Not much has changed in using animals as sentinels over the years. Crates of rabbits were placed on the cargo deck of ships transporting nerve gases during World War II, and the crew were instructed to watch for sudden animal deaths that could signal a gas release (Brankowitz, 1987). Even today, with the development of sophisticated biosensor technology, the use of animals as sentinels continues to be explored (Paddle, 1996). After the Aum Shinrikyo sarin attack in Tokyo, Japanese policemen used canaries to serve as a warning of poison gas release (Biema, 1995). The United States also planned to use chickens during the initial invasion of Iraq in 2003 (Ember, 2003). The chickens were to be used as early warnings of nerve gas agents. It was thought that if caged chickens remained alive following a warning alert, it would be safe for soldiers to remove their gas masks. Using live animals would help avoid possible false alarms with ion-mobility spectrometry biosensors. The plan was never implemented, however, as there were no controlled studies showing that chickens were likely to show effects of nerve agents before humans (Garamone, 2003). The US Environmental Protection Agency (EPA) is now considering evidence regarding the use of animals as sentinels for chemical threats (EPA, 2006).

Some of the CWAs that may pose the greatest risks to animal health are described next. For information on their mechanism of action, readers are referred to Section II of this book.

CWAS

Chlorine Gas

Clinical Signs

Chlorine gas is very irritating, and in concentrated amounts, it can even be corrosive. The eyes, skin, nose, throat, and mucous membranes can all be affected. When inhaled or ingested, chlorine combines with tissue water and forms hydrochloric acid (HCl) and reactive oxygen species (ROS). Oxidation of respiratory epithelium leads to alveolar capillary congestion and accumulation of edematous fluid (Noe, 1963). Death is due to cardiac arrest from hypoxemia secondary to atelectasis, emphysema, and membrane formation (Decker, 1988).

Ocular exposure can result in severe pain and blindness. Erythema and pain are also common after dermal exposure. Both liquid and high concentrations of chlorine gas can cause dermal burns (Raffle et al., 1994). Inhaled chlorine gas causes rhinorrhea, ataxia, syncope, muscle weakness, dyspnea, tachypnea, bronchospasm, and acute lung injury. Inhalation of high concentrations can cause laryngospasm, tachycardia, and hypoxia (Noe, 1963). Cardiovascular collapse and respiratory arrest may develop and lead to rapid death.

Chlorine is teratogenic. When given to pregnant rats, 100 ppm of chlorine caused both biochemical and metabolic effects in the newborns, while 565 mg/kg given prior to mating was embryotoxic (RTECS, 2008). Carcinogenicity can be seen with chronic exposure (RTECS, 2008).

Kinetics

Respiratory, dermal, and ocular irritation starts immediately. The speed of onset and severity of signs is directly related to the concentration (Bingham et al., 2001). The water solubility of chlorine allows it to have a greater effect on the lower respiratory tract, as a large percentage bypasses the upper airways. Acute lung injury peaks in 12–24 h. Death usually occurs within 48 h (Decker, 1988).

With mild exposure, signs disappear within 6 h, but can continue for more than 24 h with severe exposures. Exposure to moderate or severe concentrations can result in chronic respiratory dysfunction (Decker, 1988). This can be career- or life-ending if the affected animal is an equine athlete or a working dog.

Decontamination and Treatment

Move animals into fresh air and onto higher ground. Monitor respiratory rates and oxygenation status (SpO_2). If coughing or dyspnea develops, provide supplemental oxygen and ventilation. Bronchodilators should be used to counteract bronchospasm (Wang et al., 2004). Sedation and pain control may be needed so that the animal can be handled safely.

Corticosteroid use is controversial. Animal models have shown positive results in hastening recovery from severe chlorine gas poisoning; however, administration to humans has not been shown to provide any significant change (Traub et al., 2002). Wang et al. (2004) demonstrated that pigs exposed to chlorine gas responded better to a combination of aerosolized bronchodilators and corticosteroids (terbutaline, budesonide) than to either therapy alone. Sheep nebulized with 4% sodium bicarbonate had decreased mortality and improved oxygenation after inhalation of chlorine gas (Chisholm et al., 1989).

For ocular exposure, the eyes should be flushed with generous amounts of tepid 0.9% saline or tap water for at least 15 min. After flushing, fluorescein should be used to stain the eyes and check for corneal ulcers (Grant and Schuman, 1993). Bathing with dish soap and water will remove chlorine from the skin and fur or feathers.

Chlorine does not leave an environmental residue, so animals may be returned to affected pastures within hours to days, and more quickly in warm environments (Munro et al., 1999). When entering the area contaminated with chlorine gas, rescuers should wear self-contained breathing apparatus (SCBA) and protective

clothing (i.e., gloves, gowns, and masks) until the gas dissipates. The risk for secondary contamination of rescuers is low. Chlorine gas does not bind to leather or fabrics.

Species Susceptibility

Chlorine gas is heavier than air and will settle in low areas. Pets and smaller livestock may be more at risk than humans due to their proximity to the ground. There are no controlled studies showing that animals are more sensitive to chlorine gas or that they will develop signs sooner than humans.

Phosgene

Clinical Signs

Most animal exposures to phosgene are from inhalation, but there can also be dermal exposures to the liquefied material. The severity of pulmonary injury correlates with the concentration and length of exposure, and initial symptoms are not always a good indicator of prognosis (Diller, 1985; Bingham et al., 2001). Due to low water solubility, phosgene is able to penetrate deeply into the lungs, where it irritates the lower respiratory tract (Franch and Hatch, 1986). When phosgene gas contacts water in the lungs, it forms HCl, causing cellular injury (Murdoch, 1993). Phosgene also causes protein and lipid denaturation and changes in membrane structure, leading to increased pulmonary vascular permeability (Borak and Diller, 2001). This fluid accumulation in the lung interstitium and alveoli results in gas diffusion abnormalities and pulmonary edema (Diller, 1985). Pulmonary injury is exacerbated by elevated levels of leukotrienes and neutrophil chemotactic agents, including intercellular adhesion molecule-1 (Zhang et al., 2010). The neutrophils release cytokines and other reactive mediators, worsening pulmonary injury (Sciuto et al., 1995). Localized emphysema and partial atelectasis occur. Death is from anoxia secondary to pulmonary edema (Borak and Diller, 2001; Proctor and Hughes, 2004).

Dyspnea, cough, cyanosis, and hemoptysis can progress to hypoxemia and hypoventilation (Borak and Diller, 2001). Animals may develop secondary organ damage from anoxia. Dogs experience bradycardia, followed by tachycardia and progressive hypotension with severe phosgene poisoning (Patt et al., 1946). With concentrations greater than 200 ppm, phosgene can enter the blood and cause hemolysis and coagulopathies (Sciuto et al., 2001). Direct contact with liquid phosgene can cause dermal burns (Proctor and Hughes, 2004). Ocular exposure to both liquid phosgene and highly concentrated phosgene gas can cause severe eye irritation and corneal opacification (Grant and Schuman, 1993; Proctor and Hughes, 2004).

Prognosis is directly related to the severity of pulmonary injury. Animals that survive the first 24–48 h still have a guarded prognosis. These animals are more susceptible to infectious agents, as they have suppressed natural killer cell activity. Infections may become evident 3–5 days after exposure. Animals may develop chronic exercise intolerance and abnormal pulmonary function (Borak and Diller, 2001). Working dogs and horses may no longer be able to fulfill their functions.

Kinetics

Respiratory signs develop 2–6 h postexposure in most patients, but can be delayed up to 15 h with exposures to lower concentrations (<3 ppm) (Borak and Diller, 2001). Concentrations of 3–5 ppm cause immediate conjunctivitis, rhinitis, pharyngitis, bronchitis, lacrimation, blepharospasm, and upper respiratory tract irritation. Extended (170-min) exposure was fatal (Diller 1985; Proctor and Hughes, 2004). Exposure to 50 ppm for 5 min or longer will cause pulmonary edema and rapid death (Chemstar, 1996; Borak and Diller, 2001; RTECS, 2008). If the animal survives, pulmonary edema begins to resolve in 2–3 days.

Decontamination and Treatment

Move animals to fresh air and higher ground. Bathe animals with soap and water and flush eyes for 15 min with tepid water or 0.9% saline. Animals should be monitored for 24 h for the development of pulmonary edema (Borak and Diller, 2001). If animals are coughing or dyspneic, administer 100% oxygen. Animals may need to be intubated and ventilated. They can be nebulized with beta-adrenergic agonists to combat bronchospasm. Patients with pulmonary edema should be managed the same as an acute respiratory distress syndrome (ARDS) patient (i.e., mechanical ventilation with oxygen and positive end-expiratory pressure).

Rabbits exposed to toxic levels of inhaled phosgene did not develop noncardiogenic pulmonary edema if given intravenous (IV) aminophylline and subcutaneous terbutaline within 10 min of exposure (Kennedy et al., 1989). Intertracheal *N*-acetylcysteine (Mucomyst) administered to rabbits 45–60 min after inhalation of phosgene (1500 ppm/min) decreased pulmonary edema, production of leukotrienes, and lipid peroxidation, and it also maintained normal glutathione levels compared to rabbits exposed only to phosgene (Sciuto et al., 1995). Rat and rabbit studies have shown that ibuprofen also protects against acute lung injury from phosgene (Guo et al., 1990). Oxygen, sodium bicarbonate, and aerosolized surfactant have all been shown to be beneficial in dog experiments (Mautone et al., 1985). Corticosteroids, prostaglandin E1, and atropine may be helpful in reducing phosgene-induced pulmonary edema (Chemstar, 1996). Pentoxifylline has been shown

to inhibit intercellular adhesion molecule-1, which not only decreases migration, accumulation, and activation of neutrophils, but also decreases the synthesis of other pro-inflammatory cytokines (Zhang et al., 2010). Intravenous fluids should be used for cardiovascular support, but monitor for overhydration. Colloids are preferred over crystalloids, as they will remain in the vascular space for a longer period of time. Oxygen supplementation will resolve most of the arrhythmia.

Phosgene is nonpersistent in the environment. Moisture reduces air concentrations (Borak and Diller, 2001). The potential for secondary contamination of rescue personnel is low, but rescuers should wear proper protective clothing. Phosgene gas does not persist in fabric or leather.

Species Susceptibility

Phosgene is heavier than air and will settle close to the ground. This can affect species that are low to the ground or that are pastured in low-lying areas. There is no indication that animals are affected before or at lower levels than their human counterparts.

Mustard Gas

Clinical Signs

Mustard gas is a vesicant that is toxic by all routes of exposure (oral, inhalation, dermal, and ocular) (Sidell et al., 1997; Pohanish, 2002). Mustard causes both localized and systemic cellular damage, and tissues with high cell turnover are the most affected (NATO, 1973). Mustard gas can produce erythema, severe pruritus, blistering, ulceration, and necrosis of exposed skin (Borak and Sidell, 1992; Dacre and Goldman, 1996; Budavari, 2000; Pohanish, 2002). Skin lesions are most severe at warm and moist sites (genitalia, perineal regions, groin, skin folds, and axillae), due to the high number of sweat glands in these areas. Amounts as low as 0.02 mg of mustard will cause blisters (Smith et al., 1997).

Ocular exposure can cause pain, lacrimation, corneal ulceration, swelling, blepharospasm, and blindness, as the eyes are very sensitive to mustard gas (NATO, 1973; Borak and Sidell, 1992; Dacre and Goldman, 1996; Garigan, 1996). Pathognomonic signs of mustard gas poisoning include porcelain-white areas in the episcleral tissues and the formation of large, varicose veins (Grant and Schuman, 1993). Conjunctivitis and keratopathy can be seen chronically after exposure (Grant and Schuman, 1993).

Inhalation of small amounts of mustard gas produces nasal discharge, sneezing, epistaxis, and coughing within 12–24 h of exposure. Higher concentrations or longer exposures can cause pulmonary damage, hypoxia, and respiratory acidosis. Seizures may be seen with extremely acute high doses (Sidell et al., 1997).

Mustard gas is also a radiomimetic (Sidell et al., 1997). It destroys precursor cells in the bone marrow, leading to leukopenia, thrombocytopenia, pancytopenia, and anemia (Borak and Sidell, 1992; Dacre and Goldman, 1996). Infection can be seen secondary to bone marrow damage (Sidell et al., 1997). Bone marrow aplasia and death can be seen in severe cases.

Mustard gas is a possible animal teratogen. Some rat studies show abnormalities of the musculoskeletal system in the offspring of rats orally dosed with mustard gas, but only at doses high enough to be toxic to the dams, while other rat and rabbit studies showed no correlation (Dacre and Goldman, 1996; RTECS, 2008). Injection of mustards, both via IV and intraperitoneally, into male mice caused inhibition of spermatogenesis, but full recovery was seen within 4 weeks (Dacre and Goldman, 1996). Mustard gas is both a human and animal carcinogen (NTP, 2005). It has been linked to carcinomas in the skin, limbs, lungs, thorax, and leukemia in rats and mice after inhalation and IV exposure (RTECS, 2008).

Kinetics

Both liquid and vaporized mustard have rapid skin penetration. The higher the dose, temperature and humidity, the quicker the absorption (NATO, 1973). Mustard is dermally absorbed through hair follicles and sweat glands within minutes. Cellular reactions begin within 1–2 min of mustard making contact with skin or mucous membranes, but clinical effects are delayed between 2 and 24 h (Grant and Schuman, 1993; Sidell et al., 1997).

The skin initially pales and then becomes erythematous within a few hours of exposure (Requena et al., 1988). Erythema, blisters, bulla, and small vesicles form over 2–24 h. The blisters can progress for several more days. Erythema resolves over 3–7 days, while ulcers take 6–8 weeks to heal (Garigan, 1996; Sidell et al., 1997). Discoloration (brown or black hyperpigmentation) commonly occurs after resolution of the burns, especially in areas with thinner skin (Requena et al., 1988).

Ocular absorption happens within minutes. With mild ocular exposures, conjunctivitis and lacrimation begin about 4–12 h after exposure. Moderate ocular exposures produce conjunctivitis, blepharospasm, lid inflammation, corneal damage, and eyelid edema about 3–6 h post-exposure. Severe ocular exposures will lead to marked swelling of lids, corneal ulceration, corneal opacification, severe pain, and miosis in 1–2 h (Requena et al., 1988).

Inhalation produces respiratory signs (rhinorrhea, sneezing, epistaxis, and coughing) within 12–24 h of exposure. A severe exposure produces a productive cough, tachypnea, pulmonary edema (rare), and pulmonary hemorrhage within 2–4 h. Studies in dogs indicate

that equilibrium between blood and tissues was achieved within 5 min of inhalation (IARC, 1975). Ingestion of small amounts can cause hypersalivation and vomiting within 24 h, while larger amounts can cause gastrointestinal bleeding (rare) and bloody diarrhea within 3–5 days.

Mustard preferentially accumulates in fatty tissue (listed in order of decreasing concentration: fat, skin with subcutaneous tissue, brain, kidney, muscle, liver, cerebrospinal fluid, spleen, and lung) (Somani and Babu, 1989). Excretion takes place through the urine in rabbits, mice, and rats (IARC, 1975). Mustard is excreted over 72–96 h after IV administration in rats and mice (Dacre and Goldman, 1996). Complete blood count (CBC) changes are not evident for 3–5 days post-exposure. Leukopenia usually occurs between day 7 and day 10 (Garigan, 1996).

Decontamination and Treatment

Animals should be moved into fresh air. Emesis is not recommended, and activated charcoal administration after oral ingestion is controversial. Activated charcoal appears to have some beneficial effects if administered within 1 h of ingestion. Sodium thiosulfate (2% solution) given orally may help in cases of oral exposure (Borak and Sidell, 1992; Dacre and Goldman, 1996). Perforation and stricture formation can follow esophageal burns.

For ocular exposures, flush eyes with tepid water for at least 15 min. Follow with 2.5% sodium thiosulfate ophthalmic to help neutralize the mustard. The eyes need to be decontaminated quickly, as mustard disappears from the eye very rapidly, and late flushing of the eye generally provides no benefit (Sidell et al., 1997). Topical ophthalmic antibiotics and pain control should be used if corneal lesions are present (Sidell et al., 1997). Corneal transplants may be considered for valuable animals.

Animals need to be bathed with copious amounts of soap and water. If dermal decontamination is not implemented quickly, mustard will react with the skin and cannot be easily removed (Sidell et al., 1997). Sodium thiosulfate (2.5% solution) can be used dermally to neutralize mustard exposures (Garigan, 1996). Animals may also be bathed with dilute (0.5%) hypochlorite solutions (Borak and Sidell, 1992). Monitor for dermal burns. Secondary infection is common. Topical silver sulfadiazine can be applied to all burns, and an Elizabethan collar should be put in place to decrease ingestion of the ointment and self-trauma. Topically applied dexamethasone and diclofenac reduced inflammation in a mouse when applied within 4 h (Dachir et al., 2004). All equine and ovine patients should be inoculated with tetanus toxoid. Vaccination of other species should be determined on a case-by-case basis.

Monitor for respiratory irritation (such as coughing or dyspnea). If seen, monitor arterial blood gases and pulse oximetry. Thoracic radiographs may be taken, but there can be a lag time of up to 2 days before infiltrates are seen radiographically (Smith, 1999). Nebulization with 2.5% sodium thiosulfate or *N*-acetylcysteine may help neutralize the mustard gas. *N*-acetylcysteine may also be given via IV as a potential mustard gas antagonist (Garigan, 1996). Provide oxygen, ventilation, and inhaled beta agonists if needed. Dexamethasone, promethazine, vitamin E, melatonin, nitric oxide synthase inhibitors, protease inhibitors (such as doxycycline), surfactant replacement, and heparin have all shown protective effects against mustard gas poisoning in laboratory animals (Requena et al., 1988; Weinberger et al., 2011).

Serial CBCs with platelets should be monitored for 2 weeks after exposure. Antibiotics should be given if leukopenia develops (Sidell et al., 1997). Mustard can be detected in urine and body tissues for up to 1 week post-exposure using gas chromatography-mass spectrometry (GC-MS; Vycudilik, 1985). This can confirm diagnosis but is not likely to be of value in the management of the patient.

Mustard is persistent in the environment. Mustard may remain in the environment for up to 1 week in temperate areas. It disappears more quickly in hot climates and in desert conditions; persistence is reduced to about 1 day. Since mustard binds to vegetation for days to weeks, grazing animals need to be kept away from these areas (USACHPPM, 2001b).

Rescue personnel must wear protective clothing, eye protection, and a respirator, as the potential for secondary contamination is high (HSDB, 2008). Mustard gas will penetrate wood, leather, rubber, and paints.

Species Susceptibility

Animal studies of skin exposure to nitrogen and sulfur mustard show that these agents cause more severe skin lesions in hairless animals and less in fur-covered species (Smith et al., 1997). Dermal absorption of mustard varies greatly by species. Rats absorb about 75% of a dermal dose through their skin, while only 20% is absorbed through human skin (Smith, 1999). The rat dermal LD_{50} is only 5 mg/kg, while the mouse and human dermal LD_{50}s are 92 and 100 mg/kg, respectively (RTECS, 2008). However, with oral dosing, humans appear to be much more susceptible (oral LD_{50} 0.7 mg/kg for humans, and 17 mg/kg for rats). Due to these variable results, more studies are needed to determine if rats or mice would make good sentinel animals.

Lewisite

Clinical Signs

Lewisite is an arsenical compound that acts locally as a vesicant but also causes systemic effects (Sidell et al., 1997;

HSDB, 2008). Lewisite directly affects enzyme systems, resulting in decreased adenosine triphosphate (ATP) production. Lewisite also causes increased capillary permeability, leading to a significant loss of blood plasma into the extravascular space (known as *lewisite shock*) and hypotension (Sidell et al., 1997). Lung capillaries are affected not only by inhalation, but also by first pass through the lungs following dermal exposure. Pulmonary edema or ARDS can develop (Sidell et al., 1997).

Signs can be seen when lewisite is contacted dermally, orally, ocularly, inhaled, or ingested. Dermal and respiratory exposures are seen most frequently. Lewisite causes dermal, ocular, and respiratory lesions similar to those caused by mustard gas. Lewisite is about 10 times more volatile than mustard gas (Budavari, 2000).

Exposure to lewisite is very painful. Both the vapor and liquid lewisite can penetrate skin. Reddening of the skin is followed by tissue destruction (EPA, 1985a; Goldman and Dacre, 1989; Sidell et al., 1997; Pohanish, 2002). Amounts as small as 0.5 ml may cause severe systemic effects and 2 ml may be lethal. Severe edema develops secondary to increased capillary permeability. Dermal burns are deeper than those seen with mustard gas and are quicker to appear (Goldman and Dacre, 1989; Sidell et al., 1997).

Ocular exposure causes immediate pain, lacrimation, and blepharospasm. Without rapid decontamination, within 1 min, permanent blindness may occur (EPA, 1985a; Pohanish, 2002). In livestock, this is a death sentence, as they cannot survive on the range when blind. Droplets as small as 0.001 ml can cause corneal perforation and blindness (Sidell et al., 1997).

Inhalation of vapor causes irritation to the nasal passages, rhinorrhea, and violent sneezing (HSDB, 2008). Coughing and hemoptysis commonly occur (Sidell et al., 1997; HSDB, 2008). After inhalation, dogs developed necrotizing pseudomembranous laryngotracheobronchitis (Goldman and Dacre, 1989). Death can occur within 10 min after inhalation of high concentrations (EPA, 1985a).

Lewisite does not cause damage to the bone marrow or immunosuppression (Sidell et al., 1997). Arrhythmias and renal dysfunction are due to hypovolemia from fluid loss. Lewisite was fetotoxic to rats and rabbits and is a suspected carcinogen (Goldman and Dacre, 1989; RTECS, 2008).

Kinetics

Immediate pain occurs upon inhalation, dermal, or ocular contact with lewisite. Skin penetration occurs within 3–5 min, especially following liquid exposures (Sidell et al., 1997). The skin becomes red, then gray, within 15–30 min after exposure (EPA, 1985a; Goldman and Dacre, 1989; Sidell et al., 1997; Pohanish, 2002). Severe blisters develop within 12 h. The blisters rupture about 48 h after occurrence, with large amounts of fluid seeping from the site. Healing is generally complete within 4 weeks (much faster than with sulfur mustard-induced lesions).

Lewisite has extensive tissue distribution (HSDB, 2008). The highest concentrations were found in the liver, lungs, and kidneys in rabbits (>7 times blood concentration). Arsenic crosses the placenta and is excreted in the milk. Therefore, nursing animals may be at risk (Barlow and Sullivan, 1982). The elimination half-life of arsenic in rabbits is 55–75 h (HSDB, 2008). For further details on toxicity of arsenic and lewisite, see chapter 15.

Decontamination and Treatment

Remove animals from affected areas. If any coughing or respiratory distress is noticed, monitor blood gases and SpO_2. Provide oxygen and assisted ventilation as needed. Nebulized beta agonists (and possibly corticosteroids) can be used to treat bronchospasm. Monitor electrolytes and packed cell volume (PCV), as there can be fluid shifts out of the vasculature (Goldfrank et al., 2002). Urine arsenic levels may be measured, but they are not clinically useful due to the lag time before results are obtained. Watch for liver and kidney failure.

As lewisite is a vesicant, emesis is not recommended in those species that can vomit (such as dogs, cats, swine, and ferrets). Dilution with milk or water is recommended. Activated charcoal is not recommended, as severe irritation/vesication of the esophagus or gastrointestinal tract is likely to occur. Endoscopy can be performed very carefully to determine the extent of injury. Esophageal perforation, stricture formation, or both may occur.

The eyes should be flushed with copious amounts of tepid water for at least 15 min. If 5% dimercaprol [also known as *British anti-lewisite (BAL)*] ophthalmic ointment can be applied within 2 min, this may prevent a significant reaction. Application up to 30 min after exposure will lessen the ocular reaction but will not prevent all damage (Goldfrank et al., 2002).

Animals should be washed with water and dilute household bleach (5% sodium hypochlorite) as soon as possible. Application of a 5% BAL ointment within 15 min can be effective in diminishing the blistering effects of lewisite (Smith, 1999). Remove BAL ointment with soap and water after 5 min. Leaving the ointment on too long can cause stinging, itching, or urticaria. Burns should be managed with pain control, antibiotics, and debriding as needed.

A chelator should be given if there is dyspnea, pulmonary edema, or skin burns larger than palm size (Goldfrank et al., 2002). BAL is the traditional arsenic chelator, but it has numerous side effects. The deep intramuscular injections are very painful and BAL can cause hypertension, tachycardia, and vomiting.

2,3-Dimercaptosuccinic acid (DMSA, Succimer) can also be used to chelate arsenic (Graziano et al., 1978). 2,3-Dimercapto-1-propanesulfonic acid (DMPS) is used in Europe and has been effective in protecting rabbits from the lethal effects of lewisite (Aposhian et al., 1982).

Lewisite remains in the environment for about 24 h, and it can react with water to form a solid arsenoxide that also has vesicant properties. Affected areas can be treated with strong alkalis to form less harmful substances. Rescue personnel need to wear protective clothing and masks, as the risk for secondary contamination is high. Carcasses should be disposed of properly, either buried deeply (away from water supplies), rendered, or incinerated to ensure safety of the food supply.

Species Susceptibility

Lewisite has the potential to cause skin lesions in any species, but the risk is greatest in hairless animals, such as pigs, and decreases in fur-covered species (Smith et al., 1997). Mice and rats appear to be almost twice as susceptible to dermal lewisite exposures than humans (LD_{50} equals 12, 15, and 30 mg/kg, respectively) (Sidell et al., 1997; DeRosa et al., 2002; RTECS, 2008). More studies are needed to determine if rodents would be good sentinel animals.

Phosgene Oxime

Clinical Signs

In both its liquid and vapor forms, phosgene oxime causes severe pain and local tissue destruction upon contact with skin, eyes, and mucous membranes (Sidell et al., 1997). Signs depend on its route of entry, as phosgene oxime exerts its greatest effects in the first capillary bed it encounters.

Dermal, ocular, and respiratory lesions are similar to those caused by mustard gas. Inhalation and oral absorption may cause respiratory tract irritation, dyspnea, and pulmonary edema. Dermal lesions are erythematous and extremely painful. With ocular exposure to phosgene oxime, very low concentrations can cause lacrimation, inflammation, and temporary blindness, while high concentrations can cause permanent corneal lesions and blindness (Sidell et al., 1997; USACHPPM, 2001c). Death is generally due to respiratory arrest.

Kinetics

Complete absorption occurs in both dermal and inhalational exposures within seconds (Sidell et al., 1997). Dermal lesions begin to form within seconds; grayish tissue damage may be seen within several minutes, and within 1 h, the area becomes edematous. Phosgene will spread in sweat and move to other nonexposed areas of the body (DeRosa et al., 2002). Pulmonary edema can be seen on thoracic radiographs within 2 h of high-dose exposure, 4–6 h of moderate exposure, and approximately 8–24 h after low-dose exposure (Sidell et al., 1997). The skin turns brown, and blistering occurs the next day. It takes about 3 weeks for desquamation, necrosis, crust formation, and purulent exudate to occur (Sidell et al., 1997). Pain can last for several days, and healing of dermal lesions can take from 1 month to over a year.

Decontamination and Treatment

Animals should be moved into fresh air. Emesis is not recommended due to the irritant and corrosive effects of phosgene oxime. Dilution with milk or water is recommended for oral ingestions. Activated charcoal is not recommended as the primary toxicity is a local corrosive injury. Sedation and pain control (opioids) may be needed to allow safe decontamination.

Irrigate eyes with tepid water until pH returns to neutral and remains so for 30 min after irrigation is discontinued (Brodovsky et al., 2000). Time until decontamination after ocular exposure is important since phosgene oxime is absorbed within seconds. Corneal ulcers should be treated with atropine ophthalmics to prevent synechiae formation, and other ophthalmics to aid in re-epithelialization (Grant and Schuman, 1993; Brodovsky et al., 2000).

The animal should be bathed with copious amounts of water and a mild soap. Phosgene oxime reacts quickly with tissue, and decontamination is not expected to be entirely effective after pain has been produced. Sodium hypochlorite (0.5%) or isotonic sodium bicarbonate can help neutralize phosgene oxime that has not yet reacted with tissue. Burns should be managed with topical silver sulfadiazine and systemic antibiotics as needed (Roberts, 1988). Horses and sheep should receive tetanus prophylaxis. Other species should be vaccinated on a case-by-case basis.

Monitor oxygenation and thoracic radiographs in patients following significant exposures. Administer oxygen, perform endotracheal intubation, and provide assisted ventilation if needed. Nebulized beta-adrenergic agonists can help if bronchospasm develops. Administer IV fluids, but monitor for overhydration (Goldfrank et al., 2002).

Phosgene oxime is nonpersistent in the environment, and it hydrolyzes rapidly in aqueous alkaline solutions. Veterinary personnel and rescuers should wear aprons, rubber gloves, and masks when treating patients to avoid secondary contamination.

Species Susceptibility

There are no controlled studies showing that any species of animal would make a good sentinel for phosgene oxime exposure.

Cyanide and HCN

Clinical Signs

Cyanide and HCN are classified as blood agents. They cause toxicity by forming a stable complex with ferric iron (Fe^{3+}) in cytochrome oxidase enzymes. This inhibits cellular respiration, oxygen utilization, and ATP production, causing deprivation of oxygen to the body at the cellular level (Way et al., 1988). Both arterial and venous blood appears cherry red due to the accumulation of oxyhemoglobin (Bingham et al., 2001). Unhaired skin may also appear bright pink due to the high concentration of oxyhemoglobin in the venous return (HSDB, 2008). HCN and cyanogen chloride are volatile and water-soluble, and liquid forms of cyanide and HCN are the most likely to be used for terrorism.

Cyanide exposure can cause transient central nervous system (CNS) stimulation, followed by syncope, ataxia, dyspnea, seizures, paralysis, apnea, and coma (Hall and Rumack, 1986). The odor of bitter almonds may be noted in gastric or ruminal contents and expired breath. Initial tachypnea is followed by respiratory depression. Dyspnea without cyanosis can help with the diagnosis. Chickens develop tachypnea, have rapid eye blinking, hypersalivation, and lethargy (Wiemeyer et al., 1986). Blindness may occur from cyanide-induced damage to the optic nerve and retina (Grant and Schuman, 1993). Hypersalivation, vomiting, and abdominal pain may occur after ingestion (Hall and Rumack, 1986). Metabolic and lactic acidosis is commonly seen. Death can occur within minutes.

Kinetics

Cyanide and HCN can be absorbed by all routes (inhalation, oral, ocular, and dermal) (Hall and Rumack, 1986). There is rapid diffusion into tissues, and cyanide irreversibly binds to its target sites. Cyanide has a wide volume of distribution and will concentrate in red blood cells (RBCs) two to three times greater than in plasma (HSDB, 2008). Cyanide preferentially accumulates in the hypothalamus, with levels about 40% higher compared to other areas of the brain (Borowitz et al., 1994).

Cyanide is metabolized by rhodanese in the liver to thiocyanate (Hall and Rumack, 1986). Thiocyanate is excreted mainly in the urine. Without administration of an antidote, the half-life for the metabolism of cyanide to thiocyanate is 20 min to 1 h (Feldstein and Klendshoj, 1954). Cyanide can be excreted in breast milk (Soto-Blanco and Gorniak, 2003).

Decontamination and Treatment

Remove animals from the affected area. Do not induce vomiting due to the rapid progression of the clinical signs and potential for seizures, coma, or apnea. A gram of activated charcoal will bind 35 mg of cyanide, and activated charcoal may be beneficial if administered immediately after ingestion (Lambert et al., 1988). Irrigate eyes for at least 15–20 min with tepid water. Bathe animals thoroughly with soap and water.

Blood gases and serum electrolytes should be monitored and corrected as needed (Hall and Rumack, 1986). Blood cyanide levels can confirm exposure, but due to the time needed to get the results, they are not clinically useful. Provide supplemental oxygen with assisted ventilation as indicated. Animal study results for hyperbaric oxygen therapy have been questionable (Way et al., 1972). Acidosis ($pH < 7.1$) should be corrected with IV sodium bicarbonate, but acidosis may not resolve until after the administration of antidotes (Hall and Rumack, 1986). Benzodiazepines or barbiturates can be used to control seizures.

Cyanide toxicosis progresses so rapidly that treatment is rarely administered to animals in time. If the animal is still alive but in respiratory distress or a coma, antidotal agents may still be life-saving. The classic treatment for cyanide intoxication includes several steps. Sodium nitrite is given via IV over 15–20 min (fast administration causes hypotension). Sodium nitrite reacts with hemoglobin in the RBCs to form methemoglobin. Methemoglobin combines with free cyanide to form cyanomethemoglobin. Sodium thiosulfate is given after sodium nitrite. Sodium thiosulfate supplies sulfur for the rhodanese reaction (Hall and Rumack, 1987). The sulfur reacts with cyanomethemoglobin to form hydrogen thiocyanate, which is excreted in the urine.

Hydroxocobalamin (Cyanokit) has been the chelator of choice in Europe and Australia, and has been approved for use in the United States since 2007. It works by combining with cyanide to form cyanocobalamin (vitamin B_{12}; Hall and Rumack, 1987). Hydroxocobalamin has been shown to reduce mortality in rats, mice, and beagles and has the advantage of producing neither methemoglobinemia nor hypotension, as sodium nitrite does (Hall and Rumack, 1987; Borron et al., 2006). Dicobalt-EDTA (Kelocyanor) and 4-dimethylaminophenol hydrochloride (4-DMAP) are other chelators available in Europe, Israel, and Australia, but not in the United States (Hillman et al., 1974; Weger, 1990).

Other substances that have been tested in the lab on animals include: stroma-free methemoglobin solutions, alpha-ketoglutaric acid, chlorpromazine, hydroxylamine, phenoxybenzamine, centrophenoxine, naloxone, etomidate, para-aminopropiophenone, and calcium channel blockers (Ashton et al., 1980; Dubinsky et al., 1984; Leung et al., 1984; Ten Eyck et al., 1985; Johnson et al., 1986; Bright and Marrs, 1987; Yamamoto, 1990; Budavari, 2000). The use of these substances has shown positive results, but they have not been tried during actual poisoning situations.

HCN is lighter than air and has a long half-life in air. However, in open spaces, HCN is rapidly dispersed and

is diluted to nontoxic concentrations. Cyanide does not bind to soil or plant material but can mix with water. Contaminated water can be treated with ozone, hydrogen peroxide, or calcium/sodium hypochlorite bleach. Rescue personnel should wear boots, gloves, goggles, full protective clothes, and a self-contained positive pressure breathing apparatus as the potential for secondary contamination is high (NIOSH, 2005).

Species Susceptibility

There are significant interspecies differences in the toxicity of HCN (Sousa et al., 2003). Dogs appear to be more susceptible than humans to cyanide poisoning. This is thought to be due to lower levels of endogenous rhodanese (hepatic enzyme that catalyzes the sulfuration of cyanide to thiocyanate) (Aminlari and Gilanpour, 1991). Barcroft (1931) exposed both a man and a dog simultaneously to HCN gas. The 70-kg man and 12-kg dog were exposed to HCN concentrations between 500 and 625 ppm in an airtight chamber. The dog became ataxic at 50 s, unconscious at 74 s, and began to seizure at 90 s. At 91 s, the man walked out of the exposure chamber with no symptoms, although over the next 10 min, he developed transient nausea and difficulty concentrating (Barcroft, 1931). As HCN is lighter than air, it is probably not that the small dog experienced a higher exposure than the human.

Cats are more resistant to subcutaneous HCN than humans. The LDLo (SQ) for humans is 1 mg/kg, as compared to 11 mg/kg for cats (Sax and Lewis, 1989). The LDLo (oral) for HCN in humans, dogs, and rabbits is comparable (5.7, 4, and 4 mg/kg, respectively) (Sax and Lewis, 1989).

Dogs may be good sentinel animals as they appear to have increased susceptibility relative to humans based on physiological differences. More controlled studies are required, however.

Military Nerve Agents

Clinical Signs

Military nerve agents are probably the most toxic of the known CWAs. Military nerve agents are divided into G (which stands for "Germany") agents (such as sarin, soman, and tabun) and V (which stands for "venomous") agents (such as VX). Nerve agents are extremely dangerous, as they are absorbed without producing any irritation or other sensation on the part of the exposed person or animal (HSDB, 2008).

Nerve agents are organophosphates (OPs). Acute exposure to OPs can cause muscarinic, nicotinic, and CNS signs. Muscarinic effects include salivation, lacrimation, urination, dyspnea, diarrhea, and emesis (SLUDDE), along with miosis, bradycardia, hypotension, and bronchoconstriction. Nicotinic effects include muscle fasciculation and weakness (including the diaphragm), tachycardia, hypertension, and mydriasis. CNS effects include restlessness, anxiety, seizures, and coma (Garigan, 1996). VX has CNS effects that are unrelated to AChE activity and prolonged effects may be seen following convulsive doses (Young et al., 1999). Death is due to paralysis of the diaphragm, airway obstruction from increased bronchial secretions, or depression of the CNS respiratory center (Garigan, 1996).

The G agents present a vapor hazard, as they are very volatile. VX has a high dermal toxicity, even through intact skin, as the liquid does not evaporate quickly (Berkenstadt et al., 1991; Sidell et al., 1997). VX is 300 times more toxic than tabun on skin. A very small drop on the skin may cause sweating and fasciculations at the site. A larger dermal drop may cause loss of consciousness, seizures, apnea, and flaccid paralysis. The toxicity of these substances, listed in descending order on a per-weight basis, is VX, soman, sarin, and tabun (HSDB, 2008).

Delayed peripheral neurotoxicity has been reported in animal studies. Soman produced severe delayed neuropathy in the atropinized hen assay at 1.5 mg/kg (Willems et al., 1984). Sarin, tabun, and VX cause postimplantation mortality and fetotoxicity (HSDB, 2008; RTECS, 2008).

Kinetics

Nerve agents can be absorbed by any route (ocular, oral, inhalation, dermal) (HSDB, 2008; RTECS, 2008). The onset of signs and duration of effects depend on the form of nerve gas (vapor, liquid) and the route of exposure. With a vapor exposure and inhalation, local signs of nasal discharge and respiratory noise begin within 1 min to several minutes and signs can last for a few hours (mild exposure) up to 1–2 days (severe exposure) (Pfaff, 1998). Inhalation of a large amount of the vapor will result in sudden loss of consciousness, apnea, flaccid paralysis, and seizures within seconds to 2–3 min (Sidell et al., 1997). Peak effects are seen within 20–30 min, and death is usually due to respiratory failure (Berkenstadt et al., 1991).

Liquid nerve agents applied dermally cause local sweating and muscular twitching starting 3 min to 2 h after exposure. Signs last for 3–5 days. Following dermal exposure to a large drop, clinical effects start within 30 min but with small drops, a delay of up to 18 h can be seen (Sidell et al., 1997).

Ocular exposure to vapor causes miosis, conjunctival hyperemia, and eye pain within 1 min to several minutes. Signs can last 2–3 days. Liquid tabun penetrates the eye quickly and can result in death nearly as rapidly as an inhalational lethal dose (1–10 min) (EPA, 1985b). Ingestion of the liquid causes muscarinic, nicotinic, and CNS signs about 30 min after mild exposures. The signs

can last several hours up to 2–5 days, depending on the amount of exposure.

Volume of distribution is slightly different for each of the nerve agents. Sarin is distributed to the brain, liver, kidney, and plasma of mice (Little et al., 1986). Soman is distributed throughout the mouse brain, with the highest levels found in the hypothalamus (Wolthuis et al., 1986). Tabun is also found in high concentrations in the hypothalamus after IV administration in mice (Hoskins et al., 1986). Soman is unique in that it has apparent storage in body "depots" and is released over time. This release can result in eventual death in animals who survive the initial dose of soman (Wolthuis et al., 1986).

Most military nerve agents have rapid aging of the OP–enzyme complex. After aging, the inhibitor-enzyme complex becomes resistant to reactivation (Young et al., 1999). VX and tabun are exceptions to this rule, with an aging half-life ($t_{1/2}$) of greater than 40 h (Garigan, 1996). The aging $t_{1/2}$ is only a few minutes for soman and about 5 h for sarin (Garigan, 1996).

Sarin is metabolized to isopropyl methylphosphonic acid (IMPA) and excreted by the kidneys (Little et al., 1986). Approximately 50% of soman is converted to free pinacolyl-methylphosphonic acid within 1 min in mice. The half-life of this metabolite is less than 1 h (Reynolds et al., 1985).

Cholinesterase levels can take weeks to return to normal (Rengstorff, 1985). RBC AChE recovers even more slowly (several days to 4 months), depending on the severity of the depression (Grob, 1956). Pupillary reflexes also remain suppressed for weeks to 1.5 months (Rengstorff, 1985).

Decontamination and Treatment

Administer oxygen and remove the animals from the toxic environment. For ocular exposures, flush eyes with copious amounts of tepid 0.9% saline or water for at least 15 min. Wash all animals three times with either soap and water, dilute bleach solution (1:10 with water), ethanol, or a tincture of green soap (Cancio, 1993). Towelettes impregnated with alkaline chloramine and phenol are used by the military (M291 Skin Decontaminating Kit, Rohm and Haas).

Due to the rapid development of signs, emesis is not recommended after oral ingestion. Activated charcoal can be used in both oral and dermal exposures. Seizures can be controlled with diazepam, methocarbamol, or barbiturates as needed. Assisted ventilation may be necessary if signs progress.

Atropine is an antidotal treatment. It is used to reverse the muscarinic signs, but it will not reverse the nicotinic effects (muscular weakness, diaphragmatic weakness, etc.). Atropine blocks the effects of accumulated acetylcholine (ACh) at the synapse and should be continued until the nerve agent is metabolized (Midtling et al., 1985). Over-atropinization can cause hyperthermia, tachycardia, agitation, mydriasis, and ileus, which can be life-threatening in the horse.

Oximes are used to treat the nicotinic signs. Pralidoxime (2-PAM) is the oxime of choice in the United States, and it is most effective when administered in the first 1–3 h. Due to the quick aging of soman, 2-PAM is rarely given soon enough to be effective (Sidell et al., 1997). 2-PAM can be given up to 48 h after exposure to VX and tabun, due to slow aging (Sidell and Groff, 1974). Other oximes, such as obidoxime dichloride (Toxogonin, LüH-6), are used in other countries (Belgium, Israel, the Netherlands, Scandinavia, Portugal, and Germany). HI-6 is another alternative oxime that has excellent acetylcholinesterase regenerating action with VX, very good action with sarin, good response to soman, but poor or no response following tabun exposures (Hoffman, 1999).

Autoinjectors (AtroPen, Mark I, Combopen MC) are atropine or atropine and 2-PAM combinations available for human use. They are not used in veterinary medicine as they are not adjustable for different-sized patients. Experimental vaccines against nerve agent VX, and monoclonal antibodies which protect against soman, sarin, and tabun toxicity have been produced and are being tested (Dunn and Sidell, 1989).

AChE activity can be tested in plasma, serum, or whole blood. In most animal species, 80% or more of the total blood AChE activity is in the RBCs, as compared to 50% in humans; therefore, whole blood is the preferred sample for most veterinary diagnostic labs. In general, in the context of OP poisoning, whole blood AChE activity that is less than 50% of normal is generally associated with severe symptoms (Midtling et al., 1985). Furthermore, inhibition of RBC AChE is interpreted as follows: (i) 10–20%, no reliable evidence of exposure; (ii) 30–50%, mild poisoning; (iii) 50–70%, medium or moderate; and (iv) 70–90%, severe intoxication.

The G agents are volatile and evaporate over several hours. They are nonpersistent in the environment (Garigan, 1996). Environmental persistence is estimated to be 0.5–1 day for tabun, 1–2 days for soman, and 5 days for sarin. VX is an oily liquid that remains in the environment for weeks or longer after being dispersed (Garigan, 1996; Sidell et al., 1997; Munro et al., 1999; Budavari, 2000). Contaminated soil should be treated with alkaline substances (such as sodium carbonate, sodium bicarbonate, calcium hydroxide, or calcium carbonate) or chlorine compounds (sodium hypochlorite or calcium hypochlorite) (EPA, 1975).

Protective equipment (rubber gowns, aprons, and gloves), along with respiratory protection, must be worn by rescuers and veterinary personnel. Leather and fabrics absorb OPs and are extremely difficult to decontaminate. Collars, muzzles, and other items should be incinerated. For further details on decontamination of nerve agents, see chapter 76.

Species Susceptibility

Nerve agent susceptibility varies widely between species. Animals may be more at risk for greater exposures than nearby human populations. Both the G and the V nerve agents are heavier than air, and animals with a lower breathing zone will be more affected (Rabinowitz et al., 2008). Some species differences can make animals more sensitive than humans, while others will make them more resistant. Rats may be less susceptible than humans, since they possess aliesterases that can reduce the toxicity of certain nerve agents such as soman and tabun (Fonnum and Sterri, 1981; Gupta and Dettbarn, 1987). These enzymes are not present in humans. Nasal breathers, such as rodents, are capable of partially detoxifying nerve agents in the nasal pathways, presumably by hydroxylation and other mechanisms (Garamone, 2003). Carboxylesterase (CarbE) activity in guinea pigs and rabbits may provide protection from soman, when compared to humans (Maxwell et al., 1987).

RBC AChE activity also varies among species. In humans, low RBC AChE activity has been associated with increased susceptibility to nerve agents (Leng and Lewalter, 1999). Pigs, sheep, dogs, rabbits, and cats have less RBC cholinesterase activity than humans (Anonymous, 2000b). This would make these species more sensitive to nerve agents unless they have an alternative system to combat cholinesterase inhibition.

The LCt_{50} (50% lethal concentration via inhalation route) for military personnel for different nerve agents has been estimated from animal studies. Humans appear to be more sensitive to tabun than other animals. The LCt_{50} for tabun is 70 mg min/m^3 for humans, 320 mg min/m^3 for dogs, 450 mg min/m^3 for rats, and 960 mg min/m^3 for rabbits (Anonymous, 2000a; NRC, 2003). Goats are more sensitive than humans to VX. The LCt_{50} for goats is 9.2 mg min/m^3, while the human LCt_{50} is 15 mg min/m^3 (Anonymous, 2000a; NRC, 2003).

Even though the lethal nerve agent exposure level for animals may be higher than that for humans, it is still possible that animals could exhibit other nonlethal effects sooner and more noticeably than humans. Rabbits develop 90% miosis at a lower inhaled concentration of cyclohexyl sarin when compared to humans (2.71 mg min/m^3 versus 13.85 mg min/m^3) (NRC, 2003).

Another way that animals could provide an early warning is via their sense of smell. Most animals have much more sensitive olfactory systems than humans. Animals may be able to be trained to sense low nerve gas concentrations (Dalton, 2003).

It is unknown if animals may have decreased dermal absorption compared to humans due to their protective fur or feathers. Comparing dermal exposures in humans and other species also shows differences for the various nerve agents. Mice appear to be more sensitive to dermal sarin than humans; the LD_{50} values for each are 1.08 and 28 mg/kg, respectively (Sidell et al., 1997; RTECS, 2008). The mouse may also be a good sentinel animal for tabun. The dermal LD_{50} for mice is 1 mg/kg; for rats, it is 18 mg/kg, and for humans, it is 14 mg/kg. Mice may be slightly more resistant to dermal soman, with LD_{50}s of 7.8 mg/kg for mice and 5 mg/kg for humans.

There are a few cases where shared exposures to nerve agents have been reported for both animals and humans. In 1968, there was an accidental release of two different nerve agents (one is thought to have been VX) in Utah. A flock of sheep that was grazing near the base was noted to be acting "crazy in the head," and thousands died less than 24 h later (Boffey, 1968). Nearby humans, cattle, dogs, and horses did not develop symptoms. The sheep had severely depressed cholinesterase levels, as did the cattle and horses. Cholinesterase testing of dogs and humans was normal. The sheep may have been more affected due to higher exposures through ingestion of contaminated pasture, or by spending more time in the vicinity of the chemical release.

3-Quinuclidinyl Benzilate (bz)

Clinical Signs

3-quinuclidinyl benzilate (BZ) is a centrally acting synthetic anticholinergic agent. BZ is used as a hallucinogenic and incapacitating CWA. It is about 25 times more potent than atropine and has a very long duration of action. BZ is disseminated as an aerosol, with the primary route of absorption through the respiratory system.

BZ affects both the peripheral nervous system (PNS) and CNS. Peripheral anticholinergic effects can be summarized by the mnemonic "dry as a bone, red as a beet, hotter than Hades and blind as a bat." BZ inhibits glandular secretions ("dry as a bone"), leading to a dry mouth and foul breath (Holstege, 2006). Cutaneous vasodilation and skin flushing may be noted ("red as a beet") due to decreased capillary tone. Hyperthermia ("hotter than Hades") is due to elevated body temperature secondary to inhibition of sweating and inability to dissipate heat. Vision loss ("blind as a bat") is from a loss of accommodation reflexes and decreased depth of field secondary to ciliary muscle paralysis and mydriasis (Holstege, 2006). Paralytic ileus is commonly seen as a result of anticholinergic toxicity (Ketchum and Sidell, 1997; Holstege, 2006). This can lead to fatal colic in equids. Urinary retention is also a common anticholinergic effect following exposure to BZ (Ketchum and Sidell, 1997; Holstege, 2006).

CNS signs of disorientation, agitation, tremor, ataxia, stupor, coma, and seizures may occur from inhibition of central muscarinic receptors (Ketchum and Sidell, 1997;

Holstege, 2006). It is unknown if animals hallucinate like people, but they do appear distressed. Rhabdomyolysis can be seen secondary to seizures and agitation. If severe, myoglobinuric renal failure could develop (Holstege, 2006).

Other systemic signs may also occur. Sinus tachycardia is common (Ketchum and Sidell, 1997; Holstege, 2006). Moderate hypertension may occur, and tachypnea may be expected following an acute exposure. Nausea and vomiting may also occur.

Kinetics

BZ easily crosses the blood–brain barrier (BBB), leading to mostly CNS effects. Signs are dependent on the dose and time after exposure. Prolonged effects may occur depending on the dose of BZ absorbed. Tachycardia and dry mouth develop within 15 min to 4 h after exposure (Ketchum and Sidell, 1997). Peak effects occur at 8–10 h (Ketchum and Sidell, 1997).

BZ accumulates in the cerebrum following an IV injection in rats (Sawada et al., 1990). It is highly lipophilic and has a high degree of plasma protein and red cell binding. Steady state was reached in the cortex and caudate within 1–5 min. Binding to high-affinity muscarinic acetylcholine receptors (mAChRs) is essentially irreversible for the first 6 h.

BZ is excreted via the kidneys (Holstege, 2006). Only about 3% is excreted unchanged in rat urine (Byrd et al., 1992). The two major metabolites are 3-quinuclidinol and benzilic acid. Without treatment following an incapacitating dose, recovery is gradual, requiring 72–96 h (Ketchum and Sidell, 1997).

Decontamination and Treatment

Move into fresh air. Monitor animals for respiratory distress. If cough or dyspnea develops, administer supplemental oxygen. Assisted ventilation may be required. Nebulized beta-adrenergic agonists should be used if bronchospasm develops.

Due to the method of distribution (aerosol), most exposures are expected to be via inhalation. However, with animals' tendency to groom, dermal exposures can also become oral exposures. Emesis is not recommended due to potential seizures and coma. Activated charcoal or gastric lavage can be helpful after oral exposures. These procedures can be successful even if delayed, as anticholinergics slow gastrointestinal motility.

Flush eyes with copious amounts of tepid water for at least 15 min. Animals should be bathed with soap and water. Bathing will not only remove the BZ, but will also provide external cooling to combat hyperthermia. BZ may be detected in urine, serum, or blood, but there are no rapid tests to diagnose exposure to BZ, so clinical use is minimal.

Benzodiazepines can be used to control agitation. Avoid phenothiazines due to possible hypotension. Animals may need to be heavily sedated so that they do not injure themselves or others. Control seizures with a benzodiazepine, phenobarbital, or propofol. Rhabdomyolysis can occur if agitation or seizures are not controlled.

Treat arrhythmias symptomatically (lidocaine, propranolol, etc.). Physostigmine can be used to treat severe arrhythmias, but long-lasting reversal of anticholinergic toxicity does not occur. Physostigmine is ineffective if given during the first 4–6 h following the onset of BZ effects. If physostigmine is discontinued, recovery from BZ may be slightly prolonged (Ketchum and Sidell, 1997).

Monitor electrolytes and renal function tests in symptomatic patients. Administer IV fluids to maintain urine output and to protect the kidneys from myoglobinuria. The prognosis is good if animals do not develop rhabdomyolysis or secondary infection. No chronic problems are expected from BZ itself (Holstege, 2006).

BZ is stable and environmentally persistent. "Off gassing" may occur from contaminated patients. Goggles and masks should be worn by all personnel until the animals are decontaminated (Holstege, 2006). Remove contaminated collars, leashes, harnesses, halters, and other devices, and discard them, as leather and fabrics absorb BZ.

Species Susceptibility

There are no studies demonstrating that animals are more sensitive than humans.

RCAs (Lacrimators)

Clinical Signs

Chloroacetophenone (i.e., CN, mace, tear gas), chlorobenzylidene malonitrile (i.e., CS, Paralyzer, super tear gas), and oleoresin capsicum (OC; pepper spray) are lacrimators used in riot control. They are solid chemicals administered as a fine dust or aerosol spray rather than being true gases. Exposure to lacrimators causes immediate pain, blepharospasm, lacrimation, rhinorrhea, coughing, and sneezing, but usually no permanent tissue damage (Grant and Schuman, 1993; Blain, 2003). With higher ocular concentrations, chemical burns with keratitis and loss of the corneal epithelium may occur (Hoffman, 1967). A 4% weight/volume CN product has caused permanent corneal injury and ocular necrosis in animals, but no such injury was seen in a 10% w/v CS product (Gaskins et al., 1972; Grant and Schuman, 1993). Oral ingestion will also cause eye irritation, lacrimation, vomiting, and diarrhea (Blain, 2003). Laryngospasm may occur in some cases due to the irritant effects; it

can progress to pulmonary edema, bronchospasm, and bronchopneumonia.

Dermal contact with lacrimators is very painful (Pinkus, 1978). Erythema and blisters are common. The extent of dermal effects depends on the thickness of the stratum corneum, and the extent of exposure (Blain, 2003). High concentrations can cause first- and second-degree burns of the skin (Stein and Kirwan, 1964; Hu et al., 1989). No teratogenicity or carcinogenicity has been demonstrated in humans or animals (Folb and Talmud, 1989; Blain, 2003). For further details on toxicity of RCA, see chapter 11.

Kinetics

The effects of lacrimators occur very quickly. Pain, salivation, coughing, rhinorrhea, sneezing, and erythema begin within seconds of exposure and can last approximately for an hour (Blain, 2003). Delayed effects may also be seen. Conjunctivitis and ocular edema may be noted from 1–2 days following exposure. Laryngospasm and pulmonary edema may occur up to 48 h (usually 12–24 h) post-exposure. Bronchospasm may also be delayed up to 48 h post-exposure and become chronic (Folb and Talmud, 1989).

One of the CS metabolites is cyanide, but cyanide toxicosis does not appear to happen with routine use (Cucinell et al., 1971). Gastrointestinal signs resolve over 24 h (Solomon et al., 2003). Erythema disappears over 48 h and coughing may persist for weeks after exposure (Blain, 2003).

Decontamination and Treatment

Animals may need to be sedated to be able to treat them safely. Move animals into fresh air and monitor for respiratory distress. If cough or dyspnea develops, monitoring is necessary for oxygenation status. Supplemental oxygen may be needed. Laryngospasm may require intubation to permit adequate ventilation. Inhaled beta-2 agonists (i.e., albuterol and salbutamol), corticosteroids, and aminophylline may help reduce bronchospasm (Folb and Talmud, 1989). Thoracic radiographs should be monitored if pulmonary edema is expected (Stein and Kirwan, 1964).

Flush eyes with copious amounts of tepid 0.9% saline or water for at least 15 min. Diphoterine solution can be used for decontamination of both eyes and skin after exposure to lacrimators (Viala et al., 2005). Ocular signs resolve approximately 3–7 min after decontamination with diphoterine.

Animals should be bathed with soap and copious amounts of cold water. Using small amounts of water can actually increase irritation (Lee et al., 1984). Topically applied magnesium hydroxide–aluminum hydroxide–simethicone suspension (Maalox Max) caused resolution of signs within 2 min of application following exposure to OC. If chemical burns develop, clean wounds with a mild, disinfectant soap and water. Pain control and antibiotics may be needed. Tetanus toxoid should be given if burns are present. With oral ingestions, antacids may help decrease gastrointestinal signs.

Secondary contamination is common and personnel should wear aprons, rubber gloves, and masks as needed. Contaminated items can be washed in cold water (hot water will cause residual gas to vaporize) with soap or allow nonwashable items to air out for a few days. Most lacrimators dissipate quickly, but CS may be micronized and mixed with an antiagglomerant agent (CS1), which remains active for up to 5 days. A similar formulation mixed with silicone (CS2) remains in the environment for up to 45 days (Hu et al., 1989).

Species Susceptibility

There are no controlled studies showing that animals are more sensitive to lacrimators than humans.

Ricin and Abrin (Toxalbumins)

Clinical Signs

Ricin and abrin are toxalbumins, which are plant lectins with a specific affinity for animal cell receptors. *Ricinus communis* (including the castor bean plant, castor oil plant, koll, mole bean, moy bean, and palma christi) contains ricin. The castor bean plant is grown throughout the United States as an ornamental. The brown and white seeds, which resemble large ticks, contain the ricin. Most animals are exposed to ricin by eating the seeds, but ricin has been used as a CWA, a reagent for pepsin and trypsin, an experimental antitumor and immunosuppressive agent, and a commercial mole killer (Sax and Lewis, 1989; Budavari, 2000; HSDB, 2008). Abrin is found in the *Abrus precatorius* plant (including the Buddhist rosary bead, crab's eyes, Indian bead, Indian licorice seed, jequirity bean, jungle bead, love bean, lucky bean, mienie-mienie, ojo de pajaro, prayer bead, rosary pea, seminole bead, and weather plant). This tropical ornamental vine produces colored seeds that are popular for use in jewelry and other decorative items. The seeds come in three different colors: red with a black eye, black with a white eye, and white with a black eye (Niyogi, 1969).

Variable toxicity is seen in cases of oral ingestion. Seeds that are chewed are much more likely to cause clinical signs. Seeds swallowed whole may not cause any problems at all (Kinamore et al., 1980). The amount of toxalbumins in the seeds will vary by size, weight, moisture content, region, season, and the period of plant growth at the time of harvesting. The ricin content of castor beans can vary from 1% to 10% (Balint, 1974). The

abrin content in *Abrus precatorius* seeds is estimated at 0.15% (Lin et al., 1971). Toxicity and death have occurred with ingestions of one to two chewed beans of either plant. Ricin levels can be measured in plasma and urine but are not clinically useful (Kopferschmitt et al., 1983).

Vomiting, abdominal pain, and bloody diarrhea are the most common signs seen after ingestion (Kopferschmitt et al., 1983). Toxalbumins cause severe gastrointestinal lesions of the oropharynx, esophagus, and stomach. The lesions are clinically similar to alkaline burns. Fluid losses can lead to dehydration, electrolyte disturbances, hypotension, and tachycardia (Ingle et al., 1966).

Liver damage occurs in toxalbumin toxicosis. Histopathology reveals injury to the smooth endoplasmic reticulum and depletion of liver glycogen (Balint, 1978). The liver values for alanine aminotransferase (ALT), total bilirubin, aspartate aminotransferase (AST), alkaline phosphatase, and gamma-glutamyl transferase (GGT) can all be elevated. Glucose metabolism is affected by ricin. Not only do glycogen stores decrease, but gastrointestinal absorption of glucose decreases and glucose concentrations fall (Lampe, 1976). Hypoglycemia is a common finding.

Mild to moderate CNS depression is commonly observed. Seizures are reported more frequently in animals than in people (Hart, 1963). While hematuria is commonly reported, the hemagglutination that is seen in animal and laboratory work is almost never seen in actual toxicities (Waller et al., 1966).

Ricin is among the most toxic compounds known when given parenterally. Parenteral toxicity is much greater than oral toxicity. The oral lethal dose of ricin is estimated to be 1 mg/kg (Kopferschmitt et al., 1983). When given by injection, the lethal dose of ricin drops to about 1 μg/kg (Budavari, 2000). With an inhalation exposure, signs seen are cough, dyspnea, arthralgias, fever, and death (Griffiths et al., 2007). Other organ system dysfunctions may not occur. For more details on toxicity of ricin and abrin, see chapters 27 and 53.

Kinetics

Gastrointestinal effects usually develop in under 6 h, but vomiting can begin in 1–3 h postingestion of castor beans (Kopferschmitt et al., 1983). In some cases, signs may be delayed for several days. The cytotoxic effects on the liver, CNS, kidney, and adrenal glands may not occur for 2–5 days post-exposure. With an inhalation exposure symptoms begin within 8 h. Death occurs about 48 h after a parenteral or oral exposure (Budavari, 2000).

Glycoproteins are large molecules and are poorly absorbed from the gastrointestinal tract. Many cell surfaces contain receptors specific for ricin and the toxin is taken up by active transport. The primary site of distribution of ricin is the liver, spleen, and adrenal cortex in the mouse. A high concentration was also found in the bone marrow (Godal et al., 1984). In rats, abrin is distributed primarily to the liver (12%) and kidney (3%; Lin et al., 1971).

The metabolism and elimination of toxalbumins is poorly understood. Ricin is eliminated by first-order kinetics when injected via IV into mice and human cancer patients (Godal et al., 1984). The plasma half-life in humans is about 2 days (Kopferschmitt et al., 1983).

Decontamination and Treatment

There are no specific treatments for toxalbumin exposure. Aggressive decontamination is recommended. With ingestions, emesis should be induced in species that can vomit (e.g., dogs, cats, ferrets, and swine), if the animal is not already vomiting. Activated charcoal can bind orally ingested toxalbumins. Monitor asymptomatic animals for 8 h following any exposure to toxalbumins. Monitor for dehydration, electrolyte disturbances, elevated liver enzymes, and hypoglycemia.

Intravenous fluids are very important to maintain normovolemia and urine output. If hematuria is present, consider alkalinization of the urine. A goat anti-ricin polyclonal and a mouse anti-ricin A-chain monoclonal antibody have been tested and shown to neutralize ricin in castor bean extract, but they are not clinically available (Lemley and Wright, 1991; Wannemacher et al., 1991).

If the toxalbumin was distributed by air, move the animal into fresh air and monitor for respiratory distress. If cough or dyspnea develops, administer supplemental oxygen. Wash animals thoroughly with soap and water. Eyes should be flushed with copious amounts of tepid 0.9% saline or water for at least 15 min. Other treatments are the same as for an oral exposure.

Species Susceptibility

There are no controlled studies demonstrating that animals are more susceptible to developing acute effects than humans.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The lack of controlled studies comparing animals and humans needs to be addressed if animals are to be used as sentinels. The existing studies and anecdotal reports do not provide enough convincing evidence (Rabinowitz et al., 2008). Sentinels would need to demonstrate easily recognizable signs before the emergence of human illness. A good sentinel could have either greater susceptibility to a particular toxin relative to humans or a shorter latency time from exposure to onset of signs (Cottrell and Morgan, 2003).

With any suspicious outbreaks, the local health department, poison center, law enforcement agencies, and the US Federal Bureau of Investigation (FBI) should be contacted

immediately. Due to the absence of a nationwide surveillance system for animal diseases, the responsibility for detecting possible outbreaks of unusual symptoms in animals will fall to several different groups of people. Farmers, agriculture officials, veterinarians, animal control officers, wildlife rehabilitators, (animal) poison control centers, and the lay public (such as animal owners) may all be involved in detecting outbreaks.

During a chemical warfare incident, the human casualties should be addressed first, followed by the animal casualties. Situations in which herds of livestock or flocks of poultry are affected are going to be much more complex to manage than exposures to house pets. The simple logistics in getting the personnel and equipment to the site of exposure can be daunting, if not impossible. Handling livestock can be dangerous, especially to untrained personnel. The use of antidotes and other pharmaceuticals must be documented in food-producing animals and withdrawal times for meat and milk must be followed. In many herd situations, humane euthanasia may be the best solution.

CHAPTER

55

Threats to Wildlife by Chemical and Warfare Agents

Robert W. Coppock and Margitta Dziwenka

INTRODUCTION

Wildlife as a target of terrorist activity is a relatively new concept. Wildlife has been the object of criminal activity, especially removal of unwanted predators and poaching, and wildlife has suffered collateral damage during war activities. Wildlife has traditional value as a source of food, for big game hunting, as materials for garments, and as other necessities and luxuries. There is also an increased ambition to view and photograph wildlife in its natural habitat. Ecotourism is a growing industry, especially if a country has unique or rare wildlife species or spectacular habitats. Wildlife is a commercially exploited source of income in sport and trophy hunting. In some countries, wildlife-based ecotourism provides an important source of revenue. The role of government is to protect wildlife from overkilling and to protect the environmental necessities for wildlife to feed and breed; this role is generally enforced by using a variety of laws and regulations. Additional laws and enforcement measures can be used to protect wildlife from human disturbances. Terrorist activities against wildlife can be undertaken to disrupt or destroy regional income and to remove a food source from aboriginal peoples that depend on wildlife for subsistence and culture preservation. Terrorist activities by their nature are generally performed for a variety of reasons to destabilize society (Gleick, 2006). Environmental terrorism is a term that has been used to negatively label individuals or groups that want to change the manner is which natural resources are exploited, permanently altered, or destroyed (Gleick, 2006).

BACKGROUND

Wildlife can be a direct or indirect target for terrorist attack. Wildlife has a similar sensitivity to the toxic effects of physical and chemical agents as domestic animals. Essentially the same laboratory infrastructure is needed to diagnose the etiology of diseases in wildlife and domestic animals. Terrorist attacks against governmental and commercial operations could occur in more remote areas, and such attacks could have an immense impact on wildlife, including fish and other aquatic organisms. Impoundments of toxic water could be a target for terrorists for the primary purpose of contaminating potable water sources. Not linked to terrorism, there are recent examples of a large volume of toxic water being released into waterways spanning several countries with subsequent public outcry and economic impacts. The release of 50–100 tonnes of cyanide from a tailings pond into the Sasar River and eventually reaching the Danube River had a devastating impact on wildlife in Eastern Europe (Cunningham, 2005). One can only imagine the public and political reaction that would have occurred if this incident was claimed to be an act of terrorism.

Terrorist attacks could have a collateral cascading impact on wildlife. Fish and other aquatic organisms can be impacted by run-off water from fire fighting. This water could contain toxic substances and these substances could have negative impacts on wildlife. Run-off waters from burnt-over lands draining into waterways also are high in toxic substances.

Terrorist attacks can create wildlife problems. Birds and rodents can impact the recovery of biological

evidence during forensic investigations (Chipman et al., 2002).

ILLICIT AND RESTRICTED SUBSTANCES

Background

There are concerns regarding illicit pesticides being used for clandestine activities (Whitlow et al., 2005). Because of their extreme toxicity, over time the use of certain substances was limited and in some cases they were even deregistered. These compounds are especially dangerous to wildlife because residual levels in carcasses can cause relay toxicity in scavenging and opportunistic feeders.

Tetramethylenedisulfotetramine

Background

Tetramethylenedisulfotetramine (TETS; 2,6-dithia-1,3,5,7-tetraazatricyclo[3.3.1.13,7]-decane,2,2,6,6-tetraoxide, CAS No. 80-12-6, "tetramine") is emerging as an illicit neurotoxin (Barrueto et al., 2003; Whitlow et al., 2005). TETS is an odorless, white, crystalline power that is readily soluble in water, mixes with feedstuffs, and is generally considered to be tasteless. It is estimated that 50% of the rodenticides in China contain TETS (Owens et al., 2009).

Mechanism of Action

TETS selectively and irreversibly binds with the chloride channel on the γ-aminobutyric acid receptor and disrupts regulation of chloride in the neuron. Inhibitory activity in the central nervous system (CNS) is decreased and clinical manifestations are seizures, with onset occurring soon after TETS ingestion. The toxicity of TETS is generally considered to be more potent than sodium monofluoroacetate (SMFA; Compound 1080). The oral LD_{50} of TETS for most species is 0.1–0.3 mg/kg of body weight, and the total lethal dose for a human is considered to be 10 mg. Rabbits dosed with TETS 0.4 mg/kg body weight and killed 1 h later had detectable levels (0.07–0.238 μg/g) in the liver, kidney, heart, and lung (Xiang et al., 2001). TETS is excreted in urine, and urine can be used for forensic investigations (Zeng et al., 2006). Scavenging animals and birds can be poisoned with TETS because of the stability of TETS in tissues and body fluids.

Pathology and Detection

The pathology of TETS in humans has been reported (Zhou et al., 1998). Pathological observations in poisoned humans were edema of the brain, hemorrhages in the brain stem, and myocardial degeneration in the papillary muscles. Cardiac myopathies of varying distribution are a common finding in the majority of species. Human tissues and urine can be assayed for TETS (Xiang et al., 2001; Zeng et al., 2006). A reasonable assumption is that similar pathology and levels in tissues and urine would occur in other species. Analytical methods include liquid chromatography mass spectrometry and gas chromatography–mass spectrometry (Owens et al., 2009).

Sodium Monofluoroacetate and Sodium Fluoroacetamide

Background

Sodium monofluoroacetate (SMFA; Compound 1080) and sodium fluoroacetamide (Compound 1081) are candidate chemicals for terrorists and criminal activities targeting humans, domestic animals, and wildlife (Holstege et al., 2007). The toxicology of sodium fluoroacetamide is similar to SMFA (Osweiler et al., 1976). SMFA and sodium fluoroacetamide were used as pesticides (Shlosberg and Egyed, 1975; Proudfoot et al., 2006). In addition to being a synthetic chemical, SMFA and closely related compounds are found in *Dichapetulum* and other species of plants. The use of SMFA as a poison to eliminate unwanted animals and birds is restricted in many countries, primarily because of large kills in nontarget species (Ataria et al., 2000; Eason, 2002). Countries with limited indigenous mammal populations use SMFA to control imported animal species that disrupt and endanger indigenous wildlife (Eason, 2002). SMFA is water-soluble and can be easily added to water, baits, and feedstuffs. The use of SMFA can be limited to kill problem predators. For example, SMFA in some jurisdictions has been limited to sheep collars containing SMFA. In these applications, the SMFA is contained within bladders that are punctured during a predator attack (Burns and Connolly, 1995). Diagnosis of intoxication with SMFA could be delayed because the majority of attending medical professionals would not immediately suspect intoxication with a restricted substance. SMFA is essentially not detected by the sense organs. It is a white powder that has the appearance of flour or sugar, and is stable in storage over a long period of time. SMFA is heat-stable to 200°C. It is soluble in water and insoluble in ethanol and lipids. In water, it is degradable by microorganisms.

Toxicology of Sodium Monofluoroacetate

Compound 1080 is absorbed from the gastrointestinal tract, respiratory tract, mucous membranes, and wounds (Holstege et al., 2007). Different routes of exposure do not have a remarkable effect on toxicity. The mechanism of action for SMFA is blockage of the tricarboxylic acid cycle. Metabolic activation by the formation of fluorocitrate is required, a process known as lethal synthesis. Fluoroacetate is converted to fluoroacetyl-CoA and then converted by citrate synthase to fluorocitrate. Aconitase catalyzes the

TABLE 55.1 Estimated Lethal Dose of SMFA in Selected Animals

Mammal or Bird	Lethal Dose (mg/kg body wt)
Dog	0.1–0.2
Coyote and fox	0.1–0.3
Cattle	0.2–0.7
Pig	0.3–0.4
Cat	0.3–0.5
Horse	0.5–1.8
Human	0.5–5.0
Goat	0.5–0.7
Magpie	0.6–2
Rabbit	0.8
Chicken	6–18
Ducks	7–9

Source: Robinson, 1979; Ataria et al., 2000; Goh et al., 2005; Collicchio-Zuanaze et al., 2010

conversion of citrate to isocitrate and aconitase is inhibited by fluorocitrate. Inactivation of aconitase blocks the tricarboxylic acid cycle. Serum citrate levels increase and serum calcium generally decreases. Fluorocitrate also blocks the transport of citrate through the mitochondrial membrane. The heart and CNS are simultaneous targets for SMFA. Animals poisoned by SMFA are a hazard to scavengers, opportunists, and carnivores. The sensitivity of species to SMFA is given in Table 55.1.

Clinical Signs of Intoxication

Clinical signs of SMFA toxicity are due to the effects on the CNS and heart (Osweiler et al., 1976; Proudfoot et al., 2006). Herbivores can show more cardiac signs. The sequence of cardiac events is arrhythmias, tachycardia, inefficient pumping (weak pulse), and death when the heart fibrillates. Clinical signs observed are ataxia, collapse, and a short interval of agonal struggling (Robinson, 1979). Field observations are usually the discovery of a dead animal with the appearance of sudden collapse and limited evidence of agonal struggling. Carnivores generally have neurological signs of hyperesthesia, aimless wandering, frenzied running, vocalization, incoordination, emesis, opisthotonus, coma, and death. Thermoregulation may be disrupted. Death occurs from 1 to 24 h after ingestion of SMFA. Birds fall from the sky and die soon after hitting the ground, or show nervous system signs and an inability to fly. Relay intoxication by SMFA and its metabolites can occur. An animal that has ingested SMFA and vomits can be lethally intoxicated, and the animal ingesting its vomit can also be lethally intoxicated. The tissues of an animal poisoned by SMFA can be lethal to animals and birds that consume them.

Pathology

Pathological findings in SMFA poisoning are those of acute heart failure and hypoxia. Hypocalcemia can be observed in SMFA intoxication (Proudfoot et al., 2006). Tissues can be assayed for SMFA by gas chromatography methods (Okuno et al., 1984).

CYANIDE

Background

Cyanide (CN^-) is poisonous to essentially all animal species and is a listed chemical for terrorists and criminal activities. Cyanide can be placed in a variety of baits, including water bait. Sodium and potassium cyanide along with other forms of cyanide can be used. Industrial activities using water impoundments can be conducted at a narrow margin of safety and could be targets for terrorists and criminals. Cyanide is also used in the extraction of gold and silver ores. The cyanide used in the process is recycled, but some cyanide escapes into the tailing pond along with unrecovered heavy metals (Donato et al., 2007). Birds, bats, and other animals using the tailing ponds as part of their ecosystem have been poisoned (Donato et al., 2007; Griffiths et al., 2014). Catastrophic release of a large volume of tailing pond slurry containing high concentrations of cyanide and heavy metals into river systems has occurred (UNEP, 2000; Macklin et al., 2003; Cunningham, 2005). The rupture in January 2000 of a Romanian dam holding 100,000 m^3 of cyanide-contaminated slurry water caused an environmental disaster (Macklin et al., 2003; Cunningham, 2005). An estimated 50–100 tonnes of cyanide and heavy metals were released into the Sasar River and then flowed through the Lapus River to the Somes River, to the Tisza River, and emptied into the Danube River. The breach in the dam was attributed to a number of factors, including a sequence of perception events. This incident was evaluated as causing a cascade of severe wildlife mortalities. It is also feasible that terrorist or criminal activities could target tailings ponds and cause a huge sudden release of contaminated water, creating a down-river environmental disaster that targets drinking water safety, wildlife, tourism, and international relations. Cyanide also has a history of being used to control unwanted wildlife and is toxic in the marine environment (Wiemeyer et al., 1986).

Toxicology

The pathophysiology of acute cyanide poisoning is due to its rapid diffusion into tissues and impairment of

TABLE 55.2 Estimated LD_{50} of Cyanide in Wildlife

Bird or Mammal	LD_{50} (mg/kg body wt)
Black vulture	4.8
American kestrel	4
Coyote	4.1

Source: Sterner, 1979; Wiemeyer et al., 1986

oxidative phosphorylation and other biochemical pathways (Beasley and Glass, 1998). The primary enzyme target is cytochrome oxidase by the high affinity for ferric iron in the oxidized enzyme. Oxygen utilization is inhibited and lactate accumulation rapidly leads to metabolic acidosis. Clinical signs of cyanide intoxication in birds have been described (Wiemeyer et al., 1986). The progression of clinical signs of cyanide poisoning in vultures is ataxia, eye blinking, head bowing, wing droop, increased ataxia, seizures with tail fanning, opisthotonos gasping, and death. The progression of clinical signs in kestrels, owls, and quail is more violent. Time from ingestion to death is dose-dependent. The lethal dose 50 (LD_{50}) for some species is given in Table 55.2.

Terrorist and criminal actions that release cyanide into the environment can kill large numbers of wild animal species. Release of cyanide-polluted water can have long-term consequences on a freshwater system (Lakatos et al., 2003). Cyanide poisoning of wildlife can also be collateral damage due to its presence in run-off water from fire fighting and in run-off from burnt-over lands (Barber et al., 2003). Freshwater fish are highly sensitive to free cyanide. Fish mortality can occur at less than 20 µg/L (Barber et al., 2003; Eisler and Wiemeyer, 2004). The lethal level of cyanide in rainbow trout is changed by water temperature and exercise (McGeachy and Leduc, 1988). Young fish can also be sensitive to the effects of cyanide on the thyroid gland (Brown et al., 2004). Cyanide can reduce the number of viable eggs produced by sexually maturing rainbow trout (Lesniak and Ruby, 1982).

Readers are referred to Chapter 23 for more details on cyanide poisoning.

RICIN (CASTOR BEAN)

Background

Castor beans (*Ricinus communis*) and ricin have been identified as potential terror agents of terrorism. Castor beans and castor bean by-products could be used as terrorist agents targeting wildlife. Castor beans do not initiate unique clinical signs of intoxication and in waterfowl can be confused with other acute causes of death (Jensen and Allen, 1981). There are inconclusive reports of Canada geese being killed due to castor beans. In Texas, castor bean intoxication could have been the cause of deaths of 10,000 ducks in 1967, and 2,000 ducks in 1969–1970 (Jensen and Allen, 1981). The death of 1,673 ducks occurred again in Texas in 1971. A castor bean was found in the gastrointestinal tract of one duck during pathological examination. Castor beans had been grown in the area. Although inconclusive, this report does incriminate voluntary ingestion of castor beans as the cause of death in ducks.

Pathology and Toxicology

Ducks taken from the area where 2,000 ducks had died in 1969 through 1970 were examined by diagnostic procedures (Jensen and Allen, 1981). The toxins of *Clostridium botulinum* and pathogenic bacteria were not identified. Catarrhal enteritis was identified with hemorrhage into the intestine. Seed parts suggestive of *Ricinus communis* were found in scrapings of the wall of the proventriculus. Fatty degeneration of hepatocytes was observed.

In a study in which ducks were force-fed whole castor beans (Jensen and Allen, 1981), progressive signs of acute intoxication were passage of blood-streaked mucus, leg paresis, loss of mobility with wings, sitting, prone recumbency, and death. Necropsy findings were whole and fragments of castor beans and congestion of the liver. Histopathology changes included severe fatty degeneration of hepatocytes, granulocytic infiltration into portal areas, pulmonary congestion, and peribronchial hemorrhage; necrosis and hemorrhage were observed in the spleen. These findings support the field observation that some waterfowl may consume castor beans that can result in fatal intoxication.

The observation that wild ducks voluntarily ingest castor beans provides evidence that there is some risk that terrorists could successfully use ricin against wild ducks and other wild waterfowl species.

PESTICIDES

Background

The neurotoxic cholinesterase inhibitors developed for chemical warfare, also used by terrorists, can kill wildlife species. Birds and other wildlife are well-known nontarget species for insecticides through intentional poisonings and contaminated seeds, water, forage, and

prey (Schafer et al., 1983; Stone et al., 1984; Fleischli et al., 2004). Granular insecticides can be voluntarily ingested. Insecticides and neurotoxic chemical warfare agents could be used in acts of terrorism against a targeted wildlife population, and wildlife could be killed as collateral damage.

Vertebrates can be nontarget species when insecticides are applied according to the registered label (Marian et al., 1983; Hunt et al., 1995; Allen et al., 1996; Poppenga, 2012). Vertebrate deaths have been reported from illegal and off-label use of insecticides. Models can estimate the probability of bird deaths resulting from field application of pesticides (Mineau, 2002). Birds, mammals, fish, and other aquatic organisms can be nontarget species from pesticides that enter water systems from surface water.

Incidents of Intoxication

Waterways and flood areas can be contaminated with pesticides, especially insecticides, and result in bird deaths (Hunt et al., 1995; Elliott et al., 1996). Granules of carbofuran in flooded fields have been incriminated as the cause of duck deaths and the cause of death in raptors scavenging dead or debilitated ducks. Illegal use of insecticides resulting in the death of wildlife has also been reported (Allen et al., 1996). Rodenticides have been used to control unwanted rodents and caused collateral deaths (Ruder et al., 2011). The toxicology of pesticides has recently been reviewed (Poppenga, 2012; Gupta, 2012).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Wildlife generally has not been considered in the emergency management of terrorist events using chemical agents. Wildlife can be a direct target because they can be important sources of food and income for some regions and countries. Disruption of ecotourism could also be an objective of terrorists. Wildlife can also be collateral damage from terrorist attacks and acts of war. The need to manage problem wildlife at the remote investigation site for wreckage from the World Trade Center brought attention to this aspect of emergency management planning. Regardless of the cause, wildlife can be intoxicated when chemicals and physical agents are released into the environment. Emergency planning needs to include terrorist attacks on wildlife, especially in areas where wildlife is concentrated during breeding and migration, and where wildlife congregates during the nonbreeding season. Shooting of the mountain gorillas hopefully is not an indication that these events will become more common (Jenkins, 2008). There is a need to develop better models for investigating and understanding the total impact of all causes of incidents involving wildlife (Etterson, 2013).

CHAPTER

56

Toxicokinetic Aspects of Nerve Agents and Vesicants

Harald John, Frank Balszuweit, Kai Kehe, Franz Worek and Horst Thiermann

INTRODUCTION

Despite the long history of chemical warfare agents (CWAs), which were first used in large quantities during World War I, vesicants and nerve agents still represent a commonly admitted threat for military and civilian communities. Therefore, effective medical countermeasures and state-of-the-art medical care are mandatory prerequisites to take the threat of poison attacks seriously. Rising interest in effective treatment of sulfur mustard, and especially nerve agent poisoning, leads national and governmental authorities to continue programs of medical defense against toxicants. The development and continuous improvement of therapy rely on intensified knowledge of provoked pathophysiological effects, toxicology, and toxicokinetics. The latter is important when understanding the reactivity of poisons in organisms at the molecular level. Awareness of predominant biotransformation and efficient elimination processes is essential for the design of a therapeutic regimen for poisoning. For example, the development of protective scavengers is a current challenge in nerve agent defense research.

The toxicokinetic profile of a CWA in mammalian organisms depends on numerous factors, including the nature of the poison, route of exposure, and differences among species. Sophisticated study design, modern technical and analytical monitoring tools, and reliable data from literature are indispensable quality criteria that should be met when performing toxicokinetic studies. The present chapter is focused on this topic.

We will first introduce the reader to typical invasion processes of exogenous poisons. The anatomy of exposed areas of the body is discussed, emphasizing interactions with nerve agents and vesicants invading on similar routes following common absorption principles. Afterward, both classes of CWAs are discussed individually. Organophosphorus (OP) nerve agents are distinguished in terms of their physicochemical properties and toxicity, as well as invasion and distribution processes *in vivo*, which are relevant to toxicokinetic characteristics. Subsequently, special focus is given to the basics of elimination and biotransformation, describing the phenomena of detoxification and concentration decrease at the molecular level. Enzymatic hydrolysis and binding to proteins and enzymes are discussed in comprehensive detail. A few comments on excretion will finish this "journey through the poisoned body." The next several sections of the chapter are dedicated to concentration-time profiles exemplarily selected for typical routes of nerve agent exposure, followed by short introductions to predictive mathematical toxicokinetic models and to most modern bioanalytical methods that allow poison quantification and identification of biotransformation products.

Vesicants, including sulfur mustard and lewisite, are the subject of the second main part of this chapter. Coherences of invasion and distribution are presented, and the major processes of biotransformation and elimination caused by binding to proteins [and more prominently, to deoxyribonucleic acid (DNA)] are discussed. Finally, we make some comments about current bioanalytical approaches. This chapter provides readers with a comprehensive overview of the toxicokinetics of OP nerve agents and vesicants.

OVERVIEW OF INVASION PROCESSES OF CWAS

Toxicokinetics is a subfield of toxicology that studies how, how fast, and to what extent toxicants are absorbed by, distributed in, biotransformed by, and eliminated from the bodies of living organisms. These processes depend on multifaceted conditions, such as the species and gender of intoxicated organisms, the physicochemical properties of the toxicant (e.g., hydrophobicity, charge, and molecular weight), its dose and concentration, and its chemical reactivity and stability. Furthermore, the route of exposure is a crucial parameter affecting the effectiveness of incorporation and time for distribution within an organism.

Elaboration of toxicokinetic data of CWAs is essential for designing effective antidotes, improving first aid, and optimizing therapeutic regimen and medical care. It has to be considered that data obtained from *in vitro* or *in vivo* animal studies need careful extrapolation to humans, which at least requires sophisticated mathematical models to consider basic interspecies differences (Langenberg et al., 1997; Sweeney et al., 2006; Levy et al., 2007; Worek et al., 2007).

For controlled toxicological studies, the poison is most often administered subcutaneously (s.c.), intravenously (i.v.), or intramuscularly (i.m.), whereas more realistic scenarios of CWA uptake are percutaneous (p.c.) through unprotected skin, by inhalation of aerosols and vapor, or by ingestion (p.o.) of contaminated food and drink.

Such exposure events that lead to poison uptake and its distribution in an organism are part of the invasion process, whereas all steps causing a decrease in poison (e.g., elimination by degradation, biotransformation, and excretion) are part of the evasion process. For a better understanding of the pathophysiology and toxicokinetics of CWAs, an overview of the routes of poison incorporation is given in the next section, with a special emphasis on OP nerve agents and vesicants.

Percutaneous Uptake by Contact with Skin

The total skin surface of an adult human is approximately 1.8 m^2, which is very small when compared to the adsorptive surface of the lungs (100 m^2) and the gastrointestinal tract (GIT, 200 m^2; Marquardt et al., 1999). The primary function of the skin is to protect an organism against exogenous compounds present in the external environment. Nevertheless, percutaneous uptake is the predominant route of poisoning by nonvolatile and rather lipophilic agents [e.g., *O*-ethyl *S*-[2-(diisopropylamino) ethyl] methylphosphonothioate (VX)], which exhibits low vapor pressure, thus making respiratory incorporation very unlikely except for the inhalation of aerosols (Czerwinski et al., 2006). In the case of vesicant agents, such as sulfur mustard and lewisite, the skin is both a target organ, susceptible to severe local effects, and a pathway for absorption of the agent, leading to its distribution and subsequent systemic effects. The protective skin architecture is provided by a sophisticated and effective barrier built of two main components: the outer epidermis and the underlying inner dermis.

Epidermis

The epidermis is composed of various consecutive complex layers, including the stratum corneum (horny layer), stratum ludicum (clear layer), stratum granulosum (granular layer), and stratum germinativum (germinative layer), which itself is subdivided into two parts; stratum spinosum (spinous or prickle layer) and stratum basale (basal layer) (Marquardt et al., 1999). For a general overview of percutaneous poison uptake, we will now restrict the introduction to the horny and germinative layers, which are in this sense the most significant epidermal strata.

The stratum corneum is the upper stratum of the epidermis. It consists of several avascular, stratified cellular layers of dead keratinocytes characterized by a very low water content (5–10%), thus making the surface hydrophobic and reducing its permeability for polar compounds. This layer, which exhibits the character of a multilayer lipid membrane, is the major barrier hindering hydrophilic substances from invading an organism. Penetration through the horny layer is most often a passive diffusion-controlled process following Fick's law in a good approximation. Because of their lipophilic nature, liquid nerve agents and vesicants can readily penetrate the horny layer, and absorption of liquids is much more effective than that of their corresponding vapors (Blank et al., 1957). VX was shown to form a reservoir in the stratum corneum, enabling continuous delayed release of the poison (Rolland et al., 2013). Accordingly, while in contact with the skin barrier nerve agents might also react with skin proteins, thereby forming adducts and detoxifying the agent, as shown for human callus reacting with VX *in vitro* (Verstappen et al., 2012). To estimate the capability of nerve agents for skin penetration the octanol:water partition coefficient, (listed as dimensionless log *P*; see Table 56.1) can be used, which correlates to the lipophilicity of the agent (Czerwinski et al., 1998, 2006). This parameter can also be used to predict the distribution of OP agents in other tissues and blood (Langenberg et al., 1997; Sweeney et al., 2006).

Skin permeation velocity of toxic substances increases with (i) decreasing molecular weight, (ii) increasing lipophilicity, (iii) increasing area of contaminated skin, and (iv) decreasing thickness of contaminated horny layer. The thickness of the stratum corneum varies depending on the area of the body and species. Heavily strained

TABLE 56.1 Physicochemical Properties of VX and G-Type OP Nerve Agents

Agent	CAS No.	NATO Code	MW (g/mol)	Boiling Point (°C)	Vapor Pressure (mbar)	Water Solubility (g/L)	Hydrolysis Rate, $\tau_{1/2}$ (h)	log *P*(–)
Cyclosarin	329-99-7	GF	180.2	239	0.059 (25°C)[a]	3.7 (20°C)	n.a.	1.04[b]
Sarin	107-44-8	GB	140.1	158	2.8 (20°C)	Miscible	39 (pH 7.0)	0.30[b]
Soman	96-64-0	GD	182.2	190	0.53 (25°C)	21 (20°C)	45 (pH 6.6)	1.82[b]
Tabun	77-81-6	GA	162.1	237–240	0.049 (20°C)	98 (25°C)	8.5 (pH 7.0)	0.38[b]
VX	50782-69-9	VX	267.4	298	$9 \times 10 - 4$ (20°C)	30 (20°C)	1000 (pH 7.0)	2.09/0.68[b]

areas (e.g., the sole of the foot, palm of the hand, and insides of the fingers) are protected by a 400–600-µm horny layer in humans, whereas the arms, legs, and body are covered by a barrier of 8–15 µm in thickness. Since the first incidents of chemical warfare in World War I, it was observed that skin areas with a very thin horny layer, in particular the axillae and the scrotum, were most susceptible to the effects of sulfur mustard. Effects in these regions, even though they were rarely exposed to the liquid agent, were severe.

Considering thickness and structural composition of skin (e.g., the diameter and density of hair follicles, as well as the number of cell layers) is essential for choosing appropriate *in vitro* models for skin penetration. Pig skin, exhibiting a stratum corneum thickness in the ear of 8.6–28 µm, is similar to human abdominal skin (5.5–40 µm), so it offers a good model to study the agent's permeation as recently shown for VX (Vallet et al., 2008). The best model for p.c. *in vivo* exposure studies is thought to be the pig after inner ear-skin application of the agent (Chilcott et al., 2003). In contrast to persistent VX, the major fraction (98%) of a small amount of liquid sarin, which was applied p.c. to 6 human subjects, evaporated very rapidly without passing the skin because of its high volatility (Marrs et al., 2007). In the presence of organic carrier solutes, skin penetration may be enhanced, as shown for VX dissolved in isopropanol, thus doubling the permeation velocity for animal and human skin *in vitro* (Dalton et al., 2006a,b). In contrast, cooling of exposed skin regions was shown to delay entry of the agent into circulation, thus representing an optional support for the treatment of cutaneous nerve agent poisoning (Mikler et al., 2011). At the least, experimental conditions should also consider that moisture, heat, and abrasions force the transfer and uptake of permeable CWAs (Blank et al., 1957).

The germinative layer, located under the stratum corneum, consists of living keratinocytes that are responsible for the regeneration and proliferation of skin. It exhibits the highest biotransformation activity of all strata toward endogenous and exogenous substances initiating binding to carboxylesterases (CaE or CarbE). Nevertheless, sorption to cutaneous tissue may form a depot, as demonstrated for sarin (Fredriksson, 1958; Satoh and Hosokawa, 2006), which explains the delayed local fasciculation of muscles observed after s.c. administration of nerve agents (Czerwinski et al., 2006).

Dermis

The dermis (corium) consists of connective vascularized tissue composed of collagen, elastic and reticular fibers anchoring sweat and sebaceous glands, and hair follicles. Capillaries pervading the dermis and hypodermis (subcutis, located beneath the dermis) allow systemic distribution of toxic compounds once they have passed the epidermis. Therefore, percutaneously incorporated poison may be directly transported by circulation to any compartment of an organism, or it may be temporarily retained within the skin layers. In addition, it might penetrate with first-order kinetics into subcutaneous tissues and muscles, thus creating a poison depot for delayed release (Wolthuis et al., 1981; Chilcott et al., 2005). If nerve agents are kept in fat tissue, degradation by biotransformation appears rather unlikely, thus maintaining an active release system (Sweeney et al., 2006). Correspondingly, Van der Schans et al. (2003) reported that it took more than 3 h to reach a maximum concentration in blood of lipophilic VX after percutaneous administration of $1 \times LD_{50}$ to hairless guinea pigs (see the section "Percutaneous uptake," later in this chapter).

Respiratory Uptake by Inhalation

Airways and Absorption

Gaseous poison or aerosols of toxic substances are incorporated following inhalation and contact with the respiratory tract. This appears to be the predominant route of poison intake for volatile G-type nerve agents (e.g., tabun, sarin, and soman) exhibiting relatively high

vapor pressure (Table 56.1). The respiratory tract is composed of three main compartments, distinguishable by the areas and organs involved in the breathing process: (i) the extrathoracic or nasopharyngeal compartment, comprising the mouth, nose, and throat (pharynx); (ii) the tracheobronchial compartment, containing the voice box (larynx), windpipe (trachea), and right and left bronchi; and (iii) the alveolar or pulmonary compartment of the lung, which includes the bronchioles connecting the bronchi with the lobes of the lung and alveoli. The sacs and cavities of the alveoli allow diffusion-controlled oxygen and carbon dioxide exchange in the blood of pulmonary capillaries (blood–air barrier). This diffusion process follows Fick's law, whereupon the diffusion layer exhibits a thickness of 0.4–2.5 µm composed of surfactant and alveolocapillary membranes. The lung of a healthy adult person possesses 300–400 million alveoli spread over a surface of approximately 100 m^2 (Marquardt et al., 1999).

Depending on the physicochemical nature of the toxic gas or aerosol, absorption will take place at different areas of the respiratory tract. Apart from the chemical properties, the size of particles and aerosols will also affect the targeted area. Materials with diameters less than 2 µm will reach the alveoli, whereas larger ones (about 20 µm in diameter) are retained in the upper respiratory areas of the throat and bronchi, preventing gas exchange in the lung.

Absorption in the Upper Respiratory Tract

In contrast to highly lipophilic compounds, hydrophilic toxicants, characterized by higher water solubility (e.g., hydrogen chloride and fluorine), are primarily adsorbed by the wet mucosa membranes of the throat and trachea in the upper respiratory tract. This is also the primary area for G agent first-order absorption according to higher water solubility (Sweeney et al., 2006; Marrs et al., 2007). Early studies have shown that 80–90% of inhaled sarin was readily absorbed by humans when exposed to concentrations ranging from 7–43 mg min/m^3 (Oberst et al., 1959, 1968). Slightly lower rates (approximately 70%) were obtained for sarin applied to guinea pigs, dogs, and monkeys (Benschop and de Jong, 2001). More aggressive and reactive agents (e.g., vesicants and pulmonary agents) may cause harm by chemical burns, provoking time-delayed inflammation and scarring in these areas. Langenberg et al. (1998b) found significant effects of sulfur mustard in the upper respiratory tract of guinea pigs, caused by a large fraction of inhaled agent.

The nasal system of guinea pigs is more complex than that of other mammalian species, including humans. In those species, the fraction of agent absorbed or deposited in the upper respiratory system may be smaller. Consequently, the middle and lower respiratory systems are likely to be exposed to a larger amount of the agent.

Absorption in the Middle Respiratory Tract

Toxic agents with medium water solubility (e.g., chlorine and sulfur dioxide) reach farther into the middle respiratory tract, being absorbed in the bronchi and its junctions. As a result, elevated excretion of mucus, coughing, and bronchoconstriction will lead to heavy dyspnea. The respiratory tube system from the nose to the bronchioles is lined with ciliated epithelium, allowing transportation of the mucous layer produced by cells of the bronchial system from the lung into the oral cavity. This mechanism, which may be supported by coughing, allows the binding and removal of dust particles, thus protecting the alveoli from deterioration. However, once the mucus has reached the oral cavity, spontaneous swallowing might transport poison into the digestive tract of the stomach and gut (i.e., the GIT).

It is the middle respiratory tract that apparently is the most significant target in the case of respiratory exposure to sulfur mustard. Local effects, such as the formation of pseudomembranes, may both be life-threatening in the acute phase of illness after poisoning and cause long-term disability. The systemic absorption from the middle respiratory tract has never been investigated separately. However, findings from Langenberg's guinea pig model (Langenberg et al., 1998b) suggest that the largest part of inhaled sulfur mustard is deposited in that particular area.

Absorption in the Alveoli

Several toxic compounds, particularly gases of low water solubility or increased lipophilicity (e.g., carbon monoxide, hydrocyanic acid, nitrogen oxides, phosgene, and further inorganic and organic irritants) reach the alveoli and are absorbed by blood. Aggressive and reactive compounds that are inhaled may damage the epithelial cells of the alveoli, causing the liberation of edema fluid, which fatally prolongs the diffusion layer and minimizes the permeability for oxygen and carbon dioxide, finally leading to unconsciousness or death by asphyxia (toxic lung edema). Only very few hints exist for OP-induced lung edema following a yet-unraveled mechanism of action (Lainee et al., 1991; Delaunois et al., 1992; Niven and Roop, 2004). Similarly, in the case of sulfur mustard exposure, the alveoli are only of minor importance in terms of target organ for both local effects and systemic absorption (Langenberg et al., 1998b).

Nose-only Exposure Model for Controlled Respiratory Uptake in Animal Studies in Vivo

To elucidate the velocity of nerve agent absorption via the respiratory tract, which may take seconds to hours, Langenberg et al. (1998a) designed an apparatus that challenged guinea pigs by nose-only exposure with a constant stream of nerve agent vapor in air held for several minutes. As guinea pigs were not ventilated, artificially sublethal doses of soman and sarin (0.4–0.8 LC*t*50)

were applied, thus enabling the affected respiratory frequency and minute volume to be monitored. A typical concentration–time profile detected for C(–)P(+)-soman after administration of C(±)P(±)-soman is characterized by a discontinuous curvature reflecting concentration increase during absorption and concentration decrease by elimination (see the section "Respiratory uptake (nose-only model)," later in this chapter). For more detailed technical data on the nose-only apparatus, see Langenberg et al. (1998a,b) and Benschop and de Jong (2001). The same researchers also used this apparatus in subsequent experiments to investigate the respiratory uptake of vesicant agents, results of which will be discussed in the section "Respiratory uptake," later in this chapter.

Gastrointestinal Uptake by Ingestion

When an animal drinks poisoned liquids or ingests contaminated food, toxicants will be incorporated and directly transferred from the mouth, through the gullet (esophagus) and into the stomach and bowels (intestine) representing the GIT, where transfer into the circulation occurs. The physiological function of the digestive tract includes intake, breakdown, transport, and digestion of food and creation of waste (excrement). Food ingredients, as well as toxicants and their digested (biotransformed) forms, are either absorbed through the walls of the intestine and enter circulation or are eliminated by feces. The surface of the small intestine of an adult human covers more than 200 m^2 and is made up of 4–5 million tiny, fingerlike projections (villi and microvilli) covering the surface of the mucous membrane. In contrast, the resorbing areas of the large intestine (0.5–1 m^2), stomach (0.1–0.2 m^2), rectum (0.04–0.07 m^2), and oral cavity (0.02 m^2) are explicitly smaller due to lack of villi; therefore, they are of minor importance for poison uptake. Uptake by diffusion through lipid layers (hydrophobic molecules) and pores (small hydrophilic molecules) of the intestinal mucosa (following Fick's law) are the most common processes. Nevertheless, facilitated diffusion and active transport, based on affinity binding of the toxicant to carrier molecules, might also occur (Marquardt et al., 1999). The processes of pinocytosis and phagocytosis are unlikely with small CWAs. Following intestinal uptake into circulation, toxicants are directly transported to the liver, where further biotransformation by cytochrome P450 enzymes may happen. This is of essential relevance for toxification of OP pesticides, including parathion, chlorpyrifos, diazinon, and dimethoate, which are transferred into their more toxic oxon derivatives (Butler and Murray, 1997; Furlong, 2007). The liver and intestine are supposed to play very important roles in elimination of free soman, as deduced from rabbit studies at high soman dosing (Li et al., 2002).

In contrast, for sarin, it has been shown that the kidney is more important for detoxification than the liver (Little et al., 1986). However, only very limited research efforts have been undertaken to characterize this route of poison uptake for nerve agents (Sim et al., 1971; Sidell and Groff, 1974). Very high lethal oral doses were reported for tabun (rabbit: 16,300 µg/kg; rat: 3700 µg/kg; dog: 200 µg/kg) and sarin (rat: 550 µg/kg), indicating extensive hydrolysis in the GIT (Marrs et al., 2007). Very few investigations of the toxicokinetics of vesicants after ingestion have been conducted. Nevertheless, this route of exposure is supposed to result in a significant systemic absorption of an agent. The rationale behind this apparent "blind spot" of toxicokinetic investigation might be the rarity of gastrointestinal exposure during conditions of military operations. Moreover, should a GIT exposure occur, the local, rather than the systemic, effects would be life-threatening. See the section "Invasion," later in this chapter, for an in-depth discussion.

In contrast, ample work has been done with OP pesticides to address the troubling statistic of more than 500,000 deaths per year worldwide caused by accidental and suicidal ingestion (Eddleston et al., 2005, 2008a,b).

Uptake by Intravenous Injection

Intravenous uptake of CWAs is highly unlikely for realistic exposure scenarios, except perhaps for the contamination of open and bleeding wounds. Nevertheless, numerous scientific studies investigating toxicity and therapeutic treatment of CWAs made use of this route of administration. The rationale behind this design is to constitute a defined amount of poison in blood, which is immediately systemically distributed by circulation to the target compartments under conditions of 100% bioavailability. Therefore, i.v. studies are undoubtedly relevant to elaborate systemic toxicity and to characterize the impact on the whole organism. It was shown that sarin was distributed in the central nervous system (CNS) within 20–30 s after i.v. administration to mice (Waser and Streichenberg, 1988). Therefore, poison acts without delayed uptake caused by diffusion or permeation through skin, tissue, and organs, which would increase the extent of degradation and hydrolysis by biotransformation. The latter processes reduce the amount of toxic agents and hamper making a direct correlation to poison concentrations in blood. As demonstrated by Van der Schans et al. (2003) only 2.5% bioavailabilty was observed in guinea pigs, resulting from a 7-h permeation period after percutaneous administration of VX.

