto a stir plate to mix. If necessary, swirl to dislodge the medium components from the bottom edges of the container, as they have a tendency to burn during the autoclave cycle. Loosely cap the bottle or cover the flask opening with foil. Autoclave on liquid cycle according to manufacturer's recommendations. Remove the sterile medium from the autoclave. Once it has stopped bubbling, place into a preheated 55°C water bath. At this time, remove the Kellogg's supplement to the benchtop to allow it to warm to room temperature.

After the medium has cooled to 55°C (~30 min, depending on the number of flasks and the size of the water bath), transfer the cooled medium to a stir plate set on low and add 5 ml (i.e., 1/100 volume of the medium) Kellogg's supplement (see recipe). If needed, add antibiotics at this time. Pour plates using ~20 to 25 ml per 100 × 15–mm diameter plate (20 to 22 plates per 500 ml medium). After the plates have completely set and cooled, invert on the benchtop. For long-term storage (>3 days), place the plates into bags and store, inverted, at 4°C. It is convenient to store poured plates in the bags used to package the Petri plates, as they are sterile and the perfect diameter for the plates. However, it is critical to let the poured plates dry before bagging, as the moisture will condense in the cold and can lead to contaminated plates due to the growth of mold, which gets transferred into the plates via water droplets. As a rule, allow poured media to sit at least overnight, and preferably closer to 48 hr before packaging for long-term storage. If plates must be stored early, it may be beneficial to put small vent holes into the Petri dish bags to allow for air flow.

Refer to Strategic Planning for additional details.

GCP stock

To 1 liter of ddH_2O, add:
15 g proteose peptone no. 3 (Difco)
1 g soluble starch
4 g K_2HPO_4
1 g KH_2PO_4
5 g NaCl

Stir until well mixed, ~5 to 10 min. Note that the solution may not be clear, as the starch may not go fully into solution. Distribute the well-mixed medium into 200-ml bottles, filling no more that half-full. Loosely attach the bottle lids and autoclave. When the medium has cooled to room temperature, tighten the lids and store in 100-ml aliquots up to 1 year at room temperature.

Glucose solution, 20% (w/v)

Add 20 g glucose (dextrose) to 100 ml ddH_2O
Stir to dissolve
Sterilize by filtration using a 0.22-μm filter
Store up to 1 year at room temperature

Glycerol, 50% (v/v)

Glycerol stock is very viscous and difficult to measure. Add 50 ml ddH_2O to a 100-ml graduated cylinder. Carefully pour glycerol into the cylinder until the water level rises to the 100-ml mark. Cover the top of the cylinder with Parafilm and invert several times to start mixing. Add a stir bar and continue stirring to fully mix the water and glycerol. Autoclave solution to sterilize. Store up to 1 year at room temperature.

Kellogg's supplement

To 200 ml ddH_2O, slowly add 200 g dextrose (glucose) in portions, and allow each portion to dissolve before adding more. Mix until all the glucose is in solution. Add 5.0 g glutamine, 250 mg ferric nitrate, and ~10 mg Co-carboxylase (Sigma-Aldrich cat. no. C-8754). Continue stirring until all solids have gone into solution. Transfer to a 500-ml graduated cylinder and add ddH_2O to make 500 ml total volume. Return to beaker and stir for additional 5 to 10 min. Filter sterilize using a 0.22-μm filter into sterile bottles. Store up to 6 months at 4°C.

Refer to Strategic Planning for additional details.

Neutral-soluble amino acid solution

Dissolve the following amino acids in 2000 ml ddH_2O:
1500 mg L-alanine
250 mg L-arginine·Cl
385 mg L-asparagine·H_2O
9.65 g L-aspartic acid (K salt)
825 mg L-cysteine·Cl
23.3 g L-glutamic acid (Na salt)
750 mg L-glutamine
690 mg glutathione (reduced)
375 mg glycine
375 mg DL-histidine·Cl·H_2O
450 mg DL-isoleucine
1365 mg DL-leucine

continued

750 mg DL-lysine·Cl
225 mg DL-methionine
375 mg DL-phenylalanine
750 mg L-proline
750 mg DL-serine
750 mg DL-threonine
900 mg L-valine
Prepare fresh and use immediately for CDM stock solutions

Sodium bicarbonate, 4.2% (w/v)

Add 4.2 g $NaHCO_3$ to 100 ml ddH_2O
Stir to dissolve
Sterilize by filtration using a 0.22-μm filter
Store up to 1 year at room temperature

Sodium nitrite solution, 20% (w/v)

Add 20 g of $NaNO_2$ to 100 ml ddH_2O
Stir to dissolve
Sterilize by filtration using a 0.22-μm filter
Store up to 1 year at room temperature

Supplemented GCP

To GCP stock, add:
1/100 volume 4.2% sodium bicarbonate (see recipe)
1/100 volume Kellogg's supplement (see recipe) or IsoVitaleX (BBL; BD cat. no. 211875-211876)
Prepare only the amount needed for the day

COMMENTARY

Background Information

N. gonorrhoeae is an obligate human pathogen that is considered fastidious in its growth requirements. Many of the studies of gonococcal physiology were performed in the mid 1970s, during the peak years of the U.S. epidemic. Gonococci can grow in a glucose-containing medium over a pH range of 6.0 to 8.0, with an optimum pH of 7.0 to 7.5. Their temperature requirements are narrow, with growth through a range of 25° to 41°C, with an optimum of 36° to 39°C, dependent on the variant (Morse et al., 1979). It is recommended that gonococci be incubated with CO_2 at 3% to 10% as CO_2 enhances the development of exponential growth. Thus, CO_2 is necessary to initiate culture growth, but may not be necessary once exponential growth is established. It has long been reported that all gonococci require cysteine (cystine), however, recent studies found that some gonococci can utilize thiosulfate, suggesting that the cysteine supplementation may, in some cases, also serve as a sulfur source. Gonococci can utilize many forms of inorganic iron, including ferric nitrite, ferric chloride, and ferric citrate. They can also use transferrin- and lactoferrin-bound iron in the human host, as well as heme and hemoglobin (reviewed in Schryvers and Stojiljkovic, 1999). *N. gonorrhoeae* can use three carbon sources: glucose, pyruvate, and lactate (Morse and Bartenstein, 1974). Aerobically grown gonococci primarily utilize glucose via the Entner-Douderoff pathway, with minor use of the pentose phosphate pathway (Hebeler and Morse, 1976). When grown on pyruvate, the use of the pentose phosphate pathway accounts for one-third of carbon metabolism.

For many years, *N. gonorrhoeae* was considered an obligate aerobe, even when isolated from mixed infections with other known obligate anaerobic bacteria. However, the gonococcus can grow anaerobically when provided with nitrite as a terminal electron acceptor (Knapp and Clark, 1984). Under anaerobic conditions, the Entner-Douderoff pathway is used exclusively, forming lactate and acetate in equivalent amounts (Morse et al., 1974).

Many clinical gonococcal isolates show some degree of auxotrophy, which necessitates the use of rich media for isolation

and growth. These traits are often used as epidemiological markers. Some auxotroph types are correlated with antibiotic resistance. In addition, an arginine, hypoxanthine, and uracil auxotroph variant (AHU) was associated with higher rates of asymptomatic gonococcal disease. Subsequent work found that recovery of this auxotroph on standard selective media was low, due to its enhanced susceptibility to vancomycin, used as a selective agent in the medium (Morse and Bartenstein, 1980). This growth inhibition delayed diagnosis and early treatment, factors known to contribute to development of complicated gonococcal disease.

N. gonorrhoeae does not survive long at stationary phase, but undergoes autolysis following exhaustion of glucose from the medium (Morse and Bartenstein, 1974). Some of the genes responsible for this process have been identified, and appear to be related both to virulence and the natural competency of *N. gonorrhoeae*. It has been proposed that limited autolysis could play a role in altering the local integrity of the cell envelope to facilitate the uptake of DNA in the transformation process. Autolysis could also generate pools of available DNA for use by neighboring gonococci, as has been experimentally shown for a lytic peptidoglycan transglycoslase, *AtlAI* (Dillard and Seifert, 2001).

Autolysis is an enzymatic process, following first-order kinetics with a pH optimum of 8.5 and temperature maximum of 40°C. Ions have a marked effect on whole-cell lysis, with potassium enhancing and divalent cations, especially magnesium and calcium, inhibiting lysis. Magnesium and calcium limit visible whole-cell autolysis by stabilizing the outer membrane, with no effect on peptidoglycan hydrolysis (Wegener et al., 1977). It is proposed that autolysis is related to the rapid turnover of peptidoglycan of ~20% to 50% (strain dependent) per generation. Gonococci are somewhat unique in that they secrete peptidoglycan fragments into the surrounding medium. These fragments have cytotoxic properties, and are responsible for the selective killing of ciliated cells in the fallopian tube organ culture system, a primary factor in the development of gonococcal pelvic inflammatory disease (Melly et al., 1984).

Critical Parameters and Troubleshooting

While *N. gonorrhoeae* is a fastidious organism, it is not that difficult to grow in the laboratory as long as care is taken to adhere to its basic minimal requirements. These can be divided into media, appropriate inoculum, and incubation conditions.

Media

It is not unusual for *N. gonorrhoeae* strains to have complex media requirements. The GC base medium used for plate cultures is designed for clinical diagnostic studies, and has been formulated to support virtually all gonococcal strains. Most problems related to media are due to the following:

1. Impurities in the water used to make the medium or supplements. It is important to use high-quality distilled deionized (18 Ω) water.

2. Prolonged or overheating of the medium during the autoclaving process, which inactivates critical components in the medium. The medium should be yellow-gold in color. If it appears more amber in color, it may have been overheated at some point in the process.

3. Contamination of the containers in which the medium was prepared. Flasks used for the preparation of GC media must be carefully washed to remove residual starch, and thoroughly rinsed to remove all traces of detergent.

Inoculum

N. gonorrhoeae viability in frozen stock, or from large/older colonies on plates may not be sufficient to initiate strong growth in subsequent cultures. To limit problems of insufficient inoculum, consider the following:

1. Minimize thawing of frozen stock. This can be done by keeping the vial in dry ice, limiting the amount of time the vial is held in the hand, and using a suitably large scraping from the frozen stock.

2. Choose the most appropriate colonies. Use small but not confluent colonies from an overnight culture. As cultures age, the cell viability declines dramatically.

3. Chilling of the culture may decrease viability. Keep gonococcal cultures at 37°C when not in use, as benchtop conditions are below their survivable temperature range.

Incubation conditions

Incubation conditions refer primarily to the environmental conditions surrounding the culture.

1. Sufficient CO_2 for initial growth. Gonococci require CO_2 to initiate growth in both broth and plate cultures. This must be provided in the atmosphere for plate cultures, and by adding sodium bicarbonate to broth cultures.

2. Appropriate temperature range. While *N. gonorrhoeae* can grow over a temperature

range of 25° to 42°C, they strongly prefer body temperatures of 35° to 38°C.

3. Adequate aeration conditions. Unless purposely growing gonococci anaerobically, they prefer a reasonable amount of oxygen for aerobic growth. Broth cultures can be shaken at moderate speeds (200 to 250 rpm), and it is important to limit the culture volume to 20% of flask volume.

Time Considerations

Gonococcal autolysis significantly impacts the laboratory growth of *N. gonorrhoeae*, as cells do not retain viability on culture medium after reaching stationary phase. Thus, planning for any experiment with gonococci must include 1 day to obtain growth from frozen stock along with a second overnight incubation to obtain suitable numbers of viable organisms for experimental purposes. Clones from genetic studies must be recultured for continued viability every 1 to 2 days, thus being able to rapidly analyze clones is necessary for procedures that may require screening of large numbers of colonies for low-frequency events.

Genetic Manipulation of *Neisseria gonorrhoeae*

Neisseria gonorrhoeae is a Gram-negative coccus and the causative agent of the sexually transmitted disease, gonorrhea. The disease generally manifests as localized urethritis in men and cervicitis in women. In women, the infection is often asymptomatic initially, but may spread to the uterus and fallopian tubes, causing pelvic inflammatory disease, chronic pelvic pain, and infertility. Untreated infections in men or women may also cause systemic disease (disseminated gonococcal infection), which may be manifested as tenosynovitis, meningitis, or endocarditis. For laboratory workers, it is most important to remember that *N. gonorrhoeae* causes eye infections. Normally gonococcal eye infections occur in newborns infected during passage through the birth canal of an infected mother; these infections often lead to blindness if left untreated. Laboratory-acquired *N. gonorrhoeae* eye infections have been reported; therefore, it is important to wear safety glasses when performing procedures that may cause gonococci to be propelled into the air and to seek medical treatment if the eyes or other mucosal surfaces are exposed to *N. gonorrhoeae*.

Gonococci are naturally transformable and this property has greatly facilitated its study. Gonococci readily take up DNA containing the 10-bp *Neisseria* DNA uptake sequence (DUS) GCCGTCTGAA (Goodman and Scocca, 1988). The DUS is found frequently in the chromosome of *N. gonorrhoeae* and other *Neisseria* species, often in two copies as an inverted repeat. Plasmids used for transformation of *N. gonorrhoeae* must contain the DUS to be taken up efficiently. Unlike many transformable bacteria, *N. gonorrhoeae* does not regulate transformation: gonococci are transformable at all stages of growth (Sparling, 1966). However, only piliated gonococci are naturally transformable, and piliation is a phase-variable phenotype. Therefore, care must be taken to choose piliated colonies for transformation.

This unit describes methods for genetic manipulation of *N. gonorrhoeae* including various methods of mutagenesis and complementation, as well as methods for growing and purifying DNA from these bacteria.

CAUTION: *Neisseria gonorrhoeae* is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. In particular, wear safety glasses as exposure of the eyes to *N. gonorrhoeae* will cause conjunctivitis (see Critical Parameters and Troubleshooting). See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

IMPORTANT NOTE: Unless otherwise indicated, all incubations are to be performed at 37°C, 5% CO_2.

STRATEGIC PLANNING

Growth on Agar or in Liquid Medium

Gonococci are fastidious. They have multiple nutritional requirements and are generally grown in rich medium, either gonococcal base medium (GCB) or chocolate agar. They require CO_2 in the atmosphere for growth on agar plates or sodium bicarbonate in liquid medium (Morse and Bartenstein, 1974). Medium must be supplemented with Kellogg's supplements (Kellogg et al., 1963) or IsoVitalex (Becton Diconson). Recipes for gonococcal base medium and supplements are found in the Reagents and Solution section below. Gonococci should be inoculated from an agar plate into GCBL at a density

Contributed by Joseph P. Dillard
Current Protocols in Microbiology (2005) 4A.2.1-4A.2.19

Table 4A.2.1 Antibiotic Concentrations Used for a Common High- and Low-Level Overall Resistance Strains of *N. gonorhoeae*[a]

Antibiotic	MS11 (μg/ml)	FA1090 (μg/ml)
Chloramphenicol	10	2
Erythromycin	10	2
Kanamycin	80	ND
Nalidixic Acid	1.5	1.5
Penicillin G	0.3	ND
Spectinomycin	75	75
Streptomycin	100	100
Tetracycline	2	0.2

[a] Abbreviation: ND, not determined.

no less than 10^7 CFU/ml to reliably obtain a viable liquid culture. The medium must be prewarmed to 37°C. In general, inoculating to a density of 5×10^7 to 1×10^8 (OD_{540} of 0.2) is the most reliable method. Transfer may be done using a sterile Dacron swab. Do not use cotton, as these swabs may contain fatty acids which are inhibitory to some strains of *N. gonorrhoeae*. Optimal numbers of live gonococci for inoculation are obtained from agar plates 18- to 20-hr old. The doubling time for laboratory strains in liquid medium is ~60 min.

Antibiotic Concentrations for Selection in *N. gonorrhoeae* Strains

Some gonococcal strains have much higher levels of antibiotic resistance than others. It is therefore advisable to search the available literature for concentrations of antibiotic used with particular strains. Most strains, however, exhibit either high-level overall resistance levels (e.g., strain MS11) or low-level overall resistance (e.g., strain FA1090); therefore, useful antibiotic concentrations are given for these two commonly used strains (Table 4A.2.1) and may serve as a starting point for the determination of concentrations appropriate for uncharacterized strains.

BASIC PROTOCOL 1

SPOT TRANSFORMATION OF *NEISSERIA GONORRHOEAE* ON AGAR PLATES

N. gonorrhoeae can be transformed at high efficiency by growing the bacteria on agar plates in the presence of high concentrations of DNA. DNA is soaked into the plate at a few spots and the bacteria to be transformed (recipients) are streaked through the spots. Colonies arising on the spots have a high likelihood of containing transformed gonococci, often as high as 20% to 50% of total colony forming units. This method is often used for transformation with plasmids containing mutation constructs created in *E. coli*. Gonococcal DNA may be cloned into an *E. coli* plasmid and then interrupted with the gene for a selectable marker. Gonococcal DNA flanking the marker on both sides facilitates double-crossover homologous recombination and insertion of the marker into the gonococcal chromosome. To prevent the recovery of bacteria that have undergone a single-crossover recombination event and integrated the entire plasmid into the chromosome, the plasmid should be linearized before transformation. Commonly used restriction enzymes and buffers do not inhibit transformation. Therefore, the restriction digest mixture can be used directly without further purification. If the plasmid is 8 kb or larger, it is not necessary to linearize the plasmid, since *N. gonorrhoeae* processes large DNA fragments prior to DNA uptake during natural transformation (reviewed in Hamilton, 2006).

Alternatively, the ability of *N. gonorrhoeae* to incorporate plasmids into the chromosome can be used for making mutations (Hamilton et al., 2001). A single fragment of gonococcal DNA can be cloned into a plasmid in *E. coli*. Transformation with the circular plasmid, followed by selection for the antibiotic resistance marker on the plasmid will result in the isolation of transformants that have integrated the plasmid by single-crossover recombination. Since this method results in duplication of the cloned sequence, the method is often referred to as insertion-duplication mutagenesis.

Due to the high efficiency of transformation observed with this method, it is possible to introduce mutations that do not contain an antibiotic resistance gene or other selectable marker. Plasmids or PCR products containing deletions, insertions, or point mutations can be used for transformation. If plasmids are used, they should be linearized to prevent single-crossover recombination. Potential transformants can be screened by PCR for an increase or decrease in the size of the PCR product amplified from the gene of interest. If small mutations are introduced (e.g., point mutations, epitope tag insertions), it is helpful to also introduce or eliminate a restriction site, allowing potential transformants to be identified by PCR and restriction digest.

Materials

Recipient *N. gonorrhoeae* strain, frozen
GCB plates (see recipe), room temperature and 37°C
≥10 ng/μl plasmid DNA
Appropriate restriction enzyme and buffer (for double-crossover only)
GCB plate containing appropriate antibiotic (Table 4A.2.1; for fragments containing selectible markers only)
Dacron swabs (Fisher Scientific), sterile
Additional reagents and equipment for PCR (see Support Protocol)

1. Streak recipient *N. gonorrohoeae* strain from frozen stock onto a GCB plate. Incubate overnight (<24 hr).

Prepare DNA

2a. *For inserting a construct into the chromosome by double-crossover event:* Linearize the plasmid unless it is large (>8 kb). Be sure not to cut the transforming DNA away from the gonococcal DNA uptake sequence.

2b. *For performing insertion-duplication mutagenesis:* Do not linearize the plasmid.

3. Draw two 1-cm circles on the back of a 37°C GCB agar plate, where, upon streaking, the colony density will be medium and thin, respectively.

   Appropriate places would be one-third and two-thirds of the way down the middle of the plate.

4. Spot ~10 to 20 μl DNA solution (step 2a or 2b) on the agar inside the circles. Maximize the DNA concentration but do not exceed 10 μg. Allow DNA to soak into the plate.

   Amounts of DNA in the hundreds of nanograms are appropriate.

   If the spots are not dry within 10 min, it may be necessary to dry the plate in a biosafety hood with the lid of the plate removed, 20 min or less.

5. Pick a piliated colony of the recipient from the plate prepared in step 1. Streak through the DNA spots and incubate overnight.

   See Background Information for a discussion of appraising the piliation state of N. gonorrhoeae.

6a. *For transformations using fragments containing selectable markers:* Using a sterile Dacron swab, transfer and uniformly spread the colonies that grew on the spots onto a GCB plate containing the appropriate antibiotic.

6b. *For transformations using fragments without selectable markers:* Streak individual colonies to be screened onto GCB plates using an inoculating loop.

CAUTION: *See Critical Parameters and Troubleshooting for important safety considerations.*

7. Incubate transformants overnight.

If using no selection, colonies will be ready for screening in 24 hr or less. Antibiotic selection will significantly slow the appearance of transformants. Transformants selected with chloramphenicol or erythromycin may not be apparent until 36 to 48 hr.

8. Streak individual transformants onto GCB plates and screen for nonselectable mutations by PCR (see Support Protocol).

Due to transformation occurring within only some members of a colony, nonselected mutants identified by this method should be regarded as likely mixed populations and should be restreaked; the presence of the mutation in individual colonies should be verified.

BASIC PROTOCOL 2

TRANSFORMATION OF *NEISSERIA GONORRHOEAE* IN LIQUID CULTURE

Transformation of *N. gonorrhoeae* has traditionally been done in liquid culture. This method is not as efficient as transformation on agar plates as described in Basic Protocol 1; however, it can be quicker, particularly if frozen cultures of piliated bacteria are prepared ahead of time. Also, this method is less likely to give colonies representing mixed populations.

Materials

Recipient *N. gonorrhoeae* strain, frozen
GCB plate (see recipe)
≥10 ng/μl plasmid DNA
GCBL medium (see recipe) containing 5 mM $MgSO_4$, room temperature and 37°C
GCBL medium containing Kellogg's supplements (see recipe)
60% (v/v) glycerol

Dacron swabs, sterile
T-25 tissue culture flask, 37°C

1. Streak recipient *N. gonorrhoeae* strain from frozen stock onto a GCB plate. Incubate overnight.

2. Pick a piliated colony. Streak onto a GCB plate and incubate overnight (18 to 20 hr).

See Background Information for a discussion of appraising the piliation state of N. gonorrhoeae.

3. Add 20 μl plasmid DNA to 200 μl GCBL medium containing 5 mM $MgSO_4$ in a 1.5-ml microcentrifuge tube. Warm mixture to 37°C in a water bath. Maximize DNA amount (not to exceed 10 μg) and minimize DNA volume (not to exceed 20 μl).

Typical DNA amounts are in the hundreds of nanograms (~200 ng to 1 μg). Plasmids smaller than 8 kb should be linearized by restriction enzyme digestion prior to transformation unless insertion of the entire plasmid into the chromosome is desired.

4. Using a Dacron swab, prepare a recipient cell suspension by transfering 1/4 to 1/2 of all of the colonies resulting from step 2 into a 1.5-ml microcentrifuge tube containing 1 ml GCBL medium/5 mM $MgSO_4$, 37°C. Swirl the swab to suspend bacteria.

5. Prepare transformation mix by adding 20 μl recipient cells to the DNA solution (step 3). Incubate 5 to 15 min at 37°C.

6. If it is possible this strain will again be transformed, add 60% glycerol to a final concentration of 15% (v/v) to the remaining recipient cell suspension (without DNA). Flash freeze using liquid nitrogen or a dry ice/ethanol bath.

7. Transfer entire transformation mix to 2 ml GCBL containing Kellogg's supplements in a T-25 tissue culture flask (already at 37°C). Incubate flask with the lid loosened 2 to 6 hr.

Plate transformants

8a. *If selecting for antibiotic resistance:* Prepare 10-fold serial dilutions in GCBL over a range of 10^0 to 10^{-4}. Plate 100 μl of each dilution onto an individual GCB plate with the appropriate antibiotic. Incubate until colonies are observed (24 to 48 hr).

8b. *If screening without selection*: Prepare 10-fold serial dilutions in GCBL over a range of 10^{-3} to 10^{-6}. Plate 100 μl of each dilution onto individual GCB plates without antibiotics. Incubate until colonies are observed (18 to 24 hr).

9. Screen for desired mutation by PCR (Support Protocol).

ELECTROPORATION OF *NEISSERIA GONORRHOEAE*

BASIC PROTOCOL 3

Since the efficiency of electroporation is low and that of natural transformation is high, gonococci are almost never transformed by electroporation. However, there are cases where electroporation is the only reasonable option. For example, transformation of a *recA* mutant with a replicating plasmid, transformation of a nonpiliated, nonreverting strain, or transformation with DNA lacking a gonococcal DNA uptake sequence (DUS) may only be possible by electroporation. Gonococci will begin to undergo death and lysis under the washing conditions required to remove salts prior to electroporation. Different methods have been described for this purpose (Genco et al., 1991). However, it is most important to perform the washing steps and electroporation quickly in order to get the gonococci back into growth medium before too many of the recipients have died.

Materials

Recipient *N. gonorrhoeae* strain, frozen
GCB plates (see recipe) with and without antibiotic (Table 4A.2.1)
0.3 M sucrose: pass through a 0.22-μm filter to sterilize; store up to 1 year at room temperature
10 mg/μl DNA solution
GCBL medium with Kellogg's supplements (see recipe)
GCBL medium (see recipe)
Dacron swabs (Fisher Scientific), sterile
Electroporation cuvette, 2-mm gap length
Electroporatator

1. Streak recipient *N. gonorrhoeae* strain from frozen stock onto a GCB plate. Incubate overnight.

2. Using a sterile Dacron swab, transfer 50% to 100% of the colonies on the plate into 1 ml of 0.3 M sucrose at room temperature.

   Sucrose provides osmotic stabilization. Suspension of N. gonorrhoeae in low osmotic strength buffer results in autolysis and cell death.

3. Microcentrifuge 30 sec at 12,000 rpm, room temperature. Resuspend cells in 1 ml of 0.3 M sucrose and microcentrifuge again. Repeat suspension and microcentrifugation a third time. Suspend cells in 100 μl of 0.3 M sucrose.
4. Add 1 μl DNA solution.

   Plasmid DNA prepared by standard miniprep method and suspended in TE or water works well for electroporation. If arcing occurs during electroporation or if the addition of >3 μl of DNA is desired, the DNA should be concentrated by ethanol precipitation and washed twice with 70% ethanol to remove salts.
5. Transfer cell/DNA mixture into an electroporation cuvette. Electroporate with the pulse controller set at 2.5 kV, 200 Ω, and 25 μF.
6. Resuspend cells in 1 ml GCBL medium with Kellogg's supplements. Transfer culture to a GCB plate without antibiotics.
7. Incubate the plate right-side up 4 to 6 hr.
8. Wash the bacteria off the plate with 1 ml GCBL medium. Plate 50 μl onto a GCB plate containing appropriate antibiotic. Repeat for a second plate if desired. Incubate until colonies are observed (~ 24 to 48 hr).

BASIC PROTOCOL 4

SHUTTLE MUTAGENESIS OF *NEISSERIA GONORRHOEAE* DNA CLONED INTO PHSS6 PLASMIDS USING MTN*CMNS*

One of the most common methods of mutagenesis in *N. gonorrhoeae* is insertional mutagenesis using an antibiotic resistance marker to interrupt a gene or replace part or all of its coding sequence. The number of selectable markers for *N. gonorrhoeae* is limited. Researchers have reported using *cat* (chloramphenicol resistance), *ermC* (erythromycin resistance), *tetM* (tetracycline resistance), *aph*3 (kanamycin resistance), *bla* TEM-type (penicillin resistance), and the omega cassette (spectinomycin and streptomycin resistance). These markers are often introduced directly into the gene of interest cloned on a plasmid in *E. coli* and introduced into the gonococcal chromosome by natural transformation and allelic exchange. However, mutations may also be produced using plasmid or transposon insertions in the chromosome as described below.

Transposons generally do not transpose in *N. gonorrhoeae*. However, researchers wishing to make transposon mutants of gonococci have circumvented this problem in two ways. In the first method, gonococcal DNA is cloned into plasmids and mutagenized with transposons in *E. coli*, then introduced back into gonococci by natural transformation, a technique known as shuttle mutagenesis. Derivatives of Tn3 and Tn1721 have been adapted for use in gonococci, including derivatives containing reporters *lacZ*, or *phoA* (Seifert et al., 1990; Boyle-Vavra and Seifert, 1993, 1994; Haas et al., 1993). A second method is to purify gonococcal DNA and mutagenize it with transposons in vitro. Both Tn5 and Mariner derivatives have been used for this purpose in *N. gonorrhoeae* and *N. meningitidis* (Pelicic et al., 2000; Sechman et al., 2005).

Materials

E. coli strains RDP146(pTCA), RDP146(pOX38::mTnCmNS), and NS2114Sm (Boyle-Vavra and Seifert, 1993)
LB medium (*APPENDIX 4A*)
1 mM HEPES, pH 7 (optional): sterilize by autoclaving; store up to 1 year at room temperature
10 mg/μl target plasmid
LB plates (*APPENDIX 4A*) containing 40 μg/ml kanamycin
LB plates containing 40 μg/ml kanamycin and 12 μg/ml tetracycline

LB plates containing 40 μg/ml kanamycin and 25 μg/ml chloramphenicol

LB plates containing 100 μg/ml streptomycin, 40 μg/ml kanamycin, and 25 μg/ml chloramphenicol

GCB plates (see recipe) containing chloramphenicol (Table 4A.2.1)

Electoporation cuvette, 2-mm gap length

Electroporator

Additional reagents and solutions for PCR (Support Protocol; optional) and spot transformation with *N. gonorrohoeae* (Basic Protocol 1)

1. Incubate *E. coli* strain RDP146(pTCA) in LB medium several hours to overnight at 37°C.

   pTCA encodes the transposase for Tn3.

2. Microcentrifuge desired volume of cells (generally ~1.5 ml) for 30 sec at 12,000 rpm. Resuspend cells in 1 ml low ionic strength buffer, such as sterile 1 mM HEPES, pH 7. Repeat wash two more times.

3. Resuspend cells in 40 μl 1mM HEPES per planned electroporation.

4. Add target plasmid to cell suspension.

5. Transfer cell/DNA mixture into an electroporation cuvette. Electroporate with the pulse controller set at 2.5 kV, 200 Ω, and 25 μF.

6. Plate 10 and 100 μl electrotransformation mix onto LB plates containing 40 μg/ml kanamycin. Incubate overnight at 37°C.

7. Use sterile toothpicks to transfer several potential transformants onto LB plates containing 40 μg/ml kanamycin and 12 μg/ml tetracycline.

   Transformants should be resistant to both antibiotics and show two plasmids when examined by whole-cell lysis (cracking) gel (Kado and Lin, 1981; Dillard and Yother, 1994). Such transformants will serve as the primary recipient.

8. Grow *E. coli* strain RDP146(pOX38::mTn*CmNS*) and primary recipient (step 7) to mid-log phase (OD_{600} of 0.5) without antibiotics. Mate at a ratio of 1:1 for 1 hr at 37°C without shaking.

   This step brings the transposon into the strain carrying the transposase and the target plasmid.

9. Plate 100, 10, and 1 μl onto individual LB plates containing 40 μg/ml kanamycin and 25 μ/ml chloramphenicol to select for Kn^RCm^R transformants. Incubate ~16 hr at 37°C.

   Any RDP146 cells not carrying all three plasmids will be killed in this step.

10. Grow NS2114Sm to mid-log phase (OD_{600} of 0.5) in LB medium without antibiotics (~4 hr).

    This step can be started towards the end of the incubation described in step 9.

11. Wash or scrape transconjugates from plates into LB medium and mix 1:1 with mid-log phase NS2114Sm.

12. Mate 15 min in a 37°C water bath. Incubate 30 min in rotator at 37°C.

13. Plate 100, 10, and 1 μl onto individual LB plates containing 100 μg/ml streptomycin, 40 μg/ml kanamycin, and 25 μg/ml chloramphenicol. Incubate ~16 hr at 37°C.

14. If desired, screen for transposon location and orientation by PCR (see Support Protocol).

15. Transform plasmid DNA into gonococci by spot transformation (Basic Protocol 1). Select for transformants on GCB plates containing 25μg/ml chloramphenicol.

BASIC PROTOCOL 5

CHEMICAL MUTAGENESIS

Chemical mutagenesis has been used in *N. gonorrhoeae*. Its use is infrequent since directed mutagenesis is highly efficient. Chemical mutagens that directly act on the DNA are effective (Campbell and Yasbin, 1984). However, chemical mutagenesis methods that rely on error-prone repair are not, since *N. gonorrhoeae* has no SOS-type system (Black et al., 1998). The procedure below describes use of ethylmethane sulphonate (EMS). *N*-Methyl-*N′*-nitro-*N*-nitrosoguanidine (MMNG) could be used instead, at 5 μg per 10^8 cfu.

Materials

N. gonorrhoeae strain, frozen
GCB plates (see recipe)
GCBL medium with Kellogg's supplements and sodium bicarbonate (see recipe), 37°C
Ethyl methanesulfonate (EMS)
GCBL medium
GCBL medium containing 15% glycerol
GCB plates containing nalidixic acid (Table 4A.2.1)
Dacron Swab

1. Streak *N. gonorrhoeae* strain from frozen stock onto a GCB plate. Incubate overnight.
2. Using a sterile Dacron swab, transfer cells from 1/4 to 1/2 of the plate into 3 ml GCBL medium with Kellogg's supplements and sodium bicarbonate, 37°C, to an OD_{540} of 0.2. Retain a 0.5-ml aliquot.
3. Add EMS to a final concentration of 1% (v/v), e.g., 20 μl to a 2-ml culture.
4. Incubate with aeration and remove 0.5-ml aliquots at 10, 20, 30, and 40 min. For each time point, immediately microcentrifuge aliquot 30 sec at 12,000 rpm and remove supernatant. Resuspend cells with 0.5 ml GCBL.

   Do not forget to include the untreated culture (0-min time point) taken in step 2.

5. Prepare serial dilutions over a range of 10^0 to 10^{-6}. To determine killing frequency, plate 100 μl of each dilution onto an individual GCB plate for quantification of colony forming units. Plate 100 μl of each dilution onto an individual GCB plate containing nalidixic acid to determine mutation frequency.

   Point mutations in the gyrB gene result in nalidixic acid resistance (Nal^R). Thus, measuring the frequency of mutations conferring nalidixic acid resistance gives a measure of the effectiveness of the chemical mutagenesis procedure.

6. Microcentrifuge the remainder of each undiluted aliquot 30 sec at 12,000 rpm. Resuspend cells in GCBL containing 15% glycerol and freeze at –70°C.
7. After overnight growth, identify time-points exhibiting 99% to 99.9% killing and those exhibiting the highest frequency of Nal^R colonies.

   Typically 30- and 40-min time points are optimal.

8. Streak bacteria onto GCB plates from the frozen, mutagenized stock from step 6 that gave the highest mutation frequency or 99% to 99.9% killing frequency, then screen for phenotype.

COMPLEMENTATION ON THE *NEISSERIA GONORRHOEAE* CHROMOSOME

Complementation in *N. gonorrhoeae* is usually done by insertion of the gene of interest onto the gonococcal chromosome. Because a majority of DNA that enters the cell during natural transformation is single-stranded, it is not restricted, and is therefore much more efficiently incorporated than replicating plasmids. Sites that have been used for complementation include the *iga* gene encoding IgA1 protease, and an intergenic region between *lctP* and *aspC* (Mehr et al., 2000). IgA protease is not essential for growth of *N. gonorrhoeae*; therefore, it can be interrupted without affecting in vitro phenotypes (Koomey et al., 1982). However, intergenic insertions are preferred since they are not known to affect any phenotypes. In theory, most any location that does not interrupt a gene or operon will work for this process. However, significant work has gone into making the *lctP-aspC* constructs useful for gonococcal complementation. A series of plasmids was created containing more than 3 kb of the *lctP-aspC* region, interrupted by a polylinker, an antibiotic resistance marker, and in some cases, a regulatable promoter. Transformation of gonococci followed by selection for the antibiotic resistance marker leads to selection of bacteria that have incorporated the construct by double cross-over recombination. Genes cloned into the construct are thus introduced into the chromosome with the antibiotic resistance marker between *lctP* and *aspC*. Plasmid pGCC6 contains two copies of the *lac* promoter-operator, $lacI^{Q}$, allowing for inducible expression of the gene of interest, and *cat*, conferring chloramphenicol resistance (Mehr et al., 2000). Plasmid pKH35 is a smaller pGCC6 derivative with a more extensive polylinker (Hamilton et al., 2005). Plasmid pGCC4 is similar to pGCC6 but carries an *ermC* marker instead of *cat*, and pGCC2 carries only the *ermC* marker (Stohl et al., 2003).

Materials

Gene of interest
pKH35 (Hamiltan et al., 2005) or similar plasmid
E. coli
N. gonorrhoeae mutant of interest
GCB plate (see recipe) containing chloramphenicol (Table 4A.2.1)
1 M IPTG solution
Dacron swab, sterile (Fisher Scientific)
Additional reagents and equipment for preparing a miniprep (Engebrecht et al., 1991), spot transformation (Basic Protocol 1), and PCR (Support Protocol)

1. Clone gene of interest into pKH35 or similar plasmid and transform into *E. coli*.
2. Purify plasmid using standard miniprep procedure (Engebrecht et al., 1991).
3. Use 200 to 500 ng plasmid and the *N. gonorrhoeae* mutant of interest to perform spot tranformation (Basic Protocol 1) on a GCB plate.
4. Use a sterile Dacron swab to transfer all of the resulting colonies from a DNA spot onto a GCB plate containing chloramphenicol. Incubate 24 to 48 hr.
5. Pick individual colonies and screen by PCR for presence of gene of interest adjacent to *lctP* (see Support Protocol).
6. Induce expression of the gene of interest by adding of 1 M IPTG to a final concentration of 1 mM either in liquid culture or on solid medium.

ALTERNATE PROTOCOL 1

COMPLEMENTATION WITH REPLICATING PLASMIDS

Complementation with replicating plasmids is rarely performed with *N. gonorrhoeae*. During transformation, plasmid DNA is cut by a nuclease prior to entry into the cell. Unless the incoming DNA is homologous to the gonococcal chromosome or a resident plasmid, and the cut occurs in the homologous segment, the incoming plasmid cannot reform a circle. A circle can be reformed if the cell brings in more than one copy of the plasmid. Thus, transformation with replicating plasmids follows "two-hit" kinetics. Additionally, the introduced plasmid is subject to restriction, further reducing the transformation frequency. The introduced plasmid is subject to restriction, further reducing the transformation frequency. Use of replicating plasmids would be necessary for complementation of certain recombination- or transformation-deficient mutants that would be unable to take up or incorporate DNA by natural transformation. The complementing plasmid could be introduced by electroporation. Also, higher copy numbers for some replicating plasmids would facilitate increased expression of introduced genes. Plasmids have been developed for complementation in gonococci and commonly rely on the replication origin of the gonococcal β-lactamase plasmids or the cryptic plasmid. Two such plasmids are pLES2 (Stein et al., 1983) and pFP10 (Pagotto et al., 2000). In addition, broad-host range plasmids of the IncP and IncQ groups will replicate in gonococci and can be used for complementation. A complementation method based on the conjugative plasmid p*tetM*25.2 from *N. gonorrhoeae* has been described (Kupsch et al., 1996).

BASIC PROTOCOL 7

PREPARATION OF CHROMOSOMAL DNA FROM *NEISSERIA GONORRHOEAE* GROWN ON SOLID MEDIUM

Purified chromosomal DNA is required for Southern analysis of mutants and complemented strains. For PCR amplification of gonococcal genes for cloning, use of purified chromosomal DNA as template gives cleaner results with fewer false-priming products. Gonococci are less likely to autolyse when grown on agar plates as compared to growth in liquid medium. Therefore, preparation from gonococci grown on agar plates is the most reliable method for chromosomal DNA purification.

Materials

N. gonorrhoeae, overnight culture
GCB plates (see recipe)
TES buffer (see recipe)
10 mg/ml RNase A
10% SDS
Tris-buffered phenol (*APPENDIX 2A*)
Chloroform
3 M sodium acetate
95% and 70% ethanol

Dacron swab, sterile
13-ml snap-cap polypropylene tubes
1-ml pipette tips with wide bore

1. Using an inoculating loop, streak three to five colonies of *N. gonorrhoeae* onto each of eight to ten GCB plates. Incubate overnight.
2. Using one sterile Dacron swab per plate, tranfer and suspend cells in 5 ml TES buffer in a 13-ml snap-cap polypropylene tube.
3. Add 1 μl of 10 mg/ml RNase A (10 mg/ml) and 50 μl of 10% SDS. Incubate 10 min at 37°C to digest RNA.

   Lysis should occur instantly.

4. Extract with an equal volume of tris-buffered phenol. Mix by gentle inversion twenty times. Centrifuge 10 min at 6000 × *g* (7000 rpm), 4°C.
5. Transfer aqueous (top) phase to a new tube using a micropipette equipped with a wide-bore 1-ml pipette tip and repeat extraction.
6. Extract once with chloroform. Invert and centrifuge as in step 4.
7. Transfer aqueous (top) phase to a new tube. Add 1/10 vol 3 M sodium acetate and 2 vol of 95% ethanol. Mix and incubate 30 min at −20°C.
8. Centrifuge 10 min at 12,000 × *g*, 4°C.
9. Wash pellet twice with 70% ethanol.
10. Invert tube and allow pellet to dry until white or clear.
11. Suspend DNA in ∼200 to 500 µl water.

PREPARATION OF CHROMOSOMAL DNA FROM *NEISSERIA GONORRHOEAE* GROWN IN BROTH

ALTERNATE PROTOCOL 2

Growth of *N. gonorrhoeae* in liquid culture makes the preparation steps for DNA purification easier than those for preparing DNA from bacteria grown on plates. The bacteria can be harvested by centrifugation (instead of swabbing) and the recovery of bacteria is more efficient. The drawback to this method is that the cultures must be monitored closely to ensure that the bacteria are still in the growth phase and have not begun to autolyse before chromosome purification begins. Autolysed gonococcal cultures still exhibit significant optical density (OD_{540} of ∼1.2), but purification of DNA from these cultures gives low yields and mostly degraded DNA. However, if growth is monitored to ensure growing cells are used, preparation of DNA from 200 ml of late-log phase gonococci (in this protocol) provides significantly more DNA than the preparation from ten agar plates. This method does not have an RNase step. Rather, the RNA functions as carrier nucleic acid, allowing the DNA and large RNA to be easily recovered with a glass hook.

Materials

N. gonorrhoeae, frozen stock
GCB plate (see recipe)
GCBL medium with Kellog's supplements and sodium bicarbonate (see recipe), 37°C
TE buffer (*APPENDIX 2A*)
10% SDS
5 M potassium acetate
95% and 70% ethanol
Dacron swab
13-ml polypropylene tube
Glass rod
65°C water bath

1. Streak *N. gonorrhoeae* from frozen stock onto a GCB plate and incubate overnight.
2. Using a sterile Dacron swab, transfer 1/4 to 1/2 of colonies on the plate to 3 ml GCBL medium, 37°C, with Kellogg's supplements and sodium bicarbonate.
3. Incubate until culture reaches late log phase (OD_{540} of 1.0 – 1.4; ∼4 to 6 hr). Transfer to 200 ml GCBL, 37°C, with supplements and sodium bicarbonate.

4. Incubate until culture reaches late log phase (OD_{540} of 1.4; <20 hr).
5. Centrifuge culture 10 min at 3,000 × *g*, 4°C. Resuspend in 2.5 ml TE buffer on ice.
6. Transfer to a 13-ml polypropylene tube. Add 10% SDS to 1% (~300 µl of 10%) and lyse the cells 15 min at 65°C.
7. Add 1/5 vol of 5 M potassium acetate (~700 µl) and incubate an additional 15 min in a 65°C water bath. Transfer to ice and incubate 60 min.
8. Remove cell debris by centrifuging 15 min at 12,000 × *g*, 4°C. Add supernatant to 2 vol of 95% ethanol. Hook out the DNA with a glass rod.

   Addition of the cleared lysate to ethanol will cause the DNA and RNA to come out of solution and appear as long white strands or gobs floating in the liquid. A glass hook can easily be fashioned from a Pasteur pipette using a Bunsen burner. The hook should be sealed and contain at least a slight bend. If the DNA cannot be removed with a hook it can still be recovered by centrifugation.
9. Wash DNA once with 70% ethanol, allow it to dry, and resuspend in 200 to 500 µl TE.

SUPPORT PROTOCOL

PREPARING PCR TEMPLATES FROM *NEISSERIA GONORRHOEAE* COLONIES

It is often necessary to screen gonococcal transformants for the presence of the introduced mutation or construct. This process can often be done by PCR or PCR followed by restriction digest. One gonococcal colony contains sufficient DNA for this process, although it will work better with three to five colonies from the isolate. The resulting PCR product can then be examined for its size, size following digestion, or simply its presence using agarose gel electrophoresis.

Materials

N. gonorrhoeae growing on solid medium
Colony lysis solution (see recipe)
Appropriate restriction enzyme(s) and buffer(s) (optional)
Thermocycler and appropriate PCR tubes
Additional reagents and equipement for PCR (Kramer and Coen, 2001)

1. Scrape an amount of *N. gonorrhoeae* equal to one to five colonies and transfer to 50 to 100 µl colony lysis in a PCR tube.
2. Lyse cells 15 min at 94°C in a thermocycler followed by incubation for 5 min at 25°C.
3. Use 2.5 µl lysate as template to a 25-µl PCR reaction (Kramer and Coen, 2001).
4. Use 5 µl PCR product in 30 µl restriction digest, if identification of a restriction site is necessary.

   See Bloch (1995) for more information about restriction mapping.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2A; for suppliers, see SUPPLIERS APPENDIX.

Colony lysis solution

40 µl 500 mM EDTA
200 µl Tris·Cl, pH 8.5 (*APPENDIX 2A*)
100 µl Triton X-100

9.66 ml H_2O
Store up to 1 year at room temperature

Scale as needed.

GC medium base

42% (w/w) Proteose peptone #3 (15.10 g)
3% (w/w) cornstarch (1.01 g)
11% (w/w) K_2HPO_4 (4.03 g)
3% (w/w) KH_2PO_4 (1.01 g)
14% (w/w) NaCl (5.03 g)
28% (w/w) agar (10.07 g)

Weight amounts given in parentheses indicate appropriate mix for preparing GCB plates (see below).

GCB plates

36.25 g GC Medium Base (Difco; also see recipe)
1.25 g agar
1 liter H_2O
Autoclave with stir bar
Cool to 50° to 60°C
Add 10 ml filter-sterilized Kellogg's supplements I (see recipe)
Add 1 ml filter-sterilized Kellogg's supplement II (see recipe)
Pour into 100-mm plates using 20 ml per plate
Store plates sealed in bags up to 6 months at 4°C

GCBL medium

Dissolve the following in 1 liter H_2O:
15 g proteose peptone #3
4 g K_2HPO_4
1 g KH_2PO_4
1 g NaCl
Adjust pH to 7.2 with HCl if necessary
Autoclave and store indefinitely at room temperature
Add Kellogg's Supplements I & II to 1× each from individual or a combined stock (see recipe)
Add sodium bicarbonate to 0.042% (final) from a 100× stock (0.42 g in 10 ml H_2O; filter sterilize)

Unless the protocol step specifcally indicates that Kellogg's supplements or sodium bicarbonate are to be included in the medium, these reagents should be omitted.

It is only necessary to add Kellogg's supplements when the bacteria are to be grown in the medium. It is not necessary to add Kellogg's supplements when the bacteria are diluted or transformed in GCBL, i.e., steps when the bacteria are only in the medium for a short period of time. Sodium bicarbonate is added only when the bacteria are to be grown in liquid culture with aeration (in sealed tubes or flasks) and not when they are grown in static culture in a CO_2 incubator. Unless the protocol step specifically indicates that Kellogg's supplements or sodium bicarbonate are to be included in the medium, these reagents can be omitted.

Kellogg's supplements

Supplements I and II may be mixed (10 ml supplement I + 1 ml supplement II) and frozen in 11-ml aliquots. One such aliquot is sufficient to supplement 1 liter of GCB or GCBL medium (see recipe). Filter sterilize before use.

Supplement I, 100×
40 g glucose
1 g glutamine
2 mg cocarboxylase (thiamine pyrophosphate)
Adjust volume to 100 ml with H_2O
Sterilize by passing through a 0.2-μm filter
Store indefinitely at –20°C
Supplement II, 1000×
50 mg $Fe(NO_3)_3 \cdot 9H_2O$
Adjust volume to 100 ml with H_2O
Sterilize by passing through a 0.2-μm filter
Store indefinitely at –20°C

An alternative to preparing supplements is to purchase them lyophilized. Supplement IsoVitalex (Becton Dickinson) can be used in place of Supplements I & II.

Do not store Kellogg's supplements at 4°C or room temperature.

TES

250 μl 1 M Tris·Cl, pH 8 (*APPENDIX 2A*)
200 μl 0.5 M EDTA
50 μl 5 M NaCl
4.5 ml H_2O
Store up to 1 year at room temperature

COMMENTARY

Background Information

Natural transformation of *Neisseria gonorrhoeae* was first reported by Sparling (1966). Over the years it has been found that the high degree of gonococcal transformation has led to quick spread of antibiotic resistance markers throughout the gonococcal population and has created a problem for the treatment of gonococcal infections. Transformation also leads to variation in genes coding for gonococcal antigens, allowing the bacteria to avoid the host immune response (Cooke et al., 1998), although significant variation of some antigen-encoding genes occurs by intracellular recombination (Stern et al., 1986; Seifert, 1996). As is the case for many naturally transformable bacteria, the process of transformation involves the components of a type IV pilus. Multiple mutations affecting piliation or pilus function in *N. gonorrhoeae* have been shown to block natural transformation (Chen and Dubnau 2004). The gene for PilE, the pilus subunit, undergoes high frequency recombination. This recombination results in altered pilin protein sequence allowing the bacteria to escape the host immune response. However, some of the recombination events eliminate pilin expression or result in pilin proteins that cannot be assembled into pili. The resulting nonpiliated bacteria are not transformable. Therefore, care should be taken to choose colonies of piliated *N. gonorrhoeae* for transformation procedures. See Figure 4A.2.1.

The gonococcal genome sequence was completed for strain FA1090 and is accessible in GenBank (accession number AE004969). A useful annotation is available at the STD genomes website of the Los Alamos National Laboratories (*http://www.stdgen.lanl.gov*). Although there are some significant differences in the genomes of *N. gonorrhoeae* strains (Gibbs and Meyer, 1996; Hamilton et al., 2005), the sequence information obtained for strain FA1090 is generally useful for searching for genes of interest and for designing primers for cloning gonococcal genes.

Critical Parameters and Troubleshooting

Safety considerations

N. gonorrhoeae is a human pathogen. It should be used under biosafety level 2 (BSL-2) conditions (*UNIT 1A.1*). Most importantly, wear safety glasses. This is vital when working with cultures that might splatter or other conditions that might propel gonococci into the eyes of

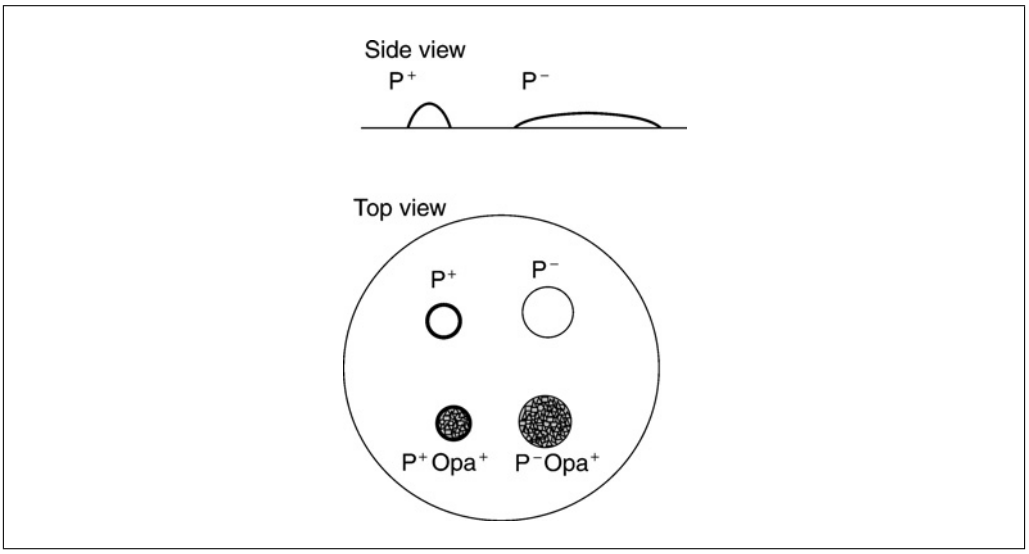

Figure 4A.2.1 Gonococcal colony morphologies. Gonococci expressing pili (P^+) form smaller colonies that appear to have a dark ring around the edge. This effect is due to the cells aggregating to form a mound. Nonpiliated cells form a pancake-shaped colony that has a greater diameter and a fuzzier edge. In addition, when the colonies are viewed with oblique substage lighting, a range of colony opacities will be detected. Colony opacity is due to presence of outer membrane opacity (Opa) proteins. Translucent (Opa^-) colonies appear clear or somewhat blue, whereas opaque colonies may appear yellow and refract the light to give an almost crystalline or granular appearance.

the researcher, such as sonication or streaking colonies with an inoculating loop. Exposure of the eyes will cause conjunctivitis. Exposure of any mucosal surface may result in infection. Gonococcal infections should be considered serious as they can result in septicemia and death. Treatment by a physician should be sought following any mucosal exposure to *N. gonorrhoeae*. Antibiotics are effective in clearing the infection.

Troubleshooting growth, death, and autolysis

One of the most difficult aspects of working with *N. gonorrhoeae* is its tendency to die in culture or to not grow when inoculated into a culture. To avoid these problems, it is best to keep gonococci under growth conditions at all times or to shorten the length of time they are in nonoptimal conditions (such as centrifugations or washes) as much as possible. It is important to prewarm media to 37°C. Streak bacteria from frozen stock onto prewarmed agar plates that contain no antibiotic. Although the bacteria may exhibit a significant level of resistance to an antibiotic while growing, they appear incapable of surviving the selection when restarting from frozen stocks. Finally it is advisable to inoculate at a density of $\sim 10^7$ to 10^8 CFU/ml when growing the bacteria in liquid culture. Although the bacteria may grow in liquid culture at lower densities, they often exhibit a growth lag lasting for a considerable period, and the lag is often followed by autolysis.

Gonococci are fastidious, requiring rich medium for growth. Complex media work best, but defined media have also been devised that will support the growth of gonococci (LaScolea and Young, 1974; Morse and Bartenstein, 1980). Furthermore, *N. gonorrhoeae* will grow in some media designed for tissue culture, particularly if supplemented with a few additional nutrients (Hamilton et al., 2001). The growth rate in the defined media is significantly reduced compared to that in rich media, and doubling time is generally ~120 min.