As outlined in previous sections, the amount of incorporated poison and its fraction interacting with target molecules to induce more- or less-specific toxicological effects may vary drastically, even under controlled

conditions of administration. However, monitoring of quantitative concentration-time profiles of the original poison and its biotransformation products is needed to elucidate the kinetic behavior and to unravel pathophysiological mechanisms. Due to the broad range of such essential variations causing a number of uncertainties, many *in vivo* and *in vitro* studies have been performed during the last 30 years of sophisticated research on protection against OP compounds (OPCs) and blister agents. The following sections will summarize the most important consolidated findings underlining the current status of toxicokinetics of the most prominent CWAs: nerve agents and vesicants.

NERVE AGENTS

OPCs as Nerve Agents

For important background information addressing the history, synthesis, basic chemical data, decontamination, toxicity, military use, and political relevance of nerve agents, we refer readers to a number of textbooks, reports, and monographs that go beyond the scope of this toxicokinetic contribution (e.g., Koelle, 1963; Franke, 1977; Munro et al., 1999; Augerson, 2000; Committee on Gulf War and Health, 2004; Langford, 2004; Marrs et al., 2007; Richardt and Blum, 2008). Nevertheless, in this section, selected chemical and physicochemical properties are considered that are of importance for understanding the toxicokinetic behavior of OPCs.

Well-known representatives of nerve agents are cyclosarin (*o*-cyclohexyl methylphosphonofluoridate; GF), sarin (isopropyl methylphosphonofluoridate; GB), soman (1,2,2-trimethylpropyl methylphosphonofluoridate; GD), tabun (ethyl dimethylphosphoramidocyanidate; GA), VX (*S*-2-diisopropylaminoethyl *o*-ethyl methylphosphonothioate), and Russian VX [*o*-isobutyl *S*-(*N*,*N*-diethylaminoethyl)methyl phosphonothioate; RVX, VR] (see Table 56.1 and Figure 56.1). Apart from these substances, a large number of additional OP toxicants with high structural similarity have been seen on experimental and laboratory levels, especially when pesticides for civilian use are included. However, the abovementioned compounds are the most prominent nerve agents in literature. This fact is obviously due to political instructions for national security and defense programs that consider historical development, large-scale production, and intended military use and focus on agents that most likely would be relevant chemical threats. Soman, for example, was produced in large amounts during the Cold War by the Soviet Union in particular, thus menacing the rest of the Western world. Therefore, toxicokinetic studies on nerve agents are mainly restricted to sarin, soman, and VX. In addition, following United Nations (UN) inspections in Iraq in the 1990s, which revealed the weaponizing of cyclosarin, some studies on the toxicokinetic properties of cyclosarin were also conducted.

Physicochemical Properties

If they are present in a highly pure state, all nerve agents are colorless and odorless liquids characterized by different vapor pressures, thus causing either very rapid evaporation with increased inhalational risk (e.g., G-type agents) or relatively high resistance abating p.c. absorption (e.g., V-type agents and cyclosarin; see Table 56.1). Therefore, visual or sensory recognition of these substances by smell or taste is nearly impossible.

Water Solubility

Water solubility is a crucial parameter affecting the toxicological potency of a compound. Solubility of nonhydrolyzed nerve agents is fundamentally determined by the hydrophobicity and extent of organic substituents. On one hand, hydrophilic compounds exhibiting great water solubility are less effectively absorbed by skin in the absence of organic carrier solutes, but they are easily distributed once they have reached aqueous biological fluids. Therefore, skin penetration of less lipophilic sarin (miscible in water) is not favored, whereas nerve agents of significant lipophilicity with low water solubility (VX: 30 g/L; GF: 3.7 g/L; see Table 56.1) penetrate skin and other hydrophobic biological membranes and mucosa unhampered (Winkenwerder, 2002). Nerve agent transfer into blood and its systemic distribution are limited, potentially provoking accumulation in fatty tissue. Nevertheless, noncovalent binding to carrier proteins of circulation (e.g., γ-globulin and albumin) may support systemic transport of not very water-soluble compounds in blood, as would be expected for VX (Vallet et al., 2008), and as commonly known for endogenous fatty acids or exogenous drugs (John and Schlegel, 1999; Li et al., 2007; Weiss et al., 2008). Table 56.1 denotes corresponding measures of solubility in water.

Octanol:Water Partition Coefficient

The lipophilicity of nerve agents and their expected partition behavior are characterized by the octanol:water partition coefficient ($\log P$). This parameter is often used as an estimate for the tendency of the toxicant to bioaccumulate in an organism. Furthermore, it is helpful to predict the penetration of skin and distribution between tissue and blood (Poulin and Krishnan, 1995; Czerwinski et al., 1998, 2006). The $\log P$ for the more polar sarin was determined to be 0.30, whereas this measure for lipophilic VX is 2.09, which documents a 50-fold higher lipid solubility. However, this ratio might be slightly different when considering the inconsistency of data

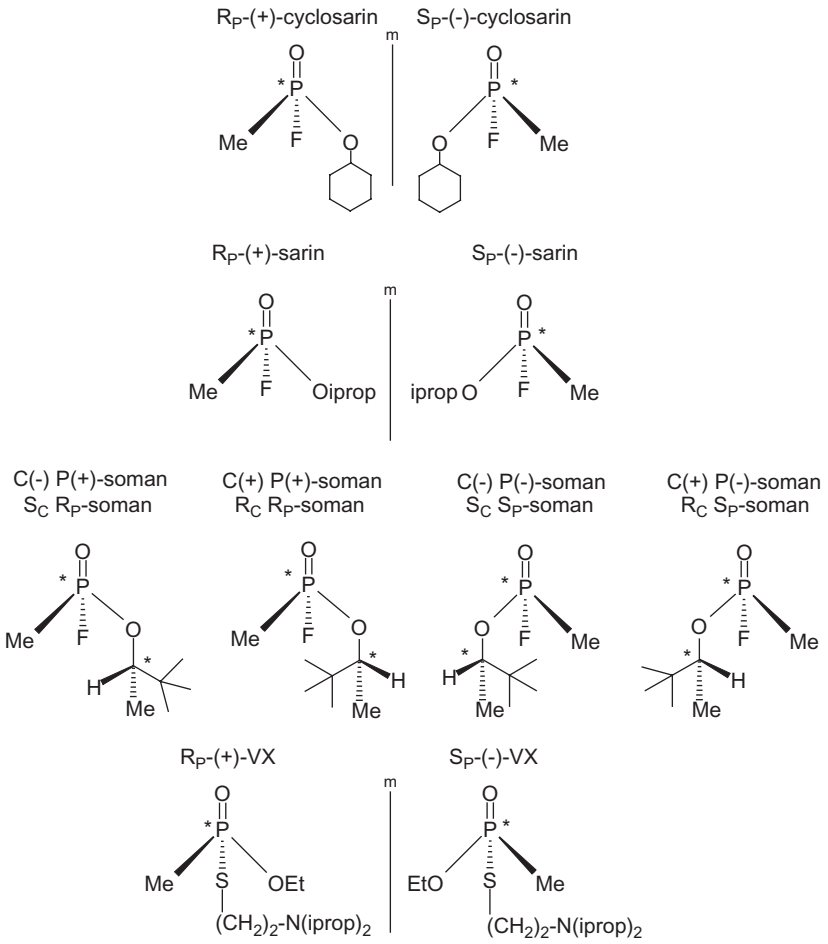

FIGURE 56.1 Structures of stereoisomeric OP nerve agents. Chirality was assigned according to the rules of Cahn, Ingold, and Prelog (Cahn et al., 1966; Prelog and Helmchen, 1982) considering oxygen of the P═O bond with minor priority compared to alkoxy substituents (Quin, 2000). Empirically found opticity is, according to Benschop and de Jong (1988), correlated to compounds obtained from stereoselective synthesis (Li et al., 2001). Chirality emerged as a crucial parameter for toxicokinetic properties. SP-isomers (P(−)-forms) of illustrated G agents (cyclosarin, GF; sarin, GB; soman, GD) are characterized by higher toxicity combined with higher stability against hydrolyzing mammalian wild-type enzymes as their corresponding RP-isomers, P(+)-forms (Table 56.3).

from literature. Table 56.1 summarizes the log P values of selected nerve agents.

Hydrolysis

In aqueous media, nerve agents undergo nonenzymatic hydrolysis, which is accelerated by very acidic and basic pH values (Franke, 1977). Hydrolysis primarily substitutes the reactive leaving group of the OPC for a hydroxy group, thus making the molecule more soluble (Figure 56.2). After cleavage of diisopropyl ethyl mercaptoamine (DESH) from the phosphorus atom of VX (Figure 56.1), the remaining ethyl methylphosphonic acid exhibits a water solubility of 180 g/L, which is six times higher than VX itself (Munro et al., 1999). Depending on pH, the alkoxy-group of VX might also be cleaved from the phosphorus atom. Hydrolysis of the reactive electronegative leaving group, which is essential for primary toxicity (inhibition of acetylcholinesterase (AChE)), deactivates the molecule, reducing its toxicity dramatically. The major hydrolysis product of sarin is isopropyl methylphosphonic acid (IMPA), which is about 10,000 times less toxic than its precursor when administered orally to rats (Munro et al., 1999). IMPA is also the most prominent biotransformation product of sarin produced *in vivo* (Little et al., 1986). The dramatically increased rate of hydrolysis under acidic conditions is presumably the most important reason for extraordinarily high lethal dose (LD_{50}) values found in laboratory animals after oral administration of nerve agents (Marrs et al., 2007). Table 56.1 summarizes hydrolysis rates expressed as periods of half-change in aqueous solutions of nerve agents near neutral pH.

Chirality

Typical production batches of nerve agents formerly intended for military use are mixtures of enantiomers

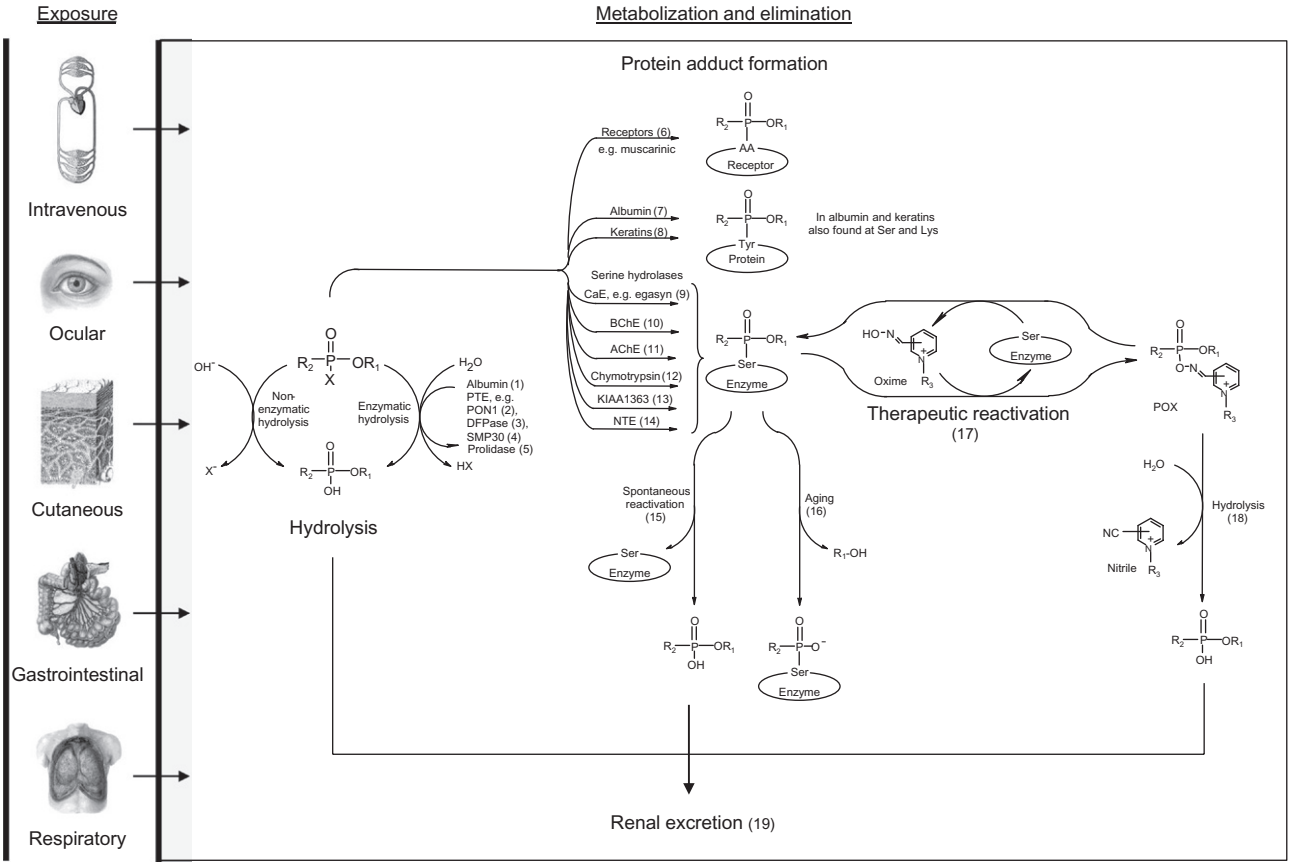

FIGURE 56.2 Elemental steps of toxicokinetics of OP nerve agents in mammalian organisms. OP nerve agents are incorporated following different routes of exposure. Whereas G agents are predominantly uptaken by the respiratory tract via inhalation, V agents mainly follow percutaneous invasion. Once the poison has reached circulation, it is distributed systemically, causing poisoning of the CNS and PNS by inhibition of AChE. Several processes of biotransformation (e.g., enzymatic and nonenzymatic hydrolysis) and elimination (e.g., formation of adducts by binding to proteins and multiple serine esterases, followed by marginal spontaneous reactivation and more prominent aging) reduce the amount of circulating poison. Therapeutic causal intervention by oximes reactivates cholinesterases under liberation of a toxic phosphoryloxime intermediate (POX), which itself undergoes immediate hydrolysis. Hydrolyzed nerve agents emanating from these chemical conversions are excreted by the kidney more prominently than by liver. Legend: AA, amino acid; AChE, acetylcholinesterase; BChE, butyrylcholinesterase; CarbE, carboxylesterase; DFPase, diisopropyl fluorophosphatase; KIAA1363, acetyl monoalkylglycerol ether hydrolase; Lys, lysine; NTE, neuropathy target esterase; PON1, paraoxonase 1; POX, phophoryloxime; PTE, phosphotriesterases; $R_{1/2}$, organic substituents, e.g., methyl, cyclohexyl, isopropyl; Ser, serine; SMP30, senescence marker protein 30; Tyr, tyrosine; X, nucleophilic leaving group; e.g., F, CN, (CH2)2-N(iprop)2. (1) Vilanova and Sogorb (1999); Manoharan and Boopathy (2006); Li et al. (2007); (2) Billecke et al. (2000); Amitai et al. (2006); Furlong (2007); (3) Blum et al. (2006); Nordgren et al. (1984); (4) Kondo et al. (2004); (5) diTargiani et al. (2010); (6) Silveira et al. (1990); (7) Black et al. (1999); Li et al. (2007, 2008); Grigoryan et al. (2009); John et al. (2010); (8) Grigoryan et al. (2009); Schopfer et al. (2010); Verstappen et al. (2012); (9) Maxwell and Brecht (2001); Satoh et al. (2002); Fujikawa et al. (2005); (10) Bartling et al. (2007); Kolarich et al. (2008); (11) Benschop and de Jong (2001); Aurbek et al. (2006); (12) Casida and Quistad (2005); (13) Nomura et al. (2008); (14) Gordon et al. (1983); Costa (2006); (15) Worek et al. (2005); Aurbek et al. (2006); (16) Worek et al. (1998, 2005); Bartling et al. (2007); (17) Sidell and Groff (1974); Kiderlen et al. (2005); Aurbek et al. (2006); Bartling et al. (2007); (18) Kiderlen et al. (2005); (19) Waser and Streichenberg (1988); Shih et al. (1994); Minami et al. (1997).

obtained from nonchiral synthesis (Figure 56.1). Sarin, cyclosarin, tabun, and VX consist of mixtures of two enantiomers; each of which differs in the chirality at the central phosphorus atom. This enables the rotation of linearly polarized light clockwise [P(+)-enantiomers] or anticlockwise [P(−)-enantiomers; see Figure 56.1]. In contrast, chirality of soman appears more complex based on two chiral centers, which reside at the phosphorus atom, P(+) and P(−), and additionally in the pinacolyl moiety, C(+) and C(−). Hence, soman occurs in four stereoisomeric conformations as two pairs of diastereomers: P(+)C(+), P(+)C(−), P(−)C(+), and P(−)C(−); (Figure 56.1). To denominate stereoisomers of nerve agents, the experimentally found rotational direction of light is typically provided, whereas assignments according to the R and S nomenclature are rare. Therefore, Figure 56.1 summarizes both absolute configurations and related optical activities of the most common nerve agents. Chirality was assigned according to the established rules of Cahn, Ingold, and Prelog (Cahn et al.,

1966; Prelog and Helmchen, 1982), considering oxygen of the P═O bond with minor priority to alkoxy substituents (Quin, 2000). Empirically found opticity is, according to Benschop and de Jong (1988), correlated to compounds obtained from stereoselective synthesis (Li et al., 2001).

It is well known that chirality of OP nerve agents causes significantly differing toxicological properties determining poison elimination by hydrolysis and kinetics of enzyme inhibition (Benschop and de Jong, 1988). Therefore, special attention should be paid to the corresponding stereoisomers when elaborating toxicokinetics. A number of studies took care of these conformational differences by administration of pure stereoisomers (Benschop and de Jong, 2001) or by enantioselective detection and quantification of poison molecules (Spruit et al., 2001; Li et al., 2003a,b; Van der Schans et al., 2003; Reiter et al., 2007, 2008, 2011; Yeung et al., 2007; Tenberken et al., 2010). Different techniques were established to produce pure (or at least enriched) enantiomers of nerve agents; e.g., (i) synthesis by use of chiral adducts subjected to reactions of defined strereochemical outcome; (ii) fractional crystallization, chromatographic separation, and isolation of mixed enantiomers; (iii) stereoselective binding to serine esterases (e.g., α-chymotrypsin); and (iv) stereoselective enzymatic hydrolysis by phosphorylphosphatases (chemoenzymatic preparation; Benschop and de Jong, 2001; Li et al., 2001).

Stereoselective enzymatic degradation of nerve agents is also a current issue in developing both novel noncorrosive decontamination systems and new therapeutics using recombinant mutated enzymes optimized for fast and exhaustive hydrolysis of most toxic isomers (Tsugawa et al., 2000; Li et al., 2001; Ghanem and Raushel, 2005; Furlong, 2007; Blum and Richardt, 2008).

Toxicity

OPCs, especially nerve agents, represent a class of highly reactive compounds undergoing nucleophilic substitution of their leaving group [e.g., F, CN, S-$(CH_2)_2$-N(iprop)$_2$; Figure 56.1] by nearly irreversible coupling to nucleophiles [e.g., strongly polarized hydroxyl groups in amino acid side chains or OH functions in aqueous media (Figure 56.2)]. Toxic effects are mainly due to derivatized enzymes which were subjected to this reaction.

Although most toxicological studies were performed as animal studies, some data about humans exist, which were obtained from military volunteers exposed to nonlethal doses of sarin (NRC, 1982, 1985), accidentally intoxicated industrial workers (Duffy et al., 1979), and poisoned civilians affected by terrorist attacks in Tokyo in 1995, Matsumoto in 1994, and Osaka (Morita et al., 1995; Okumura et al., 1996; Tsuchihashi et al., 1998). For detailed data on these events, see the reports of the Committee on Health Effects Associated with Exposures During the Gulf War (2000).

Inhibition of AChE

Phosphylation of the OH moiety of serine residue, being part of the catalytic triad in the esteratic center of AChE, represents pathophysiologically the most important reaction, resulting in enzyme deactivation. Inhibition of AChE was proved to be the predominant major reaction *in vivo*, which causes death within minutes in mammals, insects, and other species depending on acetylcholine (ACh)-mediated signal transduction. Maxwell et al. (2006) found compelling arguments that inhibition of AChE by nerve agents is the primary mechanism of OP toxicity. They correlated the median LD_{50} of highly toxic nerve agents determined from rats after s.c. administration with the corresponding bimolecular rate constants of AChE inhibition determined *in vitro*, using a probit model for interpreting the mathematical relationship.

AChE is present in the nervous system, where it is most important for toxic effects, and on the surface of red blood cells (RBCs), where its biological function is still unknown. Inactivation of AChE hinders the degradation of the neurotransmitter ACh in the synaptic cleft, which is of major importance for regulation of presynaptic and especially postsynaptic effects. Rising ACh concentrations cause permanent overstimulation of muscarinic (subtypes m1–m5) and nicotinic receptors of effector cells, leading to cholinergic crisis and, ultimately, death. Clinical symptoms of poison-induced AChE inhibition include (i) muscarinic effects (e.g., miosis, bradycardia, increased secretion of urine, saliva, tears and sweat, bronchoconstriction, and increased gastrointestinal motility); as well as (ii) nicotinic effects (e.g., muscular weakness, twitching and tremors, elevated blood pressure, and tachycardia); and (iii) central effects (e.g., headache, impaired memory and alertness, anxiety, insomnia, and most important, respiratory depression and paralysis). Death is caused by respiratory failure, as elicited by flaccid paralysis of respiratory muscles, and bronchoconstriction, together with increased bronchial secretion and central respiratory depression (Costa, 2006). Liquids or vapors from these agents can cause death within minutes after exposure. Table 56.2 summarizes the LD_{50} values for different species and routes of administration for the most common nerve agents. The relative lethality of these substances, determined in animal studies, is as follows, listed in descending order: VX, soman, cyclosarin, and tabun (Sidell and Borak, 1992).

Local irritations do not occur except by fasciculation of underlying muscles after percutaneous uptake or miosis caused by excessive stimulation of muscarinic receptors on the papillary sphincter muscles, resulting from ocular exposure (Sidell and Borak, 1992; Dabisch et al., 2008). However, clinical symptoms related to massive restraints in motoric and respiratory abilities require the reduction of AChE activity by more than

70%, as deduced by Thiermann et al. (2005) from murine diaphragm experiments. Accordingly, acute cholinergic syndromes in humans were not observed until the RBC AChE activity was inhibited by 75–80% (Sidell and Borak, 1992). Clinical symptoms may depend on the gender of the animal, as recently documented for the extent of miosis after vapor exposure to soman, cyclosarin, and VX (Dabisch et al., 2008). Male rats were approximately three times less sensitive than female rats, whereas miniature pigs show the reverse effect. This phenomenon refers to different activities of ocular AChE and butyrylcholinesterase (BChE; Dabisch et al., 2008).

Additional Targets with Potential Clinical Relevance

As binding to proteins other than AChE reduces the amount of free OP poison, these alternative targets are

to be considered when discussing toxicokinetic behavior. Albumin (Black et al., 1997a,b; Li et al., 2007, 2008; Williams et al., 2007; John et al., 2010), receptor/channel complexes (Pope, 1999), muscarinic and nicotinic ACh receptors (Bakry et al., 1988; Silveira et al., 1990), and other secondary serine hydrolase targets were shown to be chemically modified by OPCs; changing their functionality into potential pathophysiological situations by affecting noncholinergic mechanisms (Duysen et al., 2001; Casida and Quistad, 2005). In general, chemical modification of any protein and enzyme requires very high OPC concentrations that are far beyond the lethal dose of nerve agents, thus being of only minor relevance for acute poisoning scenarios (Pope, 1999). In contrast, elaboration of toxicity of the much-less-toxic OP pesticides is more and more focused on these additional targets; investigating, for example, genetic susceptibility, developmental toxicity and neurotoxicity, delayed neurotoxicity, and organophosphate-induced delayed polyneuropathy (OPIDP), a distal sensorimotor axonopathy (Costa, 2006; Balali-Mood and Balali-Mood, 2008). OPIDP is associated with OP-inhibited enzyme neuropathy target esterase (NTE), which undergoes an essential aging process of phosphylated NTE (elimination of an organic substituent from the central phosphorus atom, as shown in Figure 56.2; Costa, 2006). However, Gordon et al. (1983) demonstrated that, despite NTE inhibitory potency of the nerve agents tabun, soman, and VX, no OPIDP was induced. Nerve agent concentrations inhibiting half of the NTE activity were about three orders of magnitude higher (micromolar range) than for AChE (nanomolar range).

Using microarray technology, Gao et al. (2013) performed a toxicogenomic study on neural cells that had been exposed to VX. A huge number of affected gene expressions relevant in numerous physiological and pathophysiological processes were identified, indicating a broad variety of targets for potential harm. Specific long-term changes in the brain were also observed after exposure to nerve agents (Zhu et al., 2010; Spradling et al., 2011; Oswal et al., 2013). In addition, epigenetic changes were found in cell culture models after paraquat exposure (Song et al., 2011). The aerotoxic syndrome in humans is discussed as possibly being associated with the incorporation of OP tri-O-cresyl-phosphate (TOCP) as an additive in jet hydraulic and engine fluids (Carletti et al., 2013). However, the mechanism causing signs and symptoms is still unknown.

Elemental Steps of Nerve Agent Toxicokinetics

Although toxicological characterizations in terms of mean acute lethal doses for different species are available for all nerve agents, detailed and extensive toxicokinetic data are rare in literature for most of them, with the exception of soman and sarin (Benschop and de Jong, 2001). For VX, and in particular GF, only a very limited extent of data is available (Van der Schans et al., 2003; Reiter et al., 2007).

Invasion

Supplementary to the more common discussion on invasion processes given in the introductory overview (see the section "Overview of invasion processes of CWAs," earlier in this chapter), we now present some recent findings on skin penetration models. Nerve agents are readily absorbed through the skin, eyes, lung, and GIT. Depending on individual vapor pressures of nerve agents, different routes of poison uptake are preferred. G agents (such as sarin, soman, and tabun) are very volatile, limiting percutaneous uptake due to significant evaporation from the skin (approximately 98% for sarin). In contrast, VX exhibits high persistency due to its vapor pressure being 3,000 times lower than that of sarin (Marrs et al., 2007; see Table 56.1). Therefore, percutaneous uptake is most prominent for V agents, characterized by an absorption rate of at least 600 µg/cm^2/h, as shown for VX after inner ear-skin droplet application of 2 LD_{50} (Figure 56.2; Chilcott et al., 2005). Nevertheless, VX penetration through skin is characterized *in vitro* by a significant lag time of at least 1 h and a moderate penetration rate of about 1–2%/h (Vallet et al., 2008). These data are in accordance with early studies on human subjects demonstrating that, 3 h after percutaneous exposure of VX, only 0.4–0.6% was incorporated (Vallet et al., 2008). *In vitro* studies using guinea pig and human skin, as well as dermatomed, abdominal skin from domestic pigs, revealed significant differences in VX permeability. The highest permeability was observed for the skin of the guinea pig, whereas no significant differences in penetration kinetics were found for human skin and skin taken from a pig's flank (Dalton et al., 2006a,b). Therefore, pig skin may serve as an appropriate *in vitro* model for human skin (Vallet et al., 2008), as already established in pharmaceutical research using Franz-type diffusion cells (Franz, 1975; Simonsen and Fullerton, 2006). To predict *in vivo* human VX absorption via skin, full-thickness human abdominal skin has also been demonstrated to be appropriate (Vallet et al., 2008).

Distribution

Once nerve agents have penetrated the blood, systemic distribution, including crossing of the blood–brain barrier (BBB), causes toxicity within the CNS and peripheral nervous system (PNS). In mouse and rat studies, it has been shown that within 1 min after sublethal single-dose i.v. administration of sarin, the nerve agent was present in many other compartments (e.g., the diaphragm, heart, lung, and brain) and in much higher concentrations in the plasma, liver, and kidney (Little et al., 1986; Waser

and Streichenberg, 1988). Similar results were observed for VX (Chilcott et al., 2005) and soman, which was also found in cerebrospinal fluid with 100% bioavailability after i.v. bolus injection into pigs (Göransson-Nyberg et al., 1998; Augerson, 2000). For a mathematical description, Langenberg et al. (1997) calculated related tissue/blood partition coefficients for the distribution of soman in guinea pigs, revealing a measure of approximately 2 for liver and 1.1 for kidney; whereas the value for the lung and brain were calculated as 0.5. Sarin present in the brain did not severely inhibit AChE activity in the cortex (60%), striatum (40%), and hippocampus (56%) within 24 h (Whalley and Shih, 1989). In contrast, soman has caused more severe inhibition in these three areas (83–99%), lowering the synaptosomal sodium-dependent, high-affinity choline uptake (SDHACU) within the first 4 h in the hippocampus; whereas from 2–24 h after exposure, SDHACU increased in the striatum (Whalley and Shih, 1989). The differences are thought to be due to different aging rates and different AChE-inhibiting potencies. However, the brainstem and midbrain were influenced by neither sarin nor soman. It is assumed that active sites of the brain are affected primarily due to increased metabolic action, vasodilation, and increased blood flow in these regions (Scremin and Jenden, 1996). In contrast, 50% inhibition of AChE activity in brain was associated with death or serious signs of toxicity in mice after subcutaneous exposure (Duysen et al., 2001).

The presence of sarin, soman, and VX in the brain demonstrates the necessity for antidotes, especially AChE reactivators, to be capable of passing the BBB, representing a current scientific challenge (Lorke et al., 2008; Okuno et al., 2008).

Concentrations of sarin found in different tissues were decreased by 85% within 15 min after exposure (Committee on Gulf War and Health, 2004). Apart from active sarin, its inactivated biotransformation product, IMPA, was found in these tissues in a predominant ratio, indicating rapid *in vivo* biotransformation. This finding is discussed in the next section. Soman was mainly accumulated in the lung after s.c. challenge of rats (Shih et al., 1994) and disappeared from blood and liver 2 min after i.p. administration of 0.75 × LD_{50} to mice (Nordgren et al., 1984). In contrast, VX is more persistent *in vivo* than sarin or soman, causing delayed systemic distribution after s.c or p.c. administration. This provoked maximum concentrations of VX in blood several hours after p.c. exposure in guinea pigs (Van der Schans et al., 2003).

As outlined in the section "Toxicity," earlier in this chapter, the toxicological mechanism of action of nerve agents is based on the chemical reactivity of the nucleophilic leaving group. Therefore, biotransformation in terms of degradation by hydrolysis and binding to proteins determines bioavailability and elimination processes, regulating toxicity.

Biotransformation and Elimination

Enzymes from plasma and tissue are mainly responsible for hydrolysis of OPCs producing derivatives of phosphoric and phosphonic acids characterized by high water solubility and nearly no toxicity. *In vivo* studies in mice have shown that, within 1 min after injection, 50% of sarin was rapidly biotransformed, generating both free hydrolyzed IMPA and bound IMPA attached to esterases by phosphylation as predominant in plasma (Little et al., 1986). In contrast, V-type agents are more stable against enzymatic hydrolysis, but may undergo additional biotransformation pathways, including oxidation of nitrogen, sulfur, or both (Van der Schans et al., 2003). Due to the slow reaction velocity of nonenzymatic hydrolysis, this process is of minor importance for elimination kinetics of nerve agents under physiological conditions near neutral pH. As listed in Table 56.1, periods of half-life for nerve agent hydrolysis range from approximately 9 h for tabun to 6 weeks for VX. In contrast, the velocity of enzymatic hydrolysis in blood is much faster, defining the rate-determining step for poison elimination.

Enzymatic Hydrolysis

Enzymes that hydrolyze OPCs cleave the reactive leaving group of OPCs (e.g., F or CN) from the central phosphorus atom, initiating nucleophilic substitution by a hydroxyl group. Hydrolyzing enzyme activity is present in plasma, and to a much higher extent in kidney and liver, enabling the removal of toxicants from circulation (Sweeney et al., 2006). Early studies using an isolated hydrolyzing rat liver enzyme demonstrated degradation efficacy for nerve agents in the following order: sarin, soman, and then tabun (Little et al., 1989). Biotransformation products deactivated by hydrolysis are nearly nontoxic and easily eliminated from the organism via renal excretion (Munro et al., 1999). Despite this capability to hydrolyze OPCs, the original physiological functions and substrates of different enzymes vary significantly, not allowing assignment to a specific class of enzymes (Figure 56.2). The following section presents the most important enzyme systems relevant for nerve agent biotransformation.

Phosphotriesterases Based on historical development, different (and sometimes inconsistent) nomenclatures were used to assign enzymes that lead to the degradation of OPs. Meanwhile, the International Union of Biochemistry has introduced systematic rules and numbering to classify the relevant enzymes in the following way: hydrolases (group 3), which cleave ester links (group 3.1), that may represent carboxylester

hydrolases (group 3.1.1) or phosphoric triester hydrolases, phosphotriesterase (PTE) (group 3.1.8). The latter group contains aryldialkylphosphatase (EC 3.1.8.1) and diisopropyl fluorophosphatase (EC 3.1.8.2; Vilanova and Sogorb, 1999). As these enzymes catalyze substrate cleavage without self-inhibition, they are representatives of A-esterases.

- Paraoxonase 01 (PON1)
  Paraoxonase (PON1, EC 3.1.8.1; formerly EC 3.1.1.2) is a calcium-dependent, liver-expressed P450 PTE belonging to the class of A-esterases with broad substrate specificity toward various lactones and esters, which is present in liver and plasma associated with high-density lipoprotein particles (Vilanova and Sogorb, 1999). P450 isozymes and variants are well known for their dual role in OP biotransformation. On one hand, they bioactivate less toxic phosphorothioates to their highly toxic oxon derivatives via monooxygenase activity. On the other hand, they hydrolyze and detoxify OP insecticides, such as paraoxon, chlorpyrifos, and diazinon by dearylation, as well as nerve agents (e.g., sarin and soman) by defluorination (Davies et al., 1996; Kiderlen et al., 2005; Furlong, 2007; Figure 56.2).

  The original physiological function of PON1 is involved in inactivation of toxic products produced by lipid oxidation (Draganov and La Du, 2004). In addition, PON1 hydrolyzes OPCs, such as sarin, cyclosarin, tabun, and soman, thus accomplishing enzymatic protection against nerve agents in circulation (Billecke et al., 2000; Amitai et al., 2006; Figure 56.2). Levels and genetic variability of PON1 influence sensitivity to these specific substrates caused by Glu/Arg point mutation at position 192 of the human wild-type enzyme (Billecke et al., 2000; Dragonov and La Du, 2004). The Glu^{192} mutant is about three times more active than the Arg^{192} variant (Draganov and La Du, 2004). Despite these differentiations, rather low catalytic activity of recombinant human PON1 expressed in HEK cells occurred as a moderate stereoselective process characterized by preferred cleavage of the less toxic P(+)C(+)-enantiomer of soman (k_{cat} 1,030 min^{-1}), which happens twice as fast as for the other three stereoisomers (Yeung et al., 2007, 2008; see Table 56.3). Nordgren et al. (1984) used an enzyme isolated from swine kidney, which they called "phosphoryl phosphatase," to incubate purified enantiomers of soman *in vitro*. Whereas the less toxic P(+)-isomers (R_PS_C- and R_PR_C-soman) were hydrolyzed very rapidly ($\tau_{1/2}$ = 2 min under experimental conditions), both highly toxic P(−)-forms (S_PS_C- and S_PR_C-soman) showed much higher stability ($\tau_{1/2}$ 60–120 min). It appears likely that the predominant enzyme isolated was PON1. No stereoselective effects in the catalytic PON1 mediated hydrolysis of cyclosarin and soman using recombinant mammalian material from *E. coli* were detected by Amitai et al. (2006). No (+)-cyclosarin was detected in hemolyzed blood samples taken from swine after i.v. administration of racemic (±)-cyclosarin, whereas the (−)-cyclosarin enantiomer was present for at least 20 min after exposure (Reiter et al., 2007). These authors suppose that this phenomenon was due to rapid enzymatic and nonenzymatic hydrolysis in blood *in vivo*, but they do not discuss the potential role of PON1 explicitly. Yeung et al. (2007) conclude that variations in catalytic efficiency of hPON1 toward soman enantiomers are due to differing Michaelis–Menten constants (K_M), characterizing the stability of the enzyme–substrate complex. Consequently, site-directed mutagenesis of recombinant enzymes could cause reduction of K_M for the more toxic enantiomers, improving its hydrolyzing capacity. A tenfold to hundredfold increase in catalytic activity of wild-type hPON1 is expected to allow effective protection against incorporated nerve agents (Amitai et al., 2006; Rochu et al., 2007; Masson and Rochu, 2009). Masson and Rochu provided Chapter 70 of the previous edition. Following a directed evolution process, Goldsmith et al. (2012) succeeded in producing a recombinant variant with more than 340-fold increased catalytic activity. In addition, stereoselectivity was reversed to preferred hydrolysis of the more toxic S_P(-)-isomer of cyclosarin. Recently, the aforementioned PON1 mutant was successfully tested against 2*LD_{50} cyclosarin in a guinea pig model. Prophylactic administration of the enzyme prevented death, as well as signs and symptoms of GF poisoning (Worek et al., 2014a). In addition, this enzyme showed a catalytic activity against a broad spectrum of alkyl methylfluorophosphonates. Engineering efficient recombinant human PON1 is a current challenge in medical defense research, intending to yield an effective and biocompatible therapeutic applicable for a wide range of nerve agents exhibiting sufficient activity toward all relevant isomers (Amitai et al., 2006; Valiyaveettil et al., 2011; Kirby et al., 2013). Figure 56.2 displays its role in biotransformation and elimination.

- Senescence Marker Protein-30 (SMP30)
  The human senescence marker protein-30 (SMP30 or regucalcin, primary Swiss-Prot accession No.

Q15493) is expressed by hepatocytes and plays a role in regulation of plasma membrane Ca^{2+}-pumping activity, with the potential to rescue cells from high calcium level-induced apoptosis (Kondo et al., 2004). The expression of this liver enzyme decreases with aging. SMP30 was originally identified in rat liver and exhibits a 65% amino acid similarity to PON1 in rat species, but does not show catalytic PON1 activity toward the hydrolysis of paraoxon (Billecke et al., 1999). In contrast, mouse and rat SMP30 hydrolyze diisopropylfluorophosphate (DFP), an OPC related to nerve agents (Kondo et al., 2004). It may be speculated that this enzyme is also involved in nerve agent biotransformation in liver. This assumption is supported by the findings of Little et al. (1989), who observed hydrolysis of sarin, soman, and tabun by an enzyme derived from rat liver homogenate. Recombinant human material might also represent a valuable countermeasure for nerve agents and was expressed in *E. coli* as a properly folded and active protein (Choi et al., 2010).

- Prolidase
  Prolidase is a Mn^{2+}-dependent enzyme of 54 kDa that was purified from fibroblast cells, erythrocytes, kidney, and liver (EC 3.4.13.9) and exhibits a primary catalytic activity toward peptide-bond cleavage of dipeptides containing a C-terminal proline or hydroxyproline residue. In addition, it was found to hydrolyze G-type nerve agents tabun, sarin, soman, and cyclosarin by liberating the respective leaving groups *in vitro* with K_M values in the millimolar range. Unfortunately, recombinant human material expressed in *E. coli* exhibited a stereoselective preference for less toxic S_P-isomers; thus, it may not degrade the poison efficiently (diTargiani et al., 2010). This enzyme will affect the toxicokinetics of nerve agents and may represent an additional bioscavenger candidate when activity can be enhanced and stereoselectivity reversed.
- Diisopropyl Fluorophosphatase (DFPase)
  Some enzymes were isolated, but not unambiguously identified, from swine kidney, which exhibit DFP-cleaving activity and were denominated diisopropyl fluorophosphatase (DFPase) in older swine (Nordgren et al., 1984). This DFPase belongs to the class of A-esterases acting on DFP, tabun, and organofluorophosphates (e.g., cyclosarin, sarin, and soman). Nowadays, most recent studies define DFPase (EC 3.1.8.2, formerly assigned as EC 3.8.2.1) as a calcium-dependent PTE identified in squid *Loligo vulgaris* exhibiting unique structural properties (Blum et al., 2006). This squid-type DFPase has not yet been identified in mammalian organisms.

Nonmammalian Enzymes Several other enzymes from bacteria [e.g., PTEs or OPH, from *Pseudomonas diminuta* or *Flavobacterium* sp., OP acid anhydrolase (OPAA), from *Alteromonas* sp. and prolidases from *Pyroscoccus furiosus*, or squid (DFPase)] are also known to detoxify nerve agents, and it is of interesting relevance for novel noncorrosive decontamination approaches (Blum and Richardt, 2008; Theriot et al., 2011). So far this does not play a role in the toxicokinetics of OPCs in humans (Amitai et al., 2006; Rochu et al., 2007; Masson and Rochu, 2009). In contrast, promising studies were performed in rodents demonstrating a protective effect of OPH (Wales and Reeves, 2012). However, potential application as detoxifying antidotes remains a future challenge.

Nonproteinaceous Scavengers and Hydrolyzing Compounds Scavenging and hydrolysis of OP nerve agents *in vivo* is a major challenge in therapeutic treatment of poisoning. Compounds that enable degradation of poison to nontoxic products in the body help to minimize the toxic impact of nerve agents. In contrast to bioscavengers like PON1 or BChE, small molecules are much less immunogenic and might be of higher stability and longer half-life, representing more favorable properties for antidotal treatment. Following this idea, structures of modified β-cyclodextrins (β-CD) are currently optimized for improved hydrolysis of G- and V-type nerve agents (Estour et al., 2013). *In vitro* studies indicate reversible binding to β-CD as noninclusion (interaction with the outer surface) and as inclusion-complexes (interaction inside the hydrophobic cavity) initiating hydrolysis that might occur with enantioselective preference (Müller et al., 2013). Recently, a β-cyclodextrin derivative bearing a pyridinium oximate in 6-position of one glucose unit was synthesized and shown to possess a promising detoxification potential against a variety of alkyl methylfluorophosphonates *in vitro* (Bierwisch et al., 2014). Prophylactic i.v. injection of the β-cyclodextrin derivative prevented systemic toxicity in cyclosarin (~$2LD_{50}$) poisoned guinea pigs and preserved brain AChE activity (Worek et al., 2014b). Such compounds will seriously affect toxicokinetic behavior of poisons and support the elimination process.

Formation of Protein Adducts

Besides direct enzymatic hydrolysis of nerve agent substrates, numerous additional proteins are present in organisms that allow covalent binding to OPCs, contributing to detoxification of the poison load (Figure 56.2). Serine esterases are especially predominant targets of

nerve agents mostly undergoing irreversible adduct formation. Nevertheless, more than 75% of serine hydrolases (B-esterases) present in plasma and tissues are essentially unknown with respect to their interaction with OPCs (Casida and Quistad, 2005).

Carboxylesterase Ubiquitous glycosylated carboxylesterases (CarbE, EC 3.1.1.1), formerly named *ali-esterases*, are B-esterases belonging to the multigene enzyme superfamily of α/β hydrolases (Hosokawa and Satoh, 2006; Satoh and Hosokawa, 2006). In principle, this class of isozymes plays a major role in pharmacokinetics by hydrolytic biotransformation of exogenous ester-drugs and ester-prodrugs. However, their physiological function still remains unclear (Satoh and Hosokawa, 2006).

Carboxylesterases are very important serine esterases in plasma of nonhuman species that bind nerve agents with broad specificity, representing the major determinant for *in vivo* detoxification, especially in mice and rats (Maxwell and Brecht, 1991; Figure 56.2). Apart from catalytic CarbE activity in plasma, it is also found in several tissues and organs, including the brain, lung, kidney, and liver, thus realizing poison decrease was not only in the circulation (Satoh et al., 2002). Microsomal liver carboxylesterase 1, which is also referred to as *egasyn*, is loosely associated with a β-glucuronidase (BG) complex (Fujikawa et al., 2005). Organophosphate-inhibited egasyn causes cleavage of this complex, releasing elevated quantities of BG into circulation. Thus, BG plasma activity may serve as a sensitive biomarker for OP poisoning (Inayat-Hussain et al., 2007).

Interaction of CarbE with nerve agents follows a kinetic of first order characterized by inhibition of CarbE at the active site serine residue described by a bimolecular rate constant, k_i (Maxwell and Brecht, 2001). For noncharged nerve agents (e.g., sarin and soman), the k_i of rat serum CarbE was found to be greater than $10^6\,M^{-1}\,min^{-1}$, whereas cationic substrates (e.g., VX) are converted with poor reactivity ($k_i < 10^4\,M^{-1}\,min^{-1}$). This specificity is explained by the electrostatic characteristics of the large active site containing only a few cation-Π bonding and anionic residues (Maxwell and Brecht, 2001; Satoh and Hosokawa, 2006).

Covalent binding of OPCs to CarbE is considered an irreversible reaction of 1:1 stoichiometry, resulting in adducts that do not age (Maxwell and Brecht, 2001). In contrast, spontaneous pH-dependent reactivation liberates the enzyme, making it accessible for additional detoxification (though only to a very limited extent). At physiological pH *in vitro*, spontaneous reactivation (specified by the rate constant kr) is a poison-dependent process showing significantly different velocities depending on the size of the inhibitor (steric demand). Whereas reactivation of VX- and sarin-inhibited rat serum CarbE was faster (k_r $4.2 \times 10^{-3}\,min^{-1}$ and $3.8 \times 10^{-3}\,min^{-1}$), reactivation for soman and VR was about 10 times slower (k_r $0.44 \times 10^{-3}\,min^{-1}$ and $0.52 \times 10^{-3}\,min^{-1}$; Maxwell and Brecht, 2001). Meanwhile, Hemmert et al. (2011) produced a recombinant variant of human CarbE1 that spontaneously dephosphonylates 33,000-fold faster than the wild type after inhibition with sarin, soman, and cyclosarin. This effect was achieved by implementing a pair of histidine and glutamic acid residues proximal to the catalytic triad without changing the high-affinity binding. In addition to these differences, CarbE exhibits stereoselective properties. Nordgren et al. (1984) have demonstrated that CaE from swine liver binds to the less toxic P(+)C(+)-enantiomer of soman (R_CR_P) most efficiently, whereas conversion of highly toxic P(−)C(+)-soman (R_CS_P) happens much more slowly (Table 56.3). This fact indicates that degradation of incorporated nerve agents is primarily targeted to less toxic enantiomers, minimizing the protective effect of CaE. In contrast to G agents, no prominent enantiomeric selectivity was evident for sequestration of VX after p.c. administration (Van der Schans et al., 2003).

Consequently, striking species-dependent differences in LD_{50} values of OPCs are mainly due to variable concentrations of endogenous CarbE acting as a bioscavenger in blood (Table 56.2). Whereas mice and rats exhibit high CarbE activities, activity in rabbits and guinea pigs appears moderate. In contrast, dogs and primates, as well as humans, possess only little or no CarbE (Benschop and de Jong, 2001). These relations are obvious from s.c. soman LD_{50} values obtained from mice and guinea pigs after inhibition of CarbE (10.2 and 12.2 μg/kg), which were very similar to those obtained for dogs and primates without inhibition (9.1 and 13.0 μg/kg; Maxwell and Brecht, 1991). In contrast, the corresponding soman s.c. LD_{50} values for untreated CarbE are much higher for mice (113 μg/kg) and guinea pigs (28.2 μg/kg; Maxwell and Brecht, 1991). For these reasons, guinea pigs are most often used for *in vivo* toxicity and toxicokinetic studies intending to examine a small laboratory animal model predictive for humans. Missing CarbE activity in humans hinders efficient detoxification *in vivo*, thus keeping the toxic effect of nerve agents (Due et al., 1993). Consequently, the value of CarbE as a bioscavenger for effective clearance of OP poison from circulation has led to therapeutic concepts that were applied successfully to rodents and nonhuman primates (Maxwell and Brecht, 2001). Feasibility for human organisms has yet to be demonstrated.

Acetyl Monoalkylglycerol Ether Hydrolase KIAA1363 (primary Swiss-Prot accession No. Q6PIU2) is a human serine hydrolase derived from acetyl monoalkylglycerol ether hydrolase (AcMAGE, EC 3.1.1.) present

Rate constants for inhibition of most prominent serine esterases by nerve agents differ significantly depending on the nature of enzyme, its originating species and stereoisomers of the agent. It appears obvious that for the depicted G agents and VX, the P(−)-isomers are much more effective inhibitors than their corresponding P(+)-forms. In contrast, hydrolysis of the latter isomers happens faster than that of the toxic P(−)-variants. Hydrolytic stability is determined by PON1 activity characterized by its catalytic constant k_{cat} (last column). Both properties (inhibition and hydrolysis) cause higher toxicity for P(−)-agents *in vivo* selectively (Table 50.4). AChE, acetylcholinesterase; BChE, butyrylcholinesterase; CarbE, carboxylesterase; CVX, Chinese VX; hr wt, human recombinant wild type; k_{cat}, catalytic constant for hydrolysis; PON1, paraoxonase 1; VR, Russian VX.

in the brain, lung, heart, and kidney, which is involved in tumor cell invasiveness and lipid metabolism, but can also detoxify OPCs by hydrolysis of the reactive leaving group following transient binding to the active site serine residue (Nomura et al., 2008; Figure 56.2). This capability has been demonstrated for the pesticide chlorpyrifos and its more toxic oxon derivative. Activity toward nerve agent hydrolysis is expected, but it has not been shown so far.

Acetylcholinesterase AChE (EC 3.1.1.7) from vertebrates is deduced from a single gene (Massoulie, 2002) expressing identical enzyme primary structures on the surface of RBCs, in synapses and different organs.

Inhibition of this serine-esterase causes the most prominent pathophysiological effects, determining the severity of poisoning. Covalent binding to AChE can also be considered a step in poison elimination (Figure 56.2), which reduces the amount of incorporated poison, though only to a small extent.

AChE activity in whole blood differs significantly among mammalian species, which makes it relevant for toxicokinetic consideration. Humans exhibit a very high AChE activity in blood (651 mU/μmol hemoglobin, Hb) in contrast to smaller values for miniature pigs (297 mU/μmol Hb) and pigs (190 mU/μmol Hb; Worek et al., 2008). The bimolecular rate constants (k_i) for nerve agent-induced inhibition of AChE vary among different species. Table 56.3 gives an overview of corresponding inhibition kinetics. The k_i for inhibition of human AChE by VX, for example, is about twice as high as for pig AChE (Aurbek et al., 2006). These differences must be considered when assessing interspecies toxicokinetic data.

Nerve agents show enantioselective inhibition kinetics when reacting with AChE. Chirality at the central phosphorus atom plays the predominant role affecting higher rates of inhibition for the P(−)-isomers (S_P) than for the P(+)-forms (RP; Nordgren et al., 1984). Benschop and de Jong (2001) made great efforts to look at this stereoselectivity topic, and they determined the corresponding inhibition rate constants (k_i) for electric eel AChE *in vitro* (Table 56.3). Both P(−)-diastereomers of soman (SpS_C- and S_PR_C-soman) exhibit very high k_i values ranging from 1.8–2.8 × $10^8\,M^{-1}\,min^{-1}$, which documents their high toxicity. In contrast, the less toxic P(+)-diastereomers (RpR_C- and R_PS_C-soman) are characterized by k_i values that are 100,000 times smaller (<5 × $10^3\,M^{-1}\,min^{-1}$; Benschop and de Jong, 2001). Similar results were obtained for sarin enantiomers, which differ by a factor of 5000, revealing a k_i of 1.4 × $10^7\,M^{-1}\,min^{-1}$ for the SP-(−)-form (Table 56.3). VX enantiomers exhibit the smallest differences, because the k_i of the more toxic SP-(−)-VX (4 × $10^8\,M^{-1}\,min^{-1}$) is 200 times higher than for the RP-(+)-enantiomer (Table 56.3; Benschop and de Jong, 2001). These k_i data correspond to the order of experimentally determined LD_{50} values in mice, not considering the impact of hydrolyzing enzymes *in vivo* which also exhibit stereoselective kinetics for hydrolysis (Table 56.4; Benschop and de Jong, 2001).

AChE on the surface of RBCs shows a turnover rate of about 1% per day, enabling complete exchange within approximately 100 days after exposure (Sidell and Borak, 1992). In contrast, regeneration of synaptic AChE is assumed to be faster, reaching 7–10% turnover rates, an estimation determined by animal experiments (Grubić et al., 1981; Brank et al., 1998; Eddleston, 2008b). Both are of importance for therapeutic monitoring of poisoning, as well as for verification of exposure following bioanalytical methods.

- Spontaneous Reactivation of AChE
  Although inhibition of AChE is mainly discussed as an irreversible reaction, detailed kinetic investigations consider the process of spontaneous reactivation re-releasing an active enzyme and a hydrolyzed detoxified agent (Figure 56.2). Rate constants for spontaneous reactivation (k_s) of human AChE adducts are very small, as measured for some sarin analogs (0.01–0.052 h^{-1}), whereas the k_s for sarin, cyclosarin, and VX was too small to provoke an experimentally detectable effect (Bartling et al., 2007). Sidell and Groff (1974) demonstrated that spontaneous reactivation of RBC AChE inhibited by VX happens much faster than for sarin, which is in accordance with recent human k_s data on V agents VX 0.021 h^{-1}, VR 0.039 h^{-1}, and Chinese VX (CVX) 0.171 h^{-1} (Aurbek et al., 2006). Following point mutations in recombinant human AChE spontaneous reactivation rates for VX, VR, and CVX could be increased up to 110-fold (Trovaslet-Leroy et al., 2011). However, the toxicokinetic relevance of spontaneous reactivation is obvious from the liberation of free esterase accessible for reinhibition with 1:1 stoichiometry.

- Aging of AChE
  The cleavage of an organic substituent from the phosphorus atom, which is bound to the side chain of an amino acid residue from a protein, is described by the aging process (Figure 56.2). Promoted by specific ionic interactions of neighboring amino acid residues in AChE (and BChE), the remaining P-OH function will undergo deprotonation, leaving a negatively charged phosphorus moiety (Figure 56.2). Chandar and Ganguly (2013) investigated the aging process of soman inhibited AChE *in silico* by density functional theory (DFT) and found that dealkylation of the pinacolyl-group and migration of the methyl-group take place simultaneously, catalyzed by histidine 440 and tryptophan 84 residues located in the catalytic triad and catalytic anionic subsite, respectively. Whereas esterase adducts of sarin and soman age by cleaving alkoxy moieties from the central phosphorus atom, tabun loses its dimethylamine moiety (P–N scission) instead of its ethoxy group (Elhanany et al., 2001).

  These aged enzyme adducts are not accessible for reactivation by common antidotal oximes, limiting the success of therapeutic treatment of poisoning with OPCs. The soman–AChE adduct is known for very rapid aging ($\tau_{1/2} \approx 2$ min), causing severe problems in clinical treatment (Worek et al., 2005). Aging half-lives of phosphylated AChE and phosphylated BChE depend on the nature of the inhibiting OPC. Whereas GF-inhibited AChE exhibits a half-life of 8.7 h, the corresponding BChE derivative ages much more rapidly (2.2 h; Worek et al., 1998). The order of $\tau_{1/2}$ for aging of human AChE–nerve agent adducts was found to be, in ascending order, soman (2 min), sarin (3 h), cyclosarin (7 h), tabun (19 h), and VX (36.5 h; Worek et al., 2005). V agent-inhibited RBC-AChE ages very slowly in humans, allowing therapeutic intervention with oximes for a longer period lasting several days (Sidell and Groff, 1974; Thiermann et al., 2007).

Butyrylcholinesterase BChE (EC 3.1.1.8), formerly named *pseudocholinesterase,* is synthesized in the liver and present in blood (5 μg/mL), the synapse of neuromuscular junctions, and glia cells and axons of white matter in the brain in numerous allelic variants (Massoulie, 2002). Although BChE has long been considered a nonfunctional vestigial analog of AChE, recent findings point out a possibly more prominent role; especially in mice, where the total amount of BChE in the body is 10 times as high as AChE (Duysen et al., 2001). Correspondingly, it was observed that the activity of BChE in human whole blood was significantly higher than of AChE (Worek et al., 2008). This led to speculation that BChE may play a backup role for insufficient AChE activity in neurotransmission as deduced from the physiology of AChE knockout mice (Duysen et al., 2001) and may serve as a safeguard against diffusion of ACh into the bloodstream (Massoulie, 2002). However, mandatory experimental evidence is still missing.

Highly glycosylated BChE is a prominent target of OPCs, acting as a protective biological stoichiometric scavenger averting damage to neuronal AChE (Kolarich et al., 2008). However, common nerve agents may exhibit significantly differing inhibition rate constants (k_i); for AChE and BChE, they are approximately in the range of 10^7–$10^9\,M^{-1}\,min^{-1}$ (Bartling et al., 2007). Table 56.3 shows comparison of inhibitory potency of nerve agents against AChE and BChE. *In vivo* studies in humans suggest that VX preferentially inhibits RBC AChE much more effectively than BChE, resulting in 70% and 20% inhibition, respectively (Sidell and Groff, 1974). In addition to agent-dependent k_i values, there is a striking stereoselective dependency in BChE inhibition. The more toxic soman P(−)-enantiomers (SP) inhibit with preference when compared to their corresponding P(+)-forms (RP; Table 56.3; Nordgren et al., 1984). However, differences are not as pronounced as for AChE, but point out effective detoxification properties of endogenous BChE.

Interestingly, no clinical features result from inhibited BChE *in vivo* (Eddleston et al., 2008b). The status of plasma BChE activity is, despite all concerns, a commonly recommended measure to monitor the progress of chemical injury (Eddleston et al., 2008a).

In contrast to all studies on VX toxicokinetics and toxicodynamics published so far, Dorandeu et al. (2008) reported an unexpected and not-yet-clarified phenomenon that emerged after i.v. administration of VX to isoflurane-anesthetized and ventilated swine without oxime therapy. Time-resolved measurement of esterase activities during the experimental period of poison application revealed very fast rebound of BChE activity (from 70% inhibition to 30% within 1 h), while retaining nearly complete inhibition of whole blood cholinesterase. Design and control experiments allowed the following explanations to be excluded: (i) spontaneous reactivation, which should happen much more slowly; (ii) induced hypoalbuminemia liberating albumin as scavenger competing with BChE; and (iii) stimulated release of hydrolyzing enzymes like PON1. More probably, this observation is explained by an increased biosynthesis of BChE in the liver, an elevated release of BChE from other organs (e.g., heart, lung, or pancreas), or both. Future studies will possibly shed more light on this curious and interesting phenomenon.

As total replacement of BChE by synthesis in the liver happens within a couple of weeks, this rather long period allows experimental verification of OP poisoning, even when blood samples from poisoned humans are

collected with significant delay to the time of exposure (Sidell and Borak, 1992). Therefore, detection of BChE adducts by means of modern mass spectrometric methods is the state-of-the-art technique for proving exposure to OP nerve agents (Carol-Visser et al., 2008; Noort et al., 2006; John et al., 2008).

The relevant enzyme adducts may undergo the previously described consecutive reactions: spontaneous reactivation and aging. Jiang et al. (2013) demonstrated that human BChE can be inhibited by both enantiomers of tabun, resulting in stereospecific aging processes showing deamination for S_P-tabun and O-dealkylation for R_P-tabun. In general, aging of BChE nerve agent adducts occurs with highly different agent-dependent periods of half-change ($\tau_{1/2}$) as determined *in vitro* by Worek et al. (2005). Whereas the soman adduct typically exhibits by far the shortest $\tau_{1/2}$ (less than 1 min), cyclosarin appears much more stable ($\tau_{1/2}$ 2.2 h), followed by tabun ($\tau_{1/2}$ 7 h) and sarin ($\tau_{1/2}$ 12 h). The adduct of VX was the most stable BChE derivative characterized by a $\tau_{1/2}$ of 77 h. Spontaneous reactivation by simple hydrolysis of the serine-phosphorus bond was observed for cyclosarin, with a half-life of 20 h and much longer times for VX (63 h) and sarin (63 h; Worek et al., 2005). These data demonstrate that inhibition of wild-type BChE is nearly irreversible, lowering the amount of incorporated toxic OPCs significantly in a stoichiometric manner. Therefore, protection against nerve agent doses of up to $5.5 \times LD_{50}$ (soman and VX) was achieved with exogenous BChE from different species applied prophylactically i.m. to the guinea pig, rhesus monkey, and cynomolgus (Lenz et al., 2007). It is supposed that a dose of 200 mg BChE/70 kg will be sufficiently protective in humans against $2 \times LD_{50}$ of soman (Saxena et al., 2008). Based on this valuable protective capacity, current efforts are under investigation to use BChE from recombinant (e.g., transgenic plants or milk of transgenic animals) or natural sources for therapeutic/prophylactic treatment of nerve agent poisoning (Chilukuri et al., 2005; Lockridge et al., 2005; Huang et al., 2007; Lenz et al., 2007, 2010; Geyer et al., 2010; Saxena et al., 2011; Mumford et al., 2013). The plasma half-life of recombinant preparations is significantly prolonged by fusion to albumin (Huang et al., 2008) or pegylation (attachment of polyethyleneglycol; Chilukuri et al., 2005; Sun et al., 2013), or by polysialylation (Ilyushin et al., 2013). In addition, enhanced rapid spontaneous reactivation will deblock the enzyme, thus being accessible for subsequent binding to another OP molecule. This strategy is followed by site-directed mutagenesis of BChE, leading to a 10^5-fold increase of dephosphorylating activity (Casida and Quistad, 2005). Accordingly, substitution of histidine 117 by glycine in engineered human BChE generated a significant amount of OP hydrolase activity (Nachon et al., 2011). Feasibility for the human body still has to be shown.

Albumin Although albumin is present in blood in high concentrations (0.6 mM; 41 g/L; 50–60% of total plasma protein), it does not represent an effective scavenger for nerve agent detoxification *in vivo*, hampered by its slow reaction velocity (Li et al., 2008). Nevertheless, sarin and soman bind to albumin at active site tyrosine residue 411, as shown in neat buffered solution and crude human plasma. This inhibits the enzymatic acylamidase and esterase activity of albumin (Black et al., 1999; Li et al., 2007, 2008; Figure 56.2). Besides tyrosine 411, additional amino acid residues capable of phosphylation by nerve agents and pesticides were described by John et al. (2010) after matrix-assisted laser desorption/ionization (MALDI)–mass spectrometry (MS) analysis. Albumin also exhibits slight hydrolyzing catalytic activity against OPCs (Vilanova and Sogorb, 1999). Concerning enantioselectivity in phosphonylation of albumin by soman, contradictory results have been presented in recent studies. Li et al. (2008) did not find any enantiomeric preference, and Yeung et al. (2008) demonstrated that human serum albumin preferentially binds to the less toxic C(±) P(+)-enantiomer. However, the albumin adduct is very stable in terms of spontaneous reactivation, exhibiting extended periods of half-life (6.5 days at 25°C, pH 8.0 and 20 days at 22°C, pH 7.4); in addition, it does not show any aging phenomena (Li et al., 2007, 2008; John et al., 2010). Derivatized albumin serves as a biomarker for nerve agent exposure detectable by modern mass spectrometric techniques (Black et al., 1999; Peeples et al., 2005; Li et al., 2007, 2008; Williams et al., 2007).

Keratins Keratins are the most abundant proteins in the stratum corneum, exhibiting molecular weights of about 50–100 kDa. Formation of intermediate filaments assembled from bundles of keratin monomers cause durability and insolubility in water, representing the protective barrier of the body. Verstappen et al. (2012) found that VX and OP pesticides covalently bind to tyrosine residues in human keratins when exposed *in vitro*. MS/MS analysis revealed phosphylation in keratin 1, 6, and 10, results that are very similar to a report from Schopfer et al. (2010) documenting phosphorylation of tyrosine induced by *in vitro* incubation of chlorpyrifos-oxon with human keratin 1, 2, 9, and 10. No distinct binding motifs or consensus sequences have been identified so far that explain preferred phosphylation at specific tyrosine residues (Schopfer et al., 2010). In addition, adducts were also found at lysine residues in keratin 1 and 10. Corresponding phosphoamidate bonds showed unexpected stability (Grigoryan et al., 2009). Such binding processes might contribute to general skin absorption phenomena as observed after cutaneous exposure to VX (Chilcott et al., 2005). No pathophysiological consequences are obvious at present. These phosphylation reactions minimize the total amount of toxic nerve

agents penetrating into circulation, representing a kind of natural scavenging barrier.

Ubiquitin Ubiquitin is a small endogenous and ubiquitous protein (approximately 8,600 Da) with a nearly globular confirmation (Welchman et al., 2005). *In vivo*, it appears either as free (extracelluar space, e.g., plasma, urine, cerebrospinal fluid) or anchored molecules covalently bound to any target protein (intracellular space). Such conjugates often contain multiple ubiquitin molecules connected to long chains (poly-ubiquitinylation). The kind and extent of ubiquitin chains are crucial parameters that determine the fate of the protein with respect to proteasomal degradation. Chain prolongation requires 1 out of 7 free lysine residues to react with the C-terminal glycine of another ubiqiuitin molecule. Therefore, the presence of free, chemically unaltered ε-amino side chains is essential for correct biological function.

Recently, adducts of ubiquitin produced *in vitro* with VX, VR, and CVX were identified by different mass spectrometric methods, documenting that phosphonylation untypically occurred at at least 6 out of the 7 lysine residues selectively (Schmidt et al., 2014). An additional adduct at a tyrosine residue was also found, but to a much lesser extent. Intramolecular cyclization between the derivatized lysine and adjacent glutamic acid residues was detected. Such a reaction has never been described before for any other phosphylated protein. Cyclization will dramatically change the tertiary structure of ubiquitin. All these chemical and structural changes after reaction with V agents will surely affect biological function. It is not clear whether phosphylated ubiquitin is produced in *in vivo* poisoning scenarios or whether it is relevant to any pathophysiological situation.

Additional Proteins By means of modern, highly selective, and high-resolving mass spectrometry coupled to effective chromatographic separation, a number of mammalian proteins were shown to form covalent adducts *in vitro*. These targets include, e.g., α_2-glycoprotein 1, human transferrin, kinesin 3C motor domain 5, bovine tubulin α and β, actin α skeletal muscle, chymotrypsinogen, mouse transferrin, ATP synthase, adenine nucleotide translocase I, and porcine pepsin (Grigoryan et al., 2009; Schopfer et al., 2010). Nerve agents were found to phosphylate tyrosine, serine, threonine, and lysine residues predominantly. However, no correlation to any specific disease or evidence for any pathophysiological consequence has been reported. Nevertheless, numerous signs and symptoms in OP poisoning suggest that AChE inhibition is not the only reason behind the entire clinical picture.

Besides diverse nucleophilic side chains of amino acids from a number of endogenous proteins, OP nerve agents also form adducts with other small, nucleophilic molecules relevant for toxicokinetic analysis. Gäb et al. (2010, 2011) demonstrated that sarin, soman, and cyclosarin react with phosphate anions. Such ions are present *in vivo* or in typical phosphate buffers used for dilution of biological fluids or as solvents for kinetic measurements. G-type nerve agents (Gäb et al., 2011) and VX (Creasy et al., 2012) produce very stable pyrophosphate-like adducts fast enough to compete with sample hydrolysis in aqueous media. Similar reactivity was found for amino alcohol buffers like tris(hydroxymethyl)aminomethane (TRIS), and N-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid (TES), generating O-bound esters of methyl-O-alkyl phosphonates derived from sarin, soman, and cyclosarin (Gäb et al., 2010). These reactions might be relevant when planning and performing any kind of quantitative and kinetic analysis of G-type nerve agents.

Muscarinic Receptors It has been shown that tabun, sarin, soman, and VX bind to the muscarinic receptor subtype m_2, leading to the assumption that the ACh binding site is deactivated, causing potential additional vulnerability (Figure 56.2; Silveira et al., 1990). Despite the high affinity of nerve agents, pathophysiological effects seem to be of only minor relevance compared to AChE inhibition. However, binding to receptors will lower the concentration of toxic and reactive OPCs.

Excretion

Sarin and its corresponding nontoxic hydrolysis products (IMPA and additional methylphosphonic acids) are predominantly eliminated via the kidneys, so those organs play a more important role in detoxification than the liver (Little et al., 1986; Waser and Streichenberg, 1988). Urinary excretion happens very rapidly, as demonstrated for single-dose s.c. application of sarin, cyclosarin, and soman to rats (Shih et al., 1994). The terminal elimination half-life was found to be 3.7 ± 0.1 h for sarin and 9.9 ± 0.8 h for cyclosarin. Soman showed a biphasic elimination, with terminal half-lives of about 18.5 and 3.6 h (Shih et al., 1994). Maximum peak levels of sarin biotransformation products in urine were detected 10–18 h after exposure (Minami et al., 1997) and, after 2 days, hydrolyzed sarin products had been excreted nearly quantitatively (Shih et al., 1994). Even at 5 days, postexposure soman product recovery was only 62% (Shih et al., 1994). Excretion of soman from blood, liver, and kidneys following chemical and enzymatic hydrolysis is considered a first-order elimination process (Sweeney et al., 2006).

Concentration–Time Profiles of Nerve Agents in Blood After Various Routes of Administration

Extensive toxicokinetic studies in animal models using rats, marmosets, and guinea pigs were performed

for sarin and most often for soman, thereby considering individual concentration–time profiles of different enantiomers (Benschop and de Jong, 2001). The resulting concentration curvatures reflect the combination of toxicokinetic factors of distribution and elimination by hydrolysis and protein binding, as described previously in detail. The next section will briefly summarize the most prominent findings about stereoselectivity and related blood concentration–time profiles. In contrast to many OP pesticides, detailed toxicokinetic data on oral uptake of nerve agents is not available. Therefore, we restrict this section to i.v., s.c., p.c., and respiratory exposure. For more detail, a concise and extensive overview is given by Benschop and de Jong (2001).

Intravenous Uptake

Direct poison injection into circulation allows immediate distribution in an organism, but also enables undelayed elimination provoked by plasma components. To illustrate these impacts, we introduce some fundamental results obtained for some G agents, as depicted in Figure 56.3A (Benschop and de Jong, 2001).

As soon as 0.3 min after i.v. administration of C(±)P(±)-soman to rats, guinea pigs, and marmosets (3–6 LD_{50}), the less toxic C(+)P(+)-enantiomer degrades to nondetectable concentration, whereas its diastereomer C(−)P(+)-soman is detectable for a few minutes longer. This rapid decrease of P(+)-enantiomers is caused by fast enantioselective catalytic hydrolysis (Table 56.3). In contrast, the highly toxic P(−)-diastereomers are detected for up to 1 h or longer, showing a steep initial concentration decrease caused by systemic distribution, protein binding, and hydrolysis, followed by a more moderate concentration decline during the later elimination phase (Figure 56.3A). CarbE is expected to be the most important scavenger in laboratory animals, being essential for nerve agent elimination and causing high species-dependent variations in LD_{50} values (listed in descending order, rat, guinea pig, and marmoset), which correlate to individual CarbE concentrations (Table 56.2). Resulting concentration curvatures were fitted best by a three-exponential equation (Benschop and de Jong, 2001). Table 56.3A gives a representative example of the concentration–time profile of C(−)P(−)-soman in guinea pigs. Corresponding experiments, performed with (±)-sarin applied to guinea pigs, demonstrated that initial distribution of (−)-sarin happened an order of magnitude faster than P(−)-soman, whereas elimination was one order of magnitude slower (Benschop and de Jong, 2001). The reasons for these differences are not clarified yet, but they are expected to be due to different kinetics of hydrolysis and protein binding, causing higher persistence of (−)-sarin.

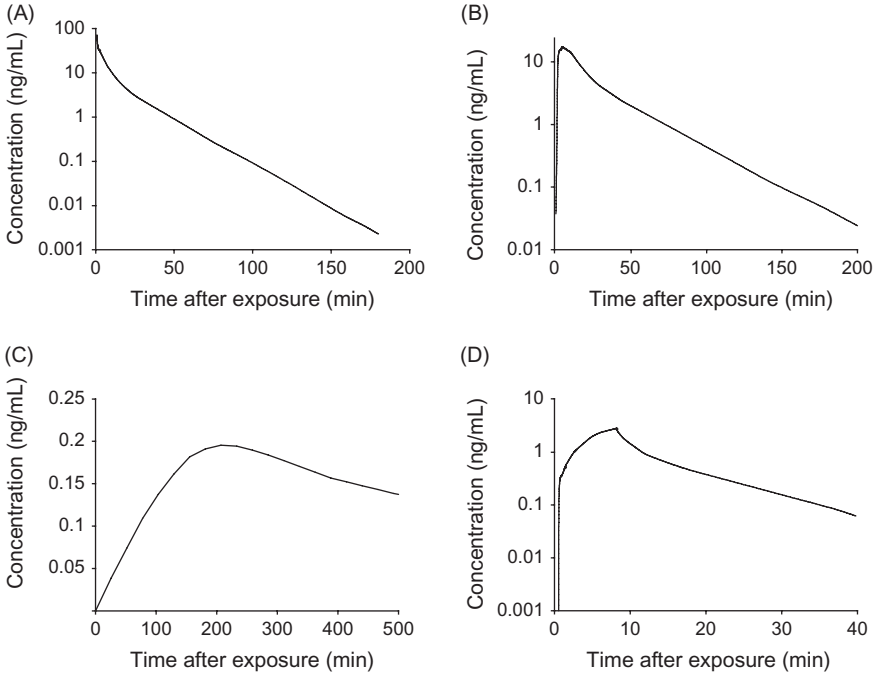

FIGURE 56.3 Concentration–time profiles of highly toxic C(−)P(−) soman and (±) VX in guinea pig blood after administration of nerve agents via different routes of exposure. Guinea pigs were challenged with C(±)P(±)-soman (A, B, D) or (±) − VX (C). A: intravenous, 6 × LD_{50} (165 µg/kg); B: subcutaneous bolus, 6 × LD_{50} (148 µg/kg); C: percutaneous bolus, 1 × LD_{50} (125 µg/kg); D: nose-only for soman vapor in air at 0.8 × LCt50 (48 mg/m^3 for 8 min). Nerve agents were applied to anesthetized, atropinized, and mechanically ventilated animals. Data fits are according to basic studies presented by Benschop and de Jong (2001; A, B, D) and by Van der Schans et al. (2003; C).

Similar results of stereospecific kinetics were also observed for tabun after i.v. challenge in swine, showing a shorter terminal half-life elimination for the less toxic (+)-tabun (Tenberken et al., 2010). In accordance, the (-)-cyclosarin enantiomer could be detected for at least 20 min after i.v. administration of racemic cyclosarin to swine, whereas the (+)-isomer could not be detected in any sample even though the first blood draw was done about 2 min after poisoning (Reiter et al., 2007). Monitoring the concentration-time profile of VX after i.v. challenge in swine, Reiter et al. (2011) also measured the concentration of its toxic hydrolysis product EA-2192 (S-[2(diisopropylamino)ethyl]methylphosphonothioic acid) by means of liquid chromatography-tandem MS (LC-MS/MS). This biotransformation was also observed in heparinized rat plasma *in vitro,* showing a notable stability, and should be considered for therapy of OP poisoning by VX.

Subcutaneous Uptake

Subcutaneous exposure is often used as a substitute for respiratory exposure due to experimental difficulties in performing controlled inhalational poisoning (Benschop and de Jong, 2001). For example, we will note a typical study illustrating the s.c. behavior of soman (Figure 56.3B). A C(±)P(±)-soman bolus injection in the scruff of a guinea pig neck resulted in a discontinuous C(−)P(−)-soman concentration–time profile following a monoexponential equation for the absorption phase and a biexponential fit for the distribution phase (Figure 56.3B; Benschop and de Jong, 2001). The steep initial concentration increase in blood indicated rapid penetration through capillary walls. Maximum concentration was not reached until 7 min after soman injection, yielding an absorption half-life of about 3.5 min. Despite some certain diastereomer-specific differences [decreased bioavailability of C(+)P(−)-soman], both P(−)-forms exhibited comparable kinetic behavior. Bioavailability was found to be 70–80% when comparing the corresponding area under the curve (AUC) to that of i.v. injection. Very similar to the i.v. characteristics mentioned previously, the toxic, more stable P(−)-isomers were detectable in blood for more than 3 h after exposure, whereas the less toxic P(+)-forms of soman could not be determined at any time. This is attributed to the high-hydrolyzing catalytic activity of PTEs in blood, skin, and other affected tissue (Table 56.3).

Percutaneous Uptake

(±)-VX dissolved in isopropanol (1 LD_{50}) was applied p.c. to hairless guinea pigs (Figure 56.3C; Van der Schans et al., 2003). Typically for p.c. exposure, concentration in blood increased very slowly, reaching its maximum between 3 and 4 h after challenge, followed by a slight decrease within the next 4 h. Despite that longer period of monitoring, the illustrated concentration–time profile only reflects the distribution and early elimination phases. This slow release is due to the formation of a depot under and in the skin, as well as to reduced hydrolytic degradation of VX *in vivo*. No prominent effects of stereoselective toxicokinetics were observed; therefore, the depicted curvature reflects the racemic mixture of analytes. Bioavailability of VX at 7 h was found to be very small compared to i.v. data (not exceeding 3%). The long-lasting elimination phase demonstrated high VX persistence in the organism, resulting in threatening concentrations with acute toxicological relevance for a longer period. Such information is important for therapeutic treatment, pointing out the necessity of long time oxime infusion.

Respiratory Uptake (Nose-only Model)

As pointed out in the section "Respiratory uptake by inhalation" earlier in this chapter, respiratory uptake is the most likely route of exposure for G agents, causing 70–80% absorption in the upper respiratory tract. The sophisticated exposure model of the nose-only design applied to guinea pigs challenged the laboratory animals free of potential distortions derived from simultaneous ocular or p.c. uptake, as occurs in vapor chambers (Langenberg et al., 1998a).

The toxicokinetics caused by administration of C(±)P(±)-soman to guinea pigs documented a discontinuous process of monoexponential function for the absorption phase followed by a biexponential fit for distribution and elimination (Figure 56.3D). C(−)P(−)-soman was detected in blood as early as 30 s after challenge, and a short-term maximum was reached immediately after terminating the 8-min exposure period (Figure 56.3D; Benschop and de Jong, 2001). Nevertheless, some depot formation might also occur when applying higher doses, causing maximum levels after completion of exposure. The concentration curvature of C(+)P(−)-soman showed a similar profile, but with consistently smaller concentrations, which is due to a higher degree of enzymatic hydrolysis (Table 56.3). In contrast, less toxic C(−)P(+)-soman was detected in very small concentrations during the exposure phase exclusively, whereas C(+)P(+)-soman was not detected at all. Curvatures for SP-(−)-sarin appeared to be very similar in terms of time for first appearance in blood and for reaching maximum concentration.

These selected representative examples indicate that concentration–time profiles are variable despite common underlying basic chemical reactions of hydrolysis and adduct formation. Despite improving medical treatment of nerve agent poisoning, the concurrence of numerous physiological and pathophysiological parameters should be understood. Therefore, establishment of a descriptive and predictive model is important for medical defense of OPCs.

Mathematical Simulation for Prediction of Nerve Agent Toxicokinetics

As is obvious from the huge number of parameters affecting toxicokinetic behavior (e.g., route of administration, nature of OPCs, hydrolyzing and bioscavenging enzymes, proteins, and distinct compartments for distribution and species specificities), mathematical modeling of this complex situation is a big challenge. Based on numerous experimental data on soman toxicokinetics, Sweeney et al. (2006) introduced a model described by mathematical algorithms that allows the prediction of concentration–time profiles evoked by i.v., s.c., or inhalational soman uptake (≥1 LD_{50}) in common laboratory animals (i.e., rat, guinea pig, and marmoset). This physiologically based pharmacokinetic model (PB/PK) benefits from the combination of relevant pharmacokinetic basics and soman-specific experiences, realizing both an excellent degree of confidence for theoretical and laboratory data, as well as extrapolation to other species. This concept is a further development of an initial model from the same working group introduced by Langenberg et al. (1997). A more detailed description of these models would go beyond the scope of this chapter. Readers are referred to the sources in the reference list at the end of the chapter.

Bioanalytical Techniques Relevant to Toxicokinetics

Elaboration of nerve agent toxicokinetics requires sophisticated analytical tools to detect and, if possible, to quantify the free toxicants, as well as adducts with proteins and enzymes. Analysis of OP nerve agents has been performed by capillary electrophoresis (CE), biosensors, MALDI-MS, desorption electrospray ionization MS (DESI MS), ion mobility time-of-flight MS (IM-TOF MS), nuclear magnetic resonance (NMR) spectroscopy, liquid chromatography-ultraviolet (LC-UV), gas chromatography (GC), and many more techniques (Hooijschuur et al., 2002; John et al., 2008).

Determination of Nerve Agents

In contrast to those rather unusual methods, GC coupled to diverse detection systems [e.g., flame ionization detector (FID), nitrogen–phosphorus detector (NPD), flame photometric detector or mass spectrometer, as well as LC methods] represents the most common techniques for OP determination, especially for biological samples. These methods offer high resolution, sufficient limits of detection, good reproducibility, and robust hardware devices. For more detailed information, readers are referred to other review articles (e.g., Hooijschuur et al., 2002; John et al., 2008).

Analysis becomes much more complex when stereoisomers are quantified separately (Figure 56.1). Enantiomers cause identical detector responses in NPD, FID, or MS. Therefore, chiral separation systems are required to overcome these detector limitations. Despite enormous progress in separation media and detector systems within the last two decades, the number of reports on chiral analysis of nerve agents valuable for toxicokinetic studies is still very small. Chiral separations make use of special chromatographic columns modified with chiral ligands.

Isomers of soman were separated by GC on a Chirasil-L-Val column, but lacked baseline separation (Benschop et al., 1981, 1985; Li et al., 2003a,b). In contrast, (+)-sarin and (−)-sarin could be completely separated by the same column (Benschop and de Jong, 2001). Another study presented a modified method using a Chiraldex gamma-cyclodextrin trifluoroacetyl GC-column coupled to an electron impact (EI)-MS, which enabled sufficient baseline separation of all four stereoisomers of soman (Smith and Schlager, 1996; Yeung et al., 2008).

Apart from the Chirasil-L-Val method, sarin enantiomers were also separated by a two-dimensional GC technique on chiral Cyclodex B material prior to NPD monitoring (Spruit et al., 2000, 2001). Additional GC-based approaches allowed baseline separation of cyclosarin enantiomers on a GAMMA DEX column monitored by EI-MS (Reiter et al., 2007), separation of VX stereoisomers on hydrodex-β-TBDAc (β-cyclodextrin; Reiter et al., 2008), and separation of tabun enantiomers on BetaDex 225 coupled to APCI-MS (Tenberken et al., 2010). VX enantiomers were also chromatographed on a Chiracel OD column by LC coupled to an electrochemical detector, yielding a lower limit of quantification of about 10 ng/mL blood (Van der Schans et al., 2003). Another LC method coupled with MS/MS detection for VX made use of CHIRALCEL OD-H and CHIRAL AGP columns (Reiter et al., 2008).

Detection of Enzyme and Protein Adducts of Nerve Agents

In contrast to the measurement of free agents, the qualitative detection of protein adducts is a very novel approach that came about by overwhelming technical progress in bioanalytical mass spectrometry. Electrospray ionization (ESI) and MALDI as soft ionization methods for mass spectrometric detection are highly valuable for the detection of biomacromolecules like DNA, peptides, and proteins (Schulz-Knappe et al., 2001; John et al., 2004, 2005). Therefore, these technologies are also favorable for the analysis of proteins interacting with nerve agents. Consequently, a number of approaches have been published that identify and characterize these adducts. Typically, protein and enzyme adducts are first isolated from complex biological matrices (e.g., blood) using affinity chromatographic methods; subsequently, they are

TABLE 56.5 Physicochemical Properties of Most Common Vesicant Agents

Agent	CAS No.	NATO Code	MW (g/mol)	Melting Point (°C)	Boiling Point (°C)	Vapor Pressure (mbar)	Water Solubility (mg/L)	Hydrolysis Rate, $\tau_{1/2}$ (h)	log P(–)

subjected to enzymatic cleavage by adding selected proteases. The resulting internal peptide cleavage products containing the derivatized (phosphylated) residues are chromatographically separated and analyzed by modern mass spectrometry. Using sophisticated MALDI-MS techniques, this general procedure allowed the identification of albumin adducts (Li et al., 2007, 2008; John et al., 2010), as well as the adducts of BChE and their aged products (Jiang et al., 2013). LC-ESI MS was applied to analyze adducts of albumin (Peeples et al., 2005; Williams et al., 2007), BChE (Noort et al., 2006; Tsuge and Seto, 2006), CarbE (Peeples et al., 2005), keratins, tubulin, actin, and transferrin (Grigoryan et al., 2009). For a more detailed description, see John et al. (2008), Schopfer and Lockridge (2012), and Black and Read (2013).

For diagnostic detection of BChE adducts of common G- and V-type nerve agents, enhanced sample throughput was achieved by automated processes in 96-well plate format, extracting plasma by immunomagnetic separation (Knaack et al., 2012). An alternative method, based on the principle of a sandwich enzyme-linked immunosorbent assay (ELISA), was presented by Wang et al. (2011) to determine OP adducts in complete BChE.

This summary underlines the great importance of modern analytical techniques to unraveling pathophysiological situations at the molecular level and to supporting toxicokinetic studies by discovering the most relevant protein-binding elimination processes.

VESICANTS

Sulfur Mustard

Overview of Sulfur Mustard

Sulfur mustard is a blistering or vesicating agent that primarily incurs damage on organs that come into immediate contact with either its liquid or vaporous form. However, severe dermal and respiratory exposure to the agent may also result in absorption of sulfur mustard, which subsequently causes additional systemic damage (Kehe and Szinicz, 2005).

Unfortunately, sulfur mustard has been used in acts of chemical warfare throughout the twentieth century, from World War I to the attacks of Saddam Hussein's former Iraqi regime against Iran and even Kurdish civilians. The simplicity of the agent and its synthesis combined with its devastating medical, psychological, and socioeconomic effects, along with the fact that no causative therapy has yet been established, may convince future aggressors (both state and nonstate parties) to use this agent in their attacks. This, in turn, necessitates medical research efforts, including toxicodynamic and toxicokinetic studies, to develop countermeasures against the effects of sulfur mustard. Table 56.5 displays the basic physicochemical properties for sulfur mustard, which constitute the fundamental reason behind many of its toxicokinetic properties. Data for lewisite, another vesicant agent described in the section "Lewisite," later in this chapter, are also shown in this table.

Toxicity of Sulfur Mustard

Figure 56.4 depicts the basic chemical mechanism by which sulfur mustard incurs its primary damage to biological molecules, which results in subsequent damage to cells, tissues, and organs.

Sulfur mustard forms an intermediate sulfonium ion that further transforms into a carbenium ion, a strong electrophile capable of reacting with nucleophile targets, primarily in DNA and RNA. Examples include the N7 in guanine (61%; Ludlum et al., 1994), the N3 in adenine (16%), and the O6 in guanine (0.1%). Even though the latter is considerably less frequent, it is of significant concern, as the repair enzyme (O6-alkylguanine-DNA-alkyltransferase) is not capable of reversing this reaction. Therefore, DNA mutation due to mispairing may occur during DNA replication, which is proposed to be the origin of subsequent cancer formation (Ludlum et al., 1986). Because of its bifunctional character, sulfur mustard also forms interstrand DNA crosslinks, in particular from one guanine to another (17%). It is estimated that a 100-μM concentration of sulfur mustard accounts for 0.28 crosslinks per 10,000 DNA bases (Shahin et al., 2001).

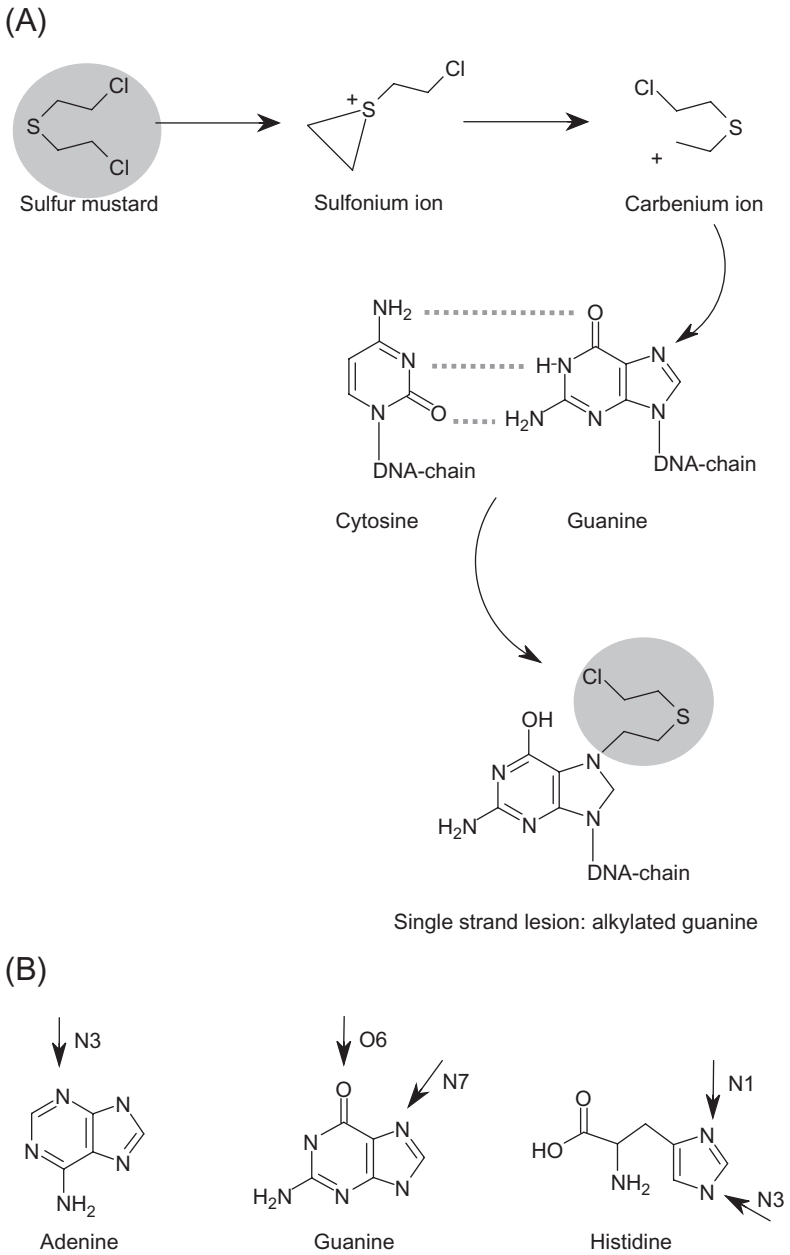

FIGURE 56.4 Sulfur mustard, its structure, mechanism of action, and targets of adduct formation. A: Mechanism of reaction of sulfur mustard and nucleotide guanine. B: Sites of alkylation by sulfur mustard. Arrows mark identified targets in nucleotides and amino acid histidine.

Membrane-bound proteins and enzymes may undergo alkylation in the presence of sulfur mustard (Kehe and Szinicz, 2005). Figure 56.4 depicts targets of alkylation in both DNA bases and amino acids. As sulfur mustard-induced DNA damage has the most significant impact on the cell's short- and long-term survivability, it is DNA alkylation that produces the most significant toxic effects, whereas effects from protein alkylation are usually visible only in the presence of high concentrations of sulfur mustard (Peters, 1947; Lodhi et al., 2001). As systemic concentrations will always be several orders of magnitude below local concentrations at the site of immediate contact, the systemic toxic effects of sulfur mustard are also most likely to result from DNA alkylation. DNA alkylation produces the most evident effects in proliferating cells; tissues with rapidly proliferating cells, such as bone marrow, suffer the most obvious damage. Toxic effects are similar to side effects from alkylating antineoplastic drugs (Dacre and Goldman, 1996). (Actually, the first antineoplastic drug was developed from a structural analog of nitrogen mustard—see Goodman et al., 1984.) Those effects include nausea,

vomiting, fever, fatigue, apathy, and loss of appetite. Bone marrow toxicity results in an initial leukocytosis, which is soon followed by leukopenia, thrombopenia, eosinopenia, and subsequent anemia (Dacre and Goldman, 1996).

Specific toxic effects of sulfur mustard have also been reported in the CNS and may range from agitation to seizures (Balali-Mood and Navaeian, 1986).

Invasion

Significant amounts of sulfur mustard may be absorbed from skin that has been in direct contact with sulfur mustard. Vapors of sulfur mustard may also be absorbed through the respiratory system.

In theory, there are two additional pathways for systemic uptake of sulfur mustard: the surface of the eyes and the gastrointestinal system. They have, however, never been investigated for the following reasons: gastrointestinal exposure to sulfur mustard is a rare phenomenon and may only occur in cases of sabotage (deliberate food poisoning) or a considerable lack of basic chemical defense measures (i.e., food consumption in a contaminated area). The local effects of exposing the gastrointestinal system to sulfur mustard are severe and life-threatening; they include strong abdominal pain, bloody diarrhea and vomiting, and rupture of stomach or duodenum. Subsequent peritonitis is often fatal (Dacre and Goldman, 1996). In comparison to life-threatening local effects of gastrointestinal exposure, any related systemic effect would be of secondary importance.

As opposed to the rarity of gastrointestinal exposure, ocular exposure is frequent among the victims of sulfur mustard attack, and local symptoms of varying severity are likely to occur whenever the individual was not protected by a respirator (mask) at the time of attack (Solberg et al., 1997). As the eye is a very sensitive organ, ocular symptoms are often among the first signs of sulfur mustard exposure. Due to the close proximity of a large number of capillary vessels and the fact that the eye constitutes a relatively weak barrier, xenobiotic substances are often rapidly absorbed (Lama, 2005). As the surface of the eye is small in comparison to the skin and the respiratory tract, the total amount of sulfur mustard that may be absorbed from the eye's surface is low. Self-protective effects of the eye, such as blepharospasm and pronounced lacrimation, may further reduce the amount of an agent that may be absorbed through this pathway. The local effects of exposure appear very severe and are a primary reason for concern in victims of sulfur mustard exposure. Whereas blepharospasm and lid edema cause transitory loss of vision—already resulting in immense distress for victims—heavy exposure may result in permanently opaque cornea and blindness. In general, early effects in the eyes are treatable with therapy and have a relatively good outcome after several weeks. In comparison, any systemic effects from transocular absorption alone would be of only minor concern. It has to be emphasized that isolated ocular exposure on the battlefield or due to terrorist attacks utilizing sulfur mustard is exceedingly unlikely. Ocular exposure would inevitably be accompanied by cutaneous and respiratory exposure. The specific rate of absorption (i.e., the amount absorbed through a given surface over a specified time) may be lower, particularly in the case of initially intact skin. However, the larger surface of the skin (and possibly the respiratory tract) would result in an amount that constitutes the major fraction of sulfur mustard absorbed, which would subsequently determine the occurrence and severity of systemic effects. Research regarding the absorption of sulfur mustard has focused on two major pathways, which are described in further detail in the subsequent sections.

Percutaneous Absorption

Penetration rates of liquid sulfur mustard were determined *in vitro* (71–294 $\mu g/cm^2/h$) on human skin with a Franz-type glass diffusion cell and correspond very well to *in vivo* data derived from human skin (60–240 $\mu g/cm^2/h$; Chilcott et al., 2000). Significant effort has been dedicated to confirm the validity of animal models by comparing data derived from these models with findings from *in vitro* human skin experiments. Chilcott et al. (2001) investigated absorption in *in vitro* models of pig ear and heat-separated human skin. Absorption was determined at $411 \pm 175\,\mu g/cm^2/h$ for pig ear skin and $157 \pm 66\,\mu g/cm^2/h$ for human skin, respectively. These data were considered to agree with earlier *in vivo* findings, even though the authors cautioned that data on effectiveness of decontaminants were completely disparate between human and pig ear skin. Logan et al. (1999) determined that sulfur mustard exposure through skin of the hairless guinea pig was $120\,\mu g/cm^2/h$.

Occlusion of the skin (i.e., covering the skin with a material that is impenetrable to air and moisture) can result in a dramatic increase in p.c. absorption. For example, in a study by Chilcott et al. (2002) using *in vitro* models of human skin, absorption rates in unoccluded controls ($4.41 \pm 1.90\,\mu g/cm^2/h$) increased to $538 \pm 193\,\mu g/cm^2/h$ under occluded conditions.

In contrast, Karvaly et al. (2008) showed that a commercially available barrier cream and a perfluoropolyether oil applied prior to exposure reduced p.c. uptake of sulfur mustard. In particular, perfluoropolyether oil was highly effective, preventing sulfur mustard exposure for a period of 20 min. A petroleum jelly ointment, however, had no protective effect, even when applied prior to exposure.

Benson et al. (2011) percutaneously exposed guinea pigs to ^{14}C-labeled sulfur mustard vapors ($525\,mg/m^3$) for 12 min, applied to three skin areas totaling $19.8\,cm^2$.

A total of 29.8 ± 5.31 µg sulfur mustard per animal was absorbed, 90% of which remained in the skin. This result agrees with an *in vitro* study by Hattersley et al. (2008) using human skin samples, which confirmed that a depot of sulfur mustard existed for at least 24 h following dermal exposure, and estimated concentrations in skin is at least 20 times above the acutely toxic concentration.

Regarding airtight vapor cups frequently used for percutaneous sulfur mustard exposure studies, Dalton et al. (2006b) validated this approach and showed that equilibrium concentrations developed within 2 min after sealing the cups and were not significantly different from calculated saturated vapor concentration (1,363 mg/m^3) when cups were placed on inert control surfaces. However, when cups were placed on samples of pig skin, percutaneous uptake of sulfur mustard lowered actual vapor concentrations to values significantly below saturation (i.e., to 592 ± 246 mg/m^3 on a 10.15 cm^2 skin surface and 740 ± 224 mg/m^3 on a 2.54 cm^2 skin surface). The authors validated the assumption that saturated vapor concentration could be used to calculate concentration—time products for percutaneous absorption studies, but they cautioned that, depending on the size of the reservoir and the skin surface, decreasing vapor concentrations had to be taken into account.

Respiratory Absorption

Langenberg et al. (1997) conducted inhalation exposure experiments in hairless guinea pigs. LCt_{50} was determined at 800 mg min/m^3. Following application of 1 LCt_{50} over 5 min, no unchanged sulfur mustard in blood was found (with a limit of detection of 5 pg/mL). Low concentrations (0.7 adducts per 10^7 nucleotides) of N7-guanine adducts of sulfur mustard were found in the lung. Concentration of N7-guanine adducts was also determined from various tissues along the respiratory tract. Actually, concentrations found were much larger, peaking at approximately 90 adducts per 10^7 nucleotides in the larynx and trachea. Concentration in the carina was lower (approximately 50 per 10^7 nucleotides), but it was still substantially higher than the abovementioned value in the lungs. The authors concluded that most of the sulfur mustard inhaled reacts in the upper airways rather than being absorbed. In animals with complex nasal systems (such as guinea pigs), only very minor fractions would reach the lung. However, they also pointed out that, in humans (along with other species with a less complex nasal system), the proportion of sulfur mustard reaching the lung may be larger.

Following inhalation of 3 × LCt_{50} (300 mg/m^3 over a period of 8 min), sulfur mustard was found in blood. Its peak concentration during the inhalation period was found to be approximately 5 ng/mL. This concentration soon declined. A mean value of 2 ng/mL was found even after 4 h. A mathematical model explaining the data during the distribution and elimination phase could not be developed. These findings were further complicated by the fact that in 2 of 12 animals, no sulfur mustard was found in any of the samples. No sulfur mustard was detected in any of the animals at 15 and 20 min (7 and 12 min postexposure, respectively) before reappearing in most of the animals at the abovementioned concentration of 2 ng/mL. The latter finding may possibly be explained by the hypothesis that the early peak in sulfur mustard concentration is due to direct inhalation (afterward, concentration declines to levels below the limit of detection), whereas the second, long-term increase in sulfur mustard concentration may be attributed to sulfur mustard absorbed from depots in the upper airways. Figure 56.5 depicts the concentration over time, following the respiratory exposure to 3 × LCt_{50} of sulfur mustard. For comparison, concentration over time after i.v. application is also depicted. The authors concluded that toxicity from sulfur mustard inhalation was due to its local, rather than its systemic, effects.

Benson et al. (2011) presented a respiratory exposure study using ^{14}C-labeled sulfur mustard. Anesthetized rats with transorally placed tracheal catheters were exposed to 250 mg ^{14}C sulfur mustard vapor/m^3 for 10 min. A total of 18.1 ± 3 µg sulfur mustard per animal was absorbed. Within 2 h postexposure, inhaled sulfur mustard was distributed and more than 70% were deposited in the carcass and pelt.

Distribution

Sulfur mustard is a strongly lipophilic substance that may accumulate in fatty tissues and has actually been detected at autopsy in a patient who died 7 days postexposure. Detailed data, as published by Drasch et al. (1987), are displayed in Table 56.6.

Obviously, these findings confirm the theoretical assumption that the lipophilic properties of sulfur mustard result in a distribution, primarily in lipophilic tissues. High concentrations found in the brain may also explain why the CNS is one of the organs exhibiting systemic effects of sulfur mustard poisoning, even though it is not a site of rapidly proliferating cells.

It should be noted that some authors have questioned the findings by Drasch et al., considering the absolute concentrations excessively high and therefore unlikely. However, as high-dose sulfur mustard poisoning is a rare event, it is nearly impossible to verify or falsify the data. One might argue that the amounts of sulfur mustard described may not even permit short-term survival. However, if most of an agent entered the organism via p.c. absorption, there is a possibility that large amounts of the agent actually had been absorbed and formed a depot without resulting in instant death, but ultimately leading to death 7 days later. Whether or not the absolute values are accurate, they at least give an impression of

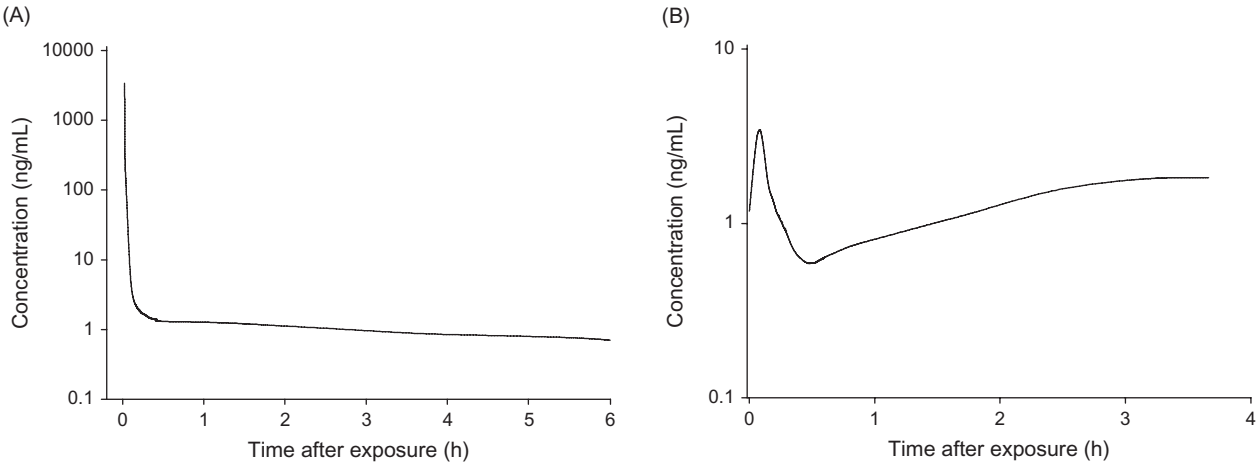

FIGURE 56.5 Concentration over time, following i.v. and respiratory exposure to sulfur mustard in the guinea pig. A: Decline of sulfur mustard exposure after i.v. injection. B: Concentration over time after respiratory exposure: initial increase in the inhalation phase, followed by a decline and a secondary increase; concentration of approximately 2 ng/mL is sustained for 4 h.

TABLE 56.6 Content of Sulfur Mustard in the Tissues of a Deceased Victim

Tissue/Organ	Concentration (mg/kg)
Fat	15.1
Skin with subcutaneous fatty tissue	11.8
Brain	10.7
Skin	8.4
Kidney	5.6
Liver	2.4
Cerebrospinal fluid	1.9
Muscle	3.9
Spleen	1.5
Blood	1.1
Lung	0.8
Urine	Not detected
Blister fluid	Not detected

Data are according to Drasch et al. (1987)

the distribution of sulfur mustard within an organism that correlates with the agent's lipophilic properties.

More recent *in vitro* experiments using human skin have confirmed the presence of unhydrolyzed sulfur mustard in the lipophilic stratum corneum and the upper epidermis. At 24 h post-exposure, the distribution ratio between epidermis and dermis has been determined to be 62–38%. Chilcott et al. (2000) also suggested that efforts to remove or neutralize the agent from these deposits might have a clinical benefit for the patient.

These findings suggest that, despite the presumably brief half-life calculated (see the section "Elimination," later in this chapter), sulfur mustard may be present in an organism for a significantly longer period of time, necessitating measures for medical personnel providing therapy and an awareness for the possibility of secondary blister formation, even 30 days post-exposure (Balali-Mood and Hefazi, 2005), as well as efforts to remove these deposits. In particular, the use of laser debridement (Graham et al., 2008) and mechanical dermabrasion (Rice, 2008) has been recommended to facilitate the healing process after dermal exposure to sulfur mustard. The effects may be partly attributed to the removal of epidermal depots of sulfur mustard.

As mentioned previously, Benson et al. (2011) confirmed that 90% of percutaneously absorbed sulfur mustard was deposited in skin, whereas more than 70% absorbed sulfur mustard was distributed to the carcass and pelt after respiratory exposure. The distribution of sulfur mustard is highly dependent on the original route of exposure. It was confirmed that a considerable amount of sulfur mustard was still present in deep lipophilic compartments even after the end of exposure.

Biotransformation

While the previously discussed findings demonstrate the stability of sulfur mustard in lipophilic tissues, the agent is rapidly hydrolyzed whenever situated in an aqueous compartment (Vycudilik, 1987). Thiodiglycol (TDG) is the primary hydrolysis product, in which the chlorine atoms have been replaced by hydroxyl groups. Karvaly et al. (2008) used subcutaneous microdialysis to monitor TDG in rats exposed to sulfur mustard. Peak concentrations of 7.2–21.7 nmol/L TDG were found, following percutaneous exposure to 2 µM sulfur mustard.

TDG may undergo oxidation to TDG sulfoxide, which is conjugated with glutathione to form 1,1′-sulfonylbis [2-*S*-(*N*-acetylcysteinyl)ethane]. Following the β-lyase pathway, the 1,1-sulphonylbis[2-(methylsulfinyl)ethane] and 1-methylsulfinyl-2-[2-(methylthio)ethylsulfonyl] ethane can be formed (Black and Read, 1995). Figure 56.6 summarizes the pathways of sulfur mustard biotransformation. No sulfo- or glucuronyl-conjugates were detected in urine after i.v. administration of sulfur mustard (Maisonneuve et al., 1993).

Halme et al. (2011) presented a method for the efficient stable isotope dilution LC-HESI-MS/MS method for verification of β-lyase biotransformation products in human urine after sulfur mustard exposure. The β-lyase products 1,1′-sulfonylbis-[2-(methylsulfinyl)ethane] (SBMSE) and 1-methylsulfinyl-2-[2-(methylthio) ethylsulfonyl]ethane (MSMTESE) were successfully detected at a concentration of 4 ng/mL, whereas the limit of quantification was established at 10 and 11 ng/mL for SBMSE and MSMTESE, respectively.

Within cells, sulfur mustard forms adducts with DNA, primarily those described above. Adducts can also be formed with nucleophilic sites of amino acids and proteins. Byrne et al. (1996) demonstrated that sulfur mustard, with two highly reactive groups was able to form protein crosslinks between cysteine residues and assumed that protein crosslink formation may actually contribute to sulfur mustard toxicity. Contrary to DNA adducts, there is no specific mechanism to reverse protein adduct formation. For this reason, there is a strong forensic interest in the detection of protein adducts of sulfur mustard, as these may provide evidence of sulfur mustard exposure for prolonged periods after an incident.

Capacio et al. (2008) developed a method to detect sulfur mustard adducts in plasma proteins by hydrolyzation (which produced TDG) and subsequent derivatization of TDG, followed by GS/MS analysis. The method was successfully applied to determine sulfur mustard adducts in rat plasma, following respiratory exposure to sulfur mustard.

A number of adducts to amino acid residues have been identified by Noort et al. (1996) and Black et al. (1997a,b). Six different histidine residues, three glutamic acid residues, and both N-terminal valines were found. Alkylated cysteine, aspartic acid, lysine, and tryptophan were also detected. While N1 and N3 histidine adducts were found to be most abundant, it was the alkylated N-terminal valine adducts that were most useful for subsequent quantification. See the section "Detection of DNA and protein adducts of vesicants," later in this chapter, for analytical details.

Noort et al. (2008) investigated the persistence of sulfur mustard adducts to albumin and hemoglobin in rats. The albumin adduct (*S*-2-hydroxyethylthioethyl)-Cys-Pro-Tyr was detectable up to 7 days after exposure, while the adduct to the N-terminal valine in hemoglobin was still detected after 28 days. The decrease of adduct concentration corresponded with albumin half-life and the lifetime of the rat erythrocyte, respectively.

Following two simultaneous cases of accidental human exposure to sulfur mustard, Smith et al. (2008) investigated the concentration of cysteine-34 adduct to albumin and adducts to glutamic and aspartic acids of plasma proteins. In the case of a more severely exposed patient who required hospitalization, both adducts were detected over a 42-day period, though they decreased by approximately 75% toward the end of that time. In a second patient who had developed a single, small blister, the albumin adduct was found during a 6-day period post-exposure.

Recently, local adduct formation after cutaneous exposure to sulfur mustard has been a focus of investigation in an effort not only to establish new forensic methods, but also to better understand vesication, the most evident symptom of sulfur mustard exposure via the skin. Adducts of sulfur mustard to cytokeratin types I and II, actin stratifin, and galectin-7 were successfully identified by Mol et al. (2008) in sulfur mustard-exposed human epidermal keratinocytes. Sulfur mustard adducts to actin, annexin A2, and keratin 9 were also found in HaCaT cells (immortalized kerationcytes) by Sayer et al. (2009).

Elimination

Following i.v. application of ^{14}C-labeled sulfur mustard in rats, 80% of the radioactivity administered was excreted via the renal pathway. Fecal excretion amounted to less than 3% (Maisonneuve et al., 1993). A study by Benson et al. (2011) in rats and guinea pigs, following respiratory and percutaneous exposure to ^{14}C-labeled sulfur mustard, confirmed predominantly renal excretion. Biotransformation products excreted in urine after accidental human exposure included TDG, TDG sulfoxide, and the bis-mercapturate of mustard sulfone (Barr et al., 2008). When comparing the concentrations of TDG and its sulfoxide, the latter was found in concentrations twice as high. When p.c. exposing weanling pigs to sulfur mustard, Graham et al. (2000) found peak levels of TDG either in the samples drawn after 6–8 h or in other cases after 24–48 h. Findings were considered to be in agreement with earlier data from rodent species and cases of accidental human exposure.

It is worth noting that background levels of TDG and TDG sulfoxide have been found in the urine of healthy individuals never exposed to sulfur mustard. For this reason, their validity as unambiguous markers for sulfur mustard exposure has been questioned. Black and Read (1995) suggested the determination of β-lyase pathway biotransformation products, which in the urine of exposed patients, were found at concentrations similar to those of TDG sulfoxide, but were not found in unexposed individuals.

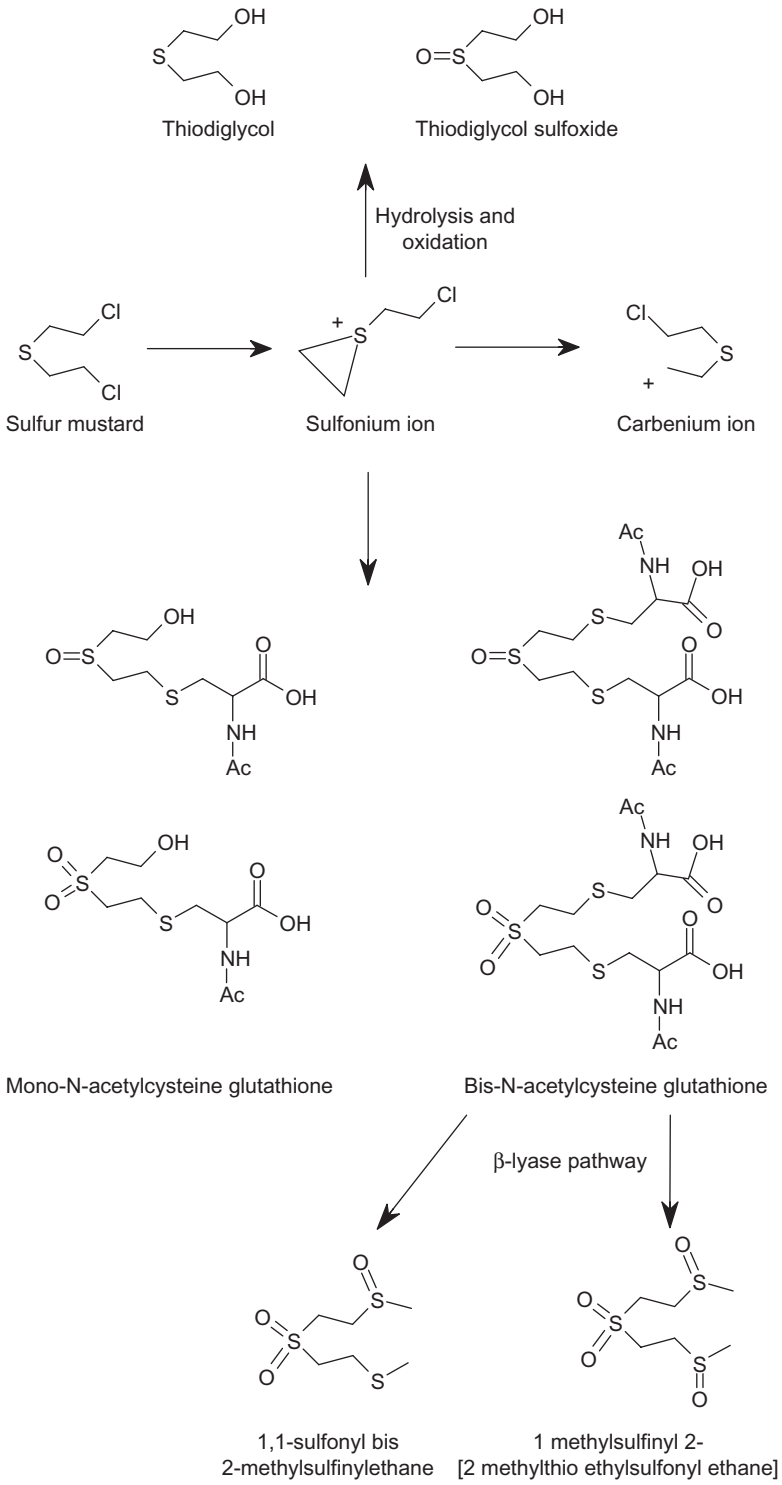

FIGURE 56.6 Biotransformation of sulfur mustard.

Lewisite

Overview of Lewisite

Lewisite (2-chlorvinyldichlorarsin) is another vesicant. It was first synthesized and described by the Belgian priest and chemist Julius Arthur Nieuwland (Nieuwland, 1904). Unlike sulfur mustard, there has never been a documented use of this substance in armed conflict. During World War I, the American military chemist Winford Lee Lewis suggested and initiated its

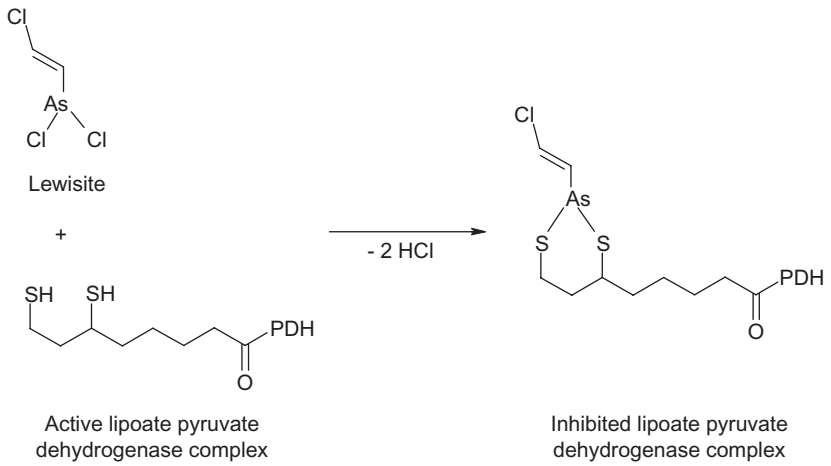

FIGURE 56.7 The structure and mechanism of action of lewisite. Lewisite forms covalent bonds with lipoic acid, inactivating the enzyme PDH.

development into a chemical weapon, but due to the 1918 armistice in Europe, it was not used on the battlefield (Vilensky and Redman, 2003).

Lewisite remains a concern because its physical properties (in particular a melting point of −18°C; see Table 56.5) might facilitate its use in cold climates. A belligerent party willing to use chemical weapons might decide that lewisite would provide a "unique" capability to wage chemical warfare even in winter or in mountainous regions. Large stockpiles of the agent were abandoned by the Imperial Japanese Army during its retreat from China in the latter stages of World War II, creating a chemical hazard that persists decades after the war (Hanaoka et al., 2006). Table 56.5 summarizes the physicochemical properties of lewisite.

Toxicity of Lewisite

The dominant element in lewisite structure is arsenic, which is able to react with sulfhydryl groups of various enzymes, disabling the enzyme in the process (Goldman and Dacre, 1989). Figure 56.7 depicts the structure of lewisite and its toxic mechanism.

Lipoic acid is particularly susceptible to this reaction and one of the most evident consequences is the inhibition of the enzyme pyruvate dehydrogenase (PDH), rapidly disabling the cell's metabolism of glucose and fatty acids. The resulting energy deficiency may lead to swift, necrotic cell death. In comparison to sulfur mustard, the latency period (from exposure to first signs and symptoms) is significantly shorter, and lewisite injuries have been described as extremely painful from an early stage. Moreover, it is a much more lethal agent and has a large systemic toxicity; 0.5 mL of the agent may produce systemic effects, whereas 2 mL (approximately 3.6 g) can be fatal (Marrs et al., 1996).

Invasion

Percutaneous Absorption

Precise data [i.e., a diffusion coefficient expressing the p.c. absorption of lewisite (amount absorbed per area and time)] is not available. However, Inns and Rice (1993) conducted p.c. toxicity studies in rabbits and determined the LD_{50} to be 5.3 mg/kg (3.5–8.5 mg/kg, 95% confidence interval). The exposed area was 2 cm^2, and exposure lasted for 6 h.

Inns et al. (1990) had also determined the LD_{50} of i.v. lewisite administration to be 1.8 mg/kg (1.6–2.1 mg/kg 95% confidence interval). It can be concluded that by exposing 2 cm^2 of rabbit skin to a dose of 5.3 mg/kg for 6 h, a dose producing the equivalent effect of 1.8 mg/kg is absorbed. No further calculations that might exaggerate the reliability of available data shall be conducted here.

King et al. (1992) conducted lewisite absorption studies on isolated perfused porcine skin flaps, using lewisite concentrations from 0.07–5.0 mg/mL. Blister formation was observed, and at higher lewisite concentrations, there was a pronounced increase of lactate dehydrogenase in blister fluid, a sign of necrotic cell death. Cellular glucose utilization was decreased at the same time, underscoring the detrimental effect of lewisite on cellular energy metabolism. At the highest concentration of 5 mg/mL of lewisite, arsenic was detected in venous blood from the perfused skin preparation. At this concentration, systemic uptake of lewisite or its degradation products and toxic effects resulting thereof are to be expected.

Respiratory Absorption

The LCt_{50} of lewisite in humans has been estimated at 1,500 mg min/m3 (ATSDR, 2007), although no

experimental data has been cited. Considering its pronounced local effects lethality can at least partly be attributed to local effects of lewisite on the respiratory tract.

Distribution

High distribution volumes per kilogram indicate extensive distribution in tissues, due to the lipophilicity of the substance. In a rabbit model, more than sevenfold more of the substance was found in some tissues (e.g., the liver, lung, and kidneys) compared to blood concentrations. That ratio was maintained over the sampling period; i.e., for at least 96 h (Snider et al., 1990).

Biotransformation

Once incorporated, unbound lewisite is quickly hydrolyzed. Its predominant biotransformation product is 2-chlorovinylarsonous acid (CVAA; Figure 56.8). Analytical methods to confirm lewisite exposure have focused on detection and quantification of CVAA, at least in the past. However, Noort et al. (2002) also pointed out that, due to the high affinity of arsenic toward sulfhydryl groups, adducts of lewisite/CVAA and cysteine residues of proteins are formed. In an *in vitro* study, incubating 14C-labeled lewisite with human blood samples, 90% of lewisite was found in erythrocytes, whereas 25–50% of arsenic was bound to globin. From these protein adducts, CVAA can be released to form an adduct with the antidote British anti-lewisite (BAL; Fidder et al., 2000). The authors were also able to identify a specific protein adduct of lewisite formed with cysteine residues 93 and 112 of β-globin. See the section "Detection of DNA and protein adducts of vesicants," later in this chapter, for analytical details. Figure 56.8 summarizes the biotransformation and reversal of adduct formation by BAL.

Elimination

Snider et al. (1990) determined the elimination of lewisite from rabbits after p.c. injection. The half-life was determined, ranging from 55–75 h. A clearance of 120 mL/h/kg was found. These findings only describe the overall elimination of arsenic from the organism following a lewisite exposure.

In vivo, unbound CVAA is quickly excreted via the renal pathway and cannot be detected in urine samples taken later than 12 h postexposure. The biological half-life of protein adducts is much longer: in blood samples taken 10 days postexposure and treated with BAL, Fidder et al. (2000) were still able to release 10% of the CVAA-BAL concentration found on day 1. Protein adducts of CVAA play an important role in the verification of potential lewisite exposure.

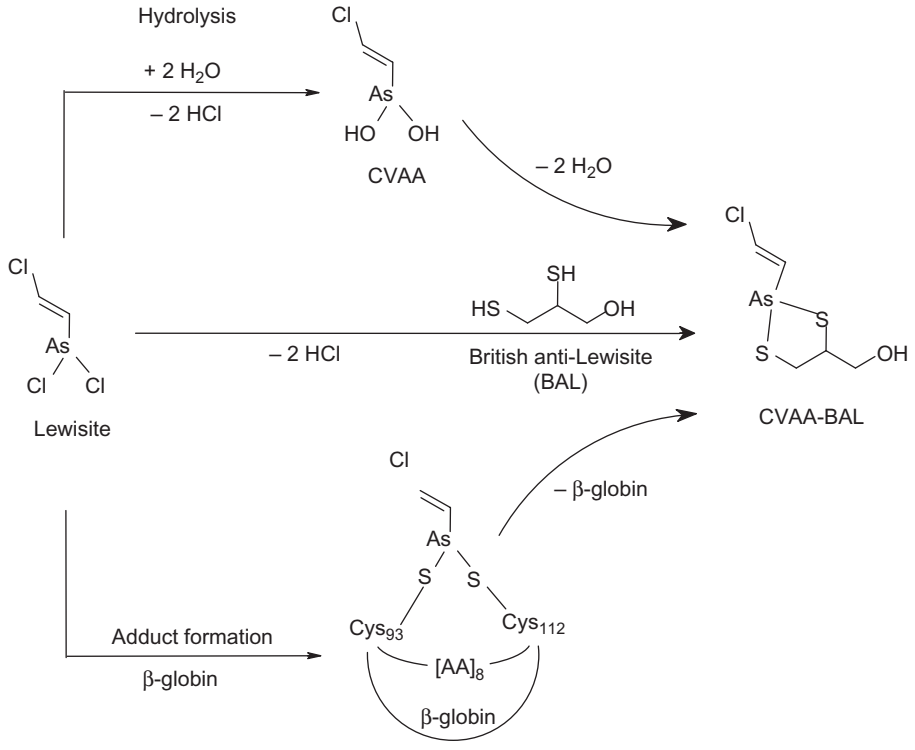

FIGURE 56.8 Lewisite biotransformation, adduct formation, and its reversal.

Bioanalytical Techniques for Quantification of Vesicants

Determination of Vesicants and Direct Biotransformation Products

When Drasch et al. (1987) determined the concentration of sulfur mustard in tissues of a deceased victim, they had to employ a combination of dichloromethane extraction and a thin-layer chromatography cleanup on silica plates, followed by derivatization with gold chloride and quantification by electrothermal atom absorption spectroscopy.

Vycudilik (1985) had already used gas chromatography-mass spectrometry (GC-MS) to confirm the presence of sulfur mustard in urine samples. Sodium chloride was added to the sample to facilitate extraction and slow down hydrolysis in the aqueous sample, and then the analyte was extracted with diethylether. The solvent was evaporated and the residue dissolved in methylene chloride. After purification—by shaking the sample solution for 1 h with silicagel—the solvent was again evaporated. The residue was again dissolved in methylene chloride and used for chromatography.

To detect TDG, TDG sulfoxide, and their acid-labile esters, Black and Read (1991) used $TiCl_3$ reduction, converting these products into single analyte TDG. TDG was then converted to its bis(pentafluorobenzoyl) derivative and quantified by GC-MS using negative ion chemical ionization. TDG sulfoxide could also be extracted directly using solid-phase extraction, followed by a Florisil cleanup. Derivatization and quantification was conducted as described previously. $TiCl_3$ was also used by Daly and O'Hehir (2007) to reduce the β-lyase pathway biotransformation product 1,1-sulphonylbis[2-(methylsulfinyl)ethane] to 1,1′-sulfonylbis[2-(methylthio) ethane] (SBMTE). This was followed by automated solid-phase extraction and LC-positive ion-ESI–tandem mass spectrometry.

Li et al. (2013) presented an ultrahigh-performance LC-tandem mass spectrometry (UPLC-MS/MS) method for simultaneous quantification of seven plasma biotransformation products of sulfur mustard. Limits of quantification ranged from 0.01 to 5.0 µg/L. The main products found in rat plasma were bis-β-chloroethyl sulfoxide (SMO), TDG, TDG sulfoxide (TDGO), 1,1′-sulfonylbis-[2-S-(N-acetylcysteinyl) ethane] (SBSNAE), 1,1′-sulfonylbis-[2-(methylsulfinyl)ethane] (SBMSE) and 1-methylsulfinyl-2-[2-(methylthio)ethylsulfonyl]ethane (MSMTESE).

Methods to detect lewisite exposure have been focused on its main biotransformation product, CVAA. Initial methods were developed for environmental samples (Bossle et al., 1989). Methods for CVAA quantification in serum were described by Fowler et al. (1991), as well as Jakubowski et al. (1993). CVAA was derivatized with 1,2-ethanedithiol and quantified using GC-MS. Logan et al. (1996) employed a similar method to detect CVAA in urine of guinea pigs exposed to lewisite.

Detection of DNA and Protein Adducts of Vesicants

Adducts of sulfur mustard can be hydrolyzed to release TDG. Lawrence et al. (2008) used this procedure, followed by extraction, derivatization, and GC-negative ion chemical ionization–mass spectrometry. A number of methods have been developed to directly detect and quantify the adducts of sulfur mustard. The most prevalent DNA adduct, N7-(2-hydroxyethylthioethyl)-guanine, was directly detected and quantified by Fidder et al. (1994, 1996a), using electrospray LC-tandem MS with multiple reaction monitoring. Benschop et al. (1997) used an immunoslotblot assay to detect this adduct in blood samples from Iranian patients, in order to verify their exposure that had occurred during the Iran–Iraq war in the 1980s.

Initial efforts by Noort et al. (1996, 1997) to detect the protein adducts of sulfur mustard focused on the 4-(2-hydroxyethylthioethyl)-L-aspartate, 5-(2-hydroxyethylthioethyl)-L-glutamate, cysteine and N-terminal valine adduct, and two histidine adducts, N1- and N3-(2-hydroxyethylthioethyl)-L-histidine. Acidic hydrolysis and pronase digestion were used to release these adducts from globin. Pronase is a mixture of proteinases isolated from the extracellular fluid of *Streptomyces griseus*. Adducts were derivatized with 9-fluorenylmethyl chloroformate, followed by identification and quantification, using GC-MS.

Even though they constitute only 1–2% of alkylated amino acids, the N-terminal valine adducts were useful for subsequent quantification efforts. N-alkylated N-terminal valine could be selectively cleaved, using pentafluorophenyl isothiocyanate as a reagent in a modified Edman procedure. The product of this reaction, pentafluorophenyl thiohydantoin, was derivatized with heptafluorobutyric anhydride and quantified by negative ion GC-MS/MS. This method was sensitive enough to confirm an *in vivo* exposure of guinea pigs 48 h after i.v. administration of 0.5 mg/kg; i.e., 6% of the LD_{50} (Fidder et al., 1996b). Recently, an improved method to detect the N-terminal valine adduct was presented by Nie et al. (2011) with a lowered limit of detection for identification of the adduct after a 20 nmol/L *in vitro* sulfur mustard exposure of human blood.

Noort et al. (1999) again used pronase to digest human serum albumin that had been incubated with sulfur mustard. The cleavage product, *S*-[2-[(hydroxyethyl)thio] ethyl]-Cys-Pro-Phe, was analyzed by micro LC-tandem mass spectroscopy.

Carol-Visser et al. (2008) had developed a method for online pepsin digestion-liquid chromatography-tandem

mass spectrometry configuration for rapid analysis of protein adducts of CWAs and demonstrated the detection of specific adducts of sulfur mustard in human serum albumin (along with sarin adducts to human butyryl cholinesterase).

Yeo et al. (2008) presented a verification method for the detection of albumin adducts of sulfur mustard by pronase digestion, followed by LC-MS-MS/MRM analysis. A blood concentration of 50 nM sulfur mustard resulted in formation of adducts that were successfully detected. Adducts of nitrogen mustards could also be detected after exposure to 100 nM HN-2 or 200 nM of HN-1 or HN-3, respectively.

Incubation of lewisite–protein adducts with BAL is capable of transferring its product 2-CVAA into a BAL-CVAA derivative. This derivative can be quantified using GC-MS. The method is able to detect a 1-nM lewisite exposure of human blood *in vitro* (Fidder et al., 2000).

A specific β-globin adduct to Cys93 and Cys112 was identified by the use of electrospray tandem mass spectrometry, as well as by chemical transformation with the cysteine-selective reagent vinylpyridine and derivatization by S-carbamylation (Fidder et al., 2000). No method for quantification of this adduct was described. As of mid-2008, no specific adducts other than the abovementioned ones have been described in literature.

Despite 90 years of research on the effects of vesicant agents and on medical countermeasures, only very limited data on toxicokinetics is available. However, technological advances in analytical chemistry have contributed to a better understanding of toxicokinetic properties of both sulfur mustard and lewisite, particularly in the last two decades. Knowledge gaps exist, but research efforts continue. The Chemical Weapons Convention (CWC) constitutes enormous progress in efforts to completely rule out future incidents of chemical warfare, and the risk of chemical weapons being used by state parties is probably lower than in any decade since 1910. On the other hand, there is a worldwide asymmetric threat, and the risk of terrorist attacks using chemical weapons cannot be ruled out. Defense experts, including medical chemical defense researchers, will be concerned about these issues for the foreseeable future. It is to be hoped that more comprehensive knowledge on both toxicodynamics and toxicokinetics will contribute to development of more effective, and possibly causative, therapies of vesicant poisoning. At the same time, the capability to unanimously prove vesicant exposure, even long after the incident, does certainly increase the possibility that any use of these CWAs will ultimately be detected and sanctioned. State-of-the-art analytical methods may play an important role in deterring and preventing acts of chemical warfare.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Measurement of toxicokinetic profiles is primarily motivated to improve in-depth understanding of the poison's fate in an organism, and thus of pathophysiological consequences. Both are important to optimize antidote treatment and therapy regimens for poisoned humans that intend to boost poison elimination and reverse toxic effects; or at least minimize harm by causal and symptomatic approaches. As outlined in this chapter, the fate of poison is regulated by multifactorial processes characterized by degradation and enzymatic biotransformation, as well as elimination by protein or DNA binding. With respect to state-of-the-art techniques and study design, only a few animal models are being investigated comprehensively for nerve agents, whereas almost no data on sulfur mustard and lewisite are available in literature.

To make matters worse, almost no human toxicity or toxicokinetic data for CWAs is available due to ethical reasons, hindering specific and tailored medical approaches. Therefore, data are to be obtained from animal studies requiring extrapolation of relevant characteristics to human conditions. As is obvious from the tabular compilations on acute lethal doses of nerve agents in different laboratory animals and different routes of exposure (Table 56.2), especially under consideration of stereoisomeric differences (Table 56.4) and underlying kinetic characteristics in terms of rate constants for serine esterase inhibition and catalytic constants for PTE-mediated hydrolysis (Table 56.3), such data are still incomplete. In addition, interspecies and intraspecies variations are enormous, limiting comparability and transferability of experimental results. There are only a limited amount of data considering specific differences between lethal and sublethal exposure scenarios. Data on tissue distribution in animals are rare and correlation to human organisms is not clarified conclusively to explain, for example, the larger persistence of nerve agents in the human body. This lack of information indicates future demands of medical defense research. There is also a rising need for combined toxicokinetic and pharmacokinetic data obtained from poisoned organisms under therapeutic treatment. This will help to find the most valuable reactivators of OP-inhibited cholinesterases, which differ dramatically in efficacy in a poison- and species-dependent manner. Taken together, results of future studies should (i) support development of mathematical models to describe and predict poison and antidote behavior *in vivo* in humans; (ii) unravel novel targets of poison on the molecular or compartmental level, which are useful as biomarkers or to identify additional pathophysiological situations; and (iii) establish novel bioanalytical methods and techniques, which allow very low quantification

limits and sufficient selectivity for stereoisomers in various tissues and compartments. Whereas a number of studies have been performed using commonly known nerve agents, there remains much more demand for further work with respect to vesicants.

CHAPTER

57

Toxicokinetics and Toxicodynamics of DFP

Miguel Sogorb, Jorge Estevez and Eugenio Vilanova

INTRODUCTION

Diisopropylfluorophosphate (DFP) is an organophosphorus compound (OP) that has not been used as a pesticide, chemical warfare agent or plasticizer. However, a search of the PubMed database yielded 3,514 results searching for different synonyms in titles and abstracts, as indicated in Table 57.1.

In other searches, using only one of the four MeSH terms (isofluorate, DFP, diisopropylphosphofluoridate, or diisopropylphosphoro-fluoridate), 3,085 results were found for those terms. Therefore, the PubMed database uses these four terms as synonyms and the same references are found in any cases. They represent most, but not all, the publications involving DFP. It should be noted that with the abbreviation of "DFP" some nonrelated publications are referred to (i.e., "bacterial DFP-flavoproteins"). Unfortunately, there is not an established tradition of indicating the CAS number for a unique reference of the chemicals in scientific publications, and standard chemical nomenclature is not always used. The statistics of the distribution of publications over time is shown in Figure 57.1.

More specifically, searching only for references mentioning DFP in the title, 597 results were produced. Although these references do not represent all the relevant references, this could be considered an indication of the number of publications for which the compound is of direct interest to the authors. Such a substantial number of publications studying or using DFP demonstrates that it is a compound that has produced a high interest in research activities.

There are several reasons to justify why DFP has been extensively used:

1. It was one of the first synthesized anticholinesterase OPs. On the basis of the ideas of a report by Lange (1930), a preparation of DFP in excellent yield was described by Saunders and Stacey in Cambridge, United Kingdom, in 1948. A US patent was filed in 1949 and proposed that DFP should be used as a chemical warfare agent. It had been previously synthesized by Schrader et al. (1937) and a patent was filed in 1938, but it was not published until 1951.
2. DFP is commercially available through suppliers of laboratory chemical reagents.
3. Radiolabeled DFP with ^{3}H or ^{32}P radioisotopes are commercially available.
4. Other fluorophosphates were synthesized and produced as chemical warfare agents (sarin and soman). However, DFP is less toxic than the G-series nerve agents and, therefore, easier to handle. DFP has been extensively used as a model compound for understanding the toxicity, mechanisms, and therapeutic strategy of the other fluoride-containing OPs.
5. DFP is able to bind to many proteins with serine, tyrosine, and other residues; therefore, it is an inhibitor of proteases and other esterases different from cholinesterases. This capacity has triggered interest in using it for toxicological, pharmacological, and biomedical research. As a consequence, DFP is accessible and has been used in several fields as follows:
   a. Inhibition of cholinesterases *in vitro* and *in vivo* for studying kinetic and molecular mechanism of inhibition and interaction of OPs.
   b. Model compound for anticholinesterase toxicity of OP and, in particular, of chemical warfare agents.
   c. Model compound of study of neurotoxicity and pharmacological studies related to cholinesterase inhibition.
   d. Model compound for development and mechanistic studies of reactivators (oximes and

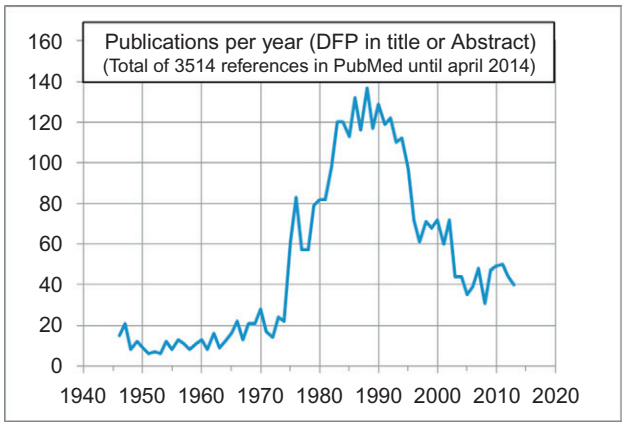

FIGURE 57.1 Statistic of publication referred to in PubMed containing DFP synonyms in the title or abstract. Data until 2013. Indicated publications per year.

others) for therapy and prophylaxis against intoxications of OPs.

e. As a tool in studies of the role of proteases in biological processes as an irreversible serine-protease inhibitor.

f. In studies related to several biological processes when esterases or other DFP-binding proteins were thought to be involved (i.e., coagulation and thrombin and prothrombin inhibition, role of lysozymes in some cardiovascular process, skin sensitization processes, neurodevelopment, neurobehavioral alterations, and others).

g. In ophthalmological studies related to glaucoma and other vision-related pathological conditions.

h. Use for labeling in study and clinical diagnosis of the turnover and life span of some human cells, such as erythrocytes, platelets, and leucocytes–granulocytes.

i. In the detection of the target of the organophosphorus-induced delayed neuropathy (OPIDN) and the so-called neuropathy target esterase (NTE), and in the understanding of the molecular mechanism of induction, including the role of the so-called aging reaction.

j. Detection of phosphorylable sites in proteins and binding to protein in serine or in tyrosine residues on esterases, proteases, and other proteins.

k. Other biological and biotechnological applications.

In brief, there are many studies in which DFP is used as a model OP compound of toxicity caused by binding to esterases (cholinesterases, NTE, others), as a tool for understanding some biological and toxicological processes, and for developing and studying therapeutic drugs and therapeutic strategies. Some of these aspects are further discussed in the next sections.

PHYSICO-CHEMICAL PROPERTIES AND CHEMICAL IDENTIFICATION OF DFP

Chemical Structure and Analogy with Other Nerve Agents

DFP is a O,O′-dialkylfluorophosphate (CAS #55-91-4) synthesized in the 1930s by procedures patented for insecticides, mold control, warfare agents, and fluorine compounds for dental protection. However, it has not been used as a warfare agent.

DFP has other names (Table 57.1), although it is most commonly called diisopropylfluorophosphate or diisopropylphosphorofluoridate, but it is also referred to as isofluorophate in some databases. It contains the oxon group (P═O) of the oxophosphates and therefore does not need a toxic activating reaction like that needed by the thiophosphates (P═S).

The two organic substitutions with isopropyl groups are bonded to the phosphorus atom through an oxygen atom (alkoxy groups), which is a third substitution of the acidic group fluorine (F), the most labile group against possible reactions of nucleophilic substitution and is considered the "leaving group" or "X-group (Figure 57.2). Therefore, DFP may be considered as F-containing oxo-organophosphate, with the expression of "phosphate" indicating the two O-substitution through oxygen atoms.

Other well-known G-nerve agents contain fluor (i.e., sarin, soman, and cyclosarin), whereas tabun contains —CN as a leaving group (Table 57.2, Figure 57.3). However, sarin and soman have one substitution by a P—O—bond, and another has a P═C bond, so they are usually named phosphonates. Phosphoroamidate compounds have also been synthesized with a non-substituted amido group (P-NH_2, i.e., methamidophos) or monosubstituted (P-NH-R) or di-substituted (P-N-(R_1,R_2)) groups. An example is mipafox (*N*,*N*′ diisopropylphosphorodiamidoflouridate) (Table 57.2).

Mipafox was developed for insecticidal use but was withdrawn for that application because of its potential for causing delayed neuropathy. It is currently used as a selective inhibitor of NTE. DFP has a common property with mipafox for inducing delayed neuropathy.

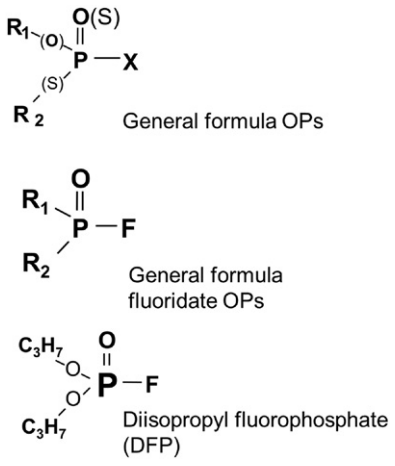

FIGURE 57.2 General structure of organophosphorus compounds and fluorophosphates. R is an alkyl or aryl group. X is the so-called leaving group.

Physico-Chemical Properties

Table 57.2 shows some basic physico-chemical properties of DFP, some nerve agents, and mipafox. DFP is a liquid (m.p. = 82°C) with a clear or slightly yellow color. It was described that dialkyl fluorophosphates produce a pleasant odor by a researcher who inhaled fumes in the process of synthesis and became intoxicated after a few minutes. Melting and boiling points are in the same range as for other nerve agents. The vapor pressure is 0.570 mmHg, which is higher than tabun but lower than sarin. We can use vapor pressure as a criterion of the facility of inhalation exposure when handling the pure liquid compound in the laboratory. It is low when compared with other liquids such as water (25 mmHg) or organic solvents (i.e., 28 mmHg toluene, 151 mmHg *n*-hexane). Therefore, handling small amounts in the laboratory for experimental studies is viable if the appropriate protective measures are used.

HISTORY OF DFP SYNTHESIS AND ITS RELATIONSHIP WITH DEVELOPMENT OF WARFARE NERVE AGENTS

DFP is used in research for understanding mechanisms of toxicity, and for therapy and prophylaxis of chemical warfare OP agents, because of its relatively low toxicity as compared with G-series nerve agents tabun (GA), sarin (GB), soman (GD), or cyclosarin (GF).

A history of monofluorophosphates has been reported by Peter Meiers (Meiers, 2014). Inorganic fluorophosphates (sodium monofluorophosphate) and organic aryl or alkyl substitutes were researched, and patents of methods of synthesis for substances intended for insecticides, warfare chemicals, and fluorophosphoric acid were filed. They are also associated with fluorine compounds for dental protection.

Willy Lange described the synthesis of some fluorophosphates, such as difluorophosphoric acid, and patented the synthesis of aryl fluorosulfonates and proposed their use as insecticides (Lange, 1930). In 1932, Gerda von Krueher, one of Lange's students, was involved in fluorophosphates research for the laboratory work performed for her PhD thesis. By heating silver monofluorophosphate with methyl or ethyl iodide, she prepared

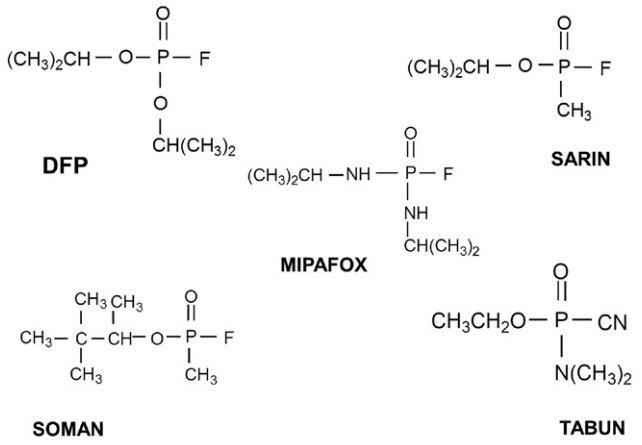

FIGURE 57.3 DFP structure and fluoro and ciano organophosphate analogues.

dialkyl monofluorophosphates. She described that initially the fumes had a pleasant odor but within a few minutes she and her colleagues began to suffer pressure in the larynx, difficulty in breathing, disturbances of consciousness, blurred vision, and painful sensitivity to light. After several hours, these symptoms resolved. Von Krueher described that the effects were not due to the acidic effects but rather from the small amount of esters. Other homologues were prepared as di-*n*-propyl and di-*n*-butyl esters. Lange considered that these compounds might be useful for pest control and offered them to I. G. Farbenindustrie, but the company had no interest at that time. Later, in 1935 at I. G. Farbenindustrie, Gerhard Schrader, Han Kükenthal, and Otto Bayer (Director of Research at Farben) patented alkylsulfonates as insecticides (Schrader et al., 1935), claiming that they were more effective than the aryl analogues proposed by Lange in 1930. They also patented dialkylaminophosphorofluorides for insecticide applications (Schrader and Bayer, 1935).

In 1937, Schrader and Kükenthal prepared several compounds and tested them for insecticidal activity. They observed that the most effective were the di-esters with an acidic group such as Cl, F, SCN, VNO, and others (Schrader et al., 1937). The highly toxic compound in the CN group with an *O*-ethyl and an *N*-dimethyl substitution was developed and is now known as tabun. Schrader also described other methods to synthesize esters of fluorophosphoric acid that were more effective than those described by Lange and Krueger, and synthesized other homologues, among them DFP. A patent was filed in 1938, but it was kept secret and not published until 1951. This patent does not refer to sarin and sarin-type compounds.

Bernard Charles Saunders (University of Cambridge, United Kingdom), considering the earlier 1932 report of Lange, prepared several new monofluorophosphoric esters and tested them for possible use as warfare agents. They were reported to the government in 1941 (Saunders, 1957), and a patent for synthesis of esters of fluorophosphoric acid was filed in 1943 (McCombie et al., 1944). The method was based on treatment of the corresponding chloro compound with a metallic fluoride such as NaF.

Willy Lange, who emigrated to the United States, worked for Procter and Gamble and at the University of Cincinnati. He performed work supported by Ozark Chemical Company. In 1943, he filed a patent for preparing anhydrous monofluorophosphoric acid and claimed that it would be used for synthesis of ester for use as insecticides (Lange and Livingston, 1943). Another related patent was registered in 1944 that also claimed the application would react with the alcohol for preparing the corresponding dialkyl esters (Lange, 1946).

In 1944, Hardy and Kosolapoff from the Monsanto Chemical Company patented the production of dialkylfluorophosphates as DFP by a procedure based on the reaction of alcohol with PCl_3 given dialkylphosphite, then chlorinating and finally fluorinating with NaF (Hardy and Kosolapoff, 1944).

In 1947, Lange and Livingstone (Monsanto) published a series of reports about fluorophoshoric acids and their derivatives (Lange and Livingston, 1947). They reported, "It has recently been shown that the esters of monofluorophosphoric acid, H_2PO_3F, which were previously known to be highly toxic, have a probable usefulness in the treatment of glaucoma and myasthenia gravis, the diisopropyl ester being especially suited for this purpose. Unpublished observations by the senior author also showed that the esters possess insecticidal properties and may act as fumigants" (Lang and Livingston, 1947).

In 1948, a preparation of DFP was described by Saunders and Stacey of Cambridge, United Kingdom (Saunders and Stacey, 1948), and a US patent was filed (McCombie et al., 1949). In 1949, another patent was filed for production of mono and dialkyl fluorophosphates. These were produced by treating alkyl polyphosphates with HF and were called dialkoxy phosphoryl monofluoride (Lange, 1949). The monoesters were purported to have low toxicity in mammals but showed fungicidal properties. For that time period in the open literature, preparation of DFP by other complicated methods has been reported, as well as studies of its effects on the nervous systems and as a potential treatment of human diseases. Further efforts regarding the application of fluorophosphoric acid and its salts were focused on the prevention of dental disease (i.e., as an additive in toothpaste).

DFP was synthesized by B. C. Saunders when he was looking for warfare agents, and it was called PF-3. It appears that he based his research on the previous study by Willy Lange and his PhD student Gerda von Krueger, who synthesized the series of mono-*o*-alkyl flourophosphoric acid with C1, C2, C3, and C4 alkyl groups. However, it was less effective than the G-series agents (sarin, tabun, soman).

DFP may be synthesized by reactions similar to that used for other OPs, for example, by causing the alcohol (isopropyl alcohol) to react with phosphorus trichloride (PCl_3) to form diisopropryl phosphite. Chlorinated and chlorine-substituted fluorine were patented by Hardy and Kosoloapoff (1944). Therefore, the process of synthesizing DFP is closely related to the development of the synthesis of organophosphates for nerve agents, insecticides, and other fluorine compounds for dental applications.

DFP has been commercially available since the 1970s from chemical suppliers, such as Sigma. Radiolabeled as [^{3}H]DFP and as [^{32}P]DFP, it has been used for labeling proteins and for toxicokinetic studies. Therefore, it has been available and used either for understanding its toxicity or for use as a tool for toxicological or pharmacological research activities.

TOXICOKINETIC AND BIOTRANSFORMATION OF DFP AND STUDIES ON DFPASE

Absorption, Distribution, and Toxicokinetic Studies

Radiolabeled [^{3}H]DFP has been used for studying its absorption and biodisposition by inhalation in the guinea pig (Scimeca and Martin, 1988) and mice (Scimeca et al., 1985), and by intravenous administration in mice (Martin, 1985). Skin penetration has been studied in pigs and humans *in vitro* (Vallet et al., 2007).

Distribution after Inhalation Exposure

The tissue disposition of radiolabeled [^{3}H]DFP and its metabolites was studied in guinea pigs after inhalation exposure from 5 min to 24 h after treatment (Scimeca and Martin, 1988). [^{3}H]DFP was rapidly distributed in all tissues. The product of hydrolysis, metabolite diisopropryl phosphate (DIP), was covalently bound to the tissue biphasic curve, with an initial phase representing a very rapid decrease in tissue concentrations, followed by a slower phase of tissue clearance for bound [^{3}H]DFP and free [^{3}H]DIP.

After 4 h, the higher proportion of radioactivity in all the tissues was in the form of bound [^{3}H]DIP. Bound [^{3}H]DIP levels did not follow a biphasic clearance curve and declined at a slower rate than [^{3}H]DFP and free [^{3}H]DIP tissue levels. By 5 min, the greatest accumulation of bound [^{3}H]DIP occurred in the liver (nearly 20% of the total body burden), with a noticeably small amount in the brain (0.1%). Total cholinesterase activity in the brain and red blood cells was inhibited by approximately 90%, with plasma pseudo cholinesterase activity and true cholinesterase activity inhibited by 99% and 97%, respectively.

Distribution After Intravenous Administration

Intravenous administration of [^{3}H]-DFP was studied in mice, and the disposition of [^{3}H]DFP in selected tissues

and cholinesterase activity and recovery were studied (Martin, 1985). After 1 min, [^{3}H]DFP had penetrated tissues and was irreversibly bound. The tissue concentrations decreased quickly and after 2 h all concentrations were less than 50 pg/mg tissue. Most radioactivity was bound to tissue as [^{3}H]DIP but decreased with time in all tissues except liver, kidneys, and fat, which reached a maximum 30 min before declining. Only in liver and kidney did appreciable quantities of [^{3}H]DIP remain after 3 days.

[^{3}H]DFP was rapidly hydrolyzed to free [^{3}H]DIP, which was found in all tissues within 1 min of [^{3}H]DFP administration. [^{3}H]DIP concentrations were equivalent to or exceeded those of [^{3}H]DFP in all tissues except brain.

Cholinesterase inhibition in plasma, diaphragm, and brain after DFP treatment (1 mg/kg, intravenous) was temporarily correlated with the concentrations of bound [^{3}H]DIP in these same tissues between 1 h and 3 days. Cholinesterase inhibition in brain and diaphragm did not correlate well with bound [^{3}H]DIP, suggesting binding to sites different from cholinesterase.

DFP treatment (1 mg/kg) induced motor hypoactivity up to 6 h after intravenous administration with a time course that did not correlate with free [^{3}H]DFP, bound [^{3}H]DIP concentrations in the brain, or with cholinesterase inhibition in the brain, which suggested that another noncholinesterase interaction was responsible.

Other older studies have been reported regarding the distribution in oxygenated blood and atrial tissue (Schuh, 1970), excretion in cats (Hansen et al., 1968a), and distribution and metabolism in the guinea pig (Hansen et al., 1968b).

In summary, DFP is rapidly distributed, bound to tissues in the form of the bound diisopropryl phosphoryl group to proteins, released as metabolite (DIP), and finally excreted, mainly in the urine. There is evidence that a high proportion of binding is to other sites different from cholinesterases. Moreover, the time course of CNS effects suggests that other noncholinesterase interactions are involved in DFP neurotoxicity.

Skin Penetration

Percutaneous penetration of [^{3}H]DFP was tested *in vitro* with human and pig skin. In the test using full skin, the absorbed dose 24 h after depot was 15.6 ± 1% in pig skin and 9.4 ± 1.5% in human skin, with a ratio of 1.7 pig:human. The penetration rates between 0.5 and 4 h were 3.22% and 1.63% dose per hour, with a ratio of 1.7 for pig:human skin. Similar behavior was observed using split-thickness skin.

The radioactivity quantified in the receptor fluid corresponds not only to intact DFP, but also to its metabolites, both tritiated. In preliminary findings, it was also found that at 24 h after exposure more than 99% of DFP reaching the receptor fluid was hydrolyzed into the skin. It was not clear if this was attributable to degradation by phosphotriesterases, by binding and dephosphorylation to proteins/esterases, or by spontaneous degradation.

Physiologically Based Pharmacokinetic/ Pharmacodynamic Studies

Two studies with physiologically based pharmacokinetic (PBPK) and pharmacodynamic (PD) models have been reported (Gearhart et al., 1990; Chen et al., 2009). Gearhart et al. (1990) developed a model for mammals in which the following factors were considered: DFP tissue/blood partition coefficients; rates of DFP hydrolysis by esterases; and DFP-esterase bimolecular inhibition rate constants determined in rat tissue homogenates. Other model parameters were scaled for rats and mice using standard allometric relationships. These DFP-specific parameter values were used to simulate *in vivo* pharmacokinetic data from mice and rats. DFP concentrations in mouse plasma and brain were successfully simulated as compared with data of single intravenous injection reported by Martin (1985) as well as AChE inhibition and its reactivation. Effects of repeated subcutaneous DFP dosing on AChE activity in rat plasma and brain (Michalek et al., 1982; Traina and Serpietri, 1984) were also well-simulated, but the return of brain AChE activity to basal levels after cessation of repeated dosing was not well-described. The model returned brain AChE activity to the original level, but in laboratory studies brain AChE never returned to basal levels, even after 35 days. These data suggest modulation of AChE synthesis with prolonged DFP exposure. This study demonstrated the possibility of using a model based on mammalian physiology and biochemistry to simulate *in vivo* data regarding DFP pharmacokinetics and AChE inhibition. Scaling of the model between rats and mice was also successful.

Another study developed a model using mice and rats (Chen et al., 2009) with the following steps. First, the influence of the variability of the rate constants for synthesis [*K*(syn)] and degradation [*K*(deg)] of AChE, and regeneration [*K*(reg)] and aging [*K*(age)] of inhibited AChE on the variability of AChE activity in venous blood and brain was calculated by a global sensitivity analysis. Second, the mouse PBPK/PD model was calibrated by optimizing the values of *K*(syn), *K*(deg), *K*(reg), and *K*(age). Third, scale-up of the D FP-induced AChE activity was performed from mouse to rat. Validation of the rat model was performed by comparing the time course of venous blood and brain AChE activities from a Monte Carlo analysis with those obtained *in vivo*. Sensitivity analysis of the verified models showed that *K*(reg) and *K*(syn) were the most influential factors of AChE activity in shorter and longer durations, respectively, after

DFP challenge. Finally, scale-up of the AChE dynamics from mouse to rat was successfully evidenced by significant overlapping between the predicted 95th percentile confidence intervals and the experimental data. These approaches hold promise for predictive simulation of organophosphate-mediated AChE inhibition in humans.

Biotransformation of DFP

DFP is a phosphoric triester; consequently, it is not subjected to bioactivation through desulfuration, as in the case of thiophosphates such as chlorpyrifos, malathion, and other OP compounds used as insecticides. DFP can be enzymatically hydrolyzed by the enzymes called phosphotriesterases or phosphoric triester hydrolases according to the nomenclature of the International Union of Biochemistry and Molecular Biology (Table 57.3). The hydrolysis of DFP releases the fluoride ion and the acidic moiety of DFP, the DIP. This hydrolysis must be considered a detoxication reaction (Sogorb and Vilanova, 2010).

There are two types of phosphotriesterases, the aryldialkylphosphatase (EC 3.1.8.1) and the diisopropylfluorophosphatase (EC 3.1.8.2). The group EC 3.1.8.1 includes paraoxonases, whereas the group EC 3.1.8.2 includes the enzymes dialkylfluorophosphatases (also known as DFPases) (Table 57.3). The enzymes belonging to both families are metal-dependent (calcium in the case of paraoxonases and magnesium in the case of DFPases) and are inhibited by chelating agents (Vilanova and Sogorb, 1999). All these enzymes also contain active centers with discrete binding pockets to accommodate the three ester moieties (Bigley and Raushel, 2013). Although there are mechanistic differences among different phosphotriesterases, in all cases the divalent metal is needed for activation of phosphoryl oxygen that is further attacked by a hydroxide group causing hydrolysis and the release of the leaving group (fluoride in the case of DFP) (Bigley and Raushel, 2013).

Paraoxonases are expressed mainly in mammals, display a broad range of substrate specificity, and are able to hydrolyze P–F bonds. Consequently, they may also hydrolyze DFP and other analogous warfare agents. DFPases are enzymes with a specific capability to break the P–F bonds and have higher efficacy than paraoxonases for the hydrolysis of DFP and related compounds. However, DFPases are not expressed in mammals. The usual biological source for studying DFPases is the squid (*Loligo vulgaris*) (Hartleib and Rüterjans, 2001; Scharff et al., 2001; Katsemi et al., 2005; Wymore et al., 2014).

DFPases are highly specific for hydrolysis of P–F bonds in DFP. These enzymes can enhance the hydrolysis of DFP and analogous warfare agents. As a result, these enzymes can be used either for the deactivation of chemical warfare agents or as prophylactic and therapeutic agents against exposures to these chemicals (Sogorb et al., 2004a). However, because DFPases are not expressed in humans, the hydrolysis of DFP by paraoxonases, despite the low specificity, is the only defense against this compound in mammals based on enzymatic hydrolysis. This book contains other chapters dealing with phosphotriesterases (both DFPases and paraoxonases) and readers are referred to those chapters for more detailed information.

- 3.1.7 Diphosphoric monoester hydrolases
- 3.1.8 Phosphoric triester hydrolases (PHOSPHOTRIESTERASES)
  - EC 3.1.8.1 aryldialkylphosphatase
  - *EC 3.1.8.2 diisopropyl-fluorophosphatase (DFPase)*

EC 3.1.8.2. *DIISOPROPYL-FLUOROPHOSPHATASE* (DFPASE)

Reaction: Diisopropyl fluorophosphate + H_2O = diisopropyl phosphate + fluoride

Other name(s): DFPase; tabunase; somanase; organophosphorus acid anhydrolase; organophosphate acid anhydrase; OPA anhydrase; diisopropylphosphofluoridase; dialkylfluorophosphatase; diisopropyl phosphorofluoridate hydrolase; isopropylphosphorofluoridase; diisopropylfluorophosphonate dehalogenase

Systematic name: Diisopropyl-fluorophosphate fluorohydrolase

Comments: Acts on phosphorus anhydride bonds (such as phosphorus-halide and phosphorus-cyanide) in organophosphorus compounds (including "nerve gases"). Inhibited by chelating agents; requires divalent cations. Related to *EC 3.1.8.1* aryldialkylphosphatase. Previously listed as EC 3.8.2.1.

Detoxication of DFP via Protein Binding

In the distribution studies described, it was observed that after administration of radiolabeled DFP, most radioactivity is bound DIP and after it is released it is free DIP.

It is then excreted mainly via urine. This suggests that, in mammals, binding to protein by phosphorylation is a main mechanism of withdrawal and detoxication. The mechanism involved in binding to proteins also explains the mechanism involved in toxicity. In the next chapter, examples of binding to protein are described either as detoxicating mechanisms (i.e., binding to albumin) or as binding to the target esterases causing toxicological consequences (i.e., acetylcholinesterase (AChE) and NTE).

Role of Albumin in the Detoxication of DFP

Albumins exhibit esterase-like activities for carboxylesters, as reported years ago (Tildon and Ogilvie, 1972; Means and Bender, 1975; Kokubo et al., 1982). These esterase activities are based in the reversible acylation of a tyrosine residue of the sequence Arg-Tyr-Thr-Arg (position 410 in bovine serum albumin and 411 in human serum albumin) (Peters, 1996a). However, it has also been suggested that this activity, at least in human serum albumin, is the result of the irreversible acetylation of 82 different amino acid residues rather than reversible acylations (Lockridge et al., 2008).

Serum albumin also displays other esterase activities against carbamates, such as carbaryl (Sogorb et al., 2004b, 2007), based on the Tyr-411 residue as the main target of the active center. The Tyr has also been proposed as a target of phosphorylation of OP compounds, such as phosphoramidates (Sogorb et al., 1998), azamethaphos, chlorfenvinphos, chlorpyrifos–oxon, diazoxon, dichlorvos, malaoxon, pirimiphos-methyl (Carter et al., 2007; Tarhoni et al., 2008), and paraoxon (Sogorb et al., 2008). Of course, it is necessary to add DFP to this list. It has been demonstrated that 1 h of *in vitro* exposure of rat and human serum albumin to 19 μM DFP causes the binding of 0.011 or 0.039 mol of DFP/mol of albumin, respectively (Tarhoni et al., 2008). In addition, this binding is prevented by exposure to most of these OP compounds (Carter et al., 2007; Tarhoni et al., 2008), which suggests that DFP and others are in competition for the same amino acid residue. Other analogous structures to DFP, such as soman, sarin, cyclosarin, and tabun, have been shown to bind to albumin via phosphorylation (Williams et al., 2007; Li et al., 2008; Read et al., 2010).

Mass spectrometry assays have allowed us to confirm the target amino acid for binding of DFP and analogous nerve agents, as well as other OP compounds such as Tyrosine-411 (Li et al., 2007, 2008). However, other target amino acids for phosphorylation of albumin have also been suggested, specifically four additional Tyr, two Ser (Ding et al., 2008), and several Lys (Grigoryan et al., 2009).

The binding of DFP to albumin, despite the fact that it can be considered an enzymatic reaction or a scavenging process with an undetermined number of target amino acids, causes the release of the fluoride ion and generates an adduct between albumin and the diisopropyl moiety. The immediate consequence is that a molecule of DFP is removed from the media and cannot reach the nervous system, where it would cause inhibition of esterases, thereby triggering the neurotoxic effects. Thus, this binding is a detoxication mechanism.

The detoxication of DFP through binding to albumin might seem irrelevant because of its low efficacy in comparison with the detoxication capability of DFPase and paraoxonase. However, the efficacy of this process is based on the high concentration of albumin circulating in the blood (40 mg/mL or 600 μM) (Peters, 1996b) that is higher than the systemic DFP concentrations compatible with the survival of the individual, but not in high turnover of the phosphorylated albumin residues. The binding of paraoxon to albumin has proven to be responsible for the detoxication of physiologically relevant paraoxon concentrations in mammals (Sogorb et al., 2008).

All these considerations allow us to predict that the binding of DFP to albumin, in addition to forming adducts with the capability to act as a biomarker of exposure, might play a relevant role in the detoxication of DFP, especially considering that paraoxonases are not very efficient in the hydrolysis of OPs with the fluoride leaving group. DFPases are not expressed in mammals and paraoxonases exhibit a double genetic polymorphism in certain individuals who are more susceptible because they express low amounts of paraoxonase with very low specific activity.

ACUTE TOXICITY OF DFP AND INTERACTION WITH ACHE

Soon after DFP was discovered, it was demonstrated that it had the capacity of inhibiting AChE irreversibly. One of the earliest published reports of a systematic study of the inhibitory properties of DFP was that of Koelle and Gilman (1946). *In vitro* log pI_{50} was reported to be 6.5 for serum BuChE and 4.2, 4.5, 4.8 for AChE from rat erythrocyte, brain, and muscle, respectively, with similar values in dogs. *In vivo* studies after intramuscular injection in rats, dogs, and monkeys were performed and inhibition, toxic effects and AChE regenerations were evaluated. Levels in the range of 0.05–1 mg/kg showed significant inhibition of serum ChE and doses of 1–5 mg/kg caused a total inhibition of erythrocyte cholinesterase. Human exposure to a dose of 0.5–2 mg/60 kg caused marked inhibition of serum BuChE, without any inhibition of erythrocyte AChE and/or toxic symptoms.

Other studies of administration of DFP to humans in the range of 0.07–0.5 mg/kg were reported (Table 57.4) with moderate ChE inhibition and some moderate alterations (Grob and Lilienthal, 1947).

TABLE 57.4 The Effect of DFP (4.0 mg/kg) and Sarin (0.3 mg/kg) on Cholinesterases and CaE activities. Atropine Sulfate (37.5 mg/kg) Administered Subcutaneously Immediately After the Organophosphate

2825.6 + 276.0*			

Source: Data obtained from Tuovinen et al. (1997).
Means ± SD are given (n=5–7); *P<0.05 compared to male mice.

Since then, a number of studies have shown AChE inhibition, including gender difference (Table 57.4) (Tuovinen et al., 1997) and effects on the different AChE forms in mice, rats, and chickens (Cisson et al., 1981; Michalek et al., 1981; Sung and Ruff, 1987).

Several routes of acute exposure have been tested, including oral, intramuscular, subcutaneous, intravenous, and intraperitoneal. LD_{50} doses are expressed in terms of mg/kg body weight and are shown in Table 57.5.

The main observed affects are those expected from cholinesterase inhibition:

- Respiratory stimulation, cyanosis, and dyspnea
- Gastrointestinal tract hypermotility, diarrhea, and hypersalivation
- Behavioral changes, such as tremors, convulsions, seizures, coma, muscle weakness, alterations in sleep time, and righting reflex
- Alterations in peripheral nerves with neuromuscular blockage and flaccid paralysis and ataxia
- Fasciculations
- Tremors

There is very little reported information regarding accidental acute toxicity in humans. It has been noted that intramuscular and oral doses in the range

DFP	9.5	400	300	250	1.80	6.0

Source: From Grob and Harvey (1957).
ChE was measured using acetylcholine as substrate. Based on the method used in brain and muscle, it cannot discriminate BuChE activity from AChE, as no specific inhibitors were used. It is indicated the I_{50} (nM) for 45 min of preincubation with the inhibitor.

of 0.07–0.1 mg/kg body weight can produce a 50% decrease of erythrocyte cholinesterase and moderate clinical symptoms (Grob and Harvey, 1957) (Table 57.6).

The acute toxicity of DFP can be well-correlated with a rapid and high degree of AChE inhibition. Table 57.7 shows the I_{50} for 45 min as reported for human cholinesterases for DFP in comparison with other nerve agents. There is a correlation between AChE inhibition and acute toxicity.

Other data regarding I_{50} for chicken brain AChE are shown in the section about delayed neuropathy (later in this chapter).

DFP IN STUDIES ON NEUROTOXICITY AND THERAPY WITH REACTIVATORS

Neuropharmacological Studies of Cholinergic System

DFP is used in studies of neurotoxicity and neuropharmacology. In most studies, DFP is used as a model compound causing depression of cholinesterase activity and an increased level of acetylcholine (ACh). They include examples of studies of rats surviving status epilepticus induced by DFP (Deshpande et al., 2010), a comparison of strain rats in their susceptibility to neurotoxicity (Gordon and MacPhail, 1993), age-related differences in rate recovery of cholinesterase and receptors (Michalek et al., 1990), inhibition of the motor system (Chemnitius et al., 1989), and alterations in energy homeostasis in skeletal muscles (Gupta et al., 1986) and brain (Gupta et al., 2001a,b).

Pharmacological effects and interactions have been a matter of many publications in which DFP is used for inducing cholinergic effects and the modulation, agonist, or antagonist, of drugs. Examples include: alteration of cannabinoid signaling and its relationship with cholinergic toxicity (Nallapaneni et al., 2008); role of opioid receptors in development of tolerance to DFP toxicity (Tien et al., 2005); preventive effect of galantamine (Saghafi et al., 2013); alteration in the patterns of GFAP upregulation (Liu et al., 2012); alteration of the muscarinic receptor density and its regional adaptation (Yamada et al., 1983a,b); and genetic and sex differences in the development of tolerance (Russell et al., 1983). The alteration of electrophysiology, nerve conduction, and action potential has been described since the early toxicological studies with DFP (Couteaux et al., 1946; Toman et al., 1947), for which the use of the squid giant axon is a frequent model (Hoskin and Prusch, 1983).

Neurobehavior and Neurodevelopment

DFP has been used as a model compound for studying neurobehavioral alterations related to the increased cholinergic effects caused by AChE inhibition. In some studies these alterations are compared with those caused by other OPs and are also related to oxidative stress (Dettbarn et al., 2006; Milatovic et al., 2006, 2014; Gupta and Milatovic, 2012, 2014; López-Granero et al., 2013).

Chronic persistent alterations in spatial learning and memory have been described after exposure to DFP (Terry et al., 2012).

Long-term changes in behavior, such as anxiety, have been reported in adult mice exposed to DFP during the pre-weanling period (Kofman and Ben-Bashat, 2006). The relationship between behavioral changes and decreased brain cholinesterase activity has been described after intracerebral injections in studies since the 1950s (White, 1956). Since then, many studies have been performed with DFP and other OPs and their neurobehavioral effects. Some of the neurobehavioral studies have been related to effects developing as a result of exposure during the prenatal and neonatal periods (Gupta et al., 1985; Das Gupta et al., 1988; Ahlbom et al., 1995; Bushnell and Moser, 2006; Slotkin, 2006).

The alteration of circadian patterns (Raslear et al., 1986) and the involvement of nitric oxide in mitotoxicity in muscle and brain hyperactivity induced by DFP have been investigated (Gupta et al., 2001a,b, 2002; Zaja-Milatovic et al., 2009).

Therapy Against Anticholinesterase Toxicity

Therapy for cholinergic symptoms continues to be a topic of interest for many researchers. DFP has been used extensively as a model compound for inducing cholinesterase inhibition as well as other nervous system proteins. Studies about kinetic mechanisms of action with oximes and other therapies continue to be an issue of current research. In experimental studies, some of the compounds tested against DFP include bipyridinum oximes (Theirmann et al., 2009), tubocuarine (Barstad, 1956), meptazinol (Galli and Mazri, 1988), 2-PAM (Tuovinen et al., 1996), and quaternary ammonium compounds (Funke et al., 1955).

DFP in Other Biological Studies

During the 1950s and 1960s, DFP (isofluorate) was used in ophthalmological studies, including studies of esotropia. Its potential therapeutic application in glaucoma and myasthenia gravis was described in 1947 (Quilliam, 1947), and other studies were later published in relation to ocular pressure (Zekman and Snydacker, 1953) and retinal detachment (Weekers and Lavergne, 1955).

During the 1960s and 1970s, studies of the mechanism of coagulation were performed using DFP as an agent for blocking endogenous thrombin (Baskova et al., 1970). The interaction of DFP with human blood coagulating factors has been studied, including factor VII (Osterud et al., 1979), factor V and factor Va (Bartlett et al., 1978), and the Hageman factor (factor XII) (Becker, 1960).

The interaction of anticholinesterase effects of DFP with cardiovascular and respiratory reflexes and cardiac failure was also the subject of some studies (Heymans and Pannier, 1946; Wolthuis and Meeter, 1968). During the 1970s, a methodology was developed and applied based on labeling proteins with [^{32}P]DFP for studying the turnover, life span, and survival of human blood cells (Matsuda, 1969). These approaches have also been applied for studying the kinetics of platelets (Leeksma, 1963; Ebbe et al., 1966, 1970; Ginsburg and Aster, 1973–1974), the survival of erythrocytes (Hjort and Paputchis, 1960; Cline and Berlin, 1963; Manunta and Cancedda, 1975; Saito and Sakai, 1977; Derelanko, 1987), and the kinetics of granulocytes and neutrophils (Dresch et al., 1971; Vorob'eva, 1976; Nowotny et al., 1978).

INTERACTION OF DFP WITH OTHER ESTERASES

Serine Proteases and Albumin: Role of Tyrosine Residues

Serine proteases are proteins containing a serine residue in their active catalytic center which has a molecular mechanism similar to esterases. Therefore, they are susceptible to phosphorylation by OPs in general and by DFP in particular. This has been the basis for DFP use in biochemical studies for blocking serine containing esterases, and thereby for stabilizing proteins and avoiding proteolysis in tissue homogenates. Moreover, DFP has been used as a tool for specific studies either for understanding the mode of action of proteases or for biological studies for testing the role of proteases in some biological processes. DFP-inhibited chymotrypsin and chymotrypsinogen were studied using P^{31} NMR (Reeck et al., 1977). DFP induced inactivation of bovine trypsinogen and chymotrypsinogen (Morgan et al., 1972). The substilisin serine protease has been analyzed by NMR (Chen et al., 2008). The involvement of DFP-sensitive proteasomes in the control of oocyte maturation has been evaluated (Takahashi et al., 1994). The evidence of the role of tryptophan residue in the interaction of DFP with alpha-chymotrypsin has been reported (Wooton and Hess, 1960). Effects on sulfhydryl proteases have also been demonstrated (Heinicke and Mori, 1959).

Human serum albumin has been demonstrated to show arylacylamidase activity sensitive to DFP (Manoharan and Boopathy, 2006). A tyrosine residue has been characterized as a target of the binding of DFP to albumin (Means and Wu, 1979). Evidence has been reported that the tyrosine residue 411 is responsible for *p*-nitrophenyl acetate catalytic hydrolysis (Tildon and Ogilvie, 1972) and that it has a critical role in detoxication of OPs, such as paraoxon and diazoxon, and carbamates, such as carbaryl (Sogorb et al., 1998, 2004b, 2007, 2008). Therefore, albumin has been suggested as a biomarker of OP nerve agent exposure (Lockridge et al., 2008; Read et al., 2010).

Inhibition of Soluble PVases of Peripheral Nerve by DFP

In the peripheral nerves, soluble carboxylesterases measured with the substrate phenylvalerate (PV) are found to have high sensitivity to DFP. Tissue preparations were preincubated with DFP at nanomolar concentrations (up to 10 nM) for different inhibition times (up to 120 min) (Figure 57.4) and with DFP at nanomolar concentrations (up to 1,000 nM) for 30 min of fixed inhibition time (Figure 57.5). Inhibition data were analyzed with model equations of one, two, and three sensitive

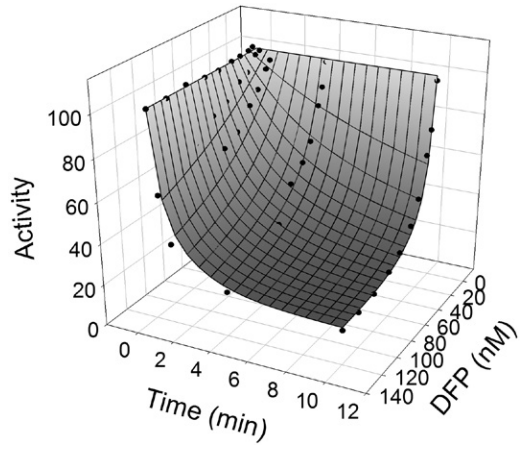

FIGURE 57.4 Kinetic inhibition 3D. Representation of the inhibition kinetics of soluble peripheral nerve PV esterase activity PVases by DFP. Inhibitory surface obtained by fitting the 3D model equation to the data corresponding to DFP inhibition. The surface reflects the result of the best model according to the *F* test. It corresponds to a model with two sensitive enzymatic components plus other resistant components.

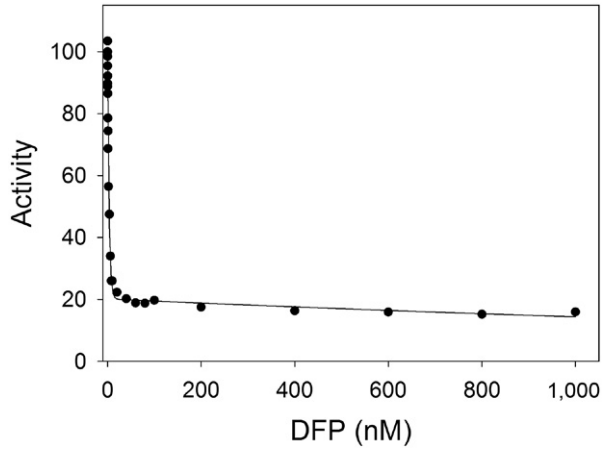

FIGURE 57.5 Fixed time inhibition. DFP 30-min fixed-time inhibition curve of soluble peripheral nerve PV esterase activity (PVase). The curve was fitted to the best model according to the *F* test (two exponential and a resistant component). Each point represents the mean of three replicates (SD <5%).

(exponential) components, with or without resistant components. The best model according to an *F* test in both experiments was a model composed of two sensitive enzymatic components, one resistant to DFP. Approximately 84% of PVase activity was highly sensitive to DFP with I_{50} (30 min) of 0.8–1.2 nM and approximately 16% was resistant (Table 57.8). The number of enzymatic components and proportions are similar to the results obtained in inhibition experiments with mipafox, PMSF, paraoxon, and S9B (Estévez et al., 2004, 2010, 2011, 2012).

DFP, OPIDN and NTE

Phosphorylation Site Identified by Radiolabeled DFP

OPIDN is a neurodegenerative syndrome induced by some but not all OPs (Johnson, 1982). An epidemiological outbreak was first described as a consequence of an adulterated alcoholic drink during Prohibition in the United States (Smith and Elvove, 1930; Smith et al., 1930), and as a consequence of an episode in Morocco in 1959 involving consumption of a lubricant oil (Travers, 1962), for which tri-*o*-cresyl phosphate was identified as the causative agent. It was demonstrated that neither AChE nor BuChE inhibition was involved as a mechanism for inducing this syndrome (Aldridge and Barnes, 1961). Adult hens were demonstrated to be an appropriate animal model for testing this syndrome in a toxicological effect protocol. The search for the target biomolecules triggering the mechanism was approached using radiolabeled [^{32}P]DFP (Johnson, 1969a). Brain tissue treated with [^{32}P]DFP indicated binding of DFP to all sensitive phosphorylable sites in proteins. The fractions of sites that can be protected by a previous incubation with a non-neuropathic OP (TEPP) were considered irrelevant sites. In the remaining sites, the small numbers that can be protected by binding with a neuropathic compound (mipafox) were considered candidates to contain the target of the toxic mechanism. In the total phosphorylable sites (approximately 600 pmol/g fresh tissue), approximately 200 pmol/g was blocked by the non-neuropathic TEPP. The fractions of phosphorylable sites are potential targets for binding with mipafox and were quantified to be approximately 33–39 pmol/g (Johnson, 1969a).

Target Site Identified as an Esterase: NTE

Johnson (1969b, 1970) assumed that phosphorylable sites would be serine-containing proteins. Several carboxylesters were tested to find a selective substrate able to interact in the same site (able to reduce the speed of [^{32}P]DFP labeling on the mipafox binding fraction). Phenyl-phenyl acetate was selected as that substrate. In other studies, PV was observed to be more selective and has been used for decades for testing the target site, the neurotoxic esterase, and was later called the NTE. NTE has been monitored as the PVase activity resistant to 40 µM paraoxon (20 min) ("B" activity) and sensitive to 40 µM paraoxon plus 60–150 µM mipafox ("C" activity), with NTE as the difference between the activity in condition B and condition C.

Protection and Induction of Neuropathy: The Role of the Aging Reaction

Some carbamates or esterase inhibitors, if dosed before DFP, have been described to be able to protect the onset of neuropathy (Johnson and Lauwerys, 1969). A series of

TABLE 57.8 Inhibition by DFP on Esterases Component in Soluble Fraction of Peripheral Nerve

	*E*1 (%)	*k*1 ($nM^{-1}min^{-1}$)	I_{50} (30 min) (nM)	*E*2 (%)	*k*2 ($nM^{-1}min^{-1}$)	I_{50} (30 min) (nM)	*R* (%)
A	38.9	0.0187	1.2	43.3	$4.1 \cdot 10^{-3}$	5.7	17.9
B	40.7	0.0274	0.8	41.7	$5.2 \cdot 10^{-3}$	4.4	17.6

The kinetic constants (ki) and the proportions of obtained esterase components from the different inhibition experiments with DFP. The I_{50} values were calculated from the kinetic constants for each component. (A) Experiment of time-progressive inhibition with different concentrations in a 3D fitting (Fig "Kinetic inhibition 3d"); (B) Experiment of fixed time inhibition with different concentrations (Fig "fixed time inhibition"). The R^2 coefficients were: 0.980 (A); 0.986 (B).

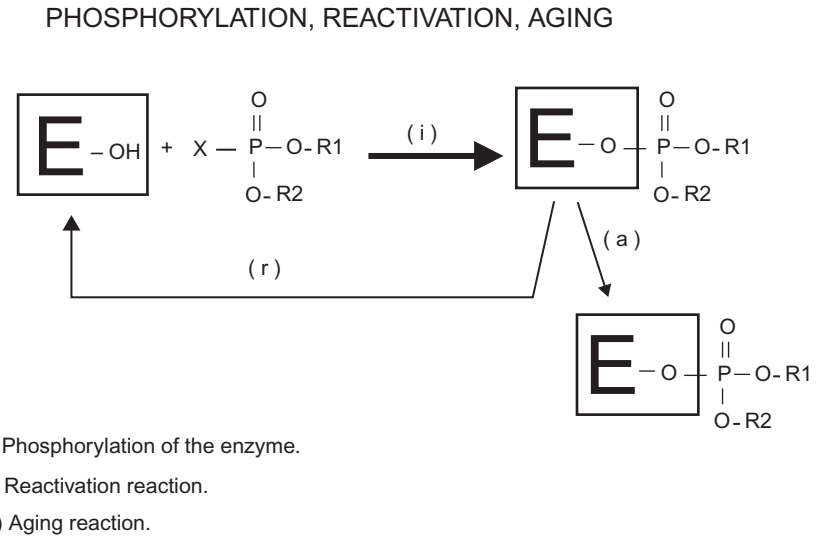

FIGURE 57.6 Reaction of phosphorylation and aging of OPs on esterases. R is an alkyl or aryl group. X is the so-called leaving group.

studies were conducted for understanding the age-related sensitivity, structure activity relationship with many OPs (Johnson, 1975a), motor nerve dysfunction (Lowndes et al., 1974), and protection by carbamates, phosphinates, and sulfonyl fluorides (Johnson, 1975b, 1976).

Although some OPs include neuropathy, phosphinates, carbamates, and sulfonyl fluorides do not; instead, they protect from a further dose of a neuropathic compound. This was hypothesized to be related to the ability of the OP for dealkylating reaction and is called an aging reaction. This was more clearly demonstrated by using radiolabeled DFP (Clothier and Johnson, 1979).

The aging process involves dealkylation of one isopropyl group (Figure 57.6). It was demonstrated by both molecular and enzymatic approaches. The loss of time of the capacity of the inhibited NTE to be reactivated by nucleophilic reagent (fluoride ion) was demonstrated, confirming the aging reaction. In contrast with AChE, the dealkylated isopropyl group in the DFP inhibited NTE remains bound to the other site ("Z") of the protein (Figure 57.7). This group may be released to the medium as isopropyl alcohol by alkaline treatment. This was demonstrated molecularly using DFP labeled with ^{3}H and ^{32}P. The molar ratio (^{3}H-isopropyl)/(^{32}P) is 2:1 in the inhibited enzyme and it is converted to 1:1 in the aged protein, confirming that one of the isopropyl groups has been released.

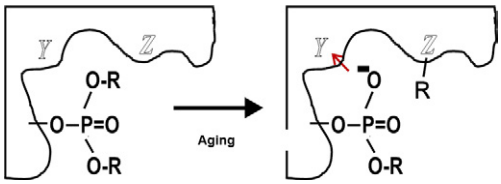

FIGURE 57.7 Aging of the DFP phosphorylated NTE protein. The aging process is a dealkylation reaction. In the case of AChE, the alkyl group is released to the medium as the corresponding alcohol. This represents the case of NTE with DFP in which the isopropyl group remains attached to the protein and is released to the medium only after an alkaline treatment. The nature of the "Z" site remains unknown.

Structure activity relationship and the relationship of the capacity of inducing neuropathy and the capacity of causing the aging reaction have been demonstrated in a wide range of OPs (Johnson, 1982). Therefore, the proposed hypothesis is that blocking the site by itself is not a sufficient requirement, and an additional modification of the function of NTE is needed. The protein alteration after the aging reaction is able to trigger the physiopathological process inducing the neuropathy.

TABLE 57.9 I_{50} on AChE and NTE

	NTE I_{50} (uM)	AChE I_{50} (nM)	AChE/NTE

Source: From Gordon et al. (1983).

This pathological process is involved in a number of molecular events, including alteration of neurofilament phosphorylation by Ca^{2+}/calmodulin-dependent protein kinase, and alteration of microtubules has been reported from the laboratory of Abou-Donia et al. (Gupta and Abou-Donia, 1993, 1999; Gupta et al., 2000). Also, using DFP as a model, c-fos mRNA expression has been reported (Damodaran and Abou-Donia, 2000; Damodaran et al., 2000, 2001; Gupta et al., 2000) as well as glyceraldehyde-3-phosphate dehydrogenase mRNA in the CNS of hens treated with DFP (Damodaran et al., 2002). Early alterations are induced by DFP on the PKA/p-CREB pathway, and differential persistence of beta-tubulin subtypes in the CNS of hens has been proposed to contribute to OPIDN (Damodaran et al., 2009).

Testing Delayed Neuropathy

The capacity of inducing neuropathy means that the compound should be able to induce a high degree of inhibition of NTE and that animals survive the acute cholinergic effect. A standard test has been adapted by the OECD as protocols 418 and 419 (OCDE, 1995a,b) and by regulatory agencies. The method involves dosing of animals with a single $5 \times LD_{50}$ dose or repetitive dose in animals protected with atropine. Animals are observed for 21 days, NTE activity in the nervous system is measured, and the animals are sacrificed 24 h after dosing (Table 57.9).

An *in vitro* approach has also been proposed based on the relative inhibition of AChE and NTE in the hen brain homogenate or in human neuroblastoma cells after testing the aging reaction from the loss of capacity or reactivation with nucleophilic reagent (Sogorb et al., 2010).

Molecular and Genomic Characterization of NTE and its Role in Embryonic Development

The molecular identification of the NTE protein and its genomic identification (encoding gene: PNPL6) was the result of research conducted by Glynn et al. (1993). For this process, proteolysis of [^{3}H]DFP-labeled polypeptide was approached. After isolation and by using a specific biotinylated inhibitor, molecular cloning was possible (Glynn et al., 1994). The protein catalytic domain was isolated and used for some studies, and phospholipase activity was demonstrated and proposed to be involved in its biological function in the neuronal maintenance (Atkins et al., 2002; Glynn, 2005; Mühlig-Versen et al., 2005; Read et al., 2009).

The role of NTE in embryonic development was envisaged in studies with NTE-deficient mice (Moser et al., 2004). The expression of NTE in mouse embryonic stem cells in differentiation (Pamies et al., 2010) and the alteration of pathways during differentiation by silencing the mRNA NTE encoding gene (PNPL6) in mouse and human cells (Pamies et al., 2014a,b), but not the inhibition by a neuropathic compound as mipafox (Pamies et al., 2014b), suggested that its role in embryonic development has no relationship with its enzymatic property or with the same mechanism inducing delayed neuropathy in adults.

In summary, the history of understanding delayed neuropathy, the identification of the target protein, and the molecular events including aging reaction in the mechanism inducing the neurodegenerative syndrome, have been very closely related to the use of DFP as a tool for research studies.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

DFP is a dialkylfluorophosphate synthesized in the 1930s for insecticides, warfare agents, and other applications. Although it has never been used for chemical warfare, it has been extensively used in research as a model compound of an AChE inhibitor and in other toxicological, pharmacological, and biomedical studies because of its lower toxicity compared with G-series nerve agents. DFP is detoxified by hydrolysis by A-esterases as the enzyme DFPase (not present in humans) and by binding to B-type esterases as the tyrosine residue of albumin and the serine residue on cholinesterases. The acute toxicity is caused by inhibition of AChE and delayed neuropathy is related to the initial inhibition of the so-called NTE. DFP is known to bind and inhibit serine proteases and other unidentified esterases. DFP has been used and is still used as a tool for many toxicological and pharmacological applications in which the consequence of protease inhibition or cholinergic effects is needed to study a pharmacological or cell biology process.

INTRODUCTION

Pharmacokinetics (PK) is the quantitative determination of drug or chemical movement (time-course concentration) throughout the body. One of the basic principles of pharmacology and toxicology is that the effect of a drug or chemical is directly related to its concentration at some target site or receptor in the different tissues of the body. This premise is the critical reason and continued justification for the development of improved PK descriptions of chemical warfare agents (CWAs). Mathematical models are applied to this type of data to simplify or reduce the description of the basic chemical–biological processes of absorption, distribution, metabolism, and excretion (ADME). These model types are driven by the basic premise that significant pharmacological or toxicological understandings are gained by knowing the internal drug/chemical concentration at the target site. Most often termed "classical" PK models, they reduce the entire body mass to either one or two mathematical compartments that represent the volume of blood, plasma and/or readily accessible extracellular spaces, and a deep compartment storage representing other tissues. The advantage of this analytical approach is the determination of a simple global description of a chemical's behavior in the body, and potentially the concentration at major target receptor sites. The major disadvantage is that these empirical models are poor at interspecies extrapolation, since the parameters do not have a physiological interpretation, and it is difficult to predict how they change when the underlying physiology changes.

Physiologically based pharmacokinetic (PBPK) models are a special type of PK model that attempts to provide more definition to the model analysis by incorporating physiological factors into the model design, like tissue volumes, blood flow rates, and species-specific enzyme characteristics that can more accurately differentiate the dose–response relationship for a chemical or drug in one species from that of another species. The power of this approach is to be able to perform laboratory studies, both *in vitro* and *in vivo*, in common experimental species to develop a complete PBPK model, and then extrapolate these results to predictions in humans based on *in silico* experimentation.

PBPK models have become useful analytical tools to interpret PK data and to interpret data from complex chemical exposure scenarios. These models are mathematical constructs that allow the coordination of species-specific physiology, chemical-specific information, and the experimental protocol for the chemical(s) of concern. The power of PBPK models lie in aiding the ability of scientists and decision makers to simulate the time-course concentration of chemicals in experimental animals and humans and to better determine estimates of actual chemical doses delivered to the target tissue, thereby providing a better prediction of response. Due to the physiologically based nature of these models, simulations of experimental data can be performed by one exposure route to validate the PBPK model, and then this model can be used to simulate and predict the kinetics and pharmacodynamics (PD) in the human by one or multiple exposure routes. This provides decision makers with a fairly rapid method of comparing results from *in vitro* and *in vivo* laboratory studies, to potentially real-world exposure scenarios. Perhaps the most useful application of these models lies in a strongly animal data-based physiologically based pharmacokinetic-pharmacodynamics (PBPK-PD) model being used

Handbook of Toxicology of Chemical Warfare Agents.

to make predictions about human responses to CWAs, across a broad range of doses and CWA types, in light of not being able to actually conduct human exposure studies.

CWAs are represented by any one of a number of chemicals exhibiting very high toxicity by various mechanisms. This chapter covers CWAs with structures as simple as carbon monoxide (CO) and as complex as botulinum toxin or ricin proteins. While this chapter could address the development of PBPK models of CWAs in general, the focus will primarily be on the organophosphate based nerve agents typically represented by sarin (GB; isopropyl methylfluorophosphonate).

DEVELOPMENT OF PBPK MODELS

Most attempts at describing PK and PD descriptions of CWAs have used classical kinetic models that are often fit to one set of animal experimental data, at lethal doses, with extrapolation to low-dose or repeated-exposure scenarios with limited confidence. This is due to the inherent nonlinearity in high dose to low-dose extrapolations. Also, the classical approach is less adept at addressing multidose and multiroute exposure scenarios, as occurs with agents like *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX), where there is pulmonary absorption of agent as well as dermal absorption. PBPK models of chemical warfare nerve agents (CWNAs) provide an analytical approach to address many of these limitations.

There are only a few PBPK models that have been developed to describe the PK and PD of CWNAs. Maxwell et al. (1988) developed a PD model for soman in the rat describing the inhibition of acetylcholinesterase (AChE) in different tissues, with mass balance equations including parameters for blood flow, tissue volumes, soman metabolism and tissue/plasma partition coefficients. This effort resulted in an accurate prediction of AChE activity in eight different tissues after intramuscular soman dosing and was able to reproduce dose–response inhibition from 10% up to 100% of the brain AChE activity. Gearhart et al. (1990) used diisopropylfluorophosphate (DFP) as a model compound for CWNAs, to develop a PBPK-PD model describing the PK of DFP and the inhibition of AChE and BuChE in all the pertinent tissues of the body (Figure 58.1). This model construct was able to predict the PK of DFP and inhibition of AChE and BuChE after acute and repeated doses by three different routes. Recently, the PBPK-PD model for DFP was reparameterized to predict GB kinetics, inhibition of AChE, and regenerated GB from bound AChE sites on red blood cells (RBCs; Gearhart et al., 2005).

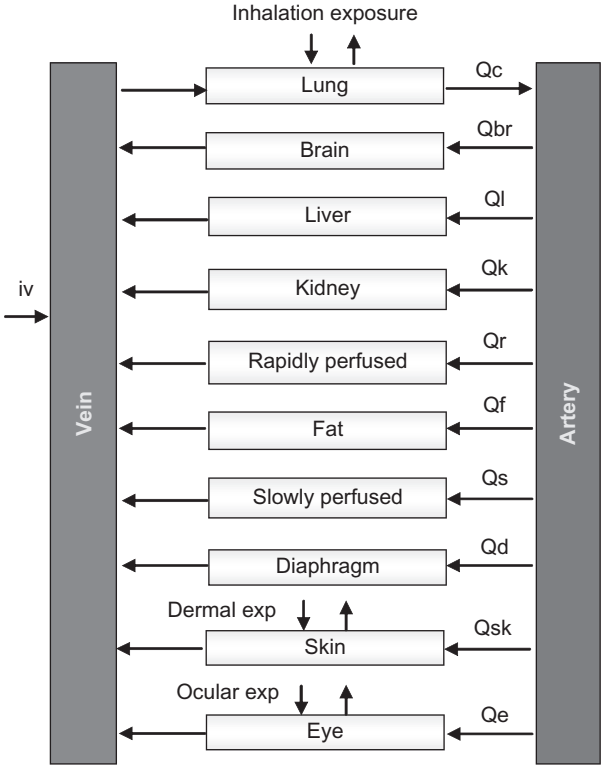

FIGURE 58.1 PBPK-PD model schematic of sarin in the Hartley guinea pig. This model structure allows for the simulation of experimental studies with dosing by IV or SC dosing and IH exposure. This model design was based on Gearhart et al. (1990) and adapted to simulate the PK and PD of sarin in the guinea pig.

The most recently developed PBPK-PD models for CWNAs have continued to focus exclusively on the most potent G agent, soman (GD), due to its rapid aging rate for permanent binding to serine sites on cholinesterase and resultant resistance to therapeutic countermeasures. The main expanded application in these modeling efforts is to multiple species, providing greater confidence in the application of the PBPK-PD method for eventual extrapolation to predictions in the species of concern (namely, humans). Sweeney et al. (2006) augmented the intravenous (IV) exposure model of Langenberg et al. (1997) for GD in guinea pigs, to predict subcutaneous dosing and inhalation exposure, as well as adding the rat and marmoset species. Both of these changes are significant additions, as subcutaneous dosing is the most common experimental method for controlled CWNA challenge to determine efficacy of therapeutic treatments. Inhalation is the primary route of threat exposure for G agents, which tend to readily form vapors, and any of the other CWNAs which, while having very low vapor pressures, still can present an inhalation hazard via aerosol droplets.

Chen and Seng (2012) extended the PBPK model simulation for GD from these previous efforts to include

the pig species, as well as the PD component predicting the inhibition of AChE and carboxylesterase (CarbE) in blood and tissues. One significant area of needed validation from Chen and Seng's model is the assumption that tissue/blood partition coefficients for GD were identical across all species for all tissues, as well as other model parameter assumptions, which could have a critical impact on the broader application to more diverse simulation scenarios (Ruark et al., 2013). For the most significant step of extrapolation to the human species and making predictions about CWNA lethality, few of these parameter values are likely to be available, an area in which Quantitative Structure Activity Relationship (QSAR) analysis can provide a viable impact (Knaak et al., 2004; Ruark et al., 2013).

There are three basic critical components to PBPK models: (i) species-specific physiological parameters, (ii) chemical-specific parameters, and (iii) specific experimental details for the studies to be simulated. Species-specific physiological parameters are the organ weights and blood flow rates for the defined compartments in the PBPK model. These values are most often available in the published literature and when lacking, are derived from the closest like species. Chemical-specific parameters that are unique for each chemical are the tissue solubility (partition coefficient), metabolism of the parent compound, and plasma and tissue-binding characteristics. Tissue solubility is most often measured experimentally for the volatile CWNAs by the vial equilibration method (Gargas, et al., 1989). Existing models for the physiological distribution of CWNAs are based on a limited number of data sets for each agent and typically rely on single exposures at relatively high doses, often in the supra-lethal range (van der Schans, et al., 2003). Mathematical models of these data have been developed, but extrapolation to low-level exposures has proven problematic (Sweeney and Maxwell, 1999). Further, there are very little experimental data and essentially no modeling efforts for repeated low-level exposures (Benschop and De Jong, 1991). Thus, new experimental data at the appropriate dose ranges appear to be required for further refinement and extension of existing PBPK models.

Much of the animal data on the biological effects of low-level exposure to GB and other nerve agents has been collected via the subcutaneous or intramuscular route, particularly in guinea pigs, because of their lack of CarbE. A good deal of data has also been collected by this dosing route or intramuscular dosing in rats, miniature pigs, and nonhuman primates. The primary exposure route of interest for human exposure is almost exclusively inhalation or dermal contact, so the quantitative implications of these laboratory exposure data for human health risk assessment is not straightforward. The most reliable tool for extrapolating across both species and exposure routes is PBPK modeling, in which species differences in physiology are taken directly into account, and equivalent systemic and tissue doses for different routes of exposure can be calculated. Such extrapolation procedures, exemplifying the integration of diverse data sets in both animals and humans, are illustrated in Figure 58.2. Here, the lower pentagon represents the dermal (or subcutaneous) exposure route for different species, while the upper pentagon represents inhalation exposure. The arrow represents the extrapolation of subcutaneous exposure data in the guinea pig to apply them to human inhalation exposure situations. In this example, the relevant biological effects observed in the guinea pig at specific subcutaneous exposures are noted. The guinea pig PBPK model then allows blood and tissue concentration time-courses corresponding to these doses to be calculated. Assuming that similar biological effects occur at similar target-site concentrations across species, the necessary inhalation exposure corresponding to the same blood and tissue concentrations in the humans can then be back-calculated using the human PBPK model for the agent. By using PBPK models in this way, human inhalation exposures are thereby quantitatively linked to the rich animal response and health effects databases.

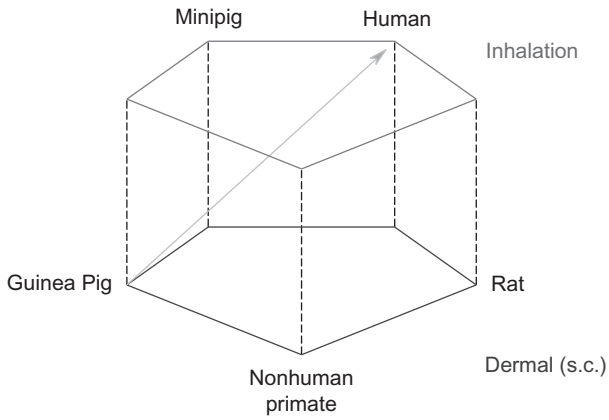

FIGURE 58.2 Schematic illustration of combined interspecies and route-to-route extrapolation. The arrow represents the extrapolation of guinea pig subcutaneous exposure data to human inhalation exposure situations.

NEED FOR IMPROVED MEASURES OF CWNA EXPOSURE—THE USE OF PBPK ANALYSIS OF DATA

Historically, cholinesterase activity has been used to evaluate exposure of humans and animals to nerve agents. Unfortunately, circulating cholinesterase activity is a relatively insensitive and imprecise marker of nerve agent exposure. By contrast, regeneration of nerve

agents from inhibited enzymes using a high fluoride concentration (fluoride regeneration) is well suited to monitoring absorbed doses resulting from low-level exposures to GB, GD, and other CWNAs (Polhuijs et al., 1997; Jakubowski et al., 2001, 2003; Adams et al., 2004). This technique has not yet been applied systematically for kinetic modeling of CWNA exposures in guinea pigs. Recently, a method for regenerating GB from blood and tissue has been developed and validated in rat, guinea pig, and pig models and provides a sensitive and quantitative means for estimating the kinetics of GB in blood (Jakubowski et al., 2004). This method is based on fluoride ion regeneration of the protein-bound agent. Fluoride ion-regenerated sarin (R-GB) was found in blood and tissues of miniature pigs exposed to sarin vapor levels ranging from miosis to lethality. The R-GB in these samples was analyzed by gas chromatography–mass spectrometry (GC–MS) after a C18 solid-phase extraction sample preparation that included fluoride ion addition and pH adjustment. Serial blood samples taken before and during miosis-level GB inhalation exposures resulted in RBC R-GB levels that steadily rose during the exposure. This demonstrated the ability of the R-GB assay as a biometric of exposure. The slopes of the lines created by plotting R-GB versus time closely correlated to the experimental exposure level. Therefore, the rates of GB absorption in these animals were proportional to the GB exposure concentration. In contrast to R-GB, monitoring AChE activity was an ineffective indicator of exposure at miosis levels in these experiments.

RELATIONSHIP BETWEEN REGENERATED SARIN AND ACHE ACTIVITY AND ITS USE AS A DOSE SURROGATE

Regenerated sarin S_R from RBCs is experimentally related to AChE activity A, as shown in Figure 58.3. It is apparent that the relationship can be adequately described in terms of a Michaelis–Menten equation, as follows:

$$A = A_{\max}\left[1 - \frac{S_R}{S_R + K_m^{eff}}\right], \qquad (58.1)$$

where $A_{\max}$ = Amax = 0.623, and K_m^{eff} = 0.006. Note that K_m^{eff} is not the true K_m for GB binding to AChE, which is the concentration of sarin needed to fill half the AChE receptors, since we do not know that the regenerated sarin is the same as the original exposure concentration. (If there were additional sarin binding sites than AChE, for example, the regenerated sarin would underestimate the exposure concentration, and the true K_m would be larger than K_m^{eff} by a certain factor.) The fact that these data fit so well to an M–M type equation strongly suggests that there is a simple proportionality between K_m^{eff} and the "true" K_m, and that sarin regenerated from RBCs is a suitable surrogate for the original exposure to sarin in blood (Figure 58.3).

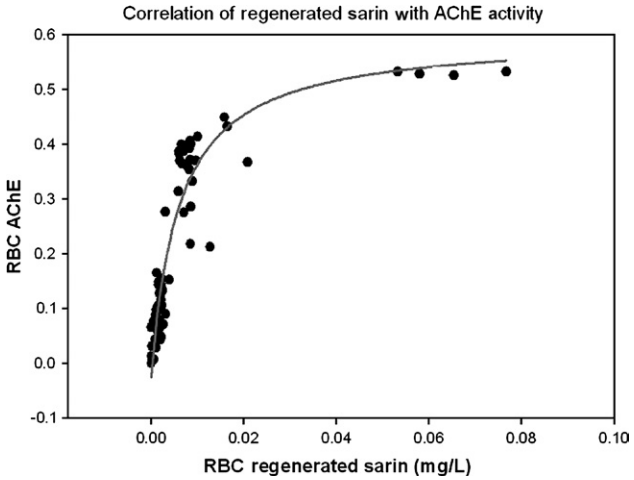

FIGURE 58.3 Plot of RBC AChE activity as a function of regenerated RBC sarin.