Gonococci are prone to die under any condition not favorable for growth. Furthermore they appear to have no true stationary phase, and are likely to be actively dying if they are not actively growing (Morse and Bartenstein, 1974; Hebeler and Young, 1975). They cannot be maintained alive on ice. Autolysis generally accompanies death, but there are conditions that can be used prevent autolysis (although the bacteria will still die). Incubation in low pH buffer (usually pH 5.5, 50 mM sodium phosphate or Tris·Cl) and/or on ice will limit autolysis. EDTA and other chelators of divalent cations greatly stimulate autolysis and should be avoided if lysis is not desired (e.g., cell fractionation procedures; Wegener et al., 1977).

Those first starting to work with *N. gonorrhoeae* often experience contamination of their liquid cultures. With a doubling time of 60 min, gonococci grow significantly slower than bacteria that commonly contaminate laboratory cultures. A useful method for overcoming this difficulty is to use streptomycin (100 μg/ml) in the medium. Many gonococcal strains, including the common laboratory strains FA1090 and MS11, carry a mutation in the *rpsL* gene conferring streptomycin resistance. The mutation is not universal; some common strains such as F62 do not carry the *rpsL* mutation.

Mapping insertions or deletions by Southern blotting

Transformants carrying mutations are generally first screened by PCR, however it is often desirable to confirm the mutation by Southern blotting. For this purpose it should be noted that gonococci have extensively methylated DNA, and many restriction enzymes do not cut gonococcal DNA efficiently.

Colony variants

Gonococci undergo spontaneous high-frequency variation of surface molecules by well described mechanisms (Seifert, 1996; Stern et al., 1986). This variation is seen in colony variants that appear on agar plates. For the purposes of growing gonococci, it should be noted that expression of pili and/or opacity proteins results in clumping during growth in liquid culture. The clumps are difficult to disperse and make it difficult to follow culture growth using OD measurements or plating. Therefore it is advisable to use non-piliated (P^-), transparent (Opa^-) variants unless these molecules are required for other purposes (e.g., transformation or adhesion and invasion assays). Piliated variants form colonies that are small and convex and thus appear to have a dark ring around them (Kellogg et al., 1963). Nonpiliated variants form larger, flatter colonies. Opacity protein expression is judged using a stereo dissecting microscope and oblique light. Opa^- variants may appear transparent or slightly blue. Opa^+ variants are opaque, somewhat yellow, and refractory (Swanson et al., 1971). Nonpiliated variants will come to predominate in liquid culture due to a slightly faster growth rate. Nearly all colonies will appear opaque on an old (>24-hr) plate due to variation occurring in a proportion of the cells in a colony at an appreciable rate.

Constructs for controlling pilin antigenic variation

Gonococci are notoriously variable, spontaneously altering pilin sequence as well as expression of genes for opacity proteins, lipooligosaccharide types, and many others. Much of the variation occurs by slipped-strand mispairing and cannot be controlled (Belland, 1991). However, pilin variation can be controlled, thereby preventing variation that might affect adherence and transformation. Two useful genetic alterations have been described that prevent pilin variation. The first, and most widely used constructs, are mutations in *recA*. Since pilin variation requires homologous recombination, mutations in *recA* or eliminating *recA* transcription eliminates pilin variation (Koomey et al. 1987). Both *recA* knockouts and *recA*-inducible constructs have been created. The *recA6* allele carries a *lac* promoter-operator upstream of *recA*, allowing recombination to occur in the presence of IPTG with virtually no recombination (and pilin variation) in the absence of induction (Seifert, 1997). It was recently shown that mutations upstream of *pilE* (the gene for the pilin subunit) will also prevent pilin variation. These insertions allow pilin expression but prevent variation (Sechman et al., 2005). Such strains are more useful since they allow normal homologous recombination required for natural transformation and genetic manipulation.

Troubleshooting transformation

If no transformants are obtained, the problem is often with the donor DNA. Impurities introduced in the preparation of plasmids from *E. coli*, such as salt or ethanol, will kill the potential *N. gonorrhoeae* recipients. In the spot transformation procedure, the bacteria will either not grow on the spot where the DNA was added to the plate or will only form very tiny colonies. Reprecipitation of the DNA followed by two washes with 70% ethanol is usually sufficient to remove the impurities. Adding more DNA to the transformation can also be helpful. Increasing the usual 100- to 200-ng amount of DNA to 1 μg may significantly increase the transformation frequency without damaging viability of the gonococcal recipients. Since DNA must contain the gonococcal DNA uptake sequence to act efficiently in transformation, it is important to make sure the DNA uptake sequence is present in the plasmid and was not cut away from the DNA of interest in preparation for transformation. Plasmids used

Table 4A.2.2 Time Considerations for Select Protocols

Protocol	Description	Time required
Basic Protocol 1 or 2	Gonococcal transformation	4-5 days
Basic Protocol 3	Electroporation	4 days
Basic Protocol 4	Shuttle mutagenesis	12-14 days
Basic Protocol 5	Chemical mutagenesis	2 days
Basic Protocol 6 or Alternate Protocol 2	Complementation	4-5 days
Basic Protocol 7	Chromosome preparation	2 days

for transformation should be linearized prior to transformation if they are smaller than ~8 kb (unless plasmid insertion in the chromosome is desired). Care should be taken to ensure that the enzyme chosen does not separate the uptake sequence from the DNA of interest. As a control for transformation a plasmid carrying a point mutation conferring antibiotic resistance is frequently used. The plasmid pSY6 conferring nalidixic acid resistance is useful for this purpose (Stein, 1991).

Anticipated Results

Transformation of *N. gonorrhoeae* is highly efficient. If using the spot transformation method to introduce mutations into the gonococcal chromosome (Basic Protocol 1), frequencies of 10% to 50% transformant/total CFUs or greater may be expected (Gunn and Stein, 1996). Screening of ten potential transformants is generally sufficient to identify the mutant of interest, even without selection. Using liquid transformation (Basic Protocol 2), frequencies ~1% may be expected. In general, the frequency will depend on the length of the homologous region targeting the mutation and the length of any heterologous sequence being inserted. Lengths of homologous DNA of ~500 to 1 kb on each side of the mutation or insertion to be introduced are sufficient to give efficient transformation. Long lengths of heterologous sequence to be inserted will greatly reduce the transformation frequency, although insertions >6 kb have been obtained (Boyle-Vavra and Seifert, 1993). The insertion of plasmids into the chromosome (Basic Protocol 1) also depends on the length of the homologous sequence with homologous regions of 300 to 500 bp resulting in transformation frequencies in the 10^{-7} to 10^{-6} range (Hamilton et al., 2001).

The insertion of plasmids into the chromosome also depends on the length of the homologous sequence with homologous regions of 300 to 500 bp resulting in transformation frequencies in the 10^{-7} to 10^{-6} range (Hamilton et al. 2001). The frequency of transformation by electroporation (Basic Protocol 3) is very low ($\sim 10^{-9}$) and will only produce a few transformants per electroporation. Shuttle mutagenesis (Basic Protocol 4) works well and has been used to produce multiple mutations in single genes or random mutations in the gonococcal chromosome (Haas et al., 1993; Boyle-Vavra and Seifert, 1993, 1994; Mehr and Seifert, 1997). The constructs for complementation on the chromosome by double-crossover recombination (Basic Protocol 6) are effective for complementation; however, as these contain significant stretches of heterologous DNA, the transformation frequencies are significantly lower than those of simple insertion mutations. The *lac* promoter used in some of the constructs gives relatively high levels of transcription of introduced genes, approaching those of strong gonococcal promoters (Seifert, 1997).

Time Considerations

Although the transformation step can take as little as 5 min, the entire procedure from streaking the bacteria to freezing down the transformed strain may take five days. Most of the time is spent waiting for the bacteria to grow. In particular, selection with chloramphenicol or erythromycin—two of the most useful antibiotics for gonococcal manipulation—significantly slows growth of the bacteria such that transformants will take one and a half to two days to form a colony.

Table 4A.2.2 provides time requirements for many of the protocols presented in this unit.

Interaction of Enterohemorrhagic *Escherichia coli* (EHEC) with Mammalian Cells: Cell Adhesion, Type III Secretion, and Actin Pedestal Formation

The interaction of enterohemorrhagic *Escherichia coli* (EHEC) with host cells is critical for colonization of the mammalian intestine. A likely first step is bacterial adhesion to enterocytes, and Basic Protocol 1 describes the assessment of bacterial binding to cultured mammalian cells. After initial adhesion, the pathogen alters the host cell by injection of effectors via a type III secretion apparatus. Basic Protocol 2 describes methods to detect type III secreted proteins in culture medium, with a method for quantitating the actin pedestal phenotype described in the Support Protocol. Finally, one of the most notable alterations induced by EHEC is the induction of localized actin assembly directly beneath bound bacteria, resulting in the formation of actin pedestals that raise them above the plane of the membrane; Basic Protocol 3 describes detection and quantitation of actin pedestals in vitro.

CAUTION: Enterohemorrhagic *Escherichia coli* (EHEC) is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic techniques should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

ADHESION OF EHEC TO MAMMALIAN CELLS

BASIC PROTOCOL 1

To establish intestinal infection, EHEC must attach to the host mucosa, an event that can be approximated in vitro using cultured cell lines. EHEC are cultured under conditions that have been found to induce the expression of bacterial factors that promote host cell interactions, and cell monolayers are infected with defined numbers of bacteria. Nonadherent bacteria are removed by washing and the monolayers are fixed and stained to visualize the bound bacteria. Microscopic quantitation of stained bacteria provides a measure of bacterial adherence. Commonly, this assay has been performed on Hep-2 or HeLa cells, but other cell lines, such as Caco-2 cells, have been used as well.

Materials

HeLa cells (ATCC #CCL-2)
HeLa cell growth medium (see recipe)
LB broth (*APPENDIX 4A*) containing appropriate antibiotic (Table A.4A.2)
Enterohemorrhagic *Escherichia coli* (EHEC) strain of interest
DMEM/HEPES (see recipe) containing appropriate antibiotic
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
HeLa cell infection medium (see recipe)
2.5% paraformaldehyde (see recipe)
PBS (*APPENDIX 2A*) containing 0.1% (v/v) Triton X-100 (store at room temperature)

Contributed by Pamela J. Savage, Kenneth G. Campellone, and John M. Leong
Current Protocols in Microbiology (2007) 5A.1.1-5A.1.14

PBS (*APPENDIX 2A*) containing 1% (w/v) BSA (add 10 ml 10% w/v BSA to 90 ml PBS)
Anti-0157 rabbit polyclonal antibody (Difco): resuspend lyophilized powder in 3 ml PBS (*APPENDIX 2A*), then dilute 1:500 (recommended) in PBS containing 1% BSA
200 U/ml Alexa568-phalloidin stock in methanol (Invitrogen)
1 mg/ml 4′,6-diamidino-2-phenyindole dilactate (DAPI) stock
2 mg/ml goat anti-rabbit-Alexa488 (Invitrogen)
Mounting medium: 1:1 (v/v) PBS:glycerol or ProLong Gold Antifade Reagent (Invitrogen)
Clear nail polish

Sterile glass coverslips, 12 mm, circular
24-well tissue culture plates
Sterile forceps
14-ml snap-cap culture tubes (e.g., Falcon)
Platform rocker
Centrifuge with plate carrier (e.g., Allegra 6 Benchtop Centrifuge; Beckman Coulter)
Glass microscope slides
Opaque slide box

Additional reagents and equipment for epifluorescence microscopy (*UNIT 2A.1*)

Day 1: Culture HeLa cell monolayers and prepare bacterial cultures

1. Place sterile coverslips into a 24-well tissue culture plate (one coverslip/well) using sterile forceps. Use three coverslips per strain to be analyzed in order to obtain triplicate samples.

2. Seed coverslips with $\sim 10^4$ HeLa cells per ml of HeLa cell growth medium. Incubate at least 16 hr.

   After overnight incubation, the HeLa cell monolayer should be ∼90% confluent. If a different cell line is used, with different growth rate or degree of spreading, initial seeding density should be adjusted to give this level of confluence.

3. For each bacterial strain, inoculate 1.5 ml LB broth (plus appropriate antibiotics; Table A.4A.2) in a 14-ml snap-cap culture tube with a single colony from freshly streaked plates. Incubate with agitation for 8 hr at 37°C until the OD_{600} is between 0.4 to 0.5.

   The antibiotic is selected based on the bacterial antibiotic resistance marker (see APPENDIX 4A).

   It is best to inoculate the bacteria early on the same day that the mammalian cells are seeded.

4. Dilute 10 µl of the bacterial culture into 5 ml DMEM/HEPES, plus the appropriate antibiotic (Table A.4A.2), in a 14-ml snap-cap culture tube or equivalent.

5. Incubate 12 to 14 hr without agitation in a 5% CO_2 atmosphere at 37°C with cap loosely fastened.

   These culture conditions result in EHEC that are capable of efficient interaction with mammalian cells and translocation of protein "effectors," including those required for actin pedestal formation, directly into these cells via a type III secretion system. For review of type III secretion by EHEC, see Garmendia et al. (2005).

Day 2: Infect HeLa cell monolayers with bacteria (Day 2)

6. Briefly mix the bacterial culture from step 5 by inversion.

   This step and the remainder of the assay can be performed on the benchtop.

7. After mixing, dilute the culture in prewarmed (37°C) HeLa infection medium such that the final concentration is 8×10^6 bacteria/ml medium.

   Calculate the concentration of bacteria in the overnight culture based on an OD_{600} reading. Previous titration has revealed that an $OD_{600} = 1.0$ of wild-type EHEC strain EDL933 reflects ~3.5×10^8 bacteria/ml. Pilot titrations of other strains, performed by plating cultures of different OD_{600} for cfu, may be required to determine the precise correlation between OD_{600} and culture density for these strains.

8. Aspirate the mammalian culture medium from each well of the 24-well dish (from step 2) into a waste vacuum flask using a Pasteur pipet. Immediately add 1 ml PBS to each well using a pipet. Aspirate immediately and repeat wash once.

   When adding PBS, the tip of the pipet should be placed against the wall of each well so as not to disrupt the cell monolayers.

9. Add 1 ml bacterial stock (from step 6) per well.

10. Cover and gently rock the tissue culture plate 5 min at room temperature.

11. Centrifuge the plate 5 min at $1462 \times g$ (1000 rpm in a Beckman Coulter Allegra 6 Benchtop Centrifuge), room temperature.

12. Incubate the plate 60 to 90 min at 37°C in a 5% CO_2 atmosphere.

13. Remove the plate from the incubator, aspirate the medium, and immediately wash the coverslips with 1 ml PBS per well. Repeat this PBS wash four times.

    These washes must be done quickly yet gently, to avoid washing the monolayer off the coverslips.

Fix cells

14. Add 0.5 ml room temperature 2.5% paraformaldehyde to each well and incubate, without agitation, at room temperature for 15 min to fix the infected monolayers. Incubate an additional 15 min with gentle rocking.

15. Aspirate paraformaldehyde and add 1 ml PBS per well. Rock the plate gently for 2 min. Aspirate PBS.

16. Add 0.5 ml PBS/0.1% Triton X-100 per well to permeabilize the monolayers. Rock the plate gently for 5 min. Aspirate.

17. Immediately add 1 ml PBS per well to wash. Rock the plate gently for 2 min. Aspirate and repeat the wash two more times.

Stain monolayers and bacteria

18. Add 275 µl of anti-0157 polyclonal antibody (recommended dilution, 1:500 in PBS/1% BSA) per well. Incubate 30 min at room temperature with gentle rocking.

    Alternatively, if using DAPI to visualize the bacteria, skip this step and proceed to step 19. Refer to Critical Parameters for further discussion pertaining to choosing DAPI or specific antibodies.

19. Aspirate medium and wash wells with 1 ml PBS per well, each time rocking gently for 5 min at room temperature. Remove wash medium and repeat two more times.

20. Using a total volume of 275 µl in PBS/1% BSA, treat monolayers with the following:

    2 U/ml (final concentration) Alexa568-phalloidin (add from 200 U/ml stock)
    1 µg/ml (final concentration; add from 1 mg/ml stock) of DAPI (if anti-0157 polyclonal antibody was added at step 18, then add sufficient 2 mg/ml goat anti-rabbit-Alexa 488 for a final concentration of 10 µg/ml, instead of DAPI).

21. Wrap plate in aluminum foil and incubate 30 min at room temperature, with gentle rocking.

22. Aspirate medium and wash with 1 ml PBS per well, each time with gentle rocking for 5 min. Aspirate medium and repeat two more times. Add 0.5 ml PBS to each well.

    Keep the plate wrapped in foil during the washes, because the fluorophores are sensitive to light.

Mount and examine

23. Spot 10 µl mounting medium (1:1 PBS:glycerol or ProLong Gold Antifade Reagent) onto each of a set of glass slides (one slide for each coverslip prepared in this protocol).

24. Remove each coverslip from its well using forceps and mount, inverted, on the its corresponding prepared glass slide. Gently blot off excess mounting medium and seal edges of coverslip with clear nail polish.

25. Allow sealant to dry in the dark and then store slides in an opaque slide box at 4°C until evaluation by fluorescence microscopy.

    The slides can be stored at 4°C for up to 4 weeks.

26. Use epifluorescence microscopy (*UNIT 2A.1*) with a 100× oil-immersion objective (final magnification with oil equal to 1000×) to visualize cells.

    The outline of individual mammalian cells can be visualized using the red channel (λ=560 to 580 nm) to detect Alexa568- phalloidin, which stains filamentous actin (and thus actin stress fibers). If antibody rather than DAPI was used to stain bacteria, visualize the antibody-labeled bacteria using the green channel (λ=490 to 505 nm). See Critical Parameters for further discussion. An excitation wavelength of 395 to 410 nm is then used to visualize DAPI-stained bacteria.

27. For each slide, score the number of bacteria bound per cell for ~50 cells; move the stage in an ordered fashion to avoid counting same field twice.

    The average of triplicate samples will thus encompass data from ~150 cells.

BASIC PROTOCOL 2

FLUORESCENT STAINING OF EHEC-INDUCED ACTIN PEDESTALS

A hallmark of an EHEC infection is the generation of actin pedestals beneath sites of bacterial attachment on the intestinal mucosa. EHEC-induced actin assembly can be reproduced in vitro by infecting cultured cell monolayers, removing unbound bacteria, and staining for F-actin accumulation at sites of bacterial binding using fluorescently labeled phalloidin, a fungal toxin that specifically binds filamentous (F)-actin.

Materials

HeLa cell infection medium (see recipe), prewarmed
Desired primary antibody against host or bacterial protein of interest, diluted appropriately in PBS/1% BSA
2 mg/ml Alexa488-conjugated secondary antibody against species in which primary antibody was raised

Additional reagents and equipment for preparing EHEC-infected HeLa cell monolayers (Basic Protocol 1, steps 1 to 11) and quantitation of actin pedestal phenotype by fluorescence microscopy (Support Protocol)

Prepare EHEC-infected HeLa cell monolayers

1. Perform Basic Protocol 1, steps 1 to 11.
2. Incubate plate at 37°C in a 5% CO_2 atmosphere for 3 hr from initial time of infection.
3. Remove the plate from the incubator, aspirate the medium, and wash monolayer twice with PBS, using 1.0 ml/well.
4. Add 0.5 ml prewarmed HeLa cell infection medium to each well and incubate 2 hr at 37°C in a 5% CO_2 atmosphere.
5. Aspirate the medium and rapidly wash monolayer five times with PBS, each time using 0.5 to 1.0 ml/well.

Fix cells

6. To fix the infected monolayers, add 0.5 ml room temperature 2.5% paraformaldehyde to each well and incubate, without agitation, at room temperature for 15 min. Incubate an additional 15 min with gentle rocking.
7. Aspirate medium and wash monolayer once for 2 min using 0.5 ml PBS/well.
8. Aspirate medium and add 0.5 ml PBS/0.1% Triton X-100 per well to permeabilize the monolayer. Incubate 5 min at room temperature with gentle rocking.
9. Aspirate the medium and wash the monolayer three times, each time for 2 min with 0.5 ml/well PBS, at room temperature with gentle rocking.

Perform staining

10. To localize a host or bacterial protein of interest, add 275 μl of desired primary antibody (diluted appropriately in PBS/1% BSA) and incubate 30 to 45 min at room temperature with gentle rocking.
11. Aspirate medium and wash coverslips three times for 5 min each with 1× PBS (0.5 ml/well) at room temperature with gentle rocking.
12. Using a total volume of 275 μl in PBS/1%BSA, treat monolayers with the following:

    2 U/ml (final concentration) Alexa568-phalloidin (add from 200 U/ml stock) to visualize filamentous actin
    10 μg/ml Alexa488-conjugated secondary antibody (add from 2 mg/ml stock) to visualize the localization of primary antibody added in step 10
    and/or
    1 μg/ml (final concentration) DAPI to visualize bacteria.

    Wrap plate in aluminum foil and incubate 30 to 45 min at room temperature with gentle rocking.

    Researchers may wish to perform their own antibody titrations to establish the optimal concentrations in this step.

13. Aspirate solution, then wash coverslips four times, each time for 5 min with 0.5 ml/well PBS at room temperature with gentle rocking. Leave final wash medium in well.

Mount and examine

14. Spot 10 μl mounting medium or ProLong Gold Antifade reagent on glass slides and mount coverslips, inverted, on the prepared slides. Seal edges of coverslips with clear nail polish and allow to dry in a dark place.

15. Store slides in an opaque slide box at 4°C until ready to perform examination using fluorescent microscopy (Support Protocol).

The slides can be stored at 4°C for up to 4 weeks.

SUPPORT PROTOCOL

QUANTITATION OF ACTIN PEDESTAL PHENOTYPE BY FLUORESCENCE MICROSCOPY

Both EHEC and EPEC-mediated actin assembly activity can be quantitated using epifluorescence microscopy to determine the percentage of cell-associated bacteria generating actin pedestals.

Materials

EHEC grown on HeLa cell monolayers and stained for actin pedestals (Basic Protocol 2)

Additional reagents and equipment for epifluorescence microscopy (*UNIT 2A.1*)

1a. *To identify bound DAPI-stained EHEC:* Visualize cells using epifluorescence microscopy under 100× magnification with an excitation wavelength of 395 to 410 nm (*UNIT 2A.1*).

1b. *To identify associated actin pedestals:* Examine cells using an excitation wavelength of 560 to 580 nm to visualize Alexa568-stained phalloidin (*UNIT 2A.1*), which localizes to filamentous actin.

2. For each slide, score the number of bacteria bound per cell and the number of pedestals as follows:

   a. Score the number of bacteria bound per cell for ~50 cells. Move the stage in an ordered fashion to avoid counting same field twice.

   b. Simultaneously, score the number of pedestals on each of these 50 cells, and thereby derive the percentage of adherent bacteria generating actin pedestals.

   The average of triplicate samples will encompass data from ~150 cells.

BASIC PROTOCOL 3

IDENTIFICATION OF PROTEINS SECRETED BY THE EHEC TYPE III SECRETION SYSTEM

The second step of colonization, intimate attachment, requires the function of the EHEC type III secretion system. When EHEC is grown in LB medium, minimal amounts of protein are secreted by this system. However, under conditions that induce the activity of the type III secretion apparatus, such as growth in DMEM/HEPES or M9 minimal media, proteins secreted via this pathway can be detected in culture supernatants (DeVinney et al., 1999). Nevertheless, because EHEC do not secrete these proteins in large quantities, it is usually necessary to concentrate the supernatant prior to analysis by SDS-PAGE. In addition, although some investigators have utilized variations of this technique to characterize the repertoire of type III secreted proteins by protein staining of the sample, due to the difficulty in obtaining large amounts of these proteins, the authors of this unit routinely use immunoblotting to determine whether a putative type III secreted protein is secreted into culture supernatants in type III secretion–dependent fashion.

Materials

Enterohemorrhagic *Escherichia coli* (EHEC) strain(s) of interest and type III secretion–deficient mutant as control

Luria-Bertani (LB) broth (*APPENDIX 4A*) containing appropriate antibiotics (Table A.4A.2)

DMEM/HEPES (see recipe) *or* M9/glucose/bicarbonate medium (optional; see recipe)

20% glycerol, sterile (see recipe)

1× and 2× SDS sample buffer (*APPENDIX 2A*)

100 mM phenylmethylsulfonyl fluoride (PMSF) stock solution and 1 mg/ml pepstatin, leupeptin, aprotinin stock solutions (see recipe for protease inhibitor stock solutions)

14-ml snap-cap culture tubes (Falcon)

Centrifuge (e.g., Allegra 6 Benchtop Centrifuge; Beckman Coulter)

0.22-μm sterile filters

Centrifugal filter concentrators with MWCO appropriate to the protein of interest (Amicon)

Additional reagents and equipment for SDS-PAGE (Gallagher, 2006), staining of proteins in gels (Sasse and Gallagher, 2003), and immunoblotting (Gallagher et al., 2004)

Grow bacteria

1. For each EHEC strain, inoculate 1.5 ml LB broth (plus appropriate antibiotics; Table A.4A.2) with a single colony from freshly streaked plates in a 14-ml snap-cap culture tube. Incubate 8 hr with agitation at 37°C until the OD_{600} is between 0.4 to 0.5.

   It is important to carry a type III secretion–deficient mutant as a control in this experiment. Refer to Troubleshooting and Critical Parameters for further information.

2. In another 14-ml snap-cap culture tube, dilute bacterial culture 500-fold into 5 ml DMEM/100 mM HEPES (pH 7.4). Incubate 14 hr without agitation at 37°C in a 5% CO_2 atmosphere.

3. Dilute the DMEM culture 1:20 into 5 ml M9/glucose/bicarbonate medium or DMEM/HEPES. Incubate 5 hr at 37°C in a 5% CO_2 atmosphere.

   The use of an M9-based medium compared to DMEM-based medium results in a relative increase in the secretion of translocated effectors (i.e., proteins that are normally injected into mammalian cells) and a reduction in translocators (i.e., secreted proteins that are required for the translocation of effectors into mammalian cells; DeVinney et al., 1999). For more information on this phenomenon, as well as a description of bacterial mutants (deficient in SepL or SepD) that secrete very high levels of effectors, refer to Background Information," identification of proteins secreted by the EHEC type III secretion system."

Prepare bacterial supernatants

4. Collect bacteria by centrifugation at 1462 × *g* (3000 rpm in a Beckman Coulter Allegra 6 tabletop centrifuge), room temperature. Reserve the supernatant(s) on ice.

5. Resuspend pellet in 1 ml of 20% glycerol, transfer to a microcentrifuge tube, and harvest by microcentrifuging 1 min at 2000 × *g*, room temperature. Remove supernatant, repeat addition of glycerol and centrifugation, and again remove the supernatant.

   Washing the bacteria in 20% glycerol is associated with less nonspecific lysis of bacteria than washing in PBS.

6. Resuspend bacterial pellet in 50 μl of 1× SDS sample buffer and reserve for SDS-PAGE (step 11).

7. Sterilize culture supernatant from step 4 by passing through a 0.22-μm filter.

8. To the sterilized supernatant, add PMSF from 100 mM stock to a final concentration of 1 M, and pepstatin, leupeptin, and aprotinin from 1 mg/ml stocks to a final concentration of 10 μg/ml each.

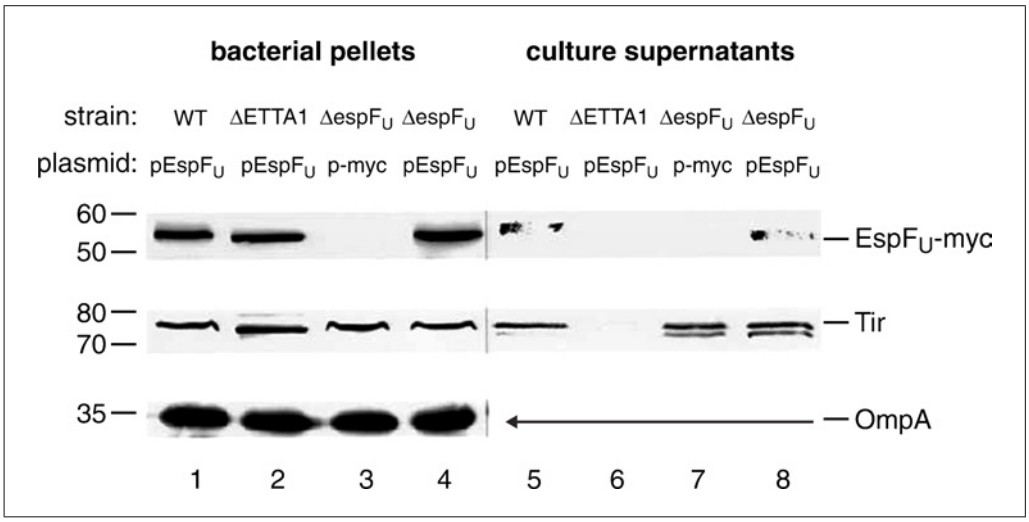

Figure 5A.1.1 Cultured bacterial strains were separated into bacterial and supernatant fractions prior to SDS-PAGE and immunoblotting, as described in Basic Protocol 3. A Type III secretion mutant (ΔETTA1) was included as a negative control and α-OmpA blotting was used as a loading-volume control. Reproduced from Campellone et al. (2004) with permission from Elsevier.

9. Concentrate the supernatants at least 50-fold using centrifugal filter devices.

   The authors have found that the centrifugal filter devices from Amicon work well for this application, but equivalent filters from other sources may be used. Filters with molecular weight cutoffs (MWCOs) of 10 kDa can be used unless very small proteins are of interest. See Critical Parameters section for a further discussion pertaining to MWCO and selection of centrifugal filters.

Analyze supernatants by SDS-PAGE

10. Add an equal volume of 2× SDS-PAGE sample buffer to the supernatant.

11. Visualize secreted protein using SDS-PAGE (Gallagher, 2006) followed by Coomassie Blue or silver staining (Sasse and Gallagher, 2003) or detect specific protein(s) by immunoblotting (Gallagher et al., 2004).

    The authors of this unit have used immunoblotting for detection of several secreted proteins, e.g., Tir or EspF$_U$ were detected by immunoblot after loading sample derived from the equivalent of 1.0 to 1.5 ml of supernatant (Campellone et al., 2004). See Figure 5A.1.1 for an example. Refer to Critical Parameters for suggestions pertaining to selection of controls.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DMEM/HEPES

Dulbecco's Modified Eagle Medium (DMEM), high-glucose formulation with L-glutamine and pyridoxine hydrochloride, without sodium pyruvate (commercially available from Invitrogen), supplemented with 100 mM HEPES (add from 1 M HEPES, pH 7.4, stock solution, also commercially available from Invitrogen). Filter sterilize and store up to 4 weeks at 4°C.

Store both the DMEM medium and the 1 M HEPES stock at 4°C until expiration dates.

Open all reagents, and prepare media, in laminar flow hood. Filter-sterilize and store at 4°C. When dividing complete medium into aliquots for use, perform all procedures in laminar flow hood.

Glycerol, 20%

Add 20 ml of 100% glycerol to 80 ml deionized water. Mix thoroughly and autoclave. Store indefinitely at room temperature.

HeLa cell growth medium

To 178 ml Dulbecco's Modified Eagle Medium (DMEM, high-glucose formulation, containing L-glutamine and pyridoxine hydrochloride, without sodium pyruvate; Invitrogen), add 20 ml heat-inactivated FBS (Invitrogen) and 2.0 ml of 100× penicillin/streptomycin (Invitrogen). Filter-sterilize and store up to 4 weeks at 4°C.

HeLa cell infection medium

To 190 ml Dulbecco's Modified Eagle Medium (DMEM, high-glucose formulation, containing L-glutamine and pyridoxine hydrochloride, without sodium pyruvate; Invitrogen) add 6.0 ml heat-inactivated FBS (Invitrogen) and 5 ml of 1 M HEPES, pH 7.4. Filter sterilize and store up to 4 weeks at 4°C.

M9/glucose/bicarbonate medium

To 750 ml sterile deionized H_2O (cooled to ≤50°C) add:
200 ml 5× M9 salts (see recipe)
2 ml 1 M $MgSO_4$
20 ml 20% (w/v) glucose (filter sterilized)
0.1 ml 1 M $CaCl_2$
44 ml 1 M $NaHCO_3$
Bring volume to 1 liter with deionized H_2O
Autoclave and store indefinitely at room temperature

M9 salts, 5×

Dissolve the following in a total volume of 1 liter deionized H_2O:
30 g $Na_2HPO_4 \cdot 7H_2O$
15 g KH_2PO_4
2.5 g NaCl
5 g NH_4Cl
Divide salt solution into 200-ml aliquots and autoclave
Store indefinitely at room temperature

Paraformaldehyde, 2.5%

Dissolve 0.5 g of paraformaldehyde in 20 ml of PBS (*APPENDIX 2A*). Heat to fully dissolve chemical but be careful not to boil solution. Make solution fresh on day of experiment. Ensure solution is at room temperature prior to use.

Volume can be adjusted depending on needs of experiment.

Protease inhibitor stock solutions

100 mM PMSF: Dissolve 0.174 g phenylmethylsulfonyl fluoride (PMSF) in 10 ml methanol.

1 mg/ml pepstatin: Dissolve pepstatin (Sigma) at 1 mg/ml in 95% ethanol with heating at ~60°C.

1 mg/ml leupeptin: Dissolve leupeptin at 1 mg/ml in water.

1 mg/ml aprotinin: Dissolve aprotinin at 1 mg/ml in water.

Store all protease inhibitor stock solutions up to 6 months at –20°C.

COMMENTARY

Background Information

Pathogenicity of EHEC

Enterohemorrhagic *E. coli* O157:H7 (EHEC) is a highly infectious Gram-negative bacterium that causes an illness often associated with the consumption of fecally contaminated food. During colonization of the large bowel, EHEC generates "attaching and effacing" (AE) lesions, characterized by loss of microvilli on the surface of the enterocyte, intimate bacterial attachment, and formation of an actin pedestal. These AE lesions may both promote colonization and contribute to compromising of the intestinal epithelial barrier. The host cell interaction has been the subject of extensive investigation based on its putative role in colonization, and each protocol in this unit addresses steps required for the production of AE lesions by EHEC. Several other likely important modifications of the host cell are associated with type III secretion of effectors, but a full discussion of this topic is beyond the scope of this protocol (for review, see Garmendia and Frankel, 2005)

In addition to host modification via type III secretion, EHEC produces a Shiga-like toxin (Stx) that can damage the intestinal mucosa and lead to hemorrhagic colitis. The toxins can be absorbed systemically, and severe cases of EHEC infection are associated with the life-threatening complication, hemolytic uremic syndrome (HUS), the triad of anemia, thrombocytopenia, and renal failure. Nevertheless, in most cases, recovery from infection occurs within 5 to 10 days with supportive treatment. The role of antibiotics in the therapy of EHEC infection is somewhat controversial, because Stx is phage-encoded and some antibiotics induce the Stx prophage, resulting in high-level production of toxin (Zhang et al., 2000).

At least two other pathogens also are capable of generating AE lesions. *Citrobacter rodentium* is a natural mouse pathogen that is often used as a model for EHEC. EPEC, mentioned extensively above, is an important cause of infantile diarrhea in the developing world and interacts with mammalian cells in culture with much greater efficiency than EHEC. Hence, as discussed above, it can serve as a useful positive control for each of the three assays described in this unit.

Adhesion of EHEC to mammalian cells

Currently, much is known about type III secretion and the role of some EHEC effectors in host cell modification (see below), but a significant gap exists in our knowledge of the mechanism of initial adherence to mammalian cells. Several potential ligands have been identified (Ebel et al., 1998; Tatsuno et al., 2001; Torres et al., 2002; Badea et al., 2003), but the identity of the adhesin(s) that mediated initial attachment of EHEC to host cell remains unclear. Historically, bacterial adhesion has been assessed using two general methods—the microscopic-based method such as that described above (Basic Protocol 1; Sherman and Soni, 1988; Donnenberg et al., 1993) or one dependent on titration of viable bacterial counts (i.e., colony forming units) of bacteria resistant to washing of the monolayer (Liu et al., 1999; Badea et al., 2003). The initial steps in both methods are identical, and the only difference lies in the mode of detection of bound bacteria. While both methods have been used successfully, in the authors' experience, the viable count assay has sometimes given a high degree of "background" binding, perhaps due to nonspecific attachment of bacteria to tissue culture plastic. Thus, the major advantage to microscopic-based evaluation lies in the ability of the investigator to exclusively count bacteria adherent to mammalian cells.

Fluorescent staining of EHEC-induced actin pedestals

The assay for actin pedestal formation was developed by Knutton et al. (1989) and has been a central assay in virtually all investigations of actin signaling by EPEC and EHEC. It is also commonly referred to as the filamentous actin staining, or FAS, assay. The striking morphology of these lesions and their specificity for pathogenic bacteria has suggested that the ability to form actin pedestals is important in colonization or disease. Thus far, however, experimental evidence directly linking actin signaling to pathogenicity is lacking (Deng et al., 2003). Nevertheless, actin pedestal formation remains a focus of research in EHEC and other attaching and effacing pathogens. Interestingly, whereas Tir is the only effector required for actin pedestal formation by EPEC, a second effector, $EspF_U$ (also known as TccP) is required in addition to Tir for pedestal formation by EHEC (Campellone et al., 2004; Garmendia et al., 2004). For both bacteria, initiation of actin signaling requires clustering of Tir in the plasma membrane, a function provided by the outer membrane protein intimin, which binds Tir and is functionally interchangeable between EPEC and EHEC.

A variety of cell lines have been used to assay actin pedestal formation. One advantage of using HeLa cells is that, not only are pedestals formed efficiently on these cells, but it is often possible to visualize most of the pedestals on a given cell in a single plane of focus because of their relatively flat morphology. Other cell lines have also been used, such as Hep-2 cells (Knutton et al., 1989), Caco-2 cells (which are physiologically more similar to colonic epithelium), and mouse embryonic fibroblasts (MEFs), which can be derived from specific knock-out cells, thereby providing a genetic test of the role of different mammalian signaling molecules in actin pedestal formation (Gruenheid et al., 2001).

Identification of proteins secreted by the EHEC type III secretion system

Type III secretion is critical to the pathogenesis of an EHEC infection. A large pathogenicity island, termed the LEE (for locus of enterocyte effacement) encodes components of a needle-like structure that spans the inner and outer membranes used for the secretion of a specific set of proteins (Jarvis et al., 1995; Abe et al., 1998; Perna et al., 1998), Some of these proteins, such as EspA, EspB, and EspD (where Esp denotes *E. coli* secreted protein), are translocators required for delivery of other secreted "effector" proteins into the host cell. Effector proteins, such as EspF, $EspF_U$, Tir, and Map, modify diverse host cell functions upon translocation (for review, see Garmendia et al., 2005). The ability to perform type III translocation is required for EHEC to establish infection and cause disease (Jarvis and Kaper, 1996). Therefore, the identification and characterization of type III secreted effectors have been essential to understanding of the pathogenesis of EHEC.

The expression of the type III secretion apparatus and effectors depends on the growth conditions of the bacterium. Secretion is very sensitive to temperature, pH, growth phase, and osmolarity (Kenny et al., 1997). Log-phase growth in DMEM, but not LB, gives rise to bacteria that are capable of type III secretion, particularly secretion of those components, such as EspA, EspB, and EspD, that are critical for translocation of effectors into the host cell. Growth in M9 minimal media reduces (but does not eliminate) the secretion of these components, and increases the secretion of effector proteins such as Tir (DeVinney et al., 1999) and $EspF_U$ (also known as TccP; Campellone et al., 2004; Garmendia et al., 2004). The growth conditions presented in the protocol are designed to optimize effector secretion. Recently it has been demonstrated that disruption of the LEE-encoded *sepD* or *sepL* genes results in enhanced secretion of effector proteins (O'Connell et al., 2004; Deng et al., 2005), an observation that has been used to identify a more complete set of effectors. Although beyond the scope of this protocol, *sepD* or *sepL* mutants may allow for more sensitive detection of effectors.

While this technique identifies proteins that are secreted by the type III apparatus, and many of these proteins are likely to be translocated into host cells, other techniques not covered here are required to document translocation. These methods rely on the translocation of hybrid proteins consisting of translocated effectors fused to enzymes (e.g., adenylate cyclase; Wolff et al., 1998) or TEM-1-β lactamase (Charpentier and Oswald, 2004) that exhibit maximal activity only upon entry into in the host cell.

Critical Parameters

Adhesion of EHEC to mammalian cells

It is important to include positive and negative controls when initially developing these assays. A reasonable positive control is enteropathogenic *E. coli* (EPEC, e.g., strain E2348/69; Levine et al., 1985), a close relative of EHEC. Unlike EHEC, EPEC possesses a bundle-forming pilus that promotes efficient bacterial binding to cultured cells. Because EPEC binds more efficiently to cells than EHEC, the authors routinely inoculate monolayers with 5- to 10-fold fewer EPEC. A nonadherent negative control, such as a derivative of *E. coli* K12 (e.g., MC1061), can be used to establish a baseline for "nonspecific" binding. Alternatively, an EHEC mutant defective for type III secretion also is largely defective for binding.

The decision to stain bound bacteria with DAPI or an EHEC-specific antibody is related to the strains being analyzed. For example, EPEC and *E. coli* K12 strains will not stain with anti-O157 antibody, so the authors routinely use DAPI staining in experiments that include either of these control bacteria. The most significant disadvantage to using DAPI is the difficulty in visualizing bacteria that are overlying the mammalian nucleus, which stains intensely with DAPI. However, because scoring of DAPI-stained samples uniformly excludes bacteria in this location, this

limitation should not significantly alter the comparison of bacterial adherence among different strains.

Fluorescent staining of EHEC-induced actin pedestals

Whereas EPEC is highly proficient at generating actin pedestals on cultured monolayers, actin pedestal formation by EHEC is somewhat variable, depending on strain, the particular source of serum, and unknown factors. The authors currently use serum from Gibco (an Invitrogen product line) with success, but other sources of serum may be equivalently efficacious. Because of this potential variability, when initially establishing this assay, EPEC may serve as a useful positive control. Alternatively, a *dam* methylase EHEC mutant is also far more proficient at generating actin pedestals than wild-type EHEC (Campellone et al., 2007) and could similarly function as a positive control.

The temperature of the paraformaldehyde solution used for fixation is critical, because the authors have found that if the paraformaldehyde is not cooled to room temperature, the bacteria-, even those bacteria that are not associated with mammalian cells, are stained nonspecifically with Alexa568-labeled phalloidin.

Identification of proteins secreted by the EHEC type III secretion system

The success of this assay is dependent on the growth conditions that induce the function of the type III secretion apparatus. Thus, bacterial growth conditions are critical. Growth in DMEM/HEPES medium (see Reagents and Solutions) promotes the secretion of translocator proteins, whereas growth in M9 minimal medium (also described in Reagents and Solutions) promotes the secretion of effector proteins while down-regulating the secretion of translocators. Moreover, to rule out the possibility that proteins found in the culture supernatant are the result of nonspecific lysis or secretion via alternative pathways, the parallel analysis of a mutant defective for type III secretion, such as an *ETTA1* deletion mutant, should be performed (Campellone et al., 2004). Similarly, the detection of Tir or other previously characterized secreted effectors in the supernatant of EHEC cultures would provide a positive control. If the putative secreted effector is also expressed by the related pathogen EPEC, this strain, which is more proficient at type III secretion in vitro than EHEC, could provide a more robust signal in this assay.

Finally, the amount of effectors present in the supernatant will obviously vary with the expression level and secretion efficiency of that particular effector. Thus, if one fails to find the putative effector in the supernatant, scaling up the amount of material loaded is a reasonable alternative.

Troubleshooting

Table 5A.1.1 presents some of the problems commonly encountered with adhesion of EHEC to mammalian cells (see Basic Protocols 1 and 2).

Anticipated Results

Adhesion of EHEC to mammalian cells

Using the protocol outlined above, the authors have typically found ~250 wild-type EHEC strain EDL933 bound per 50 mammalian cells. With EPEC strains, one typically finds 2- to 5-fold more bacteria bound per given number of cells than with EHEC (e.g.,

Table 5A.1.1 Troubleshooting Guide for Analyzing Adhesion of EHEC to Mammalian Cells

Problem	Possible cause	Solution
No bacteria bound	MOI too low	Increase number of bacteria initially added
	Washes too harsh	Prior to fixation with PFA, the washes with PBS must be very rapid yet gentle[a]
	Anti-O157 antibody or DAPI concentration too dilute	Titrate the concentration of antibody or DAPI
No mammalian cells left on coverslip	Washes too harsh and/or cells exposed to PBS for too long[b]	Prior to fixation with PFA, the washes with PBS must be very rapid yet gentle[a]
		Consider precoating glass coverslips with gelatin or polylysine in order to facilitate cell attachment

[a] See Basic Protocol 1, step 13.

[b] HeLa cells are very sensitive to serum starvation and can detach from glass coverslips in low serum conditions.

~500 to 1250 bacteria bound per 50 mammalian cells), even with the lower inoculum. At most, one or two of the negative-control *E. coli* K12 are typically bound per 50 cells.

Fluorescent staining of EHEC-induced actin pedestals

Using the protocol outlined above (Basic Protocol 2), one will normally see significant cell-to-cell variation in bound bacteria and pedestals. Many mammalian cells will not be associated with any bacteria, whereas others may harbor ten or more bound bacteria. Normalizing pedestals to bound bacteria, the authors have typically found ~75% of bound wild-type EHEC strain EDL933 are associated with easily detected actin pedestals. For EPEC, this figure is usually closer to 90%.

Identification of proteins secreted by the EHEC type III secretion system

The equivalent of 1.5 ml culture supernatant typically contains enough effector molecule for easy detection by immunoblotting (Campellone et al., 2004), although this may vary significantly depending upon the specific effector.

Time Considerations

Basic Protocols 1 and 2 require multiple days for the culturing of mammalian cell lines, as well as a day to prepare the bacterial cultures. The infection and staining steps can be completed in 1 day. Additionally, Basic Protocol 3 requires 2 days to complete: 1 day for the culturing of the bacteria and an additional day for lysate preparation and examination by immunoblotting.

Acknowledgements

The authors would like to thank Brian Skehan and Michael Brady for their helpful discussion pertaining the methods described in this unit.

Rapid Allelic Exchange in Enterohemorrhagic *Escherichia coli* (EHEC) and Other *E. coli* Using λ Red Recombination

The ability to generate defined mutations in enterohemorrhagic *Escherichia coli* (EHEC) has been essential to the analysis of its pathogenicity. The generation of such mutants has typically been done by integrating a plasmid containing the mutant gene of interest and a selectable marker followed by resolving the co-integrant to remove plasmid backbone sequences. Unfortunately, this procedure does not always transfer the mutation to the chromosome as desired, nor does it occur at a high frequency. Furthermore, the techique is time consuming and requires prior cloning of the gene of interest.

A gene replacement method for *E. coli* that has been gaining widespread adoption over the last five years involves transient expression of the bacteriophage λ Red recombination system (for review, see Court et al., 2002). The practice of using phage recombination systems to promote engineering of bacterial chromosomes is known as "recombineering." The λ Red recombineering technology has simplified allelic exchange in *Escherichia coli* K-12 and *Salmonella enterica* Serovar enteritidis, and has encouraged use of the system in pathogenic species of *E. coli*, including enterohemorrhagic (EHEC) and enteropathogenic (EPEC) *E. coli* (Murphy and Camplellone, 2003).

The regulated expression of the λ bacteriophage genes *bet* (ssDNA annealing function), *exo* (a 5′-3′ dsDNA exonuclease), and *gam* (inactivation of host RecBCD function) in *E. coli* species renders the bacteria hyper-recombinogenic and amenable to gene replacement via electroporated linear DNA substrates. These substrates can be easily generated using PCR, purified using standard DNA purification methods, and introduced by electroporation into electrocompetent bacteria. The methods presented in this unit describe the necessary plasmids and growth conditions needed to render EHEC hyper-recombinogenic, the means via which the authors' laboratory generates linear DNA substrates, and the selection methods employed to obtain potential recombinants (see Basic Protocol).

In addition, a method for the preparation of electrocompetent/hyper-recombinant EHEC cells is presented (Support Protocol), as well as an alternative for the generation of precise unmarked deletions (i.e., deletions containing no exogenous DNA sequences, such as a drug marker) in EHEC using *sacB* counterselection (Alternate Protocol). Variations of these methods and helpful hints for successful gene knockouts are provided in the Commentary section.

CAUTION: Enterohemorrhagic *Escherichia coli* (EHEC) is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

RED-PROMOTED GENE REPLACEMENT IN EHEC

BASIC PROTOCOL

The following protocol is the one used in the authors' laboratory for gene replacement in EHEC. The initial step involves generating a recombination substrate. This is most easily done by generating a PCR product which contains a drug marker flanked by 40 bp of DNA upstream and downstream of the target gene. The PCR product is purified and

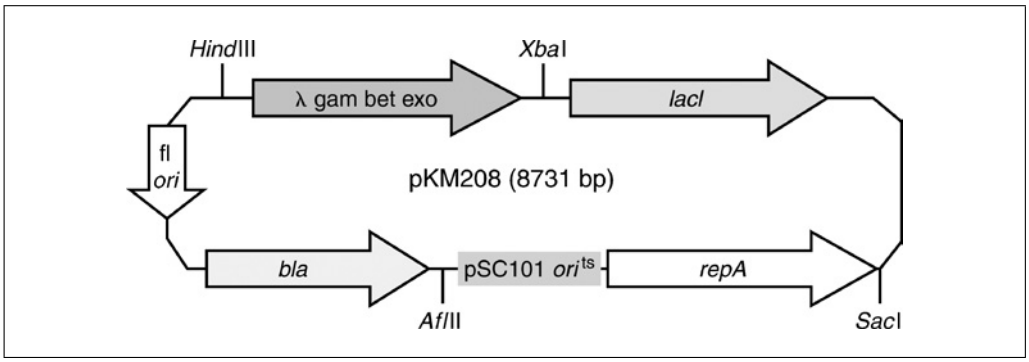

Figure 5A.2.1 Map of pKM208. Positions of key genetic elements in plasmid pKM208 (clockwise from top left): Ptac-*gam-bet-exo* operon, *E. coli lacI* repressor gene, *repA*, pSC101, ampicillin^R-encoding *bla* gene, and the f1 *ori*. A subset of unique restriction sites is shown. The *lacI* gene, contained within a *Not*I fragment (not shown), is absent from plasmid pKM201. The pSC101 ori^{ts} is a low-copy-number replicon which allows growth of the plasmid at 30°C but not at 44°C (Hamilton et al., 1989). While originally described as a tool for generating gene deletions in *E. coli*, it is used here for the Red-producing plasmid to allow for easy curing of the plasmid following Red-promoted gene replacement.

electroporated in EHEC cells containing the Red-producing plasmid pKM208 (Fig. 5A.2.1). Following electroporation, the culture is allowed to proliferate and gene replacements are selected on antibiotic selection plates.

Table 5A.2.1 presents the time required for the major components of this protocol.

Materials

Linear DNA substrate containing drug marker sequence (see Critical Parameters and Troubleshooting)
Polymerase: *Taq* polymerase (New England Biolabs)
dNTPs (*APPENDIX 2A*)
Appropriate PCR buffer (e.g., see *APPENDIX 2A*)
TE buffer (*APPENDIX 2A*)
Electrocompetent EHEC transformed with Red-producing plasmid (Support Protocol)

Table 5A.2.1 Time Considerations for Red-Promoted Gene Replacement in EHEC

Day	Activity	Time required
Day 1	Prepare and purify PCR product	2-3 hr
	Streak and incubate at 30°C to isolate single colonies of EHEC/pKM201 or pKM201 on LB/Amp	Overnight
Day 2	Prepare electrocompetent cells starting with one colony in 20 ml of LB containing antibiotic[a]	6-8 hr
	Electroporate, grow culture, and plate	2 hr
	Incubate to grow visible colonies	Overnight
Day 3	Restreak potential recombinants	15 min
	Incubate to grow visible colonies	Overnight
Day 4	PCR analysis	2-4 hr

[a]As an alternative, electrocompetent cells can be prepared ahead of time and frozen at −80°C.

Primer 1	5′ *GACGGGTTGTTACTCGCTCACATTTAATGTTGATGAAAGC* AATCTCTGATGTTACATTGC 3′
Primer 2	5′ *AAGAAAGCCTGACTGGCGGTTAAATTGCCAACGCTTATTA* TTCAACTCAGCAAAAGTTCG 3′

Figure 5A.2.2 An example of two 60-oligomer primers used to generate a PCR product for λ Red–promoted gene replacement (in this case, a Δ*lacZ*::*kan* allele). The underlined region in primer 1 contains 5′ to 3′ sequence upstream of the *aph* gene (i.e., top strand reading rightward in the *aph* region when read as a dsDNA sequence file; not shown)—the *aph* gene encodes kanamycin resistance (*kan*). The underlined region in primer 2 contains 5′ to 3′ sequence downstream from the *aph* gene, (i.e., bottom strand reading leftward in the *aph* region when read as a dsDNA sequence file; not shown). These are the sequences that will prime the PCR reaction. The region in italics in primer 1 contains 5′ to 3′ sequence from the N-terminal encoding region of *lacZ* (top strand reading rightward in the sequence file of *lacZ*; not shown), while the region in italics in primer 2 contains 5′ to 3′ sequence from the C-terminal encoding region of *lacZ* (bottom strand reading leftward in the sequence file of *lacZ*; not shown). These are the regions that will define the homology with the target gene, *lacZ*.

SOC medium (*APPENDIX 4A*)

LB plates (*APPENDIX 4A*) containing appropriate antibiotic (see Critical Parameters and Troubleshooting, Drug Markers)

Electroporator and 0.1-cm gap length electroporation cuvettes

Additional reagents and equipment for PCR (Kramer and Coen, 2001), purification of DNA from aqueous solution (Moore and Downhan, 2002), and Southern blotting (*UNIT 14B.1*; optional)

1. Order two 60-oligomer primers with the following characteristics. Try to keep the overall GC content of the primers around 50% ± 5%.

   Primer 1: Should have the first 40 bases (the 5′ end) complementary to the sequence encoding the N-terminal region of the target gene and the final 20 bases (the 3′end) complementary to the sequence on one end of the drug cassette.

   Primer 2: Should have the first 40 bases complementary to the sequence encoding the C-terminal region of the target gene, and the final 20 bases complementary to the other end of the drug cassette.

   The choice of target sequences in these primers will dictate the endpoints of the deletion. See Figure 5A.2.2 for an example.

2. Prepare a PCR reaction by combining linear DNA substrate containing drug marker sequence, primers, polymerase, dNTPs, and appropriate buffer. Perform standard PCR optimized for the sequences involved (Kramer and Coen, 2001).

3. Purify the PCR product using traditional DNA purification methods (Moore and Downhan, 2002) or commercially available PCR product purification kits.

   The purpose of this step is to remove salts from the PCR buffer that would interfere with the electroporation step that follows. In some cases, gel purification of the PCR product is warranted (see Critical Parameters and Troubleshooting, PCR Templates).

   The PCR product contains the drug marker flanked on one end by a 40-bp sequence from the N-terminal encoding region of the target gene, and on the other end by a 40-bp sequence from the C-terminal encoding region of the target gene.

4. Resuspend PCR product in TE buffer.

5. Place electroporation cuvettes in an ice-water bath for 10 min.

   Ensuring the cuvettes are cool is important as electroporation of the sample can generate excessive heat, causing a decrease in cell survival.

6. In a microcentrifuge tube, mix 1 to 5 μl purified PCR product (0.1 to 1 μg) with 50 μl electrocompetent EHEC transformed with Red-producing plasmid (pKM201 or pKM208). Transfer to the precooled cuvette and incubate 1 min on ice.

   PCR product and electrocompetent cells are combined in a microcentrifuge tube rather than directly in the electroporation cuvette to ensure adequate mixing of cells and PCR product.

7. Thoroughly (but quickly) dry the cuvette with Kimwipes. Insert it into the electroporation chamber and quickly pulse at 2200 V or voltage suggested by the electroporator manufacturer for *E. coli*.

   CAUTION*: Maintain the cap on the cuvette during electroporation of EHEC cells to prevent possible aerosol formation.*

8. Immediately add 0.5 ml SOC medium and mix thoroughly with the cells in the electroporation chamber. Transfer 0.5 ml of this mixture to a culture tube containing 1 to 2.5 ml SOC.

   It is not necessary to remove the small amount of mixture contained between the electroporation plates (< 100 μl), as this represents a small fraction of the total sample.

9. Incubate the culture 60 to 90 min at 37°C with rolling to aerate the cells.

10. *Optional*: Save a portion (0.3 ml) of the culture and use to prepare an overnight culture (5 ml total) in LB medium. Plate 0.1 ml of various dilutions of this overnight culture onto LB plates containing appropriate antibiotic.

    This step is required when expression of the drug marker has not reached appropriate levels within the first 90 min of growth following electroporation to confer resistance, as is sometimes the case when tetracycline is used. It is typically unnecessary to perform this step, but it should be tried when cells plated 60 to 90 min following electroporation fail to yield recombinants.

11. Following 60 to 90 min incubation, plate remaining SOC culture from step 9 onto LB plates containing appropriate antibiotic. Incubate overnight at 37°C.

    The appropriate antibiotic is one that selects for the marker contained on the linear DNA substrate (i.e., PCR product; step 1). See Critical Parameters and Troubleshooting, Drug Markers, for important details regarding antibiotic selection.

    The authors typically plate 0.5 ml/plate. To conserve plates, one can concentrate the cells by microcentrifuging 1 min at moderate speed (~2/3 of maximum), 4°C, resuspending in 0.25 ml SOC, and spreading the entire mixture onto one plate.

12. Identify colonies on plates (see Critical Parameters and Troubleshooting). Using an inoculating loop, pick and streak two to four colonies onto fresh LB antibiotic-selection plates. Incubate overnight at 37°C.

    The authors typically streak two colonies per plate.

13. As an alternative (or in addition) to step 12, streak a larger number of colonies (~40 streaks per plate) onto both LB and LB antibiotic-selection plates as follows.

    a. Pick a colony off the transformation plate(s) (step 11) with an inoculating loop.
    b. Transfer using one, small (0.5-cm) streak onto an LB antibiotic selection plate, followed immediately (without flaming) by a streak of similar size onto an LB plate.
    c. Incubate overnight at 37°C.
    d. Identify false positives as those that grow poorly on the LB antibiotic-selection plate relative to their growth on the LB plate.

e. Select two to four candidates that grow well on both plates and streak onto LB-antibiotic-selection plates (one to two colonies per plate) to obtain single colonies.

f. Incubate overnight at 37°C.

The presence and magnitude of false positives varies with bacterial strains, antibiotic used, drug concentrations, and the amount of culture plated in step 11. Many times it does not arise, but can be especially troublesome with the use of chloramphenicol in EHEC (see Critical Parameters and Troubleshooting). With EHEC, false positives are less of a problem if kanamycin is used as the drug marker.

14. Verify true chromosomal gene replacement via PCR (Kramer and Coen, 2001), phenotypic screens, and/or Southern blot analysis (*UNIT 14B.1*).

The authors typically use a series of colony PCR reactions to verify gene replacement (see Critical Parameters and Troubleshooting). Each of the two junctions of marker and chromosomal sequence can be verified by using one primer complementary to the drug marker and the other primer complementary to a nearby region of the chromosome not contained in the original PCR product. Amplification across the drug marker using a primer pair that flanks but does not include the original PCR product should give a product (containing the marker and flanking chromosomal sequence) of the predicted size. Finally, a primer pair specific to the putative deleted sequence should not generate an amplicon from recombinant colonies but should result in the predicted amplicon when the parental wild-type strain is used.

GENERATION OF UNMARKED CHROMOSOMAL DELETIONS IN EHEC USING SACB COUNTERSELECTION

ALTERNATE PROTOCOL

The following method is a variation of the Basic Protocol where instead of using a drug marker in place of the gene, following the protocol first used by Ried and Collmer (1987), a cassette containing the *cat* (positive selection) and *sacB* (negative selection) genes is used. SacB is a levansucrase that transfers fructosyl residues from sucrose to different cellular receptors such as alcohols, sugars, and levans (Dedonder, 1966). Expression of *sacB* kills *E. coli* in the presence of sucrose (Gay et al., 1983). Thus, two rounds of Red recombination are required: the first selects for chloramphenicol resistance (Cam^R/Suc^S), while the second inserts the precise deletion and evicts the cassette (generating Cam^S/Suc^R colonies).

The second electroporation uses a linear DNA species, typically from a previously constructed plasmid, that defines the precise deletion desired. The authors have used a plasmid that contains the upstream region of the target gene fused to the downstream region, constructed in such a way that this linear DNA can be liberated from the plamid by a restiction enzyme digest (Murphy et al., 2000). Using PCR manipulations to construct these plasmids, the authors usually fuse the first three condons of the target gene to the last three codons in order to allow translational read through of the deletion once crossed into the chromosome.

The construction of an in-frame unmarked deletion, one that contains no drug marker or other scar, is useful when one is limited by the number or availability of antibiotic resistance genes used for a particular pathogen. For instance, once a drug marker is removed from the chromosome, it can then be used at a second location within the same bacterium. Also, if one plans to test the mutant bacterial strain in animal studies, it is best to use a strain containing no antibiotic resistant determinants to (1) rule out polar effects of the drug marker (or its expression) on bacterial genes nearby the site of the deletion and (2) prevent the accidental spread of antibiotic resistant determinants in animal populations.

A potential problem with the use of *sacB* is the generation of spontaneous Suc^R colonies due to loss or mutation of the *sacB* gene. The authors have found this to be more of

Table 5A.2.2 Time Considerations for Generation of Unmarked Chromosomal Deletion in EHEC Using SacB Counterselection

Day	Activity	Time required
Day 1	Insert *Not*I fragment from pKM154 containing *cat-sacB* cassette into plasmid containing target site sequences; make minilysate	2 days
Day 3	Prepare and purify fragment containing *cat-sacB* cassette flanked by target sequences by gel purification	4 hr
	Perform first Red-promoted gene replacement (i.e., insert *cat-sacB* in place of target gene)	3 days[a]
Day 5	Perform restriction digestion on plasmid containing target site sequences to liberate deletion-containing fragment	1-2 hr
Day 6	Prepare $Cam^R/Suc^S/Amp^R$ transformant from first electroporation for electrocompetence and hyper-recombinogenicity	6-8 hr
	Perform second Red-promoted gene replacement (insert unmarked deletion in place of *cat-sacB*)	3 days[a]
Day 9	Purify candidates by streaking out for $Suc^R/Cam^S/Amp^S$ transformants; incubate at 37°C	Overnight
Day 10	Test unmarked deletions by colony PCR	2-4 hr

[a]See Table 5A.2.1.

a problem when *sacB* is on a plasmid and much less so when *sacB* is integrated into the chromosome. Starting the electrocompetent culture from a single overnight colony minimizes the presence of spontaneous *sacB* loss and mutation.

Table 5A.2.2 presents time considerations involved in performing this procedure.

Additional Materials *(also see Basic Protocol)*

3.5-kb *Not*I fragment from pKM154 (i.e., the *cat-sacB* cassette; Murphy et al., 2000)
Restriction enzyme(s) and appropriate buffer
LB plates supplemented with chloramphenicol (LB/Cam; for antibiotic concentrations, see Critical Parameters and Troubleshooting, Drug Markers)
LB plates without NaCl, supplemented with 10% sucrose (LB/Suc), room temperature and 30°C
LB plates supplemented with ampicillin (LB/Amp; for antibiotic concentrations, see Critical Parameters and Troubleshooting, Drug Markers)
Linear DNA fragments containing precise (unmarked) deletion of the region of interest (Murphy et al., 2000) suspended in TE buffer
Additional reagents and equipment for constructing plasmids (Murphy et al., 2000), purifying DNA fragments by gel electrophoresis (Moore et al., 2002), and preparing electrocompetent hyper-recombinant cells (Support Protocol, steps 2 to 12)

1. Construct a plasmid containing 0.5 to 1 kb sequence upstream of the target fused to 0.5 to 1 kb sequence downstream of the target (Murphy et al., 2000). Place a *Not*I site between the two.

The plasmid should be constructed in such a manner that a DNA fragment containing the sequence upstream and downstream of the target gene (as well as the cat-sacB cassette if the substrate is to be prepared on a plasmid; see step 2a) can be liberated as an intact fragment by a restriction digest (for details, see Murphy et al., 2000).

2a. *For preparation of recombination substrate on a plasmid:* Construct a second plasmid by placing the 3.5-kb *Not*I fragment from pKM154 (containing *cat-sacB*) into the plasmid constructed above.

While this step involves the construction of an additional plasmid, the recombination substrate will have a greater amount of flanking homology to the target site relative to the PCR-generated substrate described below (0.5 to 1 kb versus 40 bp), thus providing a greater chance of a successful gene replacement.

2b. *For preparation of substrate using PCR:* Prepare a PCR substrate containing the *cat-sacB* cassette flanked by 40 bp of DNA which contains sequence from upstream and downstream of the region of interest (Kramer and Coen, 2001).

This PCR fragment will be larger (~3.6 kb) than the PCR products described in the Basic Protocol, which are typically <1 kb). Thus, PCR-generated sequence errors in sacB that generate a SacB$^-$ phenotype (Suc^R) will have to be screened out of the pool of transformants. Use of high fidelity polymerases will likely alleviate this problem, though this has not yet been tested in the authors' laboratory.

3. If necessary (i.e., for substrates prepared on plasmids), liberate the fragment containing the *cat-sacB* cassette and flanking upstream and downstream sequences using an appropriate restriction enzyme(s). Purify the fragment by agarose gel electrophoresis (Moore et al., 2002).

This DNA fragment must be gel purified prior to electroporation, as simple transformants of uncut plasmid will appear as gene replacement candidates when performing Red-promoted gene replacement.

4. Using either the PCR product or the gel-purified restriction fragment, perform steps 5 to 11 of the Basic Protocol, selecting for Cam^R colonies.

5. Streak isolated Cam^R colonies from the transformation plate onto LB/Cam to verify positive selection, LB/Suc for negative selection, and LB/Amp to verify the presence of pKM201 or pKM208 as follows. Each set of plates can contain ~40 streaks.

a. Pick a colony off the transformation plate(s) with an inoculating loop.
b. Transfer using one, small (0.5-cm) streak onto an LB/Suc plate, followed immediately (without flaming) by a streak of similar size onto an LB/Amp plate, and again onto an LB/Cam plate.
c. Incubate 1 day at 30°C.
d. Identify Cam^R/Suc^S/Amp^R transformants. Streak onto LB/Amp plates to obtain single colonies.
e. Incubate 1 day at 30°C.

Plasmid pKM201 and pKM208 are many times lost spontaneously following electroporation, which is advantageous if one wants to study the gene knockout in an otherwise wild-type background. If it is not lost spontaneously, streaking out the transformation at 42°C will promote loss of the Red plasmid. Here, however, one needs to retain the Red plasmid for the subsequent gene eviction step. Therefore, incubation is performed at 30°C. (Red-producing plasmids contain temperature-sensitive origins of replication; see Fig. 5A.2.1.)

It should be evident here why the recombinant fragment from the second plasmid described in step 1a must be gel purified—i.e., transformation by plasmid would also yield Cam^R/Suc^S/Amp^R transformants. Minilysates can be prepared from the candidates to verify the absence of the substrate plasmid and the presence of Red-producing plasmid.

Also, a PCR test, or a phenotypic test (if available), for the gene knockout can be used at this step to verify the absence of the target gene.

For an unknown reason, selection for Suc^S mutants is more readily achieved using LB plates without sodium chloride.

6. Prepare a $Cam^R/Suc^S/Amp^R$ transformant from this second LB/Amp plate for electrocompetence and hyper-recombinogenicity as described in steps 2 to 12 of the Support Protocol.

7. Using the technique described in steps 5 to 8 of the Basic Protocol, electroporate a restriction digest of the plasmid containing the precise (unmarked) deletion of the target gene (or region of interest) constructed in step 1.

   Note that the recombining fragment need not be gel purified, since the selection in this step (Suc^R) involves loss of a chromosomal marker rather than the acquisition of an antibiotic marker carried by a potentially contaminating plasmid.

8. Incubate the culture at 37°C by rolling at least 5 hr (or overnight).

   Extra incubation time relative to Basic Protocol, step 9, is necessary since $sacB^+$ is dominant to $sacB^-$, and time is needed for recovery from electroporation shock and segregation of multiple chromosomes.

9. If the culture has been grown for 5 hr, plate onto LB/Suc plates at 0.5 ml/plate. Alternatively, if the culture has been grown overnight to saturation, prepare four 10-fold dilutions in LB medium and plate 0.1 ml of each onto LB/Suc.

10. Incubate overnight at 37°C. Select for Suc^R colonies.

11. Streak individual Suc^R colonies onto LB and LB/Cam plates to identify Cam^S transformants.

12. Simultaneously, screen for Amp^S candidates as well to identify cells that have spontaneously lost the Red plasmid. If no Amp^S transformants are found, streak at 42°C to cure the cell of the Red plasmid.

13. Verify deletion by PCR analysis (Kramer and Coen, 2001).

    See Basic Protocol, step 14, and Critical Parameters and Troubleshooting for more information.

SUPPORT PROTOCOL

GENERATION OF ELECTROCOMPETENT HYPER-RECOMBINANT EHEC CARRYING THE λ-RED FUNCTIONS

This protocol describes the growth and preparation of EHEC strains for Red recombineering. Two plasmids have been used successfully in the authors' laboratories for the λ-Red mediated recombination in EHEC: pKM201 and pKM208 (Murphy and Campellone, 2003). Both vectors are low-copy number plasmids, contain temperature sensitive origins of replication, provide ampicillin resistance, and express λ Red functions (*bet*, *exo*, and *gam*) under control of the Ptac promoter. The difference between these plasmids is that pKM208, in addition to Red, expresses the lacI repressor, while pKM201 does not. Thus, while both require IPTG for full induction, the recombination functions from pKM208 are repressed in the absence of IPTG, an advantageous situation given that continued overexpression of Red functions is mutagenic (Murphy and Campellone, 2003). (Under the conditions of transient expression described in this unit for pKM208, Red is not mutagenic.) Both of these plasmids, when induced, will render EHEC hyper-recombinogenic and promote recombination with linear dsDNA substrates.

This technique differs from other methods of electrocompetent cell preparation by the inclusion of a heat shock step. It is thought that the heat shock prepares the cells for the

shock of electroporation, resulting in higher rates of survival, and thus increased numbers of transformants. This effect can vary from 2- to 50-fold; the mechanism of this effect, and its variability, is not understood. In this description, a 20-ml starting culture is used for the prepration of electrocompetent cells, which is enough for two electroporations. The procedure can be scaled up as needed.

Materials

LB plates (*APPENDIX 4A*) containing 100 μg/ml ampicillin (LB/AMP)
EHEC containing pKM201 or pKM208 (Murphy and Campellone, 2003)
SOC medium (*APPENDIX 4A*) containing 100 μg/ml ampicillin, 30°C
100 mM IPTG (see recipe)
20% (w/v) glycerol, 4°C
30° and 42°C shaking water baths

1. Streak EHEC containing pKM201 or pKM208 onto LB plates containing 100 μg/ml ampicillin. Incubate 24 hr at 30°C.

   Lower drug concentrations are sometimes required for selecting plasmid transformants. However, once established, the transformants grow well at higher drug concentrations. The authors have observed this with pKM208 in EHEC. Thus, for transformation of EHEC with pKM208, one should try low levels of ampicillin (50 μg/ml or lower), but once established, the transformant should be maintained at 100 μg/ml. Also see Critical Parameters and Troubleshooting.

2. Inoculate 20 ml warm SOC medium containing 100 μg/ml ampicillin with one to four purified colonies.

   LB medium (APPENDIX 4A) can be used in place of SOC medium.

3. Incubate culture in a 30°C shaking water bath until the OD_{600} reaches 0.3 (cell density $\sim 10^7$ cells/ml).

4. Induce the culture by adding 100 mM IPTG to a final concentration of 1 mM.

   In the case of pKM201, IPTG is used to inactivate endogenous wild-type repressor.

5. Continue 30°C incubation as described until a cell density of $\sim 0.5–0.7 \times 10^8$ (OD_{600} of 0.5 to 0.6) is achieved. Transfer the culture to a 42°C shaking water bath and incubate 15 min.

   The authors have found that survival of EHEC and E. coli K-12 following electroporation is increased if this heat shock step is included. The increase in survivors increases the total yield of recombinants. The heat shock step may also play a role in the spontaneous loss of plasmid pKM201 and pKM208 in some of the recombinants, which is fortuitous, since the gene replacement and curing of the Red-producing plasmid occur simultaneously.

6. Chill the culture in an ice-water bath for 10 min with slow constant swirling.

7. Transfer cells to appropriate bottles and centrifuge 10 min at 5000 × *g*, 4°C. Discard the supernatant.

8. Resuspend the pellet in 1 ml of ice-cold 20% glycerol.

   The purpose of the glycerol is to protect the membranes from the shock of electroporation and to act as a cryoprotectant if the cells are to be frozen for future use.

   The use of 1 mm MOPS has been identified as an optimal component in a survey of electroporation buffers for transformation of P. aeruginosa (Farinha and Kropinski, 1990) and has been adapted for use in some of the authors' experiments, both here and in step 11.

9. Microcentrifuge suspension 30 sec at a moderate speed (e.g., ~2/3 maximum), 4°C. Carefully remove the supernatant.

10. Repeat steps 8 and 9 twice more.

11. Resuspend pellet in 90 μl of cold 20% glycerol.

    This amount of cells can be used for two electroporations (two 50-μl aliquots).

12. Use bacteria within 1 hr or freeze at –80°C for future use (up to 3 to 6 months).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

IPTG, 100 mM

Dissolve 238 mg IPTG powder (Sigma) into 10 ml deionized H_2O
Pass through a 0.2-μm filter (Acrodisc) to sterilize
Store up to 6 months at −20°C

COMMENTARY

Background Information

The mechanism of λ Red-promoted gene replacement with the PCR-generated substrates described in the Basic Protocol surprisingly does not involve many of the proteins normally associated with recombination in *E. coli* (e.g., RecA). It clearly, however, does involve the action of the λ Bet and Exo proteins acting at the ends of a linear dsDNA fragment. Given what is known biochemically about these proteins, a model for the action of Red in promoting gene replacement suggests that λ Exo degrades the 5′ strand of the dsDNA ends, and perhaps loads λ Bet onto the 3′ ssDNA ends that are generated. Bet then likely promotes annealing of the ssDNA ends to ssDNA regions of the lagging strand in the replication fork. How such a structure gets resolved to incorporate the drug marker into the chromosme in place of the target gene is not clear, but multiple possibilities are discussed by Court et al. (2002). Bet can also promote annealing to the leading stand as well, but at a lower frequency. This model is based on the work of Ellis et al. (2001) and their studies with λ Bet–promoted engineering of the *E. coli* chromosome with single-stranded oligonucleotides.

The authors have found that when the regions of homology between the flanking ends of the substrate and the target gene increase from 40 bases to 1 kb (as in the case of the plasmid-generated substrates used in the Alternate Protocol), the recombination events become more dependent upon RecA and thus likely involve host recombination RecF pathway functions. The RedF pathway has been shown to be required when these longer homology substrates are acted upon by the λ Red recombination system in vivo (Poteete and Fenton, 2000).

The use of λ Red for gene replacement in EHEC allows one to quickly make gene deletions to identify virulence factors, transfer in vitro generated mutants to their chromosomal locations, and construct hybrid versions of pathogenicity islands (Campellone et al., 2002, 2004; Murphy and Campellone, 2003). The ease with which gene knockouts can be performed and the simplicity of curing the host of the Red-producing plasmid following genetic manipulation clearly makes this the system of choice in dealing with alterations of the EHEC chromosome. The techniques described here using pKM208 have also been used to make genetic alterations in enteroaggregative *E. coli*, uropathogenic *E. coli*, and *Salmonella typhimurium* (E. Dudley, S. Slechta, and J. Roth, pers. comm. and unpublished results). In all likelihood, the general procedures described here will work for any strain of *E. coli* or related bacteria. Red-promoted gene replacement, using protocols similar to those described here, have also been demonstrated in *Shigella flexneri*, *Salmonella enterica*, and *Yersinia pseudotuberculosis* (Day et al., 2001; Uzzau et al., 2001; Derbise et al., 2003), though with varying degrees of success.

The disadvantage of this system (and virtually all gene replacement techniques) lies in the variability that different loci have with regard to their frequency of recombination. Some loci, like the *lacZ* gene in both *E. coli* K-12 and EHEC, are replaced at higher frequencies relative to other genes tested at the same time. The cause of this

variability is not known, but might result from a context effect on drug marker expression, differences in the presence and number of unknown restriction sites on DNA substrates, differential transcriptional activity, and/or nucleoid partitioning (about which little is known). Another common cause of variability is electrocompetence. The authors find that despite using identical protocols, variability in electrocompetence exist between different batches of cells. One should keep a diluted control plasmid on hand to compare the electrocompetence of cells prepared on different days.

Critical Parameters and Troubleshooting

Drug markers

The authors' laboratory prefers to use either kanamycin or chloramphenicol. However, any antibiotic marker can be used as long as it is different from the marker on the plasmid carrying the λ-Red genes (Amp^R) and is not restricted due to clinical use. (Refer to the local institutional biosafety committee.) Use the lowest drug concentration that just eliminates the background of nontransformants. Many drug markers that work well on plasmids don't do as well at single copy on the chromosome. The authors typically use 15 to 20 μg/ml chloramphenicol and 20 to 25 μg/ml kanamycin.

LB containing 50 μg/ml ampicillin (or lower if necessary) is used for the selection of EHEC cells transformed with pKM201 or pKM208. For growth of liquid cultures containing these plasmids, use LB containing 100 μg/ml ampicillin.

Drug cassette orientation

For the PCR recombination substrate, design the primers to place the drug marker colinear with genes surrounding the target (if possible). If one orientation doesn't work, try the other. The authors have seen context effects on drug expression from the chromosome, i.e., the drug marker works well in one direction, but not at all when turned around.

PCR templates

Don't use intact plasmids for PCR targets. Plasmids (even at low concentration) transform at a high efficiency following electroporation and will yield many false positives. If using a plasmid drug marker as a target, gel purify the PCR product. Better yet, use a gel-purified fragment devoid of an origin of replication as the target, or a target contained within a nonreplicative plasmid. Alternatively, one can also perform colony PCR where the drug marker is contained as a chromosomal element.

The use of long homology substrates

This is a variation of the Basic Protocol described above, where instead of using PCR-generated recombination substrates containing short regions of homology (40 bp), plasmid digests of preconstructed gene deletions containing long regions of homology (0.5 to 1 kb) are used as the source of the recombining substrate. Clearly, the use of PCR-generated substrates is the easiest and quickest route to gene replacement using λ Red. However, there are times when longer homology substrates are warranted. For instance, the overall frequency of recombination is higher with longer homology substrates. Thus, if a particular gene replacement is difficult to generate using short homology (PCR) substrates, success can sometimes be achieved using substrates containing longer regions of homology. Also, when multiple mutant alleles of an already cloned target gene need to be crossed into the chromosome, it saves time to simply clone the mutant allele into a dedicated vector containing the upstream and downstream regions of the target gene, and electroporate a digest of the plasmid (which liberates the recombining substrate) into a cell that contains the *cat-sacB* cassette in place of the target gene on the chromosome.

False positive Cam^R colonies

The authors have found that EHEC exhibits a moderate rate of spontaneous resistance to chloramphenicol. Thus, when using this drug marker, be aware that false positive will sometimes be among the true recombinants. The false positives differ from the true recombinants in both size and color. Generally, larger colonies formed on chloramphenicol plates have a greater chance of being legitimate recombinants than smaller colonies. The true test occurs upon restreaking on LB/Cam plates, where the true recombinants grow well while the false positives show discernibly weaker growth. The authors have found that starting the working culture from a single colony, rather than on overnight culture, reduces the presence of these Cam^R false postives.

Verification of mutants

A traditional method to characterize a mutant would entail Southern blot analysis (e.g., see *UNIT 14B.1*, which, although very informative, is very time consuming. Therefore, the

authors' laboratory uses a PCR-based system which can be used to check whether recombination was successful. It has been found that overnight overexpression of Red induces a 10-fold increase in the rate of spontaneous resistance to rifampicin. Note, however, under the conditions for Red expression used here, no increase in rifampicin resistance was noted. Thus, Red is not likely to be mutagenic for gene replacement purposes. Nonetheless, in *E. coli* K-12, a prudent step following Red-mediated gene replacement is to P1 transduce the mutation into a clean genetic background. Since this is not possible with EHEC, where P1 transduction has not been demonstrated, one is left with two important steps following gene inactivation: (1) cure the strain of pKM208 by growth at elevated temperature (42°C) and (2) prove no ectopic mutation has arisen by complementing the inactivated gene with a plasmid-borne wild type copy. It is always wise to complement individually derived deletion mutants to reconfirm the deletion, as well as determine if the deletion has a polar effect on downstream genes.

No transformants

Follow the guidelines and alternate protocols discussed above. If no transformants are obtained, examine cell survival after electroporation by plating on solid LB medium. In the final culture following electroporation, a survival count of $\geq 10^7$ to 10^8/ml is desired. Cell survivals $< 10^6$ indicate excessive killing. Since frequencies of gene replacement are typically in the range of 10^{-4} to 10^{-5}/survivor, excess killing will prevent successful recovery of transformants. If this happens, search for possible salt contamination in the electrocompetent cell prep or DNA substrate, lower the electroporation voltage and/or decrease or eliminate heat shock exposure.

Anticipated Results

Overall, if performed correctly, this method should yield a fair number of transformants. Typically, the authors obtain between 5 to 50 true transformants per experiment, although in some cases, only one or two transformants have been isolated. Luckily, these few transformants are generally true recombinants as verified by PCR analysis (provided they grow well on post-selection antibiotic-containing plates). The authors have found that the overall frequency of gene replacements in EHEC is not as high as *E. coli* K12. For EHEC, gene replacement frequencies fall in the range of 0 to 20 recombinants per 10^8 survivors and >100 recombinants per 10^8 survivor using long homology substrates. Some sites give higher rates (e.g., *lacZ*) while a minority of sites could not be deleted, perhaps a result of essentiality, though this has not been investigated. However, by making multiple attempts to obtain problematic gene replacments, >90% of the desired EHEC deletions were eventually obtained (B. Skehan, K. Campellone, unpub. obs.).

Time Considerations

Table 5A.2.1 and Table 5A.2.2 present time considerations for the protocols described in this unit.

Detection, Isolation, and Identification of *Vibrio cholerae* from the Environment

Until the late 1970s and early 1980s, *Vibrio cholerae*, the causative agent of cholera, was viewed as host adapted, i.e., resident in the human gut. Numerous studies conducted during the last three decades, however, have provided clear evidence establishing the microorganism as an autochthonous (i.e., native) member of the aquatic environment (Colwell and Spira, 1992). These organisms can be detected in marine, estuarine, and fresh-water environments throughout the year if appropriately sensitive methods are employed (Colwell et al., 1981; Huq et al., 1990; Louis et al., 2000, 2003). However, *V. cholerae* may not be detected for several reasons—e.g., if it is present in low numbers, if it exists in a state that does not facilitate growth, or if it is simply overlooked. When the bacteria are viable (determined by direct-detection methods) but do not grow on conventional culture media or in broth, they are termed viable but not culturable (VBNC; Xu et al., 1982; Roszak and Colwell, 1987). *V. cholerae*, along with a host of other, mostly Gram-negative bacteria, often occur as VBNC cells in the environment, an indication that this state may be an important strategy for persistence and survival of non-spore-forming microorganisms (Colwell et al., 1985; Roszak and Colwell, 1987).

Currently, many molecular-biological tools are used to study bacteria, including VBNC cells, in clinical, environmental, or industrial samples (Knight, 2000). With the availability of these tools and a renewed interest in *V. cholerae*, the presence of these bacteria in various geographical locations has been reported with increasing frequency. However, standard methods for detection and enumeration have not been universally established. The choice of method for detection and enumeration of *V. cholerae* is largely dependent on the type of sample and the desired end purpose—i.e., simple detection or isolation. Often, combinations of different methods are used for a specific type of sample. Therefore, commonly used bacteriological, molecular, and immunological methods targeted at microbiological analysis of environmental water samples will be discussed in this unit.

Several methods will be described, and investigators will have to determine the most appropriate method consistent with their purpose and needs and with the availability of resources. For the readers' convenience, Table 6A.5.1 provides an overview of the methods provided in this unit.

CAUTION: *V. cholerae* is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

STRATEGIC PLANNING

There are numerous methods and protocols available in the literature for detecting and isolating *V. cholerae*. A number of them are described in this unit; however, all may not be required in one study. In addition, availability of resources in a particular laboratory will be a critical predetermining factor in making decisions on the choice of methods to include; therefore, stepwise selection cannot be standardized. In other words, it is extremely important to contrive a strategic plan to determine the choice of methods at the beginning of the study. A general method for specimen collection and transportation is provided (Basic Protocol 1). The traditional culture method (Basic Protocol 2) is the so-called "gold standard" in bacteriology, especially when an isolate is needed for the study. In the conventional culture method, selective plates are often used to reduce the

Table 6A.5.1 Overview of Methods Presented in This Unit for Isolation and Detection of *V. cholerae*

Protocols	Included methodologies
Isolation and identification of V. cholerae using traditional methods	
Basic Protocol 1	Specimen collection and transportation
Basic Protocol 2	Conventional bacteriological culture method for *V. cholerae* and identification of presumptive isolates using standard biochemical tests
Basic Protocol 3	Serogroup determination
Molecular methods for detection and identification of V. cholerae	
Basic Protocol 4	Identification of suspected or presumptive *V. cholerae* by PCR
Basic Protocol 5	Direct PCR
Alternate Protocol 1	Multiplex PCR assay for O1, O139, and *ctxA*
Basic Protocol 6	Colony blot hybridization with labeled DNA or RNA hybridization probes
Alternate Protocol 2	Colony blotting with DIG-labeled probe
Support Protocol	DIG labeling of probes
Direct detection and/or enumeration of V. cholerae using immunological methods	
Basic Protocol 7	Direct fluorescent antibody–direct viable count (DFA-DVC)
Basic Protocol 8	Indirect fluorescent antibody (IFA) method

volume of work and to identify a specific organism or variety of organisms. Once this culture method has been used and an organism isolated, a battery of biochemical tests is employed for characterization and identification. If such colonies are picked from selective plates, the number of biochemical tests needed may decline. Therefore, the number of tests may vary depending on the source of the strain. However, as more tests are performed, more convincing and accurate results will be obtained. Serogroup determination for *V. cholerae* is described in Basic Protocol 3.

Although conventional culture methods, including biochemical tests, are routinely used, they can be time consuming as well as labor intensive. The authors have included two abbreviated alternative methods that use fewer tests for a rapid presumptive identification. Colony blot hybridization (Basic Protocol 6 and Alternate Protocol 2; probe labeling is described in Support Protocol) can be used for rapid detection of *Vibrio cholerae*, and in cases involving large numbers of samples, this method may be preferred. However, it too is dependent on the culturability of the cells.

The viable but nonculturable state represents an important phenomenon, as bacteria present in this state do not grow on conventional culture media. To demonstrate the presence of the organisms in this state, a direct-detection method should be employed, notably fluorescent antibody coupled with direct viable count (DFA-DVC; Basic Protocol 7). No subsequent bacterial isolation is possible using this method, unless a parallel sample is taken. An indirect fluorescent antibody method for detecting *V. cholerae* in environmental samples is described in Basic Protocol 8.

Molecular approaches target specific genes that are unique to the organism in question. Usually, species-specific genes are targeted. This approach is extremely valuable for monitoring the presence of the organism. A single probe, designed carefully, is very specific and will be amenable to screening a larger number of strains at one time. Likewise, a series of such probes can be used for extensive characterization of an organism. These methods can be based on both culturable and nonculturable cells. Community DNA can be used to determine the presence of an organism without culture; however, results will be dependent on the quality and quantity of the extracted nucleic acids.

Strategically, if resources are available, it is appropriate to start with the conventional culture method and the DFA-DVC method. Those samples exhibiting positive results by the DFA-DVC method can be confirmed by PCR (Basic Protocol 4). If one must avoid conventional culture, one may wish to use direct PCR (Basic Protocol 5 or Alternate Protocol 1) and DFA-DVC (Basic Protocol 7), which should provide fairly convincing results. Use of PCR alone for environmental samples may not be reliable, as background noise often poses a significant obstacle in the interpretation of results.

ISOLATION AND IDENTIFICATION OF *V. CHOLERAE* USING TRADITIONAL METHODS

Traditional methods for isolating and identifying *V. cholerae* from environmental water samples were introduced by Colwell et al. (1977), who modified protocols originally intended for clinical samples. Briefly, concentrated water, homogenized plankton samples, or both are added to an enrichment broth and incubated overnight. The alkaline nature of the enrichment broth allows differential multiplication of *Vibrio* species.

Following enrichment, aliquots are subcultured onto selective medium—thiosulfate citrate bile salts sucrose (TCBS) agar, tellurite taurocholate gelatin agar (TTGA), or both (see Reagents and Solutions for compositions)—which offer some selective advantage to *Vibrio* species and aid in the presumptive identification of *V. cholerae*. The identity of presumptive colonies is confirmed by specific biochemical tests designed to differentiate *V. cholerae* from other species and other members of the *Vibrionaceae* and *Enterobacteriaceae*. Confirmed *V. cholerae* strains are then serogrouped as O1 or O139 by simple slide agglutination using specific antisera. Strains of *V. cholerae* that do not agglutinate with specific O1 and O139 antisera are designated as non-O1/non-O139. Stock cultures of confirmed *V. cholerae* are maintained in nutrient agar containing 0.5% NaCl overlaid with oil, or as glycerol stocks at −70°C for future analysis and reference.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic techniques should be used accordingly.

Specimen Collection and Transportation

BASIC PROTOCOL 1

For isolation and detection of *V. cholerae* from the environment, the screening of concentrated water samples and plankton samples is recommended, since a combination of both specimen types provides a higher probability of *V. cholerae* detection (Huq et al., 1990; Binsztein et al., 2004; Huq et al., 2005). Clean, sterile, plastic sampling bottles (for water) and glass jars (for plankton) should be prepared and used. Sufficient sample (depending upon the parameters that need to be analyzed) should be collected in order to perform all examinations. Plankton samples are collected and concentrated using a 64-μm simple plankton net (Fig. 6A.5.1), preferably by towing (just below the surface, to a depth no more than 0.5 m); alternatively, this may be accomplished by manually pouring or mechanically pumping water into the net (Huq et al., 2005).

Processing of samples should begin soon after collection ("on site" or in situ) or within 1 hr of collection. If processing is delayed, the sample should be stored in a cool box at a temperature of 10° to 15°C until processing begins (not to exceed 8 hr; Clesceri et al., 1998). This is a critical parameter if enumeration of *V. cholerae* from the sample will be performed. A recent study suggests that transporting samples at ambient air temperature prior to processing can increase the number of *V. cholerae* strains isolated (Alam et al., 2006). Based on the type of examination, samples may require treatment, e.g., addition of direct viable count (DVC) reagents, before proceeding with further examination and testing. It is recommended that some basic physiochemical parameters—e.g., temperature, salinity, pH, dissolved oxygen, conductivity—of the water source be measured at the time of collection, for later analysis. Results of environmental studies conducted in Bangladesh have revealed a direct correlation of water temperature with clinical outbreaks of cholera. Furthermore, significant correlation of water depth, rainfall, conductivity, and copepod density with cholera outbreaks has been found, with lag periods from 0 to 8 weeks from optimum environmental conditions to cholera outbreaks (Huq et al., 2005). These parameters can be measured on site using portable meters.

Materials

500-ml plastic containers with caps (Nalgene) for water sampling, sterile
Portable meter(s) that measure temperature, dissolved oxygen and pH (dissolved oxygen and pH meter Model 210A from Orion Laboratories), and salinity (Model CO150 conductivity meter from Hach Chemical Company)
Simple plankton net, 64-μm mesh size, or nets of different mesh sizes for size filtration of plankton (Aquatic Research Instruments, *http://www.aquaticresearch.com*; Fig. 6A.5.1)
Net-mounted flow meter (General Oceanics; *http://www.generaloceanics.com/*)
Bucket of known volume (e.g., 5 liters; optional)
240-ml glass containers for plankton collection (Qorpak), sterile

To collect water sample

1a. Measure temperature, dissolved oxygen, pH, and salinity using portable meters.

2a. Uncap presterilized 500-ml plastic bottle and submerge to fill.

3a. Remove sample bottle from water. Cap bottle, leaving enough air inside for agitation and mixing.

4a. Transport samples to the laboratory for processing in a cold box (Styrofoam box with ice, 10° to 15°C), or, preferably, begin processing on site within 1 hr of collection (Basic Protocol 2).

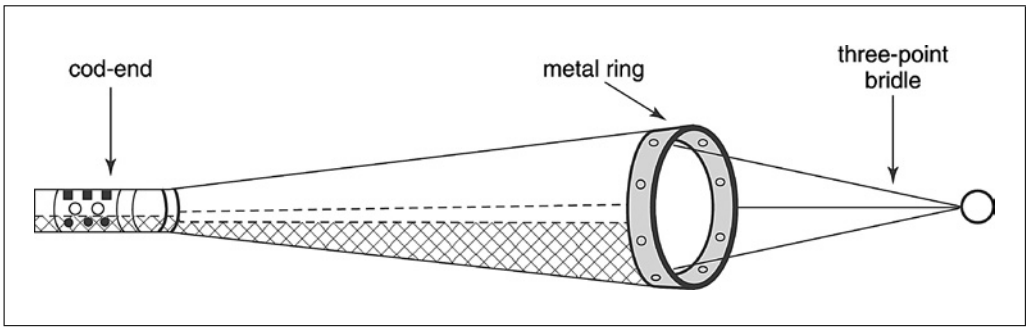

Figure 6A.5.1 Simple plankton net (Aquatic Research Instruments). The net consists of a metal ring and bridle, a heavy-duty nylon net of variable mesh size, and a PVC cod-end or collecting bucket, which can be removed for easy sample collection. A flow meter may be mounted in the mouth of the net on the metal ring to measure volume when the net is towed.

A recent study (Alam et al., 2006) found that transportation or maintenance at ambient air temperature (22° to 25°C) after collection for up to 24 hr may enhance recovery of Vibrio species. This can be a useful alternative to increasing sample volume for geographical areas and/or seasons when the density of V. cholerae is low. This aspect of the protocol may need to be optimized for the water source and environmental conditions.

To collect plankton

1b. Rinse plankton net and cod-end of the net in the body of water to be sampled.

2b. Filter 10 to 40 liters water through the plankton net by towing; use a calibrated, net-mounted flow meter to determine volume. Alternatively, pour known volumes through the net with a small bucket.

3b. Remove cod-end from plankton net and decrease volume to 100 ml by continuing to filter.

4b. Measure (with graduated cylinder) and decant plankton sample into sterile 240-ml glass container.

5b. Transport samples to the laboratory in a cold box (Styrofoam box with ice, 10° to 15°C) for processing or, preferably, begin processing on site within 1 hr of collection (Basic Protocol 2).

See annotation to step 4a for additional considerations.

Conventional Bacteriological Culture Method

BASIC PROTOCOL 2

Conventional culture methods for isolating *V. cholerae* from environmental water samples rely on an enrichment step(s) in broth and plating on selective media, followed by confirmation using a battery of biochemical and serological tests. As stated previously, some knowledge regarding the expected prevalence of *V. cholerae* in the water body to be examined is useful when determining the volume of water to collect for examination. *V. cholerae* is an autochthonous member of the estuarine and aquatic community; however, geographic location and environmental factors such as water temperature play a critical role in determining the number of culturable *V. cholerae* cells present. Most water and plankton samples require concentration, with historical knowledge of the water source helping to determine the concentration factor. Water samples should be concentrated by filtration using 0.2-μm polycarbonate membrane filters (see step 1a, below). A good starting volume is 500 ml.

Overnight enrichment is performed using alkaline peptone water (APW), pH 8.6. Some investigators recommend two successive enrichments. Surface aliquots are streaked onto selective bacteriological media. The two favored selective media used for *V. cholerae* isolation are thiosulfate citrate bile salts sucrose (TCBS) agar and tellurite taurocholate gelatin agar (TTGA), also known as Monsur medium (Monsur, 1961). *V. cholerae* produces translucent, flat, yellow sucrose-fermenting colonies with elevated centers on TCBS (Fig. 6A.5.2A). The organism produces colorless colonies on TTGA (Fig. 6A.5.2B), often with a characteristic dark center after 2 days growth, surrounded by a halo, which appears due to the hydrolysis of gelatin. Both media have advantages as well as disadvantages.

TCBS, or "cholera medium," is highly selective, inhibiting growth of Gram-positive and typical intestinal flora, which cannot grow under alkaline conditions. However, TCBS can inhibit some members of the genus *Vibrio*, including *V. cholerae* itself, as evidenced by comparing simultaneous growth of *V. cholerae* on TCBS versus nonselective media. In addition, TCBS can support the growth of several closely related bacteria, most notably *Aeromonas* and *Proteus*. One of the major advantages of this medium is that it

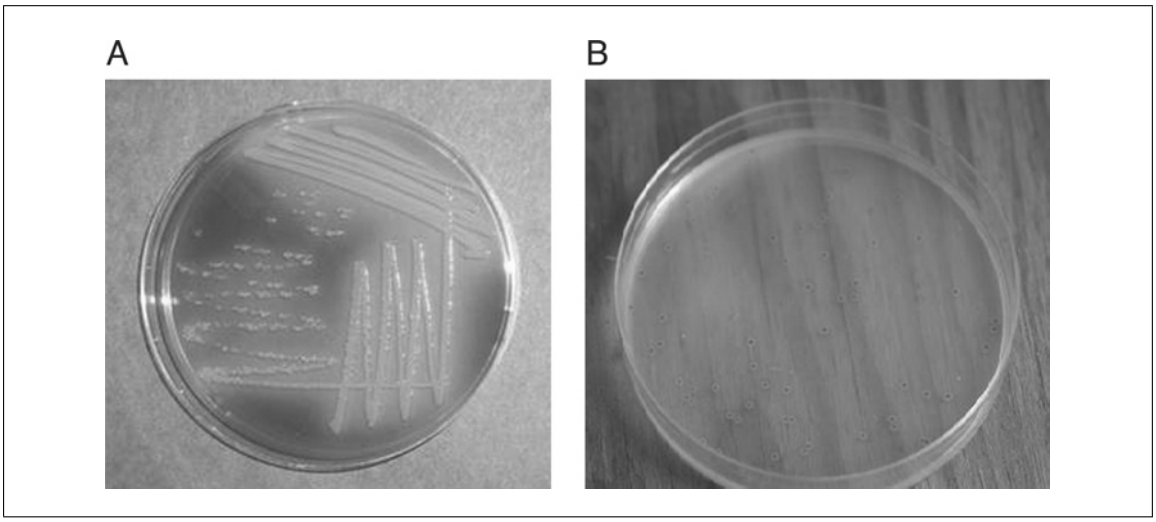

Figure 6A.5.2 Growth of *V. cholerae* O1 on (**A**) TCBS and (**B**) TTGA. Courtesy of Dr. Munir Alam, International Center for Diarrheal Disease Research, Bangladesh. For the color version of this figure go to *http://www.currentprotocols.com*.

is commercially available and does not require an autoclave to prepare plates, thereby making it possible to use the medium under field conditions, without a laboratory or autoclave. TTGA medium is generally considered less selective and less "toxic" to *V. cholerae* than TCBS, so recovery of *V. cholerae* colonies may be enhanced as compared to that obtained with TCBS; however, these plates preferably should be incubated longer (48 hr versus 24 hr for TCBS) to observe the characteristic dark center. Also, the formulation is not commercially available and the medium must be autoclaved after preparation. Once presumptive strains are purified on a nonselective medium such as gelatin agar or modified nutrient agar, they are identified and confirmed by biochemical tests and serogrouped using simple slide agglutination with polyclonal *V. cholerae* O1 and monoclonal O139 antiserum.

Materials

Plankton or water sample (Basic Protocol 1)
Enrichment flask: 150-ml Erlenmeyer flask containing 25 ml sterile alkaline peptone water (APW), pH 8.6 (see recipe); store up to 1 month at 4°C
Thiosulfate citrate bile-salts sucrose (TCBS) agar plates (see recipe)
Tellurite taurocholate gelatin agar (TTGA) plates (see recipe)
Gelatin agar (GA) plates (see recipe)
Modified nutrient agar plates (see recipe)
Filter paper (Whatman 3MM or equivalent) saturated with oxidase reagent (see recipe)
5-ml tubes of medium for biochemical tests (also see Table 6A.5.2):
- Methyl red/Voges-Proskauer (MR-VP) broth (see recipe)
- LB medium (*APPENDIX 4A*) containing 1% (w/v) L-arginine (pH 6.8) and 1 to 2 drops of 10% (w/v) phenol red
- Moeller decarboxylase broth base (see recipe) containing 1% L-lysine
- Moeller decarboxylase broth base (see recipe) containing 1% L-ornithine
- Purple broth base (see recipe) containing 1% (w/v) arabinose
- Purple broth base (see recipe) containing 1% (w/v) mannitol
- Heart infusion agar (BD Biosciences) containing 0.1% (w/v) esculin and 0.05% (w/v) ferric chloride
- Nutrient broth (BD Biosciences) with added NaCl (0%, 6%, and 8%)

Mineral oil, sterile
Kligler iron agar (KIA) slants (see recipe)

Hand-held glass tissue homogenizer, Potter-Elvehjem or Tenbroek style (Kontes), to homogenize plankton
Glass wool
Glass funnel
Filter apparatus with vacuum source
Filter membranes, 47-mm diameter, 0.22-μm pore size
30°C and 37°C incubators
Platinum inoculating loops and needles
Sterile toothpicks

Additional reagents and equipment for serogroup determination (Basic Protocol 3)

Enrich organisms in APW

1a. *For plankton samples:* Homogenize plankton samples using a hand-held glass tissue grinder by moving the pestle up and down in the tube, while rotating, 10 to 20 times. Add 1 ml homogenized plankton to an enrichment flask.

1b. *For water samples:* Filter 500 ml (or 100 to 1000 ml depending on bacterial density) of water first by gravity through glass wool and then under vacuum through a 47-mm, 0.22-μm pore size polycarbonate filter. Add the filter(s) with attached bacteria to an enrichment flask. Shake vigorously to detach bacteria from filter.

Large volumes may require more than one polycarbonate filter, as they will clog.

2. Incubate the flasks statically 16 hr (overnight) at 30°C.

The flasks should not be disturbed or agitated during or after incubation, as Vibrio species tend to migrate to the liquid-air interface.

Selectively plate for Vibrio cholerae

3. After enrichment, collect surface growth (which may be present as a whitish film) from the enrichment flask with a platinum inoculating loop and streak onto TCBS plates, TTGA plates, or both (i.e., selective plates).

4. Incubate the plates at 37°C 16 to 24 hr for TCBS or 48 hr for TTGA.

5. Subculture smooth, flat, sucrose-fermenting (yellow) colonies from TCBS (Fig. 6A.5.2A) and/or translucent, dark-centered colonies with halo zones from TTGA (see Fig. 6A.5.2B) onto GA and/or modified nutrient agar plates (i.e., nonselective plates). Continue incubation for 16 to 24 hr at 37°C.

When subculturing colonies from selective medium onto nonselective medium, touch the top center of the colony using an inoculating loop without touching the agar surface, to avoid carryover of contaminating growth-suppressed bacteria that may be present.

Characterize suspected colonies

Suspected colonies (i.e., those selected for subculture) can be characterized using a traditional battery of biochemical tests (steps 6a to 9a), an alternate KIA-oxidase-antisera protocol (steps 6b and 7b), or a simple two-test protocol (step 6c to 8c).

To characterize by traditional battery of biochemical tests and serogroup determination

6a. Pick suspected colonies from GA and/or modified nutrient agar plates using sterile toothpicks or a platinum loop. Streak onto filter paper saturated with oxidase reagent.

V. cholerae is oxidase-positive, as indicated by the rapid appearance (10 to 30 sec) of a purple color. A delayed color change (60 sec or longer) or no color change is indicative of a negative result.

Table 6A.5.2 Selected Biochemical Tests Used for the Identification of *V. cholerae*

Test	Medium	Temperature	Duration	Reagent to add prior to reading	Positive result indicates
Methyl Red	MR-VP medium	37°C	48 hr	5-6 drops methyl red indicator[a]	Ability to produce stable acid end products from glucose fermentation
Voges-Proskauer	MR-VP medium	37°C	48 hr	3 ml Barritt's reagent A[b] and 1 ml Barritt's reagent B[c]	Production of acetoin, formed from pyruvic acid during glucose fermentation
Arginine dihydrolase	LB medium (*APPENDIX 4A*) containing 1% (w/v) L-arginine (pH 6.8) and 1-2 drops of 10% (w/v) phenol red	37°C	24 hr	None	Presence of the enzyme arginine dihydrolase
Lysine decarboxylase[d]	Moeller decarboxylase broth base (see recipe) containing 1% (w/v) L-lysine	37°C	24 hr	None	Presence of the enzyme lysine decarboxylase
Ornithine decarboxylase[d]	Moeller decarboxylase broth base (see recipe) containing 1% (w/v) L-ornithine	37°C	24 hr	None	Presence of the enzyme ornithine decarboxylase
Arabinose, acid production	Purple broth base (see recipe) containing 1% (w/v) arabinose	37°C	24 hr	None	Utilization of the carbohydrate arabinose by production of acid end products
Mannitol, acid production	Purple broth base (see recipe) containing 1% (w/v) mannitol	37°C	24 hr	None	Utilization of the carbohydrate mannitol by production of acid end products
Oxidase	Oxidase reagent: 1% (w/v) *N,N,N′ N′*-tetramethyl-*p*-phenylenediamine dihydrochloride	37°C	10-30 sec	None	Presence of cytochrome oxidase
Esculin hydrolysis	Heart infusion agar containing 0.1% (w/v) esculin and 0.05% (w/v) ferric chloride	37°C	3 days	None	Hydrolysis of esculin to glucose and esculetin
Growth in nutrient broth with 0% NaCl	Nutrient broth[e] with 0% NaCl	37°C	5 days	None	Organism has minimal salt requirement
Growth in nutrient broth with 6% NaCl	Nutrient broth[e] with 6% (w/v) NaCl	37°C	5 days	None	Organism is tolerant of moderate salt concentration
Growth in nutrient broth with 8% NaCl	Nutrient broth[e] with 8% (w/v) NaCl	37°C	5 days	None	Organism is tolerant of high salt concentration

[a]Dissolve 0.1 g methyl red in 300 ml of 95% ethanol. Adjust volume to 500 ml with water. Store up to 6 months at 2° to 8°C.

[b]Dissolve 5 g α-naphthol in 100 ml absolute ethanol. Store up to 6 months at 2° to 8°C.

[c]Dissolve 40 g potassium hydroxide in 100 ml distilled water. Store up to 6 months at 2° to 8°C.

[d]For lysine and ornithine decarboxylase, it is useful to inoculate a tube of decarboxylase broth base without the addition of either amino acid for comparison as a negative control. All decarboxylase test tubes must be overlaid with mineral oil.

[e]Nutrient broth must not contain any sodium chloride.

Table 6A.5.3 Expected Results of *V. cholerae* for Selected Biochemical Tests[a]

		Results	
Test	% Positive	Positive	Negative
Methyl Red	99	Red	Yellow
Voges-Proskauer	75	Red	Copper
Arginine dihydrolase	0	Pink	Orange
Lysine decarboxylase	99	Dark purple	Yellow
Ornithine decarboxylase	99	Dark purple	Yellow
Arabinose, acid production	0	Yellow	Purple
Mannitol, acid production	99	Yellow	Purple
Oxidase	100	Purple	Clear
Esculin hydrolysis	0	No fluorescence[b]	Fluorescence
Growth in nutrient broth with 0% NaCl	100	Turbid	Clear
Growth in nutrient broth with 6% NaCl	53	Turbid	Clear
Growth in nutrient broth with 8% NaCl	1	Turbid	Clear

[a]Traditional biochemical characterization of presumptive colonies (also see Table 6A.5.2). Adapted from (Lennette et al., 1985).

[b]Loss of fluorescence is used since many *V. cholerae* strains produce melanin, which interferes with the normal indicator (darkening of butt).

7a. If a positive result is achieved using the oxidase reagent test, inoculate one tube of each of the other tests outlined in Table 6A.5.2 (eleven total after oxidase test has been performed) for each suspected colony. Inoculate a second tube of each test with a known positive control. Include a tube of decarboxylase base medium (without the amino acid supplement) as a negative control for the lysine and ornithine decarboxylase tests. Refer to Table 6A.5.3 for interpretation of results.

8a. Overlay arginine, lysine, and ornithine tubes (and decarboxylase broth base used as negative control) with sterile mineral oil. Incubate all tubes at 37°C for the duration indicated in Table 6A.5.2.

9a. Proceed to serogroup determination (Basic Protocol 3) with presumptive *V. cholerae* colonies.

Characterize colonies by simple, rapid biochemical procedure and serogroup determination

6b. Assay suspected colonies from GA and/or modified nutrient agar (from step 5) for arginine dihydrolase and esculin hydrolysis as described in Tables 6A.5.2 and 6A.5.3.

7b. Proceed to serogroup determination (Basic Protocol 3) with presumptive *V. cholerae* colonies (negative for arginine dihydrolase and negative for esculin hydrolysis).

Characterize colonies by KIA-oxidase and serogroup determination

6c. Stab-inoculate suspected colonies from GA and/or modified nutrient agar into KIA slants using an inoculating needle. Incubate at 30°C overnight.

Stab inoculation is accomplished by passing an inoculating needle that has been touched to a suspected colony on the GA or modified nutrient agar plate vertically into the surface of the agar at the center of the slant and down completely into the tube.

See WHO (1974) and Tison (1999) as well as the Commentary in this unit, for more detail.