Regenerated sarin from RBCs at high doses may exceed the total available binding capacity of the AChE receptors associated with the RBCs. There are, therefore, additional sarin binding sites proposed to be associated with RBCs that continue to bind sarin well after the AChE receptors are filled, and therefore may comprise the bulk of the regenerated sarin at high concentrations. We thus have proposed two competing binding processes: one high-affinity, low-capacity site that dominates the binding of sarin at low concentrations, and which normally releases sarin very slowly, if at all (the AChE receptors); and one relatively low-affinity, high-capacity site, that releases sarin rapidly compared with the circulation time of the blood (Figure 58.4). This latter site would dominate at higher concentrations, and in the absence of any evidence for its saturation even at these high concentrations, we approximate it as a first-order process described with simple association and dissociation rate constants k_{on} and k_{off}.

GENERAL PBPK MODEL STRUCTURE

The basic structure of the PBPK model used to describe GB PK and PD followed that of the PBPK-PD model for DFP (Gearhart et al., 1990). Tissue compartments (Figure 58.2) were added to the previous model structure describing the eye and the skin, where before, these compartments had been lumped together in rapidly perfused or slowly perfused tissues. The eye was added to provide the means of predicting miosis during CW agent exposure, from

the systemic absorption of chemicals, but more importantly, from the amount of chemical absorbed directly to the eye structures via the ocular surface via absorption and diffusion. Adding this compartment also provided a mechanism of addressing the PD effects of sarin on the eye, by correlating inhibition of AChE enzyme levels in the iris with levels of miosis. The skin was added primarily to provide an exposure route for those agents that have a significant dermal absorption potential. Decreases in absorption due to upper respiratory tract (URT) deposition were accommodated by refining the model as shown in Figure 58.5.

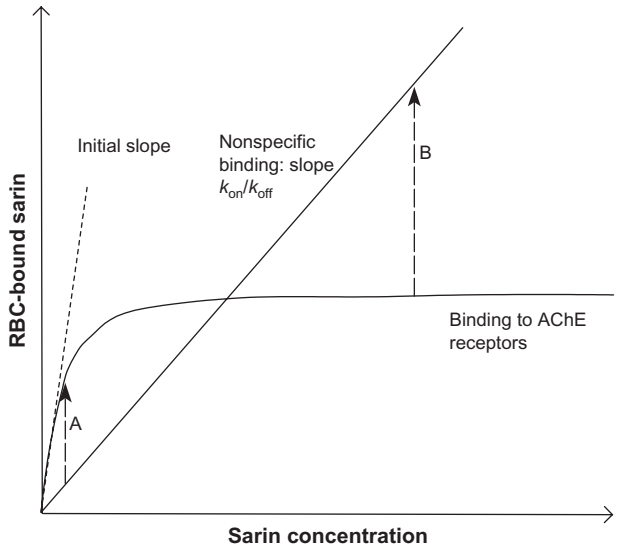

FIGURE 58.4 Hypothetical bound GB versus free sarin concentrations for saturable AChE binding, and linear nonspecific binding. The AChE binding has a higher initial slope, so it will dominate in a competitive situation at low doses (A), but it is saturable, so it will eventually be swamped by the nonspecific binding at higher doses (B).

PBPK parameters for individual organ weights were obtained from Breazile and Brown (1976); Altman and Katz (1979), and Peeters et al. (1980). Blood flows for most organs were obtained from Peeters et al. (1980) or were scaled from other rodent species. The partition coefficients were based on the values used for DFP (Gearhart et al., 1990) and soman (Langenberg et al., 1997), as well as the cholinesterase and sarinase values for tissue and blood.

The description of the interaction of GB with the mammalian system of the guinea pig followed that as described by Gearhart et al. (1990) for the CWA simulant DFP in rodents and Gearhart et al. (2005) in the Göttingen miniature pig. The description of sarin binding to AChE is shown in Figure 58.6. Sarin interaction with AChE is described by a bimolecular rate constant, causing loss of AChE activity. The inhibited AChE sites represent the amount of sarin, which can be regenerated from the RBCs.

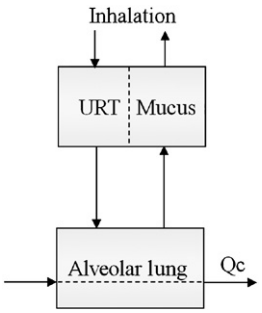

FIGURE 58.5 Detailed schematic for URT interactions for inhalation exposures.

PBPK SIMULATION OF CHOLINESTERASE INHIBITION AND REGENERATED GB

The main focus of this effort was to develop and validate methods to relate and integrate CWNA toxicity data across routes of exposure in a common species. The specific goal is to compare uptake and clearance kinetics of similar sublethal doses of GB in the blood of guinea pigs exposed to the agent by acute intravenous (IV), inhalation (IH), or subcutaneous (SC) injection. GB regenerated from blood was used as the dose metric to

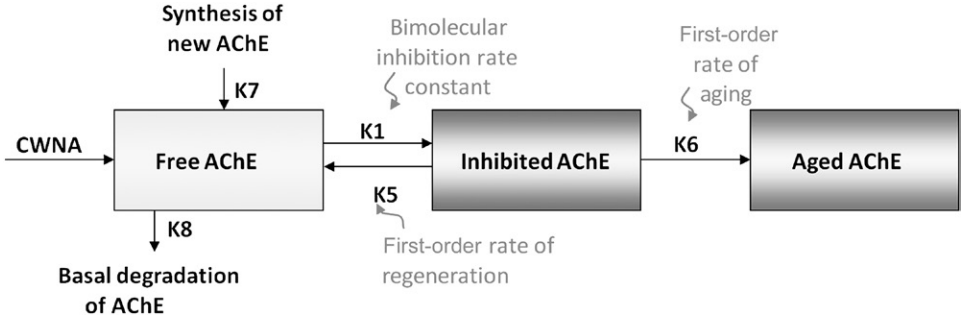

FIGURE 58.6 Schematic for AChE inhibition by sarin.

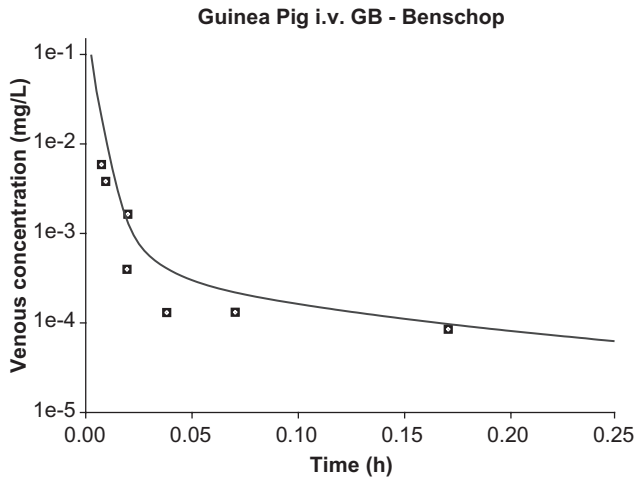

FIGURE 58.7 PBPK-PD simulation of AChE inhibition in the guinea pig after an IV GB dose of 0.8 × LD_{50} (0.0042 mg/kg body weight) (data from Benschop and De Jong, 2001—19.2 μg/kg).

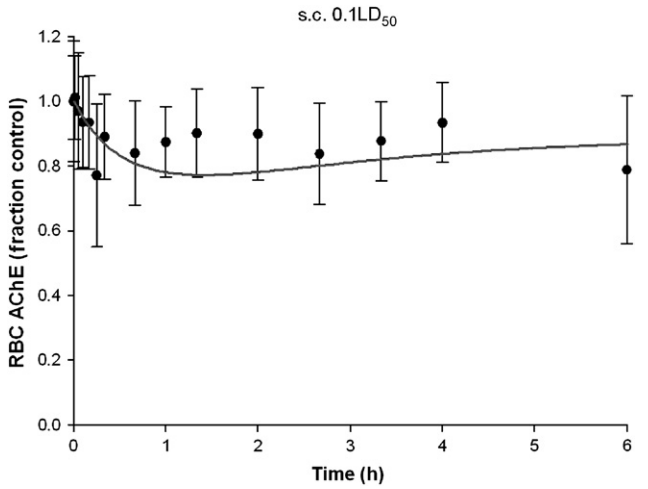

FIGURE 58.8 PBPK-PD simulation of AChE inhibition in the guinea pig after a SC dose of 0.1 × LD_{50} (0.0042 mg/kg body weight).

compare the uptake and clearance kinetics of similar doses of GB administered to guinea pigs by an IV, SC, or IH route of exposure. The resulting database will be used to derive a quantitative ratio (SC/IH) of systemically absorbed agent that will allow predictions of the atmospheric GB concentration relevant to a second species based upon subcutanous injection exposures.

Guinea pigs were exposed to sublethal levels of GB by IV, IH, and SC routes. Serial blood samples were collected in order to determine simple uptake and clearance kinetics using regenerated agent as a dose metric in a single dose (delivered via IV, SC, and IH). The resulting database was used to derive the PBPK model. This model will be used to determine a quantitative ratio (SC/IH) of a systemically absorbed agent that will allow predictions of the atmospheric GB concentration relevant to the increased guinea pig data sets based upon subcutaneous injection exposures.

Simulation of inhibited cholinesterase and regenerated GB versus the plotted data are exhibited in Figures 58.7–58.13. The methods of GB exposures or dosing shown in the figures are for either the IV, SC, or IH route. In most cases, the experimental data was well represented by the PBPK-PD model simulations. Those instances where the greatest deviation occurred between the model and the data occurred most likely because of data variability, such that the trend of the data would not follow a reproducible model behavior (Figure 58.11), or cases where there is still some question about the strength of the model parameters being used. Figures 58.7–58.10 show the model simulation of some of the key data used to determine model behavior. In each of these cases, the simulations provide a good representation of the overall magnitude and tread of the data. In some cases, as in Figures 58.7 and 58.9, there are

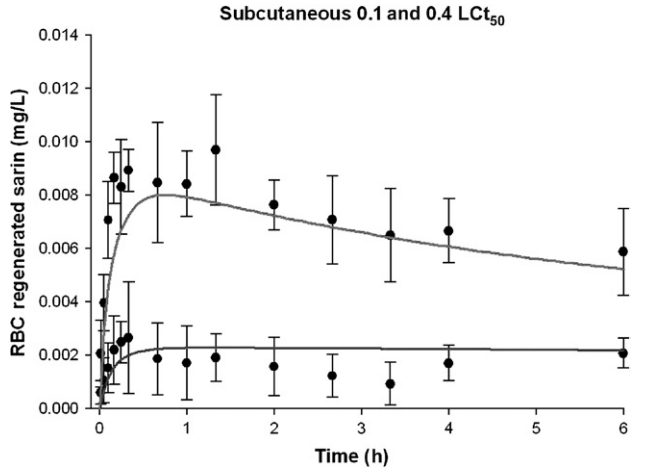

FIGURE 58.9 PBPK-PD simulation of regenerated sarin in the guinea pig after a SC dose of 0.1 × LD_{50} (0.0042 mg/kg body weight) and 0.4 × LD_{50} (0.0168 mg/kg body weight).

points during the simulation when there is either an overestimation or underestimation of the data. This type of variation between PBPK-PD simulations and data is a common occurrence whenever there is an attempt to exactly simulate time-course kinetic data for such toxicologically active a compound as GB. If it appears that significant decreases or increases in the actual experimental values are indications of real mechanisms and not just animal-to-animal variability, then that may be simulated using more sophisticated methods, as with stochastic processes where actual fluctuations in blood flows or shunting of blood could cause changes in represented concentrations outside the normal trend of the data. Certainly one major issue not addressed in this chapter is the effects of GB on its own PK, which in turn has a significant impact on key PBPK parameters such

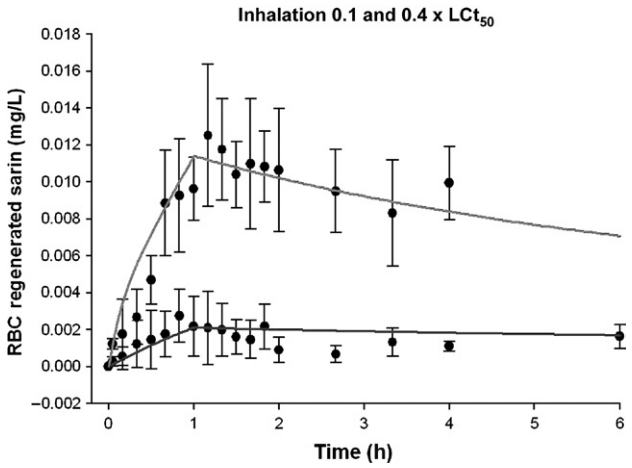

FIGURE 58.10 PBPK-PD simulation of regenerated sarin in the guinea pig after a 1-h IH exposure to sarin vapor at 0.1 × LC_{50} (0.4 mg/m^3) or 0.4 × LC_{50} (1.6 mg/m^3).

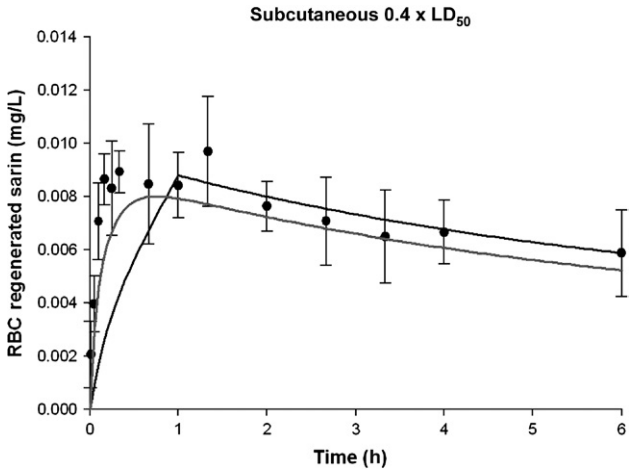

FIGURE 58.12 PBPK-PD simulation of an exposure of guinea pigs to the SC concentration equaling 0.4 of the lethal concentration affecting 50% of the exposure population (LD_{50}).

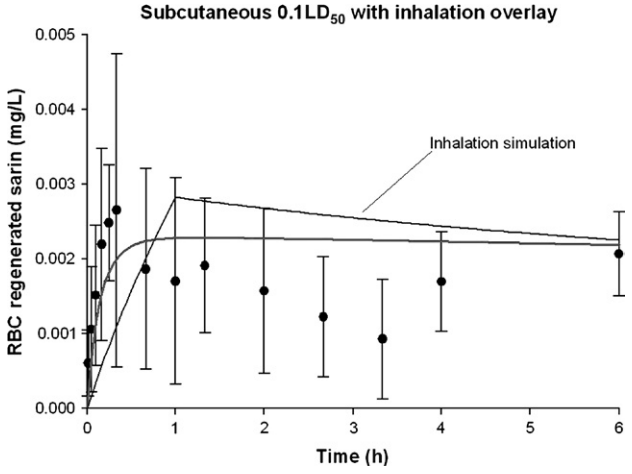

FIGURE 58.11 Overlay of the simulation of regenerated RBC sarin after a 0.1 × LD_{50} SC dose of sarin *vs.* IH dosing simulation at the inhalation concentration required to reproduce the SC data.

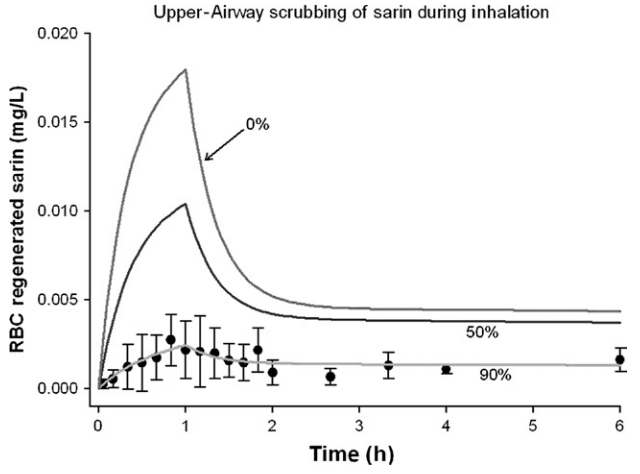

FIGURE 58.13 Upper-airway scrubbing simulations. As was previously seen with the simulation of minipig inhalation exposures, a significant percentage of the inhaled dose was scrubbed by the URT, with the best fit to the data requiring the loss of 90% of the inhaled dose.

as blood flow and respiratory ventilation parameters. A well-known response to severe CWNA exposure is a suppression of the cardiac output and respiratory ventilation, both of which could alter measured PK and PD endpoints, and if not modulated in the PBPK-PD model, lead to overestimation or underestimation of data.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The overall performance of the PBPK-PD model in predicting both the concentration of regenerated GB and the inhibition of RBC AChE was very successful for both the SC and IH routes of exposure at these doses. Previously published studies showing the significant deposition of GB in the URT were confirmed in this analysis of the inhalation of GB in the guinea pig at 0.1 and 0.4 times the LC_{50} for this species. The PBPK-PD model was utilized to equate the delivered dose of GB by SC exposure to what would be obtained after IH exposure. In this analysis, it was determined that at lower GB inhalation concentrations, there is a significant amount of deposition of the agent on the URT (Figure 58.13), material that is both hydrolyzed and resultantly inactivated, or else it is bound by a mechanism such that it presently is hypothesized to have limited activity. This is one aspect of this analysis that requires further study. To determine

the actual IH concentration that would correlate with a particular SC dose, the PBPK-PD model was exercised repeatedly, and the simulation output was overlaid on the SC simulations. This process is shown in Figures 58.11 and 58.12 for the 0.1 and 0.4 SC LD_{50} levels, respectively. This calculation showed that to reproduce the SC $0.1 \times LD_{50}$ of 0.0042 mg/kg (Figure 58.11), required an inhalation concentration of 0.08 ppm for a 1-h inhalation exposure. This value is very close to the experimentally determined value for the inhalation $0.1 \times LC_{50}$ of 0.05 ppm. The SC $0.4 \times LD_{50}$ of 0.0168 mg/kg required an inhalation concentration of 0.28 ppm for a 1-h inhalation exposure (Figure 58.12). Further simulations will need to be carried out to confirm these apparent relationships.

A previously developed PBPK-PD model for the CWNA surrogate DFP was parameterized to simulate the concentration and effects of low-level CWAs in the guinea pig after exposure by IH and SC injection. The model code was written to account for absorption of CWAs from multiple sites (respiratory tract—lower and upper, dermal, and ocular) after vapor or SC exposure. References to guinea pig physiology in the literature were used to determine the majority of organ volumes and blood flows, while some parameter values were scaled from other species. Unique features of this PBPK/PD model structure were physiological compartments for the eyes, as a source of external CWA absorption and as a site of cholinesterase binding, and the skin, as a dermal absorption pathway. One initial PD endpoint developed in this model was CWA inhibition of cholinesterases (such as AChE and BuChE). Covalent binding of sarin to cholinesterases and other proteins was also estimated by a novel parameter based on fluoride ion regeneration of the agent. The PBPK/PD model was used to simulate AChE inhibition after inhalation and subcutaneous injection of CWA and to predict potential PD effects at different tissue target sites. This preliminary model will provide a quantitative tool to predict the physiological consequences of low-level, nonlethal exposure to CWNA exposure.

CHAPTER

59

Biotransformation of Warfare Nerve Agents

Milan Jokanović

INTRODUCTION

The first organophosphorus (OP) warfare nerve agents (WNAs), tabun (GA) and sarin (GB), were developed in the 1930s by Gerhard Schrader. These, and the even more toxic soman (GD), were developed in 1944 and are members of the so-called G-agents. Together with VX, developed in 1952 in the United Kingdom, these compounds have emerged as the major WNAs known to have been produced and weaponized. The WNAs are alkylphosphonic acid esters. Tabun contains a cyanide group. Sarin, cyclosarin, and soman contain a fluorine acyl radical and are methylphosphonofluoridate esters. These WNAs contain a C-P bond not found in organophosphate pesticides. The C–P bond is very resistant to hydrolysis. VX contains sulfur and is an alkylphosphonothiolate.

The mechanism of extremely high toxicity of these agents is excessive cholinergic stimulation caused by inhibition of acetylcholinesterase (AChE) at nervous system synapses. WNAs are direct AChE inhibitors reacting rapidly with a serine hydroxyl group in the active site of AChE with the formation of a phosphate or phosphonate ester. The phosphorylated enzyme regenerates very slowly, rendering the enzyme inaccessible for its physiological substrate acetylcholine (ACh). The chirality around the phosphorus atom largely influences the toxicity of these agents, as documented in the case of soman whose P(−) isomers are much more toxic than the P(+) isomers (Benschop and De Jong, 1991; van der Schans et al., 2007; Jokanović, 2009).

Signs and symptoms of the cholinergic syndrome occurring in acute poisoning with WNAs and other OP compounds are predictable from their biochemical mechanism of action and are directly related to the levels of AChE activity. After exposure to WNAs, the symptoms of poisoning occur quickly depending on the dose taken, mainly by inhalation (G-agents). These symptoms include the following: miosis (unreactive to light); sweating, rhinorrhea, lacrimation, and salivation; abdominal cramps and other gastrointestinal symptoms; respiratory difficulties and cough; dyspnea, constriction sensation in the chest, and wheezing; twitching of facial muscles and tongue, tremors, and fasciculations; bradycardia and ECG changes, pallor, and cyanosis; and anorexia, nausea, vomiting, diarrhea, and involuntary urination and defecation. These signs and symptoms are accompanied by central effects such as dizziness, tremulousness, confusion, ataxia, headache, fatigability, and paresthesia. Finally, seizures, convulsions, twitching, coma, and respiratory failure may occur. Death usually occurs because of respiratory failure resulting from a combination of central and peripheral effects, paralysis of the respiratory muscles, and depression of the brain respiratory center (World Health Organization, 1986; Marrs and Vale, 2006; Karchmar, 2007; Jokanović, 2010; Jokanović et al., 2011).

In the case of G-agents, the intact agent is present in the organism for only several hours. The dominant metabolic pathway of G-agents is hydrolysis, a process mainly mediated by so-called A-esterases, and the metabolic products formed are corresponding *O*-alkyl methylphosphonic acids in the case of sarin, cyclosarin, and soman (Figure 59.1). VX is a less suitable substrate for A-esterases. There are also reports discussing a possible role of prolidase (EC 3.4.13.9), a naturally occurring enzyme, in hydrolysis of G-agents. In addition to hydrolysis, binding reactions of WNAs to proteins such as AChE, serum cholinesterase (ChE), carboxylesterase (CarbE), albumin, and other macromolecules also occurs. Toxicological importance of binding reactions

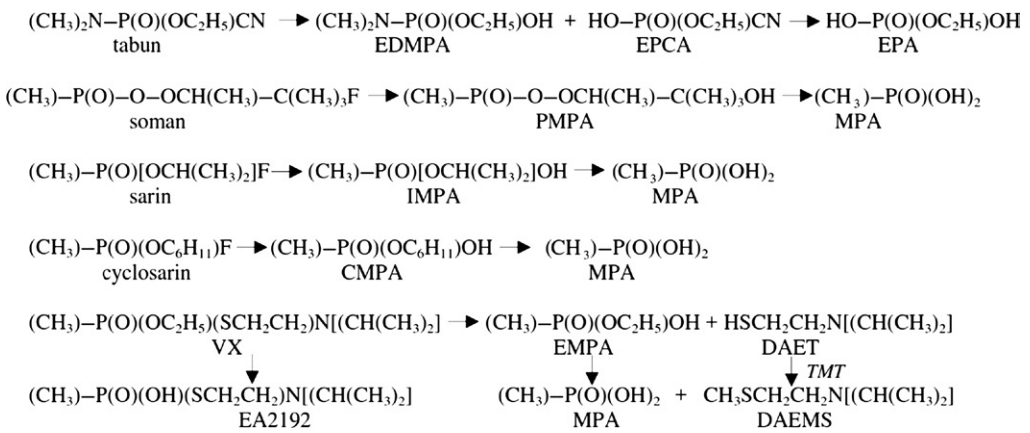

FIGURE 59.1 Metabolic detoxification of tabun, soman, sarin, cyclosarin, and VX. Abbreviations: EDMPA, ethyl dimethylaminophosphoric acid; EPA, ethyl phosphoric acid; EPCA, *O*-ethyl-cyanophosphoric acid; IMPA, isopropyl methylphosphonic acid; PMPA, pinacolyl methylphosphonic acid; CHMPA, cyclohexyl methylphosphonic acid; EMPA, ethyl methylphosphonic acid; MPA, methylphosphonic acid; DAET, 2-(diisopropylamino) ethanethiol; DAEMS, 2-(diisopropylaminoethyl) methylsulphide; TMT, thiol *S*-methyltransferase (EC 2.1.1.9) (Nakajima et al., 1998; Katagi et al., 1999; Jokanović, 2001, 2009; Evans et al., 2008; Black, 2010; Tenberken et al., 2010; Reiter et al., 2011; Black and Read, 2013; Kranawetvogl et al., 2013).

of WNA to these proteins involves decrease of free unbound concentration of WNA in blood, which causes less AChE inhibition in the nervous system. Both WNA and OP pesticides lose their acyl radicals when they react with AChE, ChE, and CarbE, and other proteins. After binding to AChE and ChE, the phosphoryl residues of soman, sarin, cyclosarin, tabun, and VX undergo an intramolecular rearrangement with subsequent loss of one phosphoryl group, known as aging reaction.

In addition, because of the reversibility of the binding reaction of sarin and soman to CarbE, it appears that CarbE are involved in metabolic detoxification of these agents to their corresponding nontoxic metabolites IMPA and PMPA (Jokanović et al., 1996; Jokanović, 2009).

Important proof supporting the significance of detoxification reactions of WNA in the body was presented by Fonnum and Sterri (1981), who reported that only 5% of LD_{50} of soman in rats, or approximately 5 μg/kg, reacts with AChE and causes acute toxic effects, whereas the remaining 95% passes through various metabolic reactions.

In this chapter, the mechanisms involved in biotransformation of WNA are discussed. Mechanisms of biotransformation of OP pesticides are beyond the scope of this chapter and interested readers are referred to other publications (Chambers et al., 2001; Jokanović, 2001, 2009; Tang et al., 2006).

CHEMICAL ASPECTS OF BIOTRANSFORMATION OF WNAS

The G-agents are anticholinesterase substances that, at sufficient concentrations, can be toxic or fatal by any route of exposure. Differences in volatility and water solubility result in varied degrees of persistence and variations in the likelihood of exposure by certain routes. Of the G-agents, tabun gives rise to the greatest number of degradation products. The metabolites of tabun EDMPA and EPCA (Figure 59.1) are apparently unstable, whereas the EPA is an excretion metabolite of tabun as well as of certain pesticides and plasticisers (Tenberken et al., 2010; Black and Read, 2013). The final metabolite of tabun is a phosphate (Black, 2010). Toxicity data are available only for a limited subset of the tabun degradation products. One of the tabun hydrolysis products, dimethylamine, is moderately toxic in terms of acute lethality but causes human irritation of the respiratory tract (Munro et al., 1999).

Sarin is metabolized to IMPA, which slowly undergoes further hydrolysis to the very stable MPA. IMPA also forms in the course of spontaneous reactivation of sarin-inhibited CarbE and ChEs. IMPA had shown low toxicity in rats and mice in all toxicity tests conducted, but has shown mild skin irritation in rabbits. Limited data suggest that MPA is nontoxic in terms of acute oral toxicity in rats and mice, but show irritant effects on human eyes and skin (Munro et al., 1999; Jokanović, 2009).

In the study by Little et al. (1986), a single sublethal dose (80 μg/kg) of radiolabeled sarin was administered intravenously to mice and the tissue distribution was followed for 24 h. Within 1 min, sarin was distributed to the kidneys, lungs, brain, liver, heart, and diaphragm. Thereafter, the concentrations in all tissues rapidly declined, and within 15 min only trace quantities of [^{3}H] sarin were found in the brain. Within the first minute, approximately half of the labeled sarin was in the form of IMPA. The highest concentrations of sarin and its

metabolites were found in the kidneys. Lower concentrations of IMPA and MPA were detected in the liver, suggesting a minor role for the liver in detoxification of sarin.

Shih et al. (1994) injected rats subcutaneously with a single dose of 75 μg/kg of sarin, cyclosarin, and soman, and measured excretion of the hydrolyzed metabolites and the alkylmethylphosphonic acids, including IMPA and corresponding MPAs. MPA was a major and common metabolite of the three compounds. Urinary excretion over the first 24 h accounted for approximately 90% of the administered doses of sarin and cyclosarin. Almost total recoveries of the given doses for sarin and cyclosarin in metabolite form were obtained from the urine. Urinary elimination was found to be rapid and the terminal elimination half-life of sarin metabolites in urine was 3.7 h. Most of the administered dose of sarin was retrieved from the urine in a metabolite form after 2 days. The terminal elimination half-life of cyclosarin in urine was 9.9 h. Soman metabolite showed a biphasic elimination curve with terminal half-lives of 18.5 and 3.6 h. Soman was excreted at a slower rate, with a recovery of only 62%. The first phase of elimination of soman results from enzymatic hydrolysis of the inactive P(+) isomers, and the slower phase is from the active P(−) isomers (Benschop and De Jong, 1991). The elimination study in rats determined IMPA in blood up to 14 h after exposure, CHMPA up to 2 days, and PMPA up to at least 3 days.

Distribution, metabolism, and elimination of sarin in humans appear to resemble findings in animals. Minami et al. (1997, 1998) detected the sarin metabolite IMPA in urine of humans after the terrorist attack in Tokyo in 1995. They found peak levels of IMPA or MPA in urine 10–18 h after exposure. The levels of IMPA in urine correlated with the clinical symptoms. They also found evidence of distribution of sarin to the human brain in 4 of the 12 people who died after exposure. IMPA and MPA were detected in urine of a patient poisoned with sarin in Matsumoto (Nakajima et al., 1998).

Biotransformation products of soman include PMPA and MPA. No biologic data were found for PMPA (Munro et al., 1999; Jokanović, 2009). It has been shown that the toxic C(±)P(−) isomers of soman react rapidly with covalent binding sites. The less toxic C(±)P(+) isomers are hydrolyzed several orders of magnitude faster than the C(±)P(−) isomers. The low toxicity of the C(±)P(+) isomers is primarily due to a low intrinsic reactivity toward AChE and rapid metabolic hydrolysis (van der Schans et al., 2007). The levels of C(±)P(−) isomers remain toxicologically relevant for periods of 50–100 min in rats, guinea pigs, and marmosets at doses of 2–3 LD_{50} (Benschop and De Jong, 1991).

VX is a potent anticholinesterase agent that can act by dermal, oral, and inhalation routes of exposure. There are certain characteristics of VX that make the agent different from G-agents, such as the following: VX is present in blood as protonated amine; it is hydrolyzed at a much slower rate than G-agents; it reacts more slowly with CarbE (because of its positively charged quaternary ammonium group) and A-esterases; and VX can be metabolized by other routes such as oxidation reactions at nitrogen and/or sulfur (Jokanović, 2009; Black, 2010). A few of the metabolic products may retain some anticholinesterase activity (such as EA2192) (Munro et al., 1999), but hydrolysis of one or more alkyl ester bonds of organophosphonic acids results in generally nontoxic alkyl methylphosphonic acids EMPA and MPA. MPA is resistant to further hydrolysis. Munro et al. (1999) discussed the metabolic degradation products of VX in mammals and found that there are approximately 25 such products and each had shown different levels of toxicity.

There are three phosphorus-containing metabolites of VX: EA2192 (which has shown some anticholinesterase activity), EMPA, and MPA (not AChE inhibitors) (Figure 59.1). EMPA appears to be the major metabolite of VX in urine (Black and Read, 2013). The presence of EA2192 metabolite in humans is important because it retains the 2-diisopropylaminoethylthio substituent that confirms exposure to VX (Black and Read, 2013). After intravenous and dermal administration of sublethal doses of VX to swine, both VX and EA2192 could be quantified during 540 min after exposure (Reiter et al., 2011). In addition, there are two nonphosphorus metabolites of VX: DAET and its methylation product DAEMS identified in human serum from a victim of the Osaka VX accident (Tsuchihashi et al., 1998). The conversion from DAET to DAEMS is catalyzed by thiol *S*-methyltransferase (EC 2.1.1.9) (Reiter et al., 2011).

Benschop et al. (2000) and van der Schans et al. (2003) studied the toxicokinetics of VX stereoisomers in hairless guinea pigs and marmosets. After an intravenous dose of 28 μg/kg (marmosets) or 56 μg/kg (guinea pigs), VX was found in the blood at toxicologically relevant levels even after 6 h. Detoxification proceeded at a slower rate in marmosets than in guinea pigs. The VX metabolite EMPA (Figure 59.1) was found in the blood of the exposed animals; however, the metabolite contributed only 5% to the recovery of the phosphonyl moieties related to the VX dose. Metabolites of VX were also evaluated in *in vitro* studies by treating liver homogenates and plasma from hairless guinea pigs, marmosets, and humans with the radio-labeled compound, ^{35}S-VX. The potential toxic metabolite VX-*N*-oxide was not found. Desethyl-VX was found after incubation of VX in plasma of all three species; however, because of its slow rate of formation, Benschop et al. (2000) concluded that it would be unlikely that VX would be present at toxicologically relevant levels after administration of VX *in vivo*. *In vitro* studies with ^{35}S-VX

revealed that a significant part of the thiol-containing leaving group (S-2-(*N*, *N*-diisopropylamino)ethane thiol) was bound to albumin.

Tsuchihashi et al. (1998) developed a method for identification of VX metabolites in serum collected from a victim of the Osaka VX incident. In the serum sample, both EMPA and DAEMS were detected. The techniques using GC-MS and GC-MS-MS were applicable to biological samples such as serum. These results provided the first documented identification of the specific metabolites of VX in a victim's serum and clarified a part of the metabolic pathway of VX in the human body. In addition, methods have been developed for measuring the VX-inhibited AChE hydrolytic product EMPA (Noort et al., 1998, 2002).

ESTERASES INVOLVED IN METABOLISM OF WNAs

Numerous esterases can react with OPs, but in a different way. The first classification was provided by the late Professor Aldridge (1953). In the first group, there were esterases that hydrolyze OPs as substrates, particularly their uncharged esters, that are not inhibited by these compounds. This group of enzymes was named *A-esterases*, although in the literature there are many other names for the same group of enzymes given according to the substrate hydrolyzed (paraoxonase, somanase, sarinase, etc.) or their chemical structure (phosphotriesterases, phosphorylphosphatases, anhydrases of OP compounds). In the second group of enzymes interacting with OPs there were *B-esterases*, which are inhibited with OPs in the progressive reaction that is time-dependent and temperature-dependent. This group of enzymes comprises AChE, ChE, CarbE, trypsin, chymotrypsin, and other enzymes. In the third group were *C-esterases* that do not interact with OP. It is paradoxical, but basically true, that OPs can be substrates for both A-esterases and B-esterases because their concentrations in blood and tissues are decreased in the presence of these enzymes.

The mechanism of interaction of A-esterases and B-esterases with WNA and other OP is similar. B-esterases initially form Michaelis complex with an OP inhibitor producing phosphorylated or inhibited enzymes that either reactivate very slowly or do not reactivate at all. However, after formation of Michaelis complex with OP, *A-esterases* catalyze hydrolysis of OP and their catalytic activity and turnover rate are very high.

A-Esterases

Classified in 1992 (International Union of Biochemistry, 1992), hydrolases of OP were described as a special entity called "phosphoric triester hydrolases," which comprise three groups of enzymes: phosphoric monoester hydrolases (EC 3.1.3); phosphoric diester hydrolases (EC 3.1.4); and phosphoric triester hydrolases (phosphotriesterases) (EC 3.1.8). Phosphoric triester hydrolases are further divided in two similar subgroups: aryldialkylphosphatases (EC 3.1.8.1) and diisopropylfluorophosphatases (EC 3.1.8.2).

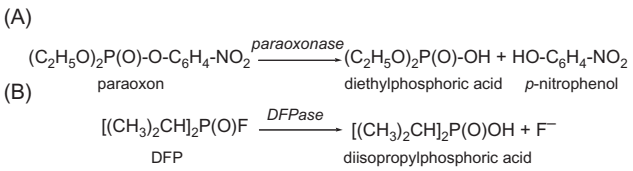

FIGURE 59.2 (A) Hydrolysis of paraoxon with aryldialkylphosphatase (paraoxonase, EC 3.1.8.1) and (B) hydrolysis of diisopropylfluorophosphate (DFP) with diisopropylfluorophosphatase (DFPase) (EC 3.1.8.2).

Aryldialkylphosphatases take part in hydrolysis of aryldialkylphosphates producing dialkylphosphate and aryl alcohol. These enzymes react with substrates such as paraoxon (Figure 59.2), and also with phosphonates and phosphinates. Other names for this group of enzymes are hydrolases of OPC, A-esterases, paraoxonases, (PON1), aryltriphosphatase, and aryltriphosphate dialkylphosphohydrolase. They are inhibited with compounds that form chelates like EDTA because they require the presence of divalent ions, mainly Ca^{2+} (Walker, 1993). Some fractions of the enzyme purified from human serum were able to hydrolyze both paraoxon and phenylacetate and it was thought for a long time that the same enzyme is responsible for both. However, enzymes hydrolyzing aryl esters are classified as arylesterases (EC 3.1.1.2).

Diisopropylfluorophosphatases take part in hydrolysis of DFP and similar compounds producing diisopropylfluorophosphoric acid and fluoride ion (Figure 59.2). These enzymes react with phosphorus anhydride bonds such as those between phosphorus and acyl radical (F^-, Cl^-, CN^-) in highly toxic OPC such as soman, sarin, tabun, and DFP, and they were accordingly named somanase, sarinase, tabunase, DFPase, diisopropylfluorophosphate fluorohydrolase, OPA anhydrase, OPAA, and OP acid anhydrolase. They are also inhibited by chelating agents, and their activity requires presence of divalent ions such as Mg^{2+}, Mn^{2+}, Co^{2+}, and Cd^{2+}, but not Ca^{2+} (Walker, 1993; Kondo et al., 2004). They exist in several forms, even in different tissues of the same species, and react differently with substrates.

In the literature, there are articles reporting an important role of senescence marker protein-30 (SM-30) in hydrolysis of DFP and similar substrates (Kondo et al., 2004; diTargiani et al., 2010). SM-30 protein was given the code EC 3.1.8.2, which was previously assigned to DFPase. After checking all available data, it appears

that both SM-30 and DFPase are the same enzymes and that their names are synonyms! Therefore, DFPase is a 34 kDa metalloprotein expressed predominantly in the liver and kidney of mammals. Although the identity of the metal ion is not clearly established, it was shown that the activity of purified DFPase from rat liver was stimulated by $MgCl_2$, $MnCl_2$, $CoCl_2$, and $CdCl_2$ (Kondo et al., 2004). It has been linked with the regulation of calcium homeostasis and the protection of cells from apoptosis. Consistent with these observations, it was found that the sequence of DFPase was identical to that of a Ca^{2+}-binding protein, regucalcin. Rat liver DFPase was shown to hydrolyze DFP, phenyl acetate, and gluconolactones. *In vivo* studies with SMP-30 knockout mice confirmed its role in the hydrolysis of DFP in the liver of these animals (diTargiani et al., 2010). A reduction of DFPase expression might account for the age-associated deterioration of cellular functions and enhanced susceptibility to harmful stimuli in aged tissue (Kondo et al., 2004).

In the literature published during the past 30 years, the term PON1 apparently covers both phosphoric triester hydrolases. In further text, to avoid possible confusion, the term A-esterase will be generally used for enzymes hydrolyzing OPs and with other terms (such as PON1, paraoxonase, etc.) as they appear in original references.

Molecular weight of human A-esterases is between 43 and 45 kDa. Human A-esterase is a protein of 355 amino acids with two polymorph sites in which arginine or glutamine are located at position 192 and methionine or leucine at position 55 (La Du et al., 1993; Li et al., 1995). The former accounts for three genotypes (QQ, RR, and QR) relating to the catalytic properties of two forms of an enzyme (types R and Q allozymes), which hydrolyze certain organophosphates at different rates. Its three-dimensional structure is also known (Benning et al., 1994; Vilanova and Sogorb, 1999). At the active site of A-esterases there are two metal cations connected via common ligand, and most other protein groups are bound to this binuclear site through imidazolium side chains from histidine groups (Benning et al., 1994). Activity of these enzymes largely depends on Ca^{2+}, which represents a necessary factor for maintaining the function of active site, and it is also possible that Ca^{2+} directly participates in catalytic reactions or maintain the conformation of amino acids at the active site. In addition, in the case of paraoxons, Ca^{2+} facilitates the release of diethylphosphate from the active site, probably by polarizing bond P=O, which makes phosphorus atoms much more sensitive to nucleophilic attack of hydroxyl ions (Vitarius and Sultatos, 1995; diTargiani et al., 2010). Human A-esterases can hydrolyze many OPs, including paraoxon, soman, sarin, tabun, chlorpyriphos and chlorpyriphos oxon, DFP, dichlorvos, diazoxon, and pyrimiphos methyl oxon.

The R allozyme (Arg192) hydrolyzes the organophosphate paraoxon at a high rate; however, it has low activity toward sarin, soman, and diazoxon. Lower activity means that more sarin would be bioavailable to exert its anticholinesterase effects. The Q allozyme, however, has high activity toward sarin, soman, and diazoxon (and low activity toward paraoxon). Thus, individuals with the Q allozyme (QQ or QR) are expected to have greater hydrolysis of sarin than individuals homozygous for the R allele (RR) (Costa et al., 1999, 2005). In Caucasian populations, the frequency of the R allele is approximately 0.3, but the frequency is 0.66 in the Japanese population (Yamasaki et al., 1997; Costa et al., 2006). This would make individuals in the Japanese population more sensitive to the toxicity of sarin, a fact that may have contributed to their morbidity and mortality after the terrorist attacks in 1995. The concentration of PON1 in human plasma (approximately 60 mg/L) varies between individuals by as much as 13-fold. PON1 activity level is determined by a combination of complex genetic interactions and environmental/dietary factors, giving rise to a 40-fold variation in PON1 for a single individual (Rochu et al., 2007). The relationship between paraoxonase polymorphisms and toxicity of OP compounds was further discussed in an excellent article by Costa et al. (2006) and other work by his team.

Paraoxonase (PON1) is a member of a family of proteins that also includes PON2 and PON3, the genes of which are placed on the long arm of human chromosome 7 (q21.22). PON2 and PON3 have approximately 65% homology to PON1, but they cannot hydrolyze WNAs and other organophosphates (Draganov et al., 2005; Aviram and Rosenblat, 2008). PON1 is synthesized primarily in the liver and a portion is secreted into the plasma, where it is associated with high-density lipoprotein (HDL) particles (Costa et al., 2005). The crystal structure for a recombinant PON1 indicates that it is a six-bladed β-propeller with two calcium ions in the central tunnel, one of which is essential for enzyme activity and the other is essential for enzyme stability (diTargiani et al., 2010). The primary physiological role of PON1 appears to be protection of low-density lipoproteins (LDL) from oxidative modifications (Mackness et al., 1993; Aviram et al., 1998; Vilanova and Sogorb, 1999; Rochu et al., 2007). Human PON1 is apparently involved in drug metabolism and in preventing atherosclerosis (diTargiani et al., 2010). Endogenous PON1 is associated with HDL that represents its main carrier in blood, and this association has been considered a crucial element for increased stability and half-life of PON1 in circulation (Gaidukov et al., 2009; Veliyaveettil et al., 2012). In addition to its role in lipid metabolism, cardiovascular disease, and atherosclerosis, PON1 has been shown to play a role in the metabolism of drugs and xenobiotics containing aromatic carboxyl esters (Costa et al., 2003).

It is also suggested that PON1 hydrolyses various lactones, including naturally occurring lactone metabolites.

The differences in the activity of A-esterases due to polymorphisms may have an important effect on toxicity of OP in humans that are occupationally or accidentally exposed. In this respect, it was proposed that humans expressing lower activity of A-esterases could be more susceptible to toxic effects of OP, and it was proposed that such individuals should not be exposed (Mackness, 1989). Hernandez et al. (2004) have confirmed this hypothesis, suggesting the association of paraoxonase phenotypes with susceptibility of humans to OP pesticides toxicity. However, additional studies are needed to fully understand the effects of A-esterase polymorphism on the capacity of detoxification and toxicity of OP.

Toxicological Relevance of A-Esterases

A-esterases purified from *Pseudomonas diminuta* and given to mice decreased inhibition of AChE in brain and ChE in serum in poisoning with paraoxon and DFP, and this effect was less significant in poisoning with soman and sarin (Tuovinen et al., 1994). Purified A-esterases have shown protective effects when given to mice before poisoning with tabun (Ashani et al., 1991a).

Haley et al. (1999) investigated PON1 genotype and serum enzyme activity in a group of 25 ill Gulf War veterans and 20 controls. Ill veterans were more likely than controls to possess the R allele (QR heterozygotes or R homozygotes) and to exhibit lower enzyme activity. This study raised the possibility that the R genotype (low sarin-hydrolyzing activity) may represent a risk factor for illness in Gulf War veterans. However, because of the very small number of participants included in the study, such findings require confirmation in a larger population (Furlong, 2000). La Du et al. (2001) also found reduced sarinase and somanase levels in plasma obtained from Gulf War veterans. In a similar study, in a group of 152 UK Gulf War veterans, the PON1 activity was lower in veterans than in a control group, but the differences were independent of PON1 genotype (Mackness et al., 2000). However, in both studies there were no indications about the extent of exposure to nerve agents and possible effects of such exposures.

B-Esterases

B-esterases are the group of enzymes that can be inhibited by OP compounds in the progressive reaction that is time-dependent and temperature-dependent. This group of enzymes comprises AChE (EC 3.1.1.7), ChE (EC 3.1.1.8), CarbE (EC 3.1.1.1), chymotrypsin, trypsin, and some other enzymes. A common feature of these enzymes is that they have a serine hydroxyl group at the active site that enables them to react with OP in a similar fashion. AChE, ChE, and CarbE are members of the α/β hydrolase family and have a high degree of overall homology in their amino acid sequences, but they differ in several critical regions that produce differences in their biochemical properties. The most significant biochemical differences in these esterases are related to the extent of aging of the OP-inhibited esterase, the size of the active site, and the ability of the OP-inhibited enzyme to undergo spontaneous or oxime-induced reactivation (Doctor et al., 2001).

Serum ChE

Although the biological role of ChE is still unclear, it is known that soman, sarin, tabun, and VX bind to ChE without any apparent toxic effects, decreasing the amount of free WNA available for inhibition of AChE in the central nervous system and erythrocytes (Jokanović, 2009). Pretreatment with human plasma ChE (hBChE) has protected laboratory mice (Ashani et al., 1991b) and monkeys (Raveh et al., 1997) from lethal and other acute toxic effects of VX exposure. Human BChE is now in an advanced stage of development as a bioscavanger and is close to obtaining marketing approval as pretreatment for OP poisoning (Saxena et al., 2011a; Trovaslet-Leroy et al., 2011). It is estimated that a dose of 200 mg is required to protect a human against $2 \times LD_{50}$ of soman (Saxena et al., 2011a). hBChE reacts with OP to form the 1:1 complex, and an intramuscular or intravenous injection protects animals against 3–5 $\times$ LD_{50} of soman, tabun, and VX (Lenz et al., 2007). A dose up to 250 mg/70 kg of hBChE is able to protect humans from $1 \times LD_{50}$ of OP (Ashani and Pistinner, 2004). Such a dose of hBChE is required because of the stoichiometric and irreversible reaction between hBChE and OP (Trovaslet-Leroy et al., 2011). Animal studies have shown that administration of large doses of hBChE provide protection against up to 5.5 $\times$ LD_{50} of soman or $8 \times LD_{50}$ of VX (Saxena et al., 2011a). Pretreatment with 7.5 mg/kg completely prevents toxicity in minipigs exposed to sarin by inhalation (Saxena et al., 2011b). hBChE derived from plasma is present in the blood of guinea pigs up to 4 days without any signs of toxicity (Saxena et al., 2011a) and without any adverse effect in rats (Nachon et al., 2013). Behavioral and physiological safety of plasma hBChE was established at 21 mg/kg in mice (Ilyushin et al., 2013) and 30 mg/kg in rhesus monkeys (Myers et al., 2012).

ChE is a serine esterase glycoprotein composed of four 85 kDa subunits, synthesized mainly in the liver, and does not have any known physiological function. From the liver, ChE is secreted to plasma and its activity correlates with the physiological and/or pathological condition of the liver. ChE can be found in more than 40 genetic variants, differing in their susceptibility to chemicals (Jokanović and Prostran, 2009). ChE may have roles in cholinergic neurotransmission (Mesulam et al.,

2002), other nervous system functions (cellular proliferation and neurite growth during the development of the nervous system), and in neurodegenerative disorders (Darvesh et al., 2003).

Variability in plasma ChE activity is a parameter of concern for characterization of population susceptibility to nerve agent exposure. Selective inhibition of AChEi ChE had no effect on the acute soman toxicity to mice (Clement, 1984). Because VX reacts with ChE, and because it reacts very slowly with CarbE (due to its positively charged quaternary ammonium group), it appears that ChE may have a significant role in detoxification of VX. Wide variations in ChE activity seen in individuals not exposed to OP but that are caused by genetic, physiological, and pathological conditions, as well as interactions with many drugs, may strongly influence the susceptibility of those individuals to OP compounds (Jokanović and Maksimović, 1997). It is possible that individuals with lower ChE activity may be more susceptible to the effects of OP including nerve agents.

Carboxylesterases (EC 3.1.1.1)

The mammalian CarbE comprise a multigene family whose gene products are located in the endoplasmic reticulum (Hosokawa and Satoh, 2006). CarbE are the enzymes that hydrolyze esters and thioesters or amide groups of carboxylic acids. They were also mentioned in the literature as aliesterases and esterase D. CarbE have a very important role in metabolism of lipids, endogenous fatty acids esters, steroids, and a large number of ester-containing drugs and prodrugs, such as salicylates, clofibrate, procaine, lorazepam, cilazapril, and other angiotensin-converting enzyme inhibitors, narcotics (cocaine, heroin), and capsaicin. CarbE also participate in detoxification of pesticides (carbofuran, pyrethroids, OPs), acrylates, mycotoxins (T2 toxin), and esters of nicotinic acid (Cashman et al., 1996). Certain isoenzymes of hepatic microsomal CarbE are involved in the metabolic activation of some carcinogens and are associated with hepatocarcinogenesis (Hosokawa and Satoh, 2006). Enzymes similar to CarbE are arylesterases (EC 3.1.1.2) that hydrolyze aromatic esters of carboxylic acids. However, this classification is not perfect because CarbE hydrolyze some aromatic esters (i.e., phenyl valerate, phenyl butyrate) and arylesterases hydrolyze certain aliphatic esters. These two enzymes can be clearly differentiated according to their interaction with OP because CarbEs are inhibited by OPs, whereas arylesterases can hydrolyze some OPs that contain aromatic groups, such as paraoxon and chlorpyriphos oxon; because of this, they were sometimes confused with A-esterases.

CarbE profile in humans is not well-known. Although CarbEs were considered to be absent from the blood plasma of humans (Li et al., 2005), they are present in human erythrocytes and monocytes as well as in human liver, kidney, lung, skin, and nasal tissue (Cashman et al., 1996). Additional literature documents the presence of CarbEs in many human tissues and fluids, including brain, milk, mammary gland, pancreas, small intestine, colon, stomach, placenta, and plasma and serum (Kaliste-Korhonen et al., 1996; Chanda et al., 2002). The lung CarbE are associated with alveolar macrophages (Munger et al., 1991). Further, CarbE are present in human tissues and organs, where exposure to nerve agent vapors would likely first occur (nasal tissues and the lung), would be distributed (erythrocytes, monocytes, plasma), and would generate effects (brain, stomach, colon, etc.). Chanda et al. (2002) indicated that full characterization of the OP-protective capabilities of CarbE requires assessment not only of the amount but also of the affinity exhibited by CarbE for the inhibitor as well as the total CarbE activity unlikely to be inhibited. The detoxification potential of CarbE is apparently complex and is an area requiring further studies.

CarbEs are proteins of molecular weight between 47 and 65 kDa that can be found in microsomal fractions of many mammalian tissues (Satoh and Hosokawa, 1998). CarbEs are synthesized in liver and secreted into plasma (via the Golgi apparatus), where they are present in soluble form. Their physicochemical and immunological properties and the sequence of amino acids are very similar, whereas their specificity toward various substrates is different (Hosokawa et al., 1995; Satoh and Hosokawa, 1998). CarbE belongs to the group of esterases with serine at its active site that hydrolyze esters of carboxylic acids in a biphasic reaction. In the first phase, carboxylic ester acylates hydroxyl group of serine at the active site, and in the second phase serine is deacylated in the presence of water (Augustinsson, 1958). The active site of CarbE comprises a peptide isoleucine-phenylalanine-glycine-histidine-serine-methionine-glycine-glycine, with serine and histidine directly participating in biochemical reactions. Physiological substrate for CarbE is probably *O*-acetyl sialic acid (Satoh and Hosokawa, 1998). CarbE can be differentiated from other serine esterases such as AChE (EC 3.1.1.7) and ChE (EC 3.1.1.8) in that AChE and ChE react with positively charged esters (ACh and butyrylcholine, respectively) and can be inhibited with carbamates, whereas CarbE does not react with positively charged esters and inhibition with carbamates occurs only at high concentrations (Gupta and Kadel, 1989). Inhibition of CarbE does not cause any known toxic effects.

The Relationship Between CarbE Activity and Toxicity of WNAs

Several studies have shown that triorthocresyl phosphate (TOCP) and its active metabolite CBDP (2-/*O*-cresyl/-4H-1:3:2-benzodioxaphosphorin oxide) (specific irreversible inhibitor of CarbE and weak

anticholinesterase agent) potentiate toxicity of soman, sarin, and tabun (Bošković, 1978; Clement, 1984; Jokanović, 1989), but not of VX agent (Bošković, 1978), probably because VX in physiological conditions is positively charged and a weak inhibitor of CarbE (Maxwell, 1992). Bošković (1978) found that pretreatment of mice with CBDP increased the subcutaneous toxicity of soman by 19.1-fold, and increased its intraperitoneal toxicity by 17.8-fold. For other nerve agents, he observed an increase of subcutaneous toxicity of sarin, tabun, and VX by 11-fold, 5-fold, and 0.24-fold, respectively. Clement (1984) observed that potentiation of soman toxicity in mice after previous administration of TOCP or CBDP was directly related to plasma CarbE and not to activity of CarbE in liver and other tissues. This effect of TOCP and CBDP was explained by phosphorylation of active sites at CarbE that occupies the binding sites for other OPs increasing their concentration in circulation and therefore their acute toxicity (Jokanović, 2001, 2009). Binding of soman to CarbE in rodents occurs specifically with the most toxic stereoisomer of the agent (Cashman et al., 1996).

The detoxification potential of endogenous CarbE to protect against the lethal effects of WNA exposure was tested by Maxwell (1992), who observed that a wide range in potentiation of toxicity of different OPs *in vivo* cannot be correlated with reactivity of these compounds toward CarbE, showing that soman toxicity in rats with inhibited CarbE was potentiated by sixfold, respectively, despite their similar inhibitory power for CarbE. It was concluded that detoxification of OP via CarbE is very important for highly toxic OPs, such as soman, sarin, tabun, and paraoxon with LD_{50} of <2 μmol/kg, whereas it is less important for less toxic OPs such as DFP (LD_{50} = 9.75 μmol/kg) and dichlorvos (LD_{50} = 98.4 μmol/kg). Keeping in mind that relatively higher concentrations of OP insecticides have to be achieved in circulation and tissues to exert toxicity, dominant factors in detoxification of less toxic OPs are A-esterases because their catalytic activity is proportional to substrate concentration and their K_m value is in the millimolar range (Jokanović, 2009).

Contrary to these findings of decreased CarbE activity increasing toxicity of many OPs, there are also data showing that increased CarbE activity can decrease toxicity of OPs. CarbE activity can be increased by approximately 80% after repeated administration of phenobarbital to rats and mice by mechanism of enzyme induction, which caused a decrease in soman and tabun toxicity by twofold, whereas toxicity of sarin was not affected, probably because plasma CarbE inhibited with sarin spontaneously reactivate very rapidly *in vitro* and *in vivo* with the half-times of 18 and 120 min, respectively (Bošković et al., 1984; Clement, 1984; Jokanović, 1989, 2009; Jokanović et al., 1996).

Various OPs inhibit both CarbE and AChE at similar concentrations ranging from 1 to 1000 nmol/L. CBDP, dichlorvos, DFP, and paraoxon show higher affinity toward CarbE *in vitro* and, as a result, their acute toxicity is lower in contrast to highly toxic OPs soman and sarin that have four- to six-times higher affinity for AChE. This relationship was confirmed *in vivo* after administration of 0.9 × LD_{50} of these compounds (Maxwell, 1992). Rat plasma CarbE appears to be more sensitive for soman and sarin than CarbE in rat liver and brain, and can be completely inhibited at sublethal doses. Significant inhibition of CarbE in liver can be obtained only at multiple lethal doses (Bošković et al., 1984). Even when two-thirds of rat liver was removed by partial hepatectomy, 5 × LD_{50} of soman was not sufficient to achieve significant inhibition of rat liver CarbE (Jokanović, 1990). Somani et al. (1992) found that interspecies variation in response to some nerve agents may be largely due to CarbE binding.

In the study of mechanism of interaction of CarbE with some OPs *in vitro*, it was found that this reaction is not irreversible, but rather reversible because of rapid spontaneous reactivation of inhibited CarbE (Jokanović et al., 1996; Jokanović, 2001, 2009). The highest rate of spontaneous reactivation was obtained for plasma CarbE inhibited with sarin and the half-time of reactivation was 18 min. These results were also confirmed in experiments *in vivo* in which rats were treated with 0.5 × LD_{50} of soman, sarin, and dichlorvos (Jokanović et al., 1996). Calculated half-times of reactivation for plasma CarbE of the rats treated with 0.5 × LD_{50} of dichlorvos, sarin, and soman were 1.2, 2.0, and 2.7 h, respectively. Similar results were reported by Gupta et al. (1987a), who found 50% of spontaneous reactivation of plasma CarbE 24 h after poisoning of rats with 100 μg/kg soman. Gupta et al. (1987b) also reported 94% of reactivation of plasma CarbE in rats treated with 200 μg/kg tabun, but 7 days after poisoning. Spontaneous reactivation of CarbE hydrolyzing phenyl valerate inhibited with paraoxon *in vitro* was observed by Barril et al. (1999).

The Role of CarbE in Detoxification of OP

CarbE participate in detoxification in three different ways. The first is hydrolysis of ester bonds in OP that contain them, such as malathion (WHO, 1986; Fukuto, 1990). The second is binding of OP to CarbE and other proteins that decrease the concentration of free OP in circulation that can react with AChE in vital tissues (Clement, 1984; Jokanović, 1989). The third role is related to all OPs that can phosphorylate CarbE by binding to serine hydroxyl group at its active site (Jokanović et al., 1996; Jokanović, 2001, 2009). During spontaneous reactivation, this phosphoryl residue is separated from the enzyme accepting hydroxyl group from water as its new acyl radical. This newly formed OP (i.e., organophosphoric

acid) is a much less potent (if at all) esterase inhibitor that represents a nontoxic metabolite of the parent OP. In the case of nerve agents, the corresponding metabolites that formed EDMPA (for tabun), IMPA (for sarin), and PMPA (for soman) are shown in Figure 59.1. CarbE activity recovered in this reaction can be inhibited again by other OP molecules. The active role of CarbE in this process is its involvement in metabolic transformation of OP to its nontoxic and biologically inactive metabolites. Because of rapid spontaneous reactivation of CarbE, one active site at the enzyme can metabolize several molecules of OP; this reaction does not occur according to stoichiometric ratio 1:1, which depends only on the stability of the bond between phosphorus from OP and oxygen from serine hydroxyl group. Tissues in which this "turnover" is rapid, such as plasma, has higher capacity for detoxification of OPs than expected because of catalytic activity of CarbE. This reaction can be very important under conditions of repeated (subchronic or chronic) exposure to low doses of nerve agents and other OP that could be inactivated through the reaction with CarbE without any apparent toxic effect.

The role of CarbE as a bioscavanger involved in detoxification of nerve agents and other OPs was investigated. The ideal OP bioscavanger would have a fast rate of reactivity for a broad range of OP compounds, a slow rate of aging, and the ability to reactivate to increase its stoichiometry as a bioscavanger. Evaluation of CarbE on these criteria suggests that it is an important candidate as an OP bioscavanger (Doctor et al., 2001). One of the most important advantages of CarbE is that OP-inhibited CarbE does not undergo the rapid aging that prevents oxime-induced reactivation of OP-inhibited ChEs. This means that OP-inhibited CarbE can be reactivated, yielding an active enzyme involved in further metabolism of OP molecules and an inactive OP metabolite.

Another advantage of CarbE is the much greater size of its active site compared with those of AChE (10-fold difference) and ChE (6-fold difference) (Saxena et al., 1999). The large active site volume of CarbE minimizes steric hindrance effects at the active site and maximizes the potential for reactivation. In a study investigating the structural specificity of AChE, ChE, and CarbE, Maxwell et al. (1998) found that AChE could accommodate OP inhibitors containing only one bulky group (e.g., isopropyl, pinacolyl, phenyl), ChE could accommodate OP inhibitors containing two of the smaller bulky groups (like isopropyl), and the active site of CarbE was sufficiently large to accommodate up to two of the largest bulky groups (e.g., phenyl groups). Therefore, CarbE had the ability to metabolize the broad spectrum of OP inhibitors. The only exception to this observation is, because of fewer aromatic residues in the active site of CarbE in comparison with ChE, reduced affinity of CarbE for positively charged OP inhibitors (such as VX), and this effect apparently has little importance for nerve agents (except VX) and OP pesticides because a few of them are positively charged (Doctor et al., 2001).

Prolidase (EC 3.4.13.9)

There are data in the literature showing that prolidase (EC 3.4.13.9), a naturally occurring enzyme of mammalian and bacterial origin, is involved in hydrolysis of G-type nerve agents. Recombinant HuPON1 and DFPase showed 10-fold lower activity toward sarin compared with recombinant human prolidase (Cheng et al., 1999; diTargiani et al., 2010; Nachon et al., 2013). Constante et al. (2012) reported that partially purified human liver prolidase hydrolyzed DFP and various nerve agents, whereas skin and kidney prolidase presented significantly lower activity against soman, tabun, and VX. Biochemical characteristics of prolidase purified from human erythrocytes, liver, kidney, and fibroblast cells are well-known. However, OP hydrolyzing activity of prolidase is still not well-understood (Wang et al., 2006; diTargiani et al., 2010; Chandrasekaran et al., 2013).

Human prolidase is a 54-kDa binuclear Mn^{+2}-dependent enzyme that breaks the amide bond in dipeptides containing proline or hydroxyproline as the C-terminal amino acid. It plays a crucial role in the recycling of proline. Prolidase is found in most tissues and in several animal species. Deficiency of this enzyme in humans results in a syndrome with a highly variable clinical phenotype, such as chronic recurrent infections, mental retardation, splenomegaly, skin lesion, and the excretion of massive amounts of iminopeptides in urine (Wang et al., 2006; Chandrasekaran et al., 2013).

PROTEIN BINDING

Proteins are amphoteric structures containing anionic and cationic reactive sites. Proteins can also participate in other interactions with xenobiotics through formation of hydrogen bonds, polarity, and electrostatic and van der Waals forces. Many xenobiotics can bind to proteins from blood such as albumin and B-esterases. Easy binding to proteins occurs with substances that are ionized at a physiological pH and those soluble in lipids such as OP. After binding of OP to proteins such as CarbE, ChE, AChE, and other macromolecules, these agents are metabolized because their acyl radical is released and phosphoryl residue remains bound to proteins. This unspecific binding of OP to blood proteins decreases OP concentration in circulation and tissues preserving AChE activity at target sites (Jokanović, 2009). Binding of OP to proteins can be limited by steric hindrance, a protein conformation factor that does not allow OP molecules to access all binding sites at the protein. The involvement of secondary noncholinergic targets (neuropathy target

esterase, fatty acid amide hydrolase, arylformamidase, acylpeptide hydrolase, and other macromolecules) in OP toxicity was reviewed by Casida and Quistad (2004).

Albumin is the most abundant protein found in plasma and has a half-life of approximately 20 days. It is a 67-kDa multifunctional monomer synthesized and secreted by the liver. Albumin has esterase-like and aryl acylamidase activities, but it does not have a catalytic active site serine (Marsillach et al., 2013). The high concentration of albumin in plasma (30–60 g/L) may balance the poor reactivity of this protein with OPs (Jokanović, 2009).

Williams et al. (2007) found that sarin, soman, cyclosarin, and tabun phosphylate a tyrosine residue on albumin in human blood. The tyrosine adducts with soman and tabun were detected in guinea pigs receiving therapy 7 days after subcutaneous administration of 5 × LD_{50} of the respective nerve agent. Bao et al. (2012) reported formation of soman, sarin, and VX adducts with the tyrosine residue of albumin when rats were exposed to sublethal doses of the nerve agents. In blood samples taken from marmosets treated with sarin, soman, cyclosarin, or tabun; tyrosine adducts were detected after 23 or 24 days (Read et al., 2010). Li et al. (2008) have shown that soman covalently binds to albumin at tyrosine 411 and that the adduct was stable ($t_{½}$ = 20 days). However, although the concentration of albumin in plasma is very high, its reactivity with soman was apparently too slow to play a major role in detoxification of the agent. The authors concluded that soman–albumin adducts could be useful for the diagnosis of soman exposure. In addition, when OP pesticides covalently bound to albumin, the adduct was stable for more than 7 days (Tarhoni et al., 2008).

Tyrosine adducts were found in guinea pigs and marmosets poisoned with sarin, soman, cyclosarin, and tabun. VX, which is less reactive than other WNAs, formed an adduct in human plasma *in vitro* only at high concentrations (Williams et al., 2007; Black, 2010; Black and Read, 2013). Tyrosine adducts were less sensitive than ChE as biomarkers with respect to exposure levels but were more stable and did not undergo an aging reaction such as OP binding to serine esterases (Read et al., 2010). However, albumin might have a larger capacity for OP binding compared with ChE and other esterases.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

After more than four decades of research of biotransformation of nerve agents soman, sarin, tabun, and VX, it can be concluded that several enzymes have a significant role in this process. Enzymes capable of hydrolyzing these agents (A-esterase, PON1) were very efficient in the breakdown of the bond between phosphorus and acyl radical, and their activity was proportional to substrate concentration. Esterases such as ChEs and carboxylesterases act by binding of OP molecules to the hydroxyl group placed in their active site, decreasing free concentration of the agents in blood, thus preventing inhibition of AChE at target sites and, subsequently, their toxic effects. In addition, binding of OP to CarbEs is reversible, indicating an active role of the enzyme in metabolic detoxification of nerve agents and other OPs. The importance of prolidase is still unclear and requires further studies. It is necessary to further investigate the role of these enzymes and other macromolecules in detoxification of OP compounds. Important issues for further research in this field should be related to the assessment of detoxification potential of carboxylesterases, the significance of A-esterase polymorphism on the capacity of detoxification, and their possible application in prophylaxis and treatment of OP poisoning in humans.

On-Site Detection of Chemical Warfare Agents

Yasuo Seto

INTRODUCTION

Chemical warfare agents (CWAs) were employed in World War I and World War II and during the Cold War, and they continue to be produced and stockpiled even today (Somani, 1992; Gupta, 2009). In the 1980s, Iraq used sarin (GB) and mustard gas (HD) in the Iran–Iraq conflict (Black et al., 1994). In 1992, the Chemical Weapons Convention (CWC), a treaty prohibiting the development, production, stockpiling, and use of chemical weapons and mandating their destruction was ratified, and it came into force in 1997 (Organization for the Prohibition of Chemical Weapons, 2014). However, in the interim, the Japanese doomsday cult group Aum Shinrikyo deployed sarin in the Japanese city of Matsumoto in 1994, and then, more infamously, in the Tokyo subway system in 1995. In both these attacks, many defenseless people were poisoned, some fatally (National Police Agency, 1996; Seto et al., 2000). The Tokyo subway sarin gas attack and the more recent US postal anthrax letter attacks in 2001 (Inglesby et al., 2002) presented a renewed threat of chemical and biological terrorism globally. To realize a safe and secure society, it is highly recommended that authorities at the national levels establish a more strengthened crisis management system for civil defense (Seto, 2006a).

In addition to the known attacks, various CWA stockpiles have been discovered in former Japanese military force facilities during land excavations (Ohashi, 2004). Injuries due to direct contact with CWAs that leaked from containers in Samukawa, Japan, have been reported (Hanaoka, 2004), and some complaints were received in Kamisu, Japan, concerning damage to human health (neurological disorders) caused by drinking water likely contaminated with degradation products from arsenic vomiting agents (Ishii et al., 2004).

In the crisis management of chemical warfare terrorism cases (Society for Countermeasures against Chemical, Biological, Radiological, Nuclear and Explosive Terrorism, 2008) and chemical weapon disposal, CWAs were monitored in public places, security checks at territorial borders, airports, large event venues, executive facilities, and demilitarization spots housing chemical weapons for protection against terrorism and workers' health. With regard to consequence management, on-site detection is initially performed by first responders for personal protection; on-site samples are then transported to laboratories for analysis for investigation and for identification of emergency lifesaving measures. In incident management, laboratory analysis is performed to provide evidence for courts in order to prosecute offenders and prevent future crimes (Figure 60.1). Among these detection schemes, rapid on-site detection is the most important for the minimization of disasters in order to eliminate the prolonged times required for transporting on-site sample specimens to a laboratory for analysis (Harris, 2002; Smith, 2002; Fittch et al., 2003). Various types of measuring technologies have been used for on-site detection and laboratory identification of CWAs and are discussed here.

PROPERTIES OF CWAs

CWAs are low-molecular-weight synthetic compounds that are fast-acting and sometimes lethal, even at low levels (Somani, 1992; Stewart and Sullivan, 1992; Marrs et al., 1996; Ellison, 2000); in terms of physical properties, CWAs can be classified into gaseous blood agents, gaseous choking agents, volatile nerve gases, volatile blister agents, nonvolatile vomiting agents, and nonvolatile lachrymators (tear gases) (Figure 60.2).

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00060-9

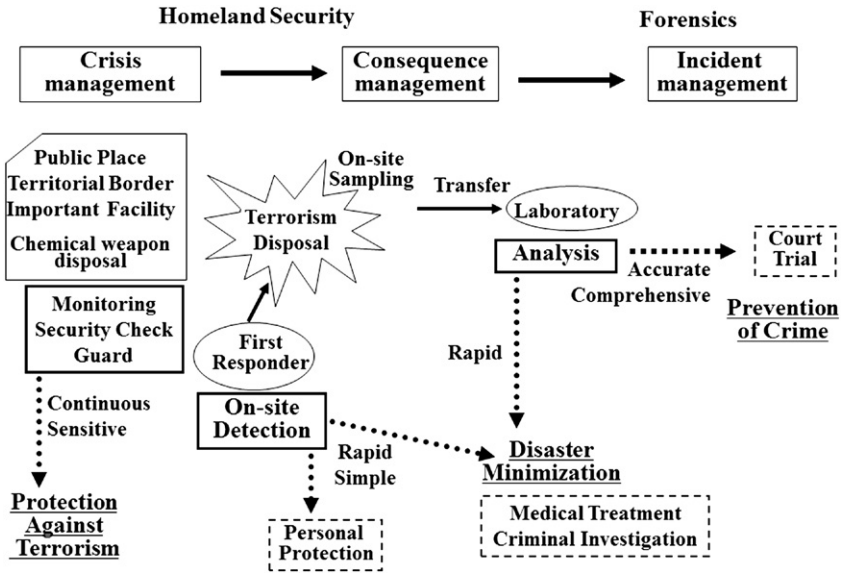

FIGURE 60.1 Detection and identification in chemical terrorism countermeasures and chemical weapon disposal.

The physical and toxicological properties of CWAs vary in many ways; namely in molecular weight, melting point, boiling point (vapor pressure), vapor density, durability in air, lethal concentration, incapacitating concentration, odor, water solubility, stability in water, effect on skin, and antidote prospects. In particular, except for slow-acting agents that manifest toxicity after several hours, such as phosgene (CG) and HD, CWAs are fast-acting. Deadly poisonous organophosphate (OP) nerve gases and toxic blister agents are registered as scheduled compounds in the CWC. Although CWAs show toxicity by skin contact and intake, inhalation toxicity against CWA vapor is mainly considered with respect to chemical warfare/terrorism cases and chemical weapon disposal, and the development of analytical technologies is conducted with the aim of CWA detection in the vapor phase. The parameter used in the description of CWA toxicity is the lethal dose value (LCt_{50}, $mg\,min/m^3$); this value indicates the vapor concentration leading to a 50% incidence of death in human beings with 1 min of inhalation.

CONCEPT OF ON-SITE DETECTION

In chemical warfare terrorism countermeasures, we must consider the dispersion of various types of CWAs, including toxic industrial compounds (TICs), except for overt cases such as previous notices of criminal acts. If clear symptoms of CWA-exposed casualties are manifest, it is possible to narrow down the types of CWAs detected. On the other hand, for chemical weapon disposal, the possible types of dispersed CWAs are obvious. In cases of exposure to CWA vapor and subsequent intoxication, monitoring technology is very important for exposure minimization and effective medical treatment. However, the requirements for the optimal performances of on-site detection technologies are not clear, with most protocols depending only on previous experience. Namely, the on-site monitoring of CWAs is quite different and an unknown field compared to other monitoring situations; therefore, not only researchers, but also first responders, have little idea of how to detect CWAs on site. Some of the required criteria for successful on-site detection are as follows: knowledge of the possible types of CWAs and their limits of alarm (LOAs), response time, time required to start the detector, recovery time after the previous alarm, accuracy (affected by interference and false positives), state of alarm, operational performance (i.e., the required technology and training), maintenance, and cost of introduction and maintenance. In addition, operational conditions, durability, and portability of necessary equipment should be considered.

For considering toxicity manifestation time and vapor dispersion situations in cases of terrorism, it is necessary to initiate the alarm for a vapor concentration of less than the vapor concentration of 1/100 of LCt_{50} within 1 min. In the case of GB, the required detection sensitivity is $1.5\,mg/m^3$; at this level, humans show few signs of intoxication, nor is there a detectable odor. In chemical weapon–disposal situations, because workers are present at the sites for a prolonged time, the time-weighted average values, which are approximately 1/100,000 of LCt_{50}, are adopted as the monitoring target for allowed operational conditions. An alarm time of less than several minutes is desired. There is a trade-off relationship between LOA, alarm time, detection accuracy,

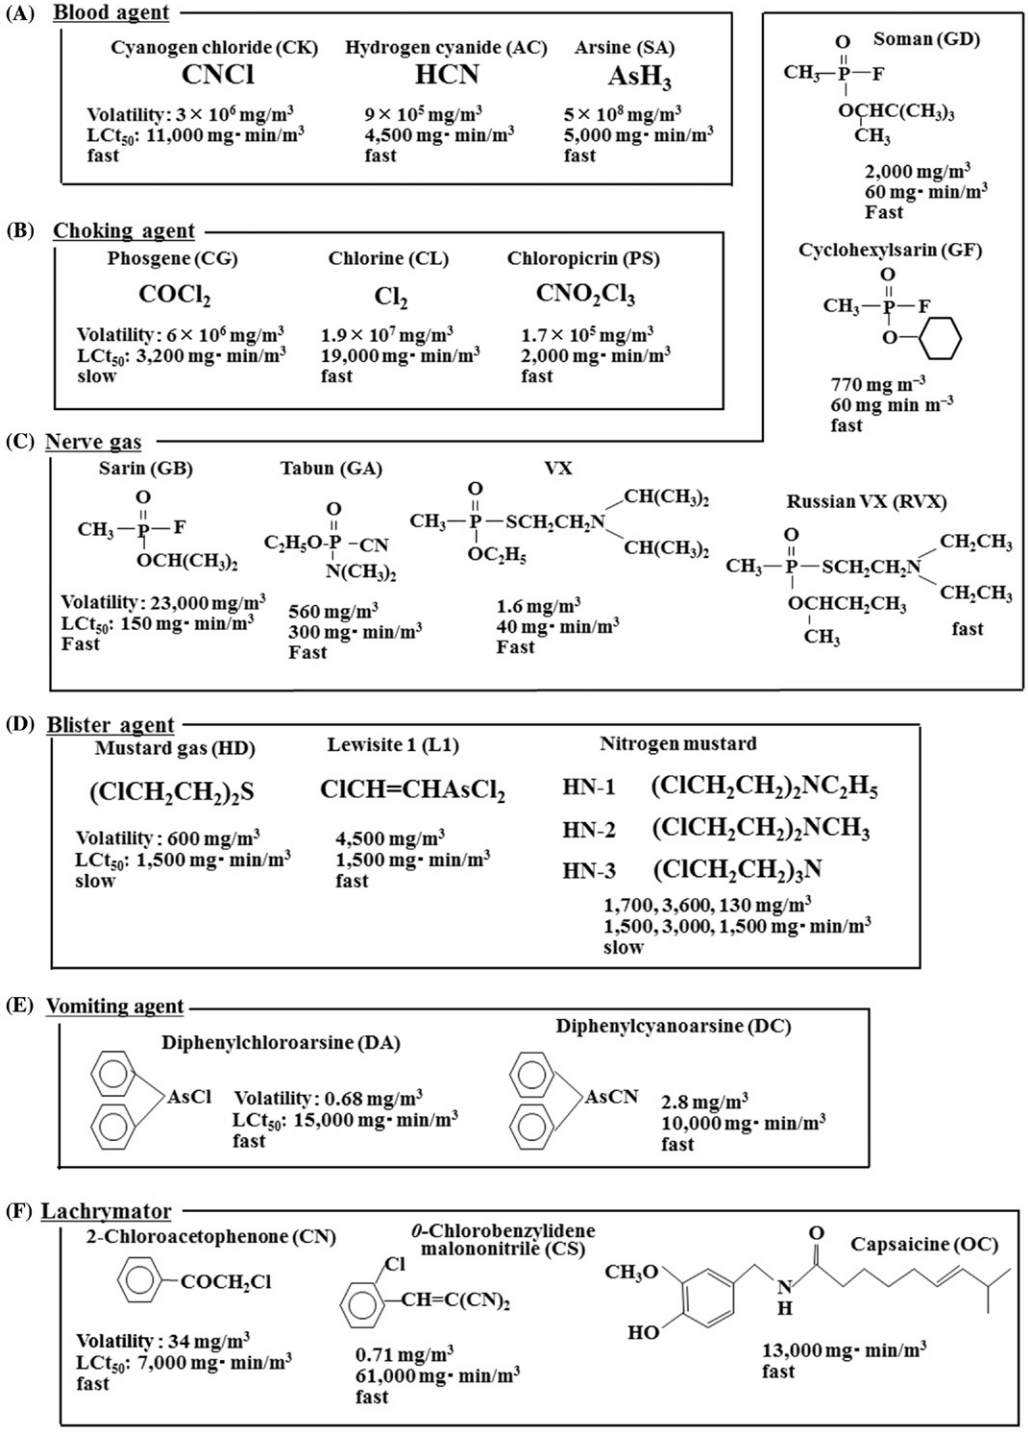

FIGURE 60.2 Chemical structures, volatility (at 25°C) and inhalation toxicity data of CWAs.

and operation; furthermore, for detection equipment employing one detection mechanism, lowering the LOA prolongs the alarm time and increases the frequency of false positives.

In previous instances for which on-site detection technology had not yet been well developed, field damage and injuries to the victims were traditionally observed and understood by using our senses; CWAs were identified through laboratory analysis and diagnostics after transferring the on-site victims' samples to specific laboratories and emergency medical hospitals. To minimize the damage caused by the terrorist activity, it is vital to obtain as much information as possible about the types and concentrations of the dispersed CWAs, which is now

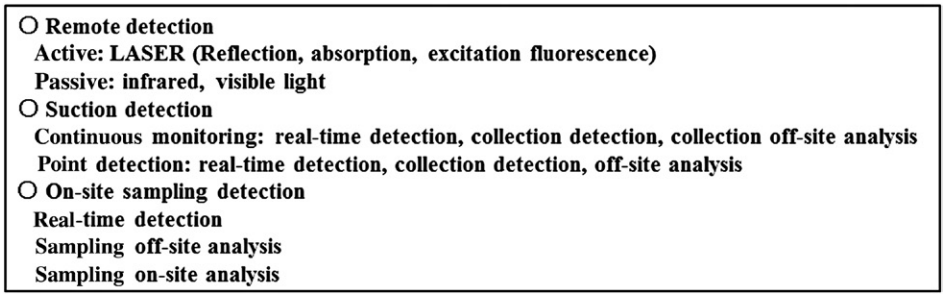

FIGURE 60.3 Concept of on-site detection for CWAs.

possible because of the development of large numbers of laboratory analytical technologies. Figure 60.3 shows the concepts in the determination of CWAs. Remote detection (stand-off detection) is the method to detect CWAs away from the dispersed site using spectroscopic technologies, and can be divided into the following two types: (i) passive detection, which refers to the detection of light emitted from the target and is mostly limited to infrared light; and (ii) active detection, which detects the secondary light (fluorescent or absorbed light—i.e., ultraviolet, visible, or infrared) emitted from the target after the sample is irradiated with primary light using equipment brought to the site, with lasers usually employed as the irradiating light source.

Because the vapor concentrations of CWAs used for terrorism are low and their toxicities are high, and because terrorism is predicted to occur at civilian locations where various types of interfering compounds exist, it is often difficult to fulfill on-site detection requirements. "Suction detection" is the method to detect CWAs by directly measuring CWAs through suction of vapors in the field, and is further divided into the following two types: (i) continuous monitoring, which involves continuous drawing of on-site air samples and detection using fixed or movable equipment; (ii) point detection, which is used to detect CWA vapor by first responders by moving portable devices into the field. In terms of CWA detection, *real-time detection* refers to the alarm signal given under the continuous drawing of air samples, while in collection detection mode, the alarm is given by detection with cycling measurements after air samples have been collected. *Collection off-site analysis* refers to CWA detection in the laboratory using collected samples transferred from the field. For solid or liquid samples and dispersed surfaces, CWAs are detected by direct contact with the detector; alternatively, they are detected by measuring the sampled or stripped specimens by inserting them into the detectors. Finally, large trailers containing mobile chemical laboratories equipped with analytical instruments are used for detection via on-site analysis.

The assessment of dangerous terrorism and chemical weapon-disposal situations by detecting fast-acting CWAs quickly at low-concentration levels must be rapid (Sidell et al., 2003). For people escaping from or arriving on the dangerous sites, injuries and casualties must be taken care of with proper emergency treatment (such as securing aeration and administering antidotes). The roles of the first responders are to install protective masks and gears and perform zoning of the dangerous sites. Field-deployability, rapid alarm capability, and ease of automated operation are most important for on-site detection, with the low frequency of false positives being a secondary requirement; however, if the frequency of false positive alarms is high during a response, it will disturb the proper and timely activities of responders at the terrorism-affected or chemical weapon–disposal sites. Various types of on-site CWA detection devices have been used by military organizations worldwide (Fittch et al., 2003), and some have been introduced for civil defense organizations such as mobile police teams, fire-defense teams, and coast guards for the purposes of counterterrorism.

CWAs can be measured by detecting the chemical constituent; the technologies for chemical detection can adopt different mechanisms depending on the target substances (Paddle, 1996). The discrimination level varies between the screening and identification methods. At present, most field equipment utilizes detection paper, gas detection tubes, ion mobility spectrometry (IMS), flame photometric detection (FPD), photoionization detection (PID), surface acoustic wave (SAW) detection, Fourier transform/infrared spectrometry (FT/IR), gas chromatography (GC), mass spectrometry (MS), or combined GC-MS technologies. Furthermore, chemical sensors, biosensors, and micro total analysis systems (μTAS) have been extensively developed. Except for highly discriminating technologies such as chromatographic or spectrometric measurements, many detectors signal an alarm only for restricted chemical species. The representative species are (as previously described) nerve gases (nerve agent), blister agents, blood agents,

including gaseous choking agents, and TICs. Vomiting agents and lachrymators are not considered because of the mechanical impossibility for detecting such nonvolatile agents and their low toxicity. Nerve gas is the most preferred target, followed by blister and blood agents. So far, CWA detection technology has been developed and utilized for deployment during military missions; thus, it is not guaranteed that such on-site equipment would work properly for real CWAs in civil defense. Considering the present situation of developed terrorism countermeasures and on-site needs, greater emphasis should be placed on the scientific development of on-site detection technology. Several research groups are engaged in the evaluation of commercially available detection equipment and are presently developing new detection technologies. Our laboratory has evaluated some commercially available detection equipment using authentic CWAs. In the following section, the evaluation results obtained in the author's laboratory are discussed (Seto et al., 2005, 2007; Seto, 2006a,b; 2014).

THE CURRRENT SITUATION OF DETECTION TECHNOLOGY

With regard to remote detection technology, passive methods for spectrophotometric measurements of CWA emission (specifically infrared light and the corresponding devices) are partially utilized in military applications. These machines can instantaneously and continuously detect the CWA vapor; however, because of background interference, practical utilization by civilian means is still a far-off prospect. The active method of measuring the reflected light from laser irradiation provides higher sensitivity than the passive method; however, the equipment for this technique is too large (on the ton scale). RAPID (Bruker Corporation, 2014) is a typical detection machine manufactured by Bruker Daltonics (Bremen, Germany). The discriminating capability with respect to analysis of the obtained spectra is significantly raised using this device; furthermore, in addition to ultraviolet, visible, and infrared light, a wide range of other light wavelengths such as milliwave and terahertz light can be detected, apart from laser excitation and Raman scattering.

Classical Manual Method

The classical manual detection tools still in use are detection paper, and gas detection tubes, which can detect the presence of CWAs by visualizing the color changes manifested by the reaction between the reagents and CWAs. Detection paper shows an instant color change in the presence of liquid forms of CWAs with a sensitivity of several $\mu g/cm^2$ (Toyobo, Japan; M8 and M9 paper, US military). Two types of pigments and pH indicators are impregnated in the cellulose paper; the paper turns brown or orange on the addition of a droplet of sarin (GB), soman (GD), or tabun (GA) (G agents in the North Atlantic Treaty Organization (NATO) code); turns red when exposed to a droplet of HD or Lewisite 1 (L1) (H agents); and turns to black or deep green with VX (a V agent). This color reaction is based on the solubility of the agents in organic solvent; thus, almost all organic solvents except water would show a false positive. Dimethyl methylphosphonate, acetone, toluene, and ethyl acetate show a false positive for G agents; 2-mercaptoethanol, carbon tetrachloride, and aniline show a false positive for H agents; and diethylamine shows a false positive for V agents. Because of the high probability of false positives, detection paper seems impractical for civilian defense (Seto et al., 2005).

Gas detection tubes show a color change with vapor CWAs with a sensitivity close to mg/m^3 concentration levels. The specific reagents are impregnated into a silica-gel support in the glass tube. When needed, both sides of the tube are opened by a cutter, the appropriate air sample volume is drawn, and the extent or length of coloring is checked by the naked eye. Commercial industrial-use gas detection tubes (Komyo Kika; Gastec, Japan) are available for the detection of blood and choking agents. However, for special agents such as nerve gases, the Dräger Safety gas detection tube (in Germany) is adequate (Takayama et al., 2007).

For nerve gases, the phosphoric acid ester tube shows a red color, which is based on a sequence of complicated procedures involving butyrylcholinesterase inhibition, substrate butyrylcholine hydrolysis, and pH indication. Positive results are shown for cholinesterase inhibitors. For HD, the thioether tube exhibits a yellow color, which is based on the reaction with silver chloride and chloramines. HD stimulants show false positives. For L1, the arsine and organic arsenicals tube shows a black color; a sequential procedure involving two types of chemical reactions allows the separate detection of both inorganic and organic arsenicals and, based on the reduction by zinc and hydrochloride and subsequent complex formation with gold and mercury, yields a gold-colored colloid. For nitrogen mustard 1 (HN 1), nitrogen mustard 2 (HN 2), and nitrogen mustard 3 (HN 3), the organic alkaline nitrogen compounds tube shows an orange-red color, which is based on the Dragendorf reaction. For hydrogen cyanide (AC), the hydrogen cyanide tube shows a pink color, which is based on oxidation by mercury chloride and subsequent pH indication. For cyanogen chloride (CK), the cyanogen chloride tube also shows a pink color, which is based on the reaction with pyridine and barbituric acid. For CG, the phosgene tube shows a blue-green color, which is based on the chemical reaction with *p*-dimethylbenzaldehyde/*N*,*N*-dimethylaniline. For chlorine (CL), the chlorine tube shows

TABLE 60.1 Detection Performance of Dräger Gas Detection Tubes

Gas Detection Tube	Agent	Limit of Alarm (mg/m^3)	Response Time (min)	Remark
Phosphoric acid ester	Sarin	0.002	5–6	
	Soman	0.02	5–6	
	Tabun	0.5	5–6	
	VX	2	5–6	
	Dichlorvos			False positive at $1\,mg/m^3$
	Methomyl			False positive at $50\,mg/m^3$

an orange color, which is based on a chemical reaction with *o*-tolidine. The LOA (i.e., the minimum concentration giving three positive results within three trials), response time, and interference of the stimulants and solvents are shown in Table 60.1. The operation involves a complicated procedure of breaking the inner liquid tube and subsequent incubation in a number of detection tubes. However, the procedure is quite tedious when employing protective gear and gloves, requiring several minutes from the start of the operation until tube coloration is observed. The gas detection tube is recommended as a supplemental means for ascertainment of CWA species after IMS screening.

Photometric Method

The photometric type of detection is based on the photometric or electronic response manifested by the physical-chemical reaction of CWAs. The flame photometric detector (FPD) instrument detects CWAs by measuring the specific phosphorus or sulfur emission line produced via combustion with hydrogen gas. AP2C (PROENGIN, 2014) is a handy portable automated FPD manufactured by Proengin (France). This detector responds rapidly to both vapor and liquid forms of phosphorus containing CWAs in the GV mode and of sulfur-containing CWAs in the H mode. Approximate concentration levels of 0.1 and $1\,mg/m^3$ for nerve gases and HD are detected in the GV and H modes, respectively (Seto et al., 2005, 2007). The simulants containing phosphorus or sulfur show false positivity, and CWAs containing neither phosphorus nor sulfur are not detected. The flame ionization detection (FID) instrument such as MicroFID II (INFICON, 2014a) detects nonspecific combustible CWAs by measuring ion production manifested by combustion with hydrogen; the LOA of this method is at sub-mg/m^3 levels

of vapor concentrations. The PID instrument detects numerous types of CWAs in a nonspecific fashion, which is based on the measurement of the produced ion current of charged gas ions by irradiation with ultraviolet light. RAE Systems (San Jose, CA) manufactures the ppbRAE VOC gas monitor, which has an LOA on the level of several tens of mg/m^3 (Seto et al., 2007; RAE Systems, 2014).

Chemical sensor technology adopting acoustic waves (Harris, 2002) is also available for CWA on-site detection. The CWAs are adsorbed reversibly onto the arrayed cells of the specific liquid phase polymer, and the acoustic wave numbers change according to the mass increase due to CWA adsorption. CWAs can be detected and discriminated by analyzing the respective wave number changes (Harris, 2003; Grate, 2000); discriminating power is increased by increasing the number of polymer cells. Portable detectors adopting arrayed SAW devices are commercially available. ChemSentry, manufactured by BAE Systems (London), adopts 10 different polymer cells and identifies CWAs as "NERV" for nerve agents, "BL" for blister agents, and "BLOOD" for blood and choking agents. As shown in Tables 60.2 and 60.3 (Matsushita et al., 2005), the LOA is rather high, the response and recovery time is long, and the number of false positives is high. This chemo-adsorptive sensor technology provides the possibility of increased discrimination by adopting arrayed cells, but because of the strong adsorption of CWAs, disturbs quick and reversible binding on the polymer arrays.

IMS Method

The IMS instrument is most frequently used for military and civil defense missions to detect not only CWAs, but also explosives and illicit drugs (Cottingham, 2003; Eiceman and Stone, 2004; Eiceman and Karpas, 2005). The drawn air sample is ionized by a β emitter or through corona discharge under atmospheric pressure, and the ionized water-cluster molecules (reactant ion peak) react with CWA molecules in the reaction region. The generated cluster ions (positive or negative) periodically traverse through the drift region and are detected on the collector. The ion mobility depends on their charge and molecular mass over cycles of several milliseconds (Figure 60.4). CWAs are recognized according to ion mobility of the resulting peak or peaks, and semiquantified according to the ion peak height (St. Louis and Hill, 1990). In the positive ion mode, a protonated water cluster possibly combines with the targets; in the negative ion mode, a water and carbon dioxide cluster attached to oxygen possibly combines with the targets, and ammonia or organic solvents are introduced as dopants (Puton et al., 2008) into the drift region, which raises sensitivity and discriminating power. Easily ionizable nerve gases show high sensitivity, while weakly ionizable blister agents do not. Low-molecular-weight blood and choking agents do not produce characteristic cluster ions; therefore, detection sensitivity is low. Because of atmospheric pressure ionization, the devices are manufactured to be rather compact, and their response times are fast. However, the resolution of the produced target ions is low compared to MS, leading to frequent false positives by many types of compounds. To raise the sensitivity and accuracy, the ionization mechanism has been improved by using electrospray, laser desorption, matrix-assisted laser desorption, and the development of new hardware (Cottingham, 2003; Kolakowski and Mester, 2007). Field-portable instruments based on high-field asymmetric-waveform IMS and differential mobility spectrometry (Guevremont, 2004) are now commercially available (Chemring Detection Systems, 2014).

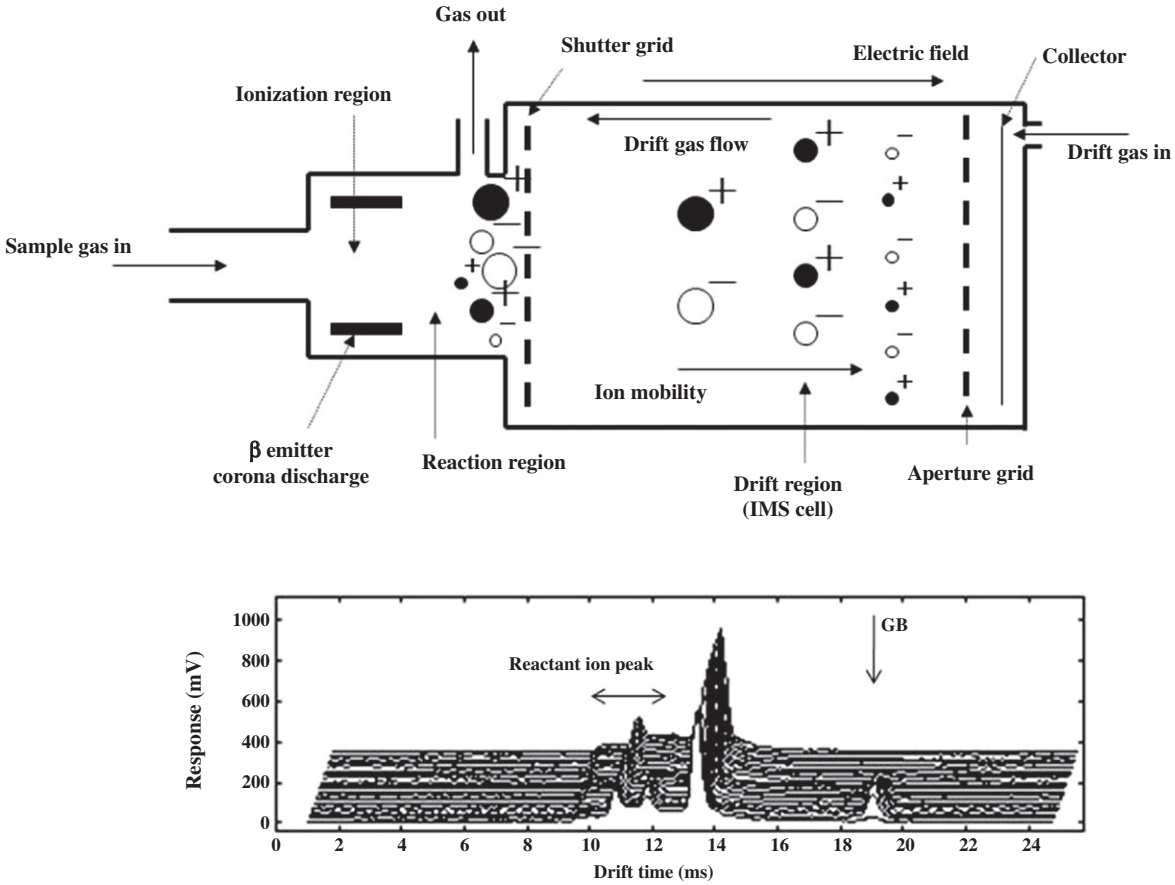

FIGURE 60.4 Ion mobility spectrometry. Detection mechanism and an exemplified spectrum. SABRE4000 (Smiths Detections Ltd, ionization ^{63}N) detected GB.

An aspiration-type device is based on discrimination by the pattern recognition of several IMS cells of different ion mobilities and polarities (Utriainen et al., 2003; Zimmermann et al., 2007). Environics Oy (Mikkeli, Finland) manufactures two types of IMS detectors. M90 (type D1-C), an aspiration-type 160 μCi ^{241}Am-bearing IMS, adopting six IMS cells and one semiconductor cell (Environics Oy, 2014), provides vapor detection of GB, GD, GA, and GF (LOA: sub-mg/m^3) as a NERVE mode alarm with a false-positive alarm against vapors of phosphorus stimulants such as dimethyl methylphosphonate. HD, L1, and HN 3 vapors (LOA: several mg/m^3) cause a BLISTER mode alarm; however, HD stimulants such as 2-chloroethyl ethyl sulfide vapor also cause a false positive alarm. AC or CK gas shows a false BLISTER alarm. CG and CL cause a BLOOD mode alarm. As shown in Tables 60.4 and 60.5, the LOA is rather low for volatile CWAs and high for gaseous CWAs, the response and recovery time is short, and the frequency of false positives is moderate (Kishi et al., 2010). The second, an aspiration-type IMS called ChemPro100 (version 6.2.5), from the same Finnish company, adopts 16 IMS cells and 1 semiconductor cell (Zimmermann et al., 2008), providing similar recognition (Maruko et al., 2006).

LCD-3.2E (Smiths Detection, 2014a), a corona discharge-type short drift tube IMS instrument, developed by Smiths Detection (London), is a useful detector showing two types of alarm: "G," for nerve gases, and H for other CWAs. Tables 60.6 and 60.7 (Sekioka et al., 2007) show the LOA, response and recovery times, and interference toward CWAs. The advanced version (LCD 3.3) provides an agent-name alarm. This instrument adapts an ammonia dopant, raising sensitivity and discriminating power. Maintenance requires that the sieve pack be frequently exchanged for proper operation. SABRE 4000, also manufactured by Smiths Detection, is a long-drift tube (high-resolution) IMS providing an agent-name alarm. As shown in Tables 60.8 and 60.9, the LOA is rather low, the response and recovery time is short, and the frequency of false positives is low (Yamaguchi et al., 2010). AIRSENSE (Schwerin, Germany) manufactures GDA2, a multisensor system consisting of an IMS, a semiconductor, a metal oxide, and a PID, enabling identification and quantification of not only CWAs, but also TICs (AIRSENSE Analytics, 2014).

Fourier Transform/Infrared Spectrometry

The FT/IR instrument detects and identifies CWAs by noninvasively and instantly measuring the infrared spectrum of the air sample (Mukhopadhyay, 2004). Considering the interference of water and carbon dioxide, their characteristic absorbance peaks in the low-wave number region are used as a specific marker. Portable FT-IR equipment is commercially available. IGA-1700 (Otsuka Electronics, Osaka, Japan) and DX-4000 (Temet, Helsinki, Finland) (Gasmet Technologies Oy, 2014) show HD ($1{,}200\,cm^{-1}$) and GB ($1{,}000\,cm^{-1}$) detection with a limit of detection (LOD) of $10\,mg/m^3$ after subtracting background water and carbon dioxide absorptions. VIR-9500 (Japan Spectroscopy Co., Tokyo) (JASCO Corporation, 2014) shows L1 detection with an LOD ($815\,cm^{-1}$) of $2\,mg/m^3$ using an 8-m light path gas cell.

Smiths Detection provides a portable FT-IR instrument, HazMatID (Smiths Detection, 2014b), which uses a diamond sensor and an extended onboard spectral library containing spectra for many organic compounds, including CWAs and suspected white powder materials. A handful of Raman spectrometer instruments are commercially available, including First Defender (Thermo Scientific, 2014) and Xantus-2 (Rigaku Corporation, 2014), which allows the quick identification of unknown solid and liquid chemicals from a vast sample library, including explosives, TICs, CWAs, white powders, and narcotics.

Gas Chromatography

The GC instrument detects CWAs by measuring the peak response appearing on the GC column (Makas and Troshkov, 2004). CWAs are distinguished on the basis of retention time and their detectability by specific detection devices (Henry, 1997). Combined with an automated air collection–thermal desorption system, GC provides a very sensitive detection (lower than $\mu g/m^3$) of nerve gases and blister agents over a 10 min cycle. O. I. Analytical, (College Station, TX), manufactures the movable GC-based MINICAMS (O.I. Analytical, 2014). GC can be hyphenated with other detection systems such as SAW (Williams and Pappas, 1999) and IMS (Buryakov, 2004; GAS, 2014), enabling it to be used to detect CWAs while having a compact body and field portability.

Mass Spectrometry

By miniaturizing the laboratory-type MS instrument and making it portable and resistant to mechanical shock, the machine can be used to detect CWAs in the field (Wise and Guerin, 1997; Smith et al., 2011a). MS provides high-resolution power, but to maintain a vacuum, the device must be large, complicating its operation. Electron ionization is usually used because of the benefit of abundant mass spectra data libraries availability (Virkki et al., 1995). On-site MS adopts a hydrophobic membrane inlet system to eliminate oxygen and nitrogen from the ionization region. The adsorbed CWAs are next introduced to the ionization region. The small molecules and strong adsorptive compounds cannot be detected by this ionization-type MS. A field-portable MS device, which has been developed for environmental TIC measurement (Horiba, Kyoto, Japan) and adopts a time-of-flight mass analyzer and pattern recognition data analysis, detects high vapor levels of GB and HD. The Riken group (Wako, Japan) and the author have developed an elemental analytical system using an electron cyclotron resonance ion source MS to detect CWAs. Phosphorus ions, chloride ions, and hydrogen cyanide fragment ions can be monitored to selectively detect nerve gases, chloride-containing CWAs, and AC and CK, respectively (Kidera et al., 2011; Urabe et al., 2014).