7c. Perform the oxidase test (step 6a) on colonies giving an alkaline slant over acid butt (purple slant and yellow butt) with no gas production or blackening of the butt due to H_2S production.

8c. Proceed to serogroup determination (Basic Protocol 3) with presumptive *V. cholerae* colonies.

BASIC PROTOCOL 3

Serogroup Determination

Over 210 serogroups of *V. cholerae* have been described to date based on antigenic properties of cell surface polysaccharides, of which serogroup O1 and O139 have been implicated in epidemics of cholera, while serogroup O37 has been held responsible for localized outbreaks of cholera in Czechoslovakia and Sudan. The remaining serogroups collectively and commonly termed "non-O1/non-O139" are predominant among the strains of *V. cholerae* isolated from the aquatic environment (Sack et al., 2003). Although reported mostly in O1 and O139 serogroups, the cholera toxin gene has been reported in non-O1/non-O139 strains, also from the aquatic environment, in India (Chakraborty et al., 2000). However, because of the epidemic potential, the method to determine O1 and O139 serogroup is described below. Strains other than O1 or O139 serogroup need not be serogrouped unless there is a special need, in which case those strains should be sent to a Reference Center for serotyping, since antisera for serogroups other than O1 and O139 are not commercially available.

Materials

Phosphate buffered saline (PBS; *APPENDIX 2A*)
V. cholerae colonies (6- to 16-hr subculture on nonselective modified nutrient agar, e.g., Basic Protocol 2)
Polyvalent antisera for serogroup O1 and O139 *V. cholerae* (BD Biosciences)
Glass microscope slides

1. Add two separate drops of PBS to a microscope slide.
2. Add a loopful of fresh growth from a 6 to 16 hr subculture of *V. cholerae* on nonselective medium to each drop, and mix.
3. Add an equal-sized drop of group O1 polyvalent antiserum to one of the drops.
4. Mix the antiserum-culture suspension by tilting the slide back and forth. Determine if the reaction clumps (i.e., agglutinates) within 0.5 to 1 min, indicating a positive result.

   Autoagglutination, i.e., clumping in the saline solution without antiserum, is indicative of a "rough" morphotype which cannot be typed by antisera. For typing of colonies with rough morphotype, see Alternate Protocol 1.

5. Test non-O1 serogroup colonies using O139 antisera, repeating steps 1 to 4, but substituting anti-O139 antiserum for anti-O1 antiserum.

MOLECULAR METHODS OF DETECTION AND IDENTIFICATION OF *V. CHOLERAE*

Following the introduction of molecular methods into bacteriology, there has been an influx of newer techniques aimed at understanding the mechanism of infection and at the detection of pathogens, or organisms with virulent properties, in clinical or environmental samples. Soon after the *V. cholerae* genome sequence was published in 2000 (Heidelberg et al., 2000), PCR-based simple molecular probes became an important tool for detecting *V. cholerae* and its antigens. Direct-detection methods have proven to be important when conventional culture methods are recognized as ineffective because of the viable but not culturable (VBNC) organisms present in samples collected for analysis.

Identification of Suspected or Presumptive *V. cholerae* by PCR

The polymerase chain reaction (Kramer and Coen, 2001) is a useful alternative to labor-intensive biochemical tests, which are sometimes difficult to interpret and often require replication. Also, many biochemical tests require an additional overnight or longer incubation before results are obtained. It is largely up to the investigator to determine at which step in the traditional, culture-based isolation procedure to switch to this molecular method. Ideally, at least minimal biochemical tests (Basic Protocol 2, step 6b or steps 6c and 7c) should be performed before switching to PCR identification, to decrease the number of strains to be screened to a manageable number. In this method, crude template is prepared by boiling to lyse the cells. This template is then amplified using PCR primers specific to *V. cholerae*, which target the internal transcribed spacer (ITS) region between 16S and 23S rDNA. It is convenient at this stage to characterize a confirmed *V. cholerae* strain by screening for several genes associated with pathogenesis (*ctxA, toxR, tcpA, zot*, and *ompU*) by PCR. PCR products are analyzed by gel electrophoresis and visualized under UV light with ethidium bromide. Positive and negative controls should be run in parallel and should include a eubacterial 16S rDNA PCR reaction on each sample to test template quality. (See Table 6A.5.4 for PCR primers, expected amplicon size and reference).

Materials

Overnight culture of putative *V. cholerae* in liquid medium or on agar plates (Basic Protocol 2)
H_2O, sterile
1× PCR amplification buffer (*APPENDIX 2A*) containing 15 mM $MgCl_2$ and 0.1% (w/v) gelatin
25 mM dNTP stock: dATP, dCTP, dGTP, dTTP (*APPENDIX 2A*)
20 μM PCR primers for ITS (Table 6A.5.4)
Taq DNA polymerase
1.5% agarose gel (Voytas, 2000)
TAE buffer (*APPENDIX 2A*)
Molecular weight ladder (e.g., Hyperladder IV, Bioline)
1 μg/ml ethidium bromide (*APPENDIX 2A*)
2-ml microcentrifuge tubes, sterile
Boiling water bath
PCR tubes
Thermal cycler (MJ Research)
UV transilluminator, handheld UV lamp, or digital gel documentation system
Additional reagents and equipment for agarose gel electrophoresis and ethidium bromide staining of gels (Voytas, 2000)

Prepare crude template

1a. *From liquid medium*: Centrifuge a 1-ml culture (overnight growth at 37°C) and resuspend in 1 ml sterile water.

1b. *From agar plates:* Resuspend a loopful of pure culture (50 to 100 colonies) of suspected or presumptive *V. cholerae* into 300 μl sterile water.

Plates should contain a fresh overnight subculture.

2. In a sterile 2-ml microcentrifuge tube, dilute suspension 1:1000 in sterile water to a final volume of 1 ml.

Alternatively, a single isolated colony can be resuspended in 20 μl sterile water.

Table 6A.5.4 PCR Primers for Genes Associated with Virulence of Toxigenic *V. cholerae* O1/O139 and Expected Amplicon Size

	16S-R	ACGGGCGGTGTGTRC		

[a]Currently, there are no published 23S rDNA PCR primers specific for *V. cholerae*.

3. Place the microcentrifuge tube containing the resuspended culture into a boiling water bath for 10 min.
4. Cool tube to room temperature by allowing tube to sit on bench (~30 min).

Perform Vibrio cholerae–specific PCR (Chun et al., 1999)

5. Set up *V. cholerae*-specific ITS (internal transcribed spacer region) PCR in a PCR tube for a total reaction volume of 25 μl containing the following:

   5 μl template (from step 4)
   1× PCR amplification buffer
   200 μM each dNTP
   800 nM forward and reverse primers for ITS (pVC-F2, pVCM-R1)
   0.625 U *Taq* DNA polymerase.

6. Amplify the *V. cholerae*-specific ITS target with the following cycling conditions:

1 cycle:	1 min	94°C	(initial denaturation)
30 cycles:	1 min	94°C	(denaturation)
	1 min	60°C	(annealing)
	1 min	72°C	(extension)
1 cycle:	10 min	72°C	(final extension).

Refer to Kraemer and Coen (2001) for information about optimizing PCR.

Perform agarose gel electrophoresis and visualize results

7. Run PCR product out on a 1.5% agarose gel in 1× TAE buffer for 1 to 2 hr at 5 V/cm (Voytas, 2000) along with a molecular weight ladder (e.g., Hyperladder IV).
8. Stain the gel by incubating in 1 μg/ml ethidium bromide staining solution for 15 min at room temperature.
9. Destain the gel by incubating in distilled water for 15 min at room temperature.
10. Visualize the products by viewing the gel using a handheld UV lamp, transilluminator, or digital gel documentation system.

The V. cholerae 16S-23S rDNA intergenic spacer region amplicon is 300 bp in size (Fig 6A.5.3, lane 2).

Screen for toxigenic factors

11. Screen ITS-PCR confirmed *V. cholerae* isolates for the toxigenic factors *toxR*, *tcpA*, c*txA*, *zot*, and *ompU* by PCR according to steps 1 to 10 above, using the PCR primers pToxR, pTcpA, pCTA, pZot, and pOmpU, respectively (see Table 6A.5.4 and Fig. 6A.5.3).

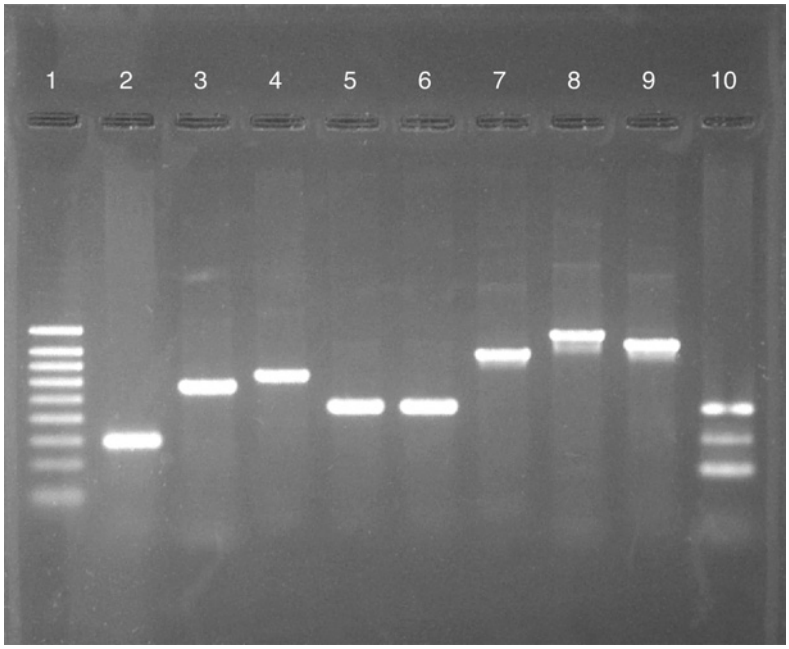

Figure 6A.5.3 Results (gel) of PCR assays used to detect and characterize *V. cholerae*. Lane 1, Hyperladder IV (Bioline); lane 2, *V. cholerae*-specific ITS; lane 3, *ctxA* (pCTA); lane 4, *tcpA* of *V. cholerae* O1 Classical; lane 5, *tcpA* of *V. cholerae* O1 El Tor; lane 6, *tcpA* of *V. cholerae* O139; lane 7, *toxR*; lane 8, *zot*; lane 9, *ompU*; lane 10, O1-O139/*ctxA* multiplex of *V. cholerae* O1 and O139. See Table 6A.5.4 for amplicon sizes.

BASIC PROTOCOL 5

Direct PCR for Environmental Samples

Despite the ubiquitous nature of *V. cholerae*, isolation and detection by traditional methods are difficult since these methods rely on cultivating the organism. These difficulties arise from several possible factors: low density, interspecific competition, cell state (VBNC), and cell health (e.g., starvation). The polymerase chain reaction offers a molecular-based alternative to the traditional culture and immunological methods (discussed later). Three types of targets are used to detect *V. cholerae* in environmental samples by PCR: species-specific genes (16S rDNA, ITS, *ompW*); serogroup-specific genes (O1 and O139 rfb); and toxin and pathogenic factor genes (e.g., *ctx, tcpA*). Briefly, water, plankton, and/or sediment samples are collected and concentrated. DNA is extracted from the samples using a modification of the method of Murray and Thompson (1980) and PCR is performed on the extracted DNA using a multiplex (*ompW* and *ctxA*) primer array. This multiplex PCR can be substituted for the total *V. cholerae* ITS-based PCR identification described in Basic Protocol 4, if desired. Positive and negative controls should be run in parallel and should include a eubacterial 16S rDNA PCR reaction on each sample to test template quality (see Table 6A.5.4 for PCR primers and references).

Materials

Water or plankton sample (Basic Protocol 1) or sediment sample
TE buffer, pH 8.0 (*APPENDIX 2A*)
10% (w/v) SDS (*APPENDIX 2A*)
20 mg/ml (2%) proteinase K
5 M NaCl
CTAB/NaCl solution (see recipe)
25:24:1 phenol/chloroform/isoamyl alcohol (*APPENDIX 2A*)
24:1 chloroform/isoamyl alcohol
Isopropanol
70% ethanol
1× PCR amplification buffer (*APPENDIX 2A*) containing 15 mM $MgCl_2$ and 0.1% (w/v) gelatin
25 mM dNTP stock: dATP, dCTP, dGTP, dTTP (*APPENDIX 2A*)
20 μM forward and reverse PCR primers (Table 6A.5.4) for *ompW* (*ompW*-F, R) and *ctxA* (*ctxA*-F, -R)
Taq DNA polymerase
1.5% agarose gel (Voytas, 2000)
TAE buffer (*APPENDIX 2A*)
Molecular weight ladder (e.g., Hyperladder IV, Bioline)
1 μg/ml ethidium bromide (*APPENDIX 2A*)

37° and 65°C water baths
Vacuum desiccator or lyophilizer
Thermal cycler (MJ Research)
UV transilluminator, handheld UV lamp, or digital gel documentation system

Additional reagents and equipment for sample collection/transportation (Basic Protocol 1) and enrichment (Basic Protocol 2), PCR (Kramer and Coen, 2001), agarose gel electrophoresis and ethidium bromide staining of gels (Voytas, 2000), and isolation of *V. cholerae* by traditional culture method (Basic Protocol 2; optional)

Enrich environmental sample

For water and plankton samples

1a. Transport samples to the laboratory as for the conventional bacterial culture method (Basic Protocol 1).

2a. Filter (water sample) or homogenize (plankton sample), then perform enrichment in APW as in the conventional bacterial culture method (Basic Protocol 2).

For sediment samples

1b. Add sediment to 100 ml distilled water until the final volume reaches 200 ml. Mix well and allow sediment to settle. Remove large particulate matter by centrifuging a 10-ml aliquot of the slurry for 8 min at 1000 × *g*, room temperature.

2b. Enrich 1 ml of the sediment slurry (supernatant from previous step) in an APW enrichment flask, as for water and plankton samples (Basic Protocol 2).

Extract DNA

3. Microcentrifuge a 1-ml aliquot from the upper surface (i.e., top 1 to 2 mm) of the APW enrichment culture for 5 min at 12,000 × *g*, room temperature.

4. Resuspend the cell pellet in 567 µl TE buffer, pH 8.0.

5. Add 30 µl of 10% SDS, then 3 µl of 20 mg/ml proteinase K. Incubate the suspension 1 hr at 37°C.

6. Add 100 µl of 5 M NaCl, then add 80 µl of CTAB/NaCl solution. Incubate mixture 10 min at 65°C.

7. Add 800 µl of 25:24:1 phenol/chloroform/isoamyl alcohol, vortex, and centrifuge 5 min at 12,000 × *g*, room temperature.

8. Transfer aqueous (upper) phase to a new microcentrifuge tube. Add 800 µl of chloroform/isoamyl alcohol (24:1), vortex, and centrifuge 5 min at 12,000 × *g*, room temperature.

9. Transfer aqueous (upper) phase to a new microcentrifuge tube. Precipitate DNA by adding an equal volume of isopropanol.

10. Microcentrifuge 5 min at 12,000 × *g*, room temperature, and remove the supernatant. Wash DNA by adding 1 ml of 70% ethanol and microcentrifuging 5 min at 12,000 × *g*, room temperature.

11. Dry pellet in vacuum desiccator or lyophilizer and resuspend in 100 µl TE buffer, pH 8.0.

Perform multiplex PCR assay for detection of ompW (V. cholerae-specific) and ctxA (toxigenicity) (Nandi et al., 2000)

12. Set up *ompW-ctxA* multiplex PCR in a PCR tube for a total reaction volume of 25 µl containing the following:

    10 to 20 ng extracted genomic DNA (step 11)
    1× PCR amplification buffer
    250 µM each dNTP
    1.2 pmol/µl forward and reverse primers for *ompW* (*ompW*-F, -R)
    0.25 pmol/µl forward and reverse primers for *ctxA* (*ctxA*-F, -R)
    0.625 U *Taq* DNA polymerase.

    This protocol may be modified for the analysis of cultured organisms by using crude template DNA (see Basic Protocol 4, step 4) in this mixture instead of extracted genomic DNA.

13. Amplify the targets with the following cycling conditions:

1 cycle:	5 min	94°C	(initial denaturation)
30 cycles:	30 sec	94°C	(denaturation)
	30 sec	64°C	(annealing)
	30 sec	72°C	(extension)
1 cycle:	7 min	72°C	(final extension).

Perform agarose gel electrophoresis and visualize results

14. Run PCR product out on a 1.5% agarose gel in 1× TAE for 1 to 2 hr at 5 V/cm (Voytas, 2000), along with a molecular weight ladder (e.g., Hyperladder).

15. Stain the gel by incubating in 1 μg/ml ethidium bromide staining solution for 15 min at room temperature.

16. Destain the gel by incubating in distilled water for 15 min at room temperature.

17. Visualize the products by viewing the gel using a handheld UV lamp, transilluminator, or digital gel documentation system.

    The ompW and ctxA amplicons are 588 and 302 bp in length, respectively.

18. Screen samples giving a positive result for isolation of *V. cholerae* using the traditional culture method as described in Basic Protocol 2, if desired.

ALTERNATE PROTOCOL 1

Alternative Multiplex PCR Assay for Detection of O1 and O139 Serogroup *V. cholerae* and *ctxA*

In the following procedure (Hoshino et al., 1998), the multiplex PCR assay is performed to confirm O1 and O139 somatic antigens and for the simultaneous detection of the toxigenic trait gene, *ctxA*. This protocol can be used in place of steps 12 to 17 of the *ompW-ctxA* method (see Basic Protocol 5) for direct detection of *V. cholerae* in environmental samples. In addition, this assay can be used in place of the *V. cholerae*-specific ITS PCR (see Basic Protocol 4) for confirmation of presumptive *V. cholerae* strains isolated by the conventional bacteriological culture method. This protocol is particularly useful for determining the O1 or O139 serogroups of strains that are of the rough morphotype (see Basic Protocol 3, step 4 annotation) in which the serogroup cannot be determined by agglutination with specific antiserum.

Additional Materials *(also see Basic Protocol 4 or 5)*

20 μM forward and reverse PCR primers (Table 6A.5.4) for O1-*rfb* (O1F2-1, O1R2-2) and for O139-*rfb* (O139F2, O139R2)
2.0% agarose gel (Voytas, 2000)

1. Prepare crude template (Basic Protocol 4) or DNA extract (Basic Protocol 5).

2. Set up O1/O139-*rfb*/*ctxA* multiplex PCR in a PCR tube for a total reaction volume of 30 μl containing the following:

   10 to 20 ng of crude DNA template (Basic Protocol 4) or extracted genomic DNA (Basic Protocol 5)
   1× PCR amplification buffer
   210 μM each dNTP
   0.5 μM forward and reverse primers for O1-*rfb* (O1F2-1, O1R2-2)
   0.27 μM forward and reverse primers for O139-*rfb* (O139F2, O139R2)
   0.17 μM forward and reverse primers for *ctxA* (VCT1, VCT2)
   0.75 U *Taq* DNA polymerase.

3. Amplify the targets with the following cycling conditions:

1 cycle:	5 min	94°C	(initial denaturation)
35 cycles:	1 min	94°C	(denaturation)
	1 min	55°C	(annealing)
	1 min	72°C	(extension)
Final extension:	7 min	72°C	(final extension).

4. Run PCR product out on a 2.0% agarose gel in 1× TAE for 1 to 2 hr at 5 V/cm (Voytas, 2000), along with a molecular weight ladder (e.g., Hyperladder).
5. Stain the gel by incubating in 1 μg/ml ethidium bromide staining solution for 15 min at room temperature.
6. Destain the gel by incubating in distilled water for 15 min at room temperature.
7. Visualize the products by viewing the gel using a handheld UV lamp, transilluminator, or digital gel documentation system.

   The O1-rfb, O139-rfb, and ctxA amplicons are 192, 449, and 308-bp in length, respectively (see Fig 6A.5.3).

8. Screen samples giving a positive result for isolation of *V. cholerae* using the traditional culture method as described in Basic Protocol 2, if desired.

Colony Blot Hybridization with Labeled RNA or DNA Probes

BASIC PROTOCOL 6

The colony lift procedure is used to immobilize DNA from bacterial colonies onto nitrocellulose or nylon filters to allow quick screening of a large number of colonies for genetic elements of interest by hybridization. The colony blot hybridization procedure is a culture-based alternative to the conventional culture method (Basic Protocol 2), so it is dependent upon the presence of *V. cholerae* in the sample as viable, culturable cells. Detection by hybridization precludes the necessity of numerous biochemical tests. Its advantage over PCR is that isolation is performed simultaneously with blot preparation, and enumeration can be performed more easily. Briefly, LB or modified nutrient agar spread plates are prepared from water samples and incubated overnight. Other plating media can be used, but the medium should be relatively rich and nonselective to allow for vigorous growth and cells with a high RNA content. Nitrocellulose (or nylon) membranes are overlaid, lifted, and treated to bind RNA (or DNA) to the membrane (Rehnstam et al., 1989). Plates to be lifted should contain 50 to 150 well defined colonies, 2.0 to 3.0-mm in size. Membranes should be handled with sterile forceps only and can be sterilized in an autoclave between two pieces of filter paper for 15 min prior to use. For RNA blots, care should be taken to minimize RNase contamination. Blots are then hybridized with labeled probe specific for *V. cholerae* (and *V. mimicus*), 5′-ACTTTGTGAGATTCGCTCCACCTCG-3′ (Heidelberg, 1997; Heidelberg et al., 2002), or toxigenic *V. cholerae* (*ctxA*). *V. mimicus* is a species closely related to *V. cholerae*, previously described as biochemically atypical *V. cholerae* (nonsucrose fermenting indicated by green colonies instead of yellow colonies on TCBS). *V. mimicus* produces a variety of toxins, including cholera toxin (potential reservoir), and has caused sporadic diarrhea (Ramamurthy et al., 1994). Fluorescently labeled probes are preferred (e.g., see Boyle and Perry-O'Keefe, 1992); however, the DIG system (Roche; see Alternate Protocol 2) offers a good alternative when a variable mode imager (such as Typhoon from GE Healthcare) or equivalent machine for detection of the fluorochrome, such as Dark Reader (Clare Chemical Research, *http://www.clarechemical.com/*), is not available.

Materials

Enrichment flask with *Vibrio cholerae* culture (see Basic Protocol 2) (for detection) or unenriched sample (for enumeration)
Alkaline peptone water (APW; see recipe)
LB plates (*APPENDIX 4A*) or modified nutrient agar plates (see recipe)
10% (w/v) SDS (*APPENDIX 2A*)
3× SSC (*APPENDIX 2A*)
Prewashing solution (see recipe), 60°C
DEPC-treated H_2O (*APPENDIX 2A*)
RNA colony blot hybridization solution (see recipe)
25 ng/μl fluorescein-labeled Vchomim1276 probe (5′-ACTTTGTGAGATTCGCTCCACCTCG-3′, with 5′ fluorescein label; Sigma Genosys)
Washing solution for colony blot hybridization with fluorescein-labeled probes (see recipe), 60°C
85-mm sterile nitrocellulose membranes, 0.22-μm (GE Water and Process Technologies)
65°C incubator
Pyrex dishes
Whatman no. 3 filter paper cut slightly larger than the nitrocellulose membranes
70°C oven
60°C water bath
Hybridization oven
Typhoon Scanner (GE Healthcare) or Dark Reader (Clare Chemical)

NOTE: All solutions should be DNase and RNase-free. For RNA colony blot hybridization, use DEPC-treated water (see *APPENDIX 2A*) to make hybridization solutions.

Prepare spread plates

1a. *For detection:* Prepare spread plates from enrichment flasks using APW as diluent by plating three 10-fold serial dilutions onto LB or modified nutrient agar plates.

1b. *For enumeration (and detection):* Prepare spread plates by plating three 10-fold serial dilutions onto LB or modified nutrient agar plates on-site without APW enrichment.

Alternatively, 100 to 500 ml of water may be filtered through the 0.22-μm nylon membranes and overlaid onto an agar plate. If this method is preferred, incubate the plate containing the membrane overnight at 30°C and then proceed to step 6.

2. Incubate plates overnight at 37°C.

Perform colony lift

3. Using a pencil, mark each membrane on the top side with the blot ID (e.g., recording the medium, sample, dilution) that matches the plate to be lifted. Also place asymmetrical orientation marks on the membrane to facilitate later comparison between membrane and plate.

4. Overlay the corresponding membrane onto each of the incubated spread plates, starting from the center to ensure there are no air bubbles.

5. Allow at least 15 min for transfer.

6. Replica plate the membrane onto a fresh modified nutrient agar plate, transferring the orientation markings. Maintain master and replica plate at 10° to 15°C, sealed with Parafilm.

Perform this step only when subsequent analysis of a positive colony is necessary.

7. For each plate, prepare two Pyrex dishes by placing a piece of Whatman no. 3 filter paper cut slightly larger than the nitrocellulose membrane into each. Prewet the filter paper in one dish with 10% SDS and the other with 3× SSC, pouring or pipetting the liquid onto the filter paper, letting it soak briefly, removing the air bubbles, then pouring off the excess. Ensure that there is no pooled liquid on the filter paper prior to placing membrane.

   It is important to use filter paper prewetted but not saturated with the appropriate solutions, to prevent colonies from over-swelling and losing their circular shape.

8. Preheat 10% SDS, 3× SSC, and the Pyrex dishes with the prewetted filter paper to 65°C.

9. Place membrane colony-side-up on the SDS-prewetted filter paper in the corresponding dish, cover the membrane with Saran Wrap or equivalent plastic wrap to prevent filter paper from drying out, and incubate 5 min at 65°C.

10. Transfer the membrane colony-side-up to the filter paper prewetted with 3× SSC, cover membrane with Saran wrap or equivalent plastic wrap to prevent the filter paper from drying out, and incubate 5 min at 65°C.

11. Transfer membranes to dry filter paper and allow to air dry 10 min at room temperature.

12. Bake membranes 15 min in a 70°C oven.

Perform RNA colony-blot hybridization

13. Wash membranes three times in 150 ml prewashing solution for 15 min at 37°C.

14. Wash membranes in 150 ml prewashing solution at 60°C, with agitation in a shaking water bath.

15. Rinse membranes in DEPC-treated water.

16. Prehybridize the membranes 30 min at 60°C in RNA colony blot hybridization solution at a ratio of 10 ml solution per 100-cm^2 of blot membrane in a hybridization oven.

    85 mm-membranes have a surface area of ~60 cm^2.

    RNA colony blot hybridization solution will form a precipitate when kept at room temperature. If this happens, heat to 40° to 50°C to resuspend.

17. Prepare a sufficient quantity of probe-containing RNA colony blot hybridization solution by adding 32 µl of 25 ng/µl fluorescein-labeled Vchomim1276 probe per 10 ml of RNA colony blot hybridization solution. At the end of the incubation in step 16, pour off the solution from the membrane and add the probe-containing RNA colony blot hybridization solution at a ratio of 10 ml solution per 100-cm^2 blot.

18. Hybridize overnight (ideally for 16 to 20 hr) at 60°C.

19. After hybridization, wash membranes 30 min at 60°C in washing solution for colony blot hybridization with fluorescein-labeled probes.

20. View/image the membrane using Typhoon Scanner or Dark Reader.

21. From replica plates, subculture colonies that were positive by blot hybridization for further analysis, if desired.

ALTERNATE PROTOCOL 2

Colony Blot Hybridization Using DIG-Labeled *ctxA* DNA Probe

The previous colony blot hybridization protocol (Basic Protocol 6) is used to detect *V. cholerae* and closely related *V. mimicus*. This protocol, on the other hand, targets only toxigenic strains of *V. cholerae*. The presence of *ctxA* is confirmed by hybridization using a *ctxA*-specific DNA probe. There may be some cross-reactivity of the probe with the heat-labile toxin (LT) of *E. coli* (Dallas and Falkow, 1980). Colony blots are prepared according to the method of Pal et al. (1992). The hybridization is done according to the DIG protocol. Readers are encouraged to consult the manual accompanying the High Prime kit (Roche); probe-labeling is described in the Support Protocol. The *ctxA* probe can be produced by PCR, using the pCTA primer set (see Table 6A.5.4), or by *Eco*RI digestion of plasmid, pKTN901, which contains a 540-bp *Xba*I-*Cla*I fragment of *ctxA* (Kaper et al., 1988).

Additional Materials *(also see Basic Protocol 6)*

Lysis buffer: 0.5 M NaOH/1.5 M NaCl (prepare fresh)
Neutralization solution 0.5 M Tris·Cl, pH 7.2 (*APPENDIX 2A*)/1.5 M NaCl (store up to 6 months at 2° to 8°C)
1× SSC (*APPENDIX 2A*)
40 μg/ml proteinase K in 1× SSC (store up to 2 months at –20°C)
DIG High Prime DNA Labeling and Detection Starter Kit II: (Roche) including:
  DIG Easy Hybridization Buffer
  10× blocking solution
  Antibody: anti-digoxigenin–AP conjugate
  CSPD
DIG-labeled *ctxA* probe (Support Protocol)
Stringency wash solution I: 2× SSC (*APPENDIX 2A*)/0.1% (w/v) SDS
Stringency wash solution II: 0.5× SSC (*APPENDIX 2A*)/0.1% (w/v) SDS
Washing solution for colony blot hybridization with DIG-labeled probes (see recipe)
Maleic acid buffer (see recipe)
Detection buffer: 0.1 M Tris·Cl, pH 9.5 (*APPENDIX 2A*)/0.1 M NaCl
Sterile nylon (or nitrocellulose) membranes, 85 mm, 0.22-μm (GE Water and Process Technologies)
UV cross-linker or transilluminator
42° and 65°C shaking incubators
Room temperature shaking water bath
Boiling water bath
Hybridization pouches
X-ray film (Kodak or Fuji) and developing facility

Prepare blots

1. Prepare LB agar spread plates as described in Basic Protocol 6, step 1.
2. Incubate plates overnight at 37°C
3. Using a pencil, mark each membrane on the top side with the blot ID (e.g., recording the medium, sample, and dilution) that matches the plate to be lifted. Also place asymmetrical orientation marks on the membrane to facilitation later comparison between membrane and plate.
4. Overlay the corresponding membrane onto each of the incubated spread plates, starting from the center to ensure there are no air bubbles.
5. Allow at least 15 min for transfer.

6. Transfer the blot onto a new LB plate keeping colony side up and incubate 3 hr at 37°C. Wrap the master plate with Parafilm and keep at 10° to 15°C.

   Master plates can be maintained in this manner for up to 2 weeks.

7. Place membranes, colony-side-up, onto Whatman no. 3 filter paper prewetted with lysis buffer in a Pyrex dish (see Basic Protocol 6, step 7, for additional considerations). Incubate 10 min at room temperature.

   It is important to use filter paper prewetted but not saturated with the appropriate solutions, to prevent colonies from over-swelling and losing their circular shape.

8. Remove the membrane from lysis buffer and place onto Whatman no. 3 filter paper prewetted with neutralization solution in a Pyrex dish. Incubate 5 min at room temperature.

9. Transfer membrane to a fresh filter paper prewetted with neutralization solution and incubate 5 min at room temperature.

10. Remove membrane from neutralization solution, place onto dry no. 3 Whatman filter paper and allow to air dry (~15 min) at room temperature, but not to complete dryness.

11. Immobilize colonies onto the membrane using a UV cross-linker or transilluminator.

    Damp membranes should be cross-linked at an output intensity of 120-mJ/cm^2, which corresponds to the optimal or auto-cross-link setting on commercially available machines. Transilluminators or hand-held UV lamps can be used, if calibrated; however, the following times should be sufficient: 1 min for 254-nm lamps or 3 min for 302-nm lamps.

12. Rinse the blot twice in 1× SSC buffer and air dry (~30 min).

13. Treat membranes 30 min at 42°C with 100 ml of 40 μg/ml proteinase K solution using gentle shaking.

14. Rinse filters three times in 1× SSC in a shaking water bath at room temperature, each time for 10 min. Allow to air dry (~30 min) at room temperature.

Prehybridize and hybridize

15. Preheat DIG-Easy Hybridization buffer to 42°C.

16. Prehybridize blots in preheated DIG-Easy Hybridization buffer for 30 min at 42°C with gentle agitation.

17. Denature the DIG-labeled *ctxA* probe by boiling for 5 min and rapidly cooling on ice. Prepare 25 ng/ml denatured probe in DIG Easy Hybridization solution.

18. Pour off prehybridization solution.

19. Add freshly prepared DIG Easy Hybridization Solution plus 25 ng/ml denatured probe and incubate overnight at 42°C.

Perform stringency washes

20. Pour off probe-containing hybridization solution.

    Probe-containing hybridization solution can be reused several times. Store up to 2 months at –20°C.

21. Wash membrane twice in stringency wash solution I for 5 min at room temperature under constant agitation.

22. Wash membrane twice in stringency wash solution II for 15 min at 65°C under constant agitation.

Detect positive colonies

23. Rinse membrane 5 min in washing solution for colony blot hybridization with DIG-labeled probes.
24. Dilute the 10× blocking solution from the kit to 1× in maleic acid buffer. Incubate the membrane 30 min at 25°C in 1× blocking solution (from kit; prepare according to manufacturer's instructions).
25. Prepare antibody solution by diluting the anti-digoxigenin–AP conjugate from the kit 1:10,000 in 1× blocking solution (prepared as in the previous step). Incubate membrane 30 min at 25°C in this diluted antibody solution for 30 min.
26. Wash the membrane twice, each time for 15 min, in solution for colony blot hybridization with DIG-labeled probes, for 15 min each.
27. Incubate membrane in detection buffer for 5 min at room temperature (25°C).
28. Place membrane in hybridization pouch. Add CSPD (from kit) to the membrane, cover and incubate at room temperature for 5 min.
29. Remove excess liquid from pouch, seal, and incubate at 37°C for 10 min.
30. Expose the membrane to X-ray film for 20 min at room temperature and develop.

    If film is under- or overexposed, repeat, varying time of exposure accordingly.

31. From master plates (step 6), subculture colonies that were positive by blot hybridization for further analysis.

SUPPORT PROTOCOL

Digoxigenin Labeling of *ctxA* Probe Using DIG High Prime Kit

PCR- or restriction digestion–generated probes can be labeled using the DIG High Prime kit (Roche), which is based on randomly incorporating digoxigenin-11-dUTP. A 563-bp *ctxA* fragment can be produced by amplifying extracted DNA from a toxigenic laboratory reference strain. The PCR product should be purified by using a PCR clean-up kit or by gel electrophoresis and extraction. Alternatively, a PCR product may be labeled during the PCR amplification using the PCR DIG Probe Synthesis Kit (Roche). A 554-bp *ctxA* probe is also available on a plasmid, pKTN901 (Kaper et al., 1988), which has been widely used (Pal et al., 1992; Islam et al., 2005). The *Xba*I-*Cla*I fragment can be removed from the plasmid by digestion with *Eco*RI, and gel purified. Labeled probes can then be used in the DIG-based hybridization as described in Alternate Protocol 2.

Materials

DNA extracted from toxigenic (*ctxA*$^+$) *V. cholerae* reference strain (ATCC)
Forward and reverse pCTA primers for amplifying *ctxA* (Table 6A.5.4)
Plasmid pKTN901 (available from Dr. James Kaper, *jkaper@umaryland.edu*) or other source of *ctxA* probe
*Eco*RI restriction endonuclease (or other restriction enzyme depending on source of *ctxA* probe) and restriction buffer
5× DIG High Prime labeling mixture (Roche)
0.2 M tetrasodium EDTA, pH 8.0
Boiling water bath
65°C water bath
Additional reagents and equipment for purifying DNA fragments (Moore et al., 2002)

1. *To generate ctxA target fragment by PCR:* Amplify extracted DNA of a toxigenic (*ctxA*$^+$) *V. cholerae* reference strain using the pCTA primer set.
2. *To generate ctxA target fragment by restriction digestion:* Digest plasmid pKTN901 with *Eco*RI for 2 hr at 37°C or digest other source of *ctxA* probe using restriction enzyme and conditions appropriate to construct.
3. Clean up PCR reaction product or digestion product by gel electrophoresis followed by gel extraction (Moore et al., 2002).
4. In a microcentrifuge tube, bring 1 μg purified *ctxA* fragment up to a total volume of 16 μl with sterile distilled water.
5. Denature by placing in a boiling water bath for 10 min, then rapidly transfer to an ice/water bath and chill 5 min.
6. Add 4 μl of 5× DIG High Prime labeling mixture to the DNA solution, mix, then microcentrifuge briefly to collect liquid at the bottom of the tube.
7. Incubate overnight at 37°C.
8. Stop reaction by adding 2 μl of 0.2 M tetrasodium EDTA and/or by heating to 65°C for 10 min.

IMMUNOLOGICAL METHODS FOR DETECTION OF *V. CHOLERAE*

Conventional culture methods are ineffective when bacterial cells have entered into the viable but nonculturable (VBNC) state. Thus, direct or indirect detection of the cells themselves becomes extremely important. The discovery of monoclonal antibodies in the 1980s and, subsequently, the development of a monoclonal antibody against *V. cholerae* O1,s triggered development of direct detection methods for this bacterial species (Xu et al., 1984; Hasan et al., 1992). Using immunological methods, the mystery concerning the inability to culture *V. cholerae* in environmental samples during inter-epidemic periods in Bangladesh was resolved by the discovery of VBNC *V. cholerae* (Roszak and Colwell, 1987; Huq et al., 1990).

Direct Fluorescent Antibody–Direct Viable Count (DFA-DVC) Method

BASIC PROTOCOL 7

The direct fluorescent antibody staining method for rapid detection of *V. cholerae* serogroup O1 and O139 is a very useful, direct, and culture-independent method. Coupled with the direct viable count method of Kogure et al. (1979), it can distinguish culturable, viable cells from viable but nonculturable cells (VBNC) of *V. cholerae* (Chowdhury et al., 1995). It is a two-step method in which samples are incubated with yeast extract in the presence of nalidixic acid, after which actively viable, substrate-responsive cells become enlarged and elongated (Kogure et al., 1979). Next, smears prepared from this suspension on a glass slide are stained with fluorescently labeled monoclonal antibody raised against the "A" factor of *V. cholerae* O1 lipopolysaccharide, which reacts with both serotype Ogawa and serotype Inaba (Colwell et al., 1990; Hasan et al., 1994). Antibodies against *V. cholerae* O139 are also available (Hasan et al., 1995). When observed under an epifluorescent microscope, elongated cells of *V. cholerae* O1 or O139 (based on the type of antibody used) exhibit a bright green–fluorescing periphery (the outer cell wall) with a dark interior (Fig. 6A.5.4). *V. cholerae* O1- and O139 DVC-DFA-positive samples can be confirmed by PCR (Binsztein et al., 2004). DFA-DVC is a rapid method by which one can determine the presence of *V. cholerae* within 8 hr (when the DVC incubation is 6 hr); however, overnight incubation with yeast extract and nalidixic acid is preferred. Kits for *V. cholerae* O1 (Cholera DFA) and O139 (Bengal DFA) DFA tests are commercially available (New Horizon Diagnostics).

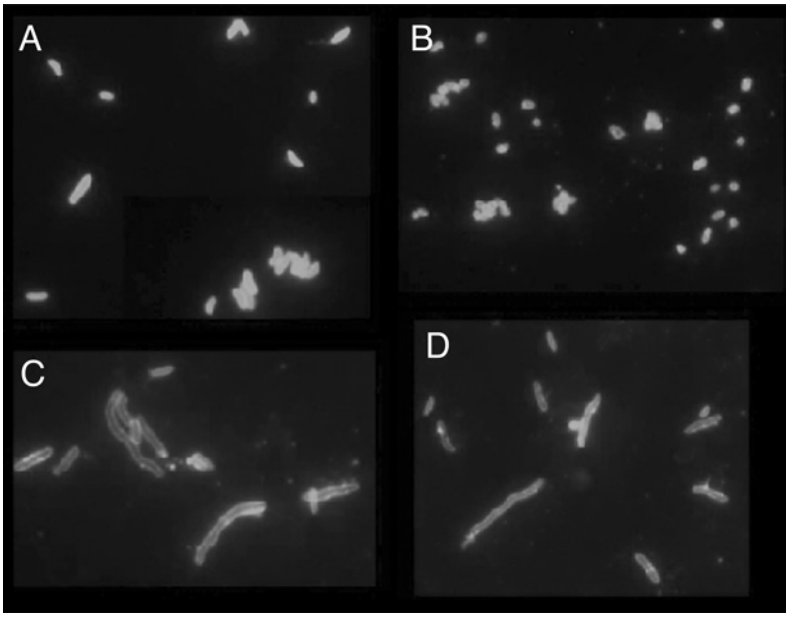

Figure 6A.5.4 DFA staining of *V. cholerae* O1 using the Cholera DFA Kit (New Horizon Diagnostics). (**A**) Fresh culture; (**B**) VBNC cells; (**C**) and (**D**), DVC-incubated cells. For the color version of this figure go to *http://www.currentprotocols.com*.

Materials

Concentrated water or homogenized plankton sample (Basic Protocol 2)
2.5% (w/v) yeast extract in distilled water
0.2% (w/v) nalidixic acid in distilled water
37% to 40% formaldehyde solution or fresh 4% formaldehyde prepared from paraformaldehyde
Absolute methanol
Cholera DFA and/or Bengal DFA kit (New Horizon Diagnostics) containing:
  FITC-conjugated DFA reagent
  Positive and negative control
  Fluorescent mounting medium
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Humidified chamber: 50-ml conical centrifuge tube containing 1 to 2 strips of water-saturated filter paper
Multiwell slides and coverslips
Epifluorescent microscope with FITC filter set

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic techniques should be used accordingly.

NOTE: All solutions should be filter-sterilized through a 0.1-μm filter, as VBNC cells of *V. cholerae* appear as small coccoid cells in a size range of 0.1 to 0.8 μm.

Perform DVC incubation

1. To 1 ml concentrated water or homogenized plankton sample (Basic Protocol 2), add 10 μl of 2.5% yeast extract and 10 μl of 0.2% nalidixic acid.

   The water sample can be concentrated by filtration through a 0.22-μm filter followed by resuspension or by centrifugation for 10 min at 12,000 × g, room temperature, followed by removal of the supernatant and resuspension.

   Freeze a parallel 1-ml sample for PCR confirmation (see Basic Protocol 5).

2. Incubate the mixture at room temperature (25°C) for a minimum of 6 hr to overnight.
3. Fix the sample by adding formaldehyde to a final concentration of 3% (v/v) and incubating 30 min at room temperature in the dark.

   Fixed samples can be stored at 4°C in the dark for up to 6 months.

Perform DFA protocol

4. Place 5 to 10 µl of the fixed sample onto a glass slide and air dry ~15 to 20 min.
5. Fix by adding 5 µl absolute methanol and air dry 1 to 5 min.
6. Add 10-µl of reconstituted FITC-conjugated specific DFA reagent from the Cholera DFA or Bengal DFA kit.

   Use of this kit is discussed in Hasan et al. (1994).

7. Incubate 30 min at 37°C in a humidified chamber. Protect slide from light.
8. Rinse slide with ~50 ml PBS. Air dry slide in the dark ~15 to 20 min.
9. Mount slide with one drop of fluorescent mounting medium and add coverslip.
10. Observe under an epifluorescent microscope (see Fig 6A.5.4).

Indirect Fluorescent Antibody (IFA) Method

BASIC PROTOCOL 8

This immunofluorescent method for detection of *V. cholerae* serogroup O1 in aquatic environmental samples was first introduced by Xu et al. (1984). Antiserum specific for O1 somatic antigen produced in rabbits was used with fluorescein isothiocyanate (FITC)–conjugated goat anti–rabbit immunoglobulin serum, with rhodamine isothiocyanate (RITC)-conjugated bovine serum albumin as the background stain. This indirect staining method was found to be very useful for detecting organisms in samples that gave negative results by culture and was subsequently modified to a direct method (Brayton et al., 1986; Huq et al., 1990). The direct fluorescent antibody method was later optimized (Hasan et al., 1994) and packaged as the Cholera DFA Kit (New Horizon Diagnostics, Inc.). The IFA protocol remains useful for laboratories where commercial DFA kits for *V. cholerae* are not readily available.

Materials

Concentrated water or homogenized plankton sample (Basic Protocol 2)
95% ethanol
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
FA Rhodamine counterstain (Becton Dickinson)
Polyvalent *V. cholerae* O1-specific antiserum (BD Bioscience)
FITC-conjugated anti-rabbit globulin goat serum (Sigma)
Low-fluorescence antiquenching mounting medium: e.g., FA (BD Biosciences) or Citifluor AF1/AF3 (Electron Microscopy Sciences)
Multiwell, Teflon-coated slides
35° and 55°C incubators
Humidified chamber: 50-ml conical centrifuge tube containing 1 to 2 strips of water-saturated filter paper
Glass coverslips
Epifluorescent microscope with FITC bandwidth filter

Prepare and fix samples

1. Add an appropriate amount (dependent on concentration of sample and well size) of each sample to be tested to a Teflon-coated multiwell slide. Air dry 15 to 20 min at room temperature.

2. Fix the sample by adding 95% ethanol to each sample-containing well. Air dry 5 to 10 min at room temperature.
3. Heat slide 10 min in a 55°C incubator.

Slides may be stored up to 1 month at −70°C at this point.

Stain samples

4. Rinse the slide(s) with ~50 ml PBS and air dry 15 to 20 min.
5. While slide is drying, equilibrate humidified chamber in 35°C incubator ~15 min.
6. To each dry sample well, add 1 to 2 drops of a 1:20 dilution of FA Rhodamine in distilled water. Incubate in humidified chamber 30 min at 35°C.

Minimize exposure to light from this step forward.

7. Rinse slide by gently flooding with ~50-ml PBS, then soak in PBS 10 min at room temperature. Remove slide from PBS and rinse again briefly in PBS.
8. Allow slide to air dry 15 to 20 min.
9. Add 5 to 10 µl of *V. cholerae* O1-specific antiserum. Incubate in humid chamber 30 min at 35°C.
10. Repeat steps 7 and 8 using fresh PBS for washing.
11. Add 1 to 2 drops undiluted FITC-conjugated anti-rabbit globulin goat serum and incubate in humidified chamber 30 min at 35°C.
12. Repeat washing steps 7 and 8 using fresh PBS.

Mount and examine slides

13. Mount each slide with a glass coverslip and a low fluorescence, anti-quenching mounting medium, such as Citifluor AF1.
14. Examine samples immediately using a epifluorescent microscope with a FITC band-pass filter.

Slides can be stored in the dark up to 1 to 2 days at 4°C.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alkaline peptone water (APW)

10 g peptone
10 g sodium chloride
Add 800 ml H_2O
Adjust pH to 8.6 with NaOH
Adjust volume to 1 liter with water
Autoclave 15 min at 121°C
Store up to 6 months at 2° to 8°C

CTAB/NaCl Solution

Add 4 g NaCl to 80 ml water and dissolve. Slowly add 10 g cetyltrimethylammonium bromide (CTAB) while heating and stirring at 65°C. Adjust volume to 100 ml with water. Store up to 6 months at room temperature.

Gelatin agar

4 g neopeptone
1 g yeast extract
5 g sodium chloride
15 g gelatin
15 g agar
Adjust volume to 1 liter with water
Autoclave to sterilize
Store up to 1 month at 2° to 8°C

Kligler iron agar

Combine the following:
20 g polypeptone
10 g lactose
1 g glucose
5 g sodium chloride
0.5 g ferric ammonium citrate
0.5 g sodium thiosulfate
0.025 g phenol red
15 g agar
Adjust volume to 1 liter with water
Boil to dissolve agar completely

Dispense 5-ml portions of the medium into 16 × 125–mm tubes (other size tubes can be used, adjust dispensed media volume to about 1/3 volume of test tube). Autoclave 15 min at 121°C. Allow tubes to solidify in a slanted position to give a generous butt (underneath a 20° to 40° slant). Store up to 6 months at 2° to 8°C.

This medium is also available commercially as a dehydrated powder from Difco (BD Biosciences).

Maleic acid buffer

0.1 M maleic acid
0.15 M sodium chloride
Adjust pH to 7.5 with solid NaOH
Prepare fresh

Methyl Red/Voges-Proskauer (MR-VP) medium

7 g peptone
5 g glucose
5 g potassium phosphate, dibasic
Adjust pH to 6.9 with HCl
Adjust volume to 1 liter with water
Autoclave to sterilize
Store up to 6 months at 2° to 8°C

This medium is also available commercially as a dehydrated powder from Difco (BD Biosciences).

Modified nutrient agar

3 g beef extract
5 g peptone
10 g sodium chloride
15 g agar

continued

Adjust volume to 1 liter with water
Autoclave
Allow medium to cool to 55°C, then pour plates
Store up to 1 month at 2° to 8°C

Moeller decarboxylase broth base

5 g peptone
5 g beef extract
0.5 g dextrose
0.01 g bromocresol purple
0.005 g Cresol red
0.005 g pyridoxal
Adjust volume to 1 liter with water
Boil 1 min to dissolve
Add 10 g L-amino acid or 20 g DL-amino acid as specified in protocol
If adding ornithine, adjust pH to 6.0 with HCl
Autoclave to sterilize
Store up to 6 months at 2° to 8°C

This medium is also available commercially as a dehydrated powder from Difco (BD Bioscience).

Oxidase reagent

Dissolve 0.05 g *N,N,N′ N′*-Tetramethyl-*p*-phenylenediamine dihydrochloride into 5 ml water. Prepare fresh

Final concentration is 1% (w/v).

Prewashing solution

Prepare the following in DEPC-treated water (*APPENDIX 2A*)

3× SSC (*APPENDIX 2A*), RNase-free
0.1% (w/v) SDS RNase-free
Prepare fresh

Purple broth base

10 g proteose peptone no. 3
1 g beef extract
5 g sodium chloride
0.015 g bromocresol purple
Dissolve in 1 liter cold water
Add carbohydrate (as specified in protocol) to 1% (w/v) final concentration
Autoclave to sterilize
Store up to 6 months at 2° to 8°C

This medium is also available commercially as a dehydrated powder from Difco or BBL (both trademarks of BD Bioscience).

RNA colony blot hybridization solution

Prepare the following in DEPC-treated water (*APPENDIX 2A*)
0.9 M NaCl
50 mM sodium phosphate, pH 8.0 (*APPENDIX 2A*)
5 mM tetrasodium EDTA
0.5% (w/v) SDS
Store up to 1 month at room temperature

Precipitation will occur upon standing at room temperature. Heat to 45° to 50°C to resuspend.

Tellurite taurocholate gelatin agar (TTGA) plates

10 g tryptone
10 g sodium chloride
5 g sodium taurocholate
1 g sodium carbonate
30 g gelatin
15 g agar
Adjust volume to 1 liter with water
Boil to completely dissolve ingredients
Final pH should be 8.5; if not, adjust with HCl
Autoclave and add potassium tellurite to 1% (w/v) final concentration
Allow medium to cool to 55°C, then pour plates
Store up to 1 month at 2° to 8°C

Thiosulfate citrate bile-salts sucrose (TCBS) agar

5 g yeast extract
10 g peptone
10 g sodium thiosulfate
10 g sodium citrate
8 g ox bile
20 g sucrose
10 g sodium chloride
1 g ferric citrate
0.04 g bromthymol blue
0.04 g thymol blue
14 g agar
Adjust volume to 1 liter with H_2O
Boil to completely dissolve; do not autoclave
Allow medium to cool to 55°C, then pour plates

This medium is also available commercially as a dehydrated powder from Oxoid.

IMPORTANT NOTE: TCBS medium is never autoclaved. Sterility is achieved (for practical purposes) by the selective ingredients added to the medium. The high concentrations of thiosulfate and citrate and the strong alkalinity of this medium largely inhibit the growth of Enterobacteriaceae. Ox bile and cholate suppress primarily enterococci. Any coliform bacteria, which may grow, cannot metabolize sucrose. Only a few sucrose-positive Proteus strains can grow to form yellow, Vibrio-like colonies. The mixed indicator thymol blue/bromthymol blue changes its color to yellow, when acid is formed, even in this strongly alkaline medium.

Washing solution for colony blot hybridization with DIG-labeled probes

0.1 M maleic acid
0.15 M sodium chloride
0.3% (v/v) Tween 20
Adjust pH to 7.5 with solid NaOH
Prepare fresh

Washing solution for colony blot hybridization with fluorescein-labeled probes

Prepare the following in DEPC-treated water (*APPENDIX 2A*)
1× SSC (*APPENDIX 2A*)
0.1% SDS
Prepare fresh

COMMENTARY

Background Information

Although microorganisms were isolated and characterized a century ago, the past three decades could be termed as the "golden age of environmental microbiology" (Leadbetter, 1997). Twenty years ago, some microbiologists estimated that perhaps 40% of all prokaryotes were recognized and understood. However, today, it would be overly optimistic to suggest a number even as high as 5%, because new methods employed in environmental microbiology have shown that many microorganisms—perhaps <1% of the microbial species in the world oceans (Venter et al., 2004)—have been cultured. Molecular probes are considered the ultimate tools for detection and characterization of microorganisms (Woese, 1994; Amann et al., 1995) without the need for culture, but probes are designed only on the basis of existing knowledge of molecular signatures of organisms that were obtained originally in pure culture (Leadbetter, 1997). The study of environmental samples is very different from clinical microbiology. The diversity of microorganisms inhabiting highly dissimilar environments is enormous. Therefore, no unique test or set of tests will be appropriate for every environment. Detecting a particular organism will depend on environmental conditions during sample collection. Investigators would be wise first to determine the kind of data or results that will be needed and the appropriateness of available methods, as well as the feasibility of carrying out the procedures to achieve the goal. If a target pathogen is not detected in a sample using a particular method or even by a set of methods, it is risky to conclude that the pathogen is not present, especially if there are other indications that it may be present. Like any bacteriological test, replication and accurate interpretation are critical to achieve reproducible results. Most importantly, it is the responsibility of the investigator to choose appropriate tests and carefully design the study, including controls; otherwise, data interpretation will be very difficult, with misleading conclusions.

Vibrio cholerae is an autochthonous member of estuarine and other aquatic communities (Colwell et al., 1977; Kaper et al., 1979; Colwell et al., 1981; Colwell and Spira, 1992) and the disease with which it is associated, cholera, is largely a waterborne disease. *V. cholerae* also frequently isolated from higher aquatic organisms, such as plankton (Huq et al., 1990; Tamplin et al., 1990; Islam et al., 1993), oysters (Hood et al., 1981; Murphree and Tamplin, 1991), and water hyacinth (Spira et al., 1981). Transmission of cholera occurs predominantly by the fecal-oral route, via ingestion of contaminated water or contaminated seafood. Endemic areas include Southeast Asia, Africa, and Latin and South America, where poverty and poor sanitation are common.

Of the over 200 recognized serogroups of *V. cholerae* (Yamai et al., 1997), only the O1 and O139 serogroups cause epidemic and pandemic cholera outbreaks. Predominantly, non-O1/non-O139 *V. cholerae* strains are isolated from the environment, even in epidemic areas. Of the O1 serogroup strains that are isolated from the environment, most are nontoxigenic; i.e., missing the genes necessary for pathogenicity (*ctxA*$^-$, *tcpA*$^-$; Roberts et al., 1982; Minami et al., 1991).

V. cholerae, along with an ever-increasing number of species of Gram-negative bacteria, is capable of entering a state of dormancy, commonly termed viable but nonculturable (VBNC or sometimes VNC; Roszak and Colwell, 1987; Colwell, 1991; Colwell and Huq, 1994). It is becoming apparent that this state is an important survival strategy and perhaps an essential part of the life cycle of these bacteria. Microcosm experiments using VBNC *V. cholerae* suggest that a large number of environmental isolates exist in this state as compared to culturable cells (Huq et al., 1990; Huq et al., 2000).

Critical Parameters and Troubleshooting

Successful detection and/or isolation of *V. cholerae* may depend upon many environmental variables in addition to the appropriateness of the method used. For example, chances of detection of *V. cholerae* O1 are higher in warmer months when the water temperature is >30°C (Louis et al., 2003; Binsztein et al., 2004). The conventional culture method presented in this unit (Basic Protocol 2) is the most common, and preferred, culture-based protocol used to isolate *V. cholerae* (Morris et al., 1979; Rennels et al., 1980). There have been a number of proposed derivatives of this technique (Basic Protocol 2), based largely on alternative media. For enrichment, alkaline bile peptone water (Spira et al., 1981), Monsur's tellurite taurocholate broth (Monsur, 1961), and sodium-gelatin phosphate broth (Rennels et al., 1980) have been proposed. A second

enrichment step may be used, but this will add an additional 6 to 8 hr to an already lengthy protocol. Equally, a number of differential or selective plating media have been proposed (Tamura et al., 1971; Chatterjee et al., 1977; Morris et al., 1979; Shimada et al., 1990). Spira and Ahmed (1981) reported that using Moore swabs may increase the number of *V. cholerae* isolated over concentration by membrane filtration; however, membrane filtration remains the favored method. The authors of this unit include a subculturing step on to nonselective medium—modified nutrient agar or gelatin agar. This step serves two purposes. First, it is critical that pure colonies be achieved before proceeding with a battery of biochemical tests; mixed cultures will give ambiguous results. Second, growth on TCBS is not satisfactory for the oxidase test or for serotyping. When characterizing by biochemical tests, the authors present eleven biochemical tests to be performed, in addition to the oxidase test (Table 6A.5.2). This list is not definitive; the battery can be increased or decreased, and/or modified.

It is well documented that PCR amplification of environmental samples can be inhibited by dissolved organics, such as humic acid. For that reason, it is suggested the DNA be extracted first, which adds only 3 to 4 hr to the protocol. For all direct PCR examinations, include the eubacterial PCR reaction to confirm template quality on samples that are negative for *V. cholerae* gene targets.

Colony blot hybridization (Basic Protocol 6 and Alternate Protocol 2) is presented here as a culture-based alternative to the conventional culture method described in Basic Protocol 2. At least three serial-fold dilutions should be spread-plated to ensure screening of an ideal number of colonies (50 to 200). As an alternative, the authors suggest filtering water directly through the membrane (0.22-μm) to be used for the colony lift, although some knowledge of the microbial density of the water sample is needed for this procedure. For the *V. cholerae*–specific RNA-colony blot/hybridization, care should be taken to eliminate RNase contamination. Diethylpyrocarbonate (DEPC; *APPENDIX 2A*) is used to eliminate the otherwise stable, ubiquitous enzymes. The *ctxA*-DNA colony blot hybridization (Alternate Protocol 2) is presented for cases in which only toxigenic *V. cholerae* is investigated. This method has two drawbacks: cross-reaction with heat labile enterotoxin (LT) of *E. coli* may occur, and it is relatively expensive if a large number of samples are to be analyzed.

DVC-DFA (Basic Protocol 7) and IFA (Basic Protocol 8) of *V. cholerae* are relatively rapid protocols compared to the other methods presented. One pitfall of these immunofluorescence methods is the confounding observation of autofluorescing constituents found in environmental water samples. All "positive" samples should be documented by digital or film photography; confirmation by PCR of a parallel sample (frozen, but not fixed) is advisable.

Table 6A.5.5 outlines some of the more common problems that may be experienced in performing the basic and alternate protocols from this unit. This is not an exhaustive list; others may be encountered. Consult the troubleshooting sections from the referenced units of *Current Protocols in Molecular Biology* (see Literature Cited) for further advice.

Anticipated Results

V. cholerae can be easily isolated from estuarine environments during the warm summer months—even in nonepidemic areas. The chance of successful isolation decreases during the colder winter months, even from samples that are positive by PCR or DFA. Figure 6A.5.2 shows the typical growth of *V. cholerae* on TCBS and TTGA media. Growth on TCBS by *V. cholerae* appears as small (1- to 3-mm diameter) flat, yellow colonies (Fig. 6A.5.2A). *V. cholerae* appear as medium to large (2- to 5-mm in diameter) flat, translucent colonies on TTGA (Fig. 6A.5.2B). There will be a zone of clearing (or halo) surrounding *V. cholerae* colonies due to hydrolysis of gelatin. A dark center usually develops after 24 hr. All strains of *V. cholerae* can exhibit various colony morphologies, including a rugose form (White, 1940). The strain in Figure 6A.5.2A exhibits two colony morphologies, translucent and opaque. For the sake of comparison, several different positive-control *V. cholerae* strains should be subcultured at the time of subculturing from APW to selective medium. The selective media TCBS and TTGA still allow the growth of other *Vibrio* species and related bacteria. For example, *V. parahaemolyticus* will appear as blue-green colonies, *V. mimicus* will appear as green colonies, and *V. alginolyticus* as larger, yellow colonies on TCBS. Therefore, colonies growing on these media are not necessarily all *V. cholerae* and are labeled "presumptive." The goal of each step in the biochemical identification method is to reduce the number of suspected or presumptive colonies, which will include other *Vibrio* species and related *Vibrionaceae*, until

Table 6A.5.5 Troubleshooting Guide for *V. cholerae* Isolation and Detection

Problem	Solution
Basic Protocol 1	
Little or no plankton in cod-end collecting bucket	Check pore size of plankton net and ensure that it is 64 μm
	Zooplankton should be sampled near dawn or dusk (1-2 hr after sunrise or before sunset) when they are nearer to the surface
	Filter more water through plankton net
Basic Protocol 2	
Failure of positive control to give correct results for biochemical tests	Use multiple positive controls
	Prepare multiple replicates for each positive control
Results of biochemical tests difficult to interpret	Ensure proper incubation temperature and time
	Tests giving variable or weakly positive result should be replicated
	For decarboxylase tests, ensure that a tube without amino acid is used, to demonstrate growth with negative result
	For esculin hydrolysis, use presence/loss of fluorescence as measure of negative/positive
Basic Protocol 3	
Autoagglutination or clumping in saline without antisera	"Rough" morphotypes cannot be serogrouped with anitsera; use O1/O139 *rfb* PCR primers with Basic Protocol 4 to test for toxigenic serogroups
Basic Protocol 4	
No PCR product with positive control	Ensure all components are added to reaction at the proper concentration
	Use fresh dNTPs
	Prepare fresh crude template of positive control as it will degrade over time
	Dilute crude template 1:5000 or more and repeat the control reaction
	Quantify crude template by gel electrophoresis (~10 μl) to ensure sufficient template concentration
PCR product with negative control	Most likely caused by carryover contamination in one of the reaction components; make new components
Basic Protocol 5	
No PCR product with positive control	Ensure all components are added to reaction at the proper concentration
	Use fresh dNTPs
PCR product with negative control	Most likely caused by carryover contamination in one of the reaction components; make new components
Alternate Protocol 1	
No PCR product with positive control	Ensure all components are added to reaction at the proper concentration
	Use fresh dNTPs
PCR product with negative control	Most likely caused by carryover contamination in one of the reaction components; make new components

Continued

Table 6A.5.5 Troubleshooting Guide for *V. cholerae* Isolation and Detection, *Contined*

Problem	Solution
Basic Protocol 6	
Positive control is negative	Ensure solutions used are RNase-free
	Increase incubation time of lysis step, especially if colonies are >3 mm
	Ensure that the correct microscope filter is used for fluorochrome selected (other fluorochromes may be used)
Positive control gives weak signal	Check scanning settings on detection instrument Increase probe concentration and/or hybridization time
Alternate Protocol 2	
Positive control is negative or weak	Ensure that solutions are used in correct order
	Overexposure to UV source will degrade DNA template; consider using positively charged nylon membranes, which do not need cross-linking
	Extend hybridization time
	Extend development time
Positive control is overdeveloped or background is high	Check hybridization temperature
	Do not allow membrane to dry
	Decrease development time
Support Protocol	
Positive control from Alternate Protocol 2 is negative or weak	Check efficiency of probe labeling reaction
	Increase probe concentration (>25 ng/ml)
Basic Protocol 7	
Positive control is negative	Ensure that the proper filter set is used on fluorescent microscope
	Bengal DFA (*V. cholerae* O139) kit positive control is sometimes poor; prepare positive control from laboratory reference strain
Basic Protocol 8	
Positive control signal is weak	Increase amount of *V. cholerae* O1 antiserum and FITC conjugate

eventually only confirmed colonies of *V. cholerae* remain. Table 6A.5.3 lists the expected results of the above prescribed biochemical tests. See Bergey et al. (1994) or Lennette et al. (1985) for more details on each of these tests. Again, it is important to include several positive controls in the biochemical test screening for comparison.

Also, the biochemical confirmation may be shortened as in the alternative "b" and "c" steps of Basic Protocol 2. Figure 6A.5.5 shows the typical reaction of *V. cholerae* on a KIA slant. Most strains of *V. cholerae* isolated from the environment will be non-O1, non-O139, and *ctxA*$^-$, so serotyping usually yields few positive colonies. For O1-positive samples, the O1 serogroup can be further classified into two biotypes, namely Classical (CL) and El Tor (ET). The two biotypes are distinguished from each other on the basis of their differences in several phenotypic properties (WHO, 1987), including hemolysis (sheep red blood cells; CL^-, $ET^{+/-}$), hemagglutination (chicken red blood cell; CL^-, ET^+; Finkelstein and Mukerjee, 1963), Voges-Proskauer reaction (CL^-, ET^+), susceptibility to polymyxin B (CL^+, ET^-; Han and Khie, 1963), and sensitivity to biotype-specific phages (Nair et al., 2002). More recent studies have identified genes unique to the classical and seventh pandemic El Tor strains.

Figure 6A.5.3 shows a gel separation of the expected amplicons for several of the PCR protocols listed in the sections above. Table 6A.5.4 lists the amplicon size for all of the PCR primers mentioned in this chapter. This is not

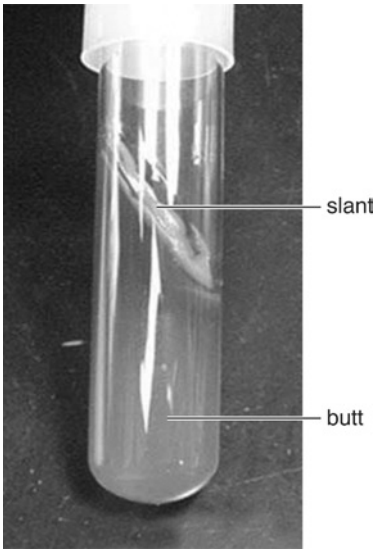

Figure 6A.5.5 Growth of *V. cholerae* in a Kligler iron agar (KIA) slant. Notice the alkaline butt and acid slant, with no gas production or blackening due to hydrogen sulfide production. For the color version of this figure go to *http://www.currentprotocols.com*.

a complete listing of all PCR primers that have been designed for *V. cholerae*-specific targets. Some thought should be given to using PCR identification protocols in lieu of biochemical tests, as PCR screening will provide a definitive answer in a shorter time period.

Figure 6A.5.4 shows the typical results of *V. cholerae* with DFA (Fig. 6A.5.4A,B) and DVC-DFA (Fig. 6A.5.4C,D). DFA-stained cells of *V. cholerae* appear as having a brightly green-fluorescing periphery with a slightly dimmer interior. Fresh, vegetative cells of *V. cholerae* have a distinctive curved-rod, or vibroid shape (Fig 6A.5.4A). VBNC cells of *V. cholerae* appear as rounded, or coccoid cells, which are harder to identify than vegetative cells (Fig 6A.5.4B). The coupling of the DVC procedure (Kogure et al., 1979) with DFA staining can alleviate the difficulty in distinguishing *V. cholerae* cells from autofluorescing objects present in water samples.

Time Considerations

One important parameter to consider in screening for *V. cholerae* is how rapidly an answer is needed. For routine monitoring of environmental water sources, time is usually not as critical as in clinical cases. In clinical settings, a rapid diagnosis is critical prior to initiating antibiotic treatment and oral rehydration. Many clinical laboratories and/or hospitals employ some form of the conventional culture-based method. If the method is followed as prescribed in Basic Protocol 2, the total time before confirmation may be up to 7 days. PCR screening can be performed in a significantly shorter period of time, 6 to 24 hr, depending on the template. DFA can also be completed in a shorter period of time, 4 hr, or 24 hr if coupled with DVC. Confirmation by colony blot hybridization can be performed in 3 days. It is important to balance time considerations with costs, as environmental water screening usually involves numerous sites and frequent sampling.

Isolation and Classification of *Bdellovibrio* and Like Organisms

Bdellovibrio and like organisms (BALOs) are commonly retrieved from natural and man-made habitats. As they are obligate predators of other Gram-negative bacteria, they should be cultivated with prey cells in two-member cultures. Their growth cycle includes two spatially separated phases: a free-swimming attack phase and an intracellular phase during which the predatory bacterium establishes, elongates, and grows within the periplasm of its host at the expense of the latter's cell content. BALO-infected prey are called bdelloplasts. Isolation from environmental samples requires separation of the small BALOs from the majority of the other bacteria to ensure that plaques are not overgrown by contaminants.

This unit describes ways to isolate BALOs from the environment (see Basic Protocol 1 and Alternate Protocols 1 to 3), store BALOs (see Basic Protocol 2), obtain host-independent derivatives (see Basic Protocol 3), synchronize BALOS (see Basic Protocols 4 and 5), separate the various phases of growth (see Basic Protocol 6), and classify BALOs (see Basic Protocol 7). BALOs are isolated in double-layered agar plates as plaques growing in top agar containing prey cells. When found at very low levels, samples containing BALOs can be enriched by incubation with potential prey prior to isolation. Host-independent (HI) mutants are readily isolated from wild-type BALOs grown in pure and dense cultures, and are grown in rich medium. The different phases of the growth cycle of both wild-type BALOs and HI mutants can be separated to obtain defined fractions. Moreover, wild-type as well as HI-mutant cultures can be synchronized to obtain a majority of cells at the same stage of the growth cycle. Classification is based on the analysis of the 16S rRNA gene with the support of specific primers.

CAUTION: Bdellovibrio and like organisms are Biosafety Level 1 (BSL-1) microbes. Such organisms are not known to consistently cause disease in healthy adult humans, and are of minimal potential hazard to laboratory personnel and the environment. Standard microbiological practices should be followed when working with these organisms. Prey cells are selected by the experimenter and may therefore vary in biosafety level(s). This should be checked prior to starting work. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

IMPORTANT NOTE: When it is important to remove prey cells from a BALO culture (i.e., DNA, RNA, or protein analysis), lytic suspensions should be passed through a 0.45-μm filter at least once. Also, filtration may have to be performed to remove contaminants carried over during the isolation of BALOs.

IMPORTANT NOTE: When working with bacteria-domain-directed primers, exercise extra care to prevent contamination of PCR reagents.

ISOLATION OF BALOS FROM ENVIRONMENTAL SAMPLES BY DIFFERENTIAL CENTRIFUGATION AND FILTRATION

BASIC PROTOCOL 1

BALO cells are small (0.25 to 0.5 × 0.75 to 1.25 μm); therefore, they can be separated from the major fraction of the bacterial population. This is achieved using differential centrifugation and filtration.

Contributed by Edouard Jurkevitch

Current Protocols in Microbiology (2005) 7B.1.1-7B.1.17

Materials

Soil or water sample suspected of containing BALOs
H_2O, sterile (for soil samples)
HM buffer, 4°C (see recipe)
Potential prey (Support Protocol)
HM top agar, molten (see recipe)
HM plates (see recipe)

1.2-μm Nucleopore filter
28°C incubator
0.45-μm syringe filters (Supor Acrodisc, Pall Corp.; Minisart, Sartorius)

1a. *For soil or rhizosphere samples:* Prepare a slurry containing 10 to 50 g soil using a 1:2 to 1:10 soil/sterile water ratio according to soil texture (i.e., less for heavy clay soils and more for light sandy soils). Shake 30 min at room temperature using a platform shaker at 150 rpm or an orbital shaker at 200 to 250 rpm.

1b. *For aquatic samples:* Collect 50 to 250 ml sample.

2. Centrifuge 5 min at 500 × *g*, 4°C. Discard the pellet.

3. Centrifuge supernatant 20 min at 27,000 × *g*, 4°C. Decant supernatant and dissolve resulting pellet in a few milliliters of cold HM buffer.

HM buffer is used in place of a richer medium to limit the growth of prey or potential environmental contaminants. This is especially important when isolating BALOs from the environment.

4. Pass through a 1.2-μm Nucleopore filter. Maintain at 4°C (up to a few days); process as soon as possible.

If a high level of contaminants (carried over from isolation) grow on the HM top agar, blurring the BALO plaques, an extra filtration through a 0.45-μm filter may be necessary. Such a step may, however, further reduce the yield of BALOs.

To deal with clogged filters, see Alternate Protocol 1 and the Troubleshooting section.

5. Prepare 10-fold serial dilutions of the filtrate in HM buffer, room temperature, at a final volume of 5 ml.

For most environments, useful dilutions range from 10^0 to 10^{-4}.

6. Prepare top-agar infusions in the following manner.

   a. Add 250 to 300 μl (5×10^9 to 10^{10} cfu/ml) suspension of potential prey to test tubes containing 4 ml molten HM top agar.
   b. Vortex quickly.
   c. Add 100 μl filtrate dilution.
   d. Vortex and quickly pour onto an HM plate.
   e. Repeat for each dilution until all dilutions have been plated.

Two to three replicate plates should be made per dilution.

7. Allow top agar to solidify at room temperature (~60 min). Seal each plate with Parafilm.

8. Incubate sealed plates upside-down for 3 to 8 days at 28°C. Check for the growth of regular lytic plaques on the background of the prey lawn.

Plaques may vary in size from one to a few millimeters in diameter.

9. Cut 1-ml pipettor tips with a sterile scalpel. Gently aspirate plaques into the tip. Resuspend individual plaques in 0.5 ml HM buffer, room temperature. Let stand for a few minutes, then vortex.
10. Place a drop of the suspension on a clean glass slide and cover with a cover slip. Check for minute, fast moving cells using phase-contrast microscopy.
11. Pass through a 0.45-μm syringe filter. Maintain at 4°C; process as soon as possible.
12. Repeat steps 5 to 11 twice more to obtain pure cultures.
13. Grow and store as described in Basic Protocol 2.

ISOLATION OF BALOS USING A FICOLL GRADIENT

ALTERNATE PROTOCOL 1

This method more efficiently recovers BALOs while preventing filter plugging with soil colloidal material such as clay. It is, however, more expensive.

Additional Materials *(also see Basic Protocol 1)*

15% (w/v) Ficoll in HM buffer (see recipe): store up to 1 day at 4°C
1.5 × 9.5–cm centrifugation tubes
Gradient maker or peristaltic pump
Tabletop centrifuge with swinging-bucket rotor

1. Prepare sample as in Basic Protocol 1, steps 1 to 3.
2. Prepare 14 ml of a 15% to 1% continuous Ficoll gradient in 1.5 × 9.5−cm centrifugation tubes using a gradient maker or peristaltic pump. Gently pipet the concentrated sample on top of the Ficoll gradient.

   If one does not have access to a gradient maker, it is possible to construct a cushion by layering four 3.25-ml phases (1%, 5%, 10%, and 15%) of Ficoll one on top of the other.
3. Centrifuge in a swinging bucket rotor 20 min at 1,620 × *g*, 4°C, with brakes set at minimum.
4. Retrieve the upper 3 ml.
5. Prepare serial dilutions and plate as in Basic Protocol 1, steps 5 to 13.

ISOLATION OF BALOS FROM THE MARINE ENVIRONMENT

ALTERNATE PROTOCOL 2

Marine BALOs have specific ionic requirements. Consequently, the media used for their isolation should be adapted to this environment. *Vibrio parahaemolyticus* is an effective prey for the recovery of marine BALOs.

Additional Materials *(also see Basic Protocol 1)*

SWYE plates (see recipe)
Vibrio parahaemolyticus P-5 (Sheffield and Williams, 1990)
Sterile ocean water (see recipe)
Polypeptone 20 (Pp) medium (see recipe)
Pp top agar, molten (see recipe)
Pp plates (see recipe)
28° and 25°C incubators

1. To SWYE plates, add 100 μl *V. parahaemolyticus* P-5 and spread evenly to distribute. Incubate 24 to 48 hr at 28°C.
2. Flood the plate with 7 ml sterile ocean water. Resuspend colonies using a sterile cell spreader.

3. Adjust the suspension to $\sim 10^9$ cells/ml (OD_{600} of 0.85).
4. If needed, concentrate by centrifuging 30 min at 10,000 × *g*, 4°C. Resuspend in an appropriate volume of Pp medium.
5. Prepare 10-fold serial dilutions of the sample in ocean water at a final volume of 10 ml in the range of 10^0 to 10^{-4}.
6. Prepare top agar infusions in the following manner.
   a. Add 1 ml prey suspension to 3.3 ml molten Pp top agar.
   b. Vortex and add 5 ml diluted sample.
   c. Vortex and quickly pour onto a Pp plate.
   d. Repeat in triplicate or duplicate for each dilution.
7. Allow top agar to solidify at room temperature (<60 min). Wrap plates in Parafilm.
8. Incubate at 25°C for at least one week.
9. Check for the growth of regular lytic plaques on the background of the prey lawn (up to 8 days). When apparent, treat plaques as in the Basic Protocol 1, steps 9 to 13, substituting Pp medium for HM buffer.

ALTERNATE PROTOCOL 3

ENRICHMENT FOR BALOS IN ENVIRONMENTAL SAMPLES

Whenever quantification is not needed and BALOs are found at very low levels, an enrichment procedure can be applied. See Basic Protocol 1 for materials.

1. Perform step 1a or 1b of Basic Protocol 1. Add potential prey to the soil slurry or aquatic sample to a final concentration of 10^{10} cells/ml. Shake 24 to 48 hr at 28°C on an orbital shaker at 200 rpm.
2. Examine samples daily for 2 to 4 days for reduction in optical density and by phase-contrast microscopy for the presence of small, highly motile cells. If no such cells are seen, prolong the incubation (up to 2 weeks).

   Alternatively, transfer a 1-ml aliquot to 30 to 50 ml of a fresh suspension of 10^8 to 10^9 cells/ml potential prey and incubate an additional 24 to 48 hr.
3. After detection of putative BALOs, treat as described in Basic Protocol 1, steps 2 to 13.

   As enriched suspension contains many BALOs, it is recommended to perform a 0.45-μm filtration step as described. This greatly reduces carried-over contaminants.

BASIC PROTOCOL 2

GROWTH AND STORAGE OF PURE BALO CULTURES

Pure cultures can be cryopreserved; however, BALO strains need to first be cultured in liquid medium.

Materials

Pure culture of BALO in double-layered agar plate (Basic Protocol 1 and Alternate Protocols 1 to 3)
Diluted nutrient broth (DNB; see recipe)
Potential prey (Support Protocol; optional)
80% glycerol, sterile
28°C incubator

1. Cut 1-ml pipettor tips with a sterile scalpel. Gently aspirate a BALO plaque from a double-layered agar plate, including some surrounding agar containing prey. Transfer to a 125-ml Erlenmeyer flask containing 5 ml DNB.

2. *Optional:* Add potential prey to a final concentration of 5×10^9 cfu/ml.

   It is recommended that this step be performed with slower growing prey.

3. Shake on an orbital shaker at 250 rpm 24 to 48 hr, 28°C.

   Suspensions should be clear or almost clear.

4. Check for BALOs by phase-contrast microcopy.

5. Concentrate by centrifuging 10 min at 10,000 × *g*, 4°C. Resuspend in 3 ml fresh DNB. Add 80% glycerol to a final concentration of 20% (v/v).

6. Transfer to appropriate tubes. Quick freeze in liquid nitrogen and store at −80°C, up to 3 to 4 years.

7. If storage of a larger volume is desired, increase culture volume by transferring a fresh BALO inoculum (1:100 to 1:50 of the final volume) in DNB containing prey as above.

ISOLATION AND CULTURE OF HOST-INDEPENDENT MUTANTS

BASIC PROTOCOL 3

Bdellovibrio and like organisms are obligate parasites and as such are retrieved from the environment using prey. However, host-independent (HI) mutants able to grow saprophytically in rich medium appear spontaneously and can be recovered at frequencies of 10^{-5} to 10^{-8}. These HI derivatives exhibit the various stages of wild-type growth, including attack phase, as well as elongating and fragmenting the cell, thereby mimicking the wild-type-cell growth cycle. The absence of prey can be advantageous in molecular analysis.

Note that HI strains lose their predatory behavior when repetitively grown in the absence of prey and also are pleiotropic. HI strains vary in growth rates and other phenotypic characteristics.

Materials

Wild-type, host-dependent BALO strain
Streptomycin-resistant (Sm^r) and -sensitive (Sm^s) prey (Support Protocol)
50 mg/ml streptomycin
Dilute nutrient broth (DNB; see recipe) with and without 50 μg/ml streptomycin
PYE medium (see recipe) containing 50 μg/ml streptomycin
PYE plates with and without host extract (see recipe)
HM buffer (see recipe; optional)
Glycerol, sterile
28°C incubator
0.45-μm syringe filter (Supor Acrodisc, Pall Corp.; Minisart, Sartorius)
Additional reagents and equipment for preparing double-layered HM plates (see Basic Protocol 1; optional)

1. Grow wild-type, host-dependent BALO strain on Sm^r prey (10^9 cells/ml) 24 hr at 28°C. Add 50 mg/ml streptomycin to a final concentration of 50 μg/ml. Incubate an additional 12 hr at 28°C for a total of 36 hr.

   Streptomycin is used to select for Sm^R BALOs.

2. Inoculate 20 ml DNB containing 10^9 cells/ml Sm^r prey and 50 μg/ml streptomycin with the 36-hr culture to a final concentration of 15% (v/v). Incubate at 28°C until the prey is consumed (∼2 hr).

3. Separate the lysate from the antibiotic by centrifuging 5 min at 10,000 × *g*, 4°C. Resuspend pellet containing BALOs in 2 ml DNB and pass through a 0.45-μm syringe filter.

4. Inoculate 50 ml of DNB containing 10^9 to 10^{10} cells/ml Sm^s prey with 1 ml filtrate. Incubate 18 to 24 hr at 28°C.

   The Sm^s prey must be the same strain as the Sm^r prey.

5. Transfer 5 to 10 ml of the resulting lytic culture to PYE medium containing 50 μg/ml streptomycin. Incubate at 28°C until growth of HI cells is apparent (3 to 7 days).

   A large inoculum of a dense BALO suspension assumes that HI mutants will appear. Streptomycin is used to contra select against remaining prey cells.

6. Plate onto PYE plates and incubate up to 7 days at 30°C. If desired, supplement plates with 7% (v/v) host extract to enhance growth.

   HI cultures develop as colonies. Pick larger colonies because tiny ones fail to grow.

7. Streak onto a PYE plate. Incubate at 28°C until colonies develop (up to 3 to 5 days). Repeat this step twice to obtain pure cultures.

8. *Optional:* To retain predatory efficiency in HI mutants, plate HI strains in double-layered HM plates (e.g., Basic Protocol 1, steps 6 to 10) or grow in HM buffer. Include Sm^s prey every second or third transfer.

   Do not subculture HI strains too many times. Start from stock after ∼3 passages.

9. To store, grow an HI colony in 15 ml liquid PYE medium. Centrifuge 5 min at 10,000 × *g*, 4°C. Resuspend in 2 ml PYE. Add glycerol to 20% (v/v) and store at −80°C.

   It is recommended to renew the culture every year.

10. To revive an HI culture, thaw and spread 100 μl on a PYE plate supplemented with 7% (v/v) host extract.

BASIC PROTOCOL 4

SYNCHRONOUS GROWTH OF WILD-TYPE BALOS

In order to study events occurring at the various stages of the growth cycle, it can be advantageous to obtain cultures in which all prey cells are infected simultaneously and the growth cycle of the predator is synchronous. This is achieved by using a surplus of predatory over prey cells, assuring concomitant infection of most prey cells.

Materials

Prey (Support Protocol)
HM buffer (see recipe), 4°C
Pure BALOs (Basic Protocol 1 or Alternate Protocols 1 to 3)
0.45-μm syringe filter (Supor Acrodisc; Pall Corp.; Minisort, Sartorius)
28°C incubator

1. Grow 50 ml prey cells to the end of exponential or early stationary phase.

2. Centrifuge 10 min at 5,000 × *g*, 4°C. Decant the supernatant and add 5 vol cold HM buffer. Repeat centrifugation and resuspend in cold HM buffer such that the final concentration is at least 5 × 10^9 cells/ml.

3. Prepare a fresh 100-ml lytic culture of BALOs on the same prey.

4. Centrifuge the BALO culture 20 min at 10,000 × *g*, 4°C. Decant the supernatant and add 5 vol cold HM buffer. Repeat centrifugation and resuspend in cold HM buffer such that the final concentration is at least 2 × 10^{10} cells/ml.

5. Check the culture by phase-contrast microscopy.

   Bdelloplasts and prey cells should be almost absent from the culture.

6. If needed, pass the BALO culture through a 0.45-μm syringe filter.

   Be aware that this may reduce the yield of attack phase cells.

7. Combine predator (step 6) and prey (step 2) at a ratio of 2:1, at final concentrations of 10^{10} and 5×10^9 cell/ml, respectively.

8. Incubate with strong shaking (~250 rpm) at 28°C.

   Prey cells are penetrated within 30 min and a full cycle completed within 2.5 to 4 hr, depending on the strains and conditions. After the first cycle, the prey culture is essentially consumed and no prey cells remain to start a second cycle.

SYNCHRONOUS GROWTH OF HOST-INDEPENDENT BALOS

BASIC PROTOCOL 5

Asynchronous host-independent (HI) cultures contain a mixture of cells found at the various stages of growth. In synchronous cultures, which are obtained by subculturing a dense suspension of HI cells, most cells are found at the same stage.

Materials

Host-independent (HI) mutant (Basic Protocol 3)
PYE medium with 7% (v/v) host extract (see recipe)
28°C incubator

1. Grow HI mutant in PYE medium with host extract at 28°C overnight.
2. Centrifuge 10 min at 10,000 × *g*, 4°C.
3. Resuspend in fresh PYE supplemented with 7% (v/v) host cell adjusted to 5 mg protein/ml to obtain a final volume 10× larger that of the overnight culture (step 1).
4. Grow at 28°C and check for culture homogeneity according to needs by phase-contrast microscopy.

   Synchrony is maintained until stationary phase (~8 to 12 hr).

   Growth can be tracked by spectrophotometry (OD_{600}).

SEPARATION OF GROWTH PHASES

BASIC PROTOCOL 6

The various growth phases—i.e., free swimming attack cells, bdelloplasts containing intraperiplasmic elongating, replicating predatory cells, and empty prey remains—can be separated to allow stage-specific analysis.

Materials

Synchronous BALO culture (Basic Protocols 4 and 5)
0.05 M potassium phosphate buffer, pH 7.2 (*APPENDIX 2A*)
Percoll
0.25 M sucrose (85.5 g/liter)
14.5 mM NaCl

70-ml ultracentrifuge tube
Sorvall Centricon T-1170 ultracentrifuge and A-641 rotor (or equivalent)

1. Centrifuge a 100-ml synchronous BALO culture 10 min at 20,000 × *g*, 4°C. Wash with 5 to 10 ml of 0.05 M potassium phosphate buffer and resuspend in a few milliliters of the same.

2. Mix five parts Percoll with four parts 0.25 M sucrose. Transfer 66 ml into a 70-ml ultracentrifuge tube.
3. Layer BALOs onto the top of the Percoll-filled tube and ultracentrifuge 30 min at 50,000 × *g*, 4°C.
4. Using gentle pipetting, first remove the floating fluffy white material, then harvest prey cell remains or bdelloplasts (depending on the growth stage) from a ring at the top of the tube.

   The floating fluffy white material is composed of a mixture of growth stages.

5. Harvest the attack phase cells from an opaque band located 1.5 cm from the bottom of the tube, also using gentle pipetting.
6. To remove Percoll, wash the retrieved fractions by diluting in 5 vol of 14.5 mM NaCl. Centrifuge 10 min at 20,000 × *g*, 4°C.
7. Resuspend in a solution appropriate for further work, such as the extraction of cellular constituents.

SUPPORT PROTOCOL

PREY PREPARATION

Prey organisms should be prepared ahead of working with BALOs. In order to accomplish this, first grow potential Gram-negative prey in an appropriate medium (e.g., see *APPENDIX 2C*). Collect cells at the end of exponential to early stationary phase. Centrifuge 10 min at 5,000 × *g*, 4°C. Wash once with HM buffer. Resuspend in HM buffer (see recipe) to a final concentration of $5 \times 10^9$to 10^{10} cfu/ml. For routine growth, prey stock can be used 10 to 14 days if kept at 4°C. The most commonly used prey include *E. coli* ML35 and various strains of *Pseudomonas fluorescens* and *P. putida*.

BASIC PROTOCOL 7

CLASSIFICATION OF BALOS

The classification of BALOs is based on the analysis of the 16S rRNA gene. BALOs belong to two recognized families, Bdellovibrionaceae and Bacteriovoracaceae, forming the order Bdellovibrionales within the δ-Proteobacteria. *Bdellovibrio bacteriovorus* is the only recognized species within the Bdellovibrionaceae, while *Bacteriovorax stolpii, Bacteriovorax marinus, Bacteriovorax littoralis*, and *Peridibacter starrii* belong to the Bacteriovoracaceae. The G+C content of the Bdellovibrionaceae is ∼50%, and that of the Bacteriovoracaceae is between 37% to 44%. Amplified rDNA restriction analysis (ARDRA) of an ∼800-bp fragment enables a first classification of BALOs. Precise phylogenetic affiliation is performed using the (almost) whole 16S rRNA gene sequence length.

Materials

BALO suspension to be analyzed
H_2O, sterile
Dimethyl sulfoxide (DMSO)
3 M $MgCl_2$
2 mM dNTPs (*APPENDIX 2A*): dATP, dCTP, dGTP, and dTTP
1× PCR reaction buffer: 500 mM KCl/100 mM Tris·Cl, pH 9 (*APPENDIX 2A*)/1% (v/v) Triton X-100
Taq DNA polymerase
Primers (Table 7B.1.1)
BSA
1% agarose gel TAE (*APPENDIX 2A*)
Ethidium bromide staining solution (*APPENDIX 2A*)
*Hae*III, *Hin*fI, and *Rsa*I restriction endonucleases and appropriate buffers

Table 7B.1.1 Primers Utilized for Classification of BALOs[a]

Primer	Sequence
BALO-targeted primer 842R	5′-CGWCACTGAAGGGGTCAA- 3′
Bacteria domain targeted primer 63F	5′-CAGGCCTAACACATGCAAGTC-3′
Bacteria domain targeted primer 907R	5′-CCCCGTCAATTCCTTTGAGTTT-3′

[a]Any general Bacteria (i.e., Eubacteria or Archaea) domain targeted primer near the 3′ end can be utilized.

NuSieve GTG agarose (FMC)
*Eco*RI restriction endonuclease and appropriate buffer (for groups C and D only; Table 7B.1.2 and Figure 7B.1.1)
0.45-μm filter (Supor Acrodisc, Pall Corp.; Minisort, Sartorius)
80°C water bath (optional)
Additional reagents and equipment for purification of DNA (Moore and Downhan, 2002) and agarose gel electrophoresis (Voytas, 2000)

Template preparation and PCR amplification

1. Pass the BALO suspension to be analyzed through a 0.45-μm syringe filter. Centrifuge 10 min at 10,000 × *g*, 4°C. Resuspend in sterile water at 1/10 the original volume.
2. Extract DNA according to a standard protocol (e.g., Moore and Downhan, 2002) or immerse in liquid nitrogen then in hot (80°C) water for 3 min, repeating twice.
3. Cool on ice, then add DMSO to a final concentration of 10% (v/v).

   CAUTION: DMSO is hazardous. See UNIT 1A.3 for guidelines on handling, storage, and disposal.
4. Prepare a PCR mix using the following recipe per each 50 μl:

   3 mM $MgCl_2$
   20 μM (each) dNTPs
   1× PCR reaction buffer
   1.25 U *Taq* DNA polymerase
   1 μM each 63F and 842R primer
   12.5 μg BSA
5. Amplify using the following program:

Initial step:	4 min	94°C	(denaturation)
35 cycles:	1 min	94°C	(denaturation)
	1 min	50°C	(annealing)
	1 min	72°C	(extension)
Final step:	5 min	72°C	(extension).

6. Verify the presence of a PCR product by running 5 μl on a 1% agarose gel in TAE (Voytas, 2000). Stain with ethidium bromide staining solution and visualize using shortwave UV light.

   The final product should be ~800 bp.

   If no amplification product is obtained, repeat the procedure (steps 1 to 6), filtering and washing BALO suspensions twice in step 1 and using general primer 907R instead of primer 842R in step 4.

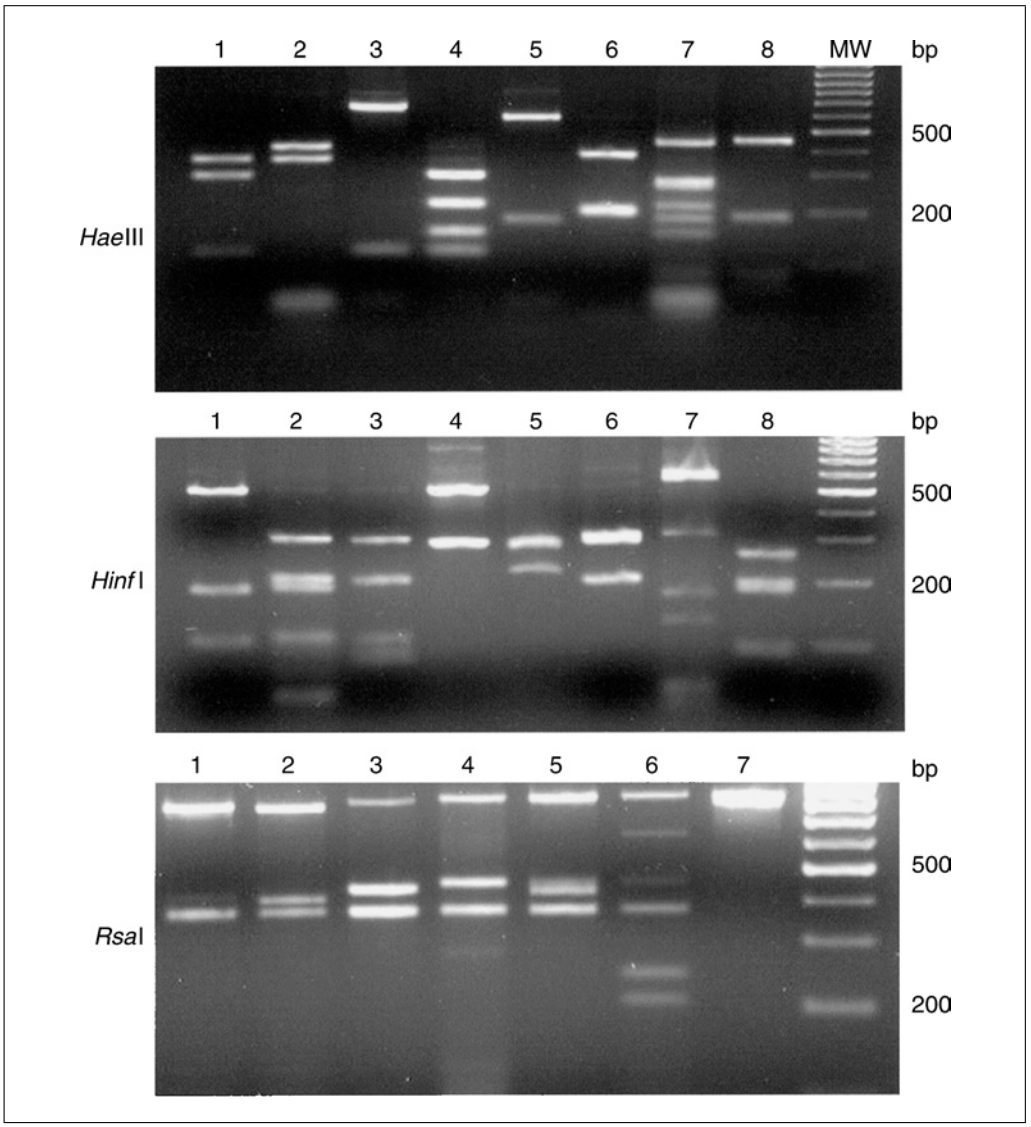

Figure 7B.1.1 Restriction patterns of amplified 16S rRNA gene fragments of *Bdellovibrio* and like organisms after digestion with *Hae*III, *Hin*fI, and *Rsa*I. Lane designated "MW" was loaded with a 100-bp molecular marker. The combination of the patterns defines the different ARDRA groups. (Reproduced with permission from Davidov and Jurkevitch, 2004).

ARDRA

7. Purify amplification products by standard techniques (e.g., Moore and Downhan, 2002).

8. Prepare separate restriction digestions according to manufacturers' protocols utilizing *Hae*III, *Hin*fI, or *Rsa*I, and ~15 µl PCR product.

   See Bloch and Grossman (1995) for general information about performing restriction digestion analysis.

9. Separate for 1 hr at 80 V in a 3% NuSieve GTG agarose gel (or equivalent) using TAE as the running buffer (Voytas, 2000). Stain the gel using 0.5 µg/ml ethidium bromide and make a record of the gel as visualized using short-wavelength UV light.

10. Compare restriction patterns to Figure 7B.1.1, find the corresponding group in Table 7B.1.2, and the phylogenetic affiliation in Figure 7B.1.2.

11. If required (i.e., organism belongs to Group C or D; Table 7B.1.2), prepare a new restriction digestion utilizing *Eco*RI to enhance resolution.

Table 7B.1.2 Patterns Obtained by ARDRA of *Bdellovibrio* and Like Organisms[a]

Group	ARDRA banding pattern[b]		
	*Hae*III	*Hin*fI	*Rsa*I
A	1	1	1
B	1	3	2
C[c]	2	2	1
D[c]	2	2	1
E	10[d]	1	1
F	3	1	1
G	1	2	2
H	1	1	2
I	9[d]	9[d]	1
J	4	4	1
K	5	5	3
L	5	5	7
M	6	6	4
N	6	6	5
O	6	6	6
P[e]	7	7	2
Q[f]	11[d]	10[d]	8[d]
R[f]	12[d]	6	9[d]
S[f]	13[d]	6	10[d]
T[f]	6	6	11[d]
U[e]	8	8	7

[a]Also see Figures 7B.1.1 and 7B.1.2.

[b]Numbers in columns relate to the lanes in Figure 7B.1.1. For example, an organism from group J would be expected to demonstrate the banding pattern shown in lane 4 when digested with *Hae*III (top panel), lane 4 when digested with *Hin*fI (middle panel), and lane 1 when digested with *Rsa*I (bottom panel).

[c]Distinguishable by restriction with *Eco*RI (for patterns, see Jurkevitch *et al*., 2000).

[d]Lanes not shown in Fig. 7B.1.1.

[e]Amplicon obtained using primer 907R instead of 842R. (Davidov and Jurkevitch, 2004, by permission).

[f]Groups Q, R, S, and T are based on in silico digestions with sequences retrieved from the GenBank.

Full gene length amplification

12. Repeat steps 1 to 5 but filtering the BALO suspension twice in step 1 and utilizing primers spanning the (whole) 16S rRNA gene in step 4.

For an example, see Marchesi et al. (1998).

Representatives from each ARDRA group can be sequenced. With this information, more precise taxonomical placement can be achieved.

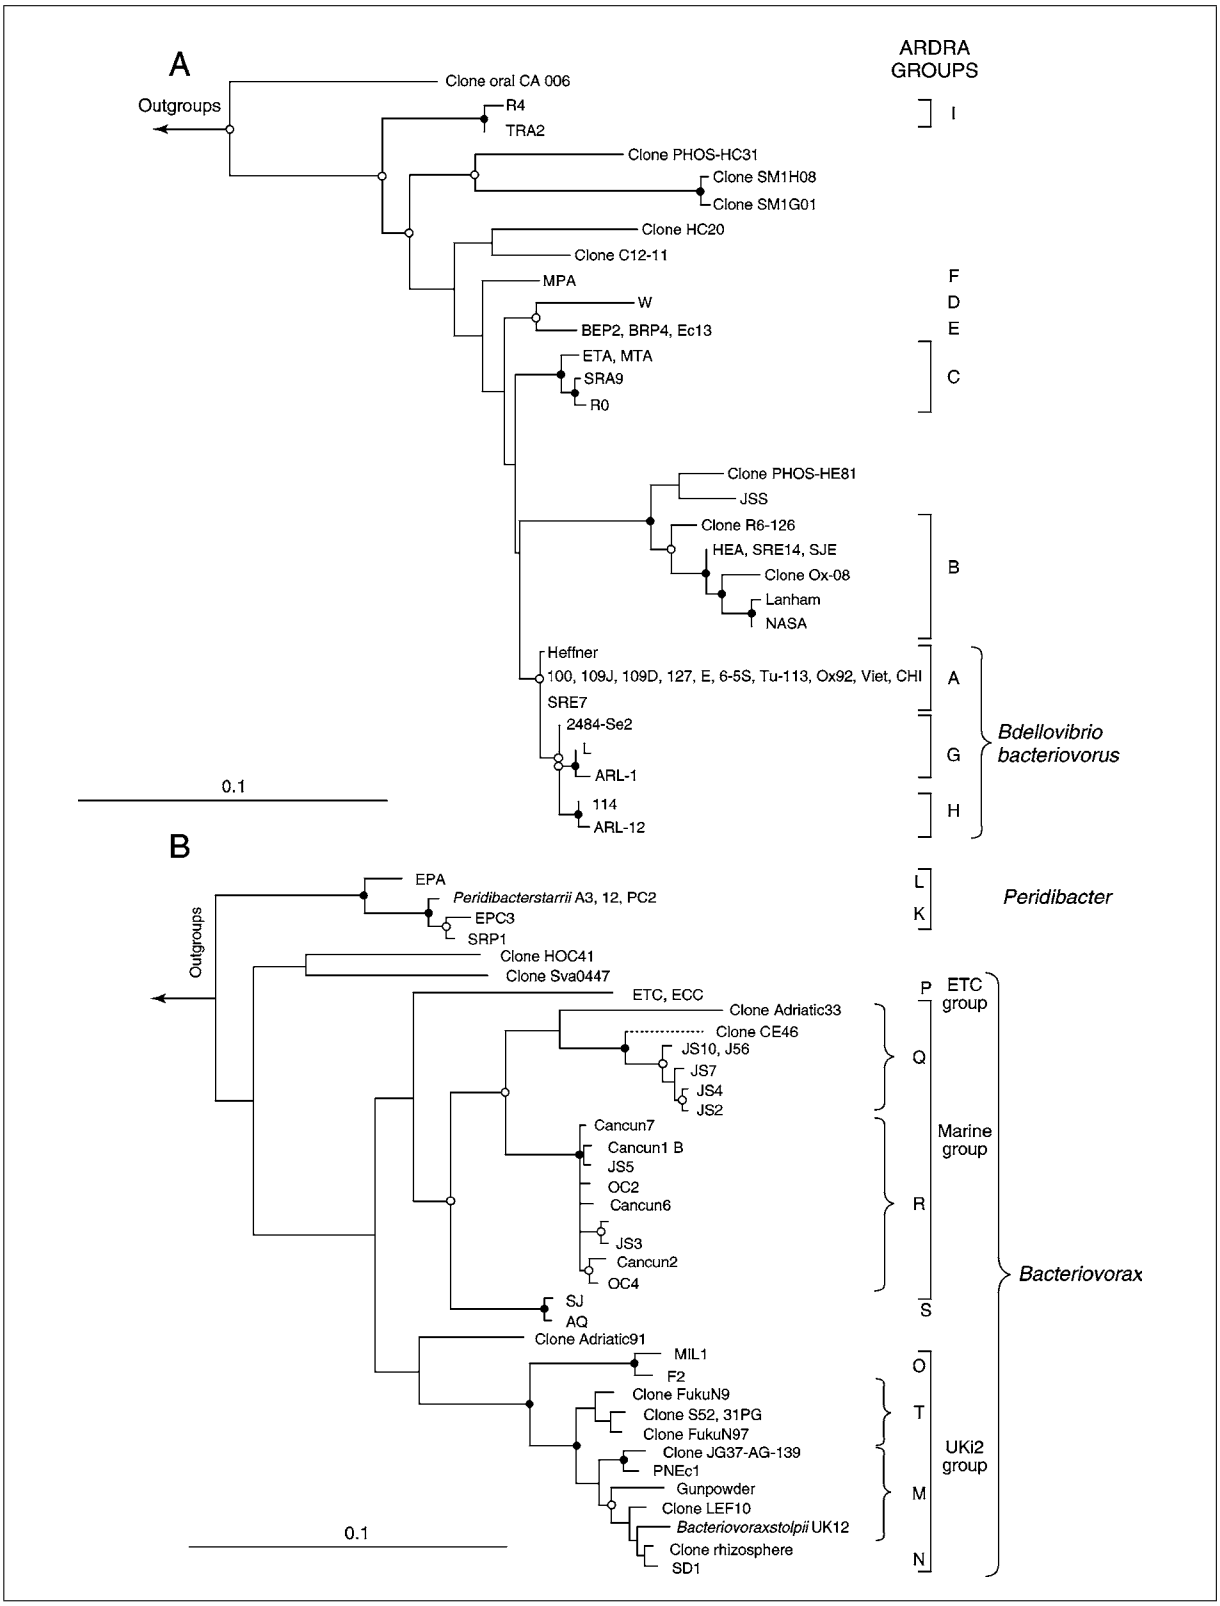

Figure 7B.1.2 Phylogenetic 16S rRNA tree of the (**A**) Bdellovibrionaceae (**B**) Bacteriovoracaceae based on maximum-likelihood analysis. The ARDRA groups shown correspond to the patterns shown in Figure 7B.1.1 and to the key in Table 7B.1.2 (Reproduced with permission from Davidov and Jurkevitch, 2004.)

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Diluted nutrient broth (DNB)

Dilute nutrient broth 1:10 in water and autoclave. Cool to room temperature. Add 6 ml of 0.5 M $CaCl_2 \cdot 2H_2O$ (3 mM final) and 3.33 ml of 0.6 M $MgCl_2.7H_2O$ (2 mM), passing each through a 0.20-μm syringe filter as it is added to the medium. Store up to 3 months at room temperature.

HM buffer

Prepare 25 mM *N*-[2-hydroxyethyl]piperazine-*N*′-[2-ethanesulfonic acid] (HEPES). Adjust to pH 7.4 with 10 N sodium hydroxide. Sterilize by autoclaving and cool to room temperature. Add 6 ml of 0.5 M $CaCl_2 \cdot 2H_2O$ (3 mM final) and 3.33 ml of 0.6 M $MgCl_2.7H_2O$ (2 mM), passing each through a 0.20-μm syringe filter as it is added to the medium.

HM plates

Prepare 25 mM *N*-[2-hydroxyethyl]piperazine-*N*′-[2-ethanesulfonic acid] (HEPES). Add agar to 1.5% final. Adjust to pH 7.4 with 10 N sodium hydroxide. Sterilize by autoclaving and cool to 60°C. Just prior to pouring, add 6 ml of 0.5 M $CaCl_2 \cdot 2H_2O$ (3 mM final) and 3.33 ml of 0.6 M $MgCl_2 \cdot 7H_2O$ (2 mM), passing each through a 0.20-μm syringe filter as it is added to the medium. Pour into standard 100-mm plates using 20 to 25 ml per plate. Let solidify and dry. Seal in bags and store up to 2 months at 4°C.

A concentration of 1.5% can be obtained by adding 15 g agar per liter medium.

HM top agar

Prepare 25 mM *N*-[2-hydroxyethyl]piperazine-*N*′-[2-ethanesulfonic acid] (HEPES). Add agar to 0.7% final. Adjust to pH 7.4 with 10 N sodium hydroxide. Sterilize by autoclaving and cool to 60°C. Add 6 ml of 0.5 M $CaCl_2 \cdot 2H_2O$ (3 mM final) and 3.33 ml of 0.6 M $MgCl_2 \cdot 7H_2O$ (2 mM), passing each solution through a 0.20-μm syringe filter as it is added to the medium. Rapidly prepare 4-ml aliquots in sterile test tubes before the agar solidifies. Prior to use, melt in an 80°C water bath, then maintain at 42°C to keep molten.

A concentration of 0.7% can be obtained by adding 7 g agar per liter medium.

Solidified tubes can be stored for 1 to 2 weeks but should be wrapped to prevent evaporation.

Host extract

Centrifuge one liter of an overnight *E. coli* culture prepared in nutrient broth (e.g., LB or NB; *APPENDIX 4A*). Centrifuge 10 min at 10,000 × *g*, 4°C. Resuspend in 10 ml HM buffer (see recipe), autoclave, and remove debris by centrifuging 10 min at 10,000 × *g*, 4°C. Retain the supernatant. Determine protein concentration using Bradford's reagent (*APPENDIX 3A*) so that the addition of extract to growth medium is standardized.

Ocean water, sterile

Obtain ocean water or prepare from sea salts such as Instant Ocean (Aquarium Systems). Autoclave and pass through a 0.2-μm filter. Store up to 2 months at room temperature.

Polypeptone 20 (Pp) medium

Dissolve 1 g polypeptone 20 (Pp) in one liter ocean water (see recipe for sterile ocean water). If necessary, add HCl to obtain a pH of 7.7 to 7.8. Autoclave and pass through a 0.2-μm filter. Store up to 3 months at room temperature.

Pp plates

Autoclave polypeptone 20 (Pp) medium (see recipe) containing 1.5% (w/v) agar. Cool to 60°C. Pour into 15 × 150–mm plates using ~60 to 65 ml per plate. Let solidify and dry. Seal in bags and store up to 2 months at 4°C.

A concentration of 1.5% can be obtained by adding 15 g agar per liter medium.

Pp top agar

Autoclave polypeptone 20 (Pp) medium (see recipe) containing 1.95% agar. Prepare 3.3-ml aliquots in sterile test tubes. Before use, melt, then maintain at 42°C to keep molten.