GC-MS technology can also be downsized for field use and is now commercially available. Inficon (East Syracuse, New York) manufactures Hapsite, a field-portable GC-MS instrument (INFICON, 2014b). Vapor is withdrawn for 30 s into the Tenax preconcentration system and thermally desorbed into a nonpolar capillary column with an elevated temperature control; the separated components are finally analyzed using an

electron ionization quadrupole mass spectrometer. GB, GD, GA, and HD are detected and identified within 12 min, with postulated LOD values of 0.2, 0.5, 8 and 0.3 μg/m^3 (Sekiguchi et al., 2006). Gaseous and weakly volatile (boiling temperature >250°C) CWAs cannot be detected. The new type of the same instrument Hapsite ER, adopting Tri-Bed TA microconcentration, provides more excellent determination against ten CWAs (Figure 60.5). Torion (American Fork, Utah) produces a field-portable GC-toroidal ion-trap MS with a solid-phase microextraction sampling inlet for CWA and related compound determination in water samples (Smith et al., 2005, 2011b; Contreras et al., 2008; Torion Technologies Inc., 2014).

Other Sensor Technologies

As for sensor technologies, chemical sensors can be used for detecting CWAs. Electrochemical sensors composed of multiwalled carbon nanotubes on indium tin oxide surfaces in connection with ferrocene–amino acid conjugates have been developed for detecting nerve gas

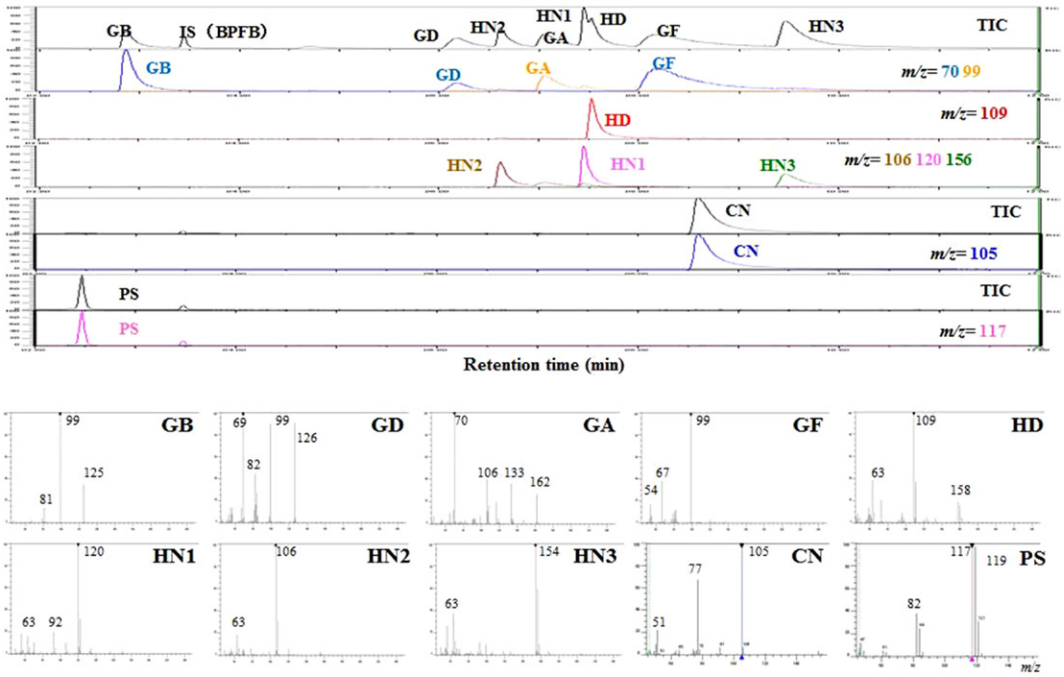

FIGURE 60.5 GC-MS data of portable apparatus, Hapsite ER. Upper: total and extracted ion chromatograms; Lower: Electron ionization mass spectra. CWAs were measured using a HAPSITE ER. GB: 34 mg/m^3; GD: 10 mg/m^3; GA: 22 mg/m^3; GF: 14 mg/m^3; HD: 2.4 mg/m^3; HN1: 6.5 mg/m^3; HN2: 12 mg/m^3; HN3: 7.4 mg/m^3; CN: 2 mg/m^3; PS 3.7 mg/m^3; IS: internal standard (BPFB). Analytical conditions: microtrap desorption, Tri-Bed TA 15 mg, 5 s at 60°C, to 180°C; column, Rtx-1MS (15 m × 0.25 mm, 1.0 µm thickness); oven: 60°C (1 min), 6°C/min to 80°C, 12°C/min to 120°C, 26°C/min to 180°C (2 min); temperatures, membrane 80°C, valve oven 70°C, probe 60°C, NEG 400°C; MS, electron ionization, m/z = 45–300, 70 eV, 300 µA, 0.79 s/scan.

degradation products and related compounds in water (Khan et al., 2008). Electrochemical sensors developed by Riken Keiki Ltd provide sensitive and specific detection of gaseous CWAs (Riken Keiki Co., Ltd, 2014), and newly developed gold nanoparticle dispersed carbon fiber electrodes to selectively detect blistering agents in corporation with Kumamoto University (Kumamoto, Japan) and our group (Matsuura et al., 2010). The field-portable instrument (SC-90, 1.9 kg) is able to detect HD vapor with a LOA of 1.5 mg/m^3.

Biosensors utilizing CWA target enzymes have been developed over the past decades (Zayats et al., 2003; Guerrieri et al., 2005; Walker and Asher, 2005). Acetylcholinesterase (AChE) is fixed on the sensor chip for nerve gas detection; by reaction with nerve gases, substrate hydrolysis velocity is lowered because of enzyme inhibition (Anzai, 2009), and the resulting electric response from a reaction, such as the formation of hydrogen peroxide by choline oxidase, can be monitored (Palleschi et al., 1992). A biosensor device utilizing organophosphorus hydrolase (Russell et al., 1999; Karnati et al., 2007) and a chemical sensor utilizing nerve gas-reactive fluorescent reagent (Zhang and Swager, 2003) have also been developed. Sanders et al. (2001) developed a unique, remote, tissue-based biosensor for the field detection of GB, GD, and HD vapors by photosynthetic fluorescence induction measurements with target Cyanobacteria (Sanders et al., 2001). However, these types of sensors are still not available for practical use. To detect AC, tyrosinase is fixed onto glassy carbon; after increasing the concentration of AC on the colloidal mineral, its inhibition is monitored by electrochemically measuring polyphenol hydrolysis (Shan et al., 2004). Nerve gases and blister agents easily hydrolyze to form characteristic compounds, and the hydrolyzed CWAs can be analyzed in wet systems utilizing µTAS capillary electrophoresis (Wang, 2004).

COMPARISON OF EXISTING ON-SITE DETECTION TECHNOLOGIES

In terms of required detection performance criteria for use by first responders, the detection sensitivity, detection accuracy, response time, recovery time, and operation are selected; results of the detection equipment examined are compared in Table 60.10. The numerical data are derived from our experiments. The evaluations are

TABLE 60.10 Comparison of Detection Performances of Various CWA Detectors

grouped into three categories; OK means acceptable, Δ means that improvement is required, and X means not acceptable. From our laboratory's experiments, a perfect device cannot be assigned that meets all the CWA detection requirements. Low sensitivity, false alarms, and strong adsorption of CWAs on devices are particularly serious problems. The gas detection tube system, which permits the detection of a wide range of CWA vapors, suffers from tedious operation and a slow response. The IMS-based detectors, which permit rapid and sensitive detection of nerve and blistering agents, show low sensitivity toward gaseous agents and false positives in response to some compounds. The FPD-based detector, which permits rapid and sensitive detection of nerve gases and HD, gives false negatives when exposed to nonphosphorus and sulfur CWAs. The PID-based detector shows nonspecific and low detection sensitivity. The SAW-based detector does not permit sensitive detection of CWAs. The FT-IR instrument, which permits noninvasive and constant detection, shows inadequate sensitivity. The GC-based detector with a concentration system, which permits sensitive detection of nerve gases and blister agents, suffers from troublesome operation and a slow response. The GC-MS-based detector, which permits sensitive identification of only volatile nerve gases and blister agents, suffers from difficult operation and slow response. Nonvolatile vomiting agents and lachrymators cannot be detected using any of this equipment.

DEVELOPMENT OF NEW ON-SITE DETECTION TECHNOLOGIES

Figure 60.6 shows a performance map of on-site CWA detection equipment distributed by physical properties of the agents. CWAs are represented in terms of volatility and toxicity, and the target agent territories and drawbacks of the detection equipment can be noted. This figure appears to show that the detection of gaseous agents and nonvolatile CWAs should be improved. For achieving a more sensitive and continuous monitoring of both volatile and nonvolatile CWAs, our laboratory, in coordination with Hitachi Ltd, has developed on-site detection methods utilizing counter-flow introduction

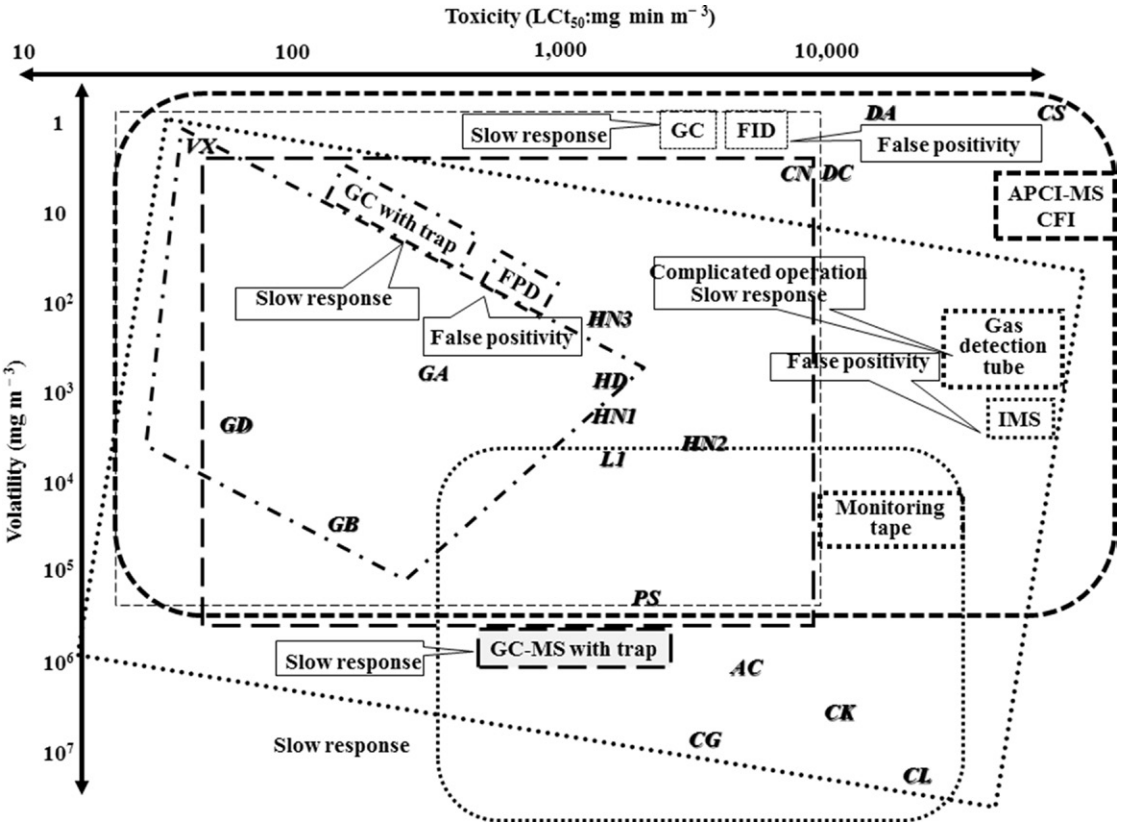

FIGURE 60.6 Performance of on-site CWA detection equipment in terms of target toxicities and volatilities. CWAs are shown in italics. The acceptable detection boundaries achieved for appropriate technologies are shown. Particular drawbacks for certain technologies are also described. *Source: Reproduced with permission from Seto et al. (2014).*

atmospheric pressure chemical ionization MS (CFI-APCI-MS; see Figure 60.7). CFI-APCI-MS technology provides soft ionization of the suctioned CWAs by corona discharge and introduction of only the produced primary target ions into the mass analyzer; the secondary interfering ions are excluded from the ionization region. The CFI-APCI technology is superior in terms of noise ion reduction, realizing ultrasensitive detection. Adopting an ion-trap mass analyzer (MS^n function), many types of nerve gases, blistering agents, vomiting agents, and lachrymators are detected within several seconds with the LOD in the sub-μg/m^3 area (Seto et al., 2013, 2014) (DS-1000, Figure 60.7).

The monitoring tape method (Nakano and Nagashima, 2001) detects hazardous gases by spectrophotometrically measuring the color change on the tape or tab impregnated with specific reagents after reacting with the suctioned air sample (Figure 60.8). The instruments using this technology, developed by Riken Keiki Ltd, are commercially available. A diffusion-type apparatus is used as the portable equipment, and by selecting the appropriate tab, the instrument can monitor the desired gases. A transmission-type apparatus is used as the fixed monitor equipment, and provides more sensitive detection. Riken Keiki and the author have developed a three tab-arrayed detector (FP-100), whereby three types of gaseous CWAs can be detected simultaneously and specifically with LODs lower than 1 mg/m^3 within 1 min. Blood agents (such as AC, CK, and arsine) and choking agents (such as CL and GC) and L1 can be detected.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

A recommended on-site detection system for considering on-site CWA detection requirements and the status of present detection technologies is shown in Figure 60.9. For portable detectors utilized by first responders, a combination of IMS instruments, equipment employing the arrayed monitoring tape method, and an electrochemical sensor is desirable. This combination encompasses the detection of CWA forms from the gaseous to the volatile state. GC-MS and gas detection tubes further assist in identifying the detected CWAs. Nonvolatile CWAs are still out of the detection range of portable equipment. For movable detectors, highly sensitive detection equipment is necessary; the combination

Left upper: structure of ionization chamber; Left lower: Signal time response for sarin by MS^3 ($MH^+ \rightarrow m/z$ 99$\rightarrow m/z$ 97) for sample air introduction with and without sarin and gasoline vapors; Right: MS^n mass spectra for sarin.

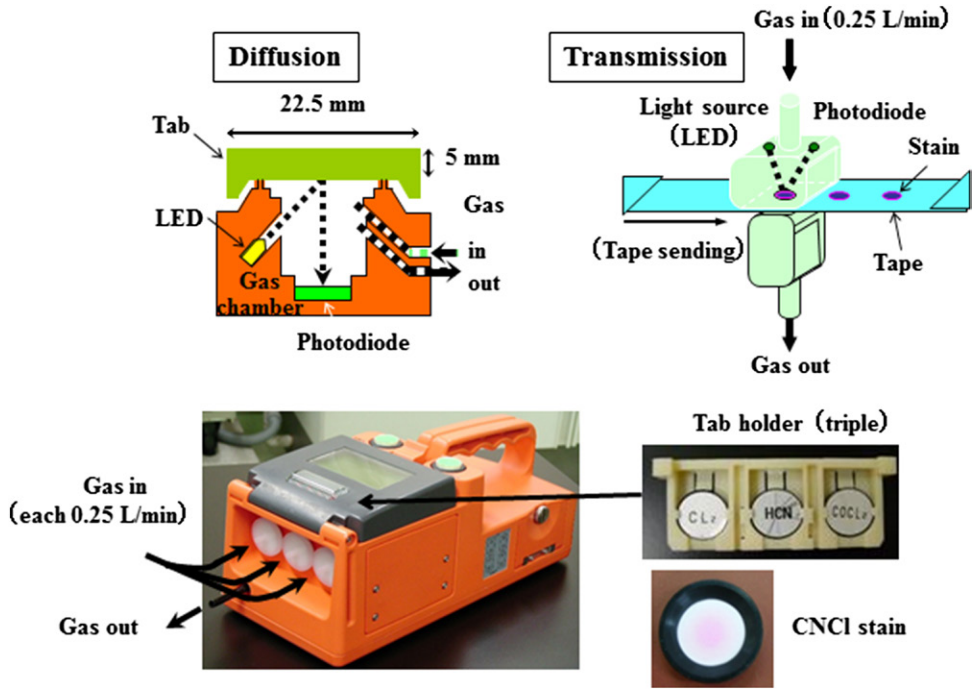

FIGURE 60.8 Monitoring tape method. Schematic detection mechanism of diffusion (upper left) and transmission (upper right) types of apparatus, and arrayed diffusion-type detector (lower left) and related tab (lower right).

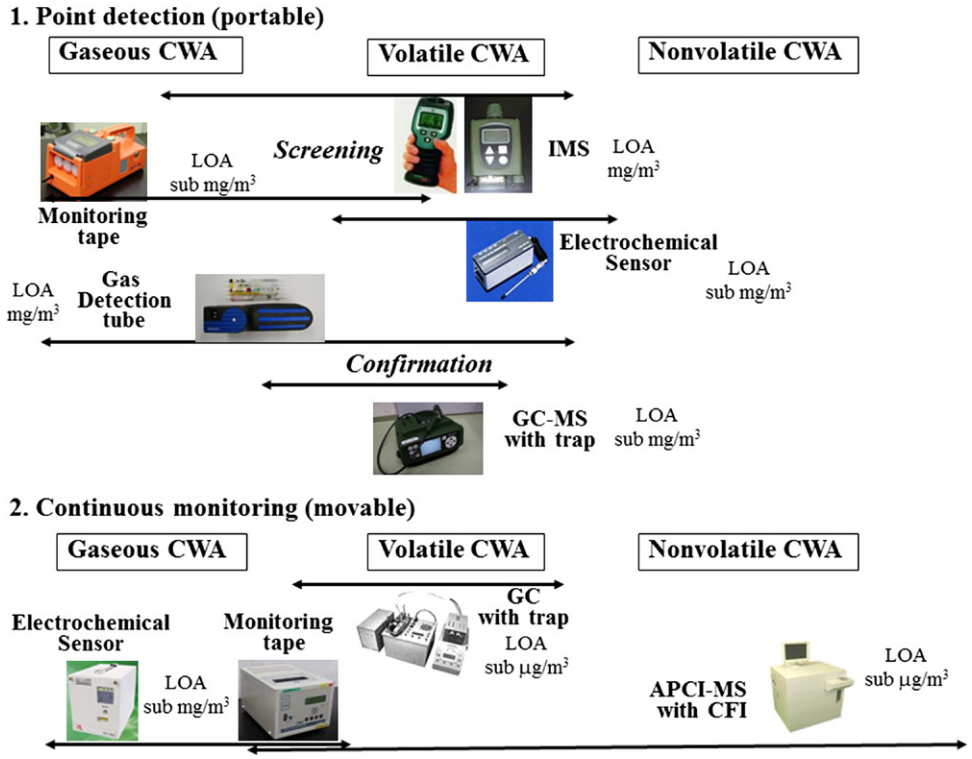

FIGURE 60.9 Recommended combinations of on-site detection equipment for (1) point detection and (2) continuous monitoring equipment for gaseous CWAs (blood agents, choking agents), volatile CWAs (nerve gases, blistering agents), and nonvolatile CWAs (vomiting agents, lachrymators). The acceptable detection boundaries for the technologies are shown, along with the LOA values.

of CFI-APCI-MS and a lined set of instruments using the transmission-type monitoring tape method or electrochemical sensor is almost ideal, handling all the CWAs with the required sensitivity. It is anticipated that new sensing technologies will be developed in the future that will overcome the problems of large size, false positives, low sensitivity, and narrow range of detection.

CHAPTER

61

Laboratory Analysis of Chemical Warfare Agents, Adducts, and Metabolites in Biomedical Samples

Marcel J. van der Schans

INTRODUCTION

Chemical warfare agents (CWAs) are the most toxic compounds ever produced. To develop medical countermeasures against the effects of these agents, analytical procedures to analyze these agents in biological matrices are essential for a better understanding of the toxicological process. The need for the analysis of biomedical samples can have several purposes. First, the agents themselves may be detected in their intact form in the case of toxicokinetic studies. Toxicokinetic studies provide a quantitative basis for the development of new strategies for prophylaxis and therapy against intoxication with CWAs. Second, verification of exposure to CWAs is another goal that requires analytical methodology for biomedical samples. Verification of exposure is needed for several reasons:

1. In the case of chemical warfare, military personnel who are exposed need a fast diagnosis to ascertain the level of exposure and the identity of the agent to give victims adequate treatment.
2. Low-level exposures to nerve agents might be associated with unexplainable phenomena, such as the Gulf War syndrome (CIA, 1997).
3. Despite the Chemical Weapon Convention treaty, large stockpiles of intact agents still exist, waiting for destruction. Personnel in such destruction facilities might have an elevated risk of exposure. Careful biomonitoring could minimize the risks associated with these activities.
4. In the case of a terrorist event, unambiguous verification is needed to verify the exposure. In case of an investigation of alleged use, analyses of biomedical samples can also be used as evidence in a court of justice.

In the summer of 2013, the Organisation for the Prohibition of Chemical Weapons (OPCW), commissioned by the United Nations, collected environmental and biomedical samples (UN Report, 2013). The analysis of the biomedical samples provided evidence that sarin was used in the suburbs of Damascus in August 2013. Methodologies for the verification of exposure to CWAs have been published in special issues of the *Journal of Analytical Toxicology* (Barr, 2004, 2008; Black, 2008). Methodology of the clinical methods has also been reviewed by Noort et al. (2002), Black and Noort (2007), and Capacio et al. (2008). This chapter is not meant as a duplicate for these references. It briefly discusses the analytical techniques that are needed for the analysis of biomedical samples. Most of the analytical methods still rely on chromatographic techniques like gas and liquid chromatography. The progress in instrument development on the detection site has been tremendous in the past few decades. Analyses based on mass spectrometry are now more or less routine. Single and triple quadrupole mass spectrometers have become affordable and automated standard configurations with mass spectrometers can now fulfill the analytical need for most type of analyses. In the past few years, mass spectrometric analyses further improved by providing analyses with precise and accurate masses and faster scan speeds that provide further gains in sensitivity.

Analyses of CWAs might need some additional requirements. For example, it might be necessary to

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00061-0

measure an intact agent at extremely low concentrations, because only these levels are relevant in view of the high toxicity of the agents. In that case, utilizing a large-volume sample introduction should be considered. This puts higher demands on the analytical configurations because the introduction of larger sample volumes also increases the matrix effect, which puts extra demands on the selectivity of the analysis. In the special case of nerve agents, it might be desirable to distinguish the stereoisomers of these compounds from each other, which requires a rather complicated analytical configuration. In this chapter, the methods for the bioanalysis of CWAs or their biomarkers are briefly described; in a case when the instrumentation for a particular analysis is more sophisticated than a standard configuration, it is discussed in more detail.

NERVE AGENTS

Nerve agents are organophosphorus (OP) compounds that rapidly inhibit acetylcholinesterase (AChE), resulting in an accumulation of acetylcholine (ACh), leading to muscle fasciculations and paralysis, and finally resulting in death (Dacre, 1984). There are several strategies available to verify exposure to nerve agents. It is not feasible to measure the intact reagent, because the half-life of these agents is only a few hours, which means that they disappear within 1 day after exposure (Benschop and de Jong, 2001; van der Schans et al., 2008a). Metabolites, often alkyl-methylphosphonic acids, are better biomarkers because they circulate for a longer period of time and are gradually excreted in urine (Shih et al., 1994; Fredriksson et al., 1995; Nagao et al., 1997; Noort et al., 1998). Several methodologies have been published to analyze these metabolites, which were found in plasma and urine (see Table 61.1 for an overview).

Most methods for determination of these compounds are based on liquid chromatography or gas chromatography, which require derivatization (Black and Muir, 2003). Selective MS–MS techniques facilitated by triple quad instruments or ion trap instruments enable the detection of hydrolysis products to the range of pg/mL (Barr et al., 2004; Riches et al., 2005). This concentration is so low that hydrolysis products can be detected in urine up to 1 week after exposure (Riches et al., 2005). Nerve agents bind to proteins such as AChE and butyrylcholinesterase (BuChE). These proteins are not excreted or metabolized rapidly (typical half-life is 12 days for BuChE) (Hall et al., 1984), which means that adducts to proteins can serve as retrospective biomarkers for exposure to nerve agents (Fidder et al., 2002; van der Schans et al., 2004). The enzymatic measurement of AChE activity, known as the Ellman assay, is the easiest method to determine nerve agent exposure (Ellman et al., 1961; Halbrook et al., 1992). The method is based on the enzymatic cleavage of the substrate acetylthiocholine into nitrobenzoate, a yellow product that can easily be measured with a low-cost colorimeter. A major drawback of the method is that the identity of the nerve agents cannot be elucidated from this measurement. Second, the intrapersonal and interpersonal variation of the ChE activity implies that a decrease of ChE activity must be relatively large to be significant (Brock, 1991). Third, the *de novo* synthesis of the enzyme restores the enzyme activity within several days within the range of the control values. Low-level exposures to nerve agents or exposures that took place several weeks before the biosample could be taken cannot be detected using this method. Instead of looking for a decrease in AChE activity, it is more efficient to detect the ChE fraction that is inhibited by the nerve agent. In that case, it is also better to look at BuChE, which has several advantages over AChE. First, BuChE is a protein present in plasma, which is an easier sample matrix to process than whole blood. Second, the concentration of BuChE is approximately 80 nM, which is approximately 10-times higher than the concentration of AChE in blood (Myers, 1952; de Jong and Wolring, 1984). This automatically means that the concentration of that biomarker is higher and therefore easier to detect. The most straightforward method to detect the adduct of the nerve agent is the fluoride reactivation method (Polhuijs et al., 1997). During incubation of a plasma sample with fluoride ions, the nerve agent adduct is released from the protein and can be extracted in a GC-compatible solvent and subsequently analyzed with GC. The lowest detectable degree of inhibition that can be determined with this method depends on the type of GC detector. Typical reasonably priced detectors like the nitrogen phosphorus detector (NPD), flame photometric detector (FPD), and mass selective detector show absolute detection limits of approximately 1 pg, which means that a concentration of 1 ng/mL can be detected using an injection volume of 1 µL. A concentration of 1 ng/mL of nerve agent is equivalent to 5–7 nM, which corresponds with approximately 10% BuChE inhibition. To be able to determine lower degrees of inhibition, higher sample volumes have to be injected, which puts higher demands on the selectivity of the separation and detection method. Better chromatographic selectivity can be obtained by two-dimensional chromatography based on the heart-cutting method, which is discussed later (see *Analysis of Nerve Agents*). Another option is to improve the selectivity of the detector. Chemical ionization with ammonia as the reaction gas is a relatively soft ionization mode, which ensures a more selective detection of only compounds with sufficient proton affinity (Degenhardt et al., 2004; Jakubowski et al., 2004; Holland et al., 2008; Solano et al., 2008). Another more expensive but recently affordable option is to use a high-resolution R–MS or MS–MS instrument, which can

provide sensitivity and selectivity for the sensitive detection of low-degree inhibition (Degenhardt et al., 2004; Solano et al., 2008). When the large volume technique is utilized, low degrees of inhibition as small as 0.1% can be confirmed. A major drawback of the fluoride reactivation method is that not all nerve agent adducts are amenable to fluoride reactivation; the best-known example is the aged adduct of soman. This problem can be solved by looking at the BuChE enzyme itself. Fidder et al. (2002) published a method based on the LC–MS analysis of nerve agent phosphylated nonapeptide (FGESAGAAS) derived after pepsin digestion of inhibited BuChE. The authors presented a procedure to extract BuChE from plasma using home-fabricated procainamide gels. The phosphylated nonapeptide is best analyzed with an LC–MS–MS instrument using the single-reaction monitoring (SRM) mode. The mass of the parent ion depends on the mass of the nerve agent that is conjugated to the peptide. During the fragmentation process, the phosphyl moiety of the nerve agent is removed first, and the characteristic daughter ions are 778, 673, and 602, which are all fragments of the native peptide.

Figure 61.1 shows the mass spectrum of the nonapeptide with methylphosphonic acid adduct that resulted after exposure to a rapid aging nerve agent such as soman. This mass spectrum has been acquired on the QTOF instrument with accurate mass determination. The spectrum shows that the mass difference between the protonated parent ion and the highest fragment corresponds with the theoretical mass of methylphosphonic

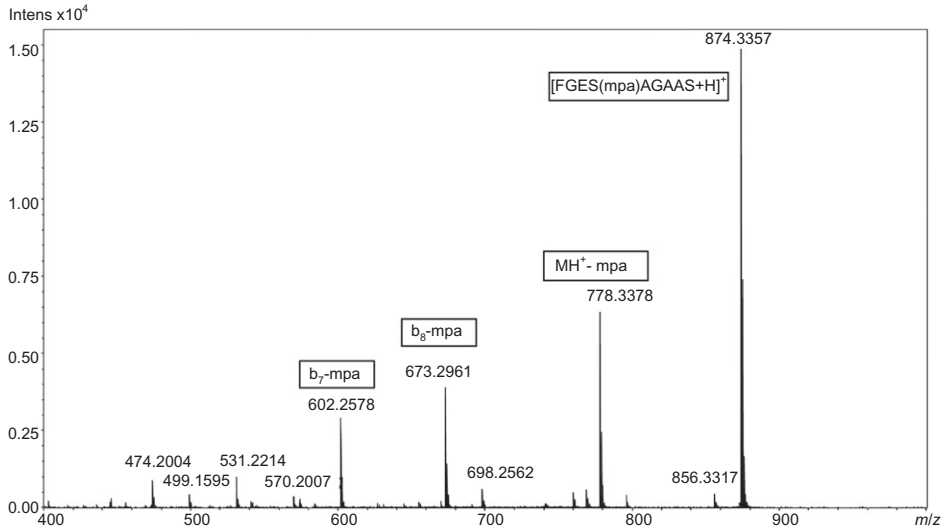

FIGURE 61.1 MS–MS spectrum of protonated ion $[MH]^+$, m/z = 874.3357, representing the nonapeptide FGESAGAAS with methylphosphonic acid adduct. The mass difference between $[MH]^+$ and "$[MH]^+$-mpa" (m/z 95.9979) is identical to the theoretical mass of methylphosphonic acid (m/z 95.9976).

acid. With this result, high-resolution mass spectrometers show their added value in unambiguous identification of CWA adducts. The analysis of the phosphylated nonapeptide and the fluoride reactivation method were both successfully applied on plasma samples that were taken from victims who had been exposed to sarin in the Tokyo subway in 1995 (Polhuijs et al., 1997; Fidder et al., 2002). In the past few years, the sample preparation procedure for the isolation of BuChE from plasma has been further improved. Sporty et al. (2010) described the use of antibody-loaded magnetic beads to isolate BuChE from plasma, which resulted in a better sample clean-up and better possibilities for automation of the method. The analysis of FGESAGAAS nonapeptide adducts is also used for the biomonitoring for exposure to other cholinesterase inhibitors. For example, Schopfer et al. (2010) used the same peptide for diagnosis of 2-(ortho-cresyl)-4H-1,3,2-benzodioxaphosphoran-2-one (CBDP) exposure.

Because of the low concentration of the biomarkers, the analyses are target-directed because a full scan would be at the cost of sensitivity, which means that low-level exposures cannot be detected. However, this is a serious problem in the case when the identity of the nerve agent is not known beforehand. Some progress has been achieved to solve this problem. The number of different OPs exceeds several thousand, but the number of different masses is only 170. Because the OPCW Schedule 1 nerve agents consist only of saturated alkyl groups with mass increments of 14 units, the number of mass possibilities can be further reduced to 36 masses, which means that only 36 multiple reaction monitoring (MRM) transitions have to be recorded (van der Schans et al., 2008a). It is anticipated that the newest mass spectrometers will be able to acquire all MRM transitions, relevant to all nerve agents.

Another approach was recently published by Noort et al. (2006). The phosphylated serine residue of nerve agent–inhibited BuChE can be converted under alkaline conditions into a dehydroalanine residue that can subsequently react with a generic tag, yielding a mutual product, whatever the identity of the nerve agent. The resulting product can be detected in the most sensitive SRM mode of the mass spectrometer.

Recently, it became recognized that albumin is also a target for nerve agents but with a lower affinity than BuChE. Therefore, nerve agent adducts to albumin are also a valuable biomarker for nerve agent and pesticide exposure (Williams et al., 2007; Read et al., 2010; van der Schans et al., 2013; Sogorb et al., 2014).

Analysis of Nerve Agents

G-Agents

The requirements for the analytical equipment of the analysis of nerve agents become more sophisticated when the fate of the nerve agents are analyzed. The toxicokinetic studies create insight into the distribution and elimination of the agents and indicate when toxicologically relevant concentrations are still present in the circulation (Benschop and de Jong, 2001; van der Schans et al., 2008b). In view of the high toxicity of nerve agents, these toxicologically relevant concentrations are in the range of pg/mL. Using gas chromatography, these levels can only be measured when large-volume samples can be introduced on the column. With higher sample

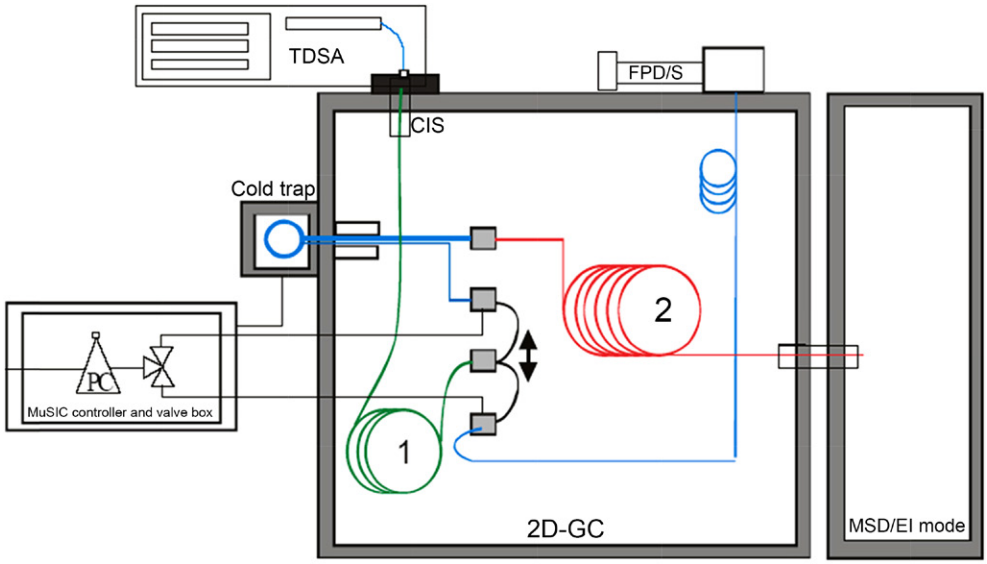

FIGURE 61.2 Large-volume (200–400 µL) thermal desorption from Tenax (300 mg, TA 60–80 mesh) followed by 2D-GC and MS detection in EI mode. (1) Precolumn. (2) Analytical column. Small part of the chromatogram of the first column is re-injected on the second analytical column. *Source: Trap and van der Schans (2007).*

volumes, the matrix effect is increased as well and higher requirements for the selectivity of the analysis are necessary. Another challenging factor is that nerve agents are chiral compounds with an asymmetrical phosphorus atom (Benschop, 1975; Benschop and de Jong, 1988). The difference in toxicity of the two isomers is several orders of magnitude, with the P(−)-isomers being most toxic (Benschop et al., 1984; Benschop and de Jong, 1988). In case of toxicokinetic studies, it is important to differentiate between the two isomers because it is essential to know which isomer is still present in the circulation. Chiral gas chromatography can fulfill this requirement for G-agents like sarin and soman. Soman has two asymmetric atoms, phosphorus and carbon, in the pinacolyl group. Therefore, the compound consists of four different stereoisomers. An optical active stationary phase like beta-cyclodextrin can be used to separate the isomers of sarin (Spruit et al., 2001). Chirasil-Val columns can be used to separate the four isomers of soman (Benschop et al., 1981, 1985). The Chirasil-Val stationary phases were synthesized at the TNO Prins Maurits Laboratory. Smith and Schlager (1996) reported the use of commercially available gamma-cyclodextrin–based columns that are also capable of separating the four isomers of soman.

In the case of toxicokinetic studies, the chiral columns were installed in a two-dimensional GC configuration according to the heart-cutting method (see Figure 61.2 for an outline). First, the introduction of large-volume samples requires additional selectivity from the chromatographic system to alleviate the matrix effect. Second, the fragile optical active phase needs to be protected from the "dirty" extracts of the biosamples and the condensating solvent in the column. Samples are introduced by thermodesorption tubes filled with TENAX material. The components are cryo-focused in a cold trap and, after a certain desorption time, flash-injected into the first column. According to the heart-cutting technique, one small section of the effluent of the first column is collected in a cold trap and then re-injected on the second analytical column with the chiral selective phase. The isomers of soman could be detected in the blood of guinea pigs at levels as small as 10 pg/mL blood (Benschop and de Jong, 1991).

Figure 61.3 shows a chromatogram of the analysis of the four isomers of soman together with one isomer of deuterated soman [d13-C(−)P(−)-soman], which was added as an internal standard.

VX

The chiral separation of VX isomers was achieved using normal phase liquid chromatography with a Chiracel OD-H column. The separation of the enantiomers of VX was first described by Kientz et al. (1994). They used a thermo-ionic detector for the selective detection of phosphorus compounds. Unfortunately, this technique was not robust enough. The same separation was also described by van der Schans et al. (2003) using electrochemical detection. The mobile phase (hexane:ethanol 95:5) was mixed after the column procedure with 0.1 M lithium perchlorate solution to ensure conductivity necessary for electrochemical detection. The system could be used to study the stereo-selective degradation of VX in *in vitro* samples such as liver homogenates and plasma. Although the electrochemical detection was

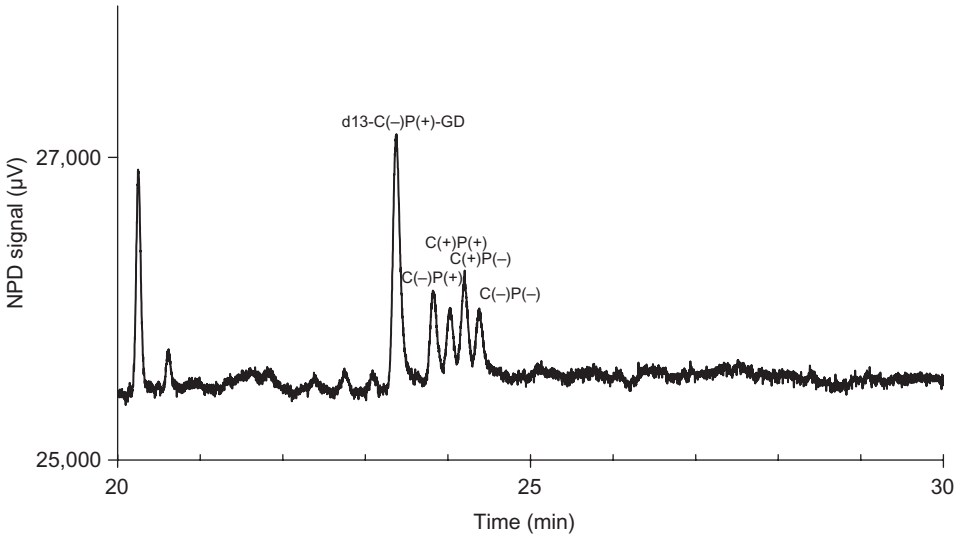

FIGURE 61.3 Typical separation of the stereoisomers of soman and internal standard. d_{13}-C(−)P(+)-soman using the 2D-GC configuration. *Source: Trap and van der Schans (2007).*

rather sensitive (absolute detection limit, 25 pg), the method was not selective enough to measure low levels of VX in extracts of biological matrices at a relevant level (<10 ng/mL). Relevant levels of VX in blood could be detected to 1 ng/mL using two-dimensional off-line LC–GC separation (van der Schans et al., 2003). Smith (2004) published the same separation using a single quadrupole mass spectrometer using atmospheric pressure chemical ionization. In that article, he focused on the separation and detection of VX to study the stereoselective degradation of VX in plasma. Reiter et al. (2008) published the chiral separation of VX isomers with gas chromatography using a HYDRODEX-β-TBDAc column. The same authors reported the chiral separation of VX isomers using LC-MS with Chiral AGP column. Using this analytical method, they were able to study the percutaneous toxicokinetics of VX in pigs.

SULFUR MUSTARD AND LEWISITE

There is a variety of biomarkers that can verify an exposure to sulfur mustard. Table 61.2 shows an overview of these biomarkers. Analogous to the nerve agents, biomarkers can be distinguished in metabolites that are excreted in urine and adducts to proteins. A disadvantage of the major metabolite, thiodiglycol, is that this compound is also present in subjects not exposed to sulfur mustard (Black and Read, 1995; Boyer et al., 2004). In that respect, the protein adducts are more reliable biomarkers for sulfur mustard exposure because these biomarkers point unambiguously to an exposure to sulfur mustard. The sulfur mustard adduct to the N-terminal valine of globin can be analyzed after a sample preparation procedure known as the modified Edman degradation (Fidder et al., 1996a,b; Noort et al., 2004a,b). Sulfur mustard also binds to cystine in albumin; this adduct can be analyzed as a tripeptide Cys-Pro-Phe with LC–MS–MS after digestion with pronase (Noort et al., 1999, 2004a,b). As an analog to the fluoride reactivation method, the sulfur mustard adduct can also be released from the protein by alkaline hydrolysis and measured as thiodiglycol. A precipitation step during the sample preparation removes endogenous thiodiglycol before it is released from the protein (Capacio et al., 2004; Lawrence et al., 2008). Unlike the nerve agents, the analyses can be target-directed and the mass spectrometer can be operated in the most sensitive SIM or SRM mode.

Table 61.2 shows that most methods rely on analytical techniques as gas and liquid chromatography combined with mass spectrometry. Most of the analyses can be performed with standard analytical configurations, without the utilization of large-volume sample introduction. The LC–MS technique is already equipped to handle sample volumes up to 100 μL, and the quality of the LC separation and tandem MS detection is normally sufficient. The concentrations of the biomarkers are normally so high that they can be detected with normal configurations. Smith et al. (2008) showed that after an accidental exposure to sulfur mustard, the albumin adduct could be measured up to several weeks after exposure. Typical detection limits using GC–MS configurations were in the pg range, which means that concentrations as small as 1 ng/mL can be detected. This level is also sufficient to detect the levels several weeks after exposure. Noort et al. (2008) demonstrated that the sulfur mustard adduct on N-terminal valine in

marmosets could be measured up to 4 weeks after exposure using GC–NICI–MS. However, in the case of toxicokinetic studies of sulfur mustard, typical concentrations at 10–100 pg/mL in blood were found and could not be measured with a normal GC–MS configuration. The utilization of large-volume sample introduction by thermodesorption and two-dimensional chromatography (analog to the configuration for chiral nerve agent analysis) enabled the detection of sulfur mustard levels as small as 10 pg/mL (Oostdijk et al., 2007). In addition to the methods based on instrumental analysis, sulfur mustard exposure can also be detected using immunoassays. Antibodies that can recognize DNA adducts have been raised. In an immune slotblot assay, exposures to sulfur mustard could be verified in DNA obtained from blood or skin (Benschop et al., 1997; van der Schans et al., 2004). The number of methods to verify an exposure to lewisite is limited. Chlorovinylarsonous acid can be found as the main metabolite in urine, and this compound can also be found as an adduct to hemoglobin (Table 61.3). The analyte can be analyzed with GC–MS using normal configurations.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The development of sophisticated analytical instruments, mainly based on mass spectrometry, enabled several analyses for bioanalysis of CWAs. Toxicokinetic studies at relevant levels (as small as 10 pg/mL blood) can now be performed. Exposures to CWAs can be verified up to several weeks after exposure because of the persistence of the biomarkers and also because of sensitive and selective instrumentation. It is anticipated that future equipment will be even more sensitive, enabling exposures that occurred weeks after the event to be discovered. Better sensitivity is also desirable to meet the criteria that are in place for identification of a compound meeting the forensic standards. Normally, identification by two techniques is needed. If these techniques are not available, then special requirements for the MS analyses are demanded. A link with the doping control analysis can be made that accepts that three ions in an SIM or SRM are needed, provided that the retention time is within a certain time window (Black, 2008). In case of analyses with tandem MS detection, two transitions are also sufficient for forensic identification. When instrumentation becomes more sensitive, it is possible that these requirements can be met. The new mass spectrometers, based on time of flight or Orbitrap, offer high-resolution mass determination that will make the identification more accurate and therefore more reliable. Criteria for their added value in unambiguous identification of CWAs and related compounds are still undergoing development, however. The newest developed mass spectrometers will offer higher scan speeds allowing the possibility

to acquire many transitions at the same time without losing sensitivity. Using that configuration, it will be possible to perform generic analyses without previous knowledge of the identity of the nerve agent.

Another interesting development is comprehensive GC–MS. Comprehensive GC offers great selectivity and resolution and is ideal for complex samples such as biomedical samples. Its combination with time-of-flight mass spectrometry offers the possibility to analyze in full-scan mode, not target-directed, with the availability of a full mass spectrum that will meet the forensic standards. The utility has been demonstrated for the detection of CWAs in complicated matrices such as fuel (Reichenbach et al., 2003). The method has also been used for the analysis of regenerated sarin in inhibited plasma (van der Meer et al., 2010). Finally, it may be expected that the sample preparation will be more or less automated. Recently, a promising result was published by Carol-Visser et al. (2008), who described the digestion and analysis of sulfur mustard adducts in albumin and the sarin adduct to BuChE.

Biosensors for the Detection of OP Nerve Agents

Jun-ichi Anzai

INTRODUCTION

Organophosphorus (OP) pesticides and nerve agents have been detected based on various principles, including spectroscopy, chromatography, microgravimetry, and electrical and electrochemical techniques. Among the devices used for detecting OP agents, electrochemical devices (such as modified electrodes) are relatively inexpensive, small, and easy to operate. One of the characteristic features of electrochemical devices is that the function and performance of electrodes can be arbitrarily regulated by modifying the surface with functional molecules, proteins, DNA, and other substances. Thus, one can develop electrochemical devices that can be used for detecting chemicals in sample solutions and in the gas phase. The modified electrodes whose surface is modified with proteins and other biological molecules are often called biosensors. For this reason, modified electrodes or biosensors have been widely used for detecting a variety of analytes, including OP agents. So far, the majority of biosensors have been developed not for environmental and toxicological purposes, but for biomedical or clinical use; this is because of the large market for the latter. A typical example of a biomedical biosensor is a biosensor used for monitoring glucose levels in the blood of diabetics. This chapter describes recent progress in the development of electrochemical biosensors and related devices for detecting OP nerve agents and pesticides.

BIOSENSORS

It is well established that electrochemical techniques are useful for determining ions and molecules in solution and gas phases. Oxidizable and reducible chemical species dissolved in solution can be detected by measuring oxidation or reduction current that is produced upon electrolysis of the species on the surface of electrodes. Usually, the output current of the system depends on the concentration of redox species in the solution. Thus, one can quantitatively determine the concentration of the analyte. Another merit of electrochemical techniques is easy identification of an analyte by recording its redox potential because the redox species can be characterized by its own potential. In other words, an appropriate electric potential has to be applied to the electrode to electrochemically oxidize or reduce specific ions or molecules for the purpose of obtaining output signals from the electrochemical reaction. For example, hydrogen peroxide (H_2O_2) is known to be oxidized according to reaction (1) (Scheme 62.1) on the surface of metal or carbon electrode set at 0.4–0.6 V. This current value often depends on the type of electrode material and on the solution conditions, while no oxidation current can be observed at electrode potentials below this value because H_2O_2 cannot be oxidized at lower electrode potentials. Thus, one can identify the redox species based on the redox potential applied to the electrode and quantitatively determine the concentration from the magnitude of the output current.

However, this is true only for the sample solutions which contain a single component, H_2O_2 in this case. The electrochemical response is more complicated if sample solutions contain two or more redox species because both species would be oxidized or reduced, and thus they contribute concurrently to the output current. This is often the case for the electrochemical determination of drugs and metabolites or other biological components in blood because many kinds of redox-active species are intrinsically contaminated in blood. Ascorbic acid (vitamin C) and uric acid (UA) are redox species found in blood, and these compounds often disturb electrochemical measurements of blood because the redox potential

SCHEME 62.1 Electro-oxidation of H_2O_2.

of vitamin C and UA overlaps with those of many kinds of drugs and biological components (Anzai et al., 1998; Hoshi et al., 2001). Another drawback of electrochemical measurements is that target analytes are often electrochemically inert, so no electric signal can be obtained with an electrode. In other words, the redox potential of many target molecules is too high to be oxidized or reduced in the reasonable potential range. The operation of electrochemical systems in high electrode potentials is impractical because the oxidation of H_2O and reduction of dissolved O_2 often disturb the measurements. For these reasons, analytes and samples to which electrochemical protocol can be successfully applied by using unmodified electrodes are rather limited.

Electrochemical biosensors are devices that are fabricated by combining proteins or other biological molecules and electrodes (Ramanavicius et al., 2006; Xu et al., 2006; Yun et al., 2007). Usually, functional proteins are immobilized on the surface of metal or carbon electrodes to effect selective determination of analytes in sample solution. Figure 62.1 schematically shows the concept and structure of electrochemical biosensors, where the surface of the electrode is modified with biomaterial that can selectively bind target analyte in a sample solution contaminated with many interfering substances. It is also possible to replace electrodes with other transducers, such as thermistors and optical devices, to prepare calorimetric and optical sensors. Among the biosensors developed so far, enzyme-based biosensors have been most extensively studied due to their high sensitivity and wide applicability in biomedical and environmental analyses. Enzyme-catalyzed reactions occur on the surface of electrode and the reaction products are oxidized or reduced electrochemically, resulting in generation of electric current as an output signal. Thus, chemical signals (i.e., the type of analyte and its concentration) can selectively be converted into electric signals through the enzyme/electrode interface. For example, the principle of operation of glucose biosensors is based on the glucose oxidase (GOx)–catalyzed oxidation reaction of glucose (reaction (2)) and electrochemical oxidation of reaction product of the enzymatic reaction (H_2O_2) (reaction (3)) (Scheme 62.2). It is clear that 2 mol of electron can be produced from 1 mol of glucose, and the concentration of glucose in the sample solution is related to the recorded electric current. It should be noted here that oxidation or reduction potential of glucose is too high to be oxidized or reduced directly on unmodified electrodes. Consequently, electrochemical determination of glucose is not possible without using GOx-modified

electrodes (or GOx biosensors). It is clear from reactions (2) and (3) that the role of enzymes in the function of biosensors is to catalytically produce redox-active species that can be electrolyzed by the electrode.

One of the merits of an enzyme biosensor is its versatility. The selectivity of biosensors directly relates to the type of enzyme used for constructing biosensors. Up to now, many kinds of enzyme sensors have been reported, other than glucose biosensors, using a variety of enzymes. A miniaturization of the sensor body is another possible advantage of enzyme sensors. In fact, miniature sensors sized in microns have been prepared

for the purpose of detecting target analyte in a single cell. The miniaturization of the sensor body would make it possible to construct a sensor array on a single tip. However, one should keep in mind that the output current decreases as the size of the electrode decreases, resulting in a suppressed signal-to-noise ratio. For routine purposes, therefore, biosensors of pencil size are usually used for easy handling. A small disk of metal or carbon material (3–5 mm in diameter) is often mounted in an insulating plastic rod (about 10 mm in diameter and 50–100 mm in length) to prepare disk electrodes.

Figure 62.2 illustrates an experimental setup for biosensor measurements. Electrochemical measurements using biosensors require three electrodes, which are called the *working electrode (enzyme-modified electrode)*, *reference electrode*, and *counter electrode.* In some cases, the three electrodes can be assembled into a single-body electrode. It is also possible to eliminate the reference electrode and use the counter electrode as a pseudo-reference electrode for specific reasons, such as miniaturization. The experimental setup shown in Figure 62.2 is a batch system, in which the electrodes are immersed in the sample solution to obtain an output signal. For constructing flow systems, the electrodes are set at a suitable place in the fluidic device, which is often used to measure a large number of samples.

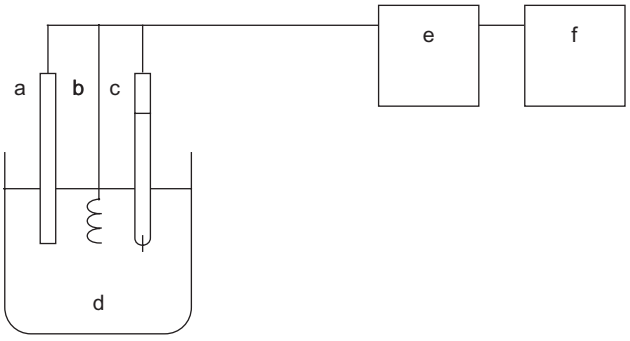

FIGURE 62.2 An experimental setup for the operation of electrochemical biosensors. (a) Biosensor, (b) counter electrode, (c) reference electrode, (d) sample solution, (e) potentiostat, and (f) recorder.

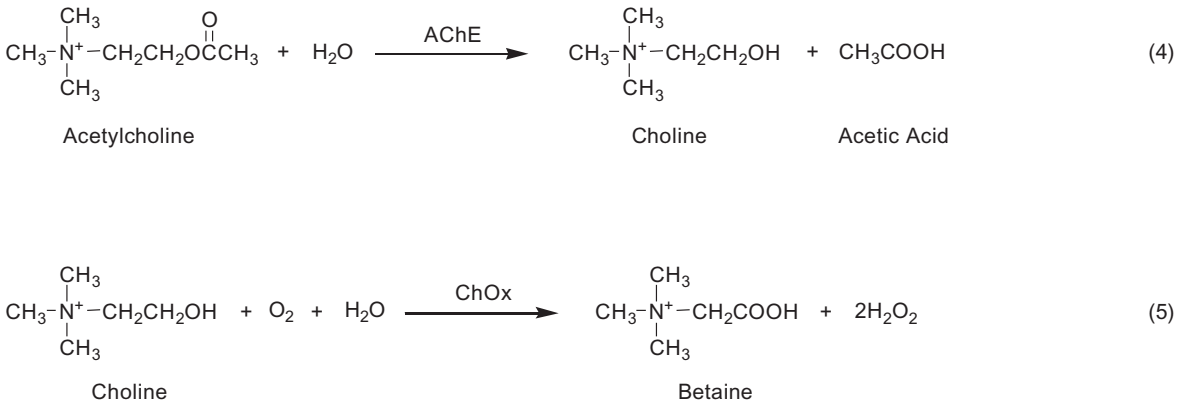
In the next section, recent studies on the determination of OP nerve agents and pesticides based on electrochemical biosensors will be discussed. The electrochemical biosensors used for detecting OP compounds can be divided into three types, depending on the type of enzymes used for constructing biosensors: (i) choline esterase (ChE)–ChOx bienzyme-modified biosensors, (ii) ChE-modified biosensors, and (iii) organophosphorus hydrolase (OPH)–modified biosensors. Also, OP biosensors based on transducers other than electrochemical devices are discussed in this chapter.

ELECTROCHEMICAL BIOSENSORS FOR DETECTING OP COMPOUNDS

ChE–ChOx Bienzyme-Modified OP Biosensors

The primary objective of ChE–ChOx bienzyme biosensors was to determine neurotransmitter acetylcholine (ACh) in biological samples (Chen et al., 1998). The redox potential of ACh is too high to be determined directly using an electrochemical reaction. For this purpose, acetylcholinesterase (AChE) was employed as ChE. AChE and ChOx were immobilized on the surface of the electrode to attain electrochemical analysis according to reactions (4) and (5) (Scheme 62.3).

The enzymatic reactions of AChE–ChOx bienzyme biosensor consist of AChE-catalyzed hydrolysis of ACh into choline and acetic acid (reaction (4)) and oxidation reaction of choline catalyzed by ChOx (reaction (5)). The latter reaction produces H_2O_2, which can be electrochemically oxidized on the electrode to generate output signal depending on the concentration of AChE. It is also possible to use an oxygen electrode in place of a metal or carbon electrode because ChOx consumes dissolved O_2 during the oxidation of choline. Therefore,



SCHEME 62.3 Enzyme reactions in AChE–ChOx bienzyme sensors.

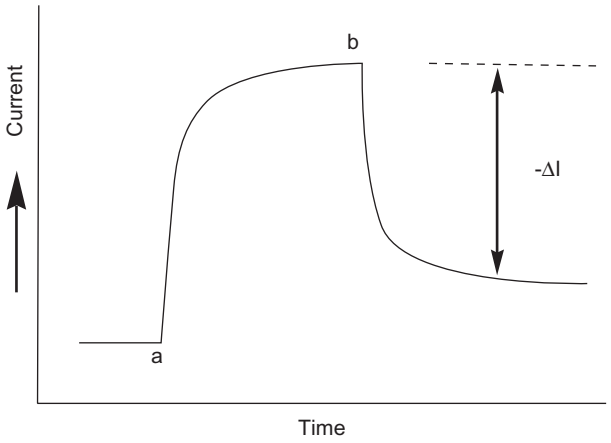


FIGURE 62.3 A typical response of inhibition-mode AChE–ChOx bienzyme OP sensors. (a) Addition of AChE and (b) addition of OP sample. – ΔI corresponds to the output signal.

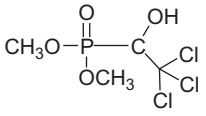

FIGURE 62.4 The chemical structure of trichlorfon.

the O_2 consumption can be detected using a commercially available O_2 electrode. The reason why AChE–ChOx bienzyme biosensors can be used for detecting OP compounds is that the catalytic activity of AChE is inhibited by OP compounds. OP compounds are known to irreversibly bind to AChE to disturb its catalytic activity. It is thus clear that reaction (4) is suppressed, in part depending on the concentration of OP, and the rate of choline production becomes lower in the presence of OP compounds, resulting in reduced response in the output current of the sensor. In fact, the change in output current of the sensor upon addition of an OP-containing sample is detected in the presence of a known concentration of ACh, as illustrated in Figure 62.3. The ΔI value depends on the concentration of OP compounds in the sample solution. Butyrylcholinesterase (BChE) is sometimes used in place of AChE, in which butyrylcholine (BCh) is used as a substrate.

According to this protocol, we have determined trichlorfon (Figure 62.4) in water samples using AChE–ChOx biosensors, which were constructed by a layer-by-layer deposition of the enzymes on the surface of a platinum disk electrode (Shi et al., 2005). The response of the sensor to trichlorfon was evaluated by a successive addition of trichlorfon into the solution of 2 mM of ACh. The output current of the sensor decreased as the concentration of trichlorfon increased over the concentration range of 1×10^{-8} to 2×10^{-5} g/mL. The lower detection limit of the sensor was found to be about 1×10^{-9} g/mL (1 ppb). A key point for constructing high-performance OP sensors in bienzyme systems may be to suitably control the ratio of the catalytic activity of AChE and ChOx in the sensor. In the present case, the catalytic activity of ChOx should be higher than that of AChE; the overall rate of the reactions is determined by the rate of the AChE-catalyzed reaction because OP compounds disturb this step. Therefore, excess amounts of ChOx usually are mixed with AChE, and the ChOx–AChE mixture is immobilized on the surface of the electrode to make the AChE-catalyzed reaction a rate-limiting step. In this situation, the overall reaction rate can be determined by the rate of the ChE-catalyzed reaction because the subsequent electrochemical oxidation of H_2O_2 is sufficiently fast. On the other hand, in our sensors, ChE and ChOx were immobilized separately, layer by layer, for optimization of the amounts of enzymes.

TABLE 62.1 AChE-ChOx Bienzyme Biosensors for Detecting OP Compounds

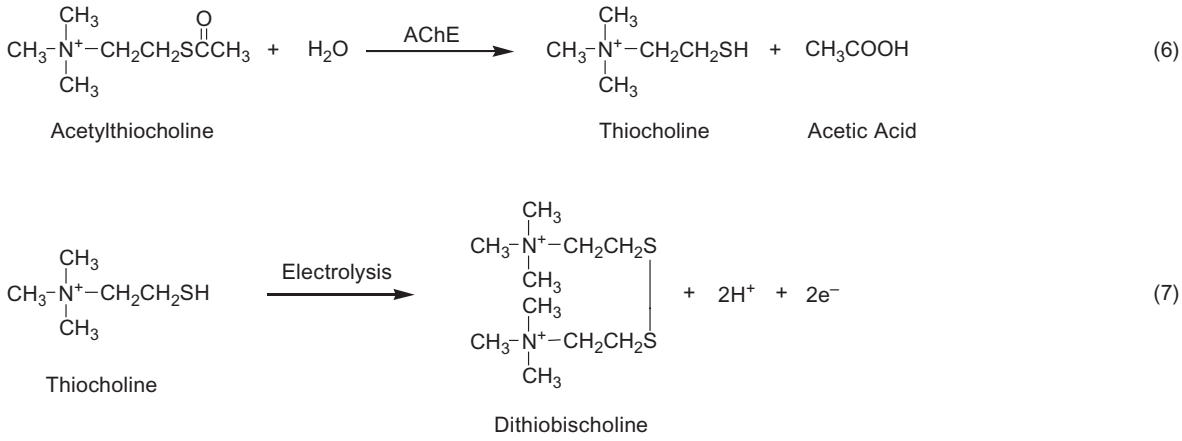
Carbon electrode		
Gold electrode	Trichlorfon (4 pM)	Shi et al. (2005)

ChE–ChOx bienzyme-modified biosensors have been widely used, mainly for detecting OP pesticides, which are summarized in Table 62.1. AChE and BChE are often used as a ChE enzyme. This type of ChE–ChOx sensor can be a convenient way to detect OP compounds, and detection time for qualitative analysis is reasonably fast. For quantitative determination of OP compounds, however, operation of the sensor is somewhat time-consuming because multiple steps (a measurement of the response to AChE and inhibition) are required.

AChE-Modified OP Biosensors

As described in the previous section, the use of a bienzyme system sometimes induces complexity in the design of biosensors originating from different catalytic activity of the enzymes. In the ChE–ChOx systems, ChOx is used to oxidize choline that is generated through ChE-catalyzed reactions because the oxidation potential of choline is too high to be electrochemically directly oxidized. It is reasonable to assume that if the reaction products can be oxidized on the electrode directly, one can remove the ChOx enzyme from the sensor design, and a ChE-modified electrode may be



SCHEME 62.4 Enzyme and electrochemical reactions in acetylthiocholine-based sensors.

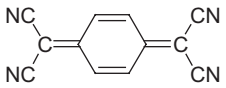

FIGURE 62.6 The chemical structure of TCNQ.

used for detecting OP compounds. This concept was tested using an AChE-modified electrode as sensor in the presence of acetylthiocholine in place of AChE as the substrate of AChE (Scheme 62.4). It was found that acetylthiocholine decomposes into thiocholine and acetic acid (reaction (6)), and the resulting thiocholine can be electrochemically oxidized to its dimer (dithiobischoline) on the surface of electrode (reaction (7)). Therefore, the output current of the sensor in the solution of a constant concentration of acetylthiocholine would depend on OP compounds in the solution. Thus, one can determine the OP concentration from the decrease in the output current, as shown in Figure 62.3.

Table 62.2 collects some properties of AChE-modified biosensors based on acetylthiocholine. As shown in reaction (7), thiocholine can be directly oxidized to dithiocholine. However, the oxidation potential of thiocholine is relatively high (approximately + 0.7 V), and thus a high background current and possible interference from oxidizable contaminants cannot be excluded. To circumvent this, electron transfer mediators (Med) are often used to oxidize thiocholine at milder potentials, as depicted in Figure 62.5, where thiocholine is oxidized into dithiobischoline by an oxidized form of the mediator, Med (ox); and the resulting reduced form of the mediator, Med (red), is oxidized at the electrode to generate the current output. In this scheme, 1 mol of thiocholine generates 1 mol of electron. For example, Carlo and coworkers modified the surface of a screen-printed carbon electrode with a thin layer of perfluorinated ion-exchanger film containing 7,7,8,8-tetracyanoquinodimethane (TCNQ) (Figure 62.6) as Med. It was found that the reduced form of TCNQ is oxidized at + 0.4 V, as opposed to the pseudo reference electrode (Ag wire; Carlo et al., 2004). The TCNQ-based biosensors were applied to a recovery test using egg, bovine meat, milk,

and honey as food matrices. No false negative or false positive samples were detected in the assay. These results indicate that TCNQ-based biosensors may be useful as a prescreening device in the analysis of food safety.

Another recent topic in the detection of OP compounds based on ChE-modified biosensors is to use carbon nanotubes (CNTs) as an electrode modifier. CNTs are known to exhibit excellent electrochemical properties originating from high catalytic activity of edge-plane-like graphite sites at the ends, as well as a large effective surface area. Lin et al. (2004) have reported that stable CNT-modified glassy carbon (GC) electrodes can be prepared by coating the surface of GC electrodes with a suspension of CNT, and they can be used for sensitive determination of thiocholine (Liu et al., 2005). Voltammetric studies have demonstrated that thiocholine is oxidized at + 0.15–0.20 V on CNT-modified GC electrodes, as compared to its higher oxidation potential of unmodified GC (+0.7 V), carbon paste (+ 0.6 V), and gold electrodes (+0.9 V). A lower detection limit of 5×10^{-6} M thiocholine was obtained under the optimal batch conditions, while the detection limit was further reduced to 3×10^{-7} M by the electrochemical detection in flow injection analysis.

The same authors further improved the CNT-modified biosensors for detection of OP compounds based on a layer-by-layer immobilization of CNTs, polymer, and AChE on the surface of GC electrodes (Liu and Lin, 2006). AChE was sandwiched with poly(diallyldimethylammonium chloride) layers on the surface of CNTs. The OP biosensor developed in this way was used to detect paraoxon (Figure 62.7) at levels as low as 4×10^{-13} M with a 6 min response time in flow injection analysis. The high stability of the sensors was another merit of this biosensor; no deterioration in the response was observed after 1 week of continuous use. Only a 15% decrease in the activity of the enzyme was observed after 3 weeks, although the authors recommended recalibration after 2 weeks. The high stability of the biosensors was ascribed to the assembling of enzymes in the sandwichlike layer structure, providing a favorable microenvironment to maintain the catalytic activity of the enzyme.

The effects of organic solvents on the performance of ChE-modified sensors were studied because OP compounds are sometimes extracted from samples using organic solvents. For this purpose, 4-aminophenyl acetate (Figure 62.8) was used as the substrate of the AChE enzyme in place of acetylthiocholine because of its high solubility in organic solvents and the redox-active nature of 4-aminophenol produced through enzymatic reaction (Scheme 62.5). Marty and coworkers prepared an AChE-modified carbon electrode by coating AChE-containing polymer film on the electrode (Andreescu et al., 2002). 4-Aminophenol was found to be oxidized on the electrode at + 0.1 V, while no redox response was observed in the range of 0–0.4 V for 4-aminophenyl acetate. An AChE enzyme modified on the electrode retained about 80% catalytic activity even in the aqueous solution containing 1–5% acetonitrile or ethanol, although more than 20% organic solvent induced nearly complete deactivation of the enzyme. This suggested that the sensor could be used in the presence of a small amount of water-miscible organic solvent in aqueous media. In fact, the AChE-modified sensor could be successfully used for determining the 10^{-9}–10^{-8} M level of OP compounds in the aqueous solutions containing 1–5% acetonitrile and ethanol.

Model OP compounds are usually used for studying the detection of nerve agents with biosensors because of the difficulty of working with nerve agents. Recently, ChE-modified disposable electrodes have been used for detecting sarin and *O*-ethyl *S*-[2-(diisopropylamino) ethyl] methylphosphonothioate (VX; Figure 62.9) in solution and in air. Arduini and coworkers have tested ChE inhibition in sarin and VX standard solution and

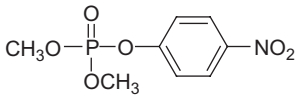

FIGURE 62.7 The chemical structure of paraoxon.

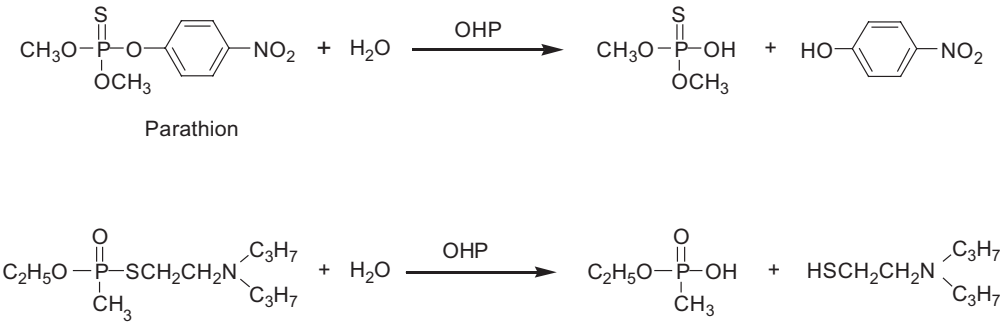

SCHEME 62.6 OPH-catalyzed hydrolysis of parathion and VX.

found lower detection limits of 12 and 14 ppb, respectively (Arduini et al., 2007). For detecting sarin gas in air, the surface of the sensor (which had been covered with a small amount of 0.05 M phosphate buffer) was exposed to a sarin stream for 30 s, and then ChE inhibition of the sensor was evaluated in solution. The sensor was found to be effective to detect sarin gas at a concentration of 0.1 mg/m^3. Thus, low concentrations of sarin gas can be detected in a few minutes using ChE-modified electrochemical biosensors.

OPH-Modified OP Biosensors

The detection of OP compounds by biosensors modified with ChE–ChOx or ChE enzymes relies on an inhibition of catalytic activity of ChE enzymes by OPs. Therefore, it is a drawback of the sensors that the magnitude of the output signal correlates inversely with the concentration of OP compounds in the sample. The protocol in measurements is somewhat complicated because the substrate of ChE has to be added in the sample solution before measurements; as a result, multiple steps are needed for OP detection. In addition, inhibition of ChE by OP compounds is usually irreversible, so reactivation of ChE activity is required with repeated use of the sensors, although this problem can be circumvented by using disposable sensor tips.

In contrast to the inhibition mode of detection in these biosensors, a direct detection of OP compounds has been proposed by means of OPH enzymes, which hydrolyze OP compounds as shown in Scheme 62.6. OPH enzymes have a rather wide spectrum of substrate selectivity and hydrolyze many kinds of OP compounds, including OP pesticides, VX, and sarin. It is obvious from the reactions shown in Scheme 62.6 that the reaction products such as 4-nitrophenol and 2-(diisopropylamino)ethanethiol can be electrochemically oxidized on the electrode to generate electric current as an output signal. Thus, OPH-modified electrodes directly detect OP compounds in a single step, as compared to the two steps required for biosensors constructed using ChE–ChOx and ChE enzymes.

FIGURE 62.10 The chemical structures of 2-(diethylamino)ethanethiol and 2-(dimethylamino)ethanethiol.

Mulchandani et al. (1999) prepared V-type nerve agent biosensors by immobilizing OPH on the surface of a CNT-modified carbon electrode (Joshi et al., 2006). They used a mutant OPH that exhibits a 20-fold greater catalytic activity toward demeton-*S* (a frequently used mimic of V-type nerve agents) than does wild-type OPH. The OP biosensors prepared in this way exhibited an electrochemical response to demeton-*S* at + 0.4 V, the higher and lower detection limits being 8.5×10^{-5} and 1×10^{-6} M, respectively, and with a sensitivity of 8×10^{-6} A/mM. A high response of the biosensors to the hydrolysis product of RVX (2-(diethylamino)ethanethiol; shown in Figure 62.10) and mimic of the hydrolysis product of VX (2-(dimethylamino)-ethanethiol; also shown in Figure 62.10) was also demonstrated, suggesting that they could be used for detecting both VX and RVX. An advantage of this sensor is its high selectivity to demeton-*S* over many possible interfering compounds belonging to OP and carbamate families, which excludes false positives in the field use of the biosensors. This biosensor was successfully applied to analyze lake water spiked with demeton-*S*. The same group developed a flow injection electrochemical detection system using an OPH-modified gold electrode. The response of the system depended linearly on the concentration of OP compounds over the range of 1×10^{-6} to 1×10^{-5} M, with a lower detection limit of 1×10^{-7} M. The authors suggested a possible use of the flow injection system for rapid screening of OP compounds (Wang et al., 1999).

Wang and coworkers prepared OPH-modified carbon electrodes as a submersible biosensor for the purpose of remote monitoring of OP compounds (Wang et al.,

1999). The biosensor mounted in a plastic tube was connected to a 50-foot shielding cable via environmentally sealed rubber connectors. It was found that, despite the 50-foot cable, the noise level of the sensor in the response to paraoxon and methyl parathion was very low. The authors suggested a possible use of the sensor for remote sensing of OP warfare agents in the field. The same group recently reported an interesting electrochemical/optical route for detection of OP nerve agents based on OPH-mediated biometallization (Arribas et al., 2005). They found that the formation of cupric-ferrocyanide (CuFeCN) particles was accelerated by nitrophenol produced through OPH hydrolysis of OP agents. Therefore, the rate of formation of CuFeCN nanoparticles (NPs) depended on the concentration of OP agents. The detection of CuFeCN particles can be carried out by either electrochemistry or optical measurement. CuFeCN is known to be redox-active, and CuFeCN deposited on the surface of a carbon electrode exhibits an oxidation peak at about + 0.7 V in its voltammogram, peak current being dependent on the concentration. Optical detection of OPs is also possible based on the color changes of the CuFeCN solutions. A light yellow color was observed in the absence of OP, while the solution became darker (orange-red) upon addition of OP due to the formation of a CuFeCN colloid. It is a merit of this system that no seed is required for CuFeCN biometallization, in contrast to seed-induced growth of gold NPs (as discussed previously).

Potentiometric OP biosensors were also prepared by coupling OPH and a glass pH electrode. The sensors were constructed by immobilizing OPH on the surface of a pH-sensitive layer of a commercially available pH electrode by crosslinking with bovine serum albumin (BSA) to form a thin film. This biosensor detects pH changes (or changes in electrode potential) originating from hydrolysis reaction of OP compounds catalyzed by OPH in the OPH-BSA film (Mulchandani et al., 1999). The best sensitivity of the sensor was obtained in the operation in a pH 8.5, 1 mM buffer, in which the sensor could detect OPs, including paraoxon, ethyl parathion, and methyl parathion, at levels as low as 2×10^{-6} M. In a similar mechanism of signal transduction, one can use pH-sensitive field effect transistors (FETs) to develop enzyme-modified FETs. Use of a FET provides superiority in miniaturization of the sensor body because a FET is usually produced through mass production on semiconductor materials (Simonian et al., 2004).

An electrochemical OP sensor by the nonenzymatic route was reported based on chemical modification of the surface of a gold electrode with ferrocene derivative (Fc). For this purpose, the gold electrode was modified with a dithioFc derivative to form an aminoFc-monolayer-modified electrode (Khan et al., 2007). The principle of operation of the aminoFc-modified electrode for OP sensing is that chloro- or cyano-substituted OP compounds covalently bind to aminoFc moieties, by which the redox potential of the surface-confined Fc can be altered. In fact, shifts of approximately 110 and 60 mV in the redox potential were observed, suggesting a possible use of the sensors for detecting OPs from the potential shifts.

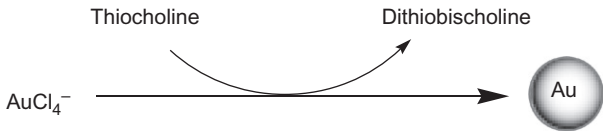

FIGURE 62.11 A thiocholine-induced growth of Au NPs.

MISCELLANEOUS BIOSENSORS FOR OP DETECTION

Different types of transducers other than electrodes have also been used to construct OP biosensors. Recent progress in the study of metal and semiconductor NPs prompted researchers to apply these materials to detect OP compounds. Willner and coworkers found that thiocholine-stimulated growth of gold NPs is inhibited by OP nerve agents depending on their concentration, enabling the NPs to be used for detecting OP compounds (Figure 62.11; Pavlov et al., 2005). A visible absorption of gold NP solution at about 550 nm originating from the plasmon absorption band of NPs increased as a result of NP growth in the presence of AChE and acetylthiocholine; this occurred because enzymatically produced thiocholine promotes the growth of NPs. In the presence of 1×10^{-8} to 1×10^{-6} M of OP compounds in the solution, however, the growth rate was significantly suppressed. NP seeds were confined on the surface of a glass plate for constructing an optical sensor system and the absorbance of the glass plate was monitored in the presence of OP agents. The NP-confined glass plate exhibited a maximum absorption at about 570 nm, and the intensity and wavelength clearly depended on the concentration of OP agent in the sample solution. The optical sensor can detect the 10^{-6} M level of OP compounds. Another merit of the NP-confined glass plate is the fact that the glass plate yields a blue-colored surface without OP agents, while the OP agents generate a weak, pale pink color, enabling OP compounds to be detected with the naked eye.

Polymer microbeads were also used for constructing an OP detection system using the fluorescence response of the microbeads. Carboxylate-functionalized polymer microbeads that had been covered with a polyvinylpyridine (PVP) layer were modified with fluorescamine (FLA). When the microbeads were exposed to the vapor

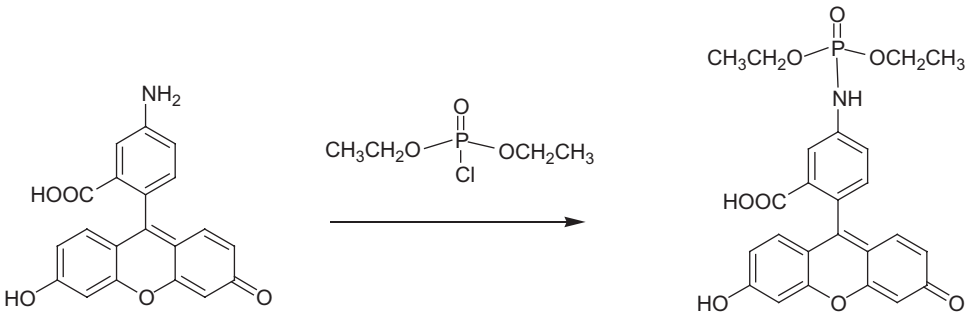

FIGURE 62.12 An enhanced fluorescence upon binding of an OP compound to FLA.

of diethyl chlorophosphate as a model OP, the fluorescence of the microbeads increased rapidly as a result of formation of a phosphoramide of FLA (Figure 62.12; Bencic-Nagale et al., 2006). A PVP layer on the surface of the microbeads served as an acceptor of hydrochloric acid (HCl) generated from phosphoramide formation. A potential use of the microbeads for constructing a sensor array was suggested for screening OP vapor.

Microgravimetry has often been used for studying mass changes on the surface using a quartz-crystal microbalance (QCM). A probe of QCM is a thin, vibrating quartz resonator sandwiched between metal electrodes. The QCM detects adsorption of substance on the surface of the quartz resonator as changes in resonance frequency of the resonator. Thus, one can detect a nanogram level of mass changes on the surface. It is a great merit of QCM that it can be operated in air for detecting adsorption of gases, as well as in solution for detecting dissolved analytes. For this reason, QCM is quite suitable for detecting nerve agents in air. Jiang and coworkers prepared a polymer film-coated quartz resonator for detecting dimethyl methylphosphonate (DMMP) vapor as a stimulant of nerve agents. The polyvinylidene fluoride (PVDF) film-coated quartz resonator was found to be sensitive to DMMP vapor at 5–60 ppm with a rapid and reversible response (Ying et al., 2007). A zeolite film was also utilized as a coating of QCM for detecting DMMP (Xie et al., 2005).

The progress in the development of microelectromechanical systems accelerated the use of microdevices for constructing biosensors. Microcantilevers (MCLs) have been chemically modified to use as sensitive probes for detecting OP compounds. It is known that adsorption of molecules on the surface of an MCL induces it to bend due to changes in surface tension, depending on the amounts of mass adsorbed, in both gas and solution phases. Usually, one side of the MCLs is modified with functional materials to effectively induce them to bend upon binding of analytes. Recently, the surface of V-shaped silicon MCLs, whose dimensions were 180 μm in length, 25 μm in width, and 1 μm in thickness, was modified with thin films containing the OPH enzyme for preparing OP biosensors (Karnati et al., 2007). The MCL-based sensors exhibited a bending response to paraoxon with a dynamic range of 10^{-7}–10^{-3} M. The conformational changes of OPH enzyme associated with the catalytic reaction are suggested to be a main factor inducing the MCL bending. It was also possible to construct MCL-based OP sensors using organic polymers and metal oxides as surface coating in place of the OPH enzyme. In these cases, adsorption OP compounds on the surface of MCLs induced bending, depending on the concentration of OPs, resulting in detection of DMMP as a model OP in air (Voiculescu et al., 2005; Zhao et al., 2006).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

This chapter described recent developments of biosensors for detecting OP nerve agents. Different detection modes using various enzymes are applicable for constructing OP biosensors using electrochemical principles. Among them, the use of the OPH enzyme is superior to other protocols due to the fact that OPH-based biosensors directly detect OP compounds in a single step, as compared to the inhibition-mode biosensors based on ChE–ChOx and ChE enzymes which require a two-step operation. A merit of electrochemical biosensors in OP detection is that a portable device can easily be prepared for in-field analysis. The easy operation of biosensors compared to chromatographic or spectroscopic measurement is another advantage. Therefore, biosensors have high potential for fast on-site screening of OP nerve agents.

Neuropathy Target Esterase as a Biomarker and Biosensor of Delayed Neuropathic Agents

Rudy J. Richardson, R. Mark Worden, Sanjeeva J. Wijeyesakere, Nichole D. Hein, John K. Fink and Galina F. Makhaeva

INTRODUCTION

Delayed neuropathic (DN) agents represent a new functional class of potential organophosphorus (OP) threats that have heretofore not been used in warfare or terrorist acts. Nevertheless, it is vital to develop effective defenses against them for three reasons. First, these materials can readily be produced by rather straightforward modifications of the structures of conventional nerve agents. Second, warning signs and symptoms of toxicity may be lacking until 1–4 weeks after exposure, when the permanent sensory deficits and paralysis associated with OP compound–induced delayed neurotoxicity (OPIDN) develop. Third, there are no established means of preventing or treating OPIDN. This chapter begins with a review of current understanding about the chemistry and mechanism of action of DN agents. It then describes how existing knowledge can be applied to generate biomarkers and biosensors for discriminating between conventional and DN agents. It ends by indicating future work needed to address the potential threat of DN agents.

OP COMPOUNDS

Conventional Nerve Agents Versus DN Agents

Conventional nerve agents, such as sarin and soman, are OP compounds of pentavalent phosphorus that are well known as threats in the context of warfare and terrorism (Sidell and Borak, 1992). These substances produce acute cholinergic toxicity and death via inhibition of acetylcholinesterase (AChE) in the central and peripheral nervous systems (Marrs et al., 1996).

In contrast to conventional nerve agents, DN agents produce permanent neurological dysfunction in the form of OPIDN rather than cholinergic toxicity and death (Richardson et al., 2013; Richardson and Makhaeva, 2014). Like conventional nerve agents, DN agents are OP compounds of pentavalent phosphorus that are readily synthesized, but they are designed to inactivate neuropathy target esterase (neurotoxic esterase (NTE)) with preference to AChE (Wu and Casida, 1995; Makhaeva et al., 2012, 2013). Because of this selectivity, DN agents may elicit little or no warning signs of acute cholinergic toxicity, so that victims of DN agents might not know they have been exposed until OPIDN develops 1–4 weeks later.

Cholinergic toxicity from OP compounds can be elicited solely by inhibition of AChE (Richardson, 2010). However, the AChE–OP conjugate can undergo an additional reaction ("aging") entailing loss of an OP ligand to yield a negatively charged phosphoryl adduct on the active site serine. Although the aging reaction has practical implications for therapy, it does not change the qualitative nature of the toxicity (Figure 63.1).

In contrast to the situation with AChE inhibitors and cholinergic toxicity, inhibition of NTE on its own is insufficient to produce OPIDN. Inhibition is the obligatory first step, but this must be followed by aging of the NTE–OP conjugate to trigger axonal degeneration

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00063-4

(Figure 63.2) (Moser et al., 2012; Richardson et al., 2013; Richardson and Makhaeva, 2014).

Thus, DN agents are distinct from conventional nerve agents in several respects. Furthermore, especially in view of their ease of synthesis, absence of initial signs or symptoms of exposure, and lack of prophylactic or therapeutic measures, it is conceivable that rogue nations or terrorist groups might consider DN agents attractive as weapons of permanent incapacitation against military and/or civilian populations. Therefore, part of an effective chemical defense strategy is to develop methods for detecting DN agents and distinguishing them from conventional nerve agents. This can be performed by exploiting the sensitivity and selectivity afforded by appropriate biomarkers and biosensors (Makhaeva et al., 2003; Malygin et al., 2003; Kohli et al., 2007a, 2010, 2014; Sigolaeva et al., 2010, 2013; Srivastava et al., 2010).

OP Compounds of Pentavalent Versus Trivalent Phosphorus

In this chapter, DN agents are defined as OP compounds of pentavalent phosphorus that produce OPIDN. Examples shown in Figure 63.3 are

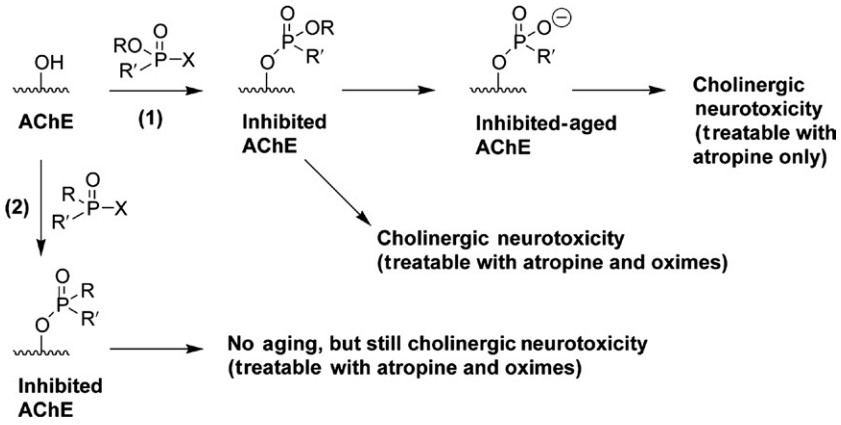

FIGURE 63.1 Reaction of AChE with an organophosphonate in pathway (1) yields a phosphonylated (inhibited) enzyme, which can undergo net loss of an R-group to yield an inhibited and aged enzyme. Inhibition alone produces cholinergic toxicity that is treatable with both atropine to counteract excess acetylcholine at muscarinic acetylcholine receptors and oximes to reactivate AChE. Aging does not change the type of toxicity, but it renders the enzyme intractable to reactivation, so that treatment with oximes becomes ineffective. Reaction of AChE with an organophosphinate in pathway (2) yields a phosphinylated (inhibited) enzyme and produces cholinergic toxicity, but because of the stability of the C—P bonds linking the R- and R′ groups to phosphorus, the phosphinyl moiety on AChE does not undergo aging, so that both atropine and oximes can be used in therapy. R, R′ = substituted or unsubstituted alkyl or aryl groups, which can be different or equivalent. X = primary leaving group (e.g., fluoride). *Source: Reproduced with permission from Richardson and Makhaeva (2014).*

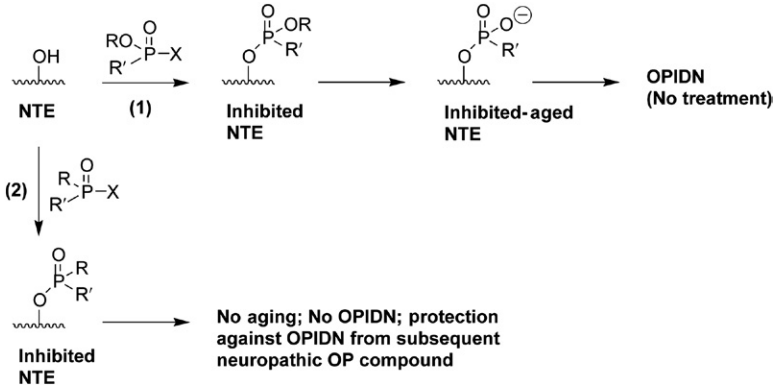

FIGURE 63.2 Reaction of NTE with an organophosphonate in pathway (1) yields a phosphonylated (inhibited) enzyme, which can undergo net loss of an R-group to yield an inhibited and aged enzyme. Inhibition alone does not produce OPIDN; both inhibition and aging are required, and there is no treatment for the neuropathy. Reaction of NTE with an organophosphinate in pathway (2) yields a phosphinylated (inhibited) enzyme, but because of the stability of the C—P bonds linking the R- and R′-groups to phosphorus the phosphinyl moiety on NTE does not undergo aging, so that OPIDN does not occur. Inhibition of NTE with a nonaging inhibitor is not biologically inert—it protects against subsequent exposures to neuropathic (ageable) NTE inhibitors. R, R′ = substituted or unsubstituted alkyl or aryl groups, which can be different or equivalent. X = primary leaving group (e.g., fluoride). *Source: Reproduced with permission from Richardson and Makhaeva (2014).*

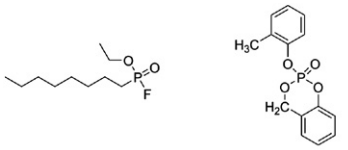

FIGURE 63.3 Examples of DN agents containing pentavalent phosphorus: EOPF and 2-(2-methylphenoxy)-4*H*-l,3,2-benzodioxaphosphorin-2-oxide (2-(2-methylphenoxy)-BDPO or CBDP), the active metabolite of the archetypal DN agent, TOCP (Wu and Casida, 1995).

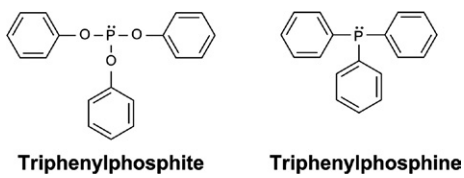

FIGURE 63.4 Examples of neuropathic OP compounds containing trivalent phosphorus: triphenylphosphite and triphenylphosphine (Eto, 1974).

ethyl *n*-octylphosphonofluoridate (EOPF) and 2-(2-methylphenoxy)-4*H*-l,3,2-benzodioxaphosphorin-2-oxide, abbreviated as (2-(2-methylphenoxy)-BDPO) or CBDP, the active metabolite of the archetypal DN agent tri-*o*-cresyl phosphate (TOCP) (Wu and Casida, 1995).

However, there are also OP compounds of trivalent phosphorus that produce neurological injury. Examples shown in Figure 63.4 are triphenylphosphite and triphenylphosphine. Comparatively little is known about the neuropathic trivalent OP compounds, but the clinical course and spatial–temporal pattern of lesions that they produce vary from OPIDN (Lehning et al., 1996), and the mechanisms of action of these compounds appear to differ from that of the DN agents. For example, triphenylphosphite produces a syndrome of delayed axonopathy and other neurodegenerative changes that could represent a variant of OPIDN, possibly via inhibition/aging of NTE (Padilla et al., 1987; Tanaka et al., 1990; Abou-Donia, 1992; Fioroni et al., 1995; Carlson and Ehrich, 2004). However, although triphenylphosphite inhibits NTE *in vitro* and *in vivo*, the nature of the adduct formed with NTE has not been elucidated, and the aging reaction of triphenylphosphite-inhibited NTE has apparently not been studied. Triphenylphosphine is another trivalent OP compound that produces delayed axonopathy, but its pathogenesis and mechanism appear to differ from those of triphenylphosphite or neuropathic OP compounds of pentavalent phosphorus. Among other differences, triphenylphosphine does not inhibit NTE *in vitro* or *in vivo* (Davis et al., 1999; Padilla et al., 1987). The remainder of this chapter deals exclusively with OP compounds of pentavalent phosphorus.

OPIDN

OPIDN, also known as OP compound–induced delayed polyneuropathy, can be produced within 1–4 weeks of a single exposure to a DN agent. With compounds that are highly selective for NTE, the first week of this period can be clinically quiescent (Davis and Richardson, 1980; Lotti, 1992; Lotti and Moretto, 2005; Richardson et al., 2013; Richardson and Makhaeva, 2014). Pathogenesis involves progressive distal degeneration of sensory and motor axons in peripheral nerves and spinal cord tracts. Accordingly, symptoms begin with paresthesias in the distal extremities, followed by sensory loss, ataxia, and flaccid paralysis. Once the disease is initiated, it advances inexorably. In keeping with its unknown mechanism of neurodegeneration, there is no cure or treatment other than general supportive therapy. Over a period of months to years, some regeneration of peripheral nerve axons may occur to reinnervate muscle. Nevertheless, the concomitant persistence of injury to descending inhibitory pathways in the spinal cord prevents complete functional recovery and permits only a shift from flaccid to spastic paralysis (Richardson et al., 2013; Richardson and Makhaeva, 2014).

Because of the insidious onset and permanent debilitating effects of OPIDN, it is essential to be able to predict the potential of a given OP compound to produce this disease as opposed to causing acute cholinergic toxicity. Furthermore, it is important to develop specific and stable biomarkers and biosensors of exposure to DN agents and devise countermeasures against them (Makhaeva et al., 2003; Malygin et al., 2003; Kohli et al., 2007a; Sigolaeva et al., 2010, 2013). To accomplish these goals, it will be necessary to acquire a level of mechanistic understanding of interactions between DN compounds and target macromolecules akin to what has been achieved for conventional (anti-AChE) nerve agents. Although there is much left to be learned about the pathogenesis and mechanism of OPIDN, sufficient knowledge exists about the apparent initiating events, such as inhibition and aging of NTE, to provide a foundation for the development of biomarkers and biosensors of DN agents.

NTE

Definition of NTE and its Potential Normal or Pathogenic Roles

NTE (UniProtKB/Swiss-Prot Q81Y17; PLPL6_HUMAN) has been categorized as a lysophospholipase (EC 3.1.1.5) because of its ability to hydrolyze phosphatidylcholine to glycerophosphocholine (UniProt, 2014). It is also known as patatin-like phospholipase

domain–containing protein 6, whose gene name is *PNPLA6*, because the catalytic domain of NTE encompasses a region with sequence homology to patatin, a phospholipase found in potatoes and other plants. Thus, it appears that NTE can function biochemically as a phospholipase, but its precise physiological role remains to be firmly established (Wijeyesakere and Richardson, 2010; Richardson et al., 2013).

The human *PNPLA6* gene encoding NTE has 35 exons (33 of them protein-coding) and 24 transcripts (Ensembl, 2014). Thus, it is not surprising that the UniProt entry for human NTE lists five protein isoforms attributed to alternative splicing (UniProt, 2014). Although UniProt has adopted isoform-1 as the canonical sequence, this chapter defines human NTE as isoform-2, which is the sequence initially reported by Lush et al. (1998) and consists of 1,327 amino acids and a molecular weight without posttranslational modifications of 146 kDa. The protein has a transmembrane domain near the N-terminus (residues 9–31) and three putative cyclic nucleotide binding domains (residues 163–262, 480–573, and 597–689), in addition to the patatin domain (residues 933–1,099), which contains the active site (Wijeyesakere et al., 2007; Wijeyesakere and Richardson, 2010).

The three-dimensional structure of NTE has not been experimentally determined, but a homology model of the patatin domain indicates that the active site serine (Ser^{966}) is located on a "nucleophilic elbow" characteristic of serine hydrolases (Wijeyesakere et al., 2007). Moreover, the model indicates that the catalytic site of NTE consists of a novel Ser-Asp catalytic dyad, as in patatin and mammalian cytosolic phospholipase A2 ($cPLA_2$), rather than the classical catalytic triad (Ser-Asp/Glu-His), as found in many serine hydrolases including AChE. Recently, mutations have been identified in NTE that are associated with motor neuron disease (NTE-MND) (Rainier et al., 2008, 2011). Constructs containing NTE-MND mutations within the catalytic domain have altered inhibition and aging kinetics (Hein et al., 2010a). In addition, cultured fibroblasts from human subjects with NTE-MND exhibit decreased NTE catalytic activity (Hein et al., 2010b). However, although fibroblasts from human subjects heterozygous for an insertion mutation expected to truncate the NTE protein had markedly reduced NTE activity (40–43% of control), these subjects were asymptomatic, indicating that decreased NTE activity alone is insufficient to produce disease.

NTE was first identified as the presumptive target of neuropathic OP compounds in the initiation of OPIDN (Johnson, 1970). Its activity in cells and tissues is operationally defined as the enzymatic hydrolysis of the nonphysiological substrate, phenyl valerate, which is resistant to inhibition by diethyl 4-nitrophenyl phosphate (paraoxon) and sensitive to inhibition by *N,N′*-diisopropylphosphorodiamidic fluoride (mipafox) under specified conditions of preincubation with inhibitors and subsequent incubation with substrate (Johnson, 1977; Kayyali et al., 1991; Makhaeva et al., 2007).

Because the full-length protein is difficult to isolate or produce, human recombinant NTE esterase domain (NEST) has been used as an NTE surrogate for studies *in vitro* that require pure protein rather than a crude preparation containing NTE (Kropp et al., 2004). NEST comprises residues 727–1,216 of NTE; it has been shown to be the shortest segment of NTE that retains esterase activity. Moreover, the catalytic properties of NEST, including its response to OP inhibitors, closely resemble those of full-length NTE (Atkins and Glynn, 2000; Atkins et al., 2002; van Tienhoven et al., 2002; Kropp et al., 2004). The catalytic activity of NEST has been shown to alter the fluidity of bilayer lipid membranes (Greiner et al., 2010), and NEST has been incorporated into a biosensor for the detection of DN agents (Kohli et al., 2007a, 2014).

Role of NTE in OPIDN

Early studies indicated that the initial molecular events in OPIDN are the concerted inhibition and aging of a threshold level (>70%) of NTE in the central and peripheral nervous systems (Johnson, 1974, 1982; Lotti, 1992; Glynn, 1999). As with other serine esterases, inhibition of NTE is thought to occur by nucleophilic attack of the active site serine (Ser^{966}) at the phosphorus of the OP compound, with displacement of a primary leaving group. Aging of the phosphylated enzyme presumably involves loss of a second ligand, leaving a negatively charged phosphyl moiety covalently attached to the active site. Note that "phosphyl" is used as a generic term for the various types of OP compounds that might be used as inhibitors of serine esterases, such as phosphates, phosphonates, phosphinates, and phosphoramidates.

The apparent necessity for aging of NTE as a trigger for OPIDN came about from analyses of structure–activity relationships. These studies revealed that NTE inhibitors fall into two functional categories, type A and type B (Johnson, 1975; Davis and Richardson, 1980; Davis et al., 1985) (Figure 63.5).

Type A NTE inhibitors produce OPIDN and include certain phosphates, phosphonates, and phosphoramidates. When type A compounds inactivate NTE, it rapidly becomes intractable to reactivation by powerful nucleophiles, such as oximes or fluoride. This inability to be reactivated has been interpreted as evidence of aging. Because loss of reactivatability takes place within minutes of inhibition by type A inhibitors and OPIDN takes 1–4 weeks to develop, aging of NTE is not the rate-limiting step in the disease process (Johnson, 1982).

Type B NTE inhibitors do not produce OPIDN and include certain phosphinates, carbamates, and

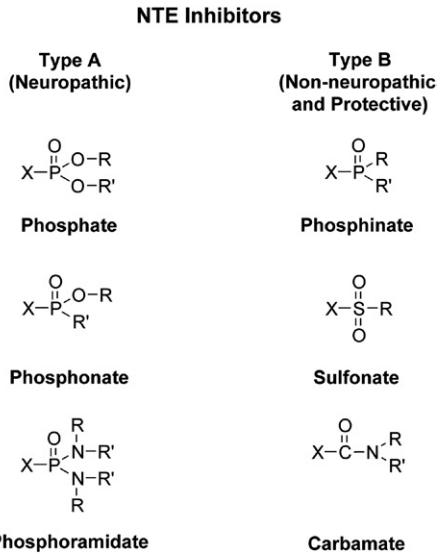

FIGURE 63.5 Subclasses of NTE inhibitors. Type A NTE inhibitors include phosphates, phosphonates, and phosphoramidates; these are neuropathic and capable of aging. Type B NTE inhibitors include phosphinates, sulfonates, and carbamates; these are nonneuropathic and not capable of aging. However, inhibition of NTE with a type B inhibitor will protect against OPIDN from subsequently administered type A inhibitors. *Source: Reproduced with permission from Richardson and Makhaeva (2014).*

sulfonates. NTE conjugates with type B compounds are considered not to undergo aging; those formed from carbamates and phosphinates can be reactivated. Moreover, carbamylated, phosphinylated, or sulfonylated NTE cannot undergo further reactions to produce a stable charged species. Despite the fact that inhibition of NTE by type B compounds does not result in OPIDN, this reaction is far from being biologically inert. Pretreatment of animals with type B inhibitors protects them against OPIDN from subsequently administered type A inhibitors, presumably by blocking the formation of aged NTE (Richardson, 1984; Davis et al., 1985; Johnson, 1990) (Figure 63.2). Protection against type A inhibitors by type B inhibitors is effective as long as inhibition of NTE by type B compounds is more than 30%, thus preventing inhibition and aging of the more than 70% of NTE required for induction of OPIDN.

It would appear that the ostensible requirement for aging of NTE in the development of OPIDN is not merely to ensure irreversible inhibition of the enzyme. Prolonged suprathreshold inhibition (>70%) of neural NTE *in vivo* by repeated dosing of nonaging inhibitors does not cause neuropathy (Johnson, 1970, 1974, 1982). Moreover, repeated low-level dosing with aging inhibitors to produce a prolonged steady-state inhibition that is below threshold (<70%) does not result in OPIDN until a higher single dose is superimposed that raises the inhibition level above threshold. In the latter scenario, there is still a delay of 10–14 days from the high point of inhibition (and presumed concomitant aging) until signs of neuropathy appear (Johnson and Lotti, 1980; Lotti and Johnson, 1980). These results suggest that simple loss of catalytic activity of NTE is not the damaging event in OPIDN. Thus, the notion has arisen that the "biochemical lesion" that triggers OPIDN is the formation of a chemically modified (aged) protein that has gained a toxic function in the neuron (Richardson, 1984; Glynn, 2000; Richardson et al., 2013).

The pathogenic role of aged NTE is not known, but it is tempting to speculate that it may be involved in an axonal self-destruct program that has been proposed to be an important mechanism in neurodegenerative disorders, such as motor neuron disease (Raff et al., 2002). Such a program might be triggered by chemically modified NTE acting through a toxic gain of function mechanism. However, experiments with conventional NTE knockouts (Winrow et al., 2003; Moser et al., 2004; Mühlig-Versen et al., 2005) and conditional NTE knockouts (Akassoglou et al., 2004), along with demonstrations of a likely role of NTE in membrane lipid metabolism (van Tienhoven et al., 2002; Quistad et al., 2003; Zaccheo et al., 2004), indicate that lethality or neuropathology can result from a loss of function of NTE (Glynn, 2006). Nevertheless, while the physiological and pathogenic roles of NTE are being deciphered, the fact that an excellent correlation exists between inhibition/aging of NTE and induction of OPIDN is sufficient to enable the pragmatic use this information for the development of biomarkers and biosensors for DN agents (Makhaeva et al., 2003, 2007).

KINETICS OF OP INHIBITOR–SERINE HYDROLASE INTERACTIONS

Introduction

The inhibitory and postinhibitory steps in the interaction of an OP compound with a serine hydrolase (E-OH) such as NTE or AChE are illustrated in Figure 63.6. The mathematical relationships describing the kinetics of irreversible inhibition of serine esterases by OP compounds and postinhibitory reactions of the enzyme–inhibitor adduct (conjugate) summarized here were elegantly set forth in the classic work by Aldridge and Reiner (1972), and synopses are available in other sources (Main, 1980; Clothier et al., 1981; Richardson, 1992). The equations featured here provide a basic foundation for determining the inhibitory potency of OP compounds against serine hydrolases, as well as the rates of reactivation or aging of the inhibited hydrolases. Such approaches can be used to assess the neuropathic potential of compounds and to distinguish conventional nerve agents from DN agents using

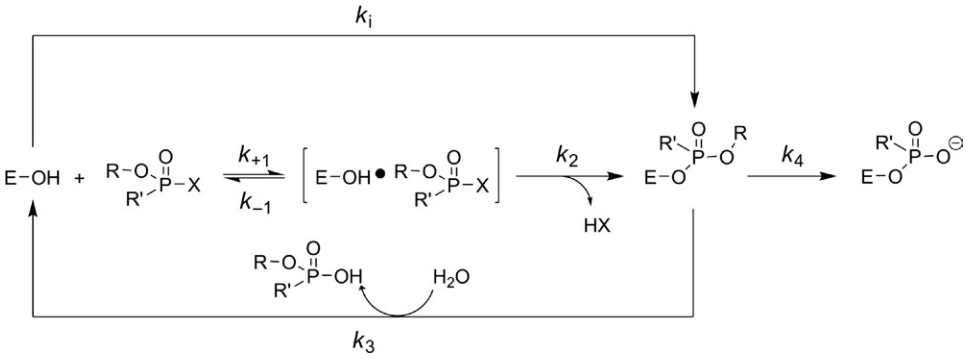

FIGURE 63.6 Reactions between a serine hydrolase and an organophosphonate inhibitor showing associated rate constants. The initial reversible reaction with forward (k_{+1}) and back (k_{-1}) rate constants forms a Michaelis-type complex. The complex can undergo phosphonylation (rate constant k_2) with expulsion of the primary leaving group, X. The overall progress of the reaction from enzyme to phosphonylated (inhibited) product is characterized by the bimolecular rate constant of inhibition, k_i. The phosphonylated enzyme can undergo spontaneous reactivation (hydrolysis in the presence of excess water) described by the pseudo-first-order rate constant, k_3, or undergo net loss of the R-group (aging) characterized by the first-order rate constant, k_4 (Richardson, 1992).

biomarkers and biosensors. For more complex scenarios beyond the scope of this chapter, other equations have been developed (Estevez and Vilanova, 2009).

Inhibition

The first step leading to E-OH inhibition is a reversible association of the OP compound (depicted in Figure 63.6 as a phosphonate) and enzyme to form a Michaelis-type complex (shown in square brackets in Figure 63.6). The associated rate constants for the forward (k_{+1}) and back (k_{-1}) reactions are shown on the double arrow (Figure 63.6). The active site serine hydroxyl of the hydrolase then engages in a nucleophilic attack on the phosphorus atom of the OP inhibitor, displacing the primary leaving group (X^-), resulting in a phosphonylated enzyme with net loss of HX. The primary leaving group, X^-, is typically a conjugate base of a strong acid, HX, such as HF. The phosphonylation rate constant is shown as k_2 (Richardson, 1992).

Considering only the first two steps in the reaction sequence, which is appropriate for most acylating inhibitors, the affinity of the inhibitor for the enzyme is given by the Michaelis-type equilibrium constant, K_a, as shown in Eq. (63.1).

$$K_a = (k_{-1} + k_2) / k_{+1} \tag{63.1}$$

The overall progress of the reaction from E-OH and inhibitor to phosphonylated enzyme is characterized by the bimolecular rate constant of inhibition, k_i. This important measure of inhibitory potency is determined by measuring the activity remaining as a function of time of preincubation with various concentrations of inhibitor. The substrate is added after the preincubation interval (Richardson, 1992). When the inhibitor concentration [OP] $\ll K_a$, k_i is given by Eq. (63.2).

$$k_i = k_2 / K_a \tag{63.2}$$

So-called ideal first-order kinetics of inhibition are obtained under the commonly observed conditions when the concentration of the Michaelis-type complex is small, k_2 is high, k_3 is much smaller than k_2, and [OP] >10[E-OH], where [E-OH] = concentration of native enzyme. In such cases we have Eq. (63.3).

$$\ln(v/v_0) = k_2[\mathrm{OP}]t/([\mathrm{OP}] + K_a) \tag{63.3}$$

In Eq. (63.3), v is the rate of enzymatic hydrolysis of its substrate at time = t, and v_0 is the rate at time zero. Substituting (% activity/100) for (v/v_0) and letting $k' = k_2[\mathrm{OP}]/([\mathrm{OP}] + K_a)$ yields Eq. (63.4).

$$\ln(\%\,\text{activity}/100) = -k't \tag{63.4}$$

Thus, primary plots of ln(% activity/100) versus t will be straight lines with slopes= $-k'$, as shown in Figure 63.7A. In addition, the experimentally determined dependence of %(activity remaining) on the preincubation time (t) and inhibitor concentration [OP] is given by Eq. (63.5).

$$\ln(\%\,\text{activity})/100 = -k_i[\mathrm{OP}]t \tag{63.5}$$

Setting Eqs. (63.4) and (63.5) equal to each other gives Eq. (63.6).

$$k' = k_i[\mathrm{OP}] \tag{63.6}$$

Therefore, a secondary plot of $-k'$ versus [OP] will yield a straight line with slope = k_i, as shown in Figure 63.7B. The k_i value thus obtained is an indication of the inhibitory potency of a given compound against a particular serine hydrolase. As stated, k_i is a measure of the

overall progress of the reaction between the inhibitor and enzyme to yield the organophosphylated product. However, it is important to realize, as shown in Eq. (63.2), that k_i is a composite of K_a, which is an indication of the affinity of the inhibitor for the enzyme, and k_2, which is an indication of the rate of phosphylation of the enzyme by the inhibitor. Inspection of Eqs. (63.2) and (63.5) shows that the units of k_i are $[OP]^{-1}t^{-1}$; for example, the k_i obtained for chlorpyrifos methyl oxon (CPMO) against hen brain microsomal NTE at pH 8.0 and 37°C (Figure 63.7) is $5.82 \times 10^4 M^{-1} min^{-1}$ (Richardson, 1992; Kropp and Richardson, 2003).

Under certain conditions, it is possible to determine the K_a and k_2 components of k_i separately. For example, if the secondary plot is not linear, then this is an indication of an appreciable concentration of a Michaelis-type complex. In this case, the K_a term must be included; by combining Eqs. (63.3) and (63.4) and rearranging, we have Eq. (63.7).

$$[OP]/k' = K_a/k_2 + [OP]/k_2 \qquad (63.7)$$

Thus, a Wilkinson plot of $[OP]/k'$ versus [OP] will yield a straight line with slope $1/k_2$, a y-intercept of K_a/k_2, and an x-intercept of K_a. Moreover, in Eq. (63.2), $k_i = k_2/K_a$; therefore, the reciprocal of the y-intercept gives k_i (Richardson, 1992).

An especially useful relationship is given by substituting a % activity of interest into Eq. (63.5) to yield the inhibitor concentration at a given time of preincubation with an enzyme that would yield the particular percent activity. For example, when $[OP]_{50} = I_{50}$ = the inhibitor concentration required to produce 50% inhibition of the enzyme at a given time, t, of incubation of enzyme and inhibitor at defined conditions of pH, temperature, and ionic strength before adding substrate, then we have Eq. (63.8).

$$[OP]_{50} = I_{50} = \ln 2/k_i t \approx 0.693/k_i t \qquad (63.8)$$

Note that in Eq. (63.8), k_i and I_{50} are reciprocally related and I_{50} is time-dependent. It is valid to calculate an I_{50} from a k_i value when ideal kinetics are observed. However, it is not valid to calculate a k_i from an experimentally determined fixed-time I_{50}, because the I_{50} alone contains no information about the kinetic behavior of the inhibition reaction. In addition, if inhibitory potency is assessed by measuring fixed-time I_{50} values, it is essential to report the time of preincubation along with the concentration, because the I_{50} decreases as the preincubation time increases (Aldridge and Reiner, 1972; Clothier et al., 1981; Richardson, 1992). For example, using Eq. (63.8), the 20-min I_{50} for CPMO against hen brain microsomal NTE at pH 8.0 and 37°C may be calculated from the k_i given as $0.693/(5.82 \times 10^4 M^{-1} min^{-1})(20 min) = 5.95 \times 10^{-7} M \approx 0.60 \mu M$ (Kropp and Richardson, 2003).

Reactivation

In Figure 63.6, the phosphonylated enzyme can undergo spontaneous reactivation via hydrolysis to yield free enzymes and a phosphonic acid, with an

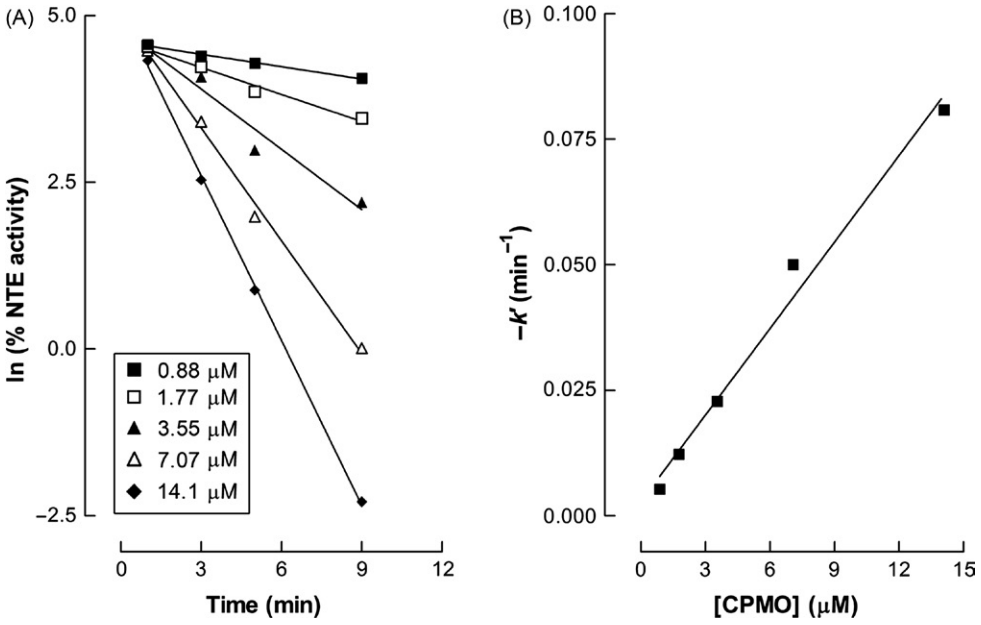

FIGURE 63.7 (A) Primary kinetic plots of ln(% NTE activity) versus time for various indicated concentrations of CPMO. (B) Slopes ($-k'$) of primary kinetic plots versus inhibitor concentration. Data are for hen brain microsomal NTE at pH 8.0 and 37°C. *Source: Reproduced with permission from Kropp and Richardson (2003).*

associated pseudo-first-order rate constant, k_3 (the reactivator, water, is present in great excess). The spontaneous rate constant of reactivation, k_3, can be obtained from Eq. (63.9).

$$\ln(100/\%\,\text{inhibition}) = k_3 t \tag{63.9}$$

The % reactivation in a reactivation experiment is determined by Eq. (63.10).

$$\%\,\text{inhibition} = [(A - A_t) / (A - A_0)] \times 100 \tag{63.10}$$

In Eq. (63.10), A is the activity of the control, A_t is the activity of the inhibited enzyme at time t, and A_0 is the activity of the inhibited enzyme at $t = 0$. In practice, reactivation is studied by preincubating the enzyme with a concentration of inhibitor that rapidly produces essentially complete inhibition. The inhibitor and enzyme are then rapidly separated or the preparation is diluted sufficiently to prevent further appreciable inhibition of free enzyme, and the return of enzyme activity is measured at timed intervals. The slope (k_3) of the least-squares best-fit line from a plot of ln(100/% inhibition) versus t is determined using linear regression from the initial linear portion of the curve. From Eq. (63.9), it can be seen that the units of k_3 are t^{-1} (e.g., min^{-1}), and that the half-life, $t_{1/2}$, the time required for 50% reactivation, can be determined from Eq. (63.11).

$$t_{1/2} = \ln 2/k_3 \approx 0.693/k_3 \tag{63.11}$$

The apparent half-life of reactivation can range from minutes to weeks, depending on the enzyme, inhibitor, pH, and temperature. Reactivation can appear to be slow or nonexistent if aging has occurred, because the aged form of the phosphylated enzyme is stable to hydrolysis and will not reactivate (Richardson, 1992; Jianmongkol et al., 1999).

Aging

As shown in Figure 63.6, the inhibited esterase can also undergo aging, such as via net loss of a labile R-group to yield the negatively charged phosphonyl adduct on the active site serine of the enzyme. Aging is characterized by a first-order rate constant, k_4, and the operational definition of this reaction is the time-dependent loss of the ability to reactivate the inhibited enzyme by powerful nucleophiles, such as fluoride ion or oximes. The method of determining aging is similar to that for reactivation. Enzyme is preincubated with a concentration of inhibitor sufficient to produce essentially complete inhibition in a relatively short time. Aliquots are then treated with a reactivator such as fluoride or an oxime, and the amount of activity relative to a nonreactivated sample is measured. The first-order rate constant of aging, k_4, can be determined from Eq. (63.12).

$$\ln[100/(\%\,\text{reactivation})] = k_4 t \tag{63.12}$$

In an aging experiment, the % reactivation is determined by Eq. (63.13).

$$\%\,\text{reactivation} = [(AR_1 - AR_2)/(AR_0 - AI_0)] \times 100 \tag{63.13}$$

In Eq. (63.13), AR_1 = activity of reactivated enzyme at t_{aging}, AR_0 = activity of reactivated enzyme at $t = 0$, AI_1 = activity of inhibited enzyme without reactivator at t_{aging}, and AI_0 = activity of inhibited enzyme without reactivator at $t = 0$. The slope (k_4) of the least-squares best-fit line from a plot of ln(100/% inhibition) versus t is determined using linear regression from the initial linear portion of the curve. From Eq. (63.12), it can be seen that the units of k_4 are t^{-1} (e.g., min^{-1}), and that the aging half-life, $t_{1/2}$, the time required for 50% aging, can be determined from Eq. (63.14).

$$t_{1/2} = \ln 2/k_4 \approx 0.693/k_4 \tag{63.14}$$

The apparent half-life of aging depends on the enzyme, inhibitor, pH, and temperature. However, NTE inhibited with most neuropathic agents exhibits aging half-lives on the order of several minutes, so that the delay of 1–4 weeks between exposure and appearance of signs of OPIDN is not due to the time required for aging of phosphylated NTE (Johnson, 1982; Richardson, 1992; Jianmongkol et al., 1999; Kropp and Richardson, 2007).

Relative Inhibitory Potency

The neuropathic potential of an OP compound depends on its ability to inhibit NTE (and presumably for the NTE–OP conjugate to undergo aging). However, an OP compound will not be able to inhibit NTE to a sufficient degree to produce OPIDN if its cholinergic toxicity is too high to permit survival of a neuropathic dose. Therefore, neuropathic potential of an OP compound is a relative concept that depends on the ability of the compound to inhibit NTE compared to its anti-AChE activity. Compounds can be screened *in vitro* for relative inhibitory potency (RIP) by measuring k_i or I_{50} values and calculating a ratio, as shown in Eq. (63.15).

$$\text{RIP} = k_i(\text{AChE})/k_i(\text{NTE}) \tag{63.15}$$

Because of the reciprocal relationship between the k_i and I_{50} described by Eq. (63.8), the RIP for fixed-time I_{50} values (determined at the same fixed-time, t) is given by Eq. (63.16).

$$\text{RIP} = I_{50}(\text{NTE})/I_{50}(\text{AChE}) \quad (63.16)$$

Thus, when the RIP is more than 1, the compound is a more potent inhibitor of AChE than NTE, and cholinergic toxicity would be expected to predominate over OPIDN. In fact, when the RIP is more than 1, the dose required to produce OPIDN tends to be greater than the median lethal dose (LD_{50}) for the compound (Richardson, 1992; Kropp and Richardson, 2003). Note that the RIP is simply a ratio of inhibitor potencies, and it could have been defined the other way around, with the k_i for NTE in the numerator. However, the convention used in the present chapter defines the RIP as shown in Eqs. (63.15) and (63.16).

For example, although CPMO, the active metabolite of the insecticide chlorpyrifos methyl, would seem to be a potent inhibitor of NTE, with $k_i = 5.82 \times 10^4\,M^{-1}\,min^{-1}$ and 20 min $I_{50} = 0.595\,\mu M$, it is a much more potent inhibitor of AChE, with $k_i = 1.09 \times 10^7\,M^{-1}\,min^{-1}$ and 20 min $I_{50} = 3.18 \times 10^{-9}\,M$ (3.18 nM), so that the RIP for this compound is 187. This value is $\gg 1$, indicating that OPIDN could not be produced unless the dose were $\gg LD_{50}$ and aggressive therapy for cholinergic toxicity were instituted (Kropp and Richardson, 2003). In contrast, the compound di-*n*-pentyl 2,2-dichlorovinyl phosphate (*n*-pentyl DCV) has an RIP of 0.03 and produces OPIDN at a dose of 2 mg/kg, which is much lower than the LD_{50} dose of 26 mg/kg (Richardson, 1992). OP inhibitors with extremely high selectivity for NTE have been synthesized (e.g., EOPF) (Figure 63.3) (Wu and Casida, 1995), which has 20-min I_{50} values for mouse brain NTE and AChE of 0.02 and 54 nM, respectively, yielding an RIP value of 3.7×10^{-4} (i.e., approximately 2,700-times more potent for NTE than AChE) (Wu and Casida, 1996). Note that EOPF is a chiral compound, and the reported I_{50} and RIP values are for the racemic mixture. Given that inhibitory potency can vary considerably between *R* and *S* forms of OP compounds (Wu and Casida, 1994), it would be of interest to perform such measurements on resolved isomers.

Because RIP values can encompass several orders of magnitude above and below 1, it is convenient to visualize such data by using log (RIP) values as shown in Figure 63.8. It can readily be seen that higher positive numbers correspond to greater cholinergic propensity, as typified by the insecticide active metabolite, CPMO. Likewise, larger negative numbers correspond to greater neuropathic potential, as exemplified by the DN agent, EOPF. It is also interesting to see the steady progression from cholinergic to neuropathic tendency exhibited by the homologous series of dialkyl 2,2-dichlorovinyl phosphates (dichlorvos (DCV)) compounds. In this and other series of alkyl OP inhibitors, increasing length of alkyl chains tends to produce decreasing potency against AChE and increasing potency against NTE until maximum selectivity is reached, after which potencies and selectivity decline (Richardson, 1992; Malygin et al., 2003). The highest potency for NTE appears to have been achieved with certain phosphonofluoridates, where the sum of alkyl and alkoxyl chain length is 12–16 atoms, including O and P; in this series, EOPF has the highest potency and selectivity for NTE (Wu and Casida, 1995, 1996).

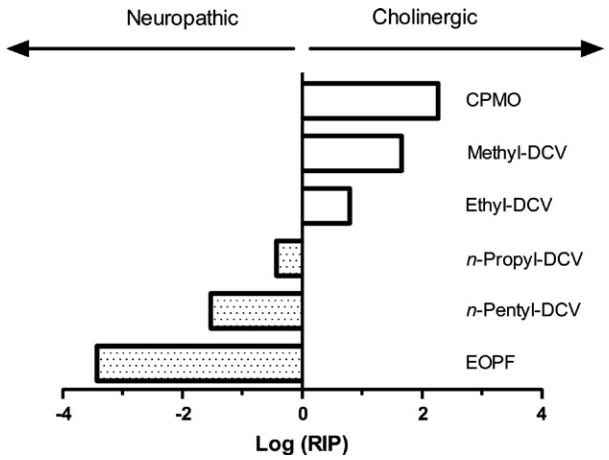

FIGURE 63.8 Spectrum of log values of RIP = k_i(AChE)/k_i(NTE), where k_i = bimolecular rate constant of inhibition. As log(RIP) becomes more positive, cholinergic potential increases; as log(RIP) becomes more negative, DN potential increases. DCV derivatives refer to symmetrical dialkyl–2,2–dichlorovinyl phosphate (dichlorvos) compounds. *Source: Data from Richardson (1992); Wu and Casida (1996); and Kropp and Richardson (2003).*

Determinations of RIP performed *in vitro* using preparations of AChE and NTE can only assess the neuropathic potential of OP compounds that are direct-acting inhibitors (i.e., compounds that do not require metabolic activation). Such preparations would also not detect effects of detoxification that might occur *in vivo*. To account for the possibility of metabolic activation/deactivation, the system can be augmented by preincubating the compound of interest with xenobiotic metabolic enzymes (or chemical activators, e.g., bromine) before mixing with AChE or NTE preparations (Barber et al., 1999). The concept of the RIP can also be extended to assaying AChE and NTE *ex vivo* and calculating activity ratios after dosing laboratory animals with the compound of interest. Because the adult hen is the species of choice for assessing the neuropathic potential of OP compounds, this species could also be used for *ex vivo* RIP determinations (Richardson, 1992; Richardson et al., 1993). However, despite the fact that rats and mice are not as suitable as hens for studying the clinical and histopathological effects of DN agents, rodent species have AChE and NTE in their nervous systems and can therefore serve as sources of these enzymes for *in vitro* or *ex vivo* determinations of neuropathic potential (Novak and

Padilla, 1986; Wu and Casida, 1996; Quistad et al., 2003; Makhaeva et al., 2014).

BIOMARKERS

Introduction

A widely quoted definition of "biomarker" is that it is "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention" (Atkinson et al., 2001). Although this definition was developed from the standpoint of pharmacology and therapeutics, it can easily be modified to apply to toxicology. In a toxicological setting, a biomarker would consist of an appropriate measure of a chemically induced pathological process (e.g., a response to a toxicant that could be considered injurious or diagnostic of potential injury). Ideally, a toxicological biomarker would represent a biological response that would be pathognomonic of a specific agent or at least a selective indicator of the effects of a class of agents. Thus, a biomarker of a DN agent would involve more than measuring the mere presence of the compound; instead, it would assess a distinctive and preferably early feature of the pathogenesis of OPIDN. Because the earliest known molecular events associated with OPIDN are the inhibition and aging of NTE, the appropriate biomarkers of DN agents would be measurements of these reactions, which could be performed via determination of inhibition and aging using enzymology, or through identification of the resulting OP–NTE conjugates using mass spectrometry.

Enzymological Measurements of NTE Inhibition and Aging

NTE activity in lymphocytes and platelets was discovered by Dudek and Richardson (1978, 1982), characterized in human populations (Bertoncin et al., 1985; Maroni and Bleecker, 1986), and used in animal (Richardson and Dudek, 1983; Schwab and Richardson, 1986; Richardson et al., 1993; Makhaeva et al., 2003) and human (Lotti et al., 1983, 1986; McConnell et al., 1999) studies to monitor exposures to potentially neuropathic OP compounds. NTE activity is not found in erythrocytes or in plasma or serum. These studies indicate that NTE in lymphocytes, platelets, or whole blood can be assayed and used as a biomarker of exposure to DN agents, particularly if the blood samples are taken within 24 h of acute exposures. Attempts to measure the aging of NTE in lymphocytes or platelets of exposed subjects have apparently not been performed. However, given that aging of NTE inhibited by DN agents typically occurs within a half-life of a few minutes (Clothier and Johnson, 1979; Johnson, 1982), aging would be complete by the time that lymphocyte samples could be taken and assayed for activity. Nevertheless, as stated, given the apparent requirement for aging as well as inhibition of NTE in OPIDN, and to help rule out false positives arising from inhibition by type B (nonaging) NTE inhibitors (Figure 63.5), aging studies should be undertaken in future work. As noted, mass spectrometry can be used to identify the phosphyl adduct on the inhibited enzyme, thus differentiating between inhibited and aged forms.

In keeping with the concept of the RIP discussed, inhibition of lymphocyte and/or platelet NTE and possibly erythrocyte LysoPC hydrolase should be used in conjunction with inhibition of erythrocyte AChE and plasma butyrylcholinesterase (BChE) to assess the likelihood that an exposure to OP compounds would produce cholinergic and/or DN effects. Erythrocyte AChE inhibition has long been used as a biomarker of exposure to conventional nerve agents or OP insecticides (Wilson and Henderson, 1992; Lotti, 1995). BChE can be sensitive to both conventional and DN agents, and its inhibition could thus serve as a general biomarker for OP agents (Kropp and Richardson, 2007; van der Schans et al., 2008; Jiang and Lockridge, 2013). For additional biomarkers of OPs, readers are referred to Gupta and Milatovic (2014).

Identification of NTE–OP Conjugates Using Mass Spectrometry

Mass spectrometry has proved to be an excellent tool for identifying the OP conjugates (adducts) of serine hydrolases such as AChE and BChE (Doorn et al., 2000, 2001b, 2003; Elhanany et al., 2001; Jennings et al., 2003; Kropp and Richardson, 2007; Li et al., 2007; van der Schans et al., 2008; Jiang et al., 2013). One approach is to reactivate inhibited esterases with fluoride and to detect the liberated OP fluoridate using gas chromatography–mass spectrometry; however, this technique cannot be used if the esterase conjugate has aged (Degenhardt et al., 2004; Solano et al., 2008). Because NTE inhibited with DN agents undergoes rapid aging (Johnson, 1982), it is important to be able to detect the aged adducts. Therefore, peptide mass mapping would be the current method of choice, whereby the active site peptide containing the phosphyl moiety on the active site serine is identified using mass spectrometry after digestion of the inactivated esterase with trypsin or other proteases (Doorn et al., 2003; Jiang et al., 2013). Although some DN agents have extremely high potency and selectivity for NTE, in general there will be some degree of inhibitory overlap with other serine hydrolases (see Figure 63.8). Accordingly, in addition to examining NTE, it would be useful to acquire mass spectrometry data for OP conjugates of other potential esterase targets, such as AChE

and BChE, with particular attention being given to the aged species.

The classical view of the aging reaction of OP-inhibited serine esterases, based on studies of soman-inhibited AChE, is that aging involves an S_N1 reaction at a ligand carbon and transient formation of a carbocation that dissociates from the enzyme (Michel et al., 1967; Shafferman et al., 1996). The traditional model has been confirmed using mass spectrometry for BChE inhibited by a variety of phosphates and phosphonates and allowed to age in the presence of [^{18}O]-H_2O (Li et al., 2007). Thus, it appears that cholinesterases inhibited by phosphates or phosphonates undergo aging via S_N1 cleavage of an O—C bond rather than S_N2 cleavage of a P—C bond.

However, it is important to realize that mechanisms of inhibition and aging can differ depending on the esterase, inhibitor, and stereochemistry of the inhibitor. For example, the aging of AChE inhibited by ethyl *N*,*N*-dimethylphosphoramidocyanidate (tabun) was shown to proceed via hydrolytic P—N bond scission with loss of dimethylamine (Elhanany et al., 2001). In addition, the mechanism of inhibition of AChE, BChE, and cholesterol esterase by the resolved stereoisomers of isomalathion has been shown to differ between the (1*R*) and (1*S*) forms, and the mechanism of aging in each case appears to proceed via S_N2 displacement of a secondary leaving group by water, involving cleavage of a P—S bond (Doorn et al., 2000, 2001a,b, 2003). A subsequent study of BChE inhibited with racemic isomalathion confirmed that the major pathway for aging involved scission of the P—S bond, but relatively small peaks in the mass spectrum indicated that O—C and S—C cleavage could also occur as minor pathways (Li et al., 2007).

For NTE inhibited by phosphates or phosphonates, the aging mechanism has been thought to be consistent with an S_N2 reaction at phosphorus (Johnson, 1982), although this hypothesis has not been rigorously tested. With respect to stereochemical influences on aging, limited studies indicate that both enantiomers of certain phosphonates inhibit NTE, but only one enantiomer undergoes aging (Johnson et al., 1985, 1986). As expected, the isomer that inhibits and ages NTE produces OPIDN. In contrast, the isomer that inhibits NTE without aging does not produce OPIDN. Furthermore, the nonaging isomer protects against neuropathy from subsequent administration of a neuropathic OP compound (Johnson and Read, 1987; Johnson et al., 1988). Some racemic phosphonates have been found to produce OPIDN at lower than expected threshold levels of inhibited/aged NTE (i.e., <70%), possibly because of potentiation or promotion of subclinical axonopathy by the nonaging enantiomer, presumably by the action of the nonaging enantiomer on one or more targets other than NTE that could be involved in repair or regeneration of neural lesions (Lotti, 1992).

Perhaps the most thoroughly investigated compound with respect to inhibition and aging of serine hydrolases is diisopropylphosphorofluoridate (DFP). Using a variety of techniques, this compound has been shown to inhibit AChE (Clothier and Johnson, 1979; Ordentlich et al., 1996, 1998; Millard et al., 1999a,b; Kropp and Richardson, 2006), BChE (Masson et al., 1997; Kropp and Richardson, 2007; Li et al., 2007), NTE (Clothier and Johnson, 1979; Williams and Johnson, 1981; Williams, 1983), and NEST (Kropp et al., 2004) by organophosphorylation of the active site serine followed by aging to yield a monoisopropylphosphoryl adduct, as shown in Figure 63.9. Esterase adducts have been directly demonstrated using mass spectrometry for AChE (Kropp and Richardson, 2006), BChE (Kropp and Richardson, 2007; Li et al., 2007), and NEST (Kropp et al., 2004), and, in the case of BChE, the mechanism of aging has been unequivocally demonstrated to involve scission of an O—C bond in an isopropyl group (Li et al., 2007). These results, taken together with those for soman-inhibited AChE (Michel et al., 1967) and BChE inactivated with a variety of phosphonates and phosphates (Li et al., 2007), indicate that it is reasonable to expect that aging of phosphonylated or phosphorylated serine esterases, including NTE and NEST, will proceed via O—C bond scission. This insight enables accurate prediction of the biomarker species to be sought in the mass spectra of serine esterases inhibited with phosphonates or phosphates.

Among the type A inhibitors of NTE (Figure 63.5), the phosphoramidates are perhaps the most enigmatic to be studied to date. For example, mipafox, the phosphoramidate analog of DFP, is capable of producing suprathreshold inhibition (>70%) of neural NTE *in vivo* and causing OPIDN (Davis and Richardson, 1980). Therefore, mipafox-inhibited NTE was expected to undergo aging (Davis et al., 1985). Early studies showed that NTE inhibited by mipafox was intractable to reactivation, indicating the possibility of aging as a mechanism for yielding a nonreactivatable enzyme (Johnson, 1982). In the case of mipafox-inhibited NTE, however, nonreactivation was thought to be too rapid to measure by standard kinetic approaches (Johnson, 1982). Consequently, aging

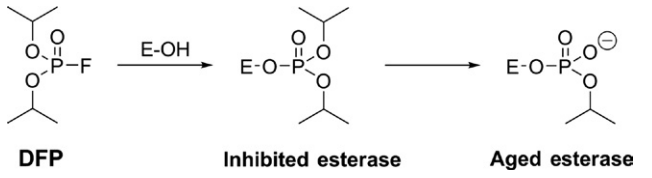

FIGURE 63.9 Inhibition and aging of serine esterases by DFP. The active site serine is organophosphorylated in the inhibition step. Aging results in net loss of an isopropyl group to yield the monoisopropylphosphoryl esterase. This mode of inhibition and aging has been established for AChE, BChE, and NTE catalytic domain (NEST) (Kropp and Richardson, 2007).

of mipafox-inhibited NTE had only been inferred and not directly demonstrated. Subsequently, Milatovic and Johnson (1993) showed that NTE inhibited by mipafox could be reactivated by prolonged treatment with KF at acidic pH. This surprising finding led to the conclusion that aging had not occurred after all. Instead, it was surmised that an unusual property of the bond between the phosphoramidate and the active site serine was responsible for the stability of the complex as well as the perturbation of NTE that leads to OPIDN.

It had been known for some time that esterases inhibited by mipafox are resistant to reactivation, but conventional aging could not be proved or disproved by classical techniques. It is also known that the phosphoramido hydrogen on *N*-alkylphosphoramidates is acidic and that its removal yields a resonance-stabilized anion (Eto, 1974). Such a mechanism would explain the relative stability of phosphoramidated esterases in a manner that does not require loss of an alkylamino group to yield a negative charge on the adduct (Richardson, 1995). Moreover, reprotonation of the phosphoramide anion would generate a neutral species subject to attack by a nucleophile and account for the reactivation of mipafox-inhibited NTE at low pH. Under the acidic conditions usually used for peptide mass spectrometry, the putative anion would be reprotonated. Thus, it can be hypothesized that the species attached to NTE after its inhibition by mipafox and allowing time for aging is the intact *N*,*N*′-diisopropylphosphorodiamido moiety. Such a result would indicate that the inhibited enzyme has not lost an isopropyl or isopropylamino group due to an aging process analogous to the net loss of an isopropyl group in the aging of DFP-inhibited NTE or NEST.

In contrast to the results for mipafox-inhibited NTE, early limited studies indicated that mipafox-inhibited BChE or AChE undergo irreversible aging, because the enzymes could be reactivated soon after inhibition, but not after 18 h (Milatovic and Johnson, 1993). The chemistry of phosphoramidates suggest that aging could involve hydrolytic loss of an alkylamino group. For example, acid-catalyzed P—N bond fission has been observed for certain *N*-alkyl phosphoramidates (Eto, 1974), and the aging of tabun-inhibited AChE has been shown to proceed via P—N bond scission with loss of dimethylamine (Elhanany et al., 2001).

Considerations of probable mechanisms of aging for mipafox-inhibited serine esterases suggest that mass spectrometry studies would support a deprotonation mechanism for NTE or NEST and hydrolytic P—N bond scission for AChE and BChE. As summarized in Figure 63.10, these expectations were borne out for human recombinant NEST, which was used as a surrogate for NTE (Kropp et al., 2004) and BChE, respectively (Kropp and Richardson, 2007). However, mipafox-inhibited AChE gave the surprising result, confirmed by immunoprecipitation and mass spectrometry, of loss of both isopropylamine groups to yield a simple phosphate adduct on the active site peptide (Kropp and Richardson, 2006). Thus, in the case of phosphoramidates, aging appears to be nonclassical for the three esterases investigated; moreover, the biomarker is distinctly different in each case.

Recently, mass spectrometry was successfully used to detect BChE adducts arising from reaction with 2-(2-methylphenoxy)-BDPO (CBDP), which has been implicated in "aerotoxic syndrome" (Carletti et al., 2011). Interestingly, the final aging product was a phosphoserine adduct, as found previously in the aging of mipafox-inhibited AChE (Kropp and Richardson, 2006).

BIOSENSORS

Nanostructured Electrochemical Biosensors to Measure Enzyme Activity

Recently developed nanofabrication methods using layer-by-layer (LBL) self-assembly provide exciting new opportunities to design multilayered, functional, biosensor interfaces to measure enzyme activity. Since the LBL technique was first introduced (Decher and Hong, 1991), significant work has been performed to fabricate polymer and organic thin films through alternating deposition of positively and negatively charged polyelectrolyte species on solid surfaces (Decher et al., 1992; Lvov et al., 1994; Decher, 1997; Schmidt et al., 1999; Ruths et al., 2000).

Polyelectrolyte layers typically have a thickness of approximately a nanometer, allowing ultrathin interfaces to be fabricated that have minimal mass-transfer resistance. LBL self-assembly using polyelectrolytes is thus well-suited for biosensor development studies, because, by minimizing mass-transfer resistances, the intrinsic enzyme kinetics can be measured. LBL assemblies of polyelectrolytes have been used to develop nanostructured biosensor interfaces that encapsulate enzymes (Sokolovskaya et al., 2005 ; Kohli et al., 2006, 2007a; Hassler et al., 2007) and functional nanoparticles (Kohli et al., 2005, 2007b).

Electrochemical biosensors that measure the activity of a protein have been widely used to determine analyte concentrations in both research and commercial applications (Prodromidis and Karayannis, 2002). Biosensors can detect protein activity either directly (Hassler and Worden, 2006) or indirectly through reaction coupling (Peteu et al., 1996, 1998). The indirect approach greatly expands the range of enzyme activities that can be characterized using electrochemical biosensors. For example, reaction coupling has been used to measure NTE activity outside of the electrode (e.g., in blood samples)

(Makhaeva et al., 2003, 2007; Sigolaeva et al., 2010, 2013) or AChE, BChE, and NEST activity incorporated into the electrode (Kohli et al., 2007a, 2014).

Electrochemical Biosensor Arrays for High-Throughput Analysis

Microsystems technologies, particularly thin-film deposition of microelectrodes and formation of microfluidic channels, have been widely applied to biological analysis systems (Bergveld, 1996; Urban, 2000), such as DNA-processing chips (Raisi et al., 2004) and other lab-on-chip implementations (Ziegler, 2000; McFadden, 2002; Kovacs, 2003). Most of these devices rely on optical transduction mechanisms (Rabbany et al., 1994; Vo-Dinh et al., 2003) that often cannot quantitatively measure several important protein activities, such as redox reactions.

In contrast, enzymatic redox reactions are readily measured using versatile electrochemical techniques. Traditionally, electrochemical measurements are performed at the "beaker scale," but newer technologies allow such systems to be miniaturized for improved performance and high-throughput analysis. Complete three-electrode electrochemical cells, including thin-film Ag/AgCl reference electrodes, have been integrated on silicon surfaces (Yun et al., 2004). Thin-film reference electrode stability has been improved using Nafion or polyurethane coatings (Nolan et al., 1997) and complex micromachined structures (Suzuki et al., 1999; Suzuki, 2000). A remaining challenge is to adapt these new technologies to the construction of miniaturized electrochemical arrays for high-throughput protein activity characterization. Such biosensor array platforms must be compatible with the self-assembled biosensor interfaces, thus establishing requirements for electrode materials, geometries, surface smoothness, and overall array architecture (Huang et al., 2013).

Assembly of Electrochemical Biosensor Interfaces for Serine Hydrolases

The natural reaction substrates and products of serine esterases are not electrochemically active. To transduce these esterase activities into an electrical signal, a two-enzyme reaction pathway can be assembled on a gold electrode. In the first reaction, the esterase of interest converts a phenyl ester (e.g., phenyl valerate) into phenol (Figure 63.11). In the second reaction, tyrosinase converts phenol first to catechol, and then to *o*-quinone (Figure 63.12), which can be electrochemically reduced back to catechol at an electrode, yielding a measurable current (Eq. (63.17)) (Kohli et al., 2007a, 2010).

$$o\text{-Quinone} + 2H^+ + 2e^- \rightarrow \text{Catechol} \quad (63.17)$$

Tyrosinase is a copper-containing oxidase (Coche-Guerente et al., 2001; Forzani et al., 2000) that possesses the two different activities illustrated in Figure 63.12. In the first step, referred to as the hydroxylase or cresolase activity, molecular oxygen is used to hydroxylate phenol to form catechol. In the second step, known as

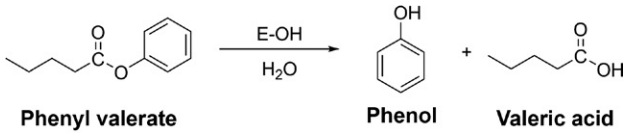

FIGURE 63.11 Reaction of a serine esterase with phenyl valerate to yield phenol and valeric acid (Kayyali et al., 1991).

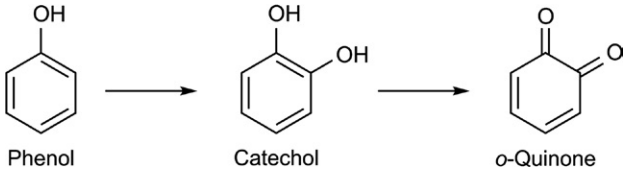

FIGURE 63.12 Reactions catalyzed by the two activities of tyrosinase. Phenol is first oxidized to catechol and then to *o*-quinone. *Source: Reproduced with permission from Kohli et al. (2007a).*

the catecholase activity, the enzyme oxidizes catechol to *o*-quinone, which is simultaneously oxidized by oxygen to its original form, with the production of water. The *o*-quinone is electrochemically active and can be reduced back to catechol, as illustrated in Eq. (63.17). Such electrodes have been used to determine esterase activities in blood samples (Sigolaeva et al., 2013).

By co-immobilizing tyrosinase with a serine esterase on a gold electrode, it is possible to establish a multistep reaction pathway that allows the activity of the esterase to be determined indirectly via measurement of *o*-quinone reduction at the electrode. The molecular architecture of a bi-enzyme sensor interface is shown schematically in Figure 63.13 (Kohli et al., 2010).

In practice, the fabrication of these bi-enzyme biosensors is relatively straightforward. Gold electrodes are scrupulously cleaned in "Piranha solution" ((concentrated) H_2SO_4: 30% (w/w) H_2O_2, 7:3 (v/v)) and then dipped in a 5 mM solution of thioctic acid in ethanol for 30 min. The electrodes are washed with ethanol, dried under nitrogen, and dipped in positively charged poly-L-lysine (PLL) solution for 45 min. The PLL solution is prepared by adding 12 mg of PLL in 50 mL of 20 mM phosphate buffer (pH 8.5). The electrodes are then rinsed with water and dipped in an aqueous solution of negatively charged tyrosinase (0.2 mg/mL) for 1 h. The last two steps are repeated 3.5 times to create 3.5 PLL-Tyr bilayers, with PLL being the topmost layer. The electrodes are washed with water and dipped in a 0.1 mg/mL solution of a serine esterase (e.g., AChE, BChE, or NEST) in 100 mM phosphate buffer, pH 7.0, for 1 h. The electrodes are then washed with water, dried under nitrogen, and dipped in phosphate buffer (0.1 M, pH 7.0) for testing. All steps are performed at room temperature (approximately 22°C) (Kohli et al., 2007a).

Electrochemical Measurements of Serine Esterase Activity

The electrochemical properties of serine esterase-containing biosensor interfaces are readily characterized. Each biosensor is immersed in a stirred buffer solution and maintained at a potential of − 100 mV (compared with an Ag/AgCl reference electrode). For example, NEST activity was measured indirectly via the output current of the electrode for a variety of phenyl valerate concentrations. As shown in Figure 63.14, the first step involves the diffusion of the ester (e.g., phenyl valerate) through a stagnant film from bulk solution to the enzyme layer. The NEST enzyme then hydrolyzes phenyl valerate to phenol, which is then oxidized to *o*-quinone by tyrosinase. Reduction of *o*-quinone at the surface of the electrode generates a current and regenerates catechol, which can then be reoxidized by tyrosinase. This internal recycling between catechol and *o*-quinone provides a mechanism for signal amplification, thereby enhancing biosensor sensitivity (Kohli et al., 2007a).

The response of the biosensor to aliquots of ester can be measured at a variety of pH values and applied potentials. For a typical NEST biosensor, the highest signal-to-background ratio is obtained at pH 7.0 and a working electrode potential of − 0.1 V relative to an Ag/AgCl reference electrode. At this potential, addition of phenyl valerate to a stirred aqueous solution triggers a rapid increase in the NEST biosensor signal, with a time constant of approximately 5 s. BChE can be substituted for NEST, with a similar current versus time response using phenyl valerate as substrate. For AChE, phenyl acetate is a better substrate than phenyl valerate. Current increases linearly with phenyl acetate concentration ($R^2 = 0.989$) in the range of 0.5–16 μM, reaching saturation at approximately 40 μM. Current versus time response and concentration calibration curves similar to those obtained for NEST and AChE can be obtained for BChE in the bi-enzyme electrode. Sensitivities of the electrodes obtained from the slopes of the initial linear portions of the concentration calibration curves were found to be 180, 25, and 87 $nA\mu M^{-1}cm^{-2}$ for AChE, BChE, and NEST, respectively, when AChE used phenyl acetate and when BChE and NEST used phenyl valerate as substrate. Control experiments were also performed in which each of the substrates was delivered to a gold electrode containing only PLL-Tyr bilayers. The current sensitivities obtained in these control experiments were negligibly small—always less than 0.5 $nA\mu M^{-1}cm^{-2}$—indicating that the signal is mediated by the esterase activity (Kohli et al., 2007a).

The ability of the biosensors to detect chemical agents was confirmed by adding a known serine esterase inhibitor, phenylmethylsulfonyl fluoride, to the solution. The electrode response decreased in a

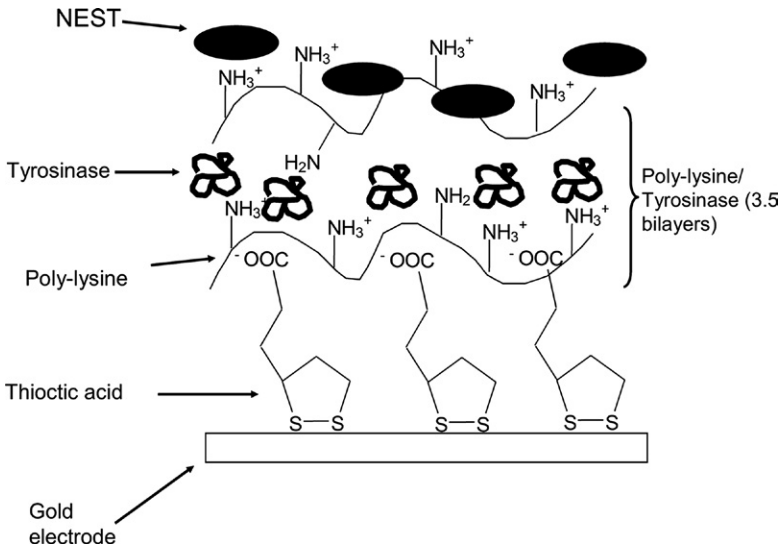

FIGURE 63.13 Molecular architecture of a bi-enzyme biosensor electrode containing tyrosinase and NTE catalytic domain (NEST). *Source: Reproduced with permission from Kohli et al. (2007a).*

concentration-dependent manner (Kohli et al., 2007a). Using a combination of biosensors containing different target enzymes (e.g., AChE and NEST), it would be possible to obtain real-time differential data that could be used to distinguish exposures to conventional versus DN agents.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Fortunately, DN agents have not yet been used in warfare or terrorism. However, their possible use must be considered seriously, because it is straightforward to design and synthesize these compounds based on established methods in OP chemistry. Thus, a conventional insecticide or nerve agent can be reengineered to produce a DN agent. The use of DN agents would be catastrophic, because there are no accepted means of prophylaxis or treatment, and the effects are devastating and permanent. NTE is the presumptive target for initiation of OPIDN. Accordingly, lymphocyte NTE has been used as a biomarker of exposure, and the NTE catalytic domain (NEST) has been incorporated into a biosensor for detection of DN agents. However, the precise physiological function of NTE and its role in the pathogenesis of OPIDN remain to be elucidated. Therefore, further mechanistic understanding is needed to improve on existing biomarkers and biosensors as well as to develop preventive and therapeutic measures.

Biomarkers of Exposure to Organophosphorus Poisons: A New Motif for Covalent Binding to Tyrosine in Proteins That Have No Active Site Serine

Oksana Lockridge, Lawrence M. Schopfer and Patrick Masson

INTRODUCTION

Schaffer et al. (1954) reported the astonishing finding that the irreversible inhibition of eel acetylcholinesterase (AChE) by the organophosphorus (OP) agent, diisopropylfluorophosphate (DFP), was the result of covalent binding to serine. In 1959, horse butyrylcholinesterase (BChE) that had been inactivated by treatment with DFP was found to have diisopropylphosphate-labeled serine in the sequence FGESAGAAS (Jansz et al., 1959). Despite this evidence, serine was not immediately accepted as the esteratic site of cholinesterases, because the pKa of serine was so high that significant reaction with OP agents was not expected (Bergmann, 1955). The crystal structures of AChE and BChE confirmed that OP agents make a covalent bond with serine. These structures also provided an explanation for the special reactivity of the active site serine (Sussman et al., 1991; Nachon et al., 2005). Nearby histidine and glutamic acid form a catalytic triad with serine that lowers the pKa of the serine, consistent with the expectation that the hydroxy-anion of serine is necessary to make a nucleophilic attack on the phosphorus. The oxyanion hole activates the OP for attack by the serine.

The covalent bond between OP and the active site serine of intact cholinesterase is stable, but not irreversible. Hydrolysis can occur with a half-life of between 10 and 35,000 min, depending on the enzyme, OP, temperature, pH, and buffer composition. The adduct becomes irreversibly bound to the enzyme after one of the alkyl groups on the OP is lost in a step called *aging* (Benschop and Keijer, 1966; Michel et al., 1967). The dealkylated OP makes a stable salt bridge with the protonated histidine of the catalytic triad, so that histidine is no longer available for the dephosphorylation step that would otherwise have restored the enzyme to an uninhibited state. Hundreds of scientists have contributed to this understanding of the mechanism of OP inhibition of AChE and BChE activity. Their studies are the foundation for the use of AChE and BChE as biomarkers of OP exposure.

OP-inhibited AChE and BChE are the established biomarkers of OP exposure (Gupta and Milatovic, 2012, 2014). The special features that make them good biomarkers are the following: (i) they react rapidly with OP at low concentrations; (ii) symptoms of acute toxicity always correlate with inhibition of AChE and BChE; (iii) AChE is present in human red blood cells, while BChE is present in human plasma, making it possible to test for OP exposure by measuring enzyme activity in a blood sample; (iv) the OP adduct (nonaged and aged) for common pesticides and nerve agents is relatively stable, making it possible to detect exposure days after the actual event; and (v) the mechanism of irreversible inhibition of AChE and BChE activity by OP is understood.

USE OF AChE AND BChE BIOMARKERS IN THE CLINIC

Most hospitals and forensic laboratories are capable of performing cholinesterase activity assays. Two examples of the usefulness of AChE and BChE activity assays are given next.

Tokyo Subway Attack with Sarin

AChE and BChE were useful biomarkers for identifying the poison that intoxicated more than 5000 people in the Tokyo subway. In March 1995, members of the Aum Shinrikyo sect dispersed the nerve agent sarin in trains on the Tokyo subway. Japanese health workers identified the poison as a cholinesterase inhibitor within 2h of seeing the first patient (Nozaki and Aikawa, 1995). A cholinesterase inhibitor was suspected because victims had physiological signs of cholinergic intoxication, including pinpoint pupils. Laboratory assays showed that red blood cell AChE and plasma BChE activities were inhibited, confirming that the poison was a cholinesterase inhibitor. There are many cholinesterase inhibitors, including OP pesticides and carbamates (CMs). In the case of some OPs, AChE inhibiting compounds are precursor molecules that need bioactivation before they are toxic to humans. The rapid onset of toxic symptoms meant that the agent used in the subway was already activated or a direct AChE inhibitor was involved that needed no activation. The fact that people were becoming intoxicated by breathing the air meant that the poison was volatile. These characteristics suggested that the poison was a nerve agent, very likely sarin. The Forensic Science Laboratory used gas chromatography–mass spectrometry (GC–MS) to identify sarin in crime scene samples (Seto, 2001). Identification of the poison as sarin was crucial to the police in their search for the perpetrators. Years later, new MS methods were developed and used to retroactively identify sarin bound to red blood cell AChE (Nagao et al., 1997) and to plasma BChE from the Tokyo subway victims (Polhuijs et al., 1997; Fidder et al., 2002).

Suicide Attempts

Exposures to OP pesticides are declining in the United States following the banning of chlorpyrifos and diazinon for residential use in 2000 (Sudakin and Power, 2007). In 2004, the number of OP exposure cases reported to the American Association of Poison Control Centers (AAPCC) was 7,181, with 4 fatalaties (Bronstein et al., 2007). In 2012, the number of cases was 3,179, with 1 fatality (Mowry et al., 2013). The subjects intentionally ingested OP pesticides for the purpose of committing suicide. In contrast, the ingestion of OP pesticides in suicide attempts is a frequent occurrence in rural communities of Sri Lanka, India, and China, where an estimated 200,000 persons die annually from OP pesticide poisoning (Eddleston and Dawson, 2012). Diagnosis is made on the basis of cholinergic signs of toxicity, smell of pesticides or solvents, and reduced BChE and AChE activity in blood. Patients who survive the suicide attempt are monitored in the hospital for several days; their plasma BChE is assayed daily because recovery of BChE activity is a marker of OP elimination from the body.

METHODS TO DETECT OP ADDUCTS ON AChE AND BChE

Cholinesterase Activity Assay

Exposure to a toxic dose of OP results in inhibition of AChE and BChE activities. The most common method to measure OP exposure is to assay AChE and BChE activities in blood using a spectrophotometric method (Ellman et al., 1961; Worek et al., 1999; Wilson et al., 2005). The drawbacks of activity assays are that they do not identify the OP agent in question. They show that the poison is a cholinesterase inhibitor, but they do not distinguish between nerve agents, OP pesticides, CM pesticides, and tightly bound, noncovalent inhibitors like tacrine and other anti-Alzheimer drugs. In addition, low-dose exposure, which inhibits less than 20% of the cholinesterase, cannot be determined by measuring AChE and BChE activity because individual variability in activity levels is higher than the percentage of inhibition.

Fluoride Reactivation Followed by GC–MS

A new method for identifying exposure to nerve agents was introduced by Polhuijs et al. (1997). The method is based on the finding that incubation of sarin-inhibited BChE with 2M potassium fluoride at pH 4 results in the release of sarin. Sarin is then extracted and analyzed by GC–MS. Polhuijs et al. (1997) applied their new method to positively identify sarin in serum samples from Japanese victims of the Tokyo subway attack. This method has the advantage that it positively identifies nerve agents and other OPs (van der Schans et al., 2004). The method has been validated by Adams et al. (2004), who found that potassium fluoride released sarin and soman from human BChE, as well as from covalent attachment to human albumin.

Identification of OP-BChE Adducts by Electrospray–Ionization Tandem MS

In clinical diagnosis of OP exposure, the tissue most readily available for study is blood. OP adducts of BChE are better candidates for study than OP adducts on

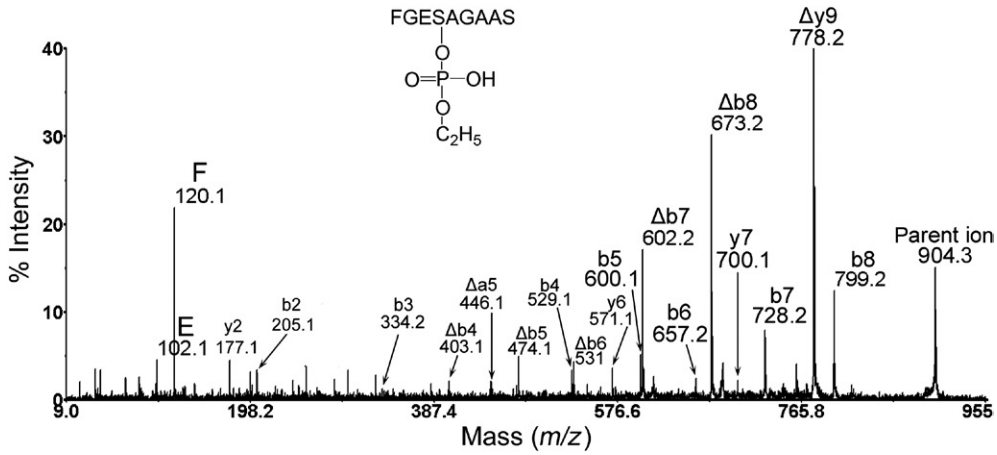

FIGURE 64.1 MS/MS spectrum of the active site peptide of human AChE, covalently bound to tabun and dealkylated by aging or by acid. The identical modified peptide is derived from human BChE treated with tabun, chlorpyrifos oxon, paraoxon, or diazoxon. The Δ symbol indicates ions that have lost the OP and a molecule of water, converting serine to dehydroalanine. The peak height for 778.2 m/z was 2.5-fold higher than indicated; it was shortened to show the less intense ions.

AChE for the following reasons. Human blood contains 5 mg of BChE and 0.5 mg of AChE per liter. The BChE is in plasma, whereas the AChE is bound to the membranes of red and white blood cells. Most OPs, with the exception of chemical warfare nerve agents, react more rapidly with BChE than with AChE.

Fidder et al. (2002) introduced an electrospray–ionization tandem MS method for diagnosing OP exposure by measuring the mass of the OP-labeled active site peptide of human BChE. His starting material was 0.5 mL of human plasma from a victim of the Tokyo subway attack. The mass of the active site peptide was higher by 120 atomic mass units than the mass of the unlabeled active site peptide. This added mass was exactly what was expected from sarin. The peptide's MS/MS fragmentation spectrum yielded the sequence of the peptide and verified that the OP label was on serine 198, the active site serine. Two important technical details described by Fidder et al. (2002) are the advantage of digesting with pepsin rather than trypsin, and the fact that during collision-induced dissociation, the OP-labeled serine decomposes to dehydroalanine, with loss of the OP plus a molecule of water.

Pepsin digestion of BChE is preferred because pepsin yields a 9-residue active site peptide $FGES_{198}AGAAS$, whereas trypsin digestion yields a 29-residue peptide $SVTLFGES_{198}AGAASVSLHLLSPGSHSLFTR$. Short peptides give a more intense signal in the mass spectrometer than long peptides. Figure 64.1 shows the MS/MS spectrum of the active site peptide FGESAGAAS, modified on serine 198 by monoethoxyphosphate. The 904.3 m/z parent ion is particularly interesting because it represents the deamidated (aged) tabun adduct, as well as the dealkylated (aged) chlorpyrifos oxon adduct, and

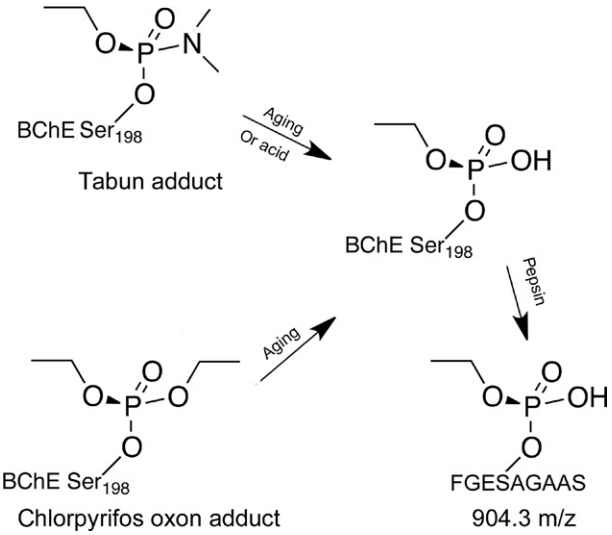

FIGURE 64.2 Aging or exposure to acid during pepsin digestion results in deamidation of the initial tabun adduct. Aging dealkylates the initial chlorpyrifos oxon adduct. Pepsin digestion yields the identical 904.3 m/z FGESAGAAS peptide covalently modified by monoethoxyphospate from human AChE, human BChE, and horse BChE inhibited by tabun, chlorpyrifos oxon, diethyl paraoxon, diazoxon, or other diethyxophosphate pesticides.

adducts with other common activated pesticides, including diethyl paraoxon and diazoxon (Figure 64.2). Thus, exposure to the nerve agent tabun yields an adduct that is indistinguishable from exposure to common pesticides. Another notable feature of the peptide in Figure 64.1 is that pepsin digestion of human AChE (Swiss protein # P22303), human BChE (Swiss protein # P06276), and horse BChE (NCBI # gi 7381418) yields the same FGESAGAAS active site peptide.

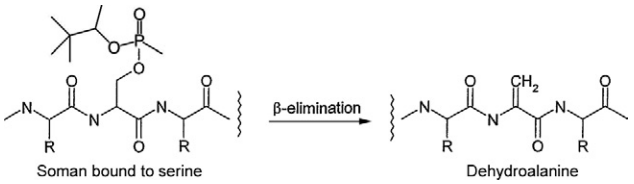

FIGURE 64.3 OP-serine loses the OP (soman in this case) plus a molecule of water when the peptide is fragmented in the mass spectrometer. This beta-elimination reaction converts OP-serine to dehydroalanine.

The acid condition for pepsin digestion causes the phosphorus–nitrogen bond to break in adducts with tabun and iso-OMPA (tetraisopropyl pyrophosphoramide). This can be used to distinguish between the reactions with Sp and Rp stereoisomers of tabun (Jiang et al., 2013a).

Mass spectrometers convert a majority of the OP-labeled serine to dehydroalanine during acquisition of MS/MS spectra. For example, all ions labeled with the Δ symbol in Figure 64.1 have dehydroalanine in place of OP-serine. Investigators who are not aware of this gas phase chemistry have a difficult time interpreting their MS/MS spectra. The conversion of OP-serine to dehydroalanine is called *beta-elimination.* The beta-elimination reaction is well documented for phosphoserine peptides (Tholey et al., 1999). Figure 64.3 shows a schematic diagram of the beta-elimination reaction for soman-labeled serine in human BChE. The ease with which the OP-serine bond breaks during collision-induced dissociation is indicated by the fact that the most intense ion in Figure 64.1 is the 778.2 m/z ion. The peptide at 778.2 m/z is the parent ion that has lost the OP and 1 molecule of water. However, serine is not restored. A molecule of water is abstracted along with the OP, converting the active site serine to dehydroalanine.

Fidder et al. (2002) showed that MS could detect adducts on human BChE with sarin, soman, dimethyl paraoxon, diethyl paraoxon, and pyridostigmine when purified BChE was treated with these poisons. Studies from other laboratories confirmed that OP-BChE adducts could be identified by MS (Tsuge and Seto, 2006; Sun and Lynn, 2007; Li et al., 2008b).

Single-Step Purification of BChE from Human Plasma

A technical difficulty with MS of OP adducts on BChE, in a clinical setting, is the need to enrich plasma samples for BChE to make it possible to detect the labeled peptide. Previously, the BChE protein was enriched from plasma by affinity chromatography on procainamide Sepharose (Fidder et al., 2002; Li et al., 2009b; Liyasova et al., 2011; van der Schans et al., 2013). In this case, the level of purity was inadequate when procainamide affinity chromatography was the only enrichment step. We had to further enrich by using gel electrophoresis or ion exchange chromatography, or by selectively extracting the OP-labeled active site peptide on titanium oxide microcolumns (Jiang et al., 2013c). A big advance was the introduction of a single-step purification method by binding to an immobilized monoclonal (Sporty et al., 2010). The commercially available monoclonal 3E8 (HAH 002-01-02 from Thermo Scientific Pierce) selectively extracts BChE from human plasma when the monoclonal is immobilized on Dynabeads Protein G (Sporty et al., 2010; Carter et al., 2013) or on Dynabeads epoxy (Marsillach et al., 2011). Two other monoclonals, mAb2 (created in the laboratory of Jacques Grassi) and B2 18-5 (created in the laboratory of Steven Brimijoin), also immunopurify BChE from plasma in a single step (Schopfer et al., 2014). BChE is released from the antibody with acetic acid. Figure 64.4 is a Coomassie-stained gel showing the effectiveness of immunopurification of BChE from plasma in a single step. A band at 85 kDa for the BChE monomer is visible. The major contaminating proteins are immunoglobulins. Immunopurified BChE released with acid is suitable for MS analysis of adducts, but it is not suitable for applications that require active native BChE enzymes because acid denatures the BChE protein.

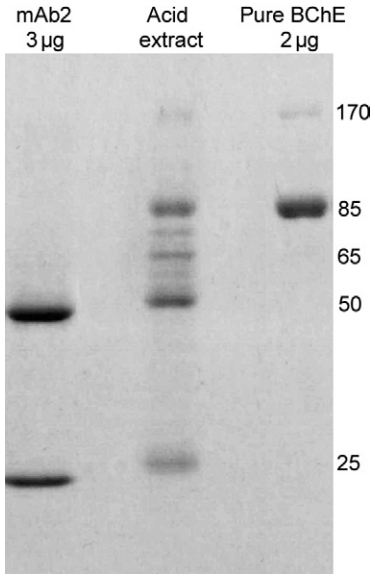

FIGURE 64.4 SDS gel stained with Coomassie Blue shows BChE purified by binding to immobilized monoclonal mAb2. The monoclonal was crosslinked to CNBr-Sepharose. About 98% of the BChE in 0.5 mL of plasma bound to 0.04 mL of beads. The BChE was released from beads with 0.4 M acetic acid. The band at 85 kDa is the BChE monomer, while the band at 170 kDa is the BChE dimer. Immunoglobulin heavy (50 kDa) and light (25 kDa) chains are major contaminants.

WHY ARE NEW BIOMARKERS NEEDED?

Not All OPs Inhibit AChE

Tri-o-cresyl-phosphate (TOCP), the contaminant in a homemade liquor called "Ginger Jake," which is responsible for delayed neuropathy and paralysis of the legs, is bioactivated in a form that inhibits neuropathy target esterase (NTE) and BChE, but not AChE at nonlethal doses (Casida and Quistad, 2004; Glynn, 2006). Large structures with a 12–20 carbon alkyl chain on the phosphorus atom inhibit fatty acid amide hydrolase but not AChE (Casida and Quistad, 2004). These examples show that OPs that do not affect AChE can react with other proteins, sometimes generating toxic symptoms. These examples also suggest that additional, unknown OP targets may exist that are sensitive to OP that do not affect cholinesterases. In order to detect exposure to such OPs, biomarkers other than cholinesterases are needed.

OP doses too Low to Inhibit AChE Cause Toxicity

Workers in India ($n = 59$) engaged in the manufacture of quinalphos had normal red cell AChE activity but complained of generalized weakness and fatigue. They had significantly low scores for memory, learning ability, and vigilance compared to controls. Plantar reflexes were abnormal in 50% of the workers. The average age of the workers was 30 ± 6 years, and the average duration of exposure to quinalphos was 5.7 years. There was no history of acute poisoning. The plant was situated in large tin sheds without adequate ventilation (Srivastava et al., 2000). The most logical explanation for their symptoms was low-dose exposure to OP.

Family tobacco farmers in Brazil ($n = 37$) used chlorpyrifos and acephate for 3 months a year, for 5.4 h a day. The average duration of exposure was 18 years. Their plasma cholinesterase activity was within the normal range and was not different between on- and off-exposure periods. Clinically significant extrapyramidal symptoms were present in 12 subjects during the pesticide application season, though this number was reduced to 9 after 3 months without exposure. Generalized anxiety disorder was diagnosed in 13 subjects, and major depression in 8 subjects. After 3 months without OP exposure, the number of subjects with psychiatric disorders declined to about half (Salvi et al., 2003). The most logical explanation for their symptoms was low-dose exposure to OP.

More examples of chronic low dose, subclinical exposure to OPs in humans, leading to chronic neurotoxicity, are cited in a number of studies (e.g., Abou-Donia, 2003; Kamel and Hoppin, 2004).

Animal studies have been directed at understanding the mechanism of low-dose OP toxicity. The studies agree that doses too low to inhibit AChE activity nevertheless have adverse effects on the animals, including disruption of adenylyl cyclase signaling (Song et al., 1997), hyperphosphorylation of calcium/cyclic adenosine monophosphate (cAMP) response element binding protein (Schuh et al., 2002), airway hyperactivity (Lein and Fryer, 2005), changes in expression levels of fibroblast growth factor in the brain (Slotkin et al., 2007), changes in serotonin receptors (Slotkin et al., 2008), inhibition of acylpeptide hydrolase (Richards et al., 2000), and disruption in lipid metabolism (Medina-Cleghorn et al., 2013).

Rats chronically treated with low doses of chlorpyrifos or DFP have long-term cognitive deficits in the absence of clinical signs of exposure (Jett et al., 2001; Terry et al., 2007, 2014). The mechanism for impairment of cognitive function may involve disruption of the microtubule transport of vesicles, organelles, and other cellular components that are synthesized in the neuronal cell body and moved down long axons to presynaptic sites (Gearhart et al., 2007).

A possible, noncholinesterase-based explanation for the neurotoxic symptoms observed in humans from the previous examples is that workers were also exposed to a combination of chemicals, including heavy metals, solvents, herbicides, and fumigants. The symptoms may actually have been caused by these chemicals and not by the OP (Kamel and Hoppin, 2004). However, the animal data cannot be explained this way because the animals were treated only with OP agents. In conclusion, OP targets that are not AChE or BChE are involved in chronic neurotoxicity. These unknown targets bind OP at doses too low to inhibit AChE.

Only Some People Have Symptoms

Not every person who has been chronically exposed to OP exhibits symptoms. For example, of 612 sheep dippers (workers who dip sheep into a chemical bath to kill insects in the wool) exposed to diazinon twice a year for 3 days at a time for 40 years, only 19% reported symptoms. In a control group of ceramics workers who had not been exposed to OPs, 5% reported similar symptoms (Pilkington et al., 2001).

The susceptibility of a minority of the population may be explained by variations in genes affecting OP metabolism. The best-studied example is paraoxonase, an enzyme that inactivates OPs (La Du et al., 2001; Furlong, 2007; Costa et al., 2013). Paraoxonase polymorphism in humans is proposed to explain why some people are resistant to OP toxicity, while others are susceptible. Another enzyme that may be involved in resistance to OP toxicity is BChE. BChE scavenges OPs, eliminating the poison before it reaches sites where it could cause harm (Doctor et al., 1991). Humans have a wide range of BChE activities, with some people having none whatsoever due to genetic variation (Manoharan et al., 2007). It is possible,

but unproven, that people with BChE deficiency are more susceptible to OP toxicity. Polymorphisms in liver cytochrome P450 enzymes may also contribute to individual susceptibility to OP toxicity. Specific cytochrome P450 enzymes bioactivate the parent organophosphorothioates to the highly toxic oxon forms. Other cytochrome P450 enzymes detoxify OPs by dearylation (Hodgson and Rose, 2007). The concentration of each isozyme varies among individuals. Thus, the relative rates for activation and detoxification and the circulating levels of the toxic form of the OP will vary between individuals.

Another possibility for variable susceptibility in the population could be genetic variation in the yet-unknown OP targets that are responsible for the symptoms. Some forms of these targets may be more sensitive to OPs than are others.

Toxic Symptoms Depend on the OP

High doses of OPs cause similar toxic effects, independent of the identity of the OPs. However, low-dose effects are not identical for all OPs (Moser, 1995). For example, a low dose of fenthion decreased motor activity in rats by 86% but did not alter the tail-pinch response, whereas a low dose of parathion did not affect motor activity but did decrease the tail-pinch response. In another example, rats given doses of different OPs that inhibited AChE to similar levels had more severe toxicity when the OP was parathion than when it was chlorpyrifos (Pope, 1999). Toxicological studies such as these have led to the conclusion that sites in addition to cholinesterase are targets of OPs. New biomarkers for these effects of OPs are needed.

In summary, AChE and BChE are not the only proteins modified by OP exposure in humans. Neurotoxicity from low doses of OPs may be explained by OP modification of heretofore unidentified proteins. Toxic symptoms from low-dose exposure to a particular OP are not identical to toxic symptoms from another OP, suggesting that the set of proteins modified by a particular OP does not overlap completely with the set of proteins modified by a different OP. Identification of new biomarkers of OP exposure could lead to new assays for OP exposure, and could lead to an understanding of the causes of low-dose toxicity.

NEW BIOMARKERS

Beta-Glucuronidase in Rat Plasma

A carboxylesterase in rat liver microsomes called *egasyn* is tightly linked to beta-glucuronidase (BG) by a complex. When egasyn binds OP, it releases BG into the blood. A single oral dose of chlorpyrifos (10 mg/kg) increased the level of BG activity in rat blood 100-fold within 2 h (Fujikawa et al., 2005). The BG activity decreased to control levels by 24 h. Thus, increased levels of BG in plasma may serve as a biomarker for OP exposure. However, increase in plasma BG activity has not been validated in other animal species or in humans. For further details on BG, refer to Satoh et al. (2010).

Acylpeptide Hydrolase in Rat Brain

Acylpeptide hydrolase is a member of the serine hydrolase family. It deacetylates the acetylated N-terminus of polypeptides. Rat brain acylpeptide hydrolase was inhibited 93% at a dose of dichlorvos (4 mg/kg, i.p.) which inhibited AChE only 47%. The *in vitro* sensitivity of acylpeptide hydrolase to chlorpyrifosmethyl oxon, dichlorvos, and DFP (IC_{50}) was 6–10 times greater than that of AChE (Richards et al., 2000). Acylpeptide hydrolase is also found in human erythrocytes, where it could potentially serve as a biomarker for low-dose exposure to OP in humans (Quistad et al., 2005), though human cases of OP exposure have not yet been tested for OP-modified acylpeptide hydrolase.

Albumin in Mouse and Guinea Pig Plasma

Mice treated with a nontoxic dose of a biotin-tagged OP called fluorophosphate (FP)–biotin had FP-biotinylated albumin in blood and muscle (Peeples et al., 2005). *In vitro* experiments identified the site in human albumin for covalent attachment of a variety of OPs as tyrosine 411 (Li et al., 2007).

Guinea pigs treated with the nerve agents soman, sarin, cyclosarin, or tabun had nerve agent-labeled albumin in their blood (Williams et al., 2007). The OPs were bound to tyrosine. The tabun-tyrosine and soman-tyrosine adducts were detected in blood 7 days postexposure, indicating that the adducts are stable. The adducts did not undergo aging and were not released from tyrosine by treatment of the guinea pigs with oxime, which is a common treatment for OP exposure that induces release of OP from AChE. MS identified OP-albumin adducts in rats treated with 1/5 LD_{50} of paraoxon (Gladilovich et al., 2010).

These examples show that OPs can bind covalently to albumin under physiological conditions, and that the resultant adducts are relatively stable. OP-albumin adducts could therefore be useful as biomarkers of OP exposure. In addition, unlike cholinesterases, the soman-albumin conjugate does not age (Li et al., 2008a), making it possible to discriminate between sarin and soman exposure.

Albumin in Human Plasma is a Biomarker of OP Exposure

The animal studies described previously provided the rationale for testing whether humans poisoned by OP have detectable OP-albumin adducts. To date, three

studies provide MS evidence that plasma from humans who ingested dichlorvos (Li et al., 2010b) or chlorpyrifos (Li et al., 2013b; van der Schans et al., 2013) contains OP-albumin adducts. Blood drawn as late as 49 days after exposure had detectable levels of OP adducts on tyrosine (van der Schans et al., 2013). Though the chlorpyrifos-poisoned patients had been treated with oximes to reverse OP binding to AChE, their albumin had detectable levels of OP adducts. This suggests that oximes do not reverse OP binding to albumin.

M2 Muscarinic Receptors in Heart and Lung

The ^{3}H-chlorpyrifos oxon binds covalently to rat heart M2 muscarinic receptors (Bomser and Casida, 2001). The site of attachment has not been identified. When guinea pigs were treated with chlorpyrifos, diazinon, or parathion at doses too low to inhibit AChE activity, the M2 muscarinic receptors lost their ability to inhibit acetylcholine release from parasympathetic nerves, causing bronchoconstriction (Lein and Fryer, 2005).

COVALENT BINDING OF OP TO TYROSINE

In a 1963 Pedler lecture, Sanger reported that ^{3}H-DFP makes a covalent bond with tyrosine in the sequence Arg*Tyr*ThrLys from human and rabbit albumin (Sanger, 1963). MS of human albumin treated with soman, chlorpyrifos oxon, FP-biotin, dichlorvos, and DFP confirmed OP modification on Tyr 411 in peptide LVry*tkKVPQVSTPTL (Li et al., 2007, 2008a), where the lowercase letters show Sanger's sequence and the asterisk indicates the labeled tyrosine.

At the time that we confirmed Sanger's observations, we thought that albumin was a special case, though we were aware that papain and bromelain had also been reported to bind ^{3}H-DFP on tyrosine (Murachi et al., 1965; Chaiken and Smith, 1969).

We soon learned differently. In a general search for proteins that bind OP, we treated live mice and mouse tissues with FP-biotin, a modified OP designed for identifying unknown targets of OP reaction. The FP-biotinylated proteins were isolated on immobilized avidin, washed with 0.1% sodium dodecyl sulfate (SDS), and separated on an SDS gel. Coomassie Blue-stained bands were excised and digested with trypsin and the proteins in the bands were identified by MS. Surprisingly, the majority of proteins that were identified were not serine esterases or proteases, which are the classical targets for OPs, nor did the identified proteins contain the consensus sequence GXSXG, which is characteristic of an active site serine. Typically, we found high-abundance proteins such as albumin and tubulin.

Though biotin–avidin complexation has been used widely to isolate specific targets, it is notorious for generating false-positive identifications. To rule out the possibility that our results were an artifact, we set out to find the OP-labeled peptide. We reasoned that convincing proof for OP labeling required identification of the labeled peptide and the labeled amino acid.

During years of MS analysis, we had consistently identified OP-labeled tubulin in mouse brain. Therefore, we studied pure bovine tubulin (Cytoskeleton, Inc., Denver, CO) by treating it with soman, sarin, FP-biotin, DFP, chlorpyrifos oxon, and dichlorvos. We isolated the OP-labeled tryptic peptides and analyzed them by fragmentation in the QTRAP 2000 and QTRAP 4000 mass spectrometers. We identified five OP-labeled peptides in tubulin (Grigoryan et al., 2008). In every peptide, the OP was covalently attached to tyrosine.

Similar MS experiments with pure human and mouse transferrin (Li et al., 2009a), and with human kinesin showed that the OP label was consistently on tyrosine. Studies with human plasma identified OP labeling on tyrosine in apolipoprotein and alpha-2-glycoprotein. Aggressive treatment of human albumin with FP-biotin and chlorpyrifos oxon led to the identification of seven OP-labeled tyrosines (Ding et al., 2008). Finally, we found that small synthetic peptides made a covalent bond with DFP, chlorpyrifos oxon, dichlorvos, and soman (Li et al., 2009a). For example, incubation of peptide RYGRK (ArgTyrGlyArgLys) with soman yielded the pinacolylphosphonate-modified peptide (Li et al., 2013a). MS analysis conclusively proved that the OP was attached to tyrosine.

MOTIF FOR OP BINDING TO TYROSINE

Comparison of the sequences of OP-labeled peptides shows no consensus sequence around the tyrosine to which the OP binds. What the peptides do have in common is the presence of a positively charged arginine, lysine, or histidine within five amino acids of the labeled tyrosine, most being within three amino acids. We suggest that these positively charged residues could interact with the phenolic hydroxyl of tyrosine to lower the pKa. Such ion-pair interactions have been shown to lower the pKa for the negatively charged partner, with a comparable rise of the pKa of the positively charged partner by as much as 4 pKa units (Johnson et al., 1981). Tyrosines with a lower pKa value would be better nucleophiles and thus better able to attack OPs.

In conclusion, most proteins that we have examined in detail using sensitive MS techniques have shown the capacity to become labeled by OP on tyrosine. However, only certain tyrosines in a protein are labeled (i.e., those on the surface and near a positively charged residue that

could potentially activate the phenolic hydroxyl group). The finding that even small synthetic peptides can be labeled by OP on tyrosine has led to the hypothesis that OP labeling on tyrosine is a general phenomenon. We propose that OP labeling on tyrosine is a new motif for OP binding to proteins.

CHARACTERISTICS OF OP BINDING TO TYROSINE

On-Rate

Little is known about the rate of OP binding to tyrosine because the recognition of this OP binding motif is new. Soman binding to Tyr 411 in human albumin has been measured and has been found to be slow, with a bimolecular rate constant of $15 \pm 3\,M^{-1}min^{-1}$ (Li et al., 2008a). We expect that other proteins will be identified whose rate of OP binding to tyrosine will be faster.

Off-Rate

The OP adduct on tyrosine 411 of human albumin is stable. The half-life for decay of the soman–Tyr 411 adduct is 20 days at pH 7.4, 22°C (Li et al., 2008a). The chlorpyrifos oxon–Tyr 411 adduct is even more stable. After 7 months at 22°C in pH 7.4 buffer, 80% of the Tyr 411 was still labeled with diethoxyphosphate, which is the adduct formed by chlorpyrifos oxon. However, at pH 8.3 and 22°C, 50% had lost the OP label in 3.6 months. OP-albumin adducts stored at −80°C are stable indefinitely at pH 8.3, 7.4, and 1.5. One advantage of a stable OP-tyrosine adduct is that it will survive in an animal long enough to allow the generation of antibodies. Another advantage of a stable OP-tyrosine adduct is that detection of OP can be made on samples long after exposure.

No Aging

OPs bound to tyrosine do not age. Aging of OP adducts on AChE and BChE is defined as the loss of an alkoxy group from the phosphorus atom. No masses representing aged OP-tyrosine adducts have been found.

Aging can confound the identification of the original OP. For example, aged sarin and soman adducts on AChE are indistinguishable because they yield the same methylphosphonate derivative. The absence of aging for OP-tyrosine adducts results in a species that is suitable for discriminating between sarin and soman adducts because the unaged adducts have different masses. Absence of aging for OP-tyrosine adducts has also been reported for albumin adducts in guinea pigs (Williams et al., 2007).

METHODS FOR DETECTING OP BINDING TO TYROSINE

MS for OP Adducts on Unknown Proteins

If the identity of the OP-labeled protein is unknown, a tagged OP (e.g., a biotinylated OP) can be used to identify the protein (Schopfer et al., 2005). After the identity of the OP-labeled protein is known, identification of the OP-labeled peptide depends on separating it from contaminating peptides. We have found that the OP-labeled peptide is frequently not found by MS unless it has been extensively purified. In some cases, it is possible to identify the labeled peptide simply by liquid chromatography–tandem MS (LC-MS/MS), where an enzymatic digest of the isolated protein is subjected to liquid chromatography (LC) on a C18 nanocolumn, and the effluent from the column is electrosprayed directly into the mass spectrometer. For other cases, offline high-pressure liquid chromatography (HPLC) purification of the enzymatic digest is necessary to obtain a purified fraction of peptides that can be introduced into the mass spectrometer.

Preliminary identification of the labeled peptides in HPLC fractions is made by mass, using matrix-assisted laser desorption/ionization (MALDI) MS (MALDI TOF–TOF 4800 from Applied Biosystems). The MS-Digest algorithm, available from the Protein Prospector website at the University of California, San Francisco (prospector.ucsf.edu/prospector/mshome.htm), is a useful tool for predicting the masses of peptides from a proteolytic digest both with and without the added mass from a particular OP. Another indispensable tool is the Fragment Ion Calculator (available from http://db.systemsbiology.net:8080/proteomicsToolkit/), which can be used to calculate the masses of ions generated during MS/MS fragmentation of a peptide. Our laboratory acquired MS/MS spectra with the MALDI TOF–TOF 4800, the QTRAP 4000, and Triple TOF 5600 mass spectrometers (AB-Sciex). Examples of MS/MS spectra for human albumin peptides labeled on tyrosine with chlorpyrifos oxon are shown in Figure 64.5.

Fluoride Treatment to Release OP from Albumin

The fluoride reactivation method has been applied to a human case of self-poisoning by chlorpyrifos (van der Schans et al., 2013). Blood drawn from the patient 49 days after she ingested chlorpyrifos yielded two products, both released from albumin with potassium fluoride. The released products were identified by LC-MS using multiple reaction monitoring (MRM). The products were diethoxyfluorophosphate (representing an albumin adduct with chlorpyrifos oxon) and

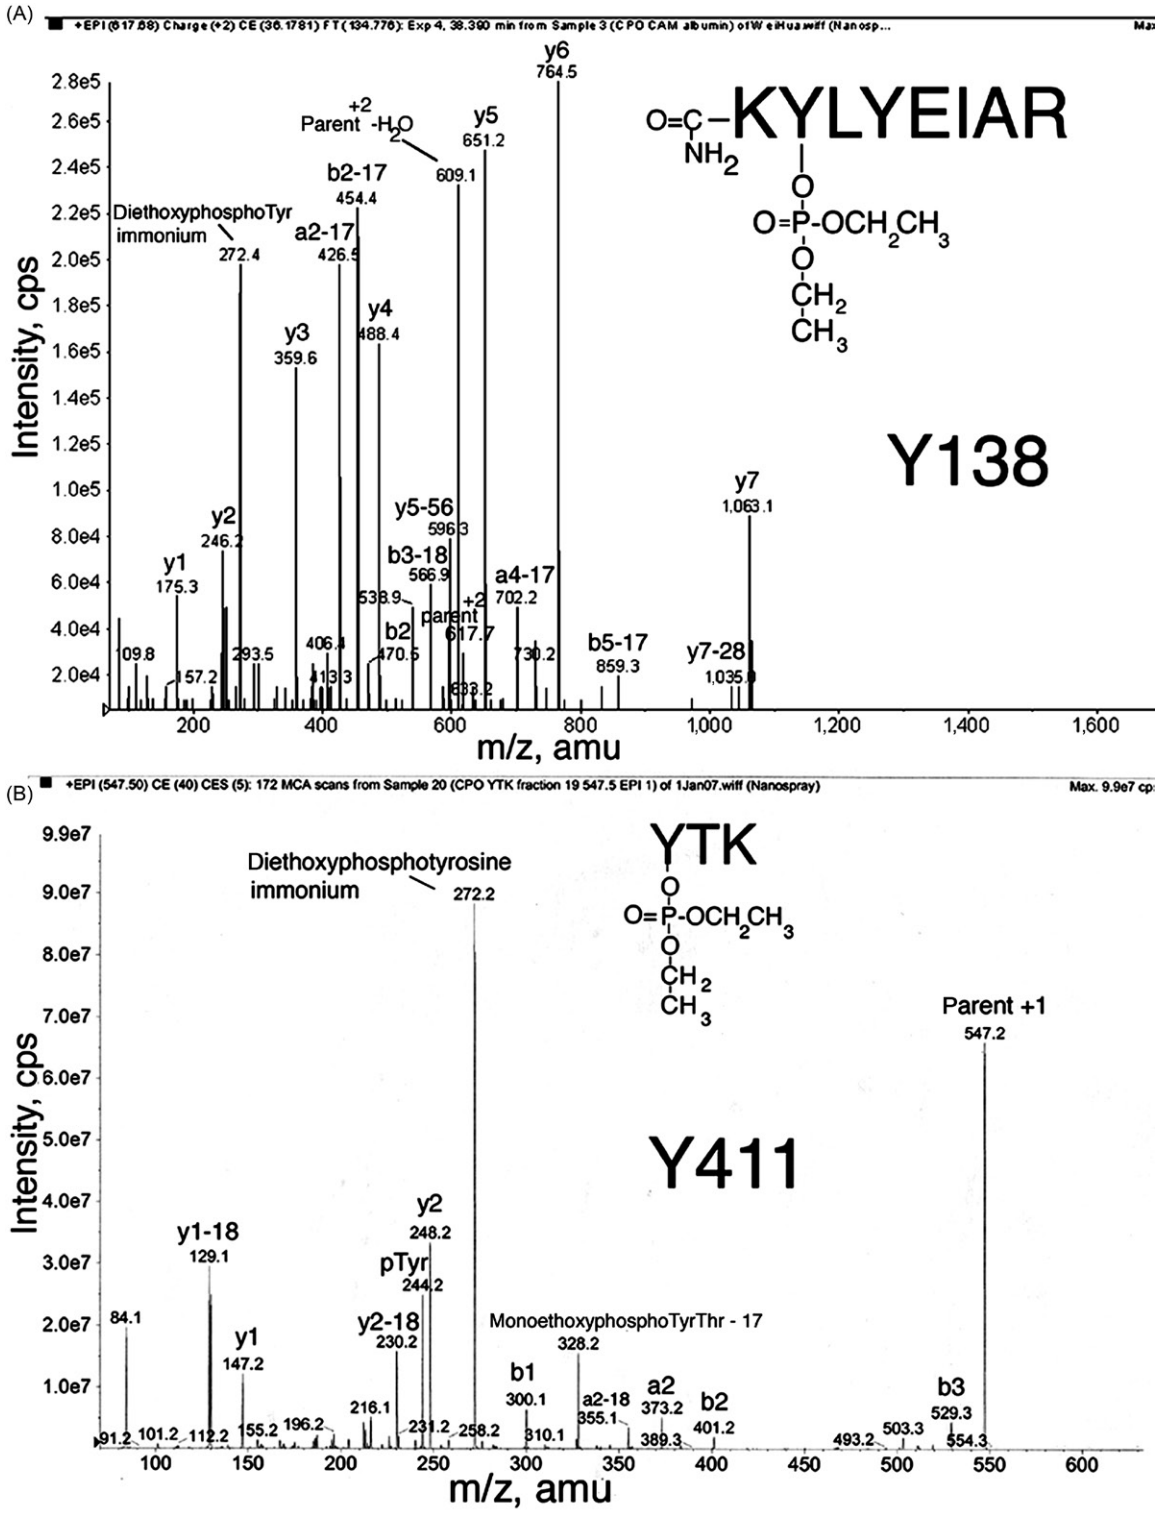

FIGURE 64.5 MS/MS spectra of human albumin peptides labeled on tyrosine with chlorpyrifos oxon. (A) The doubly charged parent ion (617.7 amu) for KYLYEIAR includes a mass of 136 amu from chlorpyrifos oxon and a mass of 43 amu from CM. Carbamylation was a by-product of denaturation in 8M urea. The presence of diethoxyphosphate on Tyr 138 is supported by the masses y7, a2—amine (17 amu), b2—amine (17 amu), b3—water (18 amu), a4—amine (17 amu), and b5—amine (17 amu), all of which include the 136 amu added mass for diethoxyphosphate. The ion at 272.4 amu is consistent with the mass of the diethoxyphosphotyrosine immonium ion; its presence supports chlorpyrifos oxon labeling of tyrosine. (B) The singly charged parent ion (547.2 amu) for YTK includes an added mass of 136 amu from chlorpyrifos oxon. The presence of diethoxyphosphate on Tyr 411 is supported by the masses of the b1 ion, the y2 ion, and the parent ion, all of which include the 136-amu mass of diethoxyphosphate. Furthermore, the characteristic ions at 272.2 amu for the diethoxyphosphotyrosine immonium ion, at 328.2 amu for the monoethoxyphosphoTyrThr ion minus amine (17 amu), and at 244.2 amu for phosphotyrosine support labeling on tyrosine. The loss of one or both alkyl groups from the diethoxyphospho adduct during collision-induced dissociation in the mass spectrometer is a common observation. *Source: Reprinted with permission from Ding et al. (2008). Copyright 2008 American Chemical Society.*

diethoxyfluorothiophosphate (representing an albumin adduct with the thiol form of chlorpyrifos). It is remarkable that the albumin adducts were still detectable 49 days after exposure, when the patient had recovered from the toxic effects.

MRM LC-MS/MS for OP Adducts When the Protein and the Modified Amino Acid Are Known

The most sensitive LC-MS/MS method for detection of OP exposure is a method called *multiple reaction monitoring* or *selective ion monitoring*. This method requires knowledge of the mass of the parent ion and masses of two or more product ions. The selection of product ions is determined experimentally with known samples because not all product ions give a good signal. The method is sensitive because the mass spectrometer selects only those ions that fit the given parent and product ions. An MS/MS spectrum is automatically acquired for samples that have the specified parent and product ions. The MS/MS spectrum allows the investigator to determine whether the ion is the OP peptide or whether it has the specified masses by coincidence. A list of the parent ion and product masses for nerve agent tyrosine adducts is published (Williams et al., 2007).

The MRM method has been used to detect nerve agent–tyrosine adducts in the blood of guinea pigs (Williams et al., 2007), carbofuran-BChE adducts in the blood of human subjects (Li et al., 2009b), OP-BChE adducts in the blood of humans poisoned by dichlorvos, chlorpyrifos, and aldicarb (Li et al., 2010a), OP-albumin adducts in the blood of humans poisoned by dichlorvos (Li et al., 2010b), nerve agent–tyrosine and nerve agent–BChE adducts in the blood of marmosets (Read et al., 2010), nerve agent–tyrosine in rat plasma (Bao et al., 2012), and OP-tyrosine adducts in the plasma of human subjects poisoned by chlorpyrifos (van der Schans et al., 2013).

The MRM method is sensitive and quantitative, but it has the disadvantage that unexpected adducts are not found. The investigator will find only known adducts. A new poison is likely to make adducts that are undetectable in an MRM method.

Pronase Digestion to Yield Single Amino Acids Modified by OPs

Digestion of OP-treated human plasma proteins with pronase yields free amino acids modified by OP (Black et al., 1999). Human plasma treated with sarin or soman contains OP-serine (from BChE) and substantially greater amounts of OP-tyrosine (from albumin and possibly other proteins as well; Black et al., 1999). This method can detect low levels of exposure because large volumes of plasma can be digested. The Porton Down laboratory has synthesized isotope-labeled internal standards (Williams et al., 2007). MRM methods have been published for the detection of nerve agent–tyrosine adducts (Williams et al., 2007; Bao et al., 2012).

Less than 1% of the albumin in plasma is modified by OP. A cleanup step is required that separates and concentrates the OP-tyrosine adduct, such as solid phase extraction (Williams et al., 2007; Read et al., 2010) or offline HPLC (Jiang et al., 2012), before the sample is analyzed by LC-MS/MS. However, the use of MRM in an LC-MS/MS protocol increases the sensitivity and specificity of detection, making it possible to identify OP-tyrosine in a pronase digest directly, without a cleanup step (van der Schans et al., 2013).

Enrichment of OP-Albumin Pepsin Peptides on PHOS-Select Iron Affinity Beads

Though several tyrosine residues on albumin can be modified by treatment with OP, the most reactive is tyrosine 411. Peptides VRY_{411}TKKVPQVST, and $LVRY_{411}$TKKVPQVST selectively bind to Fe(3+) beads at pH 11. Human plasma digested with pepsin and diluted with buffer to raise the pH to 11 is applied to a microcolumn of beads. The peptides are eluted with pH 2.6 buffer and identified by MS. The protocol enriches both the unmodified and OP-modified peptides, regardless of the identity of the OP, thus allowing quantitation of the OP-peptide relative to the unmodified peptide (Jiang et al., 2013b).

Antibody

Sensors that use an antibody to detect nerve agent–adducts on albumin are being developed but are not yet commercially available (Vandine et al., 2013).

OPS MAKE A COVALENT BOND WITH SERINE, THREONINE, TYROSINE, LYSINE, AND HISTIDINE

The first OP adducts were identified on the active site serine of AChE and BChE using a radioisotope-labeled OP. For 50 years, it was taken as dogma that an enzyme was defined as a serine hydrolase if it made a covalent bond with an OP. When a denatured protein sample made a covalent bond with an OP, the result was discarded as an outlier. Today, it is known that proteins need not be in their native structure to bind OPs. Small peptides make a covalent bond with OPs. The new tools of MS have demonstrated that proteins are modified

by OPs not only on serine, but also on threonine, tyrosine, lysine, and histidine (Grigoryan et al., 2008, 2009; Liyasova et al., 2012; Verstappen et al., 2012). To date, these additional binding sites have been demonstrated by *in vitro* reactions with high concentrations of soman, chlorpyrifos oxon, FP-biotin, dichlorvos, and cresyl saligenin phosphate, but it seems only a matter of time before new protein targets will be discovered that react with low doses of OP.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

A new motif for OP binding to tyrosine has been identified. Almost all proteins appear to be capable of binding OP covalently on tyrosine. Whether or not OP will bind to tyrosine *in vivo* depends on the concentration of the protein, the concentration of the OP, and the ionization status of the tyrosine hydroxyl group. The latter factor appears to depend on the presence of nearby positively charged residues.

Albumin is the first protein outside the serine hydrolase family to be recognized as a target of OP binding in humans. The concentration of albumin is so high (600 μM in human plasma) that albumin binds OP despite its slow rate of reaction. The reaction of albumin's most sensitive tyrosine is aided by the presence of three positively charged residues within a five-residue stretch surrounding that tyrosine. It is expected that in the future, additional proteins will be identified as targets of OP binding.

Antibodies will be used to diagnose OP exposure in a biosensor assay with blood, saliva, sweat, or urine. New biomarkers of OP exposure will be identified using MS and antibodies. The identification of new biomarkers for low-dose OP exposure is expected to lead to an understanding of how neurotoxicity is caused by OP doses that are too low to inhibit AChE. For example, it is possible that disruption of microtubule polymerization by OP-adduct formation may explain cognitive impairment from OP exposure.

Identification of new biomarkers of OP exposure may also lead to an understanding of why some people are intoxicated by low doses of OP that have no effect on the majority of the population. The new motif for OP binding to tyrosine may lead to new antidotes for OP poisoning; for example, peptides containing several tyrosines and several arginines may be effective OP scavengers.

Acknowledgments

Mass spectra were obtained with the support of the Mass Spectrometry and Proteomics core facility at the University of Nebraska Medical Center. This work was supported NIH Eppley Cancer Center grant P30CA36727, and DGA grant 03co010-05/PEA01 08 7 (to P.M.).

Monitoring of Blood Cholinesterase Activity in Workers Exposed to Nerve Agents

Daniel Jun, Jiri Bajgar, Kamil Kuca and Jiri Kassa

INTRODUCTION

Determination of the activity of blood cholinesterases (ChEs; erythrocytes, red blood cells [RBCs], and acetylcholinesterases [AChEs], EC 3.1.1.7; and plasma butyrylcholinesterase [BChE] EC 3.1.1.8) is currently the most important procedure for confirmation of the diagnosis of poisoning with organophosphorus compounds (OPs), for monitoring of the recovery of intoxicated persons, and for forensic study purposes (Karalliedde et al., 2003; Bajgar, 2004, 2005, 2013; Eddleston et al., 2005; Pope et al., 2005; Radic and Taylor, 2006; Tavaselvam and Flora, 2014). It is necessary to investigate the whole picture of intoxication, including not only biochemical examinations but also clinical signs, thus allowing more precise assessment of further prognosis. The evidence supporting AChE as the primary site of action for both OP pesticides and nerve agents has been summarized by many authors (Bajgar, 1985, 1991, 2013; Taylor, 1985; Marrs, 1993; Marrs et al., 1996; Lotti, 2000). Their findings include the following observations: symptoms of OP poisoning are similar to those of the AChE inhibitor physostigmine; the *in vivo* LD_{50} value for a variety of OPs correlates well with the inhibition efficacy to AChE determined *in vitro*; and ChE reactivators (e.g., oximes), anticholinergics (e.g., atropine, benactyzine), and reversible AChE inhibitors (e.g., pyridostigmine) can attenuate their toxicity. However, there are ample documented data showing that AChE inhibition is not the only important biochemical change during intoxication; other important changes include changes in other enzymes, neurotransmitters, immune system changes, anaphylactoid reactions, and changes in behavior. Prophylactic/therapeutic drugs might also have multiple sites of action that are similar to those observed during intoxication (Bardin et al., 1987a,b; Bajgar, 1991, 1992; Cowan et al., 1996, Kassa, 1998). Nevertheless, the first reaction of OPs is their interaction with ChEs in the blood stream (Bajgar, 1985, 1991, 2013; Benschop and de Jong, 2001) and then in the target tissues—the peripheral and central nervous system (Green, 1958, 1983; Bajgar, 1985, 1991; Gupta et al., 1985, 1987a,b, 1991; Bardin et al., 1987a,b; Marrs, 1993; Marrs et al., 1996). The delayed neurotoxic effect is induced by inhibition of the neurotoxic esterase and is not caused by inhibition of ChEs; however, only some OPs are neurotoxic in that sense (Abou-Donia and Lapadula, 1990; Johnson, 1990, 1992; Lotti, 1992; Johnson and Glynn, 1995; Slotkin et al., 2008).

The mechanism of AChE inhibition for all the OPs and nerve agents is practically the same—phosphylation (phosphorylation or phosphonylation) of the serine hydroxyl group in the esteratic site of AChE.

Monitoring the ChE changes during the intoxication is, at present, the best marker of the severity of OP or nerve agent poisoning, as well as a basis for further antidotal therapy.

Both the toxicodynamics and toxicokinetics of OPs can be explained by biochemical characteristics of their interaction with ChEs and other hydrolases (e.g., human plasma paraoxonase [PON1]). Inhibition of ChEs in the blood is the first target for OPs according to the principle of "first come, first served" (Benschop and de Jong, 2001).

AChE and BChE differ in their enzymatic properties and physiological function (Massoulié et al., 1993; Darvesh et al., 2003). However, there are other types of

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00065-8

ChEs such as benzoylcholinesterase and propionylcholinesterase. AChE splits the neurotransmitter acetylcholine (ACh) at the cholinergic synapses. A similar reaction is also observed in erythrocytes (RBC AChE), but its function is not yet known in detail, as is also the case with the function of BChE activity in plasma, although there is evidence that BChE plays an important role in cholinergic neurotransmission and could be involved in other nervous system functions, in neurological diseases, and in nonspecific detoxification processes (Darvesh et al., 2003).

DETERMINATION OF ChEs

Determination of ChE activity is based on a number of principles. In general, biological material containing the enzyme is added to the buffered or unbuffered mixture and the enzymatic reaction is initiated by adding the appropriate substrate. Different parts of the reaction mixture are determined (continuously or discontinuously), such as unhydrolyzed substrate or reaction products, either directly or indirectly (Witter, 1963; Augustinsson, 1971; Holmstedt, 1971). The conditions must be chosen very carefully because of different factors influencing the enzyme activity (Reiner and Simeon-Rudolf, 2000, 2006).