A concentration of 1.95% can be obtained by adding 19.5 g agar per liter medium.

PYE medium

Add 3 g yeast extract and 10 g Bacto peptone to 1 liter water. Sterilize by autoclaving. Cool to room temperature and add 6 ml of 0.5 M $CaCl_2 \cdot 2H_2O$ (3 mM final) and 3.33 ml of 0.6 M $MgCl_2 \cdot 7H_2O$ (2 mM), passing each through a 0.20-μm syringe filter as it is added to the medium. Store up to 3 months at room temperature.

PYE plates

Add 3 g yeast extract, 10 g Bacto peptone, and 15 g agar to 1 liter water. Cool to 60°C. If desired, add 70 ml (7% v/v final) host extract (see recipe). Add 6 ml of 0.5 M $CaCl_2 \cdot 2H_2O$ (3 mM final) and 3.33 ml of 0.6 M $MgCl_2 \cdot 7H_2O$ (2 mM), passing each through a 0.20-μm syringe filter as it is added to the medium. Pour into 15-mm plates using ~20 to 25 ml per plate. Seal in bags and store up to 2 months at 4°C.

Salt solution

0.75 g KCl
23.4 g NaCl
6.9 g $MgCl_2 \cdot 7H_2O$
Adjust pH to 7.2 with 1 N NaOH
Store indefinitely at room temperature

SWYE plates

Dissolve 10 g proteose peptone, 3 g yeast extract, and 20 g agar in 1 liter salt solution (see recipe). Sterilize by autoclaving. Cool to 60°C. Pour into standard 1.5 × 90–mm plates using ~20 to 25 ml per plate. Seal in bags and store up to 2 months at 4°C.

COMMENTARY

Background Information

Bdellovibrio and like organisms (BALOs) are small (0.25 to 0.5 × 0.75 to 1.25 μm), rod or vibrio-shaped, highly motile Gram-negative bacteria. The most striking feature of BALOs is their obligate dependence on predation of Gram-negative cells to grow and reproduce. As a result, BALOs exhibit a peculiar life cycle composed of a free-swimming attack phase and, for most BALOs, an intraperiplasmic phase during which the cell grows as a filament that finally fragments to release attack cell progeny from the ghost of the host cell (Martin, 2002). (A few strains are epibiotic and divide by binary fission.) BALOs are ubiquitous in nature and in man-made habitats. They are found in aquatic and terrestrial environments as planktonic cells or associated with biofilms. They are detected in extreme environments as well. Their impact on bacterial populations is still unclear (Jurkevitch and Ramati, 2005).

The discovery of *Bdellovibrio* and like organisms (BALOs) by Heinz Stolp in 1962 (Stolp and Pertzold, 1962) was a serendipitous one: it happened as he pursued the isolation of soil bacteriophages. The basic procedure for isolating BALOs remains similar, i.e., BALOs mixed with a potential host form plaques in double-layered agar plates. However, these plaques differ from phage plaques as they develop more slowly (appearing after 3 to 4 days)

and keep spreading for much longer (a week or more). Although this approach enables the isolation of BALOs, it suffers from a few drawbacks.

1. BALO strains differ in prey range, therefore a particular prey will only enable the growth of the predators able to use it. As most bacteria are not amenable to cultivation, a large proportion of BALOs may go undetected.

2. BALOs are usually found at relatively low levels in nature, therefore there is a risk that colony-developing bacteria, carried over during the isolation procedure, may overgrow plaques on isolation plates.

3. Filtration through 0.45-μm filters reduces the yield of BALOs. The use of a Ficoll gradient may enable a "cleaner" recovery of BALOs, but it is more expensive (Varon and Shilo, 1970).

BALOs belong to the δ-proteobacteria. They form two families, Bdellovibrionaceae and Bacteriovoracaceae. Only one species (*B. bacteriovorus*) is recognized in the former. The latter holds the two genera *Peridibacter* and *Bacteriovorax*, with *P. starrii*, and *B. stolpii*, *B. marinus*, and *B. littoralis* being their recognized species, respectively (Baer et al., 2000, Davidov and Jurkevitch, 2004). The taxonomy of BALOs is mainly based on the phylogenetic affiliation obtained from 16S rDNA analysis (see Basic Protocol 7). No clear connection has been found between BALO prey range and phylogeny. Amplified rDNA restriction analysis (ARDRA) used in conjunction with a BALO-specific primer (Jurkevitch and Ramati, 2000; Davidov and Jurkevitch, 2004) is an efficient tool for an initial determination of the phylogenetic placement of isolates (especially when a large number of strains have to be analyzed).

Host-independent (HI) derivatives of BALOs can be isolated under laboratory conditions (Seidler and Starr, 1969; Barel and Jurkevitch, 2001). These mutants are grown in rich medium and retain the phenotypes of the attack and of the replication-elongation-fragmentation phases (Basic Protocol 3). As such, they can provide information on the growth cycle without the interference of a prey.

In order to perform phase-specific analyses, cultures should be synchronous. This can be achieved with both wild-type and HI strains. Synchrony is realized with the former by using a surplus of predators over prey (Basic Protocol 4), while dilution of dense suspensions induces it in the latter (Basic Protocol 5). Further physical separation of the phases is attained by centrifugation on a Percoll cushion (Basic Protocol 6).

Critical Parameters

Amplification of the 16S rRNA gene (Basic Protocol 7) or part thereof with the polymerase-chain reaction should be performed with great care when using general primers targeting the Bacteria domain. In that case, BALO suspensions should be thoroughly filtered and washed to remove traces of the prey.

Troubleshooting

Table 7B.1.3 presents some common problems encountered when performing the protocols described in this unit, as well as their common causes and potential solutions.

Anticipated Results

Isolation from environmental samples

BALOs plaques should almost always be obtained from environmental samples. The number of plaques may vary greatly between habitats, seasons and the prey chosen, among other parameters. Usually tens to tens of thousands of plaques are formed per milliliter or gram sample.

Isolation of HI mutants

The procedure described has enabled the isolation of HI derivatives from all the strains tested so far (Seidler and Starr, 1969).

Classification

At least the family affiliation (Bdellovibrionaceae, Bacteriovoracaceae, or as yet undescribed groups) of the analyzed isolates should be obtained. Most strains originating from mesophilic, but not extreme terrestrial and aquatic habitats, may belong to one of the described ARDRA groups.

Time Consideration

Isolation from environmental samples

Plaques become apparent 3 to 8 days after inoculation. Pure cultures, obtained by plating the plaques repeatedly, should be obtained within two weeks.

Growth and storage of pure BALO cultures

This procedure should take 2 to 3 days.

Isolation of HI mutants

Isolating host-independent mutants can take up to two weeks.

Table 7B.1.3 Troubleshooting Guide for Isolation and Classification of *Bdellovibrio* and Like Organisms

Problem	Possible Cause	Solution
	Isolation from environmental samples	
No plaques	Prey not adequate	Change prey
	Very low levels of BALOs	Try enrichment protocol (Alternate Protocol 3)
Overgrowth of contaminants	Too many cells pass through 1.2-μm filter	Filter with 0.45-μm membrane
No plaques after filtration through 0.45-μm membrane	Too many BALOs are lost	Try Ficoll protocol (Alternate Protocol 1)
1.2-μm filters clogged	Too much fine material (e.g., clay)	Pass sample through a 5-μm filter step or use a Ficoll cushion prior to passing through 1.2-μm filter
	Culture of host-independent mutants	
Strains grow sluggishly	Uncertain: possibly due to lack of nutritional replacement	Plate on PYE medium supplemented with host extract and start culture from an isolated colony
Classification		
No amplification product	Target sequence in 16S rRNA gene has mismatches with primer 842R	Use primer 907R instead of 842R (see Table 7B.1.1)
DNA sequence not readable: too many multiple peaks	16S DNA from prey or a contaminant is also being amplified	Pass BALO suspension through a 0.45-μm filter twice and be extra careful with PCR reagents

Synchronous growth of BALO cultures

This procedure takes ~1 day.

Separation of growth phase

This method requires 3 to 6 hr.

Classification

Amplified rDNA restriction analysis (ARDRA) patterns can be obtained within a few days.

ABSTRACT

Bdellovibrio bacteriovorus is a Gram-negative bacterium that preys upon other Gram-negative bacteria. It does this by penetrating the outer membrane and peptidoglycan to establish itself in the periplasm where it grows at the expense of the contents of the prey cell before ultimately lysing the prey. Wild-type *Bdellovibrio* are prey-(or host-) dependent and the protocols described in this unit deal with the techniques required to grow this bacterium on its prey cells. Protocols are also presented to generate and culture host-independent mutants as well as novel protocols to evaluate *Bdellovibrio* predation. *Curr. Protoc. Microbiol.* 9:7B.2.1-7B.2.13. © 2008 by John Wiley & Sons, Inc.

Keywords: *Bdellovibrio bacteriovorus* • predator-prey interactions • luminescence assay • plaque assay • host-independent growth • storage of cultures

INTRODUCTION

Bdellovibrio are small, predatory, delta-Proteobacteria. They collide with, attach to, and invade Gram-negative bacterial prey by lysing a small temporary pore into the outer layers of the prey through which they enter and establish growth in the prey periplasm in a structure known as the bdelloplast (Tudor et al., 1990). *Bdellovibrio* growth is achieved by attaching to the cytoplasmic membrane of prey and hydrolyzing and taking up prey biomolecules for *Bdellovibrio* cell synthesis. *Bdellovibrio* grow in a filamentous form within their prey, and when nutrients are exhausted, they septate into individual cells, which synthesize flagella and swim within the bdelloplast. Ultimately, the prey outer membrane is lysed to release fresh, motile progeny *Bdellovibrio*. Their ability to prey upon many disease-causing bacteria raises the interesting possibility that they may be developed for use as biocontrol or therapeutic agents.

Routine laboratory maintenance of *Bdellovibrio* is carried out by growth on suitable Gram-negative prey cells such as *E. coli* by either the double-layer overlay technique (Rittenberg, 1982) or as prey lysates in buffer (Koval and Hynes, 1991). Alternatively, a proportion of the cells of any given population of *Bdellovibrio* can grow axenically in the absence of hosts (Seidler and Starr, 1969a). These are most commonly referred to as host-independent (HI) strains and often have many properties differing from wild-type, such as morphology (Fig. 7B.2.1) and they may or may not retain the ability to form plaques on prey lawns.

Recently, molecular genetic techniques have been developed for the manipulation of *Bdellovibrio*, and since the sequencing of the genome of *B. bacteriovorus* HD100, genes can now be targeted for insertional inactivation or deletion (Lambert et al., 2003). Basic Protocol 1 describes the standard methods of growing *Bdellovibrio* in suspensions of prey *E. coli*. Basic Protocol 2 explains further the standard procedure for rescuing *Bdellovibrio* from long-term storage. Basic Protocol 3 details growth of *Bdellovibrio* as single plaques for enumeration, which is a technique used in many experiments to determine the number of *Bdellovibrio* in a preparation. Basic Protocol 4 describes the differential filtration technique to isolate HI derivatives. Basic Protocol 5 shows how

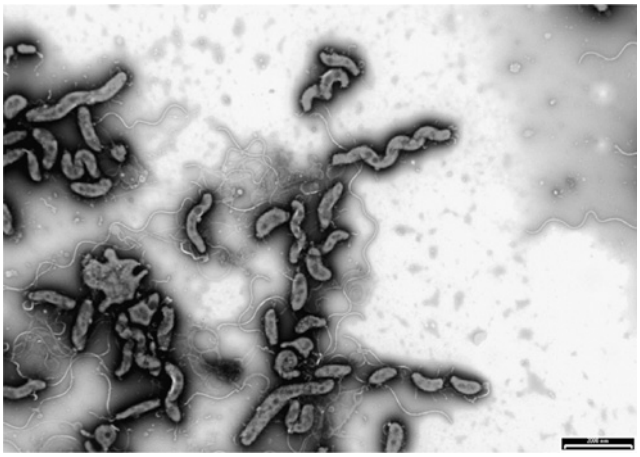

Figure 7B.2.1 Cells of *Bdellovibrio bacteriovorus* HIK3 (a host-independent derivative of strain 109J) grown in PY broth. A wide variety of cell morphology can be observed within one strain; the smaller single cells seen resemble those in predatory cultures.

such strains are grown. Basic Protocol 6 gives a robust protocol for reliable storage of *Bdellovibrio.* Basic Protocol 7 is a novel assay for observing phenotypic differences between strains.

CAUTION: Bdellovibrio bacteriovorus and *E. coli* are Biosafety Level 1 (BSL-1) organisms. Such organisms are not known to consistently cause disease in healthy adult humans, and are of minimal potential hazard to laboratory personnel and the environment. Standard microbiological practices should be followed when working with these organisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

CAUTION: Some prey cells are Biosafety Level 2 (BSL-2) pathogens. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

BASIC PROTOCOL 1

ROUTINE CULTURING OF PREY LYSATES

Wild-type *Bdellovibrio* are prey-dependent and therefore need to be grown on suitable Gram-negative prey cells such as *E. coli* K12 (refer to *APPENDIX 4A* for methods of culturing *E. coli* K12). Prey lysates are prey cells suspended in buffer with *Bdellovibrio* so that the prey are the predominant nutrient source for the predator. The HEPES buffer used here is supplemented with $CaCl_2$ (Seidler and Starr, 1969b) to increase the efficiency of prey lysis. A standard prey lysate culture described here can be scaled down to a mini lysate of 2 ml or scaled up to several liters (Koval and Hynes, 1991). Although the experimenter does not need special protection from class I containment organisms such as *E. coli*, it is preferable to conduct culturing of *Bdellovibrio* in a class II containment hood to minimize the risk of contamination by other microorganisms.

Materials

Prey cells (e.g., *E. coli* K12; refer to *APPENDIX 4A* for methods of culturing *E. coli* K12)
1% YT agar plates (see recipe for YT agar)
YT broth (see recipe)
HEPES buffer supplemented with $CaCl_2$ (see recipe)
Overnight culture of prey lysate

37°C static incubator
250-ml conical flasks or sterile universal tubes (Sterilin)
29° and 37°C shaking incubator
Phase contrast microscope with a 100× oil immersion lens

1. Streak prey cells out to produce single colonies on 1% YT agar plates and incubate inverted overnight at 37°C.

   These plates can be stored up to 2 weeks at 4°C.

2. Inoculate an appropriate amount (e.g., 50 ml) of YT broth with a single colony in a vessel at least five times the volume of the broth and incubate overnight in a 37°C incubator with shaking at 200 rpm for aeration.

3. Aseptically add the following to a sterile 250-ml conical flask:

   50 ml sterile HEPES buffer supplemented with $CaCl_2$
   3 ml of overnight prey culture
   1 ml of overnight prey lysate (from previous prey lysate)

   Incubate overnight at 29°C with shaking at 200 rpm.

   The prey should be grown as described here, or rescued from frozen stocks as described in Basic Protocol 2.

4. Check by phase contrast microscopy after 24 hr, preferably with a 100× oil immersion lens, for the presence of bdellovibrios (usually highly motile) and the absence of prey cells and bdelloplasts (indicating successful lysis of prey).

   Prey lysates of this nature retain Bdellovibrio viability for up to 2 weeks if stored at 4°C.

REVIVING *BDELLOVIBRIO* FROM FROZEN STOCKS

BASIC PROTOCOL 2

Bdellovibrio cells can be stored routinely for several years at −80°C (see Basic Protocol 6), but unlike some other bacteria, cannot normally be streaked onto media from such stocks (unless they are HI) as wild-type *Bdellovibrio* are host- (or prey-) dependent. This protocol uses the overlay technique to grow up thawed *Bdellovibrio* on prey cells.

Materials

Prey cells (e.g., *E. coli* K12; refer to *APPENDIX 4A* for methods of culturing *E. coli* K12)
1% YT agar plates (see recipe for YT broth)
YT broth (see recipe)
1% YPSC bottom agar (see recipe for YPSC broth)
25 g/liter $CaCl_2 \cdot 2H_2O$ solution, sterile
0.6% YPSC top agar (see recipe for YPSC broth)
Bdellovibrio frozen stock (made from a previous prey lysate, see Basic Protocol 6)
HEPES buffer supplemented with $CaCl_2$ (see recipe)

29° and 37°C static incubators
37°C shaking incubator
Test tubes
55°C water bath
Phase contrast microscope

Grow E. coli prey cells

1. Streak *E. coli* prey cells onto 1% YT agar plates and incubate inverted overnight at 37°C to produce single colonies.

   These plates can be stored up to 2 weeks at 4°C.

2. Inoculate an appropriate amount (e.g., 50 ml) of YT broth with a single colony in a vessel at least five times the volume of the broth and incubate overnight at 37°C with shaking at 200 rpm for aeration.

   Adjust methods for alternative prey, for example, growth can be in different media such as higher salt media and at different temperatures with many prey preferring 30°C.

Prepare YPSC overlays

3. Pour 1% YPSC agar plates, adding $CaCl_2 \cdot 2H_2O$ to a final concentration of 0.25 g/liter from a 100× stock of 25g/liter after melting the agar.

   The $CaCl_2$ would otherwise precipitate during autoclaving.

4. To a test tube, add 100 µl of the overnight culture of prey cells and 5 ml of 0.6% YPSC top agar incubated at 55°C, with $CaCl_2$ added. Quickly pour this mixture onto the bottom plate and leave undisturbed for 5 min at room temperature to set.

   The agar has to be at 55°C to ensure that it is completely molten so that the prey can be adequately mixed in a room temperature tube before pouring. Therefore, the prey must be able to withstand addition to molten agar at 55°C (as is the case for E. coli prey).

5. Spot 50 µl of a *Bdellovibrio* frozen stock onto the center of this double layer plate and incubate upright overnight at 29°C until a lawn of prey cells is observed.

6. Turn plate upside down and incubate for an additional 1 to 5 days at 29°C until clearing of the prey lawn where the *Bdellovibrio* were spotted is observed.

   Higher concentrations cause quicker clearing of the prey lawn.

7. Pick up some of the area of clearing from the soft agar layer using a 1000-µl pipet set to 250 µl. Aseptically transfer this into a mini lysate containing 2 ml HEPES buffer supplemented with $CaCl_2$ and 150 µl of overnight prey culture.

8. Incubate 1 to 2 days at 29°C with shaking at 200 rpm until lysate appears clear and phase contrast microscopy reveals the presence of bdellovibrios and lysis of prey cells.

   If the Bdellovibrio are pipetted from an area of plate that is thoroughly cleared, then the mini lysate should clear after an overnight (16 hr) incubation. If the plate has only partial clearing, then the lysate may take longer to clear.

   YPSC overlay plates can be stored up to 2 weeks at room temperature and the Bdellovibrio within remain viable, more so than if stored at 4°C.

BASIC PROTOCOL 3

GROWTH OF *BDELLOVIBRIO* AS SINGLE PLAQUES FOR ENUMERATION

For any given *Bdellovibrio*-containing sample, a range of serial dilutions can be used to produce a plate with a countable yet significant number of plaques. This technique is an invaluable way of calculating the number of live *Bdellovibrio* cells being added to an experiment. It acts as an alternative to colony-counting for non-predatory bacteria. Due to the small cell dimensions of *Bdellovibrio*, optical density readings cannot reliably be used to determine the total number of *Bdellovibrio* cells in a sample.

Materials

Prey cells (e.g., *E. coli* K12; refer to *APPENDIX 4A* for methods of culturing *E. coli* K12)
1% YT agar plates (see recipe for YT broth)
YT broth (see recipe)
1% YPSC bottom agar (see recipe for YPSC broth)
25 g/liter $CaCl_2 \cdot 2H_2O$ solution, sterile
HEPES buffer supplemented with $CaCl_2$ (see recipe)

Sample to be enumerated
0.6% YPSC top agar (see recipe for YPSC broth)

29° and 37°C static incubators
37°C shaking incubator
Test tubes
55°C water bath

Grow E. coli prey cells

1. Streak prey cells out onto 1% YT agar plates and incubate inverted overnight at 37°C to produce single colonies.

   These plates can be stored up to 2 weeks at 4°C.

2. Inoculate an appropriate amount (e.g., 50 ml) of YT broth with a single colony in a vessel at least five times the volume of the broth and incubate overnight at 37°C with shaking at 200 rpm for aeration.

Prepare YPSC overlays

3. Pour 1% YPSC agar plates, adding $CaCl_2.2H_2O$ to a final concentration of 0.25 g/liter, after melting the agar, from a 100× stock of 25 g/liter.

   The $CaCl_2$ would otherwise precipitate during autoclaving if added prior to autoclaving.

4. Prepare ten-fold serial dilutions in HEPES buffer supplemented with $CaCl_2$ of the sample to be enumerated.

5. Add 100 µl of these serial dilutions to separate test tubes with 100 µl of an overnight prey culture and then add 5 ml of 0.6% top agar YPSC incubated at 55°C, with $CaCl_2$ added to a final concentration of 0.25 g/liter. Quickly pour this mixture onto the bottom plate and leave undisturbed for 5 min at room temperature to set.

6. Incubate plates inverted 3 to 10 days at 29°C until clear plaques appear in the lawn of prey cells.

   Typically, useful dilutions are 10^{-4} to 10^{-6} for a prey lysate that has completely cleared.

GENERATION OF HOST-INDEPENDENT *BDELLOVIBRIO*

BASIC PROTOCOL 4

Host-dependent *Bdellovibrio* yield host-independent (HI) colonies at a frequency of $\sim 10^{-6}$ to 10^{-8} (pfu/cfu) upon plating on PY agar. While many HI strains retain their capacity for intraperiplasmic growth, it has been noted that continued passage of HI strains in the absence of prey cells tends to lead to a loss of their predatory ability (Seidler and Starr, 1969a). Therefore, excessive passaging of HI strains in the absence of prey should be avoided by returning to frozen stocks of strains frequently. This protocol uses the small size of predatory *Bdellovibrio* to differentially filter them from any remaining larger prey cells; these are then cultured to derive HI colonies. HI cultures exhibit diverse cellular morphologies (Fig. 7B.2.1).

Materials

Overnight prey lysate of host-dependent *Bdellovibrio*
PY agar (see recipe for PY broth)
PY broth (see recipe)

Phase contrast microscope
Petri dishes
0.45-µm syringe filters
10-ml syringe
15-ml tubes (Falcon)

Benchtop centrifuge
Plate spreaders
29°C static incubator
Bijou universal tubes (7-ml screw-top plastic tubes; Sterilin cat. no. 129B)
29°C shaking incubator

1. Grow a 50-ml prey lysate overnight (as in Basic Protocol 1) and check by phase contrast microscopy for the presence of *Bdellovibrio* and complete prey lysis, i.e., the absence of prey cells and bdelloplasts.
2. Pour plates with ~40 ml of 1% PY agar per petri dish and leave to set 10 min at room temperature.
3. Filter 10 ml of prey lysate through a 0.45-μm syringe filter attached to a 10-ml syringe into a 15-ml tube.
4. Balance the tubes and centrifuge 10 min at ~5000 × *g*, room temperature, in a benchtop centrifuge.
5. Pour off the supernatant and resuspend pellet in 100 μl of PY broth.
6. Spread entire 100 μl onto a PY plate and dry briefly by standing at room temperature with lids slightly off (preferably in a laminar flow cabinet). Incubate inverted 3 to 10 days at 29°C.
7. Check on the following day for *E. coli* growth (imperfections in filters can sometimes allow a few cells through).

   Tiny yellow colonies will start to appear, which grow slowly over several days.

8. When colonies are >1 mm, pick into 0.5 ml PY broth in a bijou universal tube and incubate at 29°C with shaking at 200 rpm.

   Growth in broth can be achieved by scraping an area containing many small colonies but such a culture would not be clonal and may have a number of plaquing (and other) phenotypes.

9. In 1 to 3 days, as the culture grows ($OD_{600} > 0.5$), add more PY broth, doubling the volume, then incubate overnight at 29°C with shaking at 200 rpm.

   This process can be continued until the required culture volume has been reached for an experiment. The culture should be incubated in a vessel at least five times the volume of the liquid.

   PY plates of HI cultures can be stored for up to 2 weeks at room temperature.

BASIC PROTOCOL 5

ROUTINE MAINTENANCE OF HI CULTURES

Unlike host-dependent strains, HI strains (Fig. 7B.2.1) can be maintained in rich broth or on plates similar to many other bacteria such as *E. coli,* although growth is relatively slow so incubation times are extended and cultures must gradually be increased in size by sequential addition of growth medium.

Materials

PY agar (see recipe for PY broth)
Frozen stock of HI strain
PY broth (see recipe)

Petri dishes
29°C static incubator
Bijou universal tubes

Conical flasks
29°C shaking incubator

Grow from frozen stocks

1. Pour a petri plate with ~50 ml 1% PY agar and leave to set 10 min at room temperature.
2. Pipet 50 µl of a thawed (5 min at room temperature) stock of HI strain onto the plate.
3. Streak repeatedly across the plate successively to obtain single colonies.
4. Incubate upright overnight at 29°C.
5. Incubate inverted for an additional 2 to 8 days at 29°C.

   A large area of yellow growth will be observed within 2 to 4 days, and later single colonies will be observed.

Grow in broth

6. When colonies are >1 mm, pick and place into 0.5 ml PY broth in a bijou universal tube and incubate at 29°C with shaking at 200 rpm.
7. In 1 to 3 days as the culture grows ($OD_{600} > 0.5$), add more PY medium, doubling the volume, then incubate overnight at 29°C with shaking at 200 rpm.

   This process can be continued until the required volume has been reached for an experiment. The culture should be incubated in a vessel at least five times the volume of the liquid.

8. At any point, add 1 ml of culture sample to a further 1 ml PY broth to increase the number of samples.

PREPARING FROZEN GLYCEROL STOCKS FOR LONG-TERM STORAGE

BASIC PROTOCOL 6

This allows storage for several years.

Materials

Culture of host-dependent *Bdellovibrio*
Culture of host-independent *Bdellovibrio*
Sterile 80% glycerol
Liquid nitrogen in suitable Dewar container

Phase contrast microscope
1.5-ml plastic freezer tubes (Nunc)
Perforated ladle/slotted spoon
−80°C freezer containing freezer box

1. Check culture of host-dependent *Bdellovibrio* by phase contrast microscopy for presence of bdellovibrios and absence of prey cells and bdelloplasts. Check host-independent *Bdellovibrio* culture for presence of bdellovibrios and absence of contaminants.
2. Pipet 700 µl of culture into 1.5-ml freezer tubes.
3. Add 150 µl of 80% glycerol and cap tube. Mix well.
4. Drop into liquid nitrogen and leave until frozen (~1 min). Remove tubes with perforated ladle or slotted spoon.
5. Place in a precooled freezer box in a −80°C freezer.

The stock can withstand several freeze-thaw cycles, but it is advisable to have many stocks and not to access one stock more than three times to ensure growth.

It is important to prepare many frozen stocks of recently isolated HI strains, as upon repeated subculturing they have been demonstrated to lose their ability to infect prey cells.

BASIC PROTOCOL 7

BDELLOVIBRIO PREDATION EFFICIENCY ASSAY ON LUMINESCENT PREY

A relationship was established between light emitted from a population of luminescent *E. coli* and predation of that population (Lambert et al., 2003). This assay was optimized to show predation efficiency of various strains by monitoring the decay in light emission over time (Fig. 7B.2.2).

Materials

Bdellovibrio mutant strains to be tested (usually kanamycin resistant due to insertional inactivation of a gene under study)
109JK control strain
Luminescent *E. coli* S17-1 (pCL100, kanamycin resistant) (Lambert et al., 2003)
E. coli S17-1 (pZMR100) (Rogers et al., 1986)
YT agar (see recipe for YT broth)
YPSC agar (see recipes for both top and bottom agar)
HEPES buffer supplemented with $CaCl_2$ (see recipe)
YT broth (see recipe)
PY broth (see recipe)
50 mg/ml kanamycin sulfate

Petri dishes
55°C and boiling water baths
1.5-ml microcentrifuge tubes
Multichannel pipettor
96-well microtiter plates for luminometer
Photoluminometer capable of reading a kinetic assay of luminescence over time in a 96-well microtiter well and with temperature control and shaking (e.g., Anthos Lucy, Perkin-Elmer Instruments Victor, BMG Labtechnology Fluostar Optima, Tecan Genios)

Grow bacterial strains

1. Grow *Bdellovibrio* mutant strains to be tested and the 109JK control strain for 3 days on luminescent *E. coli* S17-1 (pCL100) (Lambert et al., 2003), subculturing at the same time each day. On the final day, also grow *E. coli* S17-1 (pZMR100) (Rogers et al., 1986) to use to enumerate the *Bdellovibrio.*

Prepare plates and bacteria

2. Pour three 1% YT agar plates and three YPSC bottom agar plates supplemented with 50 μg/ml kanamycin sulfate per *Bdellovibrio* strain tested and melt the appropriate amount (5 ml per plate) of YPSC top agar, maintain melted agar at 55°C.

3. Prepare controls by dispensing 1 ml of each *Bdellovibrio* strain to be tested into 1.5-ml microcentrifuge tubes and boil for 5 min, then leave to cool to room temperature for at least 10 min.

4. Prepare luminescent prey by dispensing 25 ml HEPES supplemented with $CaCl_2$, 25 ml PY broth, and 2 ml of an overnight culture of *E. coli* S17-1 (pCL100) host cells into a petri dish supplemented with 50 μg/ml kanamycin sulfate.

5. Using a multichannel pipettor, dispense 200 μl of this mixture into each well of a 96-well plate suitable for reading in a luminometer.

6. Dispense 1, 2, 4, 8, 16, 32, and 64 μl of *Bdellovibrio* strains to be tested into wells of the plate, avoiding wells at the extremities of the plate as these are prone to evaporation.

7. Make the volume of all the above wells up to 264 μl with heat-killed control *Bdellovibrio* of the appropriate strain, e.g., 32 μl of heat-killed cells added to the well containing 32 μl of live *Bdellovibrio*. Include one well with just 64 μl of heat-killed cells with no live *Bdellovibrio*.

8. Incubate plate at 30°C in a photoluminometer with shaking at 200 rpm, set to read luminescence at 30-min intervals for 24 hr.

Further experiments should also be carried out with a 1:10 dilution of the Bdellovibrio and 1:10 dilution of heat-killed Bdellovibrio.

Enumerate bacteria

9. Immediately after setting the plate for incubation, enumerate samples of each of the *Bdellovibrio* strains used in the assay plate by plating at dilutions between 10^{-4} and 10^{-6} onto YPSC overlays, incubate 3 to 10 days at 30°C and then count plaques.

10. Enumerate the *E. coli* S17-1 (pCL100) in the PY broth and HEPES supplemented with $CaCl_2$ mix by plating dilutions between 10^{-4} and 10^{-6} onto YT plates and incubate overnight at 37°C.

Analyze data

11. Analyze data by plotting $\log_{10}$ luminescence against time.

From this plot, the time taken to reduce to half of the maximum $\log_{10}$ luminescence value for each amount of Bdellovibrio is calculated and this is plotted against the amount of Bdellovibrio initially added as calculated by the plaque overlay enumeration (Fig. 7B.2.3).

If a mutant strain is reduced in its efficiency of predation relative to the 109JK control, then this should be shown on this plot as the line of best fit is shifted (Fig. 7B.2.3).

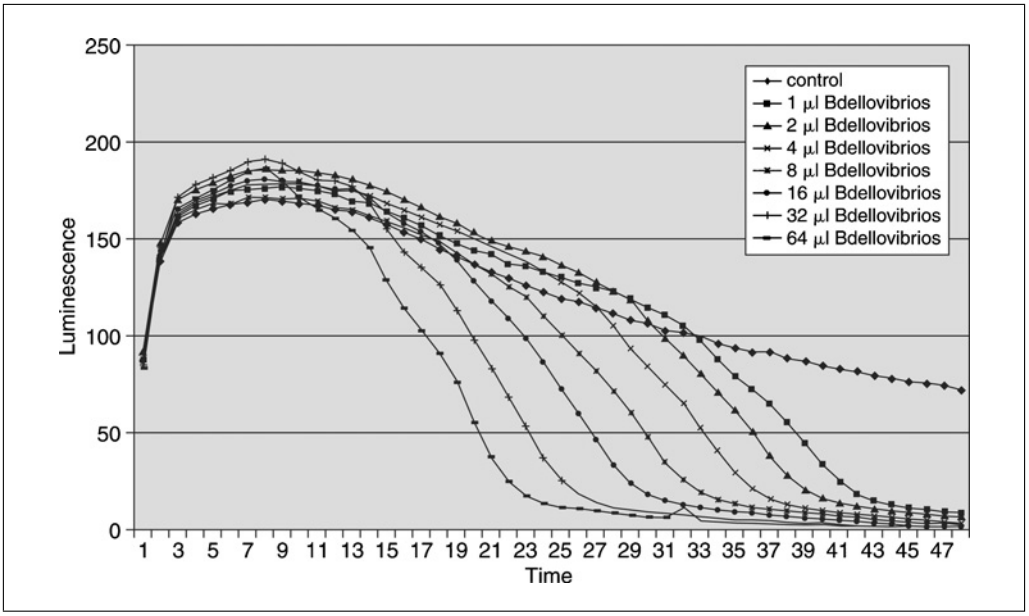

Figure 7B.2.2 Plot showing luminescence (in relative luminescent units) against time (in steps of 30 min; i.e., 1 = 30 min, 2 = 60 min, etc.) for an infection of *Bdellovibrio* on luminescent *E. coli*. After an initial rise in luminescence, more bdellovibrios added results in faster diminution of light. The suspension added contains 1×10^5 viable bdellovibrios as determined by plaque enumeration.

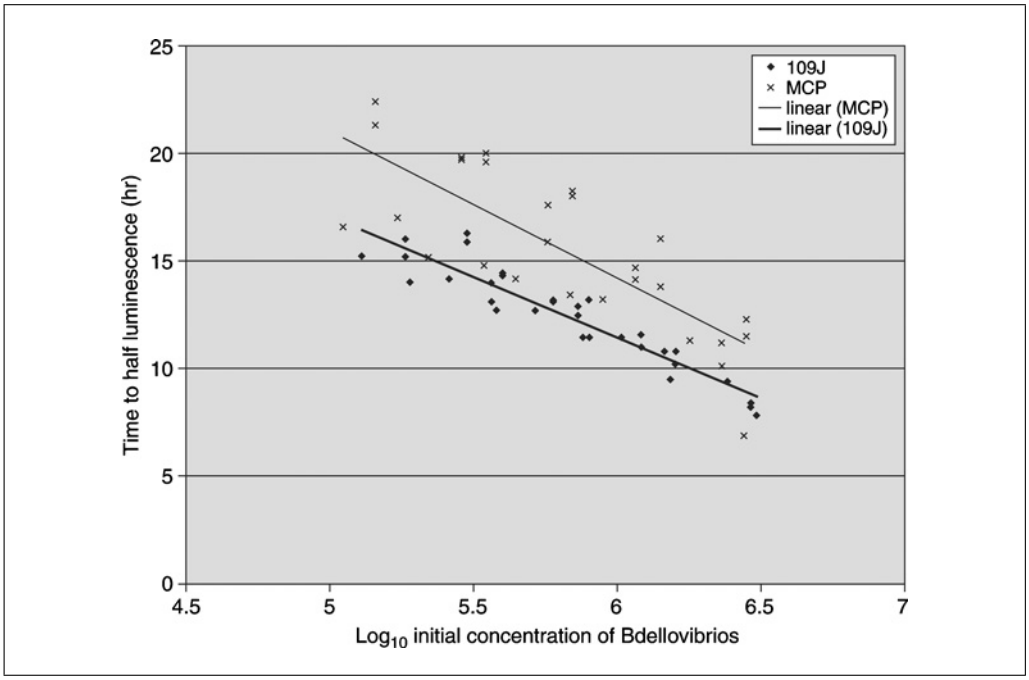

Figure 7B.2.3 Plot showing $\log_{10}$ numbers of bdellovibrios initially added against time to half $\log_{10}$ luminescence values comparing two strains; a wild type 109J and a mutant MCP strain (Lambert et al., 2003).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

HEPES buffer supplemented with $CaCl_2$

5.94 g/liter HEPES free acid
0.284 g/liter calcium chloride ($CaCl_2$) dihydrate
Adjust to pH 7.6 using 2 M NaOH
Sterilize by autoclaving
Store up to 6 months at room temperature

PY broth

10 g/liter peptone
3 g/liter yeast extract
Adjust to pH 6.8 using 2 M NaOH
Sterilize by autoclaving
Store up to 6 months at room temperature
For PY agar, add 10g/liter agar

YPSC broth

0.125 g/liter magnesium sulfate
0.25 g/liter sodium acetate
0.5 g/liter bacto peptone
0.5 g/liter yeast extract
Adjust to pH 7.6 using 2 M NaOH
Sterilize by autoclaving
Adjust to 0.25 g/liter $CaCl_2$ dihydrate using 25 g/liter stock after autoclaving
Store up to 6 months at room temperature
For YPSC bottom agar, add 10 g/liter agar
For YPSC top agar, add 6 g/liter agar

YT broth

5 g/liter sodium chloride
5 g/liter peptone
8 g/liter tryptone
Adjust to pH 7.5 using 2 M NaOH
Sterilize by autoclaving
Store up to 6 months at room temperature
For YT agar, add 10 g/liter agar

COMMENTARY

Background Information

Bdellovibrio bacteriovorus is a highly motile delta-proteobacterium that preys on other Gram-negative bacteria (Stolp and Starr, 1963). *Bdellovibrio* are ubiquitous in nature, having been discovered in a wide variety of environments that include both aquatic and terrestrial habitats as well as mammalian intestines (Varon and Shilo, 1980). Their prey includes plant, animal, and human pathogens (Martin, 2002). Thus, studying the molecular mechanisms of *Bdellovibrio* predation offers cues for the design of antibacterial agents.

Critical Parameters

One important consideration when setting up experiments with *Bdellovibrio* is the physiological state of the prey lysate. As *Bdellovibrio* cycle through attack phase and intraperiplasmic growth, and then release into attack phase again, they undergo many different developmental and metabolic states and this could have a drastic effect on the outcome of any given experiment. Similarly, newly released attack phase cells are very different from cells from older lysates (more rapidly motile and often smaller). To avoid fluctuations between experiments, it is essential to subculture at exactly specified times over a period of several days (e.g., every 24 hr for 3 days). It may also be vital to subculture for several rounds on a new prey, or under new conditions, before using the *Bdellovibrio* progeny for an experiment.

Host-independent *Bdellovibrio* appear to have an as yet unquantified reliance upon cell density, for example, small colonies seem to appear on plates mainly in high density and a relatively high inoculum per volume is necessary for consistent growth.

For culturing, all media and solutions should be sterilized by autoclaving and it is important to work with good aseptic technique. If possible, work should be carried out in a Class II biohazard fume hood to minimize the risk of contamination, although this is not essential.

Troubleshooting

Table 7B.2.1 presents commonly encountered difficulties in maintaining *Bdellovibrio*, as well as the potential causes and possible solutions.

Anticipated Results

For the culture of host-dependent *Bdellovibrio*, overlay plates should develop a large region of clearing where the *Bdellovibrio* has been spotted onto a cloudy lawn of prey cells, or individual plaques where dilutions have been used. These plaques start out as small and cloudy (2 to 4 days) and become clearer and larger over several days (3 to 10 days) incubation.

Culture of *Bdellovibrio* in prey lysates should result in the clearing of the cloudy prey lysate over 1 to 2 days and phase contrast microscopy should reveal prey cells turning into bdelloplasts (rounded prey cells containing *Bdellovibrio* within), then lysing to release small, highly motile attack phase *Bdellovibrio* cells.

Culture and generation of HI *Bdellovibrio* should produce initially (2 to 4 days) very small, yellow-orange colonies on PY plates, which grow slowly over time (3 to 10 days). Similarly, growth in broth produces yellow-orange coloration. Phase contrast microscopy should show, in addition to some small, motile attack phase *Bdellovibrio*, a very heterogeneous mix of cell morphology and size. A much smaller proportion of HI cells tend to be motile and it is not unusual to see no swimming cells at all (Fig. 7B.2.1).

Data from the predation assay on luminescent prey should show light emissions initially increasing as the prey cells grow in the nutrients, followed by the levels slowly lowering in the control with no live *Bdellovibrio*. For each well containing *Bdellovibrio*, the light levels

Table 7B.2.1 Troubleshooting Laboratory Maintenance of *Bdellovibrio*

Problem	Cause	Solution
Contamination of prey lysate	Environmental/skin bacteria	Ensure good sterile technique/work in a Class II containment hood
No clearing of overlay plate after addition of frozen stock and incubation	Frozen stock has been through too many freeze/thaw cycles	Use fresh frozen stocks with fewer than four freeze-thaw cycles
Incomplete lawn formed on YPSC overlay	Not enough viable prey cells added	Use only fresh overnight cultures and ensure correct antibiotic included
Lumpy uneven overlay	Top agar not set properly	Ensure top agar is at 55°C and pour quickly. Do not move the plate for 5 min after pouring
No lawn formed on overlay	Top agar too hot	Incubate top agar at 55°C
No plaques forming/few and cloudy plaques	$CaCl_2$ missing	Remember to add $CaCl_2$
Confluent lysis of overlay	*Bdellovibrio* not diluted enough	Use a range of dilutions to ensure an overlay with discrete plaques
HI starter broth not growing	Cells not in high enough density	Use one large (>2 mm) colony as primary inoculum in a small volume (0.5 ml) of medium, then scale up two fold, five fold, and so on
Prey cells growing on PY HI plates	Filtration of prey lysate has failed (0.45-μm filters are not perfect)	Double filter if necessary
Prey lysate not cleared after overnight incubation	Too few viable *Bdellovibrio* added	Incubate further or only use fresh lysate/large inoculum
Luminescent prey cells not emitting light	Unknown	Revert to frozen stocks

lower more quickly in a manner dependent on the initial number of *Bdellovibrio* added (Fig. 7B.2.2).

For a plot of time to half of maximum luminescence against initial amounts of added *Bdellovibrio*, the line of best fit of different strains can be compared and a mutant with lowered predation efficiency should have a noticeably different line of best fit (Fig. 7B.2.3).

Time Considerations

For each protocol (except those for HI *Bdellovibrio*), advance planning is required to grow prey cells the day before. Time required for all of the protocols is entirely reliant upon the somewhat variable growth rate of the plaques/colonies of *Bdellovibrio*. This tends to be within the range of 4 to 6 days, but can vary from 3 to 10 days.

[2]Unit for Laboratory Animal Medicine, University of Michigan, Ann Arbor, Michigan

ABSTRACT

Campylobacter jejuni is a fastidious organism, growing in microaerophilic conditions with a temperature range between 37° and 42°C. Multiple types of media can be used to cultivate it; however, Mueller Hinton broth and agar support the best *C. jejuni* growth. Optimum atmosphere for *C. jejuni* is 85% N_2, 10% CO_2, and 5% O_2. *Curr. Protoc. Microbiol.* 10:8A.1.1-8A.1.7. © 2008 by John Wiley & Sons, Inc.

Keywords: campylobacteriosis • microaerophilic growth • Mueller Hinton

INTRODUCTION

Campylobacter jejuni is one of the major causes of bacterial gastroenteritis worldwide and is primarily acquired through the ingestion of contaminated poultry products. Research on *C. jejuni* has been greatly impaired due to poor culturing techniques and genetic tools. *C. jejuni* was successfully isolated in the early 1970s, utilizing specialty agar and microaerophilic atmospheric conditions. Since its isolation, it has been connected with bacterial gastroenteritis as well as the neurological disorders Guillen-Barré Syndrome and Fisher Syndrome in humans. It is now one of the leading causes of gastroenteritis in both the developed and developing worlds. (Young et al., 2007).

C. jejuni is a fastidious organism, requiring modified atmospheric conditions, a longer growing time, a narrow temperature range, and specialized media when compared to such bacteria as *E. coli*. All these factors must be taken into consideration when working with *C. jejuni.*

STRATEGIC PLANNING

Atmosphere

Campylobacter jejuni requires microaerophilic conditions for growth. Optimum growth is maintained in a tri-gas incubator (e.g., Thermo Forma Series II Water-Jacketed CO_2 Incubator), with 85% N_2, 10% CO_2, and 5% O_2. If a tri-gas incubator is unavailable, specific gas packs (i.e., BBL Campy Pak Plus) or formulated compressed air can be applied with sealable gas chambers or plastic bags, respectively. Gas packs are expensive, and growth in plastic bags is suboptimal compared to that obtained by using a tri-gas incubator. Notes concerning the differences are in the specific protocols outlined. *C. jejuni* is also able to grow in anaerobic conditions.

Temperature

C. jejuni has a narrow temperature range of growth, with optimum growth occurring between 37° and 42°C. The bacteria are able to survive at 7°C and perform vital cellular processes such as protein synthesis; however, growth and recovery at low temperatures

Current Protocols in Microbiology 8A.1.1-8A.1.7, August 2008
Published online August 2008 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/9780471729259.mc08a01s10

is difficult (Hazeleger et al., 1998). Significant loss of viable bacteria occurs when the bacteria are left at room temperature and atmosphere for only 10 min. Therefore, when working with *C. jejuni*, the amount of time the bacteria are out of incubators and microaerophilic atmosphere must be limited.

Media

Many types of media have been used to culture *C. jejuni*. Mueller-Hinton medium, blood agar, Columbia blood agar, and BBL medium are commonly used. However, Mueller Hinton (MH) has the highest recovery rate and is recommended in this unit (Ng et al., 1985). *Campylobacter* defined medium was developed by Leach and colleagues (Leach, 1997). Although a minimal medium has not been developed that supports *C. jejuni* growth, the defined medium can be used to adjust components based on experimental needs.

Growth Conditions

C. jejuni can grow in both static and shaking broth cultures. The stringent growth conditions do not lend themselves well to a shaking apparatus. Some tri-gas incubators are equipped to have an internal shaker; however, most are not, and the gas packs in bags or jars do not always allow shaking conditions. *C. jejuni* grown in shaking cultures grow faster than those in static culture. Aggregates form when *C. jejuni* is grown in static broth (Joshua et al., 2006). This aggregation phenotype has been studied extensively, and several genes involved in this have been identified. Based on availability, the protocols suggested in this unit use static growth as the standard.

Strain Selection

Several isolates of *C. jejuni* have been used in previous research (Table 8A.1.1). Strain selection is important, and depends upon the proposed research. Strains have been isolated from chicken, human, and environmental sources. Phenotypic variation among strains from varying sources has been observed for many traits including invasion, cytolethal distending toxin (cdt) production, chick colonization, lipooligosaccharide (LOS)

Table 8A.1.1 Most Commonly Used *C. jejuni* Strains[a]

	Sources	Sequences	Notes
260.94	Human	N	GBS[b]-associated; O:41 serotype
480	Human	N	Electrocompetent; highly invasive
811681116	Human	N	Lab strain
11168	Human	Y	Gaynor (2004)
81-176	Human	Y	Contains pVir, highly virulent (Bacon, 2000)

RM1221	Human	Y	—

[a]The most commonly used isolates of *C. jejuni* are listed here, including their source of isolation and whether their genome has been sequenced to date. Strains can be acquired from individual labs working on the particular isolate.
[b]GBS, Guillain-Barré Syndrome.

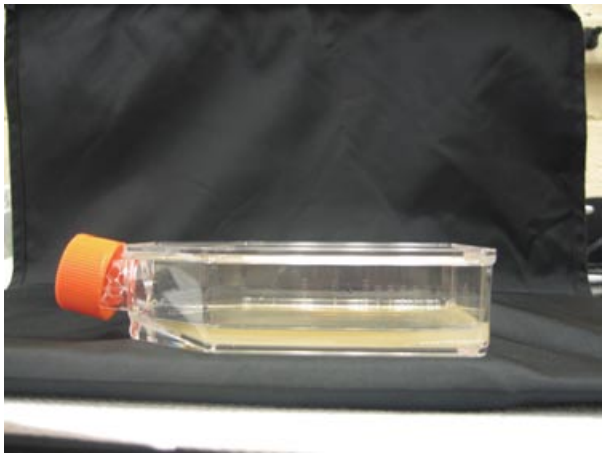

Figure 8A.1.1 Preparation of biphasic medium. In a 75-cm^2 tissue culture flask, 20 ml of MH agar were poured and solidified, followed by 20 ml of MH broth.

production, and natural transformation. The ability of *C. jejuni* to undergo natural transformation has led to a high degree of horizontal gene transfer between *C. jejuni* strains, leading to high genetic diversity among *C. jejuni* strains. *C. jejuni* strains 81-176 and 11168 are well characterized strains, and the most commonly used in pathogenesis studies.

Growth Curves

Mueller Hinton agar is the recommended medium for standard growth curves of *C. jejuni*. Biphasic MH medium, prepared in tissue culture flasks (Fig. 8A.1.1), is the classic way to perform growth curves. The biphasic medium is made using 50% MH agar and 50% MH (poured after the agar solidifies). Note that MH agar should never be microwaved for *C. jejuni* agar plates and biphasic media.

Biphasic medium is recommended for growing conditions outside of a tri-gas incubator, such as in bags or sealed containers. If a tri-gas incubator is used, growth curves can be performed in MH broth alone. However, no volume below 1 ml should be used, due to poor recovery and inconsistent growth.

Each time point should be an individual sample. Static growth of *C. jejuni* results in aggregative bacterial raft formation, and disruption of this growth has led to variable and inconsistent growth. Therefore, each time-point should be separate and undisturbed. Furthermore, each time-point should be done in triplicate to obtain a statistically significant average. Growth curves are normally performed for 36 or 48 hr.

The inoculum for a growth curve is 1×10^6 cfu/ml. From 16- to 18-hr plates, *C. jejuni* should be resuspended to an OD_{600} of 0.4. Dilute this suspension 1:10. Inoculate 80 µl of this dilution into 20 ml of medium. A standard growth curve, measured in cfu/ml over 48 hr, is shown in Figure 8A.1.2.

CAUTION: Campylobacter jejuni is a Biosafety Level 2 (BSL-2) pathogen. Follow appropriate guidelines and regulations for the handling of pathogenic microorganisms. Proper hand washing is essential, as *C. jejuni* has been shown to cause gastroenteritis at a small dose (10 to 100 organisms). See *UNIT 1A.1* and other pertinent resources for more information.

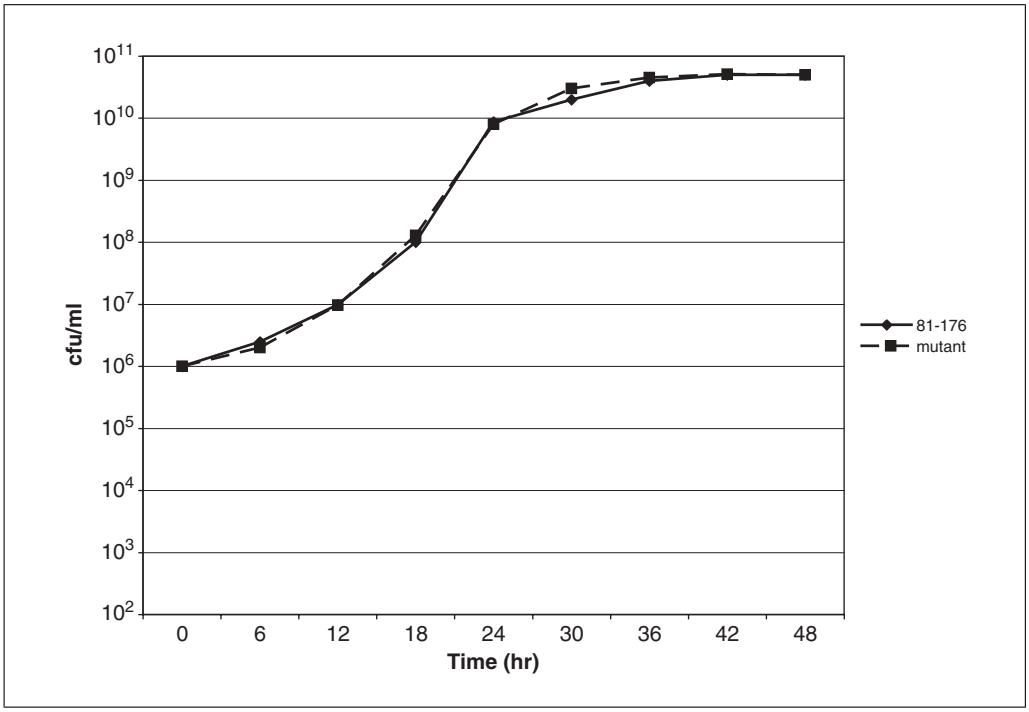

Figure 8A.1.2 Growth curve in biphasic medium of two different isolates of *C. jejuni* 81-176.

BASIC PROTOCOL 1

GROWTH OF *C. JEJUNI* FROM A FROZEN STOCK

C. jejuni is ill equipped for adjusting to changing environments in the lab, especially after being taken out of the freezer. The protocol below supports the best usable *C. jejuni* growth from frozen stocks. Time for growth depends on atmospheric conditions. The protocol outlined below uses Mueller Hinton (MH) broth or MH agar containing 10 μg/ml trimethoprim (TMP) for growing strain 81-176 in a tri-gas incubator. Selective antibiotics can be added to the medium; concentrations commonly used for culturing of and cloning in *C. jejuni* are listed in Table 8A.1.2.

Materials

C. jejuni frozen stock (Basic Protocol 2)
100 × 15–mm Mueller Hinton (MH) agar plates (BD Biosciences, cat. no. 22520; plates are poured in lab) containing 10 μg/ml trimethoprim (antibiotics added in lab)
Mueller Hinton (MH) broth (BD Biosciences, cat. no. 275730) containing 10 μg/ml trimethoprim
Equipment for maintaining *Campylobacter*-specific microaerophilic atmosphere (see Strategic Planning)

Additional reagents and equipment for streaking bacteria (*APPENDIX 4A*)

1. From frozen stock (in MH broth plus 20% glycerol; see Basic Protocol 2), heavily streak out *C. jejuni* strain on 100 × 15–mm Mueller Hinton agar plates containing 10 μg/ml trimethoprim. Grow for 16 to 20 hr in microaerophilic conditions (see Strategic Planning).

   Growth in a tri-gas incubator allows more rapid growth, while bag plating may require up to 48 hr of growth. See Strategic Planning for additional discussion of atmospheric conditions required for growing C. jejuni.

   Streaking of bacteria on agar plates is described in APPENDIX 4A.

Table 8A.1.2 Concentrations of Antibiotics Used in *C. jejuni* Research

Antibiotic	Concentration
Kanamycin	50 μg/ml
Chloramphenicol	15-20 μg/ml
Streptomycin	100 μg/ml to 2 mg/ml
Trimethoprim	10 μg/ml
Cefoperazone	20 μg/ml
Nalidixic acid	30 μg/ml
Tetracycline	12.5 μg/ml

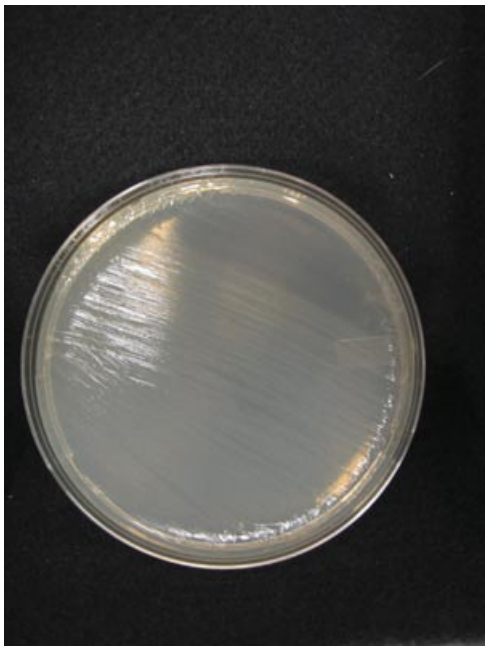

Figure 8A.1.3 Growth of *C. jejuni* 81-176 on an Mueller Hinton agar plate containing 10 μg/ml trimethoprim after 24 hr in a tri-gas incubator.

2. Restreak *C. jejuni* onto a new Mueller Hinton plate containing 10 μg/ml trimethoprim. Grow for 16 to 20 hr in microaerophilic conditions.

   Single colonies will not be observed until culture has been incubated >24 hr. Scrape up a large amount of cells from the lawn (see Figure 8A.1.3).

   After this incubation, C. jejuni is ready to be used.

   For single colonies, streak for isolated colonies on plates and grow for 48 hr or until individual colonies are observed.

3. *Optional:* If large amounts are needed, restreak a heavy inoculum onto several Mueller Hinton plates containing 10 μg/ml trimethoprim or inoculate into Mueller Hinton broth containing 10 μg/ml trimethoprim.

4. *Optional:* Passage *C. jejuni* an additional two to three times.

   Further passages from frozen stock are not recommended.

PRESERVATION OF *C. JEJUNI*

Stocks of *C. jejuni* should be kept in 20% glycerol stocks, stored at −80°C. Incubations can be performed in a tri-gas incubator or in the other recommended conditions at 37°C.

Materials

C. jejuni organisms (cannot be purchased from ATCC or similar sources; must be obtained from individual labs)
100 × 15–mm Mueller Hinton (MH) agar plates (BD Biosciences, cat. no. 22520; plates are poured in lab) containing 10 μg/ml trimethoprim (antibiotics added in lab)
Mueller Hinton (MH) broth (BD Biosciences, cat. no. 275730) containing 20% (v/v) glycerol

Sterile cotton swabs
2-ml cryotubes

1. Heavily streak out *C. jejuni* strain on an MH agar plate containing 10 μg/ml trimethoprim. Grow for 18 to 20 hr.

   After making a mutant (see UNIT 8A.2), streak for single colonies, which takes 36 to 48 hr. Pick a single colony and streak out. Finally, restreak it heavily onto a MH agar plate and carry out the following steps to preserve.

2. Swab bacteria using a sterile cotton swab from plate.

   C. jejuni will appear a pink-peach color (Fig. 8A.1.3).

3. Transfer a sufficient quantity of bacteria to 1.5 ml of Mueller Hinton broth containing 20% (v/v) glycerol in a 2-ml cryotube. Immediately freeze at –80°C.

   The frozen stock should contain a large amount of bacteria; roughly an OD_{600} of 1.5 or more

4. Never thaw frozen stocks. Instead, scrape off an ice chip from the frozen stock using a sterile implement and plate directly onto MH agar plates containing 10 μg/ml trimethoprim.

COMMENTARY

Background Information

Campylobacter jejuni is the causative agent of campylobacteriosis, a self-limiting gastroenteritis. It is one of the major causes of bacterial-associated gastroenteritis in the United States. *C. jejuni* has also been linked to Guillain-Barré Syndrome (GBS), an acute autoimmune neuropathy resulting in flaccid paralysis. Research on *C. jejuni* has been greatly impaired due to poor culturing techniques and genetic tools. *C. jejuni* was successfully isolated in the early 1970s, utilizing specialty agar and microaerophilic atmospheric conditions. Originally thought to be primarily a pathogen of animals, *C. jejuni* is now considered one of the main causes of foodborne bacterial gastroenteritis in humans. The original culturing techniques have expanded to include a number of types of media that *C. jejuni* can use. Although *C. jejuni* is a fastidious organism, its manipulation has become more standardized in recent years. A narrow temperature range, specific media, and specific atmospheric conditions must all be taken into account when growing *C. jejuni.*

Critical Parameters and Troubleshooting

If no growth is seen from the initial streaking of the frozen stock, or from subsequent re-streaks, the inoculum size or selective antibiotics may be the problem. Try to inoculate the plates with a larger amount of bacteria. A usual amount of frozen stock to be struck out is a chunk of frozen sample the size of a grain of rice. Due to the quantity of passages and relatively short bench life of *C. jejuni*, it is recommended that two sets of frozen stocks be kept with highly used strains: a backup stock and a frequently used stock. This will help diminish the possibility of contamination.

Anticipated Results

A large inoculum of frozen stock of *C. jejuni* 81-176 should grow after 18 to 24 hr. The growth will appear as a hazy lawn. The bacteria will have a pinkish-cream color when scraping the cells from the plate. After re-streaking from the overnight plate, growth of *C. jejuni* 81-176 should be observed after 18 to 20 hr. The growth will be hazy. To isolate single colonies, streak for isolation and allow growth for 48 hr.

Time Considerations

Following the protocol, large amounts of viable *C. jejuni* will be available after 36 to 48 hr in a tri-gas incubator. If gas jars are used, growth will be slower, with usable growth appearing after 40 to 48 hr, depending on the amount being streaked.

Freezing a newly constructed *C. jejuni* strain may take 4 to 5 days. Streak from a single colony. Growth will be visible after 48 hr. Heavily restreak the growth onto a new MH agar plate and incubate for another 24 to 36 hr.

Genetic Manipulation of *Campylobacter jejuni*

Lindsay Davis,[1] Kathryn Young,[1] and Victor DiRita[1, 2]

[1]Department of Microbiology and Immunology, University of Michigan, Ann Arbor, Michigan
[2]Unit for Laboratory Animal Medicine, University of Michigan, Ann Arbor, Michigan

ABSTRACT

Molecular manipulation has been a limiting factor in *C. jejuni* research for many years. Recent advances in molecular techniques adapted for *C. jejuni* have furthered our understanding of the organism. This unit is dedicated to common molecular tools in bacterial research specifically tailored for *C. jejuni*. These include colony PCR, DNA isolation, and RNA isolation. The unit also reviews techniques for genetic manipulation, such as the use of plasmids, natural transformation, electroporation, conjugation, and transposition. In addition, a reporter system, the arylsulfatase assay, can be used to study gene expression. *Curr. Protoc. Microbiol.* 10:8A.2.1-8A.2.17. © 2008 by John Wiley & Sons, Inc.

Keywords: natural transformation • arylsulfatase • genomic DNA • RNA isolation

INTRODUCTION

Molecular biology has been a limiting factor in *C. jejuni* research. Indigenous plasmids are commonly used for cloning and expression vectors. *C. jejuni* is most efficiently transformed by plasmid DNA from its own species, thereby limiting the ease of genetic manipulation. Mutations are produced in *C. jejuni* using allelic replacement via suicide plasmids. Because these methods are described elsewhere (see Hendrixson et al., 2001, for a strategy that works well for *C. jejuni*), we will not discuss them in this unit, which will focus on moving plasmids into *C. jejuni* by conjugation (Basic Protocol 1), electroporation (Basic Protocol 2), and natural transformation (Basic Protocol 3). Numerous plasmids have been developed for *C. jejuni* research and may be used in lieu of specific plasmids described here. However, those discussed (see Table 8A.2.1) are commonly used and have proven successful in many studies. An inducible expression plasmid has yet to be developed for *C. jejuni*.

Table 8A.2.1 Commonly Used Plasmids

	Stable in *C. jejuni*	Source	Notes	Antibiotic resistance	Mobilizable with pRK212.1?	Source

This unit also outlines several common molecular techniques for bacterial studies that have been adapted for *C. jejuni*. Common techniques include transposition (Basic Protocol 4), colony PCR (Basic Protocol 5), isolation of DNA (Basic Protocol 6) and RNA (Basic Protocol 7 and Alternate Protocol), and an arylsulfatase assay used as a reporter for *C. jejuni* gene expression studies (Basic Protocol 8).

The sequencing of genomes of several *C. jejuni* strains, as well as the development of a variety of genetic tools for use in *C. jejuni*, have provided the opportunity for rapid expansion in the knowledge of the biology of this organism. The protocols outlined in this unit, combined with genome sequence data, can be used to make and complement in-frame deletions, create libraries of transposon mutants, and study gene expression using gene fusions and techniques such as microarrays and qRT-PCR.

CAUTION: Campylobacter jejuni is a Biosafety Level 2 (BSL-2) pathogen. Follow appropriate guidelines and regulation for the handling of pathogenic microorganisms. Proper hand washing is essential because *C. jejuni* has been shown to cause gastroenteritis at a small dose (10 to 100 organisms). See *UNIT 1A.1* and other pertinent resources for more information.

NOTE: Incubations are performed at 37°C in a tri-gas incubator, as recommended in *UNIT 8A.1*.

BASIC PROTOCOL 1

CONJUGATION OF *C. JEJUNI* AND *E. COLI*

One method of moving DNA into *C. jejuni* is through conjugation. Conjugation is the transfer of DNA between bacteria though direct cell-to-cell contact. *E. coli* strains carrying the mobilization plasmid pRK212.1 are able to conjugate with *C. jejuni*. This technique is useful for incorporating replicating plasmids, such as pECO101, pECO102, pRY468pRY109, and pRY112 into *C. jejuni* (Yao et al., 1993; Wiesner et al., 2003). This protocol is modified from one used by the laboratory of Dr. Pat Guerry, Uniformed Service University (pers. comm.).

Materials

DNA fragment of interest
C. jejuni plasmid (e.g., pRY108 or pECO101; also see Table 8A.2.1)
Donor strain: *E. coli* DH5α [pRK212.1]
LB agar plates with appropriate selective antibiotics (*APPENDIX 4A*)
Recipient strain: *C. jejuni* (*UNIT 8A.1*)
Mueller Hinton (MH) agar plates, with and without appropriate selective antibiotics (BD Biosciences)
LB liquid medium with appropriate selective antibiotics (*APPENDIX 4A*)
Mueller Hinton (MH) broth without antibiotics (BD Biosciences)

Additional reagents and equipment for cloning of DNA (Struhl, 2000), introduction of plasmid DNA into *E. coli* (Seidman et al., 1997), growth of *E. coli* on solid medium (Elbing and Brent, 2002a) and in liquid medium (Elbing and Brent, 2002b), and growth of *C. jejuni* (*UNIT 8A.1*)

Construct E. coli donor strain

1. Clone fragment to be maintained in *C. jejuni* plasmid (i.e., pRY108, pECO101).

   Struhl (2000) contains protocols for cloning of DNA fragments.

2. Move plasmid into *E. coli* DH5α [pRK212.1].

   Seidman et al. (1997) describe methods for introducing plasmid DNA into E. coli cells.

3. Grow the transformed *E. coli* (Elbing and Brent, 2002a) on LB plates containing selection antibiotics: ampicillin (100 μg/ml), tetracycline (12.5 μg/ml), and plasmid-specific antibiotic (e.g., kanamycin, chloramphenicol).

   Chloramphenicol would be used with pECO102.

Conjugate E. coli donor strain into C. jejuni

4. Grow recipient strain on MH agar with appropriate antibiotics.

   C. jejuni can be selected for resistance to streptomycin, which does not alter its ability to colonize natural host models or to cause disease in the ferret model. The streptomycin resistance phenotype provides a counter-selectable marker for use in these conjugation experiments. Concentrations of antibiotics used in C. jejuni media are listed in Table 8A.1.2. It is also possible to select for C. jejuni using trimethoprim (10 μg/ml) or cefoperazone.

5. Streak *C. jejuni* recipient strain onto MH plate with appropriate antibiotics for 16 to 20 hr at 37°C in microaerophilic conditions (*UNIT 8A.2*). Start an overnight culture of the *E. coli* donor strain in LB liquid medium with appropriate antibiotics.

6. Inoculate 5 ml LB liquid medium containing selective antibiotic for the plasmid with 375 μl of the overnight culture of the donor strain prepared in step 5. Incubate at 37°C while shaking until $OD_{600} = 0.45$ to 0.5.

7. Resuspend recipient *C. jejuni* strain from the 16- to 20-hr plates (step 5) in 1.8 ml MH broth without antibiotics to an OD of ∼1.0.

8. Wash 0.5 ml of the donor strain culture from step 6 once by microcentrifuging 5 min at 10,000 × *g*, 4°C, removing the supernatant, adding 10 ml MH broth without antibiotics, then centrifuging again as before and removing the supernatant to eliminate any antibiotics. Resuspend donor pellet with 1 ml of *C. jejuni* recipient strain suspension.

9. Spin bacterial mixture for 2 min at full speed in microcentrifuge, and remove supernatant.

10. Resuspend cells in 100 μl MH broth without antibiotics. Spot onto an MH plate without any antibiotics.

11. Incubate plate organism-side-up at 37°C in microaerophilic conditions (*UNIT 8A.1*) for 5 hr.

12. Resuspend bacteria from plate in 1.8 ml MH broth. Pellet bacteria by centrifuging 5 min at 10,000 × *g*, 4°C, and removing the supernatant.

13. Spread bacteria on MH agar with 10 μg/ml trimethoprim (TMP), 20 μg/ml cefoperazone, 2 mg/ml streptomycin, and an antibiotic for selection of plasmid.

14. Incubate for 4 to 5 days at 37°C in microaerophilic conditions (*UNIT 8A.1*).

ELECTROPORATION OF *C. JEJUNI*

BASIC PROTOCOL 2

Electroporation of bacteria involves the application of electrical current to the bacterial cells, which permeabilizes the membrane, allowing uptake of DNA from the environment. This technique is primarily used for the incorporation of plasmid DNA. This technique was first described for *C. jejuni* by Miller et al. (1988). Electroporation of *C. jejuni* is primarily done to incorporate DNA from suicide plasmids into the chromosome of *C. jejuni*. Electroporation is useful for this because plasmids derived from *E. coli* will not transform well into *C. jejuni* by natural transformation.

Materials

C. jejuni frozen stock (*UNIT 8A.1*)
Mueller Hinton (MH) agar plates with appropriate selective antibiotics (BD Biosciences)
Mueller Hinton (MH) broth without antibiotics (BD Biosciences)
Wash buffer: 15% (v/v) glycerol/9% (w/v) sucrose
DNA of interest, to be electroporated into *C. jejuni* (15 μg DNA/reaction)
SOC medium (see recipe)

Nitrocellulose membrane (0.025-μm pore size VSWP (Millipore, cat. no. VSWP04700)
Electroporation cuvettes (BioRad Gene Pulser Cuvettes, 0.2-cm electrode; cat. no. 165-2006)
Electroporator (BioRad *E. coli* Pulser)

Additional reagents and equipment for streaking bacteria (*APPENDIX 4A*) and growing *C. jejuni* (*UNIT 8A.1*)

Grow C. jejuni

1. Streak strain (*APPENDIX 4A*) from frozen stock onto one MH agar plate containing 10 μg/ml trimethoprim (TMP). Grow for 24 hr at 37°C under microaerophilic conditions (*UNIT 8A.1*).

2. Restreak strain onto one MH agar plate containing 10 μg/ml TMP, using a heavy inoculum. Grow for 16 hr at 37°C under microaerophilic conditions (*UNIT 8A.1*).

Prepare electrocompetent C. jejuni cells

3. Resuspend bacteria in 1.8 ml MH broth (without antibiotics) using an automatic pipettor and 1-ml pipet tip by pipetting 900 μl of broth up and down across the overnight lawn of bacteria.

4. Pellet bacteria by microcentrifugation for 5 min at maximum speed, 4°C.

5. Gently resuspend pellet in 2 ml ice-cold wash buffer.

6. Pellet bacteria by centrifugation for 5 min at full speed in microcentrifuge at 4°C

7. Repeat steps 5 and 6 three times.

8. Resuspend pellet in 900 μl ice-cold wash buffer. Use immediately (keep cold on ice).

Perform electroporation

9. For large volumes (>5 μl) of DNA that have been prepared in TE buffer, dialyze DNA on top of a nitrocellulose membrane floating in 20 ml distilled deionized water for 20 min.

10. Cool electroporation cuvettes on ice.

11. In a microcentrifuge tube, combine 50 μl electrocompetent bacteria (from step 8) and 15 μg DNA. Keep on ice.

12. Transfer bacteria-DNA mix to an electroporation cuvette. Electroporate the sample at 2.5 kV, 200 Ω, and 25 μF.

    The time constant is usually ~5 msec.

13. Flush cuvette with 100 μl SOC medium. Spread bacteria onto MH agar plate containing 10 μg/ml TMP.

14. Incubate plate for 5 hr at 37°C under microaerophilic conditions (*UNIT 8A.1*).

15. Harvest bacteria by resuspending in 1.8 ml of MH broth without antibiotics. Microcentrifuge bacteria for 2 min at maximum speed and remove supernatant. Resuspend bacteria in 100 μl MH broth. Plate onto MH agar containing the appropriate selective antibiotics.

16. Incubate for 2 to 4 days at 37°C in microaerophilic atmosphere (*UNIT 8A.1*).

NATURAL TRANSFORMATION OF *C. JEJUNI*

BASIC PROTOCOL 3

C. jejuni is naturally transformable, meaning that it readily takes up DNA from the environment. Natural transformation can lead to genetic diversity within a population. It is also a useful tool for molecular biology in bacteria. This technique is useful in *C. jejuni* for the uptake of its own DNA, but not foreign DNA (i.e., *E. coli* derived) from the environment (Wang and Taylor, 1990; Wiesner et al., 2003).

Materials

C. jejuni frozen stock (*UNIT 8A.1*)
Mueller Hinton (MH) agar plates with and without appropriate selective antibiotics (BD Biosciences)
Mueller Hinton (MH) broth without antibiotics (BD Biosciences)
DNA of interest, to be transformed into *C. jejuni* (*C. jejuni* genomic DNA prepared as in Basic Protocol 6)

Additional reagents and equipment for streaking bacteria (*APPENDIX 4A*) and growing *C. jejuni* (*UNIT 8A.1*)

Grow C. jejuni

1. From frozen stock, streak strain (*APPENDIX 4A*) onto MH agar containing 10 μg/ml trimethoprim (TMP). Grow for 16 to 24 hr at 37°C under microaerophilic conditions (*UNIT 8A.1*).

2. From the 16 to 24 hr growth plate, streak strain onto MH agar containing 10 μg/ml TMP, using a heavy inoculum. Streak plates ~16 hr before the start of the transformation experiment.

3. Make fresh MH agar (without antibiotics) and pipet 1-ml aliquots into plastic tubes.

4. Resuspend the entire growth from the 16-hr plate (from step 2) in 1 ml MH broth (without antibiotics).

Perform transformation

5. Dilute the bacteria to an OD_{600} of 0.5 (~1×10^9 cfu/ml) with MH broth (without antibiotics).

6. Add 0.5 ml resuspended bacteria to each tube (from step 3) containing 1 ml of solidified MH agar. Incubate tubes for 3 hr at 37°C in microaerophilic conditions (*UNIT 8A.1*).

7. Gently mix tubes.

8. Add 5 to 10 μg of the DNA to be transformed to each tube and pipet up and down.

9. Incubate for 4 hr at 37°C in microaerophilic conditions (*UNIT 8A.1*).

10. Transfer bacteria into a microcentrifuge tube. Microcentrifuge for 2 min at maximum speed, room temperature.

11. Resuspend bacteria and plate onto MH agar containing 10 μg/ml TMP and appropriate selection antibiotics.

12. Incubate plates at 37°C in microaerophilic environment (*UNIT 8A.1*) for 2 to 4 days.

TRANSPOSON MUTAGENESIS OF *C. JEJUNI*

Transposons are DNA elements that can insert themselves relatively randomly throughout the genome. Transposon mutagenesis of *C. jejuni* has been a widely accepted tool for genetic manipulation, and this method has identified a number of *C. jejuni* genes needed for colonization and motility (Golden et al., 2000; Hendrixson et al., 2001) A number of transposons have been developed for *C. jejuni*. This section will outline the protocol for in vitro transposition of *C. jejuni* with a mariner-based transposon (Lampe et al., 1999; Hendrixson, 2001). An alternative, pOTHM, is also a mariner-based transposon method, and specifics on that system can be found in Golden et al. (2000). The delivery plasmids and corresponding transposons used in previous studies are listed in Table 8A.2.2.

Materials

5× salt buffer (see recipe)10 mg/ml bovine serum albumin (BSA)
100 mM dithiothreitol (DTT)
Donor DNA (containing transposon)
Recipient DNA (containing target of mutagenesis *or* total *C. jejuni* genomic DNA prepared as in Basic Protocol 6)
Transposase: (available from Dr. David Lampe (Lampe et al., 1999)
TE buffer, pH 8.0 (*APPENDIX 2A*)
dNTP mix: 1.25 mM each dNTP (*APPENDIX 2A*)
T4 DNA polymerase and T4 DNA polymerase buffer (Invitrogen)
T4 ligase and T4 ligase buffer (Invitrogen)
30° and 70°C water baths and 11° and 16°C recirculating water baths (or thermal cycler)
Nitrocellulose membrane (0.025 μm pore size VSWP (Millipore, cat. no. VSWP04700)
Additional reagents and equipment for phenol:chloroform extraction and ethanol precipitation of DNA (Moore and Dowhan, 2002)

Perform transposition reaction

1. Prepare transposition reaction by combining the following:

   16.0 μl 5× salt buffer
   2.0 μl 10 mg/ml BSA
   1.6 μl 100 mM DTT
   1.0 μg donor DNA
   2.0 μg recipient DNA
   500 ng transposase
   Distilled deionized H_2O to 80 μl
   Incubate reactions at 30°C for 4 hr.

Table 8A.2.2 Transposons

Plasmid	Transposon	Transposase	Reference
pFD1	HImar1	Himar1	Rubin et al. (1999); Kakuda and DiRita (2006)
pEnterprise	picard	Himar1	Hendrixson et al. (2001) or Hendrixson and DiRita (2004)
pFalcon	Solo	Himar1	Hendrixson et al. (2001) or Hendrixson and DiRita (2004)
pOTHM	Mariner	Himar1	Golden et al. (2000)

Purify DNA

2. Extract DNA once with phenol:chloroform, then ethanol precipitate DNA (Moore and Dowhan, 2002).
3. Microcentrifuge DNA 30 min at maximum speed, 4°C.
4. Remove supernatant and resuspend pellet in 40 μl TE buffer, pH 8.0.

Perform repair reactions

The repair reactions are necessary to repair small gaps at the transposon-chromosomal junctions. The first reaction (step 5) fills in the gaps, while the ligase reaction (step 8) completes repair.

5. Prepare first repair reaction by combining the following on ice (total volume, 60 μl):

   40 μl DNA from transposition reaction
   6 μl T4 DNA polymerase buffer
   4.8 μl dNTP mix
   7.7 μl distilled H_2O
   1.5 μl 1 U/μl T4 DNA polymerase.

6. Incubate the reaction at 11°C for 20 min in a recirculating water bath or thermal cycler.
7. Inactivate the polymerase by incubating the reaction at 75°C for 15 min.
8. Prepare second repair reaction by combining the following on ice:

   60 μl reaction mixture from first repair reaction (step 5)
   12 μl T4 DNA ligase buffer
   1.5 μl T4 DNA ligase
   46.5 μl dH_2O.

9. Incubate at 16°C overnight in a recirculating water bath or thermal cycler.

Use DNA for transformation

10. Dialyze DNA on top of a nitrocellulose membrane floating on 10 to 20 ml distilled deionized water for 20 min.
11. Use all of the reaction for one transformation of *C. jejuni* (see Basic Protocol 3).

PREPARATION OF *C. JEJUNI* TEMPLATE FOR COLONY PCR

BASIC PROTOCOL 5

Colony PCR is a useful tool to screen for newly constructed mutants. Individual colonies take 3 to 5 days to grow on MH agar containing 10 μg/ml TMP in microaerophilic conditions at 37°C. Once individual colonies are visible, colony PCR can be used to confirm any mutations made. The *C. jejuni* DNA preparation for PCR requires boiling the *C. jejuni* strain in K buffer. This is done by spotting the isolated colony onto a fresh plate, then resuspending the colony in K buffer and incubating the sample at 100°C.

Materials

Proteinase K
K buffer (see recipe)
100°C water bath

Additional reagents and equipment for PCR (Kramer and Coen, 2001)

1. Add proteinase K to a final concentration of 100 μl/ml in K buffer immediately before use.

2. Resuspend one or two isolated colonies in this 100 μl of K buffer containing proteinase K, using a toothpick or a similar implement.

   Spot the individual colonies onto a fresh plate of MH agar containing 10 μg/ml TMP before resuspending in K buffer and keep in microaerophilic conditions at 37°C to preserve the colonies. Individual colonies will take 3 to 5 days to grow on MH agar containing 10 μg/ml TMP in a tri-gas incubator. See UNIT 8A.1 for further information.

3. Place in 100°C water bath for 10 min.

4. Microcentrifuge 5 min at 10,000 rpm to remove cell debris.

5. Use 2 to 5 μl of the supernatant for 50-μl PCR reactions.

BASIC PROTOCOL 6

ISOLATION OF *C. JEJUNI* GENOMIC DNA

Isolated bacterial DNA can be used for a multitude of purposes, such as cloning of specific genes by PCR, sequencing, or transposon mutagenesis. Although kits such as Qiagen's Genomic DNA Isolation Kit can be utilized, higher yields of genomic DNA are achieved by using the protocol outlined here.

Materials

C. jejuni frozen stock (*UNIT 8A.1*)
Mueller Hinton (MH) agar plates (BD Biosciences) with 10 μg/ml trimethoprim (TMP)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
10 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)/0.1 mM EDTA
10 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)/0.1 mM EDTA containing 1 mg/ml lysozyme
Proteinase K
20% (w/v) SDS (*APPENDIX 2A*)
Buffered phenol (*APPENDIX 2A*)
24:1 chloroform:isoamyl alcohol
7.5 M ammonium acetate
Isopropanol
70% (v/v) ethanol
1 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)/0.1 mM EDTA
Filter paper (Whatman)

Additional reagents and equipment for growing *C. jejuni* (*UNIT 8A.1*) and phenol/chloroform extraction of DNA (Moore and Dowhan, 2002)

Days 1 and 2: Grow C. jejuni

1. From a frozen stock, streak strain onto MH with 10 μg/ml trimethoprim (TMP) agar. Grow for 16 to 24 hr at 37°C under microaerophilic conditions (*UNIT 8A.1*).

2. From the 16- to 24-hr growth plate incubated in step 1, restreak strain onto one plate of MH agar containing 10 μg/ml TMP, using a heavy inoculum. Incubate 18 hr at 37°C under microaerophilic conditions (*UNIT 8A.1*).

Day 3: Isolate and purify DNA from C. jejuni

3. Resuspend *C. jejuni* from 18-hr growth plate in PBS and microcentrifuge 5 min at 10,000 rpm, 4°C.

4. Remove supernatant and resuspend pellet in 200 μl of 10 mM Tris·Cl, pH 8.0/0.1 mM EDTA.

5. Add 400 μl of 10 mM Tris·Cl, pH 8.0/0.1 mM EDTA, containing 1 mg/ml lysozyme.

6. Incubate on ice for 5 min.

7. Add proteinase K to 20 μg/ml and mix gently.

8. Add 50 µl 20% SDS. Mix gently to clear the lysate.
9. Incubate with gentle rocking at 37°C for 30 min.
10. Add 200 µl buffered phenol. Vortex and microcentrifuge 5 min at 12,000 rpm, room temperature.

    Phenol extraction may have to be repeated a couple more times by transferring the aqueous (upper) phase to a fresh tube and adding more phenol. When the phases separate well and quickly, further phenol extractions are unnecessary.

    Additional detail on phenol/chloroform extraction of DNA is found in Moore and Dowhan (2002).
11. Extract twice with 24:1 chloroform:isoamyl alcohol.
12. Add 0.5 vol of 7.5 M ammonium acetate and mix. Fill tube with isopropanol.
13. Mix well. Allow DNA to precipitate at −80°C for at least 1 hr.
14. Collect DNA by microcentrifuging 10 min at 12,000 rpm, 4°C.
15. Carefully decant isopropanol and rinse pellet twice with 70% ethanol. Microcentrifuge 5 min at 12,000 rpm, 4°C.
16. Carefully pour off the last wash, and wick out the remaining ethanol with Whatman filter paper. Dry the pellet under vacuum in a Speedvac evaporator for about 5 min.
17. Resuspend pellet in 300 µl of 1 mM Tris·Cl, pH 7.5/0.1 mM EDTA.

    Resuspension should be allowed to take place overnight. If necessary, pipet with a large-orifice genomic tip.

ISOLATION OF RNA FROM *C. JEJUNI*

BASIC PROTOCOL 7

The protocol outlined below is a variation on the RNeasy protocol. It was modified from a procedure recommended by Drs. Nick Dorrell and Brendan Wren, London School of Hygiene and Tropical Medicine (pers. comm.). As with all RNA work, everything must be RNase-free. Clean the bench and pipets with ethanol and RNase-eliminating solutions, such as Eliminase, before starting. Make sure all solutions are prepared using RNase-free reagents and RNase-free water.

Materials

C. jejuni frozen stock (*UNIT 8A.1*)
Mueller Hinton (MH) agar plates (BD Biosciences) with 10 µg/ml trimethoprim (TMP)
Mueller Hinton (MH) broth (BD Biosciences) with 10 µg/ml trimethoprim (TMP)
RNA Protect Bacteria Reagent (Qiagen)
TE buffer, pH 8.0 (*APPENDIX 2A*) containing 1 mg/ml lysozyme
RNeasy kit (Qiagen) including:
  Buffer RLT
  Buffer RW1
  Buffer RPE
  RNA Mini Spin columns
  2-ml collection tubes
  RNase-free H_2O
2-mercaptoethanol (2-ME)
100% ethanol, ice cold
10× DNase buffer
10 U/µl DNase (Invitrogen)
Buffered phenol (*APPENDIX 2A*)

Chloroform
3 M sodium acetate, pH 5.2 (*APPENDIX 2A*)
70% (v/v) ethanol

75-cm^2 tissue culture flask
15-ml conical centrifuge tubes
Centrifuge
Spectrophotometer

Additional reagents and equipment for growing *C. jejuni* (*UNIT 8A.1*)

Grow C. jejuni

1. Grow a full lawn of *C. jejuni* from frozen stock on one MH agar plate with 10 μg/ml trimethoprim for 16 to 20 hr.
2. Prepare a biphasic 75-cm^2 tissue culture flask (*UNIT 8A.1*; see Fig. 8A.1.1) with 20 ml MH agar and 20 ml MH broth with 10 μg/ml trimethoprim (TMP).
3. Resuspend the bacteria from the prepared overnight plate (step 1) to an OD_{600} of 0.4 in MH broth with 10 μg/ml trimethoprim (TMP).
4. Dilute the bacterial suspension 1:10 with MH broth containing 10 μg/ml trimethoprim (TMP) and inoculate 80 μl into the biphasic flask.
5. Incubate for 48 hr at 37°C in microaerophilic atmosphere (*UNIT 8A.1*).
6. Transfer 4-ml aliquots of the MH broth containing the 48-hr bacterial growth into 15 ml conical tubes.

   Due to the limitations of the RNeasy Spin Column, better yield is achieved when 4 ml of the culture is used per spin column. Multiple samples can be performed and combined prior to DNase treatment, for higher yields.

Lyse bacteria

7. Add 8 ml RNA Protect Bacteria Reagent per 4 ml of the 48 hr culture in the 15-ml conical tube. Vortex for 5 sec and incubate for 5 min at room temperature.
8. Centrifuge tubes at 10 min at 10,000 × *g*, 4°C. Decant supernatant and dab on paper towel.
9. Add 400 μl TE buffer, pH 8.0, with 1 mg/ml lysozyme to each tube and resuspend the bacteria by pipetting.
10. Incubate for 10 min at room temperature, vortexing every 2 min.

Extract and purify RNA

11. Add 1200 μl Buffer RLT and 12 μl 2-mercaptoethanol to each tube, and vortex vigorously.
12. Add 1000 μl of 100% ethanol. Mix by pipetting and transfer all to an RNeasy Mini spin column.
13. Centrifuge for 15 sec at 10,000 rpm and discard the flowthrough.
14. Repeat as required, based on volume.
15. Wash an RNeasy column by adding 350 μl Buffer RW1 onto the column, microcentrifuging 15 sec at 10,000 rpm, and discarding the flowthrough. Repeat this wash a second time.
16. Add 500 μl Buffer RPE onto the RNeasy spin column. Microcentrifuge 2 min at 10,000 rpm and discard the flowthrough.

17. Place column into fresh 2-ml collection tube and microcentrifuge for an additional 1 min at 12,000 rpm, to eliminate any remaining buffer.
18. Transfer RNeasy column into a fresh 1.5-ml microcentrifuge tube.
19. Add 50 μl RNase-free water to the RNeasy membrane in the column and centrifuge for 1 min at 10,000 rpm.
20. Combine any multiple samples done from the original 48 hr overnight culture (see step 6).
21. Dilute sample to 200 μl with RNase-free water and add 20 μl of 10× DNase buffer.
22. Add 1 μl of 10 U/μl DNase to each tube. Incubate at room temperature for 1 hr.
23. Add 220 μl of buffered phenol and vortex. Let sit for 5 min at room temperature.
24. Microcentrifuge 15 min at maximum speed, 4°C.
25. Save top layer and transfer to a new microcentrifuge tube.
26. Add 1 volume chloroform, vortex, and let sit for 5 min.
27. Microcentrifuge 15 min at maximum speed, 4°C.
28. Save top layer and transfer to a new microcentrifuge tube.
29. Precipitate RNA by adding 0.1 vol of 3 M sodium acetate pH 5.2, and 2.5 vol of ice-cold 100% ethanol.
30. Incubate at −20°C overnight (or 2 to 3 hr, minimum).
31. Spin down RNA by microcentrifuging 15 min at maximum speed, 4°C.
32. Remove supernatant, then wash pellet by adding 1 ml of 70% ethanol and microcentrifuging 7 min at maximum speed, 4°C.
33. Remove supernatant and dry pellet completely.
34. Resuspend pellet in 25 to 50 μl RNase-free water.
35. Quantitate RNA by measuring OD_{260} in a spectrophotometer and determine purification of RNA by comparing OD_{260}/OD_{280} (should be >1.8 to 2.0).

    OD_{260} = 1 is equivalent to 40 μg/ml RNA.

TWO-STEP ISOLATION OF RNA FROM *C. JEJUNI* USING TRIZOL

ALTERNATE PROTOCOL

The protocol outlined below, like Basic Protocol 7, utilizes the Qiagen RNeasy kit. However, it has a Trizol extraction preceding the RNeasy columns. The extraction step is for ∼1-4 × 10^9 cfu/ml of *C. jejuni*. The Qiagen columns can easily handle up to 1-2 × 10^{10} cfu/ml of *C. jejuni* RNA as long as it was Trizol-extracted first. This is in contrast to Basic Protocol 7, which dilutes the original 10^9 cfu/ml culture to approximately 10^7 cfu/ml of *C. jejuni*. The protocol outlined below was adapted from one used by the lab of Dr. Erin Gaynor, University of British Columbia (Gaynor et al., 2005).

Additional Materials *(also see Basic Protocol 7)*

10× stop Solution: 5% (v/v) buffered phenol (*APPENDIX 2A*) in 100% ethanol
Liquid N_2
TE buffer, pH 8.0, containing 0.4 mg/ml lysozyme
Trizol reagent (Invitrogen)
Buffer RDD from RNeasy Kit (Qiagen)

Harvest bacteria

1. Prepare a 48-hr liquid culture of *C. jejuni* as described in Basic Protocol 7, steps 1 to 5.
2. Harvest from liquid culture by centrifuging 10 min at 10,000 × *g*, 4°C, removing the supernatant, and resuspending the pellet in 1× stop solution at 1/10 the original volume.
3. Invert several times to mix.
4. Microcentrifuge 5 to 10 min at 11,000 × *g*, 4°C. Aspirate supernatant.
5. *Optional:* Wash by adding 1 ml of 1× stop solution, centrifuging again as in step 4, and aspirating the supernatant.

   This optional wash removes any left-over medium and helps ensure a clean isolation.
6. Freeze in liquid nitrogen in 1ml aliquots in 1.5-ml microcentrifuge tubes and store at −80°C until ready to isolate RNA.

   This is a good stopping point if taking multiple samples over a period of time.

Perform Trizol extraction

7. Remove tubes from freezer and place into ice once thawed.
8. Resuspend bacteria in 50 μl TE buffer containing 0.4 mg/ml lysozyme.
9. Let sample sit at room temperature for ∼5 min.
10. Add 950 μl Trizol reagent and vortex for 1 min to lyse.
11. Add 200 μl chloroform. Shake for 15 sec and let sit at room temperature for 2 to 3 min.
12. Microcentrifuge 15 min at 12,000 rpm, 2° to 8°C.
13. Transfer top (aqueous) phase to a new microcentrifuge tube.
14. Slowly add an equal volume of 70% ethanol to precipitate RNA.

Perform RNeasy purification/DNase treatment

15. Apply RNA solution to an RNeasy Mini spin column in 700-μl aliquots.
16. Add 350 μl RW1 buffer. Microcentrifuge for 15 sec at maximum speed and discard flowthrough.
17. For each column, prepare a mixture of 10 μl of 10 U/μl DNase in 70 μl RDD buffer.
18. Apply the 80 μl of DNase/RDD mix to the middle of the column membrane. Leave at room temperature for 30 min to 1 hr.
19. Add 350 μl RW1 buffer to the column. Microcentrifuge 15 sec at 12,000 rpm, 4°C.
20. Put the column into a new collection tube.
21. Add 500 μl RPE buffer, microcentrifuge 15 sec at 12,000 rpm, 4°C, and discard flowthrough.
22. Add another 500 μl of RPE buffer. Microcentrifuge 15 sec at 12,000 rpm, 4°C, and discard flowthrough.
23. Microcentrifuge 2 min at 12,000 rpm, 4°C, to remove all of the RPE.

24. Transfer column to a 1.5-ml collection tube.

25. Add 50 µl RNase-free water to the membrane. Microcentrifuge 15 sec at 12,000 rpm, 4°C, to collect RNA. Store at −80°C.

ARYLSULFATASE ASSAY

BASIC PROTOCOL 8

Similar to the *lacZ* reporter system in *E. coli*, the arylsulfatase assay, described in Hendrixson and DiRita (2003), quantifies the expression of a gene of interest. Arylsulfatase cleaves sulfates from substrates, and is encoded by the *astA* gene in *C. jejuni*. The assay measures arylsulfatase activity colorimetrically, using nitrophenyl sulfate as a substrate. Arylsulfatase liberates the sulfate from nitrophenyl sulfate (a colorless compound), forming nitrophenol. Nitrophenol is yellow in color, and by monitoring a colorimetric change, this assay can be used to determine the amount of arylsulfatase activity. Briefly, a promoterless *astA* gene is cloned into the gene of interest on the chromosome of *C. jejuni*, creating an *astA* transcriptional fusion. Expression of the gene of interest can then be monitored through the arylsulfatase assay, described below.

Materials

p-Nitrophenol (Sigma, cat. no 104-8)
Arylsulfatase buffer 1 (AB1): 0.1 M Tris·Cl, pH 7.2 (*APPENDIX 2A*)
C. jejuni (*UNIT 8A.1*)
Mueller Hinton (MH) agar plates with antibiotics (BD Biosciences)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Arylsulfatase buffer 2 (AB2): 2 mM tyramine in 0.1 M Tris·Cl, pH 7.2
Arylsulfatase buffer 3 (AB3): 20 mM nitrophenyl sulfate (potassium 4-nitrophenyl sulfate; Sigma, cat. no. N3877) in 0.1 M Tris·Cl, pH 7.2 (*APPENDIX 2A*)
0.2 N NaOH
Spectrophotometer

Additional reagents and equipment for growing *C. jejuni* (*UNIT 8A.1*)

Prepare standard curve

1. Prepare standard curve using *p*-nitrophenol:

   a. Prepare 200 µM nitrophenol in buffer AB1 by dissolving 27.82 mg nitrophenol in 10 ml AB1, then diluting this solution 1:100 with buffer AB1 for a 200 µM solution.

   b. Serially dilute the 200 µM nitrophenol 1:2 with buffer AB1 for six dilutions.

   c. Read OD_{420} for the dilutions of nitrophenol. Create a standard curve of OD_{420} values versus µM nitrophenol.

Prepare bacteria

2. Streak *C. jejuni* onto MH agar containing 10 µg/ml trimethoprim and grow at 37°C for 24 hr under microaerophilic conditions (*UNIT 8A.1*).

3. Restreak heavily onto one MH agar plate. Grow at 37°C for 18 hr.

4. Resuspend the growth in PBS to an OD_{600} of 1.0.

5. Divide each sample into two 1-ml aliquots.

6. Wash one aliquot with AB1 by microcentrifuging 5 min at maximum speed, room temperature, and removing the supernatant. Add 1 ml of buffer AB1, repeat microcentrifugation, and remove supernatant. Resuspend in 1 ml AB1.

7. Wash the second aliquot in AB2 using the technique described in step 6. Resuspend in 1 ml AB2.

Perform assay

8. Add 200 µl of each sample to 200 µl of freshly prepared AB3 in microcentrifuge tubes.
9. Incubate for 1 hr at 37°C.
10. Stop reaction by adding 800 µl of 0.2 N NaOH.
11. Read OD_{420}.

    Samples in AB1 are blanks for AB2 samples.

12. Compare values to standard curve. Report data as nmol or µM nitrophenol.

REAGENTS AND SOLUTION

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DNase buffer, 10×

200 mM sodium acetate, pH 4.5
100 mM $MgCl_2$
100 mM NaCl
Store up to 1 year at −20°C

K buffer

50 mM KCl
10 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
2.5 mM $MgCl_2$
0.5% (v/v) Tween 20
Filter sterilize
Store up to 1 year at room temperature

Salt buffer, 5×

6.25 ml 80% (w/v) glycerol (50% final)
1.25 ml 1 M HEPES, pH 7.9 (125 mM final)
1.25 ml 4 M NaCl (500 mM final)
0.25 ml 1 M $MgCl_2$ (25 mM final)
1 ml H_2O
Store up to 1 year at room temperature

SOB medium

2 g Bacto tryptone (BD Biosciences)
0.5 g yeast extract (BD Biosciences)
0.05 g NaCl
10 ml 250 mM KCl
Adjust pH to 7.0 using 1 M HCl
Store up to 1 year at room temperature

SOC medium

1 ml SOB medium (see recipe)
10 µl 1 M $MgSO_4$
10 µl 1 M $MgCl_2$
20 µl 20% (w/v) glucose
Store up to 1 year at 4°C

COMMENTARY

Background Information

Since its discovery, work on *Campylobacter* species has been limited due to challenging culture requirements and limited genetic tools. However, work in recent years has contributed much to our understanding of *Campylobacter jejuni*, as well as the tools used to study it.

Critical Parameters and Troubleshooting

Conjugation

The conjugation of plasmids into *C. jejuni* from *E. coli* containing the conjugation plasmid pRK212.1 (Basic Protocol 1) is a fairly robust protocol. The protocol is quite forgiving of variation in OD_{600} of both the donor and recipient strains, as long as both are collected during exponential growth and mixed at approximately the indicated ratio. The main problem encountered during conjugation is the outgrowth of the donor *E. coli* strain on the selective plates. In general, use of multiple antibiotics to which the *C. jejuni* strain, but not the *E. coli* strain, is resistant solves this problem. In the protocol given here, trimethoprim, cefoperazone, and streptomycin are used together to eliminate growth of *E. coli*. If the recipient strain is resistant to additional antibiotics, they can be used as well. Obviously, streptomycin should only be used with streptomycin-resistant *C. jejuni* (i.e., DRH212).

Electroporation

Electroporations (Basic Protocol 2) may require more troubleshooting and repetitions to achieve introduction of foreign DNA. If the electrocompetent cells are to be used in the future, aliquots can be frozen at −80°C in 20% glycerol until they are needed. In general, if the protocol has been attempted unsuccessfully, new electrocompetent cells and DNA should be prepared before attempting the procedure again.

Electroporation is often used to make insertional mutants, where an antibiotic cassette is inserted into a gene of interest. It can also be used, with the correct intermediate strain, to replace a dual cassette (i.e., chloramphenicol resistance and streptomycin sensitivity) with an in-frame deletion or point mutation. These unmarked mutants can be much more difficult to make, often due to high background (i.e., streptomycin-resistant colonies that retain the chloramphenicol resistance/streptomycin sensitivity cassettes and have not acquired the unmarked mutation). To combat high background in these cases, the following alterations in the protocol can be tried. The electroporation plates can be incubated in a microaerophilic environment (i.e., in zip-lock bags filled with the appropriate gas mix) for the first few days and then transferred to a more stable microaerophilic environment (i.e., Campy-Pak jars or tri-gas incubator; see *UNIT 8A.1*). Additionally, several different concentrations of the selective antibiotic can be tried. If these changes do not lead to successful electroporation, one can test several colonies of the recipient strain for appropriate antibiotic resistance/sensitivity, colony purify the strain, and make a new stock for future electroporation. Alternatively, success can sometimes depend on the location of the insertion in the intermediate strain. Construct a new intermediate strain with the insertion at a different location within the gene of interest.

Natural transformation

With regard to Basic Protocol 3, it should be noted that *C. jejuni* does not efficiently take up DNA from *E. coli*.

In vitro transposition

For the transposon mutagenesis protocol (Basic Protocol 4), recipient DNA here must be *C. jejuni* derived, or it will not be taken up efficiently in the succeeding natural transformation step.

Preparation of template for PCR

The concentration of proteinase K in the K buffer is an important parameter in Basic Protocol 5. If too much proteinase K is added, no PCR product is seen, presumably because the proteinase K degrades the *Taq* polymerase. If multiple PCRs are planned, or must be performed at a later time, the supernatant can be frozen at −20°C, if removed from the cell debris after the spin in step 4.

Genomic DNA isolation

DNA isolated via Basic Protocol 6 is of sufficient quality for cloning, but not for sequencing reactions. If sequence from the chromosome is needed, use of the Qiagen Genomic DNA extraction protocols is recommended.

RNA isolation

Working with RNase-free reagents in an RNase free area is critical to Basic Protocol 7. Additionally, although the Alternate Protocol calls for on-column DNase treatment of the RNA, several labs have indicated that this

Table 8A.2.3 Time Considerations for Protocols

Protocol	Description	Time required
Basic Protocol 1	Conjugation	7-8 days[a]
Basic Protocol 2	Electroporation	5-7 days[a]
Basic Protocol 3	Natural transformation	5-7 days[a]
Basic Protocol 4	In vitro transposition	2 days[b]
Basic Protocol 5	Preparation of template for PCR	<1 day[c]
Basic Protocol 6	Genomic DNA isolation	3-4 days[a]
Basic Protocol 7 or Alternate Protocol	RNA isolation	4-5 days[a]
Basic Protocol 8	Arylsulfatase assay	3 days[a]

[a]Time indicated includes time from streaking *C. jejuni* strain out from freezer stocks to end of protocol as written. For making new strains via introduction of foreign DNA, this includes time until single colonies will appear on selective media, but not the time required to verify the identity of the new strain, isolate single colonies, and freeze down the new strain.

[b]Time does not include purification of transposase or natural transformation of transposition reaction into *C. jejuni*.

[c]Time indicated does not include time required to grow *C. jejuni* strain before beginning the protocol.

procedure does not always efficiently eliminate any contaminating DNA. If DNA contamination is a problem, perform DNase treatment as indicated in Basic Protocol 7. DNase treatment can be repeated multiple times, followed by phenol and chloroform extractions and RNA precipitation. RNA can be tested for contaminating DNA by a PCR reaction (without prior reverse transcription) and DNase treatment can be repeated until there is no PCR product.

Arylsulfatase assay

The substrate for the arylsulfatase assays (Basic Protocol 8), nitrophenyl sulfate in solution, can be unstable and degrade after long-term storage at −20°C, resulting in high background readings. If this occurs, a fresh stock of nitrophenyl sulfate should correct the problem.

Time Considerations

Table 8A.2.3 provides time considerations for the protocols in this unit. It should be noted that for protocols that aim to produce new strains of *C. jejuni*, the time indicated does not include the time to verify the identity of the new strain, colony purify the strain, and freeze the strain down into new glycerol stocks.

Laboratory Maintenance of *Helicobacter* Species

In vitro, *Helicobacter* species grow quite slowly and only under conditions of reduced (but not absent) oxygen (i.e., microaerophilic conditions) and rich media. Primary cultures may take up to 5 to 7 days to achieve optimal growth, although subsequent passages take only a few days. Identification of *H. pylori* can be made by confirming the presence of urease, catalase, and oxidase enzymes, and by observing microscopic evidence of high motility and a spiral or curved morphology (Windsor and O'Rourke, 2000). Colonies are small and round, and appear translucent against the blood agar background. *H. pylori* is resistant to sulfonamides, vancomycin, trimethoprim, and cephalothin, which allows for the creation of a very effective selective media when isolating bacteria from clinical biopsies. It is sensitive, however, to many common antibiotics including tetracycline, gentamicin, kanamycin, and penicillin. These antibiotics may therefore be used to kill extracellular *H. pylori* when performing co-culture experiments with phagocytes, or as selection markers when introducing gene cassettes into the *H. pylori* genome.

In the present unit, protocols for growing *Helicobacter* organisms on plates (Basic Protocol 1) or in liquid cultures (Basic Protocol 2) are presented first, followed by Basic Protocol 3 for culturing *H. pylori* from clinical biopsy specimens. Three support protocols are presented that describe the preparation of solid media for growth on plates (Support Protocol 1), a method for quantifying numbers of *Helicobacter* organisms in an actively growing culture (Support Protocol 2), and techniques for quantifying *H. felis* in vitro (Support Protocol 3). Additionally, a method for liquid culture of *Helicobacter* has been provided that does not require the use of a tissue culture incubator (see Alternate Protocol). Finally, methods are provided for confirming growth of *H. pylori* (see Support Protocol 4).

CAUTION: *H. pylori* and *H. mustelae* are Biosafety Level 2 (BSL-2) pathogens; *H. felis* is a BSL-1 pathogen. Adult acquisition of *H. pylori* is thought to be relatively rare, and most infected individuals remain asymptomatic and healthy for life. Follow all appropriate guidelines and regulations for the use and handling of pathogenic microorganisms. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

STRATEGIC PLANNING

Several different *Helicobacter* selective media supplements have been described (see Table 8B.1.1). Skirrow's recipe, available commercially from Difco, BBL, and Oxoid, was originally developed for isolation of *Campylobacter* species. Although Skirrow's supplement (10 μg/ml vancomycin, 5 μg/ml trimethoprim, and 2.5 IU/ml polymyxin B) plus amphotericin B has been used for isolation and culture of *Helicobacter* species, the authors have found the recipes in Table 8B.1.1 to be more effective. In particular, the so-called Glaxo selective supplement A (GSSA) is useful for the isolation of *H. pylori* from mice when attempting to adapt a new *H. pylori* strain to mice (Lee et al., 1997; McColm, 1997; McColm et al., 1995). Note, however, that use of GSSA could induce a bias into the selection/adaptation process, as some *H. pylori* isolates have been shown to be sensitive to nalidixic acid. One or the other of the supplements must be used when attempting to isolate *H. pylori* or one of the other *Helicobacter* species from a human or animal biopsy. This is particularly important for isolating bacteria from mice since they are coprophagic (they consume their own feces). For pure cultures of laboratory strains, selective medium supplementation is less critical, but in order to simplify preparation

Current Protocols in Microbiology (2006) 8B.1.1-8B.1.13

Table 8B.1.1 Supplements for Selective Media

Antibiotic	*H. pylori*	*H. pylori* GSSA[a]	*H. felis*	*H. mustelae*
Amphotericin B	2.5 μg/ml	2.5 μg/ml	2.5 μg/ml	2.5 μg/ml
Bacitracin		20 μg/ml		
Cefsulodin	16 μg/ml			16 μg/ml[b]
Nalidixic acid		10.7 μg/ml		
Polymyxin B		3.3 μg/ml	0.125 μg/ml	
Trimethoprim	20 μg/ml		20 μg/ml	20 μg/ml
Vancomycin	6 μg/ml	10 μg/ml	6 μg/ml	6 μg/ml

[a]GSSA, Glaxo selective supplement A.
[b]For *H. mustelae*, 30 μg/ml cephaloxathin may be substituted for cefsulodin. *H. mustelae* is the only one of these three *Helicobacter* species resistant to cephaloxathin.

of bacterial growth plates, it will do no harm to always use plates prepared with the indicated supplements.

BASIC PROTOCOL 1

CULTURE OF *HELICOBACTER* ORGANISMS ON SOLID MEDIUM

H. pylori is a fastidious organism capable of growing only under a narrow set of conditions. It must be cultured on nutrient-rich agars such as Columbia blood agar base supplemented with whole blood from any one of a variety of large mammals such as horse, ox, or sheep. Reduced oxygen tension is crucial; therefore, a closed-container system capable of generating microaerophilic conditions must be employed. Typically this consists of an anaerobic jar with a microaerophilic system envelope. It is also necessary to incubate for several days at 37°C before colonies can be easily observed. The different gastric *Helicobacter* species such as *H. pylori*, *H. felis*, and *H. mustelae* are distinct in colony morphology. *H. felis* is extremely motile and readily forms confluent lawns which, to the untrained eye, can resemble uninoculated plates. Therefore, the eye must be trained to detect *H. felis* growth as a sheen or haze on the plate. *H. pylori* and *H. mustelae* form small, round, translucent colonies which may first be visible at pin-prick size as early as 3 to 4 days, gradually becoming larger.

Materials

Freshly prepared blood agar plates containing appropriate antibiotic (see Support Protocol 1)
Plates containing viable *Helicobacter* colonies, liquid culture of *Helicobacter* (Basic Protocol 2), or frozen stock of *Helicobacter*
Disposable bacterial spreaders (PGC Scientific), laboratory-made glass spreaders, or inoculating loops
Anaerobic jar(s) with sealable lid(s) (BBL model no. 100 uses one GasPak and holds 12 plates; model 150 uses three GasPak envelopes and holds 36 plates.)
GasPak: BBL CampyPak Plus Microaerophilic System Envelopes with Palladium Catalyst (Becton Dickinson) or equivalent

1. Inoculate freshly prepared blood agar plates with several colonies from a viable plate using an inoculating loop; alternatively inoculate 50 to 100 μl of thawed material from a frozen stock or liquid culture.
2. Use a bacterial spreader or inoculating loop to spread the material back and forth across the entire plate from top to bottom. Turn the plate 90° and repeat.