According to the procedure and laboratory instrumentation, the most common methods of ChE determination are as follows: electrometric (Michel, 1949); titration (Nenner, 1970); manometric (Witter, 1963); colorimetric detection of the unhydrolyzed substrate (Hestrin, 1949); measurement by the change of pH using an indicator (Winter, 1960); spectrophotometric (Siders et al., 1968; Voss and Sachsse, 1970; Worek et al., 1999a, 2012); fluorimetric (Sasaki 1964; Kusu et al., 1990); radiometric (e.g., Israel and Lesbats, 1987); calorimetric (Konickova and Wadso, 1971); polarographic (Fiserova-Bergerova, 1969); enzymatic (Abernethy et al., 1986; Israel and Lesbats, 1987); and others such as near-infrared spectroscopy (Domjan et al., 1998). These methods are also suitable for the detection of ChE inhibitors using biosensors (Brimijoin and Rakonczay, 1986; De Jong and Benschop, 1988; Cremisini et al., 1995; Walker et al., 2007) or immunochemical assays for detection of chemical warfare agents (Lenz et al., 1997a,b).

A very sensitive and commonly used method for ChE determination was described by Ellman et al. (1961). This method uses thiocholine esters as substrates (acetyl- and butyrylthiocholine or others). After enzymatic hydrolysis, the relevant acid and thiocholine are released and thiocholine by its SH-group is detected using 5,5′dithiobis-2 nitrobenzoic acid (DTNB) forming 5-mercapto-2-nitrobenzoate (3-thio-6-nitrobenzoate, TNB) with an absorbance maximum of approximately 412 nm (Figure 65.1).

Reaction is monitored spectrophotometrically using a spectrophotometer or microplate reader at a convenient wavelength, usually 405, 412, or 436 nm. ChE activity can be calculated in diluted buffered solutions using a TNB extinction coefficient of 14,150 $M^{-1}\cdot cm^{-1}$ (at 412 nm) (Collier, 1973).

Sometimes this method is used with specific inhibitors (tetraisopropyl pyrophosphoramide or profenamine for BChE inhibition and BW284C51 for AChE inhibition) for selective determination of AChE or BChE activity in whole blood samples and there are many modifications described in the literature. Ellman's method is sufficiently specific and sensitive, and it is routinely used for different purposes in many laboratories around the world. Expression of the activity varies greatly, usually as μmols of substrate hydrolyzed per minute (time) per milliliter of biological material examined (e.g., plasma, serum, blood hemolysate) or per milligram of weight tissue or tissue protein. From these values, the expression of the activity in units (U) can be derived (quantity of enzyme catalyzing μmol of substrate per minute at standard conditions). In the clinical laboratory, the enzyme activity can also be expressed as 1 mol of substrate hydrolyzed per liter or kilogram (cat/L; kg) of material per second, which is the hydrolysis of 1 mol of substrate hydrolyzed per second per liter or kilogram ($mol\,s^{-1}\,L^{-1}$ or kg^{-1}). There are many publications dealing with the review and modifications of ChE determination. One of the last methodical works describing improvements in Ellman's method (Ellman et al., 1961), including a description of the methods, is an article published by Worek et al. (1999a).

FACTORS INFLUENCING ACTIVITY OF ChEs

The influencing of BChE activity by gamma irradiation, stress, gravidity, certain neurological and psychiatric disorders, hormones, and medical drugs has been demonstrated (Brown et al., 1981; Bajgar, 1985, 1998). The elevation of BChE activity is not so frequent. An increase in children with nephritic syndrome has been observed; an increased ratio of BChE:LDL cholesterol indicates an increase in the risk of cardiovascular diseases (Kutty, 1980; Navratil and Bajgar, 1987). The involvement of BChE with fat (cholesterol) metabolism has been suggested by Van Lith et al. (1991) and Van Lith and Beynen (1993). The relationship between BChE activity and experimentally induced diabetes mellitus in rats was also mentioned (Annapurna et al., 1991).

In clinical biochemistry, BChE determination in the plasma or serum is more frequently used than that of AChE in RBCs. Except for intoxication with OPs or carbamates (CMs), a BChE decrease indicates either reduced

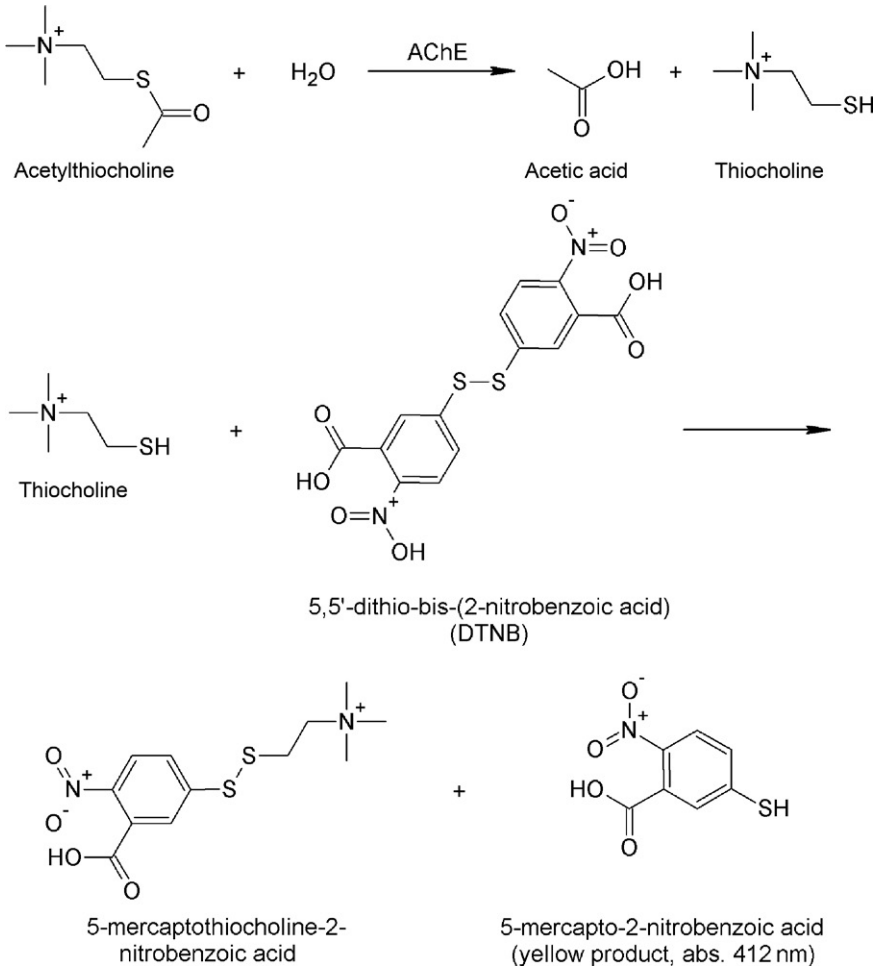

FIGURE 65.1 Acetylthiocholine is hydrolyzed by AChE to acetic acid and thiocholine, which forms yellow 5-mercapto-2-nitrobenzoic acid after reaction with Ellman reagent.

enzyme synthesis or a decrease in the number of production of cells in the liver (Masopust, 1983). A special case of diminished BChE activity is hereditary and is affected by the presence of atypical variants of BChE (Whittaker, 1980; Brown et al., 1981; Goodall, 2006).

There are many other factors influencing BChE activity, and the diagnostic importance of diminished BChE activity is important for the following states (except hereditary decrease of the activity): poisoning with nerve agents and OP/CM pesticides; congenital deficiency; liver damage; acute infection; chronic malnutrition; metastasis (especially liver); myocardial infarction; dermatomyositis; intoxication with carbon disulfide or mercury; and obstructive jaundice (Bajgar, 1991; Bardin et al., 1987a,b; Kutty, 1980; Molphy and Ratthus, 1964; Wyckoff et al., 1968).

Determination of AChE activity is not so widely used in clinical laboratories. A decrease in RBC AChE activity in pernicious anemia has been demonstrated; diminished erythrocyte AChE activity is typical for paroxysmal nocturnal hemoglobinemia and blood type ABO incompatibility (Rakonczay, 1988). AChE activity in the erythrocyte membrane can be considered an indicator of erythrocyte membrane integrity. Increased AChE activity during rectal biopsy is of great diagnostic significance in Hirschsprung disease, especially in the presence of its atypical molecular form (Bajgar and Hak, 1979; Rakonczay, 1988). There are other publications demonstrating increased AChE activity in the amniotic fluid during pathologic development of the neural tube (Bonham and Attack, 1983). AChE activity in erythrocytes and cerebrospinal fluid is also diminished in some endogenous depressions and other psychiatric disorders; however, the results presented are not quite clear at present (Skau, 1986; Bajgar, 1985; Rakonczay, 1988; Bohnen et al., 2007; Martucciello, 2008).

DIAGNOSIS OF OP POISONING

The determination of ChEs in the blood is the basic method for diagnosis and therapy monitoring for OP poisoning, although some doubts exist; some prefer the clinical signs of poisoning as a leading tool for OP poisoning diagnosis and monitoring (Bardin et al., 1987a,b). The determination of AChE and/or BChE activity in whole blood is possible. The decrease in these activities is a good marker but the diagnostic validity is limited to the statement that some factors causing a decrease in blood ChEs are present. In connection with the anamnestic data (exposure to OP or CM pesticide), this is important information. The determination of the RBC AChE or plasma BChE is more informative. There are some discussions dealing with AChE and BChE activity, but which is more important for the diagnosis? In general, AChE activity in RBCs can be considered to be more important for diagnosis of intoxication with nerve agents than plasma BChE activity. However, there are some discussions dealing with the validity of the BChE determination. This enzyme was described as not a very good marker of OP poisoning and its determination was proposed for exclusion from the recommended biochemical procedures (Molphy and Ratthus, 1964; Wyckoff et al., 1968; Bardin et al., 1987a,b). The temporal profile of BChE was studied in a cohort of 25 OP-poisoned patients to examine their relationship to the development of intermediate syndrome. The study suggests that BChE reflects the clinical course of poisoning and that intermediate syndrome may be associated with a persistent BChE inhibition (Khan et al., 2001). Israeli authors also described a direct correlation between the degree of BChE inhibition levels and the severity of intoxication with OP pesticides (Weissmann-Brenner et al., 2002). According to Aygun et al. (2002), in the acute phase of OP poisoning, low levels of AChE support the diagnosis of OP poisoning but do not show a significant relationship to the severity of poisoning. The preference of AChE determination has been demonstrated by Worek et al. (1999b)—BChE activity determination for diagnosis and therapeutic monitoring provides no reliable information about AChE status. This is in agreement with our experimental results (Bajgar, 1998). BChE activity in plasma is in some cases a good marker for diagnosis of OP pesticide poisoning. It is necessary to exclude a diminishing of BChE activity caused by the aforementioned reasons. In all cases, the simple ChE determination provides us with information about the decrease of enzyme activity without specification of the factor causing this phenomenon. A more detailed specification is possible using special methods not available in all clinical laboratories.

For the purposes of occupational medicine, the determination of ChEs in the blood of workers intoxicated with OPs is obligatory. A decrease in activity to less than 70% of normal values is an indicator that the worker should not come into contact with OPs. However, the normal values varied within the laboratories depending on the method of determination.

For practical purposes (individual and interindividual variation), determination of individual normal activity is recommended (this approach is better than that of calculating the decrease from an average value), as well as separate determination of ChEs, RBC AChE, and plasma BChE. The activity determined in human whole blood corresponds to approximately 10% of BChE and 90% of AChE. This is different in rats, in which this ratio is 29% of BChE and 71% of AChE (Bajgar, 1972). Erythrocyte AChE activity seems to be more useful for these purposes than BChE activity in plasma.

There are other biological materials available for special purposes—amniotic fluid, cerebrospinal fluid, and bioptic materials. From these samples, tissue obtained by rectal biopsy is used most frequently (diagnosis of Hirschsprung disease). Elevated AChE activity in the rectal tissue/homogenate (detected histochemically/biochemically) is one of the significant diagnostic markers indicating a need for surgical treatment of Hirschsprung disease and a criterion for diagnosis and management of obstipation (Kobayashi et al., 2002). The presence of an unusual AChE band after electrophoretic separation supports the diagnosis (Bajgar and Hak, 1979; Rakonczay, 1988). The same (either AChE elevation or the presence of a new electrophoretic AChE form) in the amniotic fluid can be applied for the diagnosis of malformation of the neural tube development during pregnancy (Bonham and Attack, 1983). AChE activity in cerebrospinal fluid is also changed in some pathological states; however, the diagnostic validity is not very high and can be considered as a complementary examination (Koponen and Riekkinen, 1991).

In OP poisoning, it is necessary to check vital functions (cardiac, ventilation) and other clinical signs and, according to the symptoms, to apply different biochemical examinations and treatment. Diagnostic criteria are mostly based on anamnesis and the state of ventilation (Bardin et al., 1987a,b; Bardin and Van Eeden, 1990). Serum electrolytes (especially potassium), Blood urea nitrogen (BUN), and creatinine are indicated to assess the degree of volume depletion by secretory losses. Arterial blood gas, blood pH, glucose, lactate, and pyruvate allow us to assess the degree of hypoxia/hypercapnia/acidosis in the presence of respiratory distress. The neurological examination involves procedures such as recording of muscle action potential of abductor digiti minimi after stimulation of nerve ulnaris. A quantitative correlation is shown between RBC AChE activity and paraoxon concentration in plasma. In these cases, muscle function was severely disturbed when the RBC AChE activity was inhibited by more than 90% (Thiermann et al., 2002).

Direct determinations of the toxic agent (nerve agent or OP pesticide) in the circulatory system are also possible. However, the parent compound will circulate intact for a short period of time and detection will not be possible for more than approximately a few hours after exposure. Metabolites circulate for a longer time and are mostly excreted in urine. A metabolite of sarin (*O*-isopropyl methylphosphonic acid) could be traced in urine and plasma from victims after the Tokyo subway sarin terrorist attack (Noort et al., 1998, 2002). For some OP pesticides (parathion, paraoxon), detection of *p*-nitrophenol in urine is an indicator of exposure (Bajgar, 1985). However, the retrospectivity of these methods is limited. Detection using an immunoassay of nerve agents was developed. The antibodies against soman may have the appropriate specificity and affinity for immunodiagnosis of soman exposure (Lenz et al., 1997a,b; Miller and Lenz, 2001).

Methods for the determination of blood ChE inhibition (AChE and BChE) do not allow the identification of the OPs and do not provide reliable evidence for exposure at inhibition levels less than 10–20%. Moreover, they are less suitable for retrospective detection of exposure due to *de novo* synthesis of enzymes. For this purpose, a method based on reactivation of phosphylated ChE and carboxylesterase (CarbE) by fluoride ions was developed. Treatment of the inhibited enzyme with fluoride ions can inverse the inhibition reaction, yielding a restored enzyme and a phosphofluoridate that is subsequently isolated and quantified by gas chromatography and phosphorus-specific or mass spectrometric detection (De Jong and Van Dijk, 1984; Polhuijs et al., 1997a,b). Human as well as monkey plasma does not contain CarbE, but its BChE concentration is relatively high (70–80 nM) (Myers, 1952; De Bisschop et al., 1987), much higher than the concentration of AChE in blood (approximately 3 nM) (Heath, 1961). The plasma of laboratory animals, such as rats and guinea pigs, contains considerable concentrations of CarbE in addition to ChEs. This method allows partial identification of the OP, whereas the lifetime of the phosphylated esterase (and consequently the retrospectiveness of the method) is only limited by spontaneous reactivation, *in vivo* sequestration, and aging. The rate of aging depends on the structure of the phosphyl moiety bound to the enzyme and on the type of esterase. Phosphylated CarbEs generally do not age. Based on this method for retrospective detection of exposure to OP, the exposure of victims of the Tokyo incident to a nerve agent, probably sarin, could be established from analysis of their blood samples (Polhuis et al., 1997a,b; Fidder et al., 2002). Fluoride-induced reactivation of OP-inhibited AChE is a reliable and retrospective method to establish OP exposure. It is limited to compounds that regenerate with fluoride ions. A novel and general procedure for diagnosis of exposure to OPs, which surpasses the limitations of the fluoride reactivation method, is described (Van der Schans et al., 2002). It is based on the rapid isolation of BChE from plasma by affinity chromatography, digestion with pepsin, and followed by liquid chromatography with the mass spectrometric analysis of phosphylated nonapeptides. The method can be applied for the detection of exposures to various OP pesticides and nerve agents including soman. This approach is very valuable and represents a new field for the improvement of diagnosis with OPs. A comprehensive review of the methods for retrospective detection of exposure to toxic scheduled chemicals has been published by Noort et al. (2001, 2002).

As mentioned previously, a decrease in ChE activity is the factor indicating (after the exclusion of other factors) an exposure to OP pesticides, nerve agents, or other ChE inhibitors. This simple determination does not allow us to make certain decisions dealing with the antidotal therapy (especially the repeated administration of reactivators) and has low prognostic validity. Therefore, a new test of the reactivation of inhibited enzyme has been described (Bajgar, 1991). The principle of the reactivation test is double determination of the enzyme activity, the first without and the second with the presence of a reactivator in the sample. The choice of reactivator is dependent on the availability of the oxime; however, in principle it is necessary to have in these parallel samples the same concentrations of reagents. The concentration of the reactivator (usually trimedoxime, but other oximes such as obidoxime, pralidoxime, or HI-6 are also possible) must be no higher than the oxime concentration that causes the hydrolysis of the substrate (acetyl- or butyrylthiocholine); in other words, the oxime concentration must be lower than 10^{-3} M (Patočka et al., 1973).

OP poisoning is very complex and there are many biochemical changes to be registered. Although the assessment of sensitivity and specificity was rather subjective, it is clear that there are two or three parameters that are most sensitive: ChE determination (depending on the type of OP, either AChE or BChE); the possible determination of OP metabolites in the blood; and determination of the phosphonyl moiety on the target enzyme (if possible). In the case of developed intoxication when convulsions occurred, tension of the blood gases is also a good marker; however, these changes are not very specific. The same approach can be applied to lactate. This is not surprising because of the existence of convulsions, including hyperactivity of the diaphragm (and thus disturbed ventilation, low oxygen saturation, and an increase in acid metabolites). It should also be mentioned that the validity of these parameters is changed during intoxication. The changes in transaminases, lactate dehydrogenase (LDH), and gamma glutamyl transferase (γ-GT), indicating liver damage, can be caused by solvents used in commercially available OP insecticides. Low validity in the number of RBC or leukocytes is also indicated. As for CS and

Thrombin-antithrombin complexes (TAT) stress markers, it is clear that OP intoxication represents a stress situation. In this context, an increase in Alanine aminotransferase (ALT) can also be considered as a stress marker and not indicative of liver damage.

Determination of inhibition for different AChE or BChE molecular forms is interesting and useful for improvement of the diagnosis of OP poisoning. It was demonstrated that these forms are inhibited in different manners—some of the forms are resistant (low-molecular-weight forms) and some of them are very sensitive (high-molecular-weight forms). When the total AChE activity is determined, the value obtained is a "mean" of the activities of these forms. The changes in the cyclic nucleotides are interesting but not valid for blood. They were determined during animal experiments with toxic OPs and are of more interest in connection with the nervous system. Esterases and AP, generally hydrolases, are sensitive but the inhibition potency of different OPs is very variable; for nerve agents, these hydrolases are not valid and, for some OP insecticides like malathion, they are sometimes more sensitive than ChEs. In conclusion, diagnosis of OP poisoning represents a serious problem. The development of the new specific methods mentioned (fluoride reactivation, tandem MS analysis of enzymatic digests of BChE) is of high importance for more precise diagnosis of OP nerve agent poisoning. The extensive review of Noort et al. (2002) dealing with biomonitoring of exposure to chemical warfare agents (not only nerve agents) is strongly recommended. From a practical point of view in the clinical laboratory, it is necessary to monitor basic physiological functions, ChEs, and other biochemical parameters, not only for diagnostic purposes but also for the regulation of treatment.

MONITORING OF BLOOD ChE ACTIVITY IN WORKERS WITH NERVE AGENTS

For the purposes of occupational medicine, the determination of ChEs in the blood of workers intoxicated with OP is obligatory. However, the normal values varied within the laboratories depending on the method of determination. Systematic monitoring of workers with nerve agents was performed at our department from 1962 to 1963; however, the results presented contain determinations during 40 years (1964–2004). Because of the large number of results, the results are limited to RBC AChE only, although plasma BChE activity was also determined.

Methods for Determination

Modified Hestrin's method (Hestrin, 1949) was used initially. This method is based on colorimetric detection of unhydrolyzed substrate, ACh. Acetylcholine reacts with hydroxylamine quantitatively in alkaline solution after reaction with $FeCl_3$. The activity was determined in RBC hemolysate with distilled water (1:20). The method was modified and activity was expressed as μmols of hydrolyzed acetylcholine per minute and per milliliter.

In 1964, a method described by Winter (1960) using an autoanalyzer (Technicon, USA) system was evaluated. The method is based on determination of acetic acid released from the substrate hydrolyzed (ACh) and detected with phenol red. AChE activity in RBC hemolysate with distilled water (1:10) was determined (pH 7.6, phosphate buffer 37°C). The activity was expressed as μmol of acetic acid released per 10 min.

From 1972 to 1975, Ellman's method (Ellman et al., 1961), modified for the autoanalyzer, was used. The activity was expressed as ncat/L. The same method was used for this determination using kinetic methods and instruments Vitatron (Eefde, Holland) (1976–1990) and Uvicon 952 (Kontron Instruments, Switzerland) from 1991 to 2004.

Correlation Among Methods

To achieve comparable results (unification of the activity, i.e., one scale), all the activities were recalculated to ncat/L. Recalculation of the activities was performed simply using the formula: U/L = 16.6667 ncat/L. However, in the case of different substrates (esters of choline and thiocholine), correction was made according to correlation analysis ($y = 2.0188x + 2.2458$ and $r_{xy} = 0.9998$). Moreover, this correlation was demonstrated previously including not only Ellman's and Winter's methods (Ellman et al., 1961; Winter, 1960) but also the potentiometric method.

Subjects

International inspectors included 28 males (two determinations, 2000 and 2002), seven were selected (more determinations), and age was unknown. There were 21 medical students (10 female, 11 male) aged 19–20 years. Workers in the department included 18 males (from these, 9 were selected for long-term study) and 23 females (from these, 13 were selected for long-term study). The last determination was performed at age 60 years (female) and 65 years (male), respectively. Ages at the beginning of the study were 24–40 years for males and 19–48 years for females. All determinations were performed during the years 1964–2004.

Data Analysis and Findings

Because of the large number of examinations, the results were demonstrated only for the RBC AChE. The

**Stands for significant differences among activities at $p \leq 0.05$.*

first step was a simple survey of AChE activities divided between females and males. The next step was analysis of individual results and trends. Some attempts to detect a decrease of AChE activity in the case of potential exposure to nerve agents were made.

The results of Hestrin's method (Hestrin, 1949) are documented as an average activity of the RBC AChE. Normal AChE activity was determined to be 104.9 ± 8.5 ncat/L and the coefficient of variation was 27.1%. The method was relatively difficult and is shown for information only. The results of AChE activities for all persons are shown in Figure 65.2. Selected results of RBC AChE activity determination are shown in Table 65.1.

The correlation of activities in hemolysate and whole blood is shown in Figure 65.3.

In general, there were certain tendencies to decrease ChE activity (especially RBC AChE activity) during

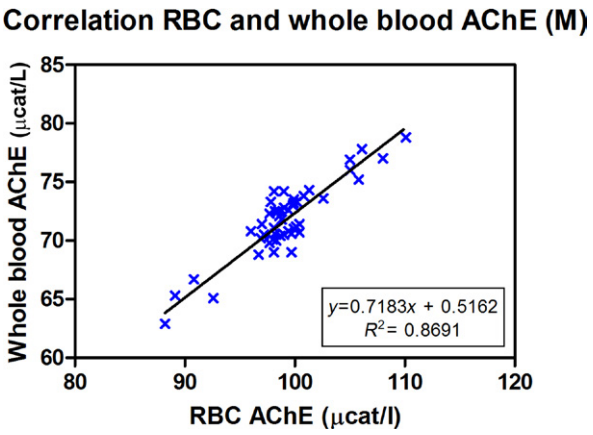

FIGURE 65.3 Correlation between RBC and whole blood AChE.

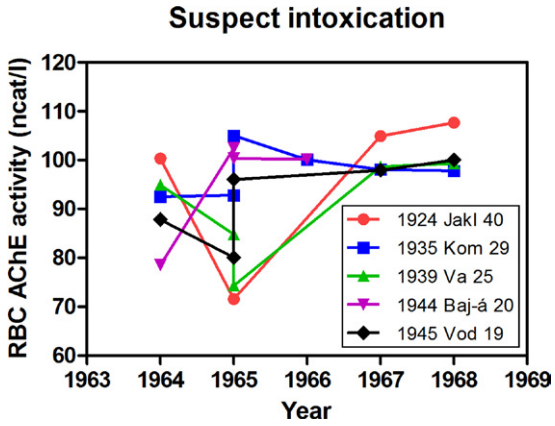

FIGURE 65.4 Suspect nerve agent intoxication.

work at the department. Some rare examples of suspect intoxications were observed in the ChE monitoring as well as an RBC AChE decrease in workers during their work with high concentrations of nerve agents (e.g., inhalation exposure experiments) (Figure 65.4).

In a practical way, the best appreciation of ChE was performed using individual norms for RBC AChE. It seems to be the most sensitive parameter for monitoring ChE changes in exposed workers, followed by sensitivity for whole blood hemolysate. Plasma BChE activity is not so specific and is a sensitive parameter. A decrease of 30% of individual norms seems to be critical for further consideration of intoxication. In conclusion, ChE determination in blood (especially RBC AChE) is a good parameter for monitoring and laboratory examination of workers with highly toxic nerve agents, reflecting possible exposure to these agents.

Variation of RBC AChE is relatively high. Therefore, individual levels were considered to be better, and the decrease of 30% under individual norms was decided to be a limit for exclusion of workers from active work with nerve agents. A further decrease can be considered

a significant diagnostic marker for suspect intoxication. According to the decrease, the classification of steps of intoxication can be assumed: a decrease of 30–50% indicates mild poisoning, 50–70% indicates medium poisoning, and 70–90% indicates severe intoxication. This decrease is in good agreement with results for humans and animals (Bajgar, 1992). Increased AChE activity was also observed for males (not significant) and is in agreement with other results (Augun et al., 2002). Similar results were obtained by other authors, for example, no significant differences in RBC AChE activity between males and females (Rumenjak, 1998) and a tendency to an increase in activity with age (not significant). In general, the values of RBC AChE activity are very good compared with the results of other authors (Rumenjak, 1998; Augun et al., 2002; Zhou et al., 2003).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

This chapter describes the sensitivity of blood ChE as a diagnostic parameter for monitoring workers exposed to nerve agents. The sensitivity to detect changes in response to nerve agent exposure is ordered as RBC AChE > whole blood ChEs > plasma BChE. Normal ChE activity assayed with different methods is in good correlation. RBC AChE or whole blood ChE can be considered a good marker for the monitoring of nerve agent exposure.

Acknowledgments

This work was supported by the long-term organization development plan 1011 of the Ministry of Defense, Czech Republic, and by the project (Ministry of Health, Czech Republic) for conceptual development of research organization 00179906.

Thanks are due to former researchers of the Department of Toxicology, Drs. A. Jakl, V. Hrdina, and J. Tulach (in memoriam) for beginning this work, and to Mrs. M. Zechovska and M. Gregorova (in memoriam) for technical assistance.

Pharmacological Prophylaxis Against Nerve Agent Poisoning: Experimental Studies and Practical Implications

Jiri Bajgar, Josef Fusek, Jiri Kassa, Kamil Kuca and Daniel Jun

INTRODUCTION

Inhibitors of cholinesterases are very important chemicals in the group of organophosphates (OPs). These compounds are used in industry, in veterinary and human medicine, and unfortunately in military (chemical warfare agents (CWAs)/nerve agents) and terrorist activities (Japanese incidents in 1994–1995). The bulk of these compounds is used as pesticides (insecticides, acaricides, etc.). According to the World Health Organization (WHO), more than 1 million serious accidental and 2 million suicidal poisonings with insecticides occur worldwide every year, and of these approximately 200,000 deaths occur, mostly in developing countries (Eyer, 2003; Bajgar et al., 2004, 2007a). The mechanism of action, prophylaxis and treatment of intoxications with OPs, is currently a very timely topic.

The term *prophylaxis* is sometimes unclear. Generally, it is limited to medical countermeasures applied just before penetration of a toxic agent into the organism without further antidotal therapy. It is also described as a pretreatment, but usually antidotal treatment is performed. Thus, when treatment is unnecessary, it can be described as prophylaxis. Although successful prophylaxis can be observed for some OPs, full protection of the organism without postexposure treatment, especially for soman poisoning, remains open. When treatment is given after the exposure, the term *posttreatment* is used. It is obvious that when the drug is administered prior to nerve agent exposure with the aim of protecting the organism, exposure to these agents is expected, and therefore post-exposure therapy can be used; i.e., *pretreatment* could be considered the right term. The term *prophylaxis* used in this chapter is limited to medical countermeasures applied shortly before penetration of a toxic agent into the organism with the aim of protecting the organism against the toxic agent.

Prophylaxis against nerve agents has been described and summarized in various publications (Bajgar et al., 2004, 2007a, 2009, 2011, 2012, 2013; Layish et al., 2005; Patocka et al., 2006; Tuorinsky, 2008; Elsinghorst et al., 2013; Kuca et al., 2013). The basic mechanism of action of OPs is based on their ability to inhibit the enzyme acetylcholinesterase (AChE; EC 3.1.1.7) at cholinergic peripheral and central synapses (Marrs et al., 1996; Bajgar et al., 2004; Masson, 2011; Colovic et al., 2013). In general, prophylaxis can be focused on protection of AChE against inhibition using reversible cholinesterase inhibitors. The level of OP can be diminished by using enzymes that hydrolyze these agents or enzymes that bind the agents (to specific proteins or to antibodies) and thereby reduce the OP level and inhibition of cholinesterases—AChE and BuChE (EC 3.1.1.8; the scavenger effect) in the organism; this can be described as detoxification. Another approach to prophylaxis is based on using present antidotes and other drugs (Bajgar et al., 2004, 2007a, 2009, 2011, 2012, 2013; Kuca et al., 2013). Different drugs or their combinations can also be used. A simple schema describing the fate of the agent in the organism and possible target sites for prophylaxis is shown in Figure 66.1.

In the schema, basic reactions for the effect of nerve agents are indicated—they are penetration of the agent into the organism through different ways of administration; after penetration into the blood (transport system), the agent is distributed to the places of metabolic and toxic effects. To stop or minimize the toxic effect, different possibilities can be explored. Because of inhibition of AChE

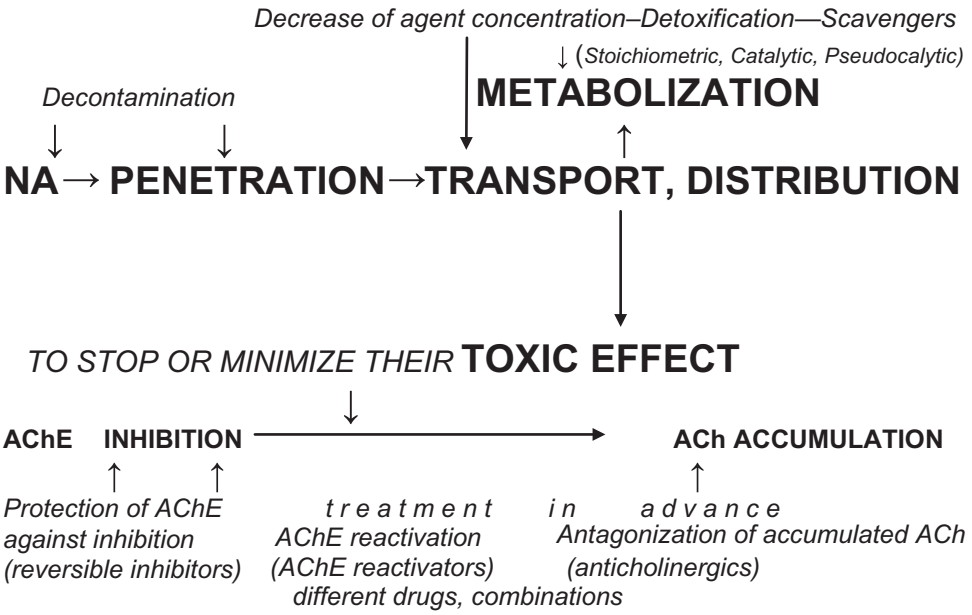

FIGURE 66.1 Four basic reactions of OP in the organism (in capitals) and possible approaches for prophylaxis (in italics). *Source: Modified from Bajgar (2004, 2009) and Gupta (2009).*

is the main, trigger, and basic pharmacodynamic factor, protection against AChE inhibition is one possible process using reversible AChE inhibitors. Treatment in advance (administration of anticholinergics and reactivators) is another possibility, and the use of different drugs minimizing the toxic action is the third possible approach for prophylaxis. Certainly, all these principles can be combined.

PROTECTION OF AChE AGAINST INHIBITION

Intact AChE is a basic requirement for normal function of the organism, and thus for effective prophylaxis. The enzyme is changed in a way that will make it resistant to OP. This can be achieved by using reversible inhibitors, preferably carbonates (CMs), which are able to inhibit AChE reversibly, and after spontaneous recovery of the activity (decarbamylation) normal AChE serves as a source of an active enzyme.

The ability of some CMs to protect an organism poisoned with an OP has been known for many years (Koelle, 1946; Koster, 1946). Physostigmine and neostigmine have been used to protect animals against DFP. The number of OPs studied for protection has been expanded, as well as the number of CMs studied. The results are very dependent on experimental conditions; nevertheless, the protective effects of physostigmine, aminostigmine, pyridostigmine, and others against AChE inhibition caused by different OPs (mostly soman) have been demonstrated (Patocka, 1989; Marrs et al., 1996; Tonkopii, 2003). It has been described that weak inhibitors are able to protect cholinesterases from strong inhibitors (paraoxon; Petroianu et al., 2005a, 2007). Non-OP inhibitors were also tested (Kassa et al., 2012; Lorke et al., 2012, 2013; Petroianu et al., 2013). It appeared from many studies that the cholinesterase inhibitor pyridostigmine was the most promising prophylactic drug, particularly against soman poisoning (Gordon et al., 1978, 2005; Patocka et al., 1991; Anderson et al., 1992; Koplovitz et al., 1992; Maxwell et al., 1993; Bajgar et al., 1994; Kassa and Bajgar, 1996; Kassa and Fusek, 1998, 2000; Tuovinen, 1998; Koupilova and Kassa, 1999; Kassa et al., 2001a,b). On the basis of these results, pyridostigmine was introduced into some military units as a prophylactic drug against nerve agents. Its prophylactic effect (like the effects of other CMs) is increased with its dose; however, with a higher dose, the side effects are also increased. This problem can be solved by adding pyridostigmine-antagonizing drugs, anticholinergics. Many anticholinergics have been tested for their ability to protect the organism against intoxication with soman (and other nerve agents). On the basis of this research, the prophylactic combination PANPAL, composed of pyridostigmine with trihexyphenidyl and benactyzine (Bajgar et al., 1994, 1996; Kassa and Bajgar, 1996; Kassa and Fusek, 1998, 2000; Fusek et al., 2000, 2006; Kassa et al., 2001a), was introduced into the Czech army, and later into the Slovak army. The presence of anticholinergics allowed for an increase in the pyridostigmine dose and, simultaneously, an increase its prophylactic efficacy (Kassa et al., 1997; Bajgar et al., 2004, 2007a; Fusek et al., 2006). Moreover, prophylaxis with PANPAL improves following post-exposure antidotal therapy with anticholinergics and oximes (Bajgar et al., 2004; Kassa,

2006). The prophylactic antidotal combination called PANPAL has no side effects, as demonstrated on volunteers: no statistically significant different changes in the actual psychic state, as well as no negative changes in the dysfunction time, were observed. An improvement of the tapping test following PANPAL administration was demonstrated. A decrease in the heart frequency 60 min following PANPAL administration lasting 480 min and returning to normal values within 24 h was demonstrated (Fusek et al., 2006).

Other CMs also have a good prophylactic efficacy, especially physostigmine and aminostigmine (due to their central effect which is contrary to pyridostigmine; Tuovinen and Hanninen, 1999; Kim et al., 2002; Tonkopii, 2003). Experimental studies with transdermal administration of physostigmine suggest a serious interest in the prophylactic use of this drug (Levy et al., 1992; Jenner et al., 1995; Walter et al., 1995; Kim et al., 2005; Cho, 2012; Cho et al., 2012). A similar approach was described with scopolamine (Che et al., 2011).

Structurally different inhibitors from the CM and OP groups were also studied. From these compounds (preferably binding to the AChE anionic site), tacrine, its 7-methoxyderivative (7-MEOTA) and huperzine A, were considered and experimentally studied with respect to prophylaxis *in vitro* and *in vivo* (Bajgar, 2004). The most interesting results were obtained with huperzine A (Lallement et al., 2002; Gordon et al., 2005; Bajgar et al., 2007b; Karasova et al., 2009; Wang et al., 2013).

SCAVENGERS

Keeping AChE intact can be achieved by eliminating the agent before its penetration into the target sites containing the enzyme. In this case, the detoxification principle can be used in two different ways: administration of enzymes splitting the OP or specific enzymes (cholinesterases) that bind the OP. The enzymes that hydrolyze nerve agents are called *catalytic* scavengers, and the enzymes that bind nerve agents are described as *stoichiometric* scavengers. OPs are bound to the exogenously administered enzyme or decomposed by the enzyme and thus the nerve agent level in the organism is decreased (the action of a "scavenger"). Enzymes, which hydrolyze OPs, were thoroughly studied by Raveh et al., (1992) and Li et al., (1995). Catalytic scavengers are enzymes displaying a turnover with OP nerve agents as substrates, allowing rapid and efficient protection (Masson et al., 1998; Ditargiani et al., 2010; Gupta et al., 2011; Kuca et al., 2013; Otto et al., 2013). Paraoxonase and similar enzymes are prospective hydrolyzing scavengers (Aharoni et al., 2004; Rochu et al., 2008; Valiyaveettil et al., 2010, 2011a,b; Trovasler-Leroy et al., 2011). On the other hand, many studies have been completed using cholinesterases as scavengers. AChE was used as a prophylaxis against OP poisoning, and a correlation has been found between protection and the blood–enzyme level in mice (Wolfe et al., 1987; Raveh et al., 1989). BuChE and AChE were observed to be very effective in protection against OP intoxication (Ashani et al., 1991; Doctor et al., 1991, 1997, 2002; Maxwell et al., 1993, 1998; Moore, 1996; Saxena et al., 1997; Bird et al., 2010). The idea to use the plasma as a source of cholinesterase to eliminate nerve agent action after peritoneal dialysis with human plasma in rats was also described (Bajgar et al., 1982), but without further development.

The administration of enzymes as scavengers seems to be very promising: the enzyme is acting at the very beginning of the toxic action, without interaction with the target tissues and without side effects (Doctor et al., 1997, 2002; Saxena et al., 2004, 2011; Huang et al., 2007). All of these features are of great interest, and they are yielding practical results—namely, isolation of the enzyme, examination for lack of an autoimmune response, and establishment of pharmacokinetic and pharmacodynamic properties (Saxena et al., 2002). Recombinant human BuChE can be produced from the milk of transgenic goats (Cerasoli et al., 2005) commercially produced as Protexia. Moreover, BuChE pretreatment also showed protective effects on AChE inhibition in the brain regions following low-level sarin inhalation exposure: the enzyme (BuChE) administered into the bloodstream does not influence erythrocyte AChE, plasma BuChE activity is increased, and the brain AChE is not affected. Following intoxication with a nerve agent, the agent is bound to plasma BuChE (now existing in excess), and proportionally bound to erythrocyte AChE; both enzymes are inhibited, however, to a lesser extent in comparison with the unpretreated situation. The part of the nerve agent bound to both enzymes represented a loss of the agent, and the diminished level of nerve agent is able to penetrate the brain. Therefore, AChE activity in the brain is protected (Sevelova et al., 2004; Bajgar et al., 2007c).

The efficacy of cholinesterases as a bioscavenger of OP can be enhanced by combining enzyme pretreatment with oxime reactivation, since the scavenging capacity extends beyond a stoichiometric ratio of cholinesterases to OP. Human BuChE has previously been shown to protect mice, rats, and monkeys against multiple lethal toxic doses of OP anticholinesterases (anti-AChEs; Maxwell, 1992; Allon et al., 1998). An interesting approach can be simultaneous administration of BuChE and reactivators; BuChE acts as a scavenger binding the nerve agents. A reactivator acting as a *pseudocatalytic* bioscavenger reactivates BuChE simultaneously, and reactivated enzyme serves as a new scavenger (Jun et al., 2007; Kovarik et al., 2010).

This approach was tested using human BuChE (Jun et al., 2011). The best reactivators were trimedoxime and

obidoxime, but only in the case of OP insecticides (paraoxon, methamidophos, and leptophos; Jun et al., 2007, 2011; Musilova et al., 2009). Thus, currently available reactivators cannot be of interest and practical use as pseudocatalytic scavengers for nerve agents.

Given our increasing knowledge of bioengineering and biotechnology, recombinant human BuChE with a good protective effect against nerve agents was obtained from transgenic animals. A connection between these two enzymes (binding and hydrolyzing) is possible, with the aim of obtaining a modified enzyme splitting OPs and simultaneously reacting with AChE as a scavenger (Broomfield et al., 1997). Antibodies against OPs are at the research stage and are more focused on the detection of OPs (Lenz et al., 1997; Miller and Lenz, 2001).

PROPHYLAXIS WITH CURRENT ANTIDOTES

The aim of this approach was to achieve a sufficient level of antidotes in the blood circulation before intoxication, so the antidotes can be tested as prophylactics. This can be characterized as "treatment in advance." The problem with their use, however, is the timing, duration, and achievement of sufficient levels of these antidotes after administration. The antidotes currently used for the treatment of OP poisoning in this context include anticholinergics, reactivators, and anticonvulsants (Bajgar et al., 2004, 2007a). The prophylactic efficacy of antidotes (as demonstrated in treatment studies) is good; administration of the antidotes typically takes place very shortly (i.e., within minutes) after intoxication. Another study showed good prophylactic efficacy of pyridostigmine or ranitidine with pralidoxime against paraoxon poisoning (Petroianu et al., 2005b, 2006). Extension of the duration of the effects of the antidote by achieving sufficient levels in the blood by oral administration is not possible (especially reactivators, as they are decomposed in the gastrointestinal tract) and therefore is excluded. Consequently, other routes of administration were sought. Transdermal administration of one of the most effective reactivators (HI-6) was shown to be the most realistic approach (Dolezal et al., 1988; Bajgar, 1991). The final result was a new prophylactic transdermal antidote TRANSANT, containing the patch impregnated with HI-6. This preparation was clinically tested (including dermal sensitivity) without any harmful effects; field testing was also successful, and TRANSANT was introduced into the Czech army and later into the Slovak army (Bajgar et al., 2004; Fusek et al., 2007). If its administration is combined with PANPAL, the two anticholinergics contained in PANPAL are able to prevent and treat symptoms of nerve agent poisoning. Therefore, a combination of TRANSANT and PANPAL administered as a pretreatment provides the best prophylactic efficacy compared to pyridostigmine or PANPAL administered alone (Bajgar et al., 2004). The anticonvulsant drugs benzodiazepines (e.g., diazepam, midazolam, alprazolam, triazolam, and clonazepam) were studied, but isolated prophylactic administration did not work to very good effect (Herink et al., 1990, 1991; Kubova et al., 1990).

PROPHYLACTIC USE OF OTHER DRUGS

Prophylactic administration of different drugs (alone or in combination) against intoxication with OPs was studied. Calcium antagonists (e.g., nimodipine), neuromuscular blockers (e.g., tubocurarine), adamantanes (e.g., memantine), and the opiate antagonist meptazinol (Galli and Mazri, 1988; Gupta and Dettbarn, 1992; McLean et al., 1992; Marrs et al., 1996; Karlsson et al., 1998; Stojiljkovic et al., 1998) were also tested, offering different results with limited practical utility. On the other hand, a positive prophylactic effect has been demonstrated with procyclidine (e.g,. antimuscarinic, antinicotinic, and the anti-NMDA receptor drug; Myhrer et al., 2002, 2003), metoclopramide (Hasan et al., 2004), clonidine (Loke et al., 2001), or procyclidine and donepezil (Haug et al., 2007). The prophylactic effect of a group of drugs with anticholinergic and/or antiglutamatergic properties (e.g., benactyzine, biperiden, caramiphen, procyclidine, and trihexyphenidyl), with respect to their anticonvulsant properties, was studied to prevent damage of the central nervous system (CNS) induced by seizures. Only procyclidine and caramiphen antagonized soman-induced seizures (Myhrer et al., 2008a; Schultz et al., 2014). Among the different drugs tested, procyclidine appears to be an effective anticonvulsant, with few cognitive side effects (Myhrer et al., 2008b). Procyclidine with physostigmine (administered transdermally) showed very good prophylactic efficacy against soman in dogs; moreover, this efficacy was increased by using antidotal therapy with HI-6 and atropine (Kim et al., 2005). Special importance can be placed on suramine (a protease inhibitor). Administration of this compound prior to soman intoxication (and followed by administration of atropine) showed good prophylactic effects (Cowan et al., 1996). However, all these studies are experimental, and they have not reached the practical output stage. The combinations of various drugs as prophylactics can be of very different character. They can be used simultaneously (a combination of different drugs) or as a pretreatment and a post-treatment with different antidotes. Administration of pyridostigmine (or other AChE inhibitors) prior to intoxication and treatment with different drugs is a typical example (Anderson et al., 1992, 1997; Kassa, 1995; Bajgar et al., 1996;

TABLE 66.1 Drugs Used in the Prophylaxis Against OP Nerve Agent Poisoning (Relatively Perspective Drugs Are in Bold)

Principle	Drug Group	Drug	Duration	Equipment of the Army	Efficacy	Comment
Protection of cholinesterase against inhibition	Carbamates	**Pyridostigmine, Aminostigmine, Physostigmine**	8 h	PYRIDOSTIGMINE BROMIDE	+++	Dose limited, side effects. Alone is not very effective, following antidotal treatment enhances its effect
		Syntostigmine, Eptastigmine, Mobam				
		Decarbofuran, Heptylphysostigmine				
	Others	**Huperzine A**				
		Tacrine, Methoxytacrine				
	Organophosphates					
		TEPP, Paraoxon				
		Ethyl-4-nitrophenylphosphonate				
	Aminophenols	Eseroline				
Simulation of treatment	Anticholinergics	**Biperidene**, **Scopolamine**, **Benactyzine** Atropine, Aprophen, Hyoscine				Transdermal administrations of scopolamine, physostigmine and HI-6 were studied
		Adiphenine, Caramiphen				
		Pentamethonium, Mecamylamine				
		Trihexyphenidyl				
	Reactivators	HI-6				
		PAM, Obidoxime, Trimedoxime, Methoxime	8 h	TRANSANT (HI-6, transdermal admiministration)	+	Alone is not effective
	Others	**Suramine** Benzodiazepines, Tubocurarine Memantine, Procyclidine Nimodipin, Clonidine				
Detoxification	Cholinesterases enzymes hydrolyzing OP monoclonal antibodies against OP	**Butyrylcholinesterase, Mutants**				Very perspective PROTEXIA®
		Acetylcholinesterase				
		Triesterase Paraoxonase				
Combinations			8 h	PANPAL (pyridostigmine, trihexyphenidyle, benactyzine)	++++	Efficacy is increased with following antidotal treatment
				PANPAL + TRANSANT	+++++	In combination, the best prophylactic efficacy

Kassa and Bajgar, 1996; Tuovinen and Hanninen, 1999; Kim et al., 2002). Aerosolized scopolamine was described to protect guinea pigs against inhalation toxicity to sarin (Che et al., 2011). There are other combinations as well, such as the administration of triesterase (Tuovinen and Hanninen, 1999; Tuovinen et al., 1999), procyclidine (Kim et al., 2002; Myhrer et al., 2002, 2003), clonidine (Loke et al., 2001), or sustained release of physostigmine and scopolamine (Meshulam et al., 2001). The results depend on experimental conditions, but this approach (administration of different drugs) has yielded some good results. However, up to now, they have been only on an experimental level.

Clearly, there is a wide range of prophylactics. The drugs used in prophylactics against nerve agents are summarized in Table 66.1. Some of them (bolded in the

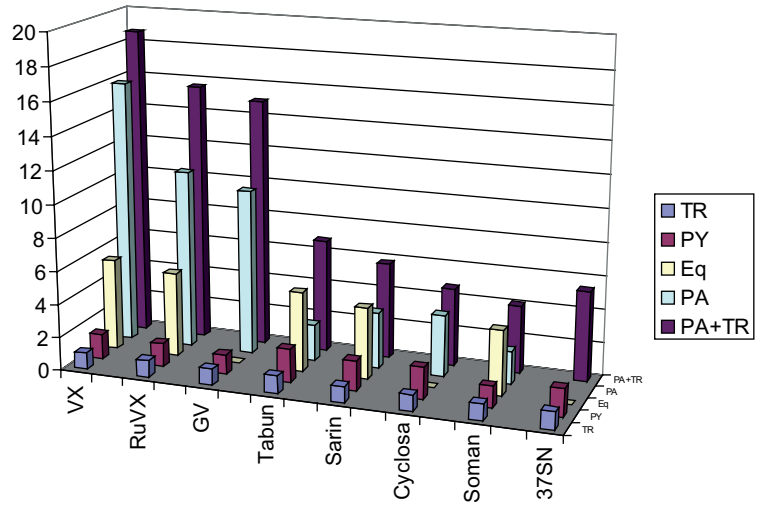

FIGURE 66.2 Efficacy (expressed as a prophylactic index) of different prophylactics (TR: TRANSANT; PY: Pyridostigmine; Eq: equine butyrylcholinesterase; PA: PANPAL; PA + TR: combination of PANPAL and TRANSANT) against selected nerve agents in rats. The results are means only. Prophylactic effect of equine butyrylcholinesterase was not tested for 2-(dimethylamino)ethyl *N*,*N*-dimethylphosphoramidofluoridate (GV), cyclosarin, and 37SN. *Source: Elaborated using data from Bajgar (2009, 2011, 2012).*

table) can be studied further. Only three prophylactics have been introduced into armies—pyridostigmine alone; PANPAL, composed of pyridostigmine, benactyzine, and trihexyphenidyl; and TRANSANT (dermal administration of HI-6). Another prophylactic drug, Protexia, can be considered as well. The efficacy of different prophylactics against nerve agents expressed as prophylactic indexes is shown in Figure 66.2.

Current prophylactics have a few problems. Reversible cholinesterase inhibitors have side effect caused by their parasympathomimetic activity. This issue can be addressed by adding anticholinergic drugs. Isolated administration of anticholinergics also can be helpful prophylactically; however, this effect can be supported by adding reversible inhibitors. The main problem of bioscavengers is immunoreaction, which can be solved by modifying the scavenger. Using the approach of the treatment in advance, reactivators are used, but the main issue is their route of administration. Further, conducting additional research into improving prophylaxes is difficult.

A comparison of features of different prophylactics is summarized in Table 66.2. Various criteria are used, including cost, side effects, and difficulty of use. The best combination of effects, cost, and accessibilty is observed when PANPAL and TRANSANT are used together. These prophylactics are shown in Figure 66.3.

It appears from these results that simple prophylaxis (without post-exposure treatment) against OP is insufficient. Therefore, pyridostigmine is important as a prophylactic drug, especially when it is combined with post-exposure antidotal treatment. For further development, it is necessary to search for novel prophylactic drugs and new routes of administration. In this context, preparations of cholinesterases are of special importance for the development of more effective prophylactics.

TABLE 66.2 Comparison of Various Prophylactics Using Different Criteria of Their Evaluation

Criterium	Pyridostigmine	PANPAL	Protexia	TRANSANT
Introduced in other armies	Yes	No	No	No
Introduced in the Czech army	No	Yes	No	Yes
Accessibility	++++	++	++	++
Cost	+	++	++++	+++
Difficulty to use	+	+	++ (i.v., i.m.)	++ (self-help)
Prophylactic effect	+	+++	+++	alone ineffective
Side effects in recommended dose	No	No	Antigenic properties	No
Duration of prophylaxis	6–8 h	6–8 h	5–8 h	8 h
Increase of effect of followed antidotal treatment	+	++	No	++

PANPAL

TRANSANT

FIGURE 66.3 Two prophylactics: PANPAL (top) and TRANSANT (bottom).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

There are many drugs being tested for their prophylactic efficacy against nerve agent intoxication. However, only three of these (pyridostigmine alone, PANPAL, and TRANSANT) have been introduced into military practice. The prospective approach for the future seems to be to search for more effective drugs or their combinations using modern techniques (e.g., molecular modeling), including new routes of administration, and the use of purified enzymes, especially cholinesterases and paraoxonases produced by biotechnology.

CHAPTER

67

Prophylactic and Therapeutic Measures in Nerve Agents Poisoning

Trond Myhrer and Aas Pål

INTRODUCTION

Nerve agents are regarded as the most toxic means among all chemical weapons. The first nerve agents were originally synthesized during the 1930s in Germany in attempts to achieve more efficient pesticides based on organophosphorus compounds. Tabun was the first one synthesized, followed by sarin and soman. VX is another type of nerve agent that was originally developed in the United Kingdom when searching for new insecticides. The organophosphorus nerve agents are highly potent irreversible inhibitors of the enzyme acetylcholinesterase (AChE) that hydrolyzes acetylcholine (ACh). Accumulation of ACh in the synaptic cleft results in overstimulation of muscarinic and nicotinic receptors. This cholinergic overactivity can affect all organ systems. The toxic signs in humans include pinpoint pupils (miosis), bronchoconstriction, hypersalivation, increased lung secretions, sweating, diarrhea, loss of consciousness, seizures, and respiratory arrest. Miosis appears to be a very sensitive index of direct exposure and can be painful for several days. Chest tightness, rhinorrea, and increased salivation can occur within seconds or minutes of inhalation of nerve agent. If exposure is substantial, then death may occur from respiratory arrest within minutes. Individuals moderately exposed usually recover completely, although Electroencephalogram (EEG) abnormalities have been reported in those severely exposed to sarin 6–8 months after the terror attack in Japan (Murata et al., 1997).

BACKGROUND

Exposure to nerve agents requires immediate medical treatment. For this purpose, military personnel are issued with autoinjectors containing countermeasures for self-administration or "buddy aid." Antidotes against nerve agents are based on drugs acting at the muscarinic receptors and Gamma-amino-butyric-acid, A-receptor ($GABA_A$) receptors (McDonough and Shih, 1997). In addition, partial protection against nerve agents can be obtained by the use of reversible (carbamate) AChE inhibitors shielding a portion of AChE from irreversible inhibition by nerve agents before nerve agent exposure. Furthermore, reactivation of any unaged AChE by an oxime is regarded as important immediate treatment after nerve agent exposure.

A number of armed forces have based their therapy against nerve agent intoxication on an oxime (obidoxime, 2-PAM, HI-6), an anticholinergic (atropine), and a $GABA_A$ agent (diazepam, avizafone) combined with carbamate (pyridostigmine) pre-treatment (Aas, 2003). However, such treatment regimens can reduce immediate lethality, but they do not attenuate the occurrence of nerve agent-induced seizure activity and concomitant convulsions, unless atropine is administered early and at a high dose (McDonough and Shih, 1997). Such seizures rapidly progress to status epilepticus, a condition that is strongly associated with mortality and brain damage in experimental animals (Shih et al., 2003). Thus, there is an urgent need to search for novel strategies able to prevent or terminate nerve agent-induced seizures. For this reason, the present chapter focuses on animal studies (guinea pigs, rats, monkeys) designed to acquire novel insights into the neuropharmacological mechanisms of nerve agent-induced seizures and neuropathology.

MECHANISM OF ACTION

It has been hypothesized that several neurotransmitter systems become involved sequentially in the initiation

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00067-1

and maintenance of seizures elicited by nerve agents (McDonough and Shih, 1997). The progression of events can conceptually be divided into three phases. An early cholinergic phase lasting from the time of exposure to approximately 5 min after onset of seizures is dominated by high cholinergic activity followed by a transitional phase of cholinergic and glutamatergic hyperactivity, and finally a predominantly glutamatergic phase after approximately 40 min (McDonough and Shih, 1997). In the latter study, a substantial body of evidence has been provided in support of this model.

Nerve agent intoxication results in inhibition of AChE and a tremendous buildup of ACh, leading to protracted muscarinic receptor activation. This activation seems to happen in a dose-related manner. The higher the dose of soman, the shorter the latency to onset of seizures and the greater the likelihood of early death in rats (Myhrer et al., 2006a). The brainstem respiratory drive is vulnerable to increased cholinergic input, because the function of the respiratory center is disrupted. Both muscarinic and nicotinic antagonists can protect the respiratory center against cholinergic overstimulation (Kubin and Fenik, 2004). In compliance with this notion, the nicotinic antagonist mecamylamine in high doses can prolong survival in mice intoxicated by soman (Hassel, 2006). The functional integrity of the diaphragm is not significantly compromised by soman, unless a dose of 14× LD_{50} is used in cats (Rickett et al., 1986). After a soman dose of 5× LD_{50}, the latency to seizure onset is approximately 1 min, whereas the latency is approximately 14 min when the dose of soman is 1× LD_{50} in rats (Myhrer et al., 2003; 2006a). The change in ACh levels throughout the brain has been reported to precede that of any other neurotransmitter (Fosbraey et al., 1990). The increases in glutamate occur in a number of brain regions with different time courses after seizures have started (McDonough and Shih, 1997). According to the three-phase model, efficacious pharmacological countermeasures against nerve agents should preferentially exert cholinergic and glutamatergic antagonism along with GABAergic agonism.

PROPHYLACTIC MEASURES

Animal Studies

It takes a higher dose of anticonvulsants to terminate seizures induced by soman than other classical nerve agents such as tabun, sarin, cyclosarin, and VX (Shih and McDonough, 2000). This suggests that a drug capable of stopping soman-generated seizures would be equally effective for the treatment of seizures evoked by other nerve agents. This is the reason why soman is the nerve agent most frequently used in animal models to evaluate potential anticonvulsant drugs.

Pyridostigmine does not penetrate the blood–brain barrier (BBB) to any extent and therefore provides very limited protection of the brain (Aas, 2003). For this reason, some recent investigations of prophylactic treatment in animals have focused on physostigmine as an AChE inhibitor, because this carbamate (in contrast to pyridostigmine) readily crosses the BBB (Birtley et al., 1966). Although physostigmine in optimal doses does not protect against a lethal dose of soman, it appears effective when used along with an anticholinergic drug in guinea pigs (Philippens et al., 2000). Physostigmine in combination with scopolamine has been reported to protect guinea pigs effectively against soman, sarin, and tabun (Philippens et al., 2000; Wetherell et al., 2002). Similar protective effect has also been obtained with monkeys. Pre-treatment of rhesus monkeys with physostigmine and scopolamine or physostigmine and trihexyphenidyl 25 min before exposure to 2× LD_{50} of soman results in survival without convulsions or loss of consciousness (von Bredow et al., 1991).

The cholinergic and glutamatergic antagonist, procyclidine, in combination with physostigmine, has been demonstrated to assure full protective effects against convulsant doses of soman in rats and guinea pigs without any need for post-exposure treatment (Kim et al., 2002). Because physostigmine has a rather short half-life, it will preferably require continuous administration. In a study of rats, osmotic minipumps were implanted subcutaneously, allowing sustained delivery of physostigmine and procyclidine in 3 days before exposure to a soman dose of 1.3× LD_{50}. This treatment exerted full protective effects against lethality, convulsions, learning and memory impairments, and physical incapacitation (Choi et al., 2004). In a subsequent study in beagle dogs, a matrix-type patch attached to the abdominal side of the animal delivered physostigmine and procyclidine for 2 days before being challenged with one of various doses of soman (2–10× LD_{50}). The patch delivery protected against seizures and death up to 4× LD_{50} of soman. When the patch was combined with HI-6 and atropine injected intramuscularly 1 min after soman exposure, protection was achieved up to a dose of 6× LD_{50} (Kim et al., 2005).

In a study from our laboratory, the combined effects of physostigmine and procyclidine were tested against various doses of soman. Physostigmine (0.1 mg/kg) in combination with procyclidine doses of 1, 3, or 6 mg/kg effectively prevents the development of convulsions and hippocampally monitored seizures when the doses of soman were 1.3×, 1.6×, or 2× LD_{50}, respectively (Figure 67.1). Results from [^{3}H]MK-801 binding experiments show that procyclidine inhibits the phencyclidine site at the N-methyl-D-aspartic acid (NMDA) receptor in a concentration-dependent manner (Myhrer et al., 2004a). Physostigmine (0.1 mg/kg) and procyclidine in a dose of

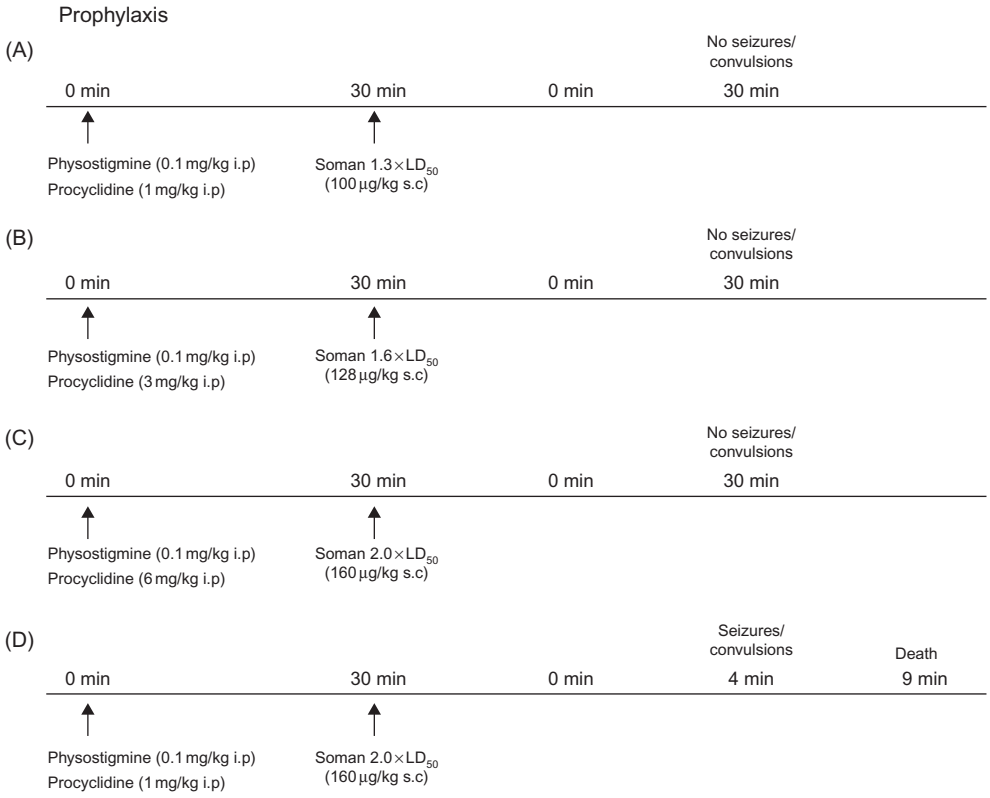

FIGURE 67.1 Experimental design for demonstration of anticonvulsant effects of a fixed dose of physostigmine combined with increasing doses of procyclidine relative to increasing doses of soman (A–C). Insufficient dose of procyclidine compared with soman results in early death (D).

1 mg/kg do not prevent convulsions/seizures when the soman dose is 1.6× LD_{50}. Subsequent treatment with scopolamine in doses of 0.5 or 1 mg/kg immediately after (3 min) seizure onset shows that only the highest dose can produce a reliable termination (Figure 67.2). When scopolamine (1 mg/kg) is given later (10 min) after onset of seizures, no effect is obtained. The sustained seizures were subsequently treated with diazepam (10 mg/kg) and pentobarbital (30 mg/kg), and finally terminated 25 min after onset. In rats given inadequate prophylaxis, both modified convulsions and seizures are seen. It is recommended that moderate doses of prophylactics should be used to avoid adverse effects on cognitive functions, because insufficient prophylaxis can be compensated for by adjunct treatment (Myhrer et al., 2004a).

To avoid the problem with a short-lasting prophylactic drug, the AChE inhibitors huperzine, donepezil, and galantamine may offer alternatives with long-lasting efficacy. Both rats and guinea pigs are well-protected against soman-induced seizures and neuropathology when pretreated with huperzine, whereas pyridostigmine does not have such effects (Lallement et al., 1997; Tonduli et al., 2001). Donepezil alone does not protect well against seizures evoked by soman, but when donepezil is combined with procyclidine, significant protection is obtained in rats (Haug et al., 2007). Galantamine in combination with atropine administered before a convulsant dose of soman can effectively protect guinea pigs against seizures (Albuquerque et al., 2006).

When pyridostigmine is combined with benactyzine and trihexyphenidyl (exerting both cholinergic and glutamatergic antagonism) in rats, effective protection is obtained against signs of neurotoxicity induced by soman. However, the combination with pyridostigmine and biperiden is reported to be even more efficacious than the former combination against soman poisoning (Kassa et al., 2003).

The results from studies of prophylactic treatment presented so far are in compliance with the notion that seizures are triggered by cholinergic hyperactivity followed by sustained high cholinergic activity for approximately 5 min after seizure onset. An exception has been seen when MK-801 given before soman can prevent the occurrence of seizures in both guinea pigs and rats (Braitman and Sparenborg, 1989; Shih et al., 1991). In the latter studies, however, MK-801 was combined with other drugs (pyridostigmine, atropine, and pralidoxime or HI-6, respectively). Hence, it is difficult to rule out the possibility that MK-801 interacted with effects of the additional drugs. HI-6 has been shown to decrease the release of ACh when hippocampal slices are exposed to soman (Øydvin et al., 2005). Microinfusions of MK-801

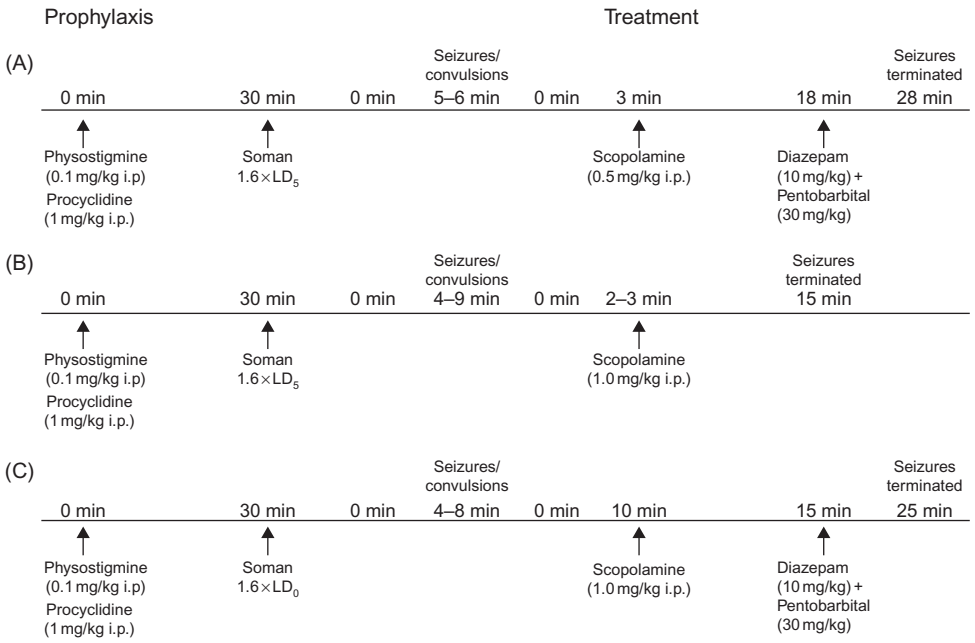

FIGURE 67.2 Experimental design for demonstration of how insufficient prophylactic treatment can be compensated for by adjunct post-exposure treatment. Low dose of scopolamine requires additional treatment (A). High dose of scopolamine is sufficient to terminate seizures (B). High dose of scopolamine given outside the cholinergic window requires additional treatment (C).

or ketamine into the seizure-controlling region, area tempestas, do not cause anticonvulsant effects against soman intoxication, whereas microinfusions of atropine or scopolamine do so (Myhrer et al., 2008a). Moreover, systemic administration of solely MK-801 or N-(1-(2-thienyl)cyclohexyl)piperidine (TCP) before soman does not prevent the occurrence of seizures (Carpentier et al., 1994; Myhrer et al., 2008a).

It is crucial that prophylactics used to protect military personnel, and possibly first responders, against lethal doses of nerve agents do not by themselves produce impairment of cognitive capability. This issue appears to be neglected in nerve agent research (Myhrer et al., 2004b). In the latter study, it was examined whether physostigmine, scopolamine, and various doses of procyclidine might reduce rats' innate preferences for novelty (Figure 67.3). When these drugs were tested separately, the results showed that physostigmine (0.1 mg/kg) and procyclidine (3 mg/kg) do not affect preference for novelty, whereas scopolamine (0.15 mg/kg) and procyclidine in a higher dose (6 mg/kg) result in a preference deficit. The combination of physostigmine and scopolamine or physostigmine and procyclidine (6 mg/kg) causes a marked deficit in preference for novelty. A much milder deficit is observed when physostigmine is combined with lower doses (1 or 3 mg/kg) of procyclidine. The latter combinations also have milder adverse impact on the animals' interests in the test environment and activity measures than the former combinations. In a more recent study, a regimen consisting of HI-6 (125 mg/kg), levetiracetam (50 mg/kg), and procyclidine (20 mg/kg) has been shown to protect effectively against a soman dose of 1.3× LD_{50} (Myhrer et al., 2013b). However, the cognitive impairment in the novelty test is similar to that seen after the combinations of physostigmine and scopolamine or physostigmine and procyclidine (6 mg/kg) (Myhrer and Enger, unpublished results).

Administration of physostigmine and procyclidine for 3 days by means of minipumps (72 and 432 µg/kg/h, respectively) in rats does not affect passive avoidance performance (Choi et al., 2004). A similar administration of physostigmine and scopolamine for 2 weeks in marmosets results in normal performance in a two-choice discrimination serial task. However, the concentration of scopolamine used is equivalent to an acute dose of 0.009 mg/kg, which is considerably lower than doses that have been shown to affect marmoset cognitive performance (e.g., 0.06 mg/kg) (Muggleton et al., 2003).

In a behavioral study of rats, potential cognitive effects of a group of anti-Parkinson drugs (with excellent anticonvulsant properties against nerve agents) were examined in the novelty test (Myhrer et al., 2008b). It was shown that benactyzine (0.3 mg/kg), caramiphen (10 mg/kg), and trihexyphenidyl (0.12 mg/kg) reduce rats' innate preferences for novelty, whereas biperiden (0.11 mg/kg) and procyclidine (3 mg/kg) do not. When benactyzine, caramiphen, or trihexyphenidyl are combined with physostigmine, the cognitive impairment disappears. This counteracting effect, however, produces changes in locomotor and rearing activity not seen by

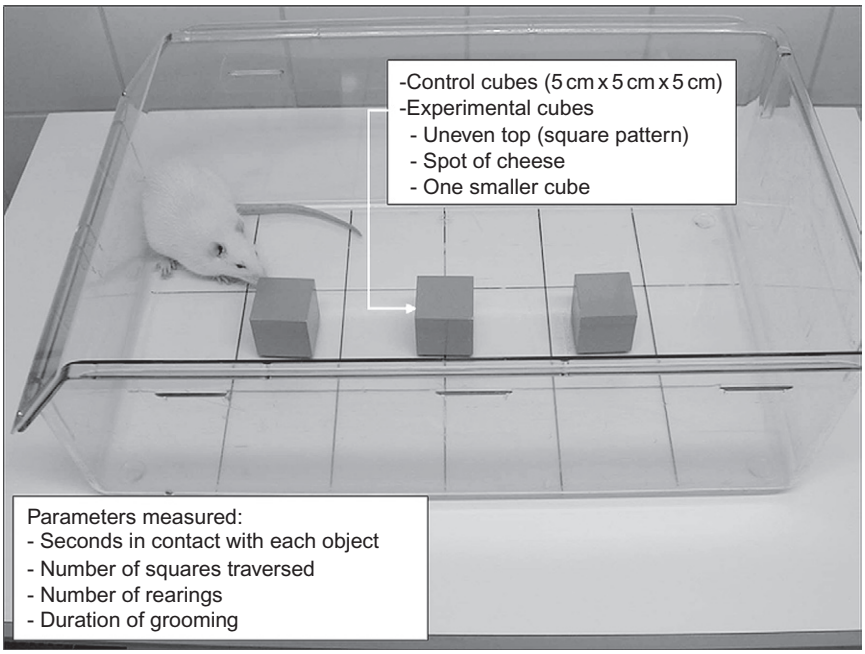

FIGURE 67.3 Novelty test measuring rats' innate preference for novelty, locomotor activity, rearing, and grooming. Testing is performed in three sessions (one per day). Each session consists of 5 min of exploring with neutral cubes present (phase 1) and phase 2 (5 min) occurs after 10 min in the home cage, during which the central cube has been replaced by a novel one. The novelty is represented by uneven top (session I), tiny bit of cheese on one side (session II), or smaller cube (session III).

each drug alone. AChE inhibitors and anticholinergics used as prophylactics can offset each other, but exceptions are observed in a previous study (Myhrer et al., 2004b) when a very potent anticholinergic (scopolamine), or a high dose of procyclidine, still results in cognitive deficits despite co-administration with physostigmine. The half-life of physostigmine is 17 min in plasma and 16 min in the brain of rats (Somani and Khalique, 1986). A crucial issue is how physostigmine is able to antagonize receptor blocking effects of anticholinergics by increasing the level of ACh and thus reduce or prevent cognitive impairment. This apparently subtle balance is probably attained in different ways for other relevant AChE inhibitors used as pre-treatment against nerve agents, such as donepezil, huperzine, and galantamine. To equalize cognitive side effects of potent anticovulsants by use of AChE inhibitors is not recommendable, because accurate adjustments for differences in half-life would be required for acute doses. Use of continuous delivery, however, may circumvent the problem with a different half-life of combining drugs.

Human Use

Pre-treatment with the carbamate, pyridostigmine, is a well-established method to protect against nerve agent intoxication in the armed forces in a number of nations (Aas, 2003). A tablet (30 mg) of pyridostigmine bromide is supposed to be taken every 8 h by the service personnel. The rationale behind this use is that carbamate occupies a portion of the available AChE (15–40% of the erythrocyte AChE) and renders it inaccessible to nerve agents in the blood, because nerve agents only bind to unprotected enzymes (Leadbeater et al., 1985). The AChE has been reversibly inhibited by pyridostigmine spontaneous decarbamoylates, and the enzyme is again able to hydrolyze ACh. Because pyridostigmine does not penetrate the BBB to any extent under normal circumstances, it only protects the peripheral nervous system. Pyridostigmine has been reported to have negligible physiological and psychological side effects (Leadbeater et al., 1985). However, in a recent meta-analysis, it is stated that carbamate can cause side effects in predisposed individuals (Golomb, 2008).

Physostigmine (a carbamate) readily crosses the BBB and has been considered a convenient replacement of pyridostigmine. Based on a series of animal studies, the combination of physostigmine and the cholinergic antagonist, hyoscine (scopolamine), has been brought to the level of clinical trials in the United Kingdom (Scott, 2007). The problem with the relatively narrow time window and potential side effects of physostigmine has been solved by continuous co-administration with hyoscine in terms of transdermal delivery. The pharmacological antagonism between these two drugs probably alleviates the potentially adverse effects produced by each

drug alone. This pre-treatment regimen is supposed to be less reliant on supporting therapy than the use of pyridostigmine (Scott, 2007).

The prophylactic combination of pyridostigmine with trihexyphenidyl and benactyzine has been introduced in the Czech Army. The presence of two anticolinergics made it possible to increase the dose of pyridostigmine and thus enhance the prophylactic efficacy (Bajgar, 2004). This combinational regimen (designated PANPAL) has been reported to have no side effects as demonstrated in volunteers; no changes in the psychic state or dysfunctions were observed. Actually, an improvement of tapping test performance was found after administration of PANPAL (Bajgar, 2004). For further details, see chapter 66.

The use of human plasma-derived butyrylcholinesterase to neutralize the toxic effect of nerve agents *in vivo* has been shown to increase survival and protect against attenuated cognitive function after nerve agent exposure. No post-exposure autoinjectors are necessary (Lenz et al., 2007). This bioscavenger is currently being produced by using outdated human blood and is ready for clinical trials. Both military personnel and potentially some first responders are relevant groups needing protection by biological scavengers.

THERAPEUTIC MEASURES

Animal Studies

Post-exposure treatment of animals consists of two categories: immediate and subsequent therapies. In the first category, drugs with anticholinergic effects will be of preference, whereas drugs with antiglutamatergic effects will be of preference in the second category according to the three-phase model. Drugs enhancing $GABA_A$ neurotransmission (diazepam and other benzodiazepines) are effective during all phases of nerve agent intoxication (McDonough and Shih, 1997). Immediate therapy also includes an oxime to reactivate nonaged inhibited AChE.

Reactivation of inhibited AChE is considered to be an important element in post-exposure treatment. Bispyridinium oximes can reactivate the phosphorylated enzyme if they are administered before the change from the reactivatable to the unreactivatable state, the process referred to as "aging." The "aging" process is fastest with soman in brain and diaphragm preparation (a few minutes) compared with other nerve agents (Sun et al., 1979). However, administration of oximes after "aging" has already occurred can enhance survival (McDonough and Shih, 1997). The oximes pralidoxime and obidoxime have been widely used, but HI-6 appears to be a promising substitute in treatment of intoxication with nerve agents. HI-6 has relatively low toxicity and is efficient in the treatment of soman intoxication (Clement, 1982; Hamilton and Lundy, 1989; Kusic et al., 1985; Lundy et al., 2011; Van Helden et al., 1992; Walday et al., 1993). A disadvantage of HI-6 is its lack of stability in aqueous solutions that require storing as powder in a separate chamber in the autoinjector (Thiermann et al., 1996).

Anticholinergic drugs and an oxime are usually applied after prophylactic treatment (pyridostigmine). Anticholinergics have optimal efficacy during the cholinergic phase (i.e., from exposure to approximately 5 min after onset of seizures). Such drugs are classified as muscarinic receptor antagonists, and they are not able to counteract the nicotinic signs of intoxication like muscle fasciculation, muscle fatigue, and weakness (McDonough and Shih, 2007). The rat brain is provided with the muscarinic receptor subtypes M1–M5. However, effective drugs against nerve agents have been shown to be anticholinergics with high specificity toward M1 (McDonough and Shih, 1997). The antinicotinic anticholinergic agent, mecamylamine, does not have anticonvulsant efficacy in rats poisoned with soman (Shih et al., 1991). The effectiveness of potent centrally active anticholinergics has been shown to be at least as good as diazepam in terminating nerve agent-induced convulsions (McDonough and Shih, 1997). Rats pretreated with HI-6 (to reduce lethality) were given a soman dose of 1.6× LD_{50} and received anticonvulsants 5 or 40 min after onset of seizures. The results show that anticholinergics (scopolamine, atropine, benactyzine, trihexyphenidyl) can effectively terminate seizure activity at 5 min, but not at 40 min after seizure onset (McDonough and Shih, 1993). These anticholinergics are as effective and potent as anticonvulsants as if they had been given as pre-treatment.

In our laboratory, we have examined the efficacy of a triple combination of drugs with adequate anticonvulsant effects and a dual combination with inadequate anticonvulsant effects followed by adjunct therapy (Myhrer et al., 2006a). The results show that combined (mixed as a single compound) intramuscular injections of HI-6 (42 mg/kg), atropine (14 mg/kg), and avizafone (3 mg/kg) administered 1, 16, and 31 min after exposure to a soman dose of 4× LD_{50} completely terminate seizures with a moderate mortality rate (25%). When the soman dose was lowered to 3× LD_{50}, the anticonvulsant effect was complete, and no rats died within 24 h. Rats challenged with 5× LD_{50} of soman all died within 10 min. Without avizafone in the combination, seizures induced by 3× or 4× LD_{50} of soman cannot be terminated unless an adjunct therapy consisting of procyclidine (6 mg/kg), diazepam (10 mg/kg), and pentobarbital (30 kg/kg) is given, and the mortality rate is comparatively high (78%). Administration of the adjunct therapy alone 6–16 min after 4× LD_{50} of soman stopped the seizure activity, but all the rats died within 24 h (Myhrer et al., 2006a). The latter study shows that administration of

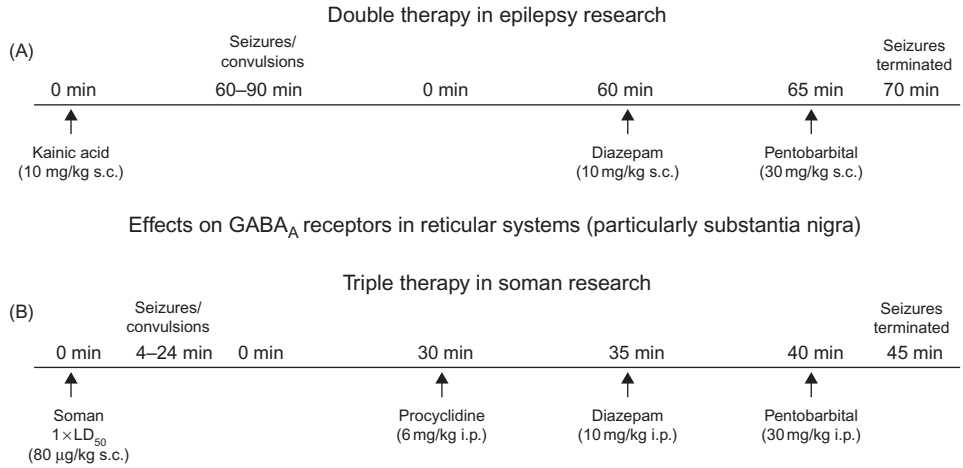

FIGURE 67.4 Experimental design revealing anticonvulsant effects of diazepam and pentobarbital in epilepsy research (A). Anticonvulsant effects achieved by triple regimen when administered 30–40 min after onset of seizures (B).

countermeasures (mimicking autoinjectors) soon after exposure to a relatively high dose of nerve agent can prevent death, even without pre-treatment of the animals.

The great challenge in treatment of nerve agent-poisoned victims seems to be the cases of long delays before treatment can start. Seizures lasting beyond 40 min are increasingly difficult to terminate (Lallement et al., 1999; Carpentier et al., 2001). Even conservative estimates suggest that it will take at least 30 min for emergency personnel to access individuals unprepared for exposure to nerve agents. Even soldiers properly provided with protective masks, gloves, and clothes may need medical help, because poor training, poor discipline, or bad luck can lead to intoxication of nerve agents (Lallement et al., 1999). Hence, there is a pertinent need to search for novel strategies capable to control nerve agent-generated seizures well after their onset.

Drugs that enhance $GABA_A$ neurotransmission have been shown to be effective in intoxicated animals during all phases of seizures by counteracting the elevated level of glutamatergic activity (McDonough and Shih, 1997). Seizures induced by kainic acid or lithium/pilocarpine in rats can be terminated 1 h after onset by the administration of diazepam and pentobarbital (Du et al., 1995). This potent combination of two $GABA_A$ agonists may create a promising anticonvulsant therapy if it is supplied with an anticholinergic agent. Procyclidine was chosen for this purpose, because this drug exerts antagonism on both muscarinic and nicotinic receptors and additionally has antagonistic effects on NMDA receptors (Kim et al., 2002). Procyclidine (6 mg/kg), diazepam (10 mg/kg), or pentobarbital (30 mg/kg) does not stop soman-induced seizures when administered separately, but both convulsions and seizure activity are terminated when these agents are given together. This triple therapy is 100% effective when administered 30–40 min (5 min between each injection) after onset of convulsions (Figure 67.4) (Myhrer et al., 2003).

In both military and civilian contexts, it would appear somewhat inconvenient for medical personnel to administer three injections of antidotes to achieve termination of seizure activity. It would be more expedient to replace diazepam and pentobarbital by a single $GABA_A$ modulator assuring corresponding anticonvulsant impact. However, systemic administration of $GABA_A$ modulators does not differentiate well between their anticonvulsant properties (Shih et al., 1999). In a study based on microinfusion of GABAergic modulators into seizure-controlling areas in the rat brain (area tempestas and substantia nigra), it was found that muscimol, ethanol, and propofol possess the best anticonvulsant potencies against soman seizures among the agents examined (Myhrer et al., 2006b). In a subsequent study, it was shown by systemic administration that procyclidine (10 mg/kg) combined with either muscimol (20 mg/kg), ethanol (3 mg/kg), or propofol (50 mg/kg) can effectively terminate soman-induced seizures when administered 5 min apart at 30–35 min after onset. Procyclidine and propofol are considered the most relevant double regimen to replace the previous triple regimen consisting of procyclidin, diazepam, and pentobarbital (Myhrer et al., 2006c).

It has been demonstrated that untreated seizures/convulsions induced by soman result in extensive neuropathology and pronounced cognitive deficits in the Morris water maze (Filliat et al., 1999; Raveh et al., 2002; 2003). In our laboratory, we investigated whether there is a relationship between the extent of neuronal pathology and degree of dysfunction in the performance of cognitive tasks after soman-induced convulsions that had lasted for 45 min (Myhrer et al., 2005). One behavioral task used was the novelty test (Figure 67.3) that

FIGURE 67.5 A three-choice simultaneous brightness discrimination test. The rats (deprived of water) learn that they receive water from the well in the positive cylinder (in this case gray, which is used for half of the rats in each group; the other half have a black cylinder). The criterion (five correct choices in succession) is obtained after 2 days of training. Thirteen days after acquisition, the rats are tested for what has been retained of the learning principle (gray or black positive cylinder).

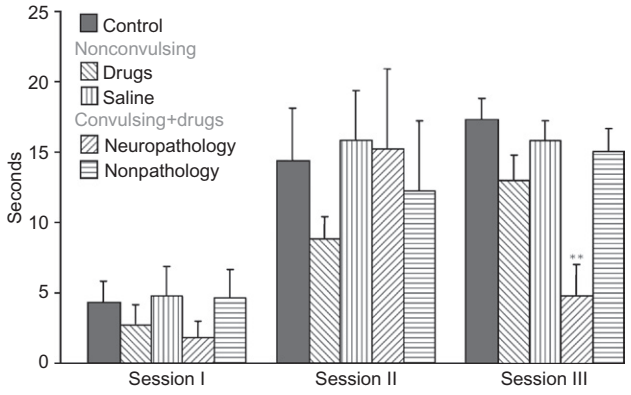

FIGURE 67.6 Mean (SEM) measures of preference for novelty 9–11 days after exposure to soman. Preference for novelty is expressed as the difference in seconds between exploring of novel versus neutral objects. Drugs given are procyclidine (6 mg/kg), diazepam (10 mg/kg), and pentobarbital (30 mg/kg). **Significantly different from all other groups ($p<0.01$).

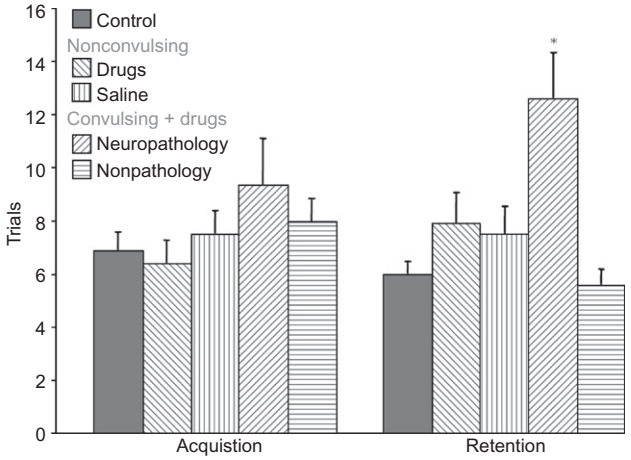

FIGURE 67.7 Mean (SEM) performances (trials to criterion) of acquisition (14–15 days after soman) in the brightness discrimination task. Drugs are as in Figure 67.6. *Significantly different from all other groups ($p<0.05$).

has proven particularly sensitive in revealing cognitive dysfunctions after selective disruptions of entorhinal projections (Myhrer, 1988, 1989). The other behavioral task used was a simultaneous brightness discrimination test (Figure 67.5) for assessing memory function. A three-choice version of this task has proven sensitive to selective hippocampal or rhinal lesions (Myhrer, 2000). When the convulsions are stopped after 45 min with the triple regimen (procyclidine, diazepam, pentobarbital), the results show that the neuronal pathology (assessed with Fluoro-Jade B staining) varies from none at all to 30% damage in the index areas (hippocampus, amygdala, piriform cortex). Cognitive deficits are seen in the novelty test (11 days after exposure) (Figure 67.6) and retention of the brightness discrimination task (28 days after exposure) among the rats with neuropathology (Figure 67.7). Furthermore, significant correlations between neuropathology scores and behavioral measures have been found for the animals that convulsed. It is concluded that early management of soman-induced convulsions is of major importance in preventing neuropathology and accompanying cognitive impairments (Myhrer et al., 2005).

In a number of studies, attempts have been made to terminate soman-triggered seizures/convulsions well after their onset. However, unlike the studies from our laboratory (Myhrer et al., 2003, 2005, 2006c), previous studies have been based on animals also treated before the exposure to soman. Marked anticonvulsant effects have been obtained in guinea pigs pretreated with pyridostigmine, administered atropine 1 min after a convulsant dose of soman, and treated with ketamine 30–120 min after poisoning (Dorandeu et al., 2005). Treatment with the combination of 2,3-dioxo-6-nitro-1,2,3,4-tetrahydrobenzo(f)quinoxaline-7-sulfonamide (NBQX) and TCP 30 or 50 min after onset of soman-induced seizures has pronounced anticonvulsant impact on rats pretreated with HI-6 and atropine (Lallement et al., 1994b). When pretreated rats (HI-6) are given a single drug of a number of anticholinergics or antiepileptic agents 40 min after onset of soman-evoked seizures, the anticonvulsant efficacy is rather modest (McDonough and Shih, 1993; Shih et al., 1999).

Seizures evolving to status epilepticus (seizure activity for 30 min or more) are strongly associated with death or brain damage. The first signs of neuropathology are

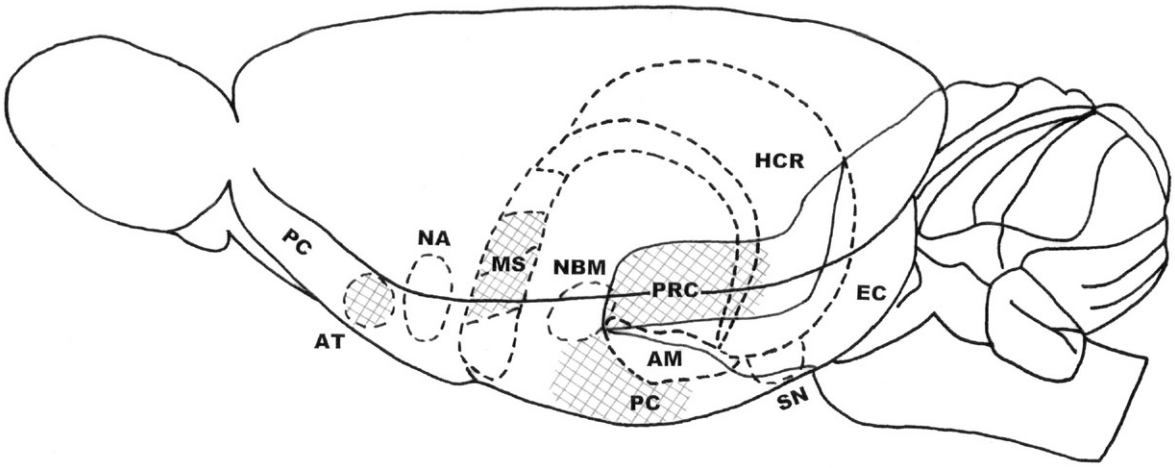

FIGURE 67.8 Lateral view of the rat brain showing neuronal target areas for nerve agents. Anticonvulsant efficacy was obtained by lesions in the area tempestas (AT), medial septum (MS), piriform cortex (PC), or perirhinal cortex (PRC) (crosshatched areas). Lack of anticonvulsant effect was seen by damaging the nucleus accumbens (NA), nucleus basalis magnocellularis (NBM), hippocampal region (HCR), amygdala (AM), substantia nigra (SN), or entorhinal cortex (EC).

usually detectable approximately 20 min after onset of soman-generated seizures in rats (Lallement et al., 1994a; McDonough et al., 1995). The mechanism behind sustained epileptiform activity may be related to increased inactivation of $GABA_A$ receptors along with an upregulation of NMDA receptors (Chen and Wasterlain, 2006). The net outcome of these changes would require comparatively high doses of antiglutamatergic drugs to control nerve agent-induced seizures well after onset. This situation appears to comprise the biggest challenge within nerve agent research.

A triple regimen consisting of procyclidine, diazepam, and pentobarbital has been shown to effectively terminate soman-evoked seizures in rats when administered 30–40 min after onset. A refinement of the triple regimen resulted in a double regimen composed of procyclidine and propofol that can stop seizures 30–35 min after they have been triggered by soman. However, both the triple and double regimens would need monitoring of vital functions, because pentobarbital and propofol can suppress normal function of the respiratory center in the brainstem. Thus, alternative approaches making it possible to design anticonvulsants predominantly affecting the forebrain have to be perfected.

Epileptiform activity does not spread randomly throughout the brain, but seems to be generated and propagated by specific anatomical routes (Gale, 1988; Löscher and Ebert, 1996). This suggests that certain propagation pathways may function as common denominators for the development of certain types of epileptiform activity, independent of the ways seizures are triggered. Within the rat brain, there are areas with control mechanisms able to attenuate all aspects of convulsive activity. The localization of such control areas have been identified in preclinical epilepsy research by use of lesion and microinfusion techniques. Our intent has been to use corresponding techniques in nerve agent research. Although the ultimate purpose is to develop pharmacological therapies that will be effective after exposure to nerve agents, a prophylactic experimental design has to be applied. Target areas for nerve agents that can act as seizure-controlling sites can be mapped by selective lesions.

If selective damage to a brain structure ensures anticonvulsant effects against nerve agent intoxication, then the constellation of receptor types in the damaged area may provide clues for designing drugs with powerful anticonvulsant properties. Primary structures are those containing large assemblies of cholinergic neurons and areas demonstrated to have control capabilities in experimental epilepsy. Aspiration lesion of the medial septum (Figure 67.8) causes prevention or increased latency to onset of convulsions, whereas damage to the nucleus basalis magnocellularis or nucleus accumbens does not have anticonvulsant effects in rats exposed to a convulsant dose of soman (Myhrer et al., 2007). Rats with aspiration lesion of the seizure-controlling area tempestas in the anterior piriform cortex display marked anticonvulsant behavior in response to soman, whereas such effect is not seen when the substantia nigra is destroyed (Myhrer et al., 2007). Similar lesions made in the perirhinal cortex or posterior piriform cortex produce anticonvulsant efficacy against soman intoxication, but anticonvulsant impact is not achieved when lesions are made in the entorhinal cortex, hippocampal region, or amygdala (Myhrer et al., 2008c).

Pharmacological agents with potential anticonvulsant efficacy in the brain areas that have been identified as

target sites for generation of seizures (the area tempestas, medial septum, perirhinal cortex, posterior piriform cortex) have been used in microinfusion studies (Myhrer, 2010). In the area tempestas, cholinergic, but not glutamatergic, antagonism is likely the active property of the anti-Parkinson agents, caramiphen and procyclidine, because the NMDA antagonists ketamine and MK-801 do not have anticonvulsant effects (Myhrer et al., 2008a). The $GABA_A$ modulators muscimol, ethanol, and propofol produce anticonvulsant effects, whereas diazepam and pentobarbital do not (Myhrer et al., 2006b). In the medial septum, only muscarinic receptors seem to be the effective ones, because ketamin and muscimol do not produce anticonvulsant effects (Myhrer et al., 2009). In the perirhinal cortex, both muscarinic and glutamatergic receptors have to be blocked simultaneously (procyclidine) to achieve anticonvulsant effect. Neither scopolamine alone nor ketamine alone causes anticonvulsant effects (Myhrer et al., 2010a). The positive effect of NBQX suggests that alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors are critical for anticonvulsant impact in the perirhinal cortex (Myhrer et al., 2010a). Furthermore, modulation of metabotropic glutamate receptors (mGluRs) in the perirhinal cortex also has anticonvulsant effects. Injection of 2-methyl-6-(phenylethynyl)pyridine (MPEP) (antagonizing mGluR5) or DCG-IV (agonistic effect on both mGluR2 and mGluR3) results in marked anticonvulsant efficacy (Myhrer et al., 2010b). In a more recent study, double infusions of anticonvulsants were used to reach a larger area of the perirhinal cortex. With such a technique, MPEP protects 67% of the rats from having soman-induced seizures, whereas for DCG-IV protection is 83% (Myhrer et al., 2013a). These findings suggest that there is an early increase of glutamatergic activity in the perirhinal cortex. In the posterior piriform cortex, modulators of muscarinic receptors (scopolamine) and $GABA_A$ receptors (muscimol) seem to be the effective ones (Myhrer et al., 2010a). According to the results cited, efficient anticonvulsant pre-treatment has to be based on pharmacological agents affecting a number of subreceptors.

Powerful anticonvulsant efficacy can be obtained by microinfusion of drugs into seizure-controlling brain sites in rats before exposure to nerve agent. However, focal administration of anticonvulsants after seizure onset has modest impact. Repeated infusions of atropine into the medial septum after a comparatively low dose of soman (0.9× LD_{50}) can finally stop seizure activity (Lallement et al., 1992). Similarly, repeated infusions of atropine into the area tempestas after onset of seizures induced by soman (1.3× LD_{50}) have evident anticonvulsant impact, but the seizure activity recurs 10–15 min after each injection (Myhrer and Enger, unpublished data). Thus, there are reasons to believe that large parts of the neuronal network must be affected systemically by anticonvulsants to stop ongoing seizures. Successful termination of seizures well after their onset probably requires a combination of drugs, each with optimal effects in some of the seizure-controlling brain areas.

Procyclidine emerged as the most potent anticonvulsant drug tested in the microinfusion studies (Myhrer, 2010). Enhancement of procyclidine's excellent anticonvulsant efficacy in the seizure-controlling sites of the forebrain would allow a novel and interesting approach. A drug with such enhancing properties has been developed in preclinical epilepsy research. Levetiracetam (Keppra®) is an antiepileptic drug that strongly enhances the anticonvulsant effects of compounds affecting either glutamatergic or GABAergic neurotransmission (Kaminski et al., 2009). It has also been reported that levetiracetam may both reduce release of ACh and reduce postsynaptic responsiveness in cholinergic synapses (Oliveira et al., 2005). Levetiracetam (50 mg/kg) combined with either procyclidine (20 mg/kg) or caramiphen (20 mg/kg) terminate seizure activity, but the survival rate is considerably higher for levetiracetam and procyclidine than for levetiracetam and caramiphen. Both therapies can also save the lives of rats that were about to die 5–10 min after seizure onset. Prophylactic use of the combination therapies 20 min before exposure to soman prevent onset of seizures more effectively when levetiracetam is combined with procyclidine than caramiphen (Myhrer et al., 2011).

We have performed a study in which effects of a physostigmine regimen (HI-6, scopolamine, physostigmine) were compared with those obtained by our procyclidine regimen (HI-6, levetiracetam, procyclidine) against various doses of soman at different times after intoxication. The prophylactic potencies of the regimens were also examined (Myhrer et al., 2013b). The results show that both regimens administered two times (1 and 5 min after exposure to 3×, 4×, or 5× LD_{50} of soman) effectively prevent or terminate epileptiform activity within 10 min. Both regimens also protect against death, and the rats recovered well. However, when the regimens were administered 10 and 14 min after a soman dose of 1.6× LD_{50}, only the procyclidine regimen terminates seizure activity and protects all rats against death. When rats pretreated with pyridostigmine received treatment 20 and 24 min after a soman dose of 1.3× LD_{50}, only the procyclidine regimen successfully stopped seizures and prevented death among all rats. When the regimens were given as prophylactic treatment 20 min before a soman dose of 1.3× LD_{50}, both the physostigmine and procyclidine regimens prevented convulsions, but only the procyclidine regimen yielded neuroprotection (Myhrer et al., 2013b).

Not all combinations derived from microinfusion studies will work equally well. For example, the potency of the metabotropic glutamate modulators DCG-IV and

TABLE 67.1 Anticonvulsant and Life Preserving Effects of Four Treatments Regimens on Soman-Induced (1.3× LD_{50}) Seizures 20 min After Onset in Rats Pretreated with Pyridostigmine (0.1 mg/kg)

Drugs	Dose mg/kg	*N*	Antiseizure Response		Lethality Response (24 h)	
			Ratio	Percent	Ratio	Percent
HI-6	125					
Scopolamine	1	6	0/6	0	6/6	100
Physostigmine	0.1					
HI-6	125					
Levetiracetam	50	6	6/6	100	0/6	0
Procyclidine	20					
HI-6	125					
Procyclidine	20	8	6/8	75	3/8	35
DCG-IV	4					
HI-6	125					
Procyclidine	20	7	5/7	71	2/7	29
MPEP	30					

Based on results from Myhrer et al. (2013b,c).

MPEP is very powerful in the perirhinal cortex (Myhrer et al., 2013a). However, when administered systemically together with procyclidine and HI-6, both combinations exert effective anticonvulsant impact, but they do not reach the same high level as the procyclidine regimen (Table 67.1). The multifunctional properties of procyclidine (antiglutamatergic and anticholinergic) seem to profit from the enhancing effects of levetiracetam, whereas the single function of DCG-IV and MPEP (antiglutamatergic) does not result in increased anticonvulsant capacity when combined with levetiracetam and HI-6 (Myhrer et al., 2013c).

Human Use

Oximes should be used as soon as possible after exposure to nerve agents, because of the short time window of the aging process. The human *in vitro* half-life for soman-inhibited AChE is 1.3 min, for sarin-inhibited AChE it is 3 h, and for tabun-inhibited AChE it is 13 h (Vale et al., 2007). When aging has occurred, new AChE has to be synthesized. It is the extremely short aging time of soman that led to the development of carbamate (pyridostigmine) prophylaxis for nerve agent poisoning. A number of nations use the oxime obidoxime (e.g., Finland, Germany, Norway, the Netherlands), whereas others use P2S (United Kingdom), 2-PAM (United States), or HI-6 (Canada, Sweden) (Aas, 2003). To date, there is no single oxime available that has high efficiency in reactivating AChE inhibited by any known nerve agent. However, HI-6 is considered by most countries to be a very promising oxime after exposure to most nerve agents (Aas, 2003).