3. Cover the plates and place them in anaerobic jar(s).

   When culturing H. pylori and H. mustelae on plates, keep the plates inverted during incubation. For Helicobacter felis, however, do not invert the plates. H. felis is very motile, and the extra moisture that drips down onto the plate when cultured in the noninverted fashion helps it to grow (see Critical Parameters and Troubleshooting and APPENDIX 4A).

   Some laboratories include a water-soaked paper towel in the anaerobic jar to provide a humidified atmosphere. However, adding water to the GasPak envelope (see step 4) helps accomplish the same purpose. Because of the high moisture content in the anaerobic jars, it is important to disinfect the jars thoroughly between uses; it may be useful to include an antifungal and/or selective antibiotic supplement in the medium as well (see Table 8B.1.1).

4. Cut the corner off of a GasPak envelope, separate the edges, and place inside the anaerobic jar with the catalyst facing the outside. Add 10 ml water to each envelope, then seal the top of the anaerobic jar. Place the jar in a 37°C incubator or environmental control room.

   There are several different types of gas-generating GasPaks available. Be sure to select the correct one or the Helicobacter organisms may not grow.

   If an incubator is available in which three gases can be controlled, or if custom-blended gas cylinders can be obtained, these may be used in lieu of anaerobic jars and GasPaks. The incubator should be set to deliver 5% to 7% O_2/10% CO_2 with the balance N_2. If the incubator allows control of two gases plus air, set it at 20% to 35% air (which yields 5% to 7% oxygen), 10% CO_2, and the balance N_2. Some trial and error may be required to determine the optimum gas mixture for a particular incubator.

5. After 3 to 4 days open the jar and examine the plates for growth. If no growth or only low growth is observed, plates can be returned to the jar with a fresh GasPak for another 2 to 3 days.

   H. pylori and H. mustelae will form distinct pinhead-sized colonies which gradually become larger and easier to identify. Colonies on densely cultured plates may merge into a confluent lawn that displays a distinctive sheen when the plate is viewed at an angle. Thus, if individual H. pylori or H. mustelae colonies are to be counted, timing is important and it may be necessary to examine the plates at two or three different time points. H. felis tends to form confluent sheets within several days of culture. Early examination may allow for enumeration of individual colonies, but these colonies may be very small and difficult to detect.

PREPARATION OF BLOOD AGAR PLATES FOR GROWTH OF *HELICOBACTER* SPECIES

SUPPORT PROTOCOL 1

Successful culture of *Helicobacter* organisms requires the use of fresh nutrient blood agar plates. Commercially prepared plates may work, but the freshness of these plates cannot be controlled and they can often be too old or too dry. Additionally, they will lack the appropriate selective antibiotics. Unless one has access to a reliable bacteriology laboratory that can prepare fresh plates to specifications, it is better to prepare them in one's own laboratory. Any one of several nutrient agars recommended for growth of fastidious organisms will work, including Columbia Agar Base, Mueller-Hinton Agar Base, and Blood Agar Base (available from BBL, a trademark of Becton Dickinson). The important thing is that the plates be relatively fresh and moist. When preparing the plates, let the agar harden only until it solidifies (not overnight). If the plates are not to be used immediately, store in sealed plastic sleeves at 4°C for no longer than 2 to 3 weeks.

Materials

Nutrient agar base: Columbia Agar Base, Mueller-Hinton Agar Base, or Blood Agar Base (available from BBL; also see *APPENDIX 2C*)
Stock solutions of antibiotics (see Table 8B.1.1)

Defribrinated whole blood (horse, sheep, or ox), sterile (Cleveland Scientific)

1000-ml Erlenmeyer or round-bottom glass flasks or 1000-ml tissue culture bottles
56°C water bath
100-mm sterile polystyrene petri dishes with sleeves

1. Weigh out manufacturer's recommended amount of nutrient agar base for 500 ml medium and add to a flask or bottle containing 500 ml distilled or tap water. Swirl until all the powder is dispersed and freely suspended.

   Settling will occur but it is best not to have any deposits of dry medium when autoclaving.

2. Loosely cover vessels and autoclave under standard conditions for liquid reagents (18 psi/120°C) for 20 min.

3. Remove containers from autoclave and place in a 56°C water bath.

   This allows the medium to cool enough for addition of the blood and antibiotics without denaturing their activity but still being warm enough to prevent the agar from solidifying.

4. Add the appropriate amount of the antibiotics required for the particular *Helicobacter* species (see Table 8B.1.1).

5. Add 35 ml defibrinated whole blood, previously warmed to room temperature.

   Alternatively, "laked" whole blood, which has been frozen and thawed to produce hemolysis, may be used; however, the authors have not found this to be necessary.

6. Remove the flask from the water bath and gently mix until the blood is distributed uniformly. Keep the formation of bubbles to a minimum.

   This is best accomplished by rolling the flask at an angle on the counter top.

7. Immediately dispense the medium into 100-mm petri dishes and remove bubbles by flaming. Stack the warm plates into groups of four or five and allow to cool at room temperature (only until agar has hardened).

   Stacking will allow the agar to cool more slowly and minimize the amount of condensation that forms on the lids (except for the top plate). However, unstacked plates will solidify more quickly.

8. Following solidification of the agar, place plates in a plastic sleeve and store at 4°C until needed.

BASIC PROTOCOL 2

CULTURE OF *HELICOBACTER PYLORI* IN LIQUID MEDIUM

Helicobacter may also be grown in liquid media formulations. Several strategies can be used, depending on the species. Several nutrient-rich media such as Brain Heart Infusion or *Brucella* broth will support growth when supplemented with 10% heat-inactivated fetal bovine serum (FBS). Reduced oxygen tension can be supplied either through the use of a closed container system capable of generating microaerophilic conditions, or, in the case of *H. pylori*, by using a CO_2 incubator. Incubation at 37°C is required for growth. Exponential growth or even saturated cultures can be obtained in as little as 24 hr, depending on the inoculating dose.

Materials

Brucella broth or other suitable liquid medium supplemented with 10% (v/v) heat-inactivated FBS
Agar plate containing a heavy growth of viable *H. pylori* (Basic Protocol 1)

Disposable bacterial spreaders (PGC Scientific) or laboratory-made glass spreaders
25-cm^2 polystyrene tissue culture flasks
37°C, 5% CO_2 incubator

1. Place 1 ml of *Brucella* broth/10% FBS medium on to the center of an 100-mm *H. pylori* plate culture.
2. Using a sterile bacterial spreader, lift *H. pylori* from plate by continuous gentle raking of the surface. Slightly tip plate forward and gather liquid towards the front rim.
3. Transfer suspension of *H. pylori* to a 25-cm^2 tissue culture flask containing 10 ml of *Brucella* broth/FBS media.

   The recovered volume will be <1 ml as some of the liquid is absorbed by the solid medium.
4. Attach the cap of the flask so that it is loose enough to allow gas exchange but not loose enough to fall off.

   Alternatively, flasks with vented caps may by used and screwed on tightly.
5. Place flask in a 37°C, 5% CO_2 incubator standing upright.

   The authors have noticed that keeping the flask upright results in more reliable growth, possibly due to the increased depth of the medium.
6. Allow culture to grow overnight. Check for *Helicobacter* growth by placing the flask horizontally on an inverted microscope at 40× magnification. When the agitation of the culture has stabilized, look for highly motile bacteria by focusing just above the bottom of the flask.
7. Passage culture by transferring a small aliquot to another flask containing 10 ml *Brucella* broth/FBS medium.

   Passage before viability begins to decline (OD of 0.2 to 0.3 or lower).

   The volume of the aliquot used for passage is highly variable and must be based on the density of the culture and how soon one would like the new culture to reach saturation. Generally, 100 to 200 μl of a healthy culture will generate a saturated culture within 24 to 48 hr. At this point, larger cultures can be started by using 60 ml medium in a 75-cm^2 flask or 100 ml in a 150-cm^2 flask.

CULTURE OF *HELICOBACTER* SPECIES OTHER THAN *H. PYLORI* IN LIQUID MEDIUM

ALTERNATE PROTOCOL

Static liquid cultures able to grow under standard tissue culture incubator conditions have only been described for *H. pylori* (see Basic Protocol 2). Other gastric *Helicobacter* species such as *H. felis* require continuous shaking; therefore, alternative methods for growth are required. Unavailability of a CO_2 incubator or unwillingness of colleagues to allow the use of a tissue culture incubator for growth of bacterial cultures (because of concerns about contamination) may also favor alternative strategies. Most gastric pathogens are readily grown in the same liquid culture medium described in Basic Protocol 2 when placed in a suitable flask within an anaerobic jar on a rotary shaker.

Additional Materials *(also see Basic Protocol 2)*

Automatic pipetting device (e.g., Drummond Pipet-Aid or, for volumes ≤1 ml, Gilson Pipetman or equivalent automatic pipettor)
5-ml culture tubes
500-ml Erlenmeyer or tissue culture bottles that fit inside BBL model no. 100 anaerobic jar
Anaerobic jar(s) with sealable lid(s) (BBL model no. 100 or equivalent)
GasPak: BBL CampyPak Plus Microaerophilic System Envelopes with Palladium Catalyst (Becton Dickinson) or equivalent
37°C rotary shaker with 2-liter brackets to accommodate a BBL model no. 100 anaerobic jar

Additional reagents and equipment for quantification of *Helicobacter* (see Basic Protocol 2; see Basic Protocol 3 for *H. felis*) and examining wet mount of *Helicobacter* (Support Protocol 4)

1. Place 1 ml *Brucella* broth/10% FBS medium on to the center of an *H. pylori* plate culture.
2. Using a sterile bacterial spreader, lift *H. pylori* from plate by continuous gentle raking of the surface. Slightly tip plate forward and gather liquid towards the front rim.
3. Transfer harvested bacteria into a 5-ml sterile tube using an automatic pipetting device.
4. Place an aliquot equivalent to the bacteria harvested from one-half of a plate (0.5 ml) into a sterile 500-ml Erlenmeyer flask containing 100 ml Brucella medium/FBS.

   It is also possible to passage a small volume of an existing, actively growing liquid culture. The inoculum will vary between 1 and 10 ml depending on the viability of the culture and the speed at which one wishes new growth to occur.
5. Place the flask containing the inoculated medium within an anaerobic jar.
6. Cut the corner off of the GasPak envelope, separate the edges, and place inside the anaerobic jar with the catalyst facing the outside. Add 10 ml water to each envelope, then seal the top of the anaerobic jar.
7. Seal the jar and place in a 2-liter flask bracket on an orbital shaker at 37°C.
8. Incubate with shaking at 125 rpm for 24 to 48 hr.
9. At the end of this incubation, or earlier, remove an aliquot of the culture and determine optical density (see Support Protocol 2; see Support Protocol 3 for *H. felis*).

   An optical density of 0.1 at 550 nm should yield ~10^7 cfu/ml, but this should be verified by means of one's own growth curve (see Support Protocol 2).
10. Prepare a wet mount (see Support Protocol 4) and examine for motility and absence of contamination with other bacteria.

SUPPORT PROTOCOL 2

QUANTIFICATION OF *HELICOBACTER* ORGANISMS

Both *H. pylori* and *H. mustelae* will form individual colonies when grown on a blood-containing agar base. Thus, serial dilution and counting of colonies can be use to quantify both *H. pylori* and *H. mustelae*. However, for speed and convenience it may be more efficient to prepare a growth curve so that the concentration of bacteria can be determined simply by measuring optical density while growing as a liquid culture.

The following method uses *H. pylori* as an example; however, other *Helicobacter* species can also be quantified using this procedure, with the exception of *H. felis*, which should be treated as described in Support Protocol 3.

Materials

Brucella broth or other suitable liquid medium supplemented with 10% (v/v) heat-inactivated FBS
Actively growing liquid culture of *H. pylori* (see Basic Protocol 2 or Alternate Protocol)
Freshly prepared blood agar plates containing appropriate antibiotic (see Support Protocol 1)
25-cm^2 tissue culture flask
37°C, 5% CO_2 incubator

Spectrophotometer with visible wavelength spectrum, preferably with adapter for microcuvette
Cuvette or microcuvette
Sterile tubes for preparing dilutions
Disposable bacterial spreaders (PGC Scientific) or laboratory-made glass spreaders

Additional reagents and equipment for microaerophilic plate culture of *Helicobacter* (Basic Protocol 1)

1. Place 10 ml *Brucella* broth/5% FBS media in a 25-cm^2 tissue culture flask and inoculate with 100 μl of a log-phase culture of *H. pylori*. Place in a 37°C, 5% CO_2 incubator.
2. Several times each day, resuspend the bacteria uniformly by swirling the flask, remove a 100-μl aliquot, and transfer to a cuvette or microcuvette for the spectrophotometer.

   Depending on the viability of the starting culture, it may take 1 to 3 days, or even longer, to complete the growth curve.

3. Determine the OD_{550} of the culture using *Brucella* broth/10% FBS as a blank.
4. Using sterile tubes, prepare serial 10-fold dilutions of the aliquot from $1:10^2$ to $1:10^5$.
5. Inoculate 10 μl of each dilution onto a blood agar plate supplemented with antibiotics and spread uniformly using a bacterial spreader until no liquid remains on the plate. Mark each plate or fraction of plate used with the time point and dilution.

   To reduce the number of plates required, each plate can be divided into half or even thirds using a marker on the bottom of the plate and distributing each 10-μl inoculum only within the marked boundaries.

6. Cover plates and place in anaerobic jars with GasPaks as described in Basic Protocol 1.
7. Repeat steps 2 to 6 with the liquid cultures until OD_{550} approaches 0.5.
8. Evaluate plates at 4 to 5 days and enumerate colonies, back-calculating for dilution and volume to determine the number of colony forming units (cfu) per milliliter.

   For example, if 10 μl of a 1:1000 dilution yields 25 colonies, then there are $100 \times 1000 \times 25$ cfu $= 2.5 \times 10^6$ cfu per milliliter of the original sample.

9. Plot OD_{550} versus cfu to obtain the growth curve.

   As noted above the authors have found that an OD_{550} of 0.1 generally yields $\sim 10^7$ cfu in their laboratories. However, the specific conditions in another laboratory could be quite different, so it is best to complete one's own growth curve.

10. Repeat this procedure at least twice and average the results in order to obtain a reasonably accurate growth curve.

QUANTIFICATION OF *HELICOBACTER FELIS*

SUPPORT PROTOCOL 3

H. felis will not reliably form individual colonies, and even when individual colonies are observed with *H. felis*, these colonies may under-represent the number of viable organisms present. To attempt an estimation of the number of "cfu" of *H. felis* in stock cultures, the authors have used two approaches. The first is to use an *H. pylori* growth curve as a surrogate for an *H. felis* growth curve. Therefore, if the *H. pylori* growth curve indicates that an OD_{550} of 0.1 equals 10^7 cfu of *H. pylori*, a reasonable extrapolation would be that an OD_{550} for a culture of *H. felis* would also represent $\sim 10^7$ cfu of *H. felis*. The second approach is to prepare a subconfluent culture of *H. felis* and make serial

dilutions of this culture into *Brucella* broth. Pipet an aliquot of appropriately diluted culture into a hemacytometer (*APPENDIX 4A*) and quickly count the number of motile organisms at 400× total magnification. This is difficult, as a high-power microscope objective must be used and *H. felis* bacteria are highly motile and can move into and out of the hemacytometer grid squares. The authors have found that these two methods give numbers which are in reasonable agreement with each other.

BASIC PROTOCOL 3

PREPARING CLINICAL BIOPSIES FOR CULTURE OF *HELICOBACTER PYLORI*

Gastric pinch biopsy material is routinely taken during endoscopy from subjects presenting with symptoms of active gastritis or peptic ulcer disease. Along with identification of *H. pylori* in histologic tissue sections, culture of viable *H. pylori* remains the definitive test for a positive diagnosis of *H. pylori* infection. Additionally, the tremendous genetic and phenotypic diversity between *H. pylori* isolates provides incentives for continuing to isolate novel clinical isolates for further experimental analysis in the laboratory. *H. pylori* can be recovered from the gastric biopsy material of infected subjects by homogenizing the tissue and inoculating nutrient blood agar plates. The use of a urease test broth (see Support Protocol 4) to store or transport the biopsy can provide preliminary evidence of the presence of *H. pylori* if the indicator dye turns bright red within 24 hr of retrieval.

Usually, several pinch biopsies can be obtained from each subject during endoscopy. One or more biopsies are placed into a single tube for culture. In addition to culture, it is generally useful to send additional biopsies to a histology lab for embedding, sectioning, and staining. These biopsies should be collected into 10% buffered formalin. If sufficient biopsies are available, it may also be useful to deposit one or more into a freezing vial and then immerse into liquid nitrogen and store at –80°C or lower, e.g., for RNA isolation.

Materials

Gastric pinch biopsy material
Transport medium (see recipe) in sterile tubes
Brucella broth or other suitable liquid medium supplemented with 10% (v/v) FBS
Freshly prepared blood agar plates containing appropriate antibiotic (see Support Protocol 1)
Sterile forceps
Sterile disposable pellet pestles and 1.5-ml microcentrifuge tubes (Kontes, cat no. 749520)
Disposable bacterial spreaders (PGC Scientific) or laboratory-made glass spreaders
Additional reagents and equipment for microaerophilic plate culture of *Helicobacter* (Basic Protocol 1)

1. Retrieve gastric biopsy material from clinical laboratory in transport medium.

   Biopsies should be obtained for culture as soon as possible after endoscopy, although the authors have had some success in culturing from biopsies stored overnight at room temperature in transport medium.

2. Using sterile forceps, remove biopsy pieces from the transport medium tubes and place in sterile 1.5-ml microcentrifuge tube (provided along with a disposable pellet pestle) with 0.1 ml *Brucella* broth/10% FBS.

3. Grind the tissue using the sterile disposable pellet pestle and add an additional 0.1 ml *Brucella* broth/FBS.

4. Inoculate 10 µl of the homogenate onto a blood agar plate with the appropriate selective antibiotics and spread with inoculating loop or spreader.

5. Cover plates, place in anaerobic jars with GasPaks, and culture as described in Basic Protocol 1, steps 3 to 5.

CONFIRMATION OF *HELICOBACTER PYLORI* GROWTH

SUPPORT PROTOCOL 4

Although the use of selective antibiotics will greatly reduce the growth/isolation of non-*Helicobacter* organisms from animal stomachs, it is still necessary to be sure that the organisms recovered are in fact a *Helicobacter* species. While nucleic acid fingerprinting or PCR procedures can be employed for this, there are also simple morphologic and biochemical tests which can be used to screen suspected *Helicobacter* growth on plates. This is done by using an inoculating loop to pick material from a plate with visible growth and then examining the morphology of the organisms by phase-contrast microscopy of a wet mount and/or of Gram-stained organisms (*APPENDIX 3C*). Additional confirmatory procedures include testing the bacteria for urease, catalase and oxidase activity; these techniques are also described below.

All of the gastric *Helicobacter* species produce large amounts of the enzyme urease, which can cleave urea into carbon dioxide and ammonia. The ammonia is thought to buffer the acidity of the stomach and thus aid the bacteria in its colonization. It is possible, particularly in experimental animals, for other urease-positive micro-organisms (e.g., *Proteus* species) to colonize the stomach. Thus, the combination of colony morphology, urease test, oxidase test, catalase test, and spiral morphology/motility in a wet mount are used to confirm the identity of *H. pylori*. As noted above, nucleic acid fingerprinting and PCR techniques can be used for further verification.

Wet mount/morphology

Viable *Helicobacter* species will be highly motile, and if enough bacteria are placed on the slide they can be easily located by phase-contrast microscopy at 400× to 1000× total magnification. *H. felis* is relatively long and possesses a distinct corkscrew morphology with tight spirals. *H. pylori* and *H. mustelae* are shorter with less distinct spirals. In general, they have a comma- or gull wing–like shape. In a healthy culture, the bacteria will appear to be "swimming" about quite rapidly. An overgrown culture may yield an optical density in the desired range, but observation of low or no mobility will indicate lack of viability. Thus it is important to always check cultures for morphology and motility.

Urease test

Place a loopful of material into 0.3 ml Stuarts urease test broth (see recipe). The broth should turn pink within minutes.

Catalase test

Place a loopful of material into 0.5 ml of 3% H_2O_2. Viable *Helicobacter* will form bubbles.

Oxidase test

Either place a loopful of material into a drop of distilled water on a Bacto Differentiation Disk Oxidase (BD Biosciences, cat. no. 1633) or place a disk over a colony or area of growth on a plate with a drop of distilled water. A pink or maroon color within 10 to 20 min, eventually changing to almost black, indicates a positive test.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2A*; for suppliers, see *SUPPLIERS APPENDIX*.

Stuart's urease test broth

0.1 g yeast extract
0.091 g KH_2PO_4
0.095 g Na_2HPO_4
20.0 g urea
0.010 g phenol red
1 liter distilled H_2O
Adjust pH to 6.9 using a small quantity of HCl

Note that this recipe has 100-fold less buffering capacity than some commercially available urease test broths. If the test broth is used with a higher buffer concentration, it will be less sensitive and will give many false negatives. The authors usually make only 500 ml at a time and then use part of that as transport medium (see recipe).

Transport medium for Helicobacter

To Stuart's urease test broth (see recipe), add 20 g glucose or sucrose per 100 ml. Filter sterilize and store up to several months at 4°C.

COMMENTARY

Background Information

Helicobacter pylori is a Gram-negative microaerophilic spiral bacterium which predominantly inhabits the antral region of the human stomach (Marshall and Warren, 1984; Suerbaum and Michetti, 2002). While *H. pylori* can be found in the body or fundus of the stomach or in the gastric metaplasia of the duodenum, it seems well adapted only to gastric tissues. It is not found, for instance, in normal small or large intestine or in the esophagus. The organism resides within the mucus layer of both surface and glandular epithelium. This ecologic niche serves to protect the organism from the harsh environmental conditions of the stomach and from host effector mechanisms. However, despite the fact that host responses are ineffective in clearing the organism, *H. pylori* induces a state of active/chronic gastric inflammation (involving both neutrophils and lymphocytes) in all infected individuals. While there is no overt disease in most infected people, a subset of infected individuals may develop peptic ulcers, gastric cancer, or gastric mucosa–associated lymphatic tissue (MALT) lymphoma. The outcome of infection is determined by a complex interplay between bacterial virulence factors and the host response. Individuals with high gastric acid output who are infected with virulent *H. pylori* strains may be predisposed towards antral-predominant infections and gastritis leading to peptic ulcer disease, while those individuals with lower gastric acid are prone to infection of both the antrum and body of the stomach, and to pangastritis, atrophy of glandular and parietal cells in the body/fundus of the stomach, and gastric adenocarcinoma.

Assessment of the *H. pylori* genome has revealed a great deal of diversity between isolates (Jiang et al., 1996; Tomb et al., 1997; Suerbaum, 2000). Thus, although the complete genomes of two distinct isolates have been published, a hypervariable region of the chromosome has been identified that can house up to 7% of the total number of genes (Alm et al., 1999). Many of these genes are specific to individual isolates. This can make complete characterization of the *H. pylori* phenotype difficult. Additionally, although plasmids have been identified in *H. pylori* strains, few stable *Helicobacter* plasmids suitable for cloning and expression techniques have been described or developed (Kleanthous et al., 1991; Stanley et al., 1992; Bereswill et al., 2005). Introduction of genes directly into the chromosome can be accomplished via natural transformation or electroporation with *E. coli* cloning vectors, but the transformation efficiency of *H. pylori* strains varies dramatically; therefore, specific isolates must be identified that facilitate genetic manipulation (Tsuda et al., 1993).

From a host defense and pathogenesis point of view, animal models for *H. pylori* infection are useful in helping to understand disease processes and vaccine development (Nedrud, 1999). Therefore, a future unit in this series will detail protocols for infecting mice with *Helicobacter felis* and *Helicobacter pylori* and for infecting ferrets with *H. mustelae* and characterizing the bacterial load and gastric pathology.

The procedures in this unit describe how to grow *Helicobacter* organisms using plates or liquid cultures, how to quantify *Helicobacter* species, and how to recover *H. pylori* from clinical biopsies. *Helicobacter* species tend to grow well on media previously established for other enteric fastidious organisms (e.g., see *APPENDIX 2C*), although the addition of animal blood or sera is often required. The growth of pure cultures of *Helicobacter* species has facilitated the study of *Helicobacter* genetics, microbiology, virulence, and immunology. Since *Helicobacter* species are associated with a growing number of gastric and extragastric pathologies, the ability to grow *Helicobacter* species successfully can be an important skill.

Critical Parameters and Troubleshooting

H. pylori and other *Helicobacter* species are considered fastidious organisms which can be difficult to isolate and propagate. Both temperature and oxygen tension are critical parameters for optimal growth. If inoculation of plates from a frozen stock is unsuccessful, the condition of the anaerobic jar and the integrity of the seal when assembled should be tested. However, even if no problems can be identified, it is worthwhile to try again, since establishing the initial culture can be difficult (see Anticipated Results). Similarly, it is not uncommon for established cultures to lose viability and fail to grow when passaged. The jar seal should be checked to make sure that the proper oxygen tension is being obtained. The freshness/moisture of the plates being used to passage the bacteria should also be assessed.

Although bacterial contamination of pure cultures is rare when proper technique is utilized, the presence of mold can be more problematic. Generally, mold contamination occurs under two circumstances. First, plates often get contaminated when they are examined for growth and then placed back in the anaerobic jars for further growth. This is in large part due to removal of the plate lid to get a better look at the colony morphology. The second source of mold contamination is often due to the collection of water on the lids of inverted plates. When the water collects between the edge of the plate and lid, it effectively forms a bridge to the outside of the plate. If mold spores are present inside the jar, they may get inside the plate by this water route. A solution is to maintain the plates right side up, but the collection of water droplets on the agar itself can compromise the ability of the bacteria to grow as isolated colonies, and, if plates are being grown for quantitative counts, reliable numbers may be difficult to obtain. Disinfecting the bell jars between use can also help to reduce mold growth, as can the inclusion of an anti-fungal (amphotericin B) in the growth medium.

If cultures (either plate or liquid) overgrow, the bacteria may die or become coccoid in nature. Although coccoid organisms may not technically be dead, their viability can be difficult to determine. Overgrown, dying, or coccoid cultures will yield a measurable optical density; however, this optical density will not be a true reflection of number of fully viable cfu of *Helicobacter* organisms. Thus, examination of bacterial cultures by wet mount for active motility and expected morphology (see Support Protocol 4) is a critical parameter. When using a growth curve and the optical density to estimate the number of organisms present, it is critical to be on the "up side" of the growth curve rather than on the "down side" or plateau. *Helicobacter* organisms grow much more slowly than many other bacteria, and it is important to check their progress periodically to avoid waiting too long before passaging them or using them for in vitro analysis.

Except for disease conditions characterized by low stomach acidity, where gastric bacterial overgrowth by many species can occur, *Helicobacter* species are usually the only bacteria that can successfully colonize the human stomach. In coprophagic animal species such as mice, however, numerous bacterial species can routinely be cultured from stomach tissues. Thus, recovering clinical or experimental *H. pylori* isolates from gastric biopsies can be associated with contamination by other bacterial species. Normally, few bacteria survive in the gastric mucosa, but when contaminants are present, *Proteus vulgaris* may be suspected. It tends to be resistant to the common *H. pylori* selective media. This is further complicated by the fact that *Proteus* is one of the few enteric bacteria that also produces a urease enzyme, often leading to false-positive urease tests. *Proteus* also tends to grow quickly and forms large sheets, effectively covering any *H. pylori* that might be present as small isolated colonies. Therefore, it is important to plate many dilutions of clinical biopsy homogenates in the hopes that *H. pylori* can be isolated from the background of *Proteus* growth. The combined results of colony morphology observation and the urease, catalase, and oxidase tests, as well as the distinctive morphology (spiral or gull-wing shape) and high motility of *Helicobacter* organisms observed in a wet mount is

usually sufficient to distinguish *Helicobacter* species from *Proteus* species.

Anticipated Results

Establishing viable cultures of *H. pylori* and other *Helicobacter* species may take several attempts, especially when starting from a frozen stock. However, if multiple plates are inoculated or repeated attempts are made, viable cultures can be obtained as long as the anaerobic jars are properly sealed. Performing subsequent passages from a viable culture is generally much more reliable and the setup is easy to maintain. One can expect to observe fairly large and healthy colonies every 3 to 4 days once these cultures are growing. Likewise, once liquid cultures are established, one should expect to passage cultures every 1 to 2 days. Even if microscopic examination reveals dense growth but minimal motile organisms, these cultures may still be viable and suitable for inoculation into fresh media.

Recovering viable *H. pylori* from clinical gastric biopsies can be challenging. It is common for laboratories that perform this function on a regular basis to fail to isolate *H. pylori* even when the rapid urease test is positive. The site of biopsy source, freshness of the biopsy, antibiotic treatment of the subject, and bacterial density within the biopsy can all effect the success of isolating *H. pylori* from human tissue.

Time Considerations

The time necessary to culture *Helicobacter* species on solid media will vary, depending on whether or not blood agar plates have been prepared in advance. It will also vary with the number of plates to be inoculated. In general, plates can be prepared and ready for culturing in several hours. Preparation of the medium and autoclaving takes less than an hour. The two most time-consuming steps are allowing the temperature of the media to cool to 56°C, and allowing the medium to gel adequately following pouring of the plates. The whole procedure can be accomplished in one morning or afternoon. The actual inoculation of plates and preparation of the jars for incubation take only a few minutes.

The number of bacteria in a stock culture can be approximated in a few minutes by measuring the OD_{550} and referring to a growth curve. Rigorous determination of cfu takes longer, but by using the OD and a growth curve, one or two dilutions can be picked for inoculation onto plates, which takes only a few minutes. The plates must then be incubated for several days, but actual counting of colonies after they appear also takes only a few minutes. Homogenization of tissue biopsies and inoculation of the relevant plates will take a few minutes per biopsy. Counting colonies on plates should only require 1 or 2 min per plate unless a very large number of colonies are present. Likewise, testing the cultures for urease, catalase, and oxidase can be performed in a few minutes, provided that the necessary reagents are prepared ahead of time.

Liquid media can be prepared more quickly than solid media because there is no need to pour plates and allow them to gel. It should only take 2 to 3 hr to prepare, sterilize, and cool the medium (to anywhere between 37°C and room temperature) and much of this time is spent waiting, so that other tasks can be performed concurrently. The medium (without serum or antibiotics) can be prepared in advance and stored for at least 1 month. Adding stock solutions of antibiotics and serum and inoculation of the media with *Helicobacter* organisms takes only a few minutes. Preparation of stock antibiotic solutions can be done in 30 min, if necessary.

Construction of a growth curve for liquid cultures requires 1 to 2 weeks, but a large part of the time is spent waiting for the cultures to grow. The actual hands-on time is much shorter, and once the growth curve is prepared under standardized conditions it need not be repeated unless laboratory conditions change dramatically. The first step in a growth curve is to inoculate a liquid culture. This takes only a few minutes. Then, at regular intervals (from every 30 min to several times per day depending on the rate of growth), the optical density must be determined for an aliquot of the liquid culture, which then also needs to be serially diluted and inoculated onto a fresh series of plates. This procedure may take 1 to 2 hr per day. The fresh plates then need to be incubated for several days until individual colonies are visible. If no colonies are yet visible, the plates are returned to the incubator. When colonies become visible, they must be counted. Simply checking the plates takes only a few minutes, but counting colonies can take 1 to 2 hr depending on how many plates were incubated at the same time. Because the whole procedure will have to be repeated to obtain a reasonable average, it can stretch over perhaps 2 weeks, with actual hands-on time consuming 8 to 16 hr; even more time may be required if the culture plates have not been prepared in advance. Since this is a time-consuming and labor-intensive process, it pays to take great

care in doing it and to think twice about altering culture conditions in a way that would require constructing a new growth curve. Note also that, at some time point, the optical density of the growth curve may continue to rise, but that the number of viable cfu will plateau and then decrease.

ABSTRACT

Listeria monocytogenes is an intracellular foodborne pathogen that causes listeriosis, an infection characterized by gastroenteritis, meningitis, encephalitis, and maternofetal infections in humans. *L. monocytogenes* enters the host via contaminated foods, invades the small intestine, translocates to mesenteric lymph nodes, and spreads to the liver, spleen, brain and, in pregnant women, the fetoplacental unit. Many pathogenicity tests for studying *L. monocytogenes* have been developed, including tests using laboratory animals. A number of small animal species can be experimentally infected with *Listeria*. Mice and guinea pigs can be infected either intragastrically or intravenously, and virulence evaluated either by enumerating bacteria within infected target organs or by evaluating the 50% lethal dose (LD50). Although mice and guinea pigs can be infected with *Listeria* by a variety of routes, the intragastric route is the most relevant to the human foodborne listeriosis. *Curr. Protoc. Microbiol.* 10:9B.1.1-9B.1.17. © 2008 by John Wiley & Sons, Inc.

Keywords: *Listeria monocytogenes* • listeriosis • foodborne pathogen • infection • animal model

INTRODUCTION

Listeria monocytogenes causes listeriosis, a foodborne infection characterized by bacterial dissemination from the intestinal lumen to the central nervous system and the fetoplacental unit. Many pathogenicity tests for studying *L. monocytogenes* have been developed, including tissue culture assays, fertilized hen egg tests, and tests using laboratory animals. A number of small animal species, including mice and guinea pigs, can be experimentally infected with *Listeria*, the mouse species being the most frequently used. Although mice and guinea pigs can be infected with *Listeria* by a variety of routes, the intragastric route is the most relevant to human foodborne listeriosis. Mice can be infected either intragastrically (see Basic Protocol 1) or intravenously (see Basic Protocol 2), and virulence evaluated either by numerating bacteria within infected target organs (see Basic Protocol 3) or by evaluating the 50% lethal dose (LD50; see Basic Protocol 4). The infectious process following intragastric inoculation of *Listeria* can be also assessed in the guinea pig model (see Alternate Protocol).

As a proper cultivation of *L. monocytogenes* is a critical first step for the success of in vivo experiments, a method for preparing *Listeria* inoculum is also described (see Support Protocol).

All strains of *Listeria monocytogenes* are not equally virulent (Barbour et al., 2001; Larsen et al., 2002; Roche et al., 2005). Since the *L. monocytogenes* reference strain *EGDe* genome sequence has been determined (Glaser et al., 2001) and *EGDe* is used by a large number of laboratories, protocols presented here use this strain, but other *Listeria* strains (wild types and mutants) can also be used. The animal model, its genetic

background, and the route of infection are critical for the outcome of the infection (Cheers et al., 1978; Barbour et al., 1996; Lecuit et al., 2001; Czuprynski et al., 2003; Khelef et al., 2006; Cossart and Toledo-Arana, 2008. Procedures presented here use *iFABP-hEcad* mice and Hartley guinea pigs for intragastric infection, and BALB/c mice for intravenous infection.

CAUTION: Listeria monocytogenes is a Biosafety Level 2 (BSL-2) pathogen. Follow all appropriate guidelines and regulations for use and handling of pathogenic microorganisms.

CAUTION: These experiments require Animal Biosafety Level 2 (ABSL-2) conditions. Follow all appropriate guidelines and regulations for use and handling of infected animals. See *UNIT 1A.1* and other pertinent resources (*APPENDIX 1B*) for more information.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for care and use of laboratory animals.

NOTE: The proper handling and restraint of animals needs to be mastered before any inoculations. The experimenter needs to be fully aware of inherent dangers such as accidental needle stick when performing these techniques.

NOTE: The procedure requires familiarity with basic methods for animal care, handling, and restraint (see Donovan and Brown, 2006a).

IMPORTANT NOTE: The success of these protocols is dependent on proper use of aseptic techniques.

BASIC PROTOCOL 1

MOUSE INTRAGASTRIC (IG) INFECTION

In order to increase the permissiveness of the mouse following oral inoculation, a transgenic mouse model expressing human E-cadherin in enterocytes was generated. In this transgenic model, *L. monocytogenes* directly targets enterocytes. This leads to *L. monocytogenes* internalization into these cells and allows the subsequent crossing of the intestinal barrier, followed by bacterial multiplication in the small intestine lamina propria, and dissemination to mesenteric lymph nodes, liver, and spleen (Lecuit et al., 2001).

For this assay, bacteria resuspended in phosphate-buffered saline to the appropriate concentration are inoculated by intragastric gavage into slightly anesthetized mice. This infection route, used at the recommended dose, establishes a sublethal systemic infection that is a suitable model of systemic listeriosis allowing bacterial enumeration in infected organs (see Basic Protocol 3). For LD50 determination, several doses of inoculum must be administered to several groups of mice (see Basic Protocol 4).

Materials

6- to 8-week-old sex-matched *iFABP-hEcad* mice
Bacterial inoculum (Support Protocol)
Phosphate-buffered saline (PBS), sterile
Brain heart infusion (BHI) agar plates
150 mg/ml $CaCO_3$ in PBS, prepare fresh

Housing cages for the mice
Personal protective equipment (e.g., laboratory coat, gloves, and eye protection)
37°C incubator
Sterile 1-ml syringe with a long, bulbous-ended needle (e.g., animal feeding needle 20-G × $^1/_2$ in. with silicon tip)

Additional reagents and equipment for the anesthesia of rodents (Donovan and Brown, 1998)

Prepare animals

1. Acclimate 6- to 8-week-old sex-matched mice to the animal facility environment for at least 1 week prior to infection.

   Animals should be acclimated under standard lighting and temperature conditions with food and water.

2. Starve animals (giving only water) for 12 hr before infection.

   This is done to prevent the delivery of the inoculum into the stomachs of mice that were engorged with mouse chow, which could lead to aspiration of the inoculum in the lung, and also to diminished variability between animals.

3. Just before injection, thaw an aliquot of bacteria on ice. Dilute bacteria appropriately in sterile PBS to achieve 0.2 ml per mouse at 2.5×10^{10} cfu/ml.

   The standard dose recommended for L. monocytogenes EGDe via the intragastric route is 5×10^9 cfu per mouse, delivered in a volume of 0.2 ml. However, lower inocula (10^9, 10^8) also lead to systemic infection, with highly reproducible differences between wild-type (wt) bacteria and isogenic mutants.

4. To confirm the titer of the starting suspension, plate, in duplicate, 0.1 ml of serial dilutions (10^{-7}, 10^{-6}, 10^{-5}, 10^{-4}) on sterile BHI agar plates, and incubate the plate 24 to 48 hr at 37°C.

5. Fill the syringe with an inoculum of 0.2 ml containing the bacteria number to be injected, mixed with 0.3 ml of 150 mg/ml $CaCO_3$ suspension in PBS.

   Use a 1-ml syringe with a long, bulbous-ended needle (e.g., animal feeding needle 20-G × 1-1/2 with silicon tip). The amount of material that can be injected orally is ~0.5 ml.

   $CaCO_3$ buffering is used to reduce the gastric acidity and to decrease inter-individual variability which depends upon gastric repletion and pH.

Perform inoculation

6. Remove the mouse from the cage by its tail.

   At this point, mice can be anesthetized (Donovan and Brown, 1998) before gavage. The standard inhalant anesthetics for laboratory animal use are either isoflurane or halothane, delivered to effect in concentrations up to 5% for initial induction.

7. Hold the mouse by the skin on either side of the base of the neck and exert a slight downward and forward pressure under the mandible to tilt the head up slightly, thus aligning the oral cavity and pharynx with the esophagus.

8. Insert the bulbous-ended needle over the tongue into the esophagus and stomach.

9. Slowly inject the inoculum.

   Agents to be administered must be in suspension or solution, and at room to body temperature.

10. After completing the injection, carefully withdraw the needle, place the mouse back into its cage, and continue injections with additional animals. When injections are complete, check the animals for normal behavior and then return them to their housing location with food.

    In case of anesthesia, carefully follow the full recovery of the animal.

11. Discard the needle and syringe and disinfect work instruments and area.

Animals are then either observed every day for determination of mortality (see Basic Protocol 4), or they are euthanized and dissected for determination of bacterial counts from organs (see Basic Protocol 3).

Perform calculations

12. One or two days after incubation at 37°C, count colonies on plates (step 4) and calculate the initial titer of the suspension as follows: cfu/ml = MCC/(VP × DF).

    Where MCC is the mean colony count of replicate countable plates, VP is the volume plated, and DF is the dilution factor of the sample in the plate.

13. Calculate the *Listeria* load delivered by the IG inoculation as: cfu = cfu/ml × DF × VD.

    Where cfu/ml is the initial inoculum titer (step 11), DF is the dilution factor used to prepare the suspension (step 3), and VD is the volume delivered (step 3).

BASIC PROTOCOL 2

MOUSE INTRAVENOUS (IV) INFECTION

In nontransgenic mice, the intravenous route, as opposed to the oral route, can produce a lethal infection, and thus allows bacterial enumeration in infected organs but also the determination of the LD50 for various *Listeria* strains. The infection by intravenous route in the mouse model is widely used for immunological studies.

In this technique, bacteria resuspended in phosphate-buffered saline to an appropriate concentration are inoculated intravenously into lateral veins of the tail.

The IV injection route requires skill in locating one of the two lateral veins of the tail and making sure that the needle is inserted into the vein and not into the surrounding tissue.

This infection route, used at the recommended dose, establishes a sublethal systemic infection that is a suitable model for study of bacterial count in infected organs (see Basic Protocol 3). For LD50 determination, increasing doses of inoculum must be injected (see Basic Protocol 4).

For more details concerning intravenous injection of mice, see Donovan and Brown (2006b).

Materials

6- to 8-week-old female BALB/c mice
Bacterial inoculum (Support Protocol)
Phosphate-buffered saline (PBS), sterile
BHI agar plates

Personal protective equipment (e.g., laboratory coat, gloves, and eye protection)
37°C incubator
Housing cages for the mice
Heat lamp
Restraining device for mice (Harvard Apparatus)
Sterile 1-ml syringe with a small diameter needle (e.g., 26-G × $\frac{3}{8}$ in.)
Sterile gauze

Prepare animals

1. Acclimate 6- to 8-week-old female mice to animal facility environment for ≥1 week prior to infection procedure.

    Animals should be acclimated under standard lighting and temperature conditions with food and water.

2. Just before injection, thaw an aliquot of bacteria on ice. Dilute bacteria appropriately in sterile PBS to achieve 0.3 ml per mouse at 3.3×10^4 cfu/ml.

   The standard dose for L. monocytogenes EGDe via the intravenous route is 10^4 cfu per mouse, delivered in a volume of 0.3 ml.

3. To confirm the titer of the starting suspension, plate, in duplicate, 100 µl of serial dilutions (10^{-3}, 10^{-2}, 10^{-1}, 10^0) on sterile BHI agar plates, and incubate the plate 24 to 48 hr at 37°C.

4. Place the mouse cage under a heat lamp to allow gentle warming in order to promote vasodilation.

   This will increase circulation to the surface blood vessels (as the mouse regulates its body temperature) and expand the diameter of the veins in the tail. Time will depend on the intensity of the lamp. It is essential to observe the mice while they are warming and ensure that they do not become heat stressed while under the lamp. If mice appear to be agitated or heat stressed, remove the cage immediately from beneath the lamp.

5. While the mice are warming, set up a restraining device.

   Numerous devices have been described to facilitate intravenous injections into lateral tail veins, some of which can be obtained commercially (e.g., Harvard Apparatus). Basically, these consist of a cylinder of appropriate diameter, with adjustable length divider, and a slotted end for exteriorizing the tail.

Perform inoculation

6. Fill the syringe with the desired amount of inoculum to be injected. Remove any air bubbles from the syringe and needle.

   Use a 1-ml syringe with a small diameter needle (e.g., 26-G × $\frac{3}{8}$ in.). The amount of material that can be injected IV is ~0.3 ml. Absolutely no air can be accidentally injected, as this may cause a fatal air embolism.

7. When the mice are sufficiently warmed, remove a mouse from the cage by its tail. Holding on by its tail, place the mouse head first into the cylinder of the restraining device.

8. Locate one of the two lateral veins of the tail. Hold the tail with the thumb and first finger, curling the end of the tail slightly over the finger.

   For more details on the injection procedure, see Donovan and Brown, 2006b.

9. Line up the needle exactly in line with the vein and insert the needle into the vein.

   If the needle is in the vein the tip of the needle will be visible inside of the vein. It is desirable to make the first injection attempt as close to the tip of the tail as possible, so that a second attempt, if necessary, can be safely made more proximally or on the opposite vein.

10. Slowly inject the inoculum.

    If the needle is in the vein, the red color of the vein will fade for almost the entire length from the injection site to the tail base near the mouse body as the injected material temporarily flushes the blood. If the needle is not in the vein, a whitening around the injection site will swell up and the plunger will not move easily. Stop injecting and "try again" at a site more proximal (nearer) to the body or use the other lateral vein.

    CAUTION: *NEVER force the syringe if the vein was missed, as this may result in a potential aerosol of the bacterial suspension should the needle hub dislodge from either the syringe or the tail.*

11. After the injection, carefully withdraw the needle and use gauze to apply digital pressure at the injection site for hemostasis.

12. Place the infected mouse in a spare cage and continue injections with the other animals. When injections are complete, check the animals for normal behavior and then return them to their housing location.

13. Discard the needle and syringe and disinfect work instruments and area.

Animals are then either observed every day for determination of mortality (see Basic Protocol 4), or they are euthanized and dissected for determination of bacterial counts from organs (see Basic Protocol 3).

Perform calculations

14. One or two days after incubation of plates (step 3) at 37°C, calculate the initial titer of bacterial stock suspension (se Basic Protocol 1, step 12) and then calculate the *Listeria* load using the dilution factor of the IV suspension (see step 2 above).

ALTERNATE PROTOCOL

GUINEA PIG INTRAGASTRIC (IG) INFECTION

In the guinea pig animal model, *L. monocytogenes* is able to induce a gastroenteritis resembling that observed in humans following intragastric infection. Moreover, *L. monocytogenes* is able to induce a dose-dependent lethality following dissemination to the systemic circulation (Lecuit et al., 2001; Khelef et al., 2006).

In this protocol, bacteria resuspended in phosphate-buffered saline to an appropriate concentration are inoculated by intragastric gavage into anesthetized guinea pigs.

Guinea pigs almost never bite and, although very emotive, can be easily calmed and are very easy to handle. They should always be forewarned before being approached, either by being able to see or hear their would-be handler. They should be lifted by grasping them firmly and gently over their shoulders, with two fingers behind and two in front of the forelimb. The rump should be supported by the other hand when lifting. Essentially the same grip may be used to immobilize the animal, if the hind legs are grasped and extended and the animal is placed on its back on a table top or counter.

The IG infection route, used at the recommended dose, establishes a sublethal systemic infection that is a suitable model for study of bacterial count in infected organs (see Basic Protocol 3). For LD50 determination, increasing doses of inoculum must be injected (see Basic Protocol 4).

Two persons are needed for the infection, one handling the animal, the other one performing the injection.

Materials

300-g, sex-matched Hartley guinea pigs
Bacterial inoculum (Support Protocol)
Phosphate-buffered saline (PBS), saline
BHI agar plates, sterile
15 mg/ml ketamine in sterile PBS, prepare fresh
25 mg/ml $CaCO_3$ in PBS, prepare fresh

Personal protective equipment (e.g., laboratory coat, gloves, and eye protection)
37°C incubator
1-ml syringe with a small diameter needle (e.g., 26-G × $^3/_8$ in.), sterile
20-ml syringe
Sterile suction catheter (1.7-mm × 270-mm; Vygon, ref. no. 530.05)
Animal cages

Additional reagents and equipment for the anesthesia of rodents (Donovan and Brown, 1998)

Prepare animals

1. Acclimate 300-g, sex-matched guinea pigs to animal facility environment for ≥1 week prior to infection procedure.

   Animals should be acclimated under standard lighting and temperature conditions with food and water.

2. Starve animals (giving only water) for 48 hr before infection.

   This is done to prevent the delivery of the inoculum into engorged stomachs and also to diminish variability between animals.

3. Just before injection, thaw an aliquot of bacteria on ice. Dilute bacteria appropriately in sterile PBS to achieve 1 ml per animal at 10^{10} cfu/ml.

   The standard dose for L. monocytogenes EGDe via the intragastric route is 10^{10} cfu per animal, delivered in a volume of 1 ml.

4. To confirm the titer of the starting suspension, plate, in duplicate, 0.1 ml of serial dilutions (10^{-7}, 10^{-6}, 10^{-5}, 10^{-4}) on sterile BHI agar plates, and incubate the plate 24 to 48 hr at 37°C.

5. Remove the guinea pig from the cage.

6. For light anesthesia, inject guinea pig intramuscularly with 1 ml of 15 mg/ml ketamine in PBS.

   Use a 1-ml syringe with a small diameter needle (e.g., 26-G × $\frac{3}{8}$ in.). For guinea pigs, ketamine is usually administrated at 50 mg/kg.

7. Wait a few minutes for the anesthesia to take effect.

   The effect of the anesthesia can be determined by toe pinch method.

Perform inoculation

8. Fill a 20-ml syringe with 5 ml of 25 mg/ml $CaCO_3$ in PBS.

9. Fill a 1-ml syringe with 1 ml containing the desired amount of inoculum to be injected.

10. When anesthetized, hold the guinea pig by the skin on either side of the base of the neck and exert a slight downward and forward pressure under the mandible to tilt the head up slightly, thus aligning the oral cavity and pharynx with the esophagus.

11. Insert a suction catheter intragastrically until feeling a light resistance (∼15 cm).

    This procedure is facilitated if carried out by two experimenters. In our experience, home-made suction catheters should be avoided, because of the harmful effect of their distal extremity, which is not smooth enough.

12. Adapt the 20-ml syringe to the catheter and slowly inject intragastrically 5 ml of 25 mg/ml $CaCO_3$ solution.

    $CaCO_3$ is used to reduce the gastric acidity and to diminish variability between animals.

    Agents to be administered must be in suspension or solution, and at room to body temperature.

13. Replace the 20-ml syringe with the 1-ml syringe without removing the catheter, and slowly inject intragastrically 1 ml of inoculum.

14. After completing the injection, carefully withdraw the catheter and place the inoculated guinea pig in a spare cage and continue injections with additional animals.

    While the animal is anesthetized and nonreactive, pay attention not to put the animal's eyes or nose in contact with the sawdust or other bedding material.

15. When injections are complete, check the animals for full recovery and normal behavior after anesthesia, and then return them to their housing location.

16. Discard the needle, syringes, and the catheter. Disinfect work instruments and work area.

Animals are then either observed every day for determination of mortality (see Basic Protocol 4), or they are euthanized and dissected for determination of bacterial counts from organs (see Basic Protocol 3).

Perform calculations

17. One or two days after incubation of plates (step 4) at 37°C, calculate the initial titer of bacterial stock suspension (see Basic Protocol 1, step 12) and then calculate the *Listeria* load using the dilution factor of the IG suspension (see step 3 above).

BASIC PROTOCOL 3

ORGAN RECOVERY AND BACTERIAL ENUMERATION

After ingestion of contaminated food, *Listeria* crosses the intestinal barrier and infects intestinal cells. *Listeria* then disseminates via the lymph and the blood up to the liver and the spleen, and then to the brain and to the placenta after crossing the blood-brain and fetoplacental barriers. Following intravenous or oral inoculation of mice and guinea pigs, the spleen and liver represent the main targets of this pathogen, as the majority of the bacteria are found in these organs. Secondary dissemination to the brain and the placenta may also occur in these animal species, although it does not appear to be as frequent and efficient as it is in humans.

This protocol describes the procedure for harvesting the target mouse organs to be analyzed after infection by *Listeria* (i.e., the small intestine, the mesenteric lymph nodes, the liver, and the spleen), and for bacterial enumeration after organ homogenization. The technique described is applicable to the guinea pig model with minor modifications. Other organs can be harvested if required, for example the brain, the placenta in the case of a pregnant animal model listeriosis, or the lung in the case of pulmonary infection.

CAUTION: All processing of tissues derived from infected animals must be done in an appropriate laboratory equipped with a Class II biohazard hood. All homogenization of infected tissues should be done in the biohazard hood, which protects the user from the significant aerosols generated by tissue grinding and disruption techniques.

Materials

Infected 6- to 8-week-old sex-matched mice (Basic Protocol 1 *or* Basic Protocol 2)
70% ethanol in a spray bottle
Phosphate-buffered saline (PBS), sterile
Dulbecco's minimum essential medium (DMEM)
100 mg/liter gentamicin in sterile PBS, prepare fresh
Sterile Brain Heart Infusion (BHI) medium
BHI agar petri plates, sterile

Personal protective equipment (e.g., laboratory coat, gloves, and eye protection)
15- or 50-ml conical polypropylene centrifuge tubes, sterile
Sterile dissection instruments including:
- Medium dissection scissors
- Tissue forceps
- Small iris scissors
- Iris forceps
- Small-toothed forceps
- Surgical scissors
- Dissecting pins

Styrofoam or cork cutting board and pins
Paper towels
20°C incubator
Rotor-stator homogenizer (IKA UltraTurrax T25, or similar)

Additional reagents and equipment for the euthanasia of rodents (Donovan and Brown, 2006c)

Prepare work area

1. Prepare in advance sterile 15-ml tubes (mouse) or 50-ml tubes (guinea pig) to collect organs. Carefully label the tubes and place on ice.
2. Prepare sterile surgical instruments on a sterile surgical field.

Obtain organs

3. Euthanize the infected mouse by CO_2 inhalation (Donovan and Brown, 2006c). Carefully verify that the mouse is dead.
4. In a Class II biohazard hood, Place the mouse on to its back on Styrofoam or cork board covered with a paper towel, and wet its fur with 70% ethanol to minimize contamination with hair.
5. Pin extremities to Styrofoam or cork board to immobilize animal.
6. With forceps, grab hold of the skin above the urethral opening. Using small iris scissors, cut along the midline from the groin to the chin.

   Be careful to only cut the skin and not the muscle wall underneath.

7. While still grasping the lower peritoneum, make an incision from the start of the first incision to down near the knee on both sides of the animal.

   You should end up with an incision that looks very similar to an upside down Y. Take care not to cut the bladder or the intestines.

8. Peel the skin back from the muscle and peritoneal wall underneath.
9. Open up the abdomen by making an incision in the midline of the peritoneal wall and peeling it back.
10. Remove the spleen, which is behind the stomach and attached to the blood circulation by a single set of blood vessels (splenic artery and vein). Put the spleen into a 15-ml (mouse) or 50-ml (guinea pig) ice-cold empty sterile tube and place on ice.
11. With small-toothed forceps, grasp underneath the right lateral lobe of the liver to a point across the inferior vena cava and the hepatic hilum.
12. Use iris scissors to gently flip these lobes back over the forceps to grasp these lobes as well as the common bile duct.
13. With a firm hold on these tissues, make an incision with the scissors between the liver and the diaphragm and cut the inferior vena cava, freeing the liver.
14. Extricate the liver as one organ with a quick but gentle upward motion. Place the liver in a 15-ml (for mouse) or 50-ml (for guinea pig) ice-cold empty sterile tube and place on ice.