Most nations have issued their military personnel with two to three autoinjectors containing atropine and an oxime. Additionally, some nations have provided their soldiers with one autoinjector containing diazepam or avizafone (Aas, 2003). Atropine has to be administered at relatively high doses (2 mg or more) because of its competitive nature (competes with ACh). The use of autoinjectors speeds the uptake of the drug because of a spraying effect as the needle plunges into the muscle, resulting in the distribution of drug within a larger muscle area, allowing for more rapid drug uptake than by using conventional needle and syringe (Sidell et al., 1974). However, atropine in too high doses can result in inhibition of sweating and the potential for inducing heat casualties. Even a dose of 2 mg combined with heavy work in a hot environment may induce a core temperature that is too high.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

This chapter has focused on the development of novel countermeasures against nerve agents to improve existing prophylactic and post-exposure treatments. Effective prophylactic treatment can be achieved by using a fixed dose of physostigmine in combination with varying doses of procyclidine. Increased lethal doses of soman can be counteracted by corresponding increases in the dose of procyclidine. However, the higher the doses of procyclidine, the more pronounced the cognitive side effects. Moderate doses of procyclidine should be preferred, because insufficient prophylaxis can be compensated for by adjunct treatment in terms of diazepam and pentobarbital. Because a slight cognitive impairment might be inevitable with effective prophylactics, reduced reliance on pre-treatment appears preferable.

Immediate treatment with atropine and an oxime is very efficacious against nerve agent intoxication. However, subsequent treatment well after onset of seizures represents a huge problem in nerve agent research, because of the refractory nature of the epileptiform activity. A medical therapy has been developed through studies of microinfusions of anticonvulsants into seizure-controlling sites in the forebrain of rats. From these studies, procyclidine was revealed as the most potent anticonvulsant, and its potency was further enhanced when combined with the antiepileptic levetiracetam during systemic administration. The regimen is very effective against supralethal doses of soman (3 × , 4 × , 5× LD_{50}) when given 1 and 5 min after intoxication. When the treatment was administered 10 and 14 min or 20

and 24 min after soman exposure, the procyclidine regimen was able to terminate seizures and preserve lives. When used as prophylactic therapy, the regimen has powerful effect against seizures and provides effective neuroprotection. The procyclidine regimen has apparent capacities to serve as a universal therapy against soman intoxication in rats. In a microinfusion study, the importance of determining the unique pharmacological thresholds for producing anticonvulsant responses in the specific brain structures activated during nerve agent-induced seizures has further been emphasized (Skovira et al., 2012). The ultimate aim should be the development of well-tolerated anticonvulsants that can be administered by the soldiers themselves regardless of the time after nerve agent intoxication.

INTRODUCTION

There are millions of chemical compounds known to humanity, but only a limited number are weaponized by conventional militaries. The Organization for the Prohibition of Chemical Weapons (OPCW), the 184-member watchdog agency enforcing the guidelines of the Chemical Weapons Convention (CWC), has identified 55 chemical agents and their precursors that can be used as weapons (OPCW, 2005). Although some of the chemicals are well known [e.g., sarin, soman, *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX), mustard], other less obvious choices for chemical terrorism include industrial chemicals such as chlorine and toxic precursors, which are considered "weapons of opportunity."

In the hands of terrorists, chemical warfare agents (CWAs) and toxic industrial chemicals (TICs) pose significant threats to civilian populations. A 2002 report to the US Congress by the Central Intelligence Agency (CIA) reported that terrorist groups "have expressed interest in many toxic industrial chemicals—most of which are relatively easy to acquire and handle—and traditional chemical agents, including chlorine and phosgene" (DCI, 2002). While traditional chemical warfare nerve agents are attractive to terrorist groups, they require a significant degree of financial resources and capital knowledge to manufacture. Furthermore, the United States and remaining signatory members of the CWC have pledged nonproliferation of CWAs (OPCW, 2005). Unfortunately, millions of tons of TICs continue to be manufactured annually in the United States alone. While they support the wide variety of products generated on a daily basis, including dyes, textiles, medicines, solvents, plastics, paints, and insecticides, they are lethal compounds in the hands of terrorists.

Chemical terrorism is the intentional use of toxic chemicals to inflict mass casualties on an unsuspecting military or civilian population, including children. Such an incident could quickly overwhelm local and regional public health resources and emergency medical services. In addition to the use of CWAs and TICs, an act of chemical terrorism may involve the targeting of industrial factories, tanker cars, or vehicles containing toxic substances with conventional explosives near residential communities or schools. Regardless of the methods used, the release of toxic chemicals by terrorists embodies a real and serious threat to US national security and public health. They can quickly incapacitate those who are exposed and can lead to mortality if not recognized and treated promptly. Moreover, the toxicity of these agents can be enhanced in children due to pediatric vulnerabilities. It is imperative to recognize the different ways that children may react to toxicity compared to adults.

BACKGROUND

Even though many efforts have been made to protect the United States from terror threats, it remains paramount for the scientific community to continue building the knowledge base regarding CWAs and better understand the toxicities that can occur when children are exposed. Unfortunately, pediatric treatment recommendations are often extrapolated from adult data,

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00068-3

even though it is well recognized that pediatric patients should not be regarded as miniature adults. Children present unique vulnerabilities to these chemicals, and special considerations should be taken.

Due to the possibility of pediatric casualties from chemical agent attacks, several pediatric advocacy groups, such as the American Academy of Pediatrics (AAP), have commented on the urgent need for pediatric chemical casualty research (Blaschke and Lynch, 2003). The Committees on Environmental Health and Infectious Diseases have provided the following consensus statement regarding children and chemical–biological threats (CEH/CID, 2000).

> Because children would be disproportionately affected by a chemical or biological weapons release, pediatricians must assist in planning for a domestic chemical–biological incident. Government agencies should seek input from pediatricians and pediatric subspecialists to ensure that the situations created by multiple pediatric casualties after a chemical–biological incident are considered.

After the terrorist attacks of September 11, 2001, the AAP initiated a number of initiatives to address the need to prepare for terrorism against children. For example, the AAP created a Task Force on Terrorism, a comprehensive web resource to disseminate information on terrorism and its impact on children. In addition, the AAP has published several reports and policy statements to provide guidance for healthcare practitioners preparing for a mass chemical casualty event. These efforts were augmented by the passage of several key federal legislative acts aimed at improving public health emergencies and their response to chemical terrorism. Finally, the Centers for Disease Control and Prevention (CDC) created the Strategic National Stockpile (SNS) site as a national repository of antibiotics, chemical antidotes, and antitoxins. The SNS contains a pediatric formulary, along with compounding materials that would assist clinicians in creating dosage forms appropriate for pediatric administration of chemical antidotes (CEH/CID, 2006) in the event of chemical terrorism.

Indeed, chemical terrorism on US soil is a very sobering possibility in the future. A significant subset of casualties from a mass chemical exposure will be comprised of vulnerable populations such as children and the elderly. In the hopes of better understanding the impact of such an event, it is necessary to learn from historical incidents and case studies where children were exposed to toxic chemicals and treated.

In this chapter, the CWAs and "weapons of opportunity" most likely to be used by terrorists to inflict casualties will be examined, along with a brief historical account and discussion of the unique challenges of managing pediatric chemical casualties. The sections focusing on each chemical agent will highlight the pediatric-relevant vulnerabilities and guidelines for medical management. The final two sections will discuss decontamination of children and recommendations to help prepare healthcare managers and providers in the event of a chemical event. It is hoped that this compilation will provide the necessary guidance and treatment recommendations on how best to treat children involved in a chemical attack.

HISTORY OF PEDIATRIC CHEMICAL CASUALTIES

Historically, chemical attacks were limited to the battlefield, and casualties were predominantly military personnel. In turn, the majority of our knowledge concerning management of chemical casualties has come from the experiences of treating members of the military. Today, the threat of chemical use is extended to civilian populations as state and nonstate sponsored terrorists target innocent civilians. The risk of chemical and biological terrorism is more tangible since the events of September 11, 2001 and the intentional spread of anthrax through the US Postal Service. Terrorists expanded their scope and threat to inflict mass civilian casualties on a scale never before seen. The threat from attack has moved from the traditional battlefield to the home front. Innocent civilians, including children, are now prime targets for groups to foment terror and destabilize governments. Even before the attack on the World Trade Center towers, the twentieth century witnessed numerous instances where civilian populations were exposed to toxic chemicals or targeted on a grand scale.

During the flurry of chemical barrages across trench lines in World War I, children from bombed towns in France and Belgium were treated at British, French, and American "gas" hospitals as a result of CWA exposure. Numerous reports of civilian casualties from mustard, chlorine, and phosgene are well documented in British archives (Thomas, 1985). After the final tally of civilian casualties from gas warfare was complete, participants saw how ill prepared their civilians were against such weapons. School-age children learned the importance of protective measures against chemicals through donning gas masks and evacuating contaminated areas (Figure 68.1).

Civilians have been unintended and, in some cases, intended targets of CWAs since World War I. While cyanide was used on Jewish prisoners in World War II, chemical weapons would not be used again during combat on civilian populations until the Iran–Iraq War. In the spring of 1987, Saddam Hussein bombed the Iranian city of Sardasht with mustard munitions, resulting in thousands of civilian casualties (Foroutan, 1996a,b, 1998a–c).

Following the attack on Sardasht, Iraq attacked Kurd settlements in early 1988, leading to the infamous attack

on Kurdish residents of Halabja in March. Thousands of innocent civilian ethnic Kurds perished during the chemical attack, and 75% of them were women and children. Mustard and nerve agents were dropped on civilians from helicopters and planes, and eyewitnesses reported large smoke clouds causing great morbidity and mortality among children (Hay and Roberts, 1990).

While the list of nations who have not signed the international treaty to ban chemical weapons is short, it is not surprising that one of those countries has recently been in the international spotlight for stockpiling and deploying chemical weapons in its ongoing civil war. In July 2012, Syria admitted to possessing stocks of chemical weapons. Rebels in northern Syria employed chemical weapons in the town of Khan al-Assal, and opposition forces reported use of chemical weapons (phosphorus bombs) in the Damascus suburb of al-Otaybeh in March 2013. Similar attacks were reported on March 24 in the town of Adra, and on April 29 in the city of Saraqeb. Escalating tensions led to the worst use of chemical weapons since Saddam Hussein's ethnic cleansing of Kurds from northern Iraq in 1988. Another attack happened in the early morning hours on August 21, 2013, in multiple civilian locations on the outskirts of the Syrian capital of Damascus. Concluding a monthlong investigation by the United Nations, Secretary-General Ban Ki-Moon confirmed that sarin nerve gas was indeed the culprit in this rocket assault (Figure 68.2). Sarin gas was deployed in either opposition-held or contested regions containing significant numbers of civilians. Many of the reported casualties were women and children, arriving with constricted pupils, profuse salivation, and hypotonia. News agencies posted numerous photographs

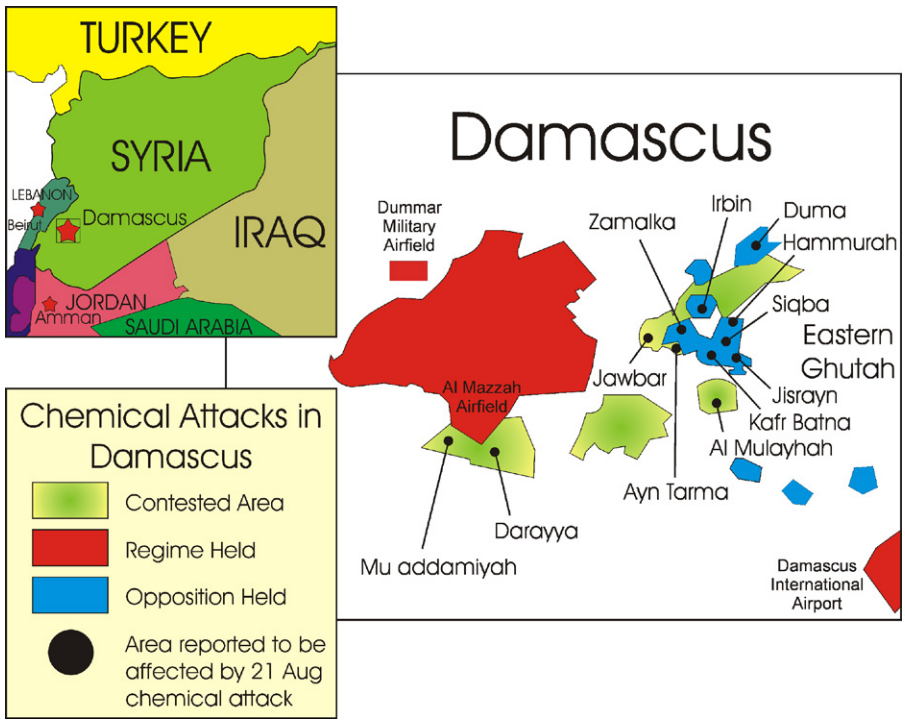

FIGURE 68.2 Areas in and surrounding Damascus reportedly affected by sarin rocket attacks on August 21, 2013.

involving pediatric casualties in the aftermath of the sarin rocket attack. While final numbers of the actual civilian death toll from sarin are unknown, Damascus field hospitals and clinics reported up to 1,300 dead, with pediatric numbers climbing into the hundreds. The full extent of morbidity among sarin survivors of the attack is also unknown, but it is clear that hospitals were unprepared to handle the mass influx of casualties with sufficient stockpiles of nerve agent antidotes. Damascus is a reminder of the horror and threat posed by nerve agents.

These events confirm the devastating reality that chemical threats pose to our unprotected population today. A military and civilian response to the use of chemical weapons on American soil may not be a matter of if, but rather when. These events underscore the need for all pediatric-related healthcare workers to prepare for a mass casualty incident involving CWAs or TICs.

CHALLENGES TO MANAGING PEDIATRIC CHEMICAL CASUALTIES

Overview

Managing the pediatric victims of chemical terrorism is an especially difficult challenge. In addition to the obvious physiologic and anatomic differences in children compared to adults (Table 68.1), there are important psychological and behavioral differences that put children at risk (Rotenberg and Newmark, 2003). Anecdotal reports have claimed that children are likely to be the first to manifest symptoms, to develop more severe manifestations, and to be hospitalized for other related illnesses. In fact, it is anticipated that children will be overrepresented among the initial index cases in a mass civilian exposure to toxic chemicals. Children have many characteristics that make them vulnerable to toxic exposures. The smaller mass of a child automatically reduces the dose of toxic agents needed to cause observable or lethal effects. Studies involving organophosphates (OPs), compounds related to nerve agents, have shown that immature animals have greater vulnerability. Some OPs produce the same degree of lethality in juveniles at a fraction of the dose producing lethality in adults (Rotenberg and Newmark, 2003). Children exhibit an exceptional vulnerability to both the acute and chronic effects of chemicals and are disproportionately more susceptible than adults. The increased toxicity seen in children compared to adults from various routes of exposure can be attributed to a wide variety of factors (shown in Exhibit A). These unique anatomical and physiological considerations described next cause the rates of absorption, distribution, metabolism, and excretion of toxic chemicals and drugs to differ in children with respect to adults.

TABLE 68.1 Summary Chart of Pediatric Vulnerabilities and Implications for Clinical Management

Unique Vulnerability in Children	Implications and Impact from Chemical Toxicity
BODY COMPOSITION	
• Larger BSA/body mass • Lower total lipid/fat content	• Greater dermal absorption • Less partitioning of lipid soluble components
VOLUME STATUS	
• More prone to dehydration • Chemical agents lead to diarrhea and vomiting	• Children can be more symptomatic and show signs of severe dehydration
RESPIRATORY	
• Increased basal metabolic rate/greater minute volume	• Enhanced toxicity via inhalational route
BLOOD	
• Limited serum protein-binding capacity • Greater cutaneous blood flow	• Potential for greater amount of free toxicant and greater distribution • Greater percutaneous absorption
SKIN	
• Thinner epidermis in preterm infants • Greater cutaneous blood flow	• Increased toxicity from percutaneous absorption of chemical agents
ORGAN SIZE/ENZYMATIC FUNCTION	
• Larger brain/body mass • Immature renal function/ lower renal function • Immature hepatic enzymes	• Greater CNS exposure • Slower elimination of renally cleared toxins, chemicals and metabolites • Decreased metabolic clearance by hepatic phase I and II reactions
ANATOMICAL CONSIDERATIONS	
• Short stature: breathe closer to ground where aerosolized chemical agents settle • Smaller airway • Greater deposition of fine particles in the upper airway • Higher proportion of rapidly growing tissues	• Mustard significantly affects rapidly growing tissues • Exposure to chemicals can have significant impact on bone marrow, developing CNS • Increased airway narrowing from chemical agent-induced secretions
CNS	
• Higher BBB permeability • Rapidly growing CNS	• Increased risk of CNS damage
MISCELLANEOUS	
• Immature cognitive function • Unable to flee emergency • Immature coping mechanisms	• Inability to discern threat, follow directions, and protect themselves • High risk for developing PTSD

EXHIBIT A

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS UNIQUE TO CHILDREN

- Differences in anatomy
- Allometric scaling factors (e.g., increased surface area-to-volume ratio)
- Cardiovascular status
- Permeability of the pediatric blood–brain barrier (BBB)
- Dermatologic factors (e.g., increased cutaneous blood flow; Simonen et al., 1997; Fluhr et al., 2000)
- Increased skin pH (Behrendt and Green, 1958; Fluhr et al., 2004)
- Plasma protein binding
- Volume of distribution (V_d)
- Organ size and maturity
- Pharmacokinetic maturity (e.g., metabolic differences; Fairley and Rasmussen, 1983)

Respiratory Vulnerability

Inhaled doses in young children may be greater than in adults. Some studies have demonstrated a twofold increase in respiratory tract exposure per unit surface area compared to adults (Bennett and Zeman, 1998). Deposition of fine particles is higher in young children (ages 7–14) than adults when the data are normalized by lung surface area (Bennett and Zeman, 1998) and an even greater deposition has been modeled for younger children (Martonen et al., 2000). The higher respiratory rate and minute volumes per respiratory surface area of a child means that they will inhale a greater dose of a toxic chemical vapor (Rotenberg and Newmark, 2003). Also, children can become intoxicated simply through breathing air that is closer to the ground. Many toxic chemicals display a high vapor density, causing them to distribute closer to the ground (CSMC, 2003). This may lead to greater toxicity for a child than an adult. In addition, children have less endurance than adults in terms of using their respiratory accessory muscles, putting them at risk for respiratory failure.

Children are especially susceptible from toxic chemicals due to their unique airway anatomy (Figure 68.3). These differences include a greater degree of subglottic narrowing, diminished airway diameter, tendency for nose-breathing, and large tongue size relative to the mouth (Rotenberg and Newmark, 2003). OP nerve agents induce bronchospasm and bronchoconstriction during a cholinergic crisis. In comparing the effect of a nerve agent on adult and pediatric airways, Figure 68.3 illustrates that a similar change in airway diameter results in a greater percentage increase of airway resistance in children. In addition, copious glandular secretions during a cholinergic crisis may further restrict airflow through an already narrow airway. Therefore, children are at higher risk for toxicity from inhalational chemical exposure.

Volume Status Vulnerability

The circulatory system of children can be severely affected by chemical attacks (Rotenberg and Newmark, 2003).

Children have lower fluid reserves than adults, so small fluid volume losses can cause significant effects. For example, a 5-kg child experiencing severe dehydration (15% body weight loss) loses 750 mL of fluid. A significant loss of fluid from the gastrointestinal tract as a result of chemical-induced glandular secretions can affect intravascular volume. Also, children are more prone to vomiting and diarrhea than adults. Therefore, children may dehydrate faster during a chemical event (CSMC, 2003).

Neurological Vulnerability

The immature central nervous system (CNS) of children can lead to greater toxicity (Rotenberg and Newmark, 2003). Toxic agents can often transverse the immature BBB in children. Infants and children are at greater risk of seizures than adults. This is concerning because seizures are common in cases of moderate to severe nerve agent intoxication. Infants are at the highest risk of toxicity due to their susceptibility to imbalances of neurotransmitter systems. Prolonged seizures, or status epilepticus, can cause neuronal injury and deficits of normal brain development in children.

Dermatological Vulnerability

Barrier thickness, cutaneous blood flow, surface-to-volume ratio, temperature, hydration, and skin pH are important factors to consider in the assessment of pediatric dermatological vulnerabilities. The skin of newborns, while appearing vulnerable, has the same histologic features of adult skin with some differences, including immaturity of collagen, hair follicles, and sebaceous glands. While newborns and young children are often described as having thinner skin than adults, the stratum corneum, the most superficial layer of the skin, is thinner in premature infants than in full-term infants, children, and adults (Rutter and Hull, 1979; Harpin and Rutter, 1983; Nopper et al., 1996). The skin of a child, however, does not differ significantly compared to adults, as evidenced by similar measurements of skin physiological parameters

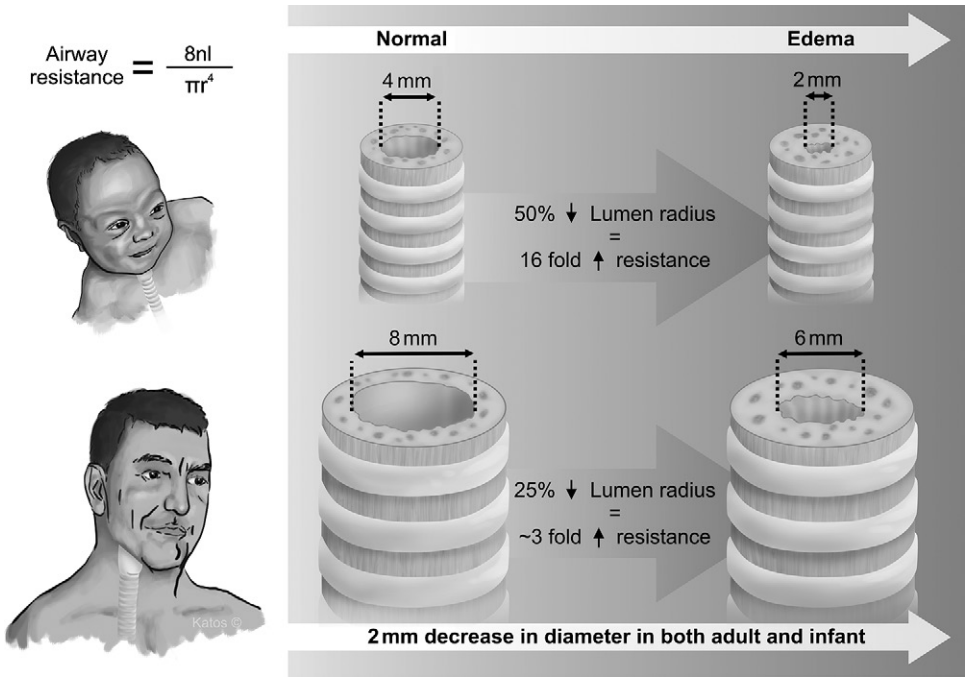

FIGURE 68.3 Comparison of pediatric and adult airways. The most important factor to consider in pulmonary toxicity from cholinesterase inhibition is the airway resistance through the conducting portion of the respiratory system. Airflow from the trachea and mainstem bronchi to the small bronchioles can be characterized as airflow through a series of straight tubes or laminar flow (West, 1995; Guyton and Hall, 2005). Poiseuille's law provides a relationship between flow rate and radius of the tube ($F = P\pi r^4/8nl$), where n is the coefficient of viscosity, P is the pressure difference across the length l of the airway section, r is the radius of the airway, and F is the airway flow rate. Since the resistance to flow R is driving pressure P divided by flow F, using the analogy of Ohm's law, the following relationship for airway resistance R can be derived ($R = 8nl/\pi r^4$). The effect of a 2-mm change in airway diameter on airway resistance is illustrated for both an infant and an adult. *Bottom panel* (adult scenario): a 2-mm reduction in the airway radius as a result of nerve agent-induced bronchoconstriction results in a 25% reduction and a corresponding increase in airway resistance by approximately threefold. *Top panel* (infant scenario): a similar reduction in a child decreases the airway lumen by 50% and increases airway resistance by 16-fold. *Source: Illustrations are copyright-protected and printed with permission by Alexandre M. Katos.*

(e.g., transepidermal water loss, skin pH, and stratum corneum capacitance and conductance; Fluhr et al., 2000). Children 3 months old have the same abdominal skin stratum corneum thickness as 11-year-olds and adults (Fairley and Rasmussen, 1983).

Moreover, children have larger surface area-to-volume (mass) ratios, resulting in greater absorption of chemicals. The skin surface area of infants and toddlers is very large compared to their body weight. An increase in the surface area-to-body weight ratio increases their potential absorption to dermal exposures of chemicals. For instance, a typical infant weighs a fraction (1/20) of a 70-kg male adult, but an infant's surface area is only 1/8 as great. The total skin surface area that is exposed per kilogram of body weight, therefore, is 2.5 times higher for infants than adults (Lynch and Thomas, 2004). Burns with extensive skin loss, as seen with certain chemical exposures, can cause significant water loss and toxicity in children (Lynch and Thomas, 2004). Despite the few prospective scientific studies on skin vulnerability in the pediatric population, it can be summarized that the thin, immature skin of preterm infants and the unique dermatological properties of children put them at higher risk for toxicity from percutaneous chemical exposure (CSMC, 2003).

Plasma Protein Binding, Volume of Distribution, and Organ Maturity

Children may be at an increased risk of chemical toxicity due to having lower levels of plasma proteins. One factor affecting the amount of free chemical/drug in the circulation is the fraction bound to plasma protein. Neonates have a low protein-binding capacity for albumin and alpha-1-glycoprotein (Besunder et al., 1988; Kearns and Reed, 1989; Clewell et al., 2002) and a decreased ability to conjugate and excrete bilirubin, which binds to plasma proteins. This can lead to a smaller pool of available protein-binding sites in plasma (Ginsberg et al., 2004). A lower serum protein-binding capacity equates to a greater fraction of free chemical available in the circulation, and therefore increased toxicity.

The volume of distribution or V_d (liters per kilogram of body weight) of chemicals/drugs is an important factor to consider in pediatrics. Because of the expanded water content in early life (newborns and infants), water-soluble chemicals may tend to have a larger volume of distribution. Toxic lipophilic agents, on the other hand, will be decreased in their partitioning to fat because of the lower

body lipid content in young children compared to older children and adults (Kearns and Reed, 1989; Morselli, 1989; Clewell et al., 2002). It can be argued that due to these lower fat stores, lipophilic agents such as nerve agents will reach higher concentrations in the plasma, leading to an increased chance of chemical toxicity.

Another factor affecting tissue distribution of chemicals in children is organ size per body weight. The brain is disproportionately large in young children. This fact, combined with an immaturity and permeability of the BBB in young children, leads to higher brain concentrations of some chemicals and the potential for enhanced neurotoxicity (Saunders et al., 2000). Liver mass per body weight is greatest in the early postnatal period and other tissues (liver, kidney, lung, and brain) undergo rapid growth during the first 2 years of life (NRC, 1993). These organs are at increased risk for toxicity in children due to their disproportionately larger size per body weight.

Organ maturity in the pediatric population is another factor affecting clearance of toxic agents and therapeutics. In particular, renal clearance is diminished in children compared to adults. Glomerular filtration rate and transporter (secretory) systems in the proximal convoluted tubule are decreased at birth (Kearns and Reed, 1989; Morselli, 1989). In addition, cardiac output, while higher in children, has a lower percentage reaching the kidneys (Ginsberg et al., 2004). This will tend to decrease renal clearance even more, leading to even greater plasma levels of toxic agent. A consequence of immature kidney function and reduced clearance in children can be seen with nerve agents since the parental forms of nerve agents and their metabolites undergo hydrolysis with predominantly renal elimination.

One might consider that renal clearance is faster due to allometric scaling differences in children compared to adults. According to the rules of allometric scaling, smaller organisms have greater respiratory rates, cardiac output, nutrient and oxygen demands, and basal metabolic rates than larger organisms. This appears true for children because respiratory rate, cardiac output, and liver mass are greater per body weight than adults. However, faster metabolic rates are not seen in neonates because of immaturity of hepatic enzymes and reduced hepatic clearance, leading to a prolonged toxic agent/drug half-life and longer duration of action.

Metabolic Vulnerability

Children are unable to detoxify toxic agents as efficiently as adults because they have less mature metabolic systems (Rotenberg and Newmark, 2003). In particular, phase I oxidative systems, phase II conjugating systems, and miscellaneous other systems (e.g., serum esterases, hydrolases, and dehydrogenases) are all immature in children compared to adults. Neonates and children up to 1 year are most affected in their maturing enzymatic function with the greatest effect seen in the first 2 months of life. This leads to slower metabolic clearance of many drugs, toxic chemicals, and activated metabolites, leading to significant toxicity in this age group (Ginsberg et al., 2004). In addition, several authors have reported a reduced activity of AChEs, pseudocholinesterases, and arylesterases (paraoxonase) in premature and full-term newborns (Stead, 1955; Lehmann et al., 1957; Augustinsson and Brody, 1962; Ecobichon and Stephens, 1973). These levels do not reach adult levels until 1 year of age (Morselli, 1976). In addition, newborns possess levels of paraoxonase, the enzyme that detoxifies OP pesticides, that are half of those found in the general adult population (Rotenberg and Newmark, 2003). Other studies suggest that newborns have paraoxonase levels fourfold lower and activities threefold lower than their mothers (Holland et al., 2006).

Traumatic Injury Vulnerability

Another special challenge to managing pediatric patients is the fact that trauma and injury often accompany chemical attacks (Abraham et al., 2002). Chemical exposures are often dispersed through explosive devices. Traumatic injury patterns differ in children compared to adults. Due to the smaller size of children, multiple trauma occurs more frequently. Compared to adults, children often sustain more head trauma due to their relatively large head size and weaker supportive musculature. Also, their more compliant skeletal system provides less protection to internal organs, leading to greater internal injuries without overlying fractures.

Neurobehavioral Vulnerability

Immature cognitive function can put children at risk during a chemical attack (Rotenberg and Newmark, 2003). Children lack the ability to discern threat, to protect themselves, or to follow directions. Infants, toddlers, and young children do not have the motor skills to flee from the site of an incident (CEH/CID, 2000). This can adversely affect their avoidance of a contaminated area and decontamination in the event of exposure. During decontamination, procedures for children who have been separated from their caregivers must be taken into consideration. Without guidance, children may not be able to follow directions for the decontamination process (Wheeler and Poss, 2003).

Psychological Vulnerability

Children have fewer coping skills when sustaining or witnessing injuries such as parental or sibling death (Henretig et al., 2002b). These events can produce either short- or long-term psychological trauma. It is not

unusual for children involved in attacks to suffer from posttraumatic stress disorder (PTSD) related to what they have experienced (CEH/CID, 2000; ARC, 2002). During the management of a chemical event, there are certain behaviors that make the management of children difficult. Children are often influenced by the emotional state of caregivers, requiring providers to remain calm. Also, fear or discomfort may cause children to disobey or act out against providers of care (see Table 68.1) (Blaschke et al., 2003).

Even beyond the behavior of children, there are other barriers to emergency management. The high-pressure hoses and cold water that are used to decontaminate victims can expose children to significant additional risk (CSMC, 2003). Use of these items can result in hypothermia and skin damage. Also, emergency care providers often need to wear bulky full protective suits when treating victims. These suits make it difficult to treat very small children who might need intricate procedures such as blood draws. One constant challenge that is consistent with the management of children is the lack of pediatric formulations of specific therapeutics (e.g., autoinjectors containing oxime). Antidotes for chemical agents are often not available in ready-to-administer pediatric dosages, although some progress has been made in this area. In the event of a true chemical event, there is a risk that pediatric centers would be overwhelmed and the ability to expand the number of pediatric hospital beds may be limited (CEH/CID, 2000). Finally, most healthcare workers are not fully aware of the management or presentation of toxic signs and symptoms of chemical agent exposure. This problem is exacerbated because children typically present differently than adults.

Other Vulnerabilities

In addition to the vulnerabilities listed previously, other factors can put children at greater risk for toxicity from chemical agent attacks. For instance, the fluid and food intakes of children differ significantly from adults, with greater water and milk consumption per weight. Children ingest about 100 mL/kg per day of water compared to the 40–60 mL/kg per day ingested by adults. Therefore, if water or milk supplies become contaminated, children would feel a greater impact than adults. Also, the diets of children include greater consumption of foods that can be contaminated, such as fruits and vegetables (CEH/CID, 2006).

Medical Response Vulnerability

Due to the myriad of factors outlined here that make the management of pediatric chemical exposures challenging, it is not surprising that healthcare practitioners often lack the knowledge or are not sufficiently trained to handle a mass influx of pediatric casualties. This deficiency was clearly documented in a study done by Schobitz et al. (2008), when pediatric and emergency medicine residents were tested on the medical management of pediatric victims of biological and chemical terrorism (Schobitz et al., 2008). A test containing essential content was developed and validated by experts. This test was given to volunteer residents and was re-administered 5 months after a lecture on the content. The 34 pediatric residents and 15 emergency medicine residents who took the exam scored a median of 65% and 73%, respectively. The authors investigated the benefit of the lecture and found that the 16 residents who attended the lecture and completed the posttest achieved a median score of 70%. For the 20 residents who did not attend the lecture but completed the posttest, a median score of 66.6% was recorded. The authors concluded that there are significant knowledge deficits among pediatric and emergency medicine residents in their abilities to handle pediatric victims of biological and chemical terrorism. A suggestion was made to incorporate educational curriculum on preparedness into residency curriculums (Schobitz et al., 2008).

EXHIBIT B

PEDIATRIC CASE HISTORY—NERVE AGENTS

Nerve Agent Exposure in Nazhmar, Iran

One victim of an attack on the village of Nazhmar on March 22, 1988, was a young child of unreported age and weight. He presented immediately with marked miosis and was comatose. Breathing was irregular, and foamy secretions were protruding from his mouth and nose. The patient was working very hard to breathe and noted to be using his accessory muscles of respiration. Wheezing was obvious on auscultation, and he showed obvious difficulty on exhalation. Upon suction removal of oral and nasal secretions, the patient was noted to have progressively rigid extremities, to the extent that venous access became difficult. The secretions were noted to become bloody. Over a 15-min period, a total of 7.5 mg of atropine was administered in three treatments. The patient was noted to improve, with eye opening, moaning, and speaking two-word phrases. As his muscle tone decreased, his breathing improved, but wheezing was still evident. The child was decontaminated after treatment and subsequently discharged after an hour. At the time of discharge, secretions were not completely dried up, but his pupils were fully dilated and reactive to light (Foroutan, 1998c).

EFFECTS OF SPECIFIC AGENTS

Nerve Agents

Introduction

Nerve agents pose a real threat to our unprotected civilian population. They can quickly incapacitate those who are exposed and can lead to mortality if not recognized and treated promptly. The toxicity of these agents can be enhanced in children due to pediatric vulnerabilities. Also, it is important to recognize the different ways that children may react to toxicity compared to adults.

The major nerve agents are the G-series (tabun, sarin, cyclosarin, and soman) and V-series (VX) compounds, which are clear, colorless, tasteless, and in most cases, odorless. They have been demonstrated to penetrate normal clothing and skin. Also, these agents are highly toxic, as evidenced by the fact that as little as 10 mg of VX on the skin is considered to be an LD_{50} in adults (Rotenberg and Newmark, 2003). In addition, these agents produce toxicity rapidly compared to biological agents. Most G-series nerve agents are highly volatile, and can be dispersed into aerosols that are inhaled by victims. One of the G-series agents, sarin, is volatile and may sink close to the ground (in undisturbed air) where children breathe. Nerve agents may also be disseminated in liquid form. Treatment for dermal exposure begins with rapid topical decontamination.

Although our military experience managing toxicity from nerve agent exposure is limited, exposures to related chemicals such as the OP class occur commonly each year in the United States. In 2006, there were a total of approximately 5,400 OP exposures across the United States (Bronstein et al., 2007). OPs, such as malathion, are commonly used as pesticides. OP toxicity manifests in a similar fashion as toxicity from nerve agents; however, this chemical class is considerably less toxic. One case series of 16 children who experienced poisoning with OPs confirmed that pediatric patients present with toxicity differently than adults (Lifshitz et al., 1999). These children often did not manifest the classic muscarinic effects (such as salivary secretions and diarrhea) seen in adults.

Mechanism of Toxicity

Nerve agents cause toxicity by inhibiting esterase enzymes, especially acetylcholinesterase (AChE; Rotenberg and Newmark, 2003). When nerve agents bind to AChE, they prevent hydrolysis of acetylcholine (ACh). When ACh accumulates in the synaptic space of neurons, this leads to overstimulation of muscarinic and nicotinic receptors that is often termed *cholinergic crisis*. Also, it is important to note that the nerve agent–AChE bond undergoes a reaction called *aging* (Dunn and Sidell, 1989). Once this process is complete, the enzyme becomes irreversibly inactivated. This aging process dictates the need for prompt therapy to prevent irreversible toxicity.

Clinical Presentation

The signs and symptoms of a cholinergic crisis can be remembered using the mnemonic BAG the PUDDLES (Figure 68.4); these range in severity from lacrimation and urination to seizure activity (Rotenberg and Newmark, 2003). The manifestations of cholinergic crisis seen in a particular individual depend on the dose and route of exposure, as well as the duration of exposure. If death occurs from nerve agents, it is primarily attributed

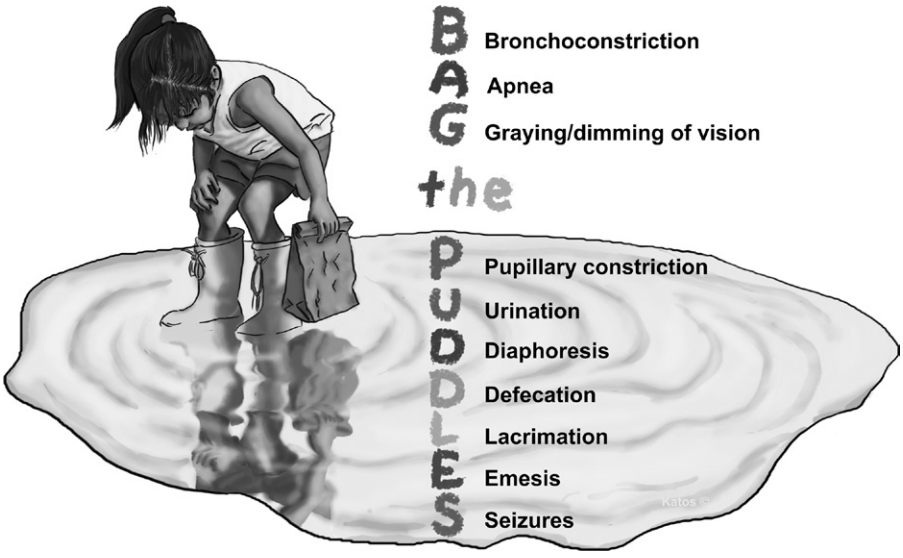

FIGURE 68.4 Helpful mnemonic for cholinergic crisis (BAG the PUDDLES). *Source: Illustrations are copyright-protected and printed with permission by Alexandre M. Katos (Rotenberg and Newmark, 2003).*

to respiratory failure. Nerve agents affect the respiratory system by causing central apnea, flaccid neuromuscular paralysis, bronchoconstriction, and profound glandular secretions (Hilmas et al., 2006).

Children present a clinical picture that can be very different to that observed in adults. Children in cholinergic crisis may not necessarily manifest with miosis (constriction of pupils) (Rotenberg and Newmark, 2003). In fact, one case series demonstrated absence of miosis in 43% of pediatric victims. Many of the pediatric case reports involving nerve agent exposure in children in Halabja and Damascus involved mydriasis (pupil dilation), so children may not always follow a classic picture of cholinesterase inhibition with regard to pupillary findings. Studies involving pediatric exposure to OPs have suggested the appearance of isolated CNS effects (such as stupor and coma) in the absence of peripheral muscarinic effects. Pediatric victims of OP intoxication display significant muscular weakness and hypotonia in the absence of glandular secretions in 70–100% of cases involving moderate to severe levels of exposure (Rotenberg and Newmark, 2003). For adults, a presentation of central intoxication (weakness and hypotonia) from OPs without peripheral muscarinic signs and symptoms would be extremely atypical.

Unfortunately, there are no data on the long-term effects of nerve agent poisoning in children, and the effects must be extrapolated from what has been discovered in the adult population (Rotenberg and Newmark, 2003). Surveillance studies performed on victims of the sarin attacks in Japan revealed a wide range of sequelae, such as continued respiratory problems, vision disturbances, headache, and fatigue. Neuropsychiatric problems were also reported as a delayed effect.

Laboratory Findings

Use of cholinesterase levels is limited, especially for confirmation of exposure (Rotenberg and Newmark, 2003). Treatment should not be delayed for these levels to return. Levels should be used after exposure only to confirm diagnosis (after treatment has begun), to monitor recovery, or for forensic investigation.

Pediatric Vulnerability

Children have several vulnerabilities, putting them at risk of increased toxicity from this class of chemical agents. A child's smaller mass alone reduces the dose needed to cause symptoms or lethality. For volatile nerve agents, children are especially at risk for respiratory toxicities due to their anatomic differences compared to adults. Their smaller airways can become compromised by the large amount of secretions and the bronchospasm caused by the agents. Also, a greater dose of nerve agent will be inhaled in children due to their higher respiratory rate and minute volumes.

Treatment

The overall treatment approach to nerve agent exposure focuses on airway and ventilatory support, aggressive use of antidotes (atropine and pralidoxime), prompt control of seizures, and decontamination as necessary (Henretig et al., 2002a). Atropine is used for its antimuscarinic effects, and oxime is used to reactivate AChE. The combination of atropine and pralidoxime chloride (2-PAM Cl) is recommended for the prompt treatment of all serious cases. The timing of atropine and 2-PAM Cl administration is critical. In short, the sooner these antidotes are given, the better the outcome. Oxime therapy is rendered ineffective if given after the enzyme aging process has been completed (Dunn and Sidell, 1989). This fact has led to the use of autoinjectors because of their ability to rapidly administer intramuscular doses of these medications. However, there are no current Food and Drug Administration (FDA)–approved pediatric autoinjectors for 2-PAM Cl. Other administration routes and methods include intravenous (IV) or intraosseous (IO) for atropine and slow IV or continuous infusion for 2-PAM Cl. Data show that peak plasma concentrations of medications administered from autoinjectors are achieved in less than 5 min versus 25 min for intramuscular (IM) administration using a needle and syringe (Rotenberg and Newmark, 2003). The mainstay of adult therapy includes the use of autoinjector technology containing atropine and 2-PAM. Recently, a dual-chambered autoinjector called the Antidote Treatment Nerve Agent Autoinjector (ATNAA) has received FDA approval for the military and Duodote for civilian emergency medical technicians and first-responders (see Figure 68.5). Meridian also produces the older Mark I kit (Figure 68.6), which is composed of separate autoinjectors for atropine and 2-PAM.

These products are provided by Meridian Medical Technologies, which has partnered with the US Department of Defense to be the only FDA-approved supplier of nerve agent antidotes. The Mark I kit and the single autoinjector devices deliver 600 mg of 2-PAM Cl and 2 mg of atropine (AtroPen) in seconds. This kit was developed originally for administration to soldiers, not for children, and with the approval of the Duodote system, the Mark I kit will most likely become antiquated. The autoinjector technology incorporates a spring-loaded needle to disperse medication in an all-or-nothing fashion. It is impossible to give partial doses of an autoinjector to children. Drug dosing of atropine and 2-PAM Cl in pediatrics is primarily weight based, so a standard dose cannot be used. Pediatric versions of the Mark 1 kit are available overseas but are not currently available in the United States (PEAP, 2004). In June 2003, the FDA approved pediatric doses of the AtroPen (atropine autoinjector) to respond to the lack of pediatric-specific therapy (Meadows, 2004). Meridian's AtroPen

is now available in four dosages, 0.25, 0.5, 1, and 2 mg (Figure 68.7). The 0.25-mg dose should be used for infants weighing less than 7 kg, the 0.5 mg treats patients weighing 7–18 kg, the 1 mg treats patients weighing 18–41 kg, and the 2 mg dose should be used for children and adolescents who weigh more than 41 kg. The needle length

for these autoinjectors is 0.8 inches, with a needle gauge of 22. The administration technique of autoinjectors in children is shown in Figure 68.8. Since the AtroPen delivers only atropine and not 2-PAM Cl, there continues to be a limitation to the prompt treatment of children. This fact has caused groups such as the pediatric expert advisory panel from the National Center for Disaster Preparedness to recommend the use of the Mark 1 kit before using the AtroPen (PEAP, 2004). Information on how to use the Mark 1 kit for children is given in Table 68.2. The use of adult dose-based autoinjectors in children has been addressed. Amitai et al. (1999) reviewed 240 instances of accidental pediatric atropine injections using adult dose-based autoinjectors. A low incidence of toxicity was found, with no seizures, arrhythmias, or death. Subsequently, several pediatric guidelines have suggested adult-dose atropine and 2-PAM Cl autoinjectors can be safely used in children larger than 13 kg and inserted 0.8 in.

Administration of atropine and 2-PAM Cl must be done cautiously (Rotenberg and Newmark, 2003). Atropine can cause increased heart rate, dry mouth and skin, and near vision can be affected for up to 1 day. Because sweating is prevented, elevated temperatures and heat stress may be observed. Exposure to 2-PAM Cl can cause double or blurred vision and dizziness (Anon, 2002). Doses must be reduced with renal insufficiency. If a medication is given too quickly as an IV

injection, laryngospasm and rigidity can occur. Higher doses can cause hypertension while lower doses can cause mild electrocardiogram (ECG) changes (Rotenberg and Newmark, 2003).

Although benzodiazepines are not considered to be an antidote, their use in the treatment of nerve agent exposure is critical (Rotenberg and Newmark, 2003). Status epilepticus can often occur as the nerve agent crosses the BBB and causes irritation. Benzodiazepines are the only effective agents that have been proven to treat nerve agent-induced seizures. This group of medications should be used for both prevention and treatment. It is recommended that if more than one organ is impaired, there is impaired consciousness or muscle twitching, and benzodiazepines should be quickly administered. In choosing a specific medication, various agents can be used. Our military department uses the medication diazepam that is administered as an autoinjector (Figure 68.9). In Israel, there is a move toward using midazolam for their population. Some physicians are recommending the use of lorazepam in the pediatric population. Regardless of which medication is used, repeat doses may be needed. For the pediatric population, benzodiazepines should be considered if there is any suspicion of seizure. Nonconvulsive status and subtle seizures are common in infants and children, making it difficult for healthcare providers to recognize nerve agent toxicity.

TABLE 68.3 Management of Mild/Moderate Nerve Agent Exposures

Nerve Agents	Severity of Symptoms	Management: Antidotes[a] Age	Antidotes[a] Dose	Benzodiazepines (If Neurological Signs) Age	Benzodiazepines (If Neurological Signs) Dose
Tabun, sarin, cyclosarin, soman, VX	**Mild/moderate symptoms** • Localized sweating • Muscle fasciculations • Nausea • Vomiting • Weakness/floppiness • Dyspnea • Constricted pupils • Blurred vision • Rhinorrhea • Excessive tears • Excessive salivation • Chest tightness • Stomach cramps • Tachycardia • Bradycardia	Neonates and infants <6 mo	**Atropine** 0.05 mg/kg IM/IV/IO to max 4 or 0.25 mg AtroPen® and **2-PAM** 15 mg/kg IM or IV slowly to max 2 g/h	Neonates	**Diazepam** 0.1–0.3 mg/kg/dose IV to a max dose of 2 mg OR **Lorazepam** 0.05 mg/kg slow IV
		Infants (6 mo–4 yrs)	**Atropine** 0.05 mg/kg IM/IV/IO to max 4 or 0.5 mg AtroPen® and **2-PAM** 25 mg/kg IM or IV slowly to max 2 g/h	30 days–5 yrs	**Diazepam** 0.05–0.3 mg/kg IV to a max of 5 mg/dose OR **Lorazepam** 0.1 mg/kg slow IV not to exceed 4 mg
		Children (4–10 yrs)	**Atropine** 0.05 mg/kg IV/IM/IO to max 4 or 1 mg AtroPen® and **2-PAM** 25–50 mg/kg IM or IV slowly to max 2 g/h	5 yrs and older	**Diazepam** 0.05–0.3 mg/kg IV to a max of 10 mg/dose OR **Lorazepam** 0.1 mg/kg slow IV not to exceed 4 mg
		Adolescents (>10 yrs) and adults	**Atropine** 0.05 mg/kg IV/IM/IO to max 4 or 2 mg AtroPen® & **2-PAM** 25–50 mg/kg IM or IV slowly to max 2 g/h	Adolescents and adults	**Diazepam** 5–10 mg up to 30 mg in 8 h period OR **Lorazepam** 0.07 mg/kg slow IV not to exceed 4 mg

Source: Anon (2002) and Rotenberg and Newmark (2003).

[a]*In general, pralidoxime should be administered as soon as possible, no longer than 36 h after the termination of exposure. Pralidoxime can be diluted to 300 mg/mL for ease of IM administration. Maintenance infusion of 2-PAM at 10–20 mg/kg/h (max 2 g/h) has been described. Repeat atropine as needed every 5–10 min until pulmonary resistance improves, secretions resolve, or dyspnea decreases in a conscious patient. Hypoxia needs to be corrected as soon as possible.*

For each of the medications used to treat nerve agent toxicity, there are weight-based dosing recommendations for pediatric patients. The exact dose to utilize for a specific patient will depend on two critical factors: the severity of the exposure and the weight or age of the patient. Pediatric-dosing recommendations for medications used to treat mild to moderate nerve agent exposure are displayed in Table 68.3. Dosing recommendations to treat severe nerve agent exposure are displayed in Table 68.4.

Perioperative Care of Children with Nerve Agent Intoxication

As mentioned earlier, it is not uncommon for chemical exposures and trauma to occur at the same time, requiring surgery. It is important to realize that many drugs used for perioperative management can exacerbate the side effects encountered with nerve agent exposure. Nerve agents can cause drug interactions with medications typically used for resuscitative efforts (Abraham et al., 2001). Anesthetics, such as sodium pentothal and propofol, cause cardiac depression, an effect exacerbated by the excessive muscarinic activity induced by nerve agents. Doses of these drugs may need to be reduced. Use of volatile anesthetics may be preferable because they bronchodilate and reduce the need for nondepolarizing drugs. When nondepolarizing drugs are used, they are often reversed by the use of neostigmine, which affects AChE activity. Halothane should be avoided in infants because the cardiac side effects can be accentuated in the presence of nerve agents. Depression of the cardiovascular system by halothane may cause further bradycardia, hypotension, and reduction in cardiac output. In general, the use of muscle relaxants is not recommended in the setting of nerve agent toxicity. Nerve agents provide a depolarizing block, and in the presence

TABLE 68.4 Management of Severe Nerve Agent Exposures

Nerve Agents	Severity of Symptoms	Management: Antidotes[a] Age	Antidotes[a] Dose	Benzodiazepines (If Neurological Signs) Age	Benzodiazepines (If Neurological Signs) Dose

of inhibited AChE activity, drugs such as succinylcholine can have longer effects than expected (Rotenberg, 2003b).

Careful use of analgesia is important when caring for victims of nerve agent exposure (Abraham et al., 2001). In general, opioids are considered safe to use because they do not act on the cholinergic system directly. However, some side effects of the drugs, such as histamine release and rare muscle rigidity, can cause difficulty in patient management. Careful dose titration and monitoring for side effects is critical. However, there is one opioid that can have an interaction with nerve agents. Remifentanil, a potent opioid, contains an ester linkage susceptible to hydrolysis because it is partially metabolized by plasma cholinesterase. This is the same enzyme that is inactivated by nerve agents, resulting in a prolonged duration of action for remifentanil. Therefore, use of remifentanil in the postoperative care of nerve agent-exposed victims is not recommended, as other analgesics are available (Rotenberg, 2003b). Compared to other CWAs, patients exposed to nerve agents pose unique challenges for medical and surgical management.

Summary

Nerve agent exposures must be handled quickly and efficiently. When children are exposed, it is important to remember that antidote dosing will be determined by the patient's weight and the severity of exposure. Progress has been made to provide pediatric-specific autoinjectors; however, since 2-PAM Cl is not yet available in a pediatric autoinjector form, adult autoinjectors can be used (but carefully) to manage pediatric patients.

Carbamates/Organophosphates

Introduction

Carbamates and OPs are chemicals that are often used as fungicides, insecticides, or pesticides and possess actions similar to nerve agents. These compounds are considered weapons of opportunity since their primary use is not by conventional militaries. In the United States, toxicity from these compounds is fairly rare. In 2006, there were approximately 1,200 cases of carbamate exposures and 1,500 OP exposures documented for children 19 years old and younger (Bronstein et al., 2007).

Although there were a few fatalities reported in 2006 from these substances, these fatalities occurred only in older individuals.

In general, the toxicity of these compounds resembles that of nerve agents, but it is less severe. Pediatric cases of toxicity reported in the literature are often due to accidental poisoning, when a young child ingests chemicals placed in unsecured or unlabeled containers. Exposure also can come by consuming foods that have been sprayed with pesticides. Most of the writings on pediatric toxicity from these agents includes retrospective reviews coming out of Israel, where use of these substances as a pesticide for the home and agriculture is common. A retrospective review of 37 cases from the United States has also been published (Zwiener and Ginsburg, 1988).

Mechanism of Toxicity

These compounds inhibit the hydrolysis of the neurotransmitter ACh by the enzyme AChE within the mammalian nervous system (Zwiener and Ginsburg, 1988). This inhibition causes ACh levels to rise, thus causing cholinergic hyperstimulation at muscarinic and nicotinic receptors. There are important differences in the way carbamates and OPs bind to AChE, as well as their ability to affect the CNS. Carbamates are reversible inhibitors of cholinesterase enzymes. Carbamates create a reversible bond to the cholinesterase enzyme through carbamylation, which can spontaneously hydrolyze and reverse the toxicity. Carbamate poisoning produces toxicity similar to that of OPs; however, the toxicity is usually of a shorter duration and less severe in nature (Lifshitz et al., 1994). In contrast, OPs inhibit cholinesterase via an irreversible bond of phosphate radicals to the active esteratic site of the enzyme (Lifshitz et al., 1999). Thus, the toxicity is more severe.

Clinical Presentation

OPs and carbamates have different receptor activities in the mammalian nervous system. OPs have effects on muscarinic and nicotinic receptors and can cause neurological effects in the CNS (Levy-Khademi et al., 2007). Carbamates are thought to cause only parasympathetic muscarinic effects, with limited nicotinic and CNS effects (Sofer et al., 1989). However, there are case reports in children that have revealed the presence of CNS effects with carbamate exposures (de Tollenaer et al., 2006). One pediatric case series stated that the signs and symptoms from carbamate poisoning were indistinguishable from OP exposures, with severe CNS depression, and stupor and coma occurring in eight cases (Sofer et al., 1989).

Muscarinic hyperstimulation leads to a clinical presentation of miosis, lacrimation, salivation, bradyarrhythmia, urinary incontinence, and intestinal hypermotility (Levy-Khademi et al., 2007). Nicotinic hyperstimulation leads to fasciculations, weakness, and paralysis of skeletal muscles. CNS effects include depression and agitation with coma and seizures occurring in the most severe cases for adults. Generalized tonic–clonic seizures have been seen in several pediatric exposure cases reported in the literature (Zwiener and Ginsburg, 1988).

Additional toxicities that have been reported in children include diarrhea, pulmonary edema [which was associated with OP exposure but not carbamate exposure (Lifshitz et al., 1999)], acute pancreatitis, hyperglycemia (Weizman and Sofer, 1992), dyspnea, sweaty cold skin (Sofer et al., 1989), respiratory distress or failure, lethargy, and tachycardia (Zwiener and Ginsburg, 1988).

Laboratory Findings

Key findings that have been reported include significant hypoxia, acidosis, and carbon dioxide retention (Sofer et al., 1989). Also, hyperglycemia, hypokalemia, and leukocytosis were observed in a case series of OP exposures (Levy-Khademi et al., 2007). A study done on 17 children with typical OP or carbamate poisoning looked at laboratory abnormalities that are associated with acute pancreatitis. Five of the patients (30%) had laboratory values consistent with pancreatitis with elevated immunoreactive trypsin, amylase, and serum glucose. None of the patients had hypocalcemia, renal dysfunction, or acidosis, and all experienced complete recovery of pancreatic function. The authors concluded that acute pancreatitis, due to anticholinesterase (anti-AChE) intoxication, is not uncommon in the pediatric population (Weizman and Sofer, 1992). Pancreatitis has been described in adult exposures, and the association has been investigated in animal studies (Weizman and Sofer, 1992).

Another laboratory value that is often obtained in these exposures is serum pseudocholinesterase. Serum pseudocholinesterase activities are often assessed as normal in children because the reference standards may not be reliable when assessing them. To add to the complexity, the normal range of serum cholinesterase activity is wide (Sofer et al., 1989). Researchers have described the limitations of this measurement in determining therapy for children. In fact, it is recommended that a therapeutic and diagnostic trial of atropine should be given whenever there is any possibility of intoxication with these chemicals (Sofer et al., 1989).

Additional laboratory abnormalities that have been reported in children are cardiac disturbances. Prolonged QTc intervals were reported in a few children exposed to OPs. However, there was spontaneous resolution, with no evidence of ventricular dysrhythmia on ECG (Levy-Khademi et al., 2007).

Pediatric Vulnerabilities

The clinical picture of anti-AChE intoxication in children is very different than that of adults. Often, clinicians have difficulty in diagnosing the exposure in pediatric

EXHIBIT C

PEDIATRIC CASE HISTORIES—CARBAMATES/ ORGANOPHOSPHATES

Carbamate Exposure in a Child

A 7-year-old female, previously healthy, was exposed to an unknown quantity of the fungicide pesticide manganese ethylene-bis-dithiocarbamate (maneb). She was admitted to the pediatric intensive care unit (PICU) with status epilepticus. She had experienced abdominal pain with nausea, vomiting, and headache for approximately 3 days prior to admission. On the day of admission, she was pale, unconscious, staring, and hypotonic. Upon examination, it was determined that she also had severe hypothermia (32.5°C) and hypoventilation. In addition, she was found to have a combined metabolic and respiratory acidosis and elevated blood glucose levels. Routine diagnostic investigations such as blood counts, electrolytes, liver/renal function, cerebrospinal fluid (CSF), and blood cultures, were normal. Urine/blood toxicology screens for barbiturates and benzodiazepines were negative. Liquid chromatographic-mass spectrometry confirmed the presence of maneb in her blood. Upon admission, the patient was intubated and her convulsions were treated with benzodiazepine. Within 24 h, there was a complete recovery of all neurological signs. Repeat physical and neurological exams were normal at 48h. She was discharged 3 days after admission in good condition (de Tollenaer et al., 2006).

Case History: OP Exposure in a Child

A 2-year-old, previously healthy male ingested approximately 10 mL of the OP insecticide demeton-*S*-methyl. Upon discovery of the ingestion, the child was disrobed and washed in the bathtub and then taken to the local hospital. Upon admission, which was approximately 30 min following the ingestion, the child was vomiting and salivating. Atropine was administered. He was then transferred to a larger hospital. During transport, he continued to have excessive salivation and experienced bradycardia. These episodes were treated with additional doses of atropine. Upon admission to the larger hospital, he was salivating, vomiting, and experiencing bronchial hypersecretion. At that time, his pupils were dilated, with no reaction to light, and he was tachycardic, with a pulse rate of 150 bpm. At the hospital, gastric lavage was performed and additional doses of atropine administered. He was intubated prior to the completion of gastric lavage and given diazepam for sedation. Bradycardia (<100 bpm) caused the physicians to administer additional atropine. Due to the complexity of the case, the patient was transferred again, to a hospital better equipped to handle his case. Upon that admission, the patient's blood pressure was 110/60 mm Hg, pulse 100 bpm, temperature 37.6°C, and his pupils were still dilated and unresponsive. Due to continued bronchial hypersecretion, additional atropine was administered. Obidoxime was administered twice, once at 9.5 and 11.5 h after the ingestion. After the oxime therapy, his condition stabilized, and he was able to be extubated approximately 13 h after ingestion. Over the next 4 days, atropine was administered periodically to control mild bronchial hypersecretion. Electrolytes and chest X-rays were normal during the entire course of illness. A low hemoglobin and high alkaline phosphatase were the only abnormal labs. The patient was discharged 8 days after the ingestion in good condition. Plasma cholinesterase levels were initially decreased (<400 U/L), but they rose into the normal range by discharge. A 12-month follow-up revealed that the child had no signs of neurological sequelae (Rolfsjord et al., 1998).

patients. In fact, in a retrospective review of OP/carbamate toxicity cases that were admitted to a children's medical center in the United States, the transfer diagnosis was incorrect in 80% of the patients (Zwiener and Ginsburg, 1988). Patients were misdiagnosed with a wide variety of disease states that ranged from head trauma to cranial aneurysm to diabetic ketoacidosis. It was noted that the difficulty in identifying nicotinic and muscarinic signs in children may have contributed to the high misdiagnosis rate. For example, it may be difficult to distinguish normal infant crying from excessive lacrimation (Zwiener and Ginsburg, 1988).

The lack of classic muscarinic effects does not exclude the possibility of cholinesterase inhibitor poisoning in young children with CNS depression. In one case series, tearing and diaphoresis were not observed in pediatric patients (Lifshitz et al., 1999). Miosis was absent in a number of pediatric patient cases reported in the literature with 27% of children in one case series lacking miosis on admission (Zwiener and Ginsburg, 1988). The percentage was 20% in another case series of pediatric patients (Sofer et al., 1989).

Adult literature states that the most important signs of OP toxicity are fasciculations and miosis. In one

published pediatric case series, fasciculations were quite infrequent, occurring in only 16% of cases (Sofer et al., 1989). Another pediatric case series verified this result, with the frequency of fasciculations being 22% (Zwiener and Ginsburg, 1988).

Another difference is the cardiac manifestations that are seen in adults compared to children. In one pediatric case series, cardiopulmonary manifestations were the least common, with tachyarrhythmias being more common than the bradyarrhythmias that are typically seen in adults (11 patients versus 1 patient) (Levy-Khademi et al., 2007).

Compared to adults, neurological manifestations of toxicity were the most common in children. In one case series, significant hypotonia and muscle weakness were observed in all children (Lifshitz et al., 1999). In addition, severe CNS depression with stupor and coma occurred in all the cases (Lifshitz et al., 1999). In another case series, coma occurred in 54.8% and seizures in 38.7% of children who were accidentally exposed to OPs (Levy-Khademi et al., 2007). It can be theorized that the more permeable BBB in young children permits penetration of the toxic agents into the brain, thus causing CNS depression. Another theory is that in young children, cholinesterase inhibitors have a stronger affinity to AChE in the CNS and less affinity to cholinergic synapses in the autonomic ganglia (Lifshitz et al., 1999). Accumulation of toxic compounds or their metabolites in the brain could also result in severe CNS dysfunction. Another thought is that the hypoxemia that has been observed in several pediatric cases could contribute to CNS depression (Sofer et al., 1989).

Treatment

In all pediatric cases, supportive care was used to balance electrolyte disturbances and oxygen was administered for hypoxic episodes. Often, patients were intubated and given mechanical ventilation due to the excessive salivation and bronchial hypersecretion. Gastric lavage was utilized in one case of OP ingestion (Rolfsjord et al., 1998). The treatment of OP intoxication mimics that of nerve agent exposures. Atropine and an oxime (such as pralidoxime) are the agents of choice for OP exposures. Atropine therapy alone is recommended for carbamate exposure because carbamates reversibly inhibit AChE, so there is little need for an agent such as an oxime, which reactivates the enzyme. In cholinesterase inhibitor poisoning, atropine will alleviate most of the muscarinic signs, few of the CNS symptoms, and almost none of the nicotinic symptoms (Lifshitz et al., 1999).

Although atropine use is standard, clinicians are sometimes faced with the dilemma of administering atropine to a pediatric patient with an elevated heart rate. Due to the fact that children may manifest tachycardia with toxic exposures and the fact that the chronotropic effects of atropine may be minimal in infants and small children compared with healthy young adults, one group of authors suggests that atropine should not be withheld or administered in subtherapeutic doses in tachycardic infants and children with OP or carbamate exposure. Their experience with pediatric patients showed that for patients with tachycardia at the time that atropine was administered, their heart rate decreased and none of the patients developed cardiac arrhythmias (Zwiener and Ginsburg, 1988).

Use of oximes is well accepted for OP exposures, but their role in carbamate poisoning is controversial. Animal studies have shown oxime use can increase toxicity when treating carbaryl exposure (Lifshitz et al., 1994). Therefore, there is a general guideline that oximes should be avoided if a carbamate exposure is suspected. One case series reported the routine use of oxime therapy for carbamate exposures in children (Lifshitz et al., 1994). Marked clinical improvement was observed in all patients, regardless of whether they were exposed to an OP or a carbamate. In addition to the retrospective review of cases, the authors completed an *in vitro* study of oxime use with carbamate toxicity and discovered that oximes play a minor role in direct reactivation of human carbamylated AChE. Due to this finding, the authors concluded that the current guideline to avoid oxime use in a carbamate exposure is valid.

Fortunately, in most cases of OP or carbamate toxicity, pediatric patients recovered fully if they were diagnosed rapidly and appropriate treatments were administered in a timely fashion.

Summary

There is a limited amount of literature available describing the toxicities of OP and carbamate exposure in pediatrics. What literature is available describes major differences between the manner that children manifest toxicity compared to adults. It is critical to understand these differences so that patients are not misdiagnosed and appropriate therapy is not delayed. In general, the CNS toxicities are greater in children than in adults with coma, stupor, and seizures being common. It is important to recognize that if therapy is given in a timely manner, complete recovery is often the outcome for children exposed to these toxic agents.

Vesicants

Introduction

Blister agents or vesicants are chemicals that cause blister or vesicle formation upon dermal contact. Agents such as mustards or lewisite have been used as CWAs in the past (Yu et al., 2003). Although these agents have less toxicity than nerve agents, they cause prolonged

morbidity. There are two types of mustard: sulfur mustard (HD) and nitrogen mustards (HNs). HD caused more casualties in World War I than any other chemical weapon. It caused a significant number of casualties, both civilian and military, during the Iran–Iraq War of the 1980s. HD vapor is the route most likely to be used by terror groups (Yu et al., 2003). It affects multiple organ systems including skin, eyes, respiratory and gastrointestinal tracts, and bone marrow (Yu et al., 2003). Nitrogen mustards, on the other hand, have never been used on the battlefield and will not be discussed further.

Lewisite, a vesicant with HD-like properties, causes a similar constellation of signs and symptoms involving the skin, eyes, and airways, as well as systemic effects (e.g., increased capillary permeability) after absorption. However, it does not produce immunological suppression like mustard. Another difference is that the management of lewisite toxicity includes an antidote, British anti-lewisite (BAL) (Yu et al., 2003).

Mechanism of Toxicity

HD rapidly penetrates cells and generates a highly toxic reaction that disrupts cell function and eventually causes cell death (Sidell et al., 1997). It is classified as an alkylating agent, targeting poorly differentiated and rapidly reproducing cells (Yu et al., 2003). Death is a result of massive pulmonary damage complicated by infection.

Clinical Presentation

Mustard can cause local effects on skin, airways, and eyes; however, large doses can cause fatal systemic effects (Yu et al., 2003). In a study of clinical findings among children exposed to vesicants, ocular, cutaneous, and respiratory signs were the most prevalent (Azizi and

EXHIBIT D

PEDIATRIC CASE HISTORIES—VESICANTS

Mustard Gas Exposure in 14 Children and Teenagers from Halabja, Iraq

Mustard gas was used on the civilian population during the Iraq–Iran War (1980–1988). A case series of 14 children and teenagers affected by mustard gas was reported by Momeni and Aminjavaheri (1994). They found that facial involvement was the most frequent disorder (78%), followed by genital (42%) and trunk and axillar lesions (both 14%). The most prominent laboratory abnormality was eosinophilia (in 12% of patients). As far as the time course of toxicity, skin lesions appeared 4–18 h after exposure, and then erythema developed within 20–30 h. After the erythema, blisters appeared. The authors concluded that the time of onset of toxicity was shorter and more severe in children and teenagers compared with adults (Momeni and Aminjavaheri, 1994).

Clinical Cases from Mofid Medical Center (Mustard Exposure Following the Halabja Attack on March 17, 1988)

A 3-year-old male presented to Mofid Medical Center 8 days after the Halabja chemical attack with fever (39.5°C), tachycardia (140 bpm), and tachypnea (respiratory rate (RR) 60). Cutaneous skin lesions were mild, but erythema and edema covered 45% of his skin surface area. Ocular and respiratory findings were as previously described. Laboratory findings were unremarkable except for a mild anemia. Chest roentograms revealed hilar congestion and consolidation bilaterally. The fever continued despite antibiotic therapy. On day 10 of admission (18 days after exposure), the patient developed leukocytosis with 82% polymorphonuclear neutrophils (PMNs) and worsening respiratory distress. The patient finally died 21 days after exposure.

An 8-year-old Iranian male presented at 5:30 p.m. with fever (40°C), severe agitation, delirium, and somnolence 24 h after exposure to chemical agents the previous day in Halabja. BP was 110/70 mm Hg, and the patient was notably tachycardic (120 bpm), and tachypneic (RR 42). The patient was noted to have serious dermatologic, ocular, and respiratory impairment. Erythema, vesicles, erosions, bullae, ulcerations, and edema were present on 35% of the body. Ocular manifestations included conjunctivitis and palpebral edema. At this point, the patient was working hard to breathe, as evidenced from accessory muscles of respiration (sternocleidomastoid). On physical examination of the lungs, wheezing and crepitation were noted throughout the lung field. Laboratory findings were the following: Na^+ 139, K^+ 4.1 mEq/L, BUN 25 mg/dL, calcium 7.3 mg/dL, and WBC 9,900/mm^3, with 90% neutrophils. Arterial blood gases (ABGs) were as follows: pH 7.30, pCO_2 31, pO_2 65, and HCO_3 15.1. Chest roentograms showed bilateral infiltrates. The patient died 24 h after admission and 48 h after exposure, despite receiving supportive care (Azizi and Amid, 1990).

Amid, 1990). Ocular findings consisted of the following: conjunctivitis (94%), palpebral edema (81%), eye closure (63%), keratitis (38%), blepharospasm (25%), corneal ulceration (19%), and chemosis (6%). Cutaneous signs included erythema (94%), hyperpigmentation (75%), ulceration (69%), erosion (63%), blister (56%), edema (50%), vesicles (31%), and hypopigmentation (13%). Respiratory signs included dyspnea (63%), crepitation (50%), and wheezing (25%).

Other pediatric signs of mustard exposure were photophobia, lacrimation, ophthalmalgia, and eye burning (94%). Dry cough (81%), dermal pain, and burning (94%) were also frequent complaints. Less frequent complaints were diplopia, itchy eyes, sore throat, sneezing, nasal secretions, dyspnea, burning sensation of the upper respiratory tract, suffocation, and dysphonia (Azizi and Amid, 1990).

Initial dermal signs of toxicity consist of erythema, occurring 4–8 h after exposure. Pruritus can occur with or prior to erythema (Azizi and Amid, 1990; Yu et al., 2003). Over the next 24 h, large yellowish blisters form in areas of thin skin, such as the groin and underarms. Eye damage can occur, ranging from pain and irritation to blindness. Mustard also causes clinical effects that can be delayed for hours (Azizi and Amid, 1990; Sidell et al., 1997; Yu et al., 2003). This causes victims not to recognize toxicity until well after exposure. During this time lag, sulfur mustard works to subclinically damage the skin. This latent period is significant because the shorter the latent period, the more severe the exposure and the worse the outcome.

The CNS and bone marrow can also be affected, as displayed by symptoms of fatigue, headache, and depression (Sidell et al., 1997). HD can also lead to pneumonia, the cause of death for many HD casualties in World War I due to lack of antibiotics. A leukopenic pneumonia usually occurs between 6 and 10 days after HD exposure. The manifestation of leukopenia (specifically lymphopenia) results from the myelosuppressive effects of mustard agents.

Laboratory Findings

While there is no diagnostic confirmatory test for mustard exposure, some laboratory tests can prove useful. As described previously, inflammation and infection will show up as fever and leukocytosis. Erythrocyte sedimentation rate (ESR) has been shown to be elevated in patients after mustard exposure (Motakallem, 1988). Some of these patients were in the pediatric age range of 0–18 years. Complete blood count (CBC) determinations may show abnormalities depending on the severity of the vapor inhalation or exposure (Azizi and Amid, 1990; Yu et al., 2003). The CBC may show a low hematocrit and leukopenia if the exposure was severe. There may be only a transient decrease in white blood cells (WBCs), with subsequent recovery. In pediatric cases of HD vapor exposure, decreases in hematocrit and/or WBC were likely to occur in the first 2 weeks, with the lowest levels of Hb, Hct, WBC, and neutrophil count observed in the 6th- to 10th-day samples after exposure (Azizi and Amid, 1990).

These pediatric patients also suffered from clear signs of hypoxemia and renal failure (Azizi and Amid, 1990). Unfortunately, serum creatinine and renal function tests (RFTs) were not found in the charts. ABGs may provide useful information, but they may show a varied picture. In one pediatric study of mustard casualties, most cases (43%) showed simple metabolic acidosis. The other groups showed the following:

- Mixed metabolic acidosis and respiratory alkalosis (29%)
- Simple respiratory alkalosis (14%)
- Mixed metabolic and respiratory acidosis (7%)
- Mixed metabolic alkalosis and respiratory acidosis (7%).

Blood urea nitrogen can be elevated with mustard exposure, but it does not necessarily predict outcome or mortality. Blood urea nitrogen was significantly elevated in severe mustard exposure cases in the Azizi study; three of the four pediatric mustard victims that died showed very high blood urea nitrogen (Azizi and Amid, 1990). While elevations in blood urea nitrogen were found in many of the pediatric casualties from mustard exposure, blood urea nitrogen returned to normal levels soon afterward in survivors.

Pediatric Vulnerability

The effects of sulfur mustard on children are more severe than on adults (Yu et al., 2003). Premature infants have thinner skin, and the dermal–epidermal junction is not fully developed in children (Rutter and Hull, 1979; Harpin and Rutter, 1983; Nopper et al., 1996; Seidenari et al., 2000; Mancini, 2004); therefore, the time between exposure and onset of blisters is shortened, and the number and severity of blisters will be more severe (Yu et al., 2003). In fact, lesions in children exposed to mustard have been shown to be more severe. Initial index cases of mass casualties are typically children. Eye findings tend to be greater in children because of their inability to protect themselves and tendency to rub their eyes (Azizi and Amid, 1990; Yu et al., 2003). Children are also shown to be more susceptible to pulmonary injury for reasons previously discussed. One case report looked at the long-term effects of mustard exposure in a child (Dompeling et al., 2004). This child suffered an acute, severe chemical pneumonia; the long-term consequence was chronic bronchiolitis. Finally, signs of gastrointestinal toxicity may be greater in children secondary to fluid losses in combination with lower intravascular volume reserves (Yu et al., 2003).

TABLE 68.5 Management of Vesicant Exposures

Vesicant Agents	Symptoms	Antidotes/Treatment
Mustard	• Skin erythema and pruritis • Development of large yellow blisters leading to ulcers • Eye damage • Inhalational damage: hoarseness and cough, mucosal necrosis, toneless voice, nausea, vomiting	**Decontamination:** soap, water, no bleach Copious water irrigation for eyes **Pulmonary management:** cough suppressants, throat lozenges **Skin management:** topical agents used for burns (1% silver sulfadiazine), antibiotics for secondary infections (Neosporin®), antihistamines for itching (diphenhydramine 1 mg/kg/dose orally q6–8 h max 300 mg/day, hydroxyzine 0.5 mg/kg/dose orally q6–8 h) **Immune system management:** G-CSF (filgrastim) 5–10 micrograms/kg/day subcutaneous for neutropenia
Lewisite	• Shock • Pulmonary injury • Blisters	**Decontamination:** soap, water, no bleach **Antidote:** BAL-dimercaprol may decrease systemic effects of lewisite **Pulmonary management:** BAL 3–5 mg/kg deep IM q4 h × 4 doses (dose depends on severity of exposure and symptoms) **Skin management:** BAL ointment **Eye management:** BAL ophthalmic ointment

Source: Momeni and Aminjavaheri (1994) and Yu et al. (2003).

While the decision to evacuate and hospitalize HD casualties is based on the extent [total body surface area (TBSA) >5%], severity of the skin lesions, and the recognition of multiple organ involvement (Graham et al., 2005), the threshold to hospitalize children with HD injuries should be lower. One reason is that vapor mustard used by terrorists may cause extensive pulmonary involvement while producing mild skin blisters.

Treatment

While decontamination and supportive therapy are the mainstays of treatment, antidotes to counteract HD vapor, aerosol, or liquid exposures do not exist (Yu et al., 2003). Adult decontamination may include bleach solutions; however, this method can cause greater toxicity in children. Soap and water are the preferred agents to use for decontamination in children. Supportive care consists of the management of pulmonary and skin manifestations, such as the use of cough suppressants and topical silver sulfadiazine for burns (Azizi and Amid, 1990; Sidell et al., 1997; Yu et al., 2003). Pediatric dosage and treatment recommendations for vesicant exposure are displayed in Table 68.5.

There are currently no standardized guidelines of casualty management or drugs available to prevent HD effects on skin and mucous membranes (Sidell et al., 1997; Graham et al., 2005). The mainstay of treatment is prompt decontamination, blister aspiration or deroofing (epidermal removal), physical debridement, irrigation, topical antibiotics, and sterile dressing application for cutaneous HD injuries. Current treatment strategies rely on symptomatic management to relieve symptoms, prevent infections, and promote healing. The general recommendations are described in the *Medical Management of Chemical Casualties Handbook* (USAMRICD, 2000a), the *Field Management of Chemical Casualties Handbook* (USAMRICD, 2000b), and other references (Graham et al., 2005). We will discuss the aspects of treatment that relate to the pediatric population. Most pediatric casualties will involve multiple organ systems (e.g., skin, ocular, gastrointestinal, bone marrow, and respiratory), as documented by Iranian physicians treating pediatric casualties of HD vapor during the Iran–Iraq War (Azizi and Amid, 1990).

Dermatological Management

Managing mustard skin lesions is especially challenging in the pediatric population. The goal of blister management is to keep the patient comfortable, keep the lesions clean, and prevent infection. Children especially will be extremely anxious at the sight of bullae and erythema, in addition to the burning, pruritis, and allodynia associated with HD blisters (Sidell et al., 1997). Anxiolytics may be appropriate to calm them down and prevent them from picking at bullae. Burning and itching associated with erythema can be relieved by calamine or soothing lotions and creams such as 0.25% camphor, menthol corticosteroids, antipruritics (i.e., diphenhydramine),

and silver sulfadiazine cream (Azizi and Amid, 1990; Sidell et al., 1997). Pain and discomfort can be relieved with systemic analgesics. Systemic analgesics such as morphine should be given liberally before manipulation of the burned area.

Vapor mustard typically causes a first- or second-degree burn, while liquid mustard produces damage similar to a third-degree burn. In either case, tense bullae are the hallmark of HD injuries. Bullae are typically dome-shaped, thin-walled, 0.5–5.0 cm in diameter, superficial, translucent, yellowish, multiloculated, honeycombed (Moradi et al., 1986), and surrounded by erythema (Sidell et al., 1997). Preventing children from breaking the blisters can be a challenge, especially when constant friction from clothing and blankets is irritating to the skin. These areas should be wrapped in protective dressings. Graham et al. (2005) have made an important point about the existence of a reservoir of unbound HD in human skin following a vapor (Logan et al., 2000) or liquid exposure, leading to an off-gassing period. They suggested that this off-gassing period can last for 24–36 h, whereby application of an occlusive dressing is not beneficial to prevent vapor buildup (Graham et al., 2005).

It is recommended that small blisters (<1 cm) should be left alone on the child, but the immediate area should be cleaned, irrigated daily, and covered with topical antibiotic (Sidell et al., 1997). Petroleum gauze bandage dressings should be wrapped around these unbroken blisters and changed every few days. Larger blisters (>1 cm) should be unroofed and irrigated several times a day with saline, sterile water, clean soapy water, or Dakin's solution and covered with topical antibiotic cream or ointment. It should be noted that blister fluid does not contain mustard (Buscher and Conway, 1944) and therefore does not represent a hazard to the healthcare worker. Options for topical antibiotic creams in children include silver sulfadiazine, and triple-combination antibiotic (bacitracin, neomycin sulfate, and polymyxin B sulfate; Sidell et al., 1997) but not mafenide acetate, which can cause toxicities in children (Ohlgisser et al., 1978; Geffner et al., 1981). These topical antibiotics should be applied to the area of bullae and surrounding areas of erythema. There is no information comparing the use of this combination (triple-antibiotic topical ointment) in children with use in other age groups.

While skin healing can take months to complete, pigment changes (hyperpigmentation or hypopigmentation) can persist (Sidell et al., 1997; Graham et al., 2005). It is also important to note that not all burn injuries require treatment at a burn center. Patients will require aggressive pain management and close observation for the systemic effects of HD exposure. Skin grafting, although rare, has been successfully used for deep burns (Ruhl et al., 1994).

Ophthalmology

The objective for any ophthalmology consultation on pediatric HD injuries involving the eye is the prevention of scarring and infection (Sidell et al., 1997). Eyes exposed to HD should be irrigated to remove traces of vesicant. Severe ocular involvement requires topical antibiotics (such as tobramycin OD) applied several times a day. Topical steroids may be useful in the first 48 h after exposure. Temporary loss of vision may also occur after mustard exposure (Motakallem, 1988; Azizi and Amid, 1990; Sidell et al., 1997). The patient should be reassured that vision loss is not permanent and is due to palpebral edema, not corneal damage.

Respiratory System

The conducting and ventilation portions of the respiratory tract are affected with HD vapor, necessitating a pulmonary examination (Azizi and Amid, 1990; Sidell et al., 1997; Dompeling et al., 2004). Bronchodilators are useful to diminish hyperreactive airways and should be used if a prior history of asthma or hyperreactive airways is documented. Further support with humidified oxygen may be required. Ventilatory support may be required for severe cases of HD vapor exposure before laryngeal spasm makes intubation difficult. Bronchoscopy is critical for diagnosis, therapeutic dilation against HD-induced tracheobronchial stenosis, and removal of pseudomembranes that cause airway obstruction.

Since the toxic bronchitis produced by HD is nonbacterial, antibiotic therapy should not be given during the first 3–4 days (Sidell et al., 1997). Continuous monitoring of sputum for Gram's stain and culture growth is necessary to identify the specific organism responsible for the late-developing superinfection. The presence of leukopenia in children, a grave sign of HD exposure, will require aggressive support with combination antibiotic treatment.

Gastrointestinal Tract

Atropine or common antiemetics can be given to provide relief from nausea and vomiting, early signs of HD intoxication (Yu et al., 2003). Excellent choices for pediatric-specific antiemetics include medications such as promethazine, metoclopramide, and ondansetron (Sidell et al., 1997). Persistent vomiting and diarrhea are later signs of systemic toxicity requiring prompt fluid replacement.

Bone Marrow Suppression

As a radiomimetic, HD affects rapidly dividing tissues like bone marrow in addition to the gastrointestinal tract (Sidell et al., 1997; Graham et al., 2005). HD destroys hematopoietic precursor cells; WBCs have the shortest life span and decrease in number first, followed by red

blood cells (RBCs) and thrombocytes. The bone marrow suppression that is sometimes seen can be treated with filgrastim injections. This medication stimulates the bone marrow to create and release WBCs.

Other Treatment Considerations

Fluid status, electrolytes, and urine output should be monitored in the HD-intoxicated patient. Tetanus prophylaxis should also be administered because fatal tetanus may occur even after a small, partial-thickness burn (Marshall et al., 1972).

Summary

Pediatric exposures to vesicants can be quite toxic; however, in contrast to nerve agent exposures, HD causes significantly greater morbidity than mortality. While mustard did not cause many deaths in World War I, death from HD exposure is usually due to massive pulmonary damage, complicated by infection (bronchopneumonia) and sepsis. Children often show a quicker onset and greater severity of toxicity. Skin and eye toxicity occurs in the form of blisters or irritation that can result in blindness for the most severe cases. Except for lewisite, vesicant exposures must be managed with supportive care and rapid decontamination.

Pulmonary Agents

Introduction

In January 2002, a CIA report stated that terrorist groups may have less interest in biological materials than in chemicals such as cyanide, chlorine, and phosgene (DCI, 2002), which are able to contaminate food and water supplies (Sidell et al., 1997; Graham et al., 2005). The targeting of children has the potential to destabilize governments and create widespread terror. Industrial chemicals, such as chlorine and phosgene, have advantages that make them potential candidates to be used by terrorists in the future. Both chlorine and phosgene are fairly easy to manufacture and handle, prompting national concern over their future use. In the United States alone, millions of tons of chlorine and phosgene are produced annually toward the manufacture of various products (Burklow et al., 2003). A detailed discussion of the general mechanisms of chlorine and phosgene toxicity can be found elsewhere in this book and will not be explored further here.

Clinical Presentation

Pediatric signs and symptoms of chlorine gas exposure include predominantly ocular, nasal, oropharyngeal, and pulmonary irritation of membranes (Burklow et al., 2003). The hallmark of intoxication by these choking agents involves respiratory complaints. Minor chlorine exposures can lead to burning of the eyes and throat, which indicate mucous membrane irritation. More severely exposed patients may complain of cough, choking, sore throat, shortness of breath, chest tightness, difficulty breathing, and other respiratory-related complaints. Clinical findings may also include lacrimation, rhinorrhea, laryngeal edema, hoarseness, aphonia, stridor, expiratory wheezing, tracheitis, and cyanosis (Güloğlu et al., 2002; Traub et al., 2002). Tachypnea may develop as a direct result of pulmonary irritation, and tachycardia has been demonstrated in some studies. Many pediatric patients with a prior history of reactive

EXHIBIT E

PEDIATRIC CASE HISTORY—PULMONARY AGENTS

Chlorine Gas Exposure in an Adolescent

A 14-year-old male, previously healthy except for a history of asthma, was exposed to chlorine gas by mixing household bleach with vinegar. Immediately, he began to cough and have difficulty breathing. His symptoms worsened over the next hour, leading to an admission to the local emergency room. Upon admission, the physical exam revealed that the patient was in respiratory distress, with bilateral crackles and diffuse wheezing. He also had conjunctival irritation. Vital signs were pulse 100 bpm, blood pressure 130/80 mm Hg, respiratory rate 20 breaths/min, and temperature 97°F. His initial oxygen saturation while breathing room air was 92%. A venous blood gas suggested mild CO_2 retention with a pH of 7.35, PCO_2 of 53 mm Hg, and a PO_2 of 33 mm Hg. Chest radiograph showed bilateral alveolar infiltrates with a normal heart size, which is indicative of acute lung injury. Sinus tachycardia was demonstrated on the ECG. The patient was treated with oxygen, multiple doses of nebulized albuterol, and oral prednisone. Despite these measures, his overall respiratory status continued to decline, and a repeat pulse oximetry while on 50% oxygen showed a saturation of 85%. Due to his worsening condition, he was intubated and transported to another hospital with a PICU. Upon intubation, it was noted that the patient had copious secretions. After admission to the PICU, the patient developed acute respiratory distress syndromes (ARDS) and needed ventilatory management for 19 days, along with additional doses of albuterol and methylprednisolone. After extubation, he was placed on a prednisone taper and discharged with no evidence of residual pulmonary dysfunction (Traub et al., 2002).

airway disease are at increased risk of chlorine-induced bronchospasm (Burklow et al., 2003).

Pulse oximetry may indicate low oxygen saturation (Traub et al., 2002). While ABGs usually indicate hypoxemia, carbon dioxide levels have been shown to be decreased, increased, or normal (Güloğlu et al., 2002; Traub et al., 2002). A hyperchloremic metabolic acidosis may show up on blood chemistries due to systemic absorption of hydrochloric acid.

Pulmonary edema, the most significant morbidity from pulmonary agents, can be seen on chest roentograms (Burklow et al., 2003). Pulmonary edema may develop as early as 2–4 h after exposure; radiographic evidence typically appears later. Pulmonary edema may progress to the point of producing Kerley B lines on chest x-rays. These lines are often described as rungs of a ladder running perpendicular to the lateral margin of the lungs beginning at the costophrenic angle. Chest radiographs will often show opacities of acute lung injury. Pneumomediastinum has also been reported in chlorine gas exposure (Traub et al., 2002).

Pulmonary function tests (PFTs) are not helpful (Pherwani et al., 1989; Traub et al., 2002) in this circumstance. A study of schoolchildren exposed to a chlorine gas leak reported a predominantly obstructive pattern on PFTs. This could be explained by congestion and edema narrowing the central airways rather than smaller ones.

Pediatric Vulnerability

Chlorine is a pungent green–yellow gas, twice as heavy as air (Güloğlu et al., 2002) and settles near the ground (Traub et al., 2002; Burklow et al., 2003). This poses a problem for children, leading to increased exposure for this population in the event of release, either accidentally or via an act of terror. Children can be exposed as a result of the following activities: inhaling chlorine vapors at swimming pools (Burklow et al., 2003), mixing of household bleach (sodium hypochlorite) with acidic cleaning agents (Traub et al., 2002), and industrial accidents (Pherwani et al., 1989). Phosgene, a dense gas heavier than air, is a more lethal pulmonary agent than chlorine. While the smell of chlorine is associated with swimming pools, phosgene odor is described as smelling like freshly mown hay (Burklow et al., 2003).

Initially, both agents cause intense irritation of the mucosal membranes (Burklow et al., 2003) and coughing (Güloğlu et al., 2002; Traub et al., 2002). This is typically followed by a feeling of suffocation (Burklow et al., 2003). Morbidity from pulmonary agents is the direct result of pulmonary edema, appearing 2–4 h after chlorine exposures. Since children have a smaller fluid reserve (Rotenberg and Newmark, 2003), pulmonary edema can cause rapid dehydration or even shock (Burklow et al., 2003). Due to the higher respiratory rates and minute volumes of children (Rotenberg and Newmark, 2003), exposure to pulmonary agents will be greater (Burklow et al., 2003). Concerning the effects on children exposed to pulmonary agents and subsequent treatment, there are many documented clinical case studies in the literature looking at accidental exposures and industrial accidents (Pherwani et al., 1989; Güloğlu et al., 2002; Traub et al., 2002).

Treatment

The first line of treatment for children exposed to pulmonary agents is decontamination. Decontamination can be as simple as removing the victim from the source to fresh air, followed by the removal of contaminated clothing (Burklow et al., 2003). Supportive care includes administration of humidified air, supplemental oxygen, water irrigation, and high-flow oxygen delivered via positive pressure for pulmonary edema (Traub et al., 2002; Burklow et al., 2003). Further treatment may include surgical debridement and supportive care with medications, such as albuterol for bronchospasm, corticosteroids for inflammation, and antibiotics for any secondary bacterial infections. Antidotes or specific postexposure treatments do not exist for this class of agents. Supportive treatment recommendations are shown in Table 68.6.

Summary

Chlorine and phosgene are two chemicals that can cause severe pulmonary toxicity due to pulmonary edema and direct damage to the lungs. Treatment involves decontamination and supportive care. Special care needs to be provided for exposed children because they are at higher risk for toxicity because of their unique vulnerabilities.

Cyanide

Introduction

Cyanide is used in plastic processing, electroplating of metals, metal tempering, extraction of gold and silver, fumigants, and photographic development (Baskin and Brewer, 1997; Rotenberg, 2003a). It is also found in vehicle exhaust, tobacco smoke, certain fruit pits, and bitter almonds. The major cyanide-containing compounds used by the military in World War I were hydrogen cyanide, cyanogen chloride, and cyanogen bromide. Cyanide is also liberated during the combustion or metabolism of nitrogen-containing polymers of natural and synthetic origin (Riordan et al., 2002). Cyanides can cause lethality through the inhalation of cyanide vapor or ingestion (Prajapati et al., 1992). Cyanide poisoning leads to death in minutes, but it can be effectively treated with antidotes if diagnosed quickly. Pediatricians, medical first-responders, and firefighters need to recognize victims of cyanide poisoning

TABLE 68.6 Management of Pulmonary Agent Exposures

Pulmonary Agents	Symptoms	Treatment
Chlorine	• Lacrimation • Rhinorrhea • Conjunctival irritation • Cough • Sore throat • Hoarseness • Laryngeal edema • Dyspnea • Stridor • ARDS • Pulmonary edema	**Decontamination:** Copious water irrigation of the skin, eyes, and mucosal membranes to prevent continued irritation and injury **Symptomatic care (no antidote):** Warm/moist air, supplemental oxygen, positive pressure O_2 for pulmonary edema **Bronchospasm:** Beta-agonists (albuterol) **Severe bronchospasm:** Corticosteroids (prednisone) (also used for PTS with H/O asthma but use unproven) **Analgesia and cough:** Nebulized lidocaine (4% topical solution) or nebulized sodium bicarbonate (use unproven)
Phosgene	• Transient irritation (eyes, nose, throat, and sinus) • Bronchospasm • Pulmonary edema • Apnea • Hypoxia	**Decontamination:** Wash away all residual liquid with copious water, remove clothing **Symptomatic care:** ABCs, hydrate, positive pressure O_2 for pulmonary edema **Bronchospasm:** Beta-agonists (albuterol), corticosteroids INH/IV, furosemide contraindicated **Hypoxia:** Oxygen

Source: Burklow et al. (2003).

in order to initiate immediate intervention (Baskin and Brewer, 1997; Rotenberg, 2003a). Cyanide is one of the few chemicals for which an effective antidote exists.

Mechanism of Toxicity

The cyanide ion kills aerobic organisms by shutting down oxidative phosphorylation in the mitrochondria, and therefore the utilization of oxygen in cells (Baskin and Brewer, 1997; Riordan et al., 2002). Cyanide has a propensity to affect certain organs (e.g., brain, heart, and lungs) more than others (Baskin and Brewer, 1997; Rotenberg, 2003a). Significant exposure can lead to central respiratory arrest and myocardial depression. Cyanide also acts as a direct neurotoxin (Rotenberg, 2003a), disrupting cell membranes and causing excitatory injury in the CNS (Baskin and Brewer, 1997; Riordan et al., 2002).

PEDIATRIC CASE HISTORY—CYANIDE

Case History: Cyanide Exposure in a Child

A 2-year-old, previously healthy, 12-kg male ingested an unknown quantity of an acetonitrile-containing sculptured nail remover. The product contains an aliphatic nitrile that releases inorganic cyanide upon human metabolization. The child was brought into the emergency room because of lethargy approximately 10 h after the ingestion. Although the child was acting normally at the time of ingestion, 8 h later he was found to be moaning, poorly responsive, and having just vomited. In the emergency room, he was pale and lethargic, responding only to deep pain. Abdomen and neck exam was normal, and the lung exam revealed bilateral coarse breath sounds with a normal chest roentgenogram. Extremities were mottled and cool, with a delayed capillary refill time. Vital signs showed a temperature of 36.9°C, pulse of 140 bpm, respiratory rate of 56/min, and blood pressure of 70/30 mm Hg. ABG measurements showed a pH of 6.95, PCO_2 of 11 mm Hg, and PO_2 of 114 mm Hg. His electrolytes revealed the following levels: sodium of 137 mmol/L, potassium of 5.1 mmol/L, chloride of 114 mmol/L, bicarbonate of 4 mmol/L, serum creatinine of 70.7 μmol/L, glucose of 15.8 mmol/L, and blood urea nitrogen of 5 mmol/L. The WBC count was 9.5×10^9/L, and the hematocrit was 31%. Sinus tachycardia, at a rate of 160 bpm, with normal intervals and axis, was observed on the ECG. Serial whole-blood cyanide levels were obtained, with the initial level being 231 μmol/L (600 μg/dL) 12 h after exposure. The patient was given oxygen, sodium bicarbonate, and fluid resuscitation. Electrolyte and acid–base disturbances were corrected, and no antidotal therapy was administered due to prompt response on supportive therapies. The patient was discharged from the hospital 3 days after admission in good condition (Caravati and Litovitz, 1988).

Clinical Presentation

Cyanide is an uncommon cause of childhood poisoning. In 2006, there were only 12 reported cases of cyanide exposure in the pediatric population (<19 years) (Bronstein et al., 2007). Since the signs of toxicity (see Exhibit F) are so similar to carbon monoxide poisoning, which accounts for the largest group of poisoning deaths among children, clinicians must have a high index of suspicion to make the diagnosis (Prajapati et al., 1992; Riordan et al., 2002). Rotenberg describes a typical toxidrome induced by cyanide (Rotenberg, 2003a), which includes a rapid progression from hyperpnea, anxiety, restlessness, unconsciousness, seizures, apnea, and finally reaching death. Skin, blood, and fundi may be cherry red upon physical examination due to the inability of mitochondria to extract oxygen. In reported cases of accidental cyanide ingestion by children, other signs of toxicity included nausea, vomiting, abdominal pain, headache, lethargy, slurred speech, ataxia, stupor, coma, and respiratory depression. In addition, delayed vomiting occurred due to the slow metabolization of the chemical compound acetonitrile to cyanide, a process that can take 6–14 h after the ingestion (Geller et al., 2006).

Laboratory Findings

ABGs can provide clues of cyanide exposure. Classic cases are presented with severe metabolic acidosis, elevated anion gap, and high lactate concentrations (Rotenberg, 2003a). Impaired cellular respiration will lead to a high oxygen content in venous blood (Riordan et al., 2002; Rotenberg, 2003a). Thus, a reduced arterial-venous oxygen saturation difference suggests this diagnosis. Blood cyanide levels are confirmatory (Baskin and Brewer, 1997; Riordan et al., 2002; Rotenberg, 2003a) but will only delay the diagnosis, which must be based on the initial clinical presentation. Immediate therapeutic intervention with provision of 100% supplemental oxygen and administration of specific antidotes is paramount. An almond-like odor on the breath may alert a clinician that a person may have been exposed to cyanide, but up to 40% of the general population is unable to detect this odor.

Pediatric Vulnerability

Children are especially vulnerable to cyanide attacks (Rotenberg, 2003a). A larger exposure to cyanide vapor occurs due to the higher respiratory rates and higher surface-to-volume ratios in children. Cyanide liquid causes greater and more rapid absorption when it comes against the immature skin barrier of children. Lower body mass and immature metabolic processes can render children more susceptible than adults to toxicity from cyanide exposure. It has also been noted that children seem more susceptible to ingestion poisoning, as demonstrated by various cassava and apricot pit exposures where the severity of toxicity was greater than that seen in adults who were also ingesting these products. In fact, it has been theorized that due to children's higher gastric acidity, which leads to greater absorption, they experience more severe toxicity than adults when cassava is ingested (Geller et al., 2006). A case report of potassium cyanide ingestion among 10 children reported that the initial symptoms included abdominal pain, nausea, restlessness, and giddiness (Prajapati et al., 1992). Cyanosis and drowsiness were also noted, but the signature cherry-red skin color was not reported. Postmortem examination of the 2 children that died showed bright red blood and congested tissues. These 2 children consumed powder packets of potassium cyanide mixed in water, while the other 8 children licked the powder, leading to less toxicity. The survivors were managed with aggressive supportive care, including gastric lavage, oxygen, and IV fluids.

Treatment

The mainstay of treatment in cases of cyanide toxicity in the United States consists of supportive treatment and use of a multistage antidote kit (Baskin and Brewer, 1997; Riordan et al., 2002; Rotenberg, 2003a). Table 68.7 details pediatric doses used for the medications in this kit, which contains amyl nitrite, sodium nitrite, and sodium thiosulfate. Antidotes should be provided only for significantly symptomatic patients, such as those with impaired consciousness, seizures, acidosis, hypotension, hyperkalemia, or unstable vital signs (Goldfrank et al., 1998). Even when patients are rendered comatose by the inhalation of hydrogen cyanide gas, antidotes may not be necessary if the exposure is rapidly terminated, the patient has regained consciousness on arrival to the

Other treatment: evacuation, decontamination, 100% O_2, and correction of acidosis, hypovolemia, and seizures.

hospital, and there is no acidosis or abnormality of the vital signs (Peden et al., 1986).

Supportive Therapy

Regardless of the antidote available, treatment will always consist of supportive therapy (Rotenberg, 2003a). Supportive therapy alone may reverse the effects of cyanide even in the face of apnea (Peden et al., 1986; Baskin and Brewer, 1997; Rotenberg, 2003a). Supportive therapy includes decontamination, which includes gastric lavage and administration of activated charcoal if appropriate, oxygen, hydration, and anticonvulsants. Decontamination measures should take place prior to patient transport to a medical center. First-responders and healthcare professionals should in turn take precautions not to intoxicate themselves through direct mouth-to-mouth resuscitative efforts (Riordan et al., 2002). They must also wear personal protective equipment when transporting the victims to areas with adequate ventilation (Rotenberg, 2003a). Clothes are an obvious source for recontamination of the victim, so they must be removed. Subsequently, the skin should be flushed with copious amounts of water. The temperature of the water becomes a major consideration for children, who may not tolerate the extremes. Depending on the hospital size, antidote kits may or may not be available. Therefore, the time when supportive care is implemented becomes extremely important.

Antidotal Therapy

The US standard cyanide antidote kit uses a small inhaled dose of amyl nitrite followed by IV sodium nitrite and sodium thiosulfate (Anon, 1998; Rotenberg, 2003a). This antidote converts a portion of the hemoglobin's iron from ferrous iron to ferric iron, converting the hemoglobin into methemoglobin. Cyanide is more strongly drawn to methemoglobin than to the cytochrome oxidase of cells, effectively pulling the cyanide off the cells and onto the methemoglobin (Berlin, 1970; Baskin and Brewer, 1997). Once bound with the cyanide, the methemoglobin becomes cyanmethemoglobin (Anon, 1998). Therapy with nitrites is not innocuous, since methemoglobin cannot transport oxygen in the blood. The doses given to an adult can potentially cause a fatal methemoglobinemia in children or may cause profound hypotension. Treatment of children affected with cyanide intoxication must be individualized based upon their body weight and hemoglobin concentration. Once an ampule of amyl nitrite has been broken one at a time into a handkerchief, the contents should be held in front of the patient's mouth for 15 s, followed by 15 s of rest. This should be reapplied using this interrupted schedule until sodium nitrite can be administered. Continuous use of amyl nitrite may prevent adequate oxygenation. Taylor Pharmaceuticals, the manufacturer of the kit, recommends the dose for children of sodium nitrite to be 6–8 mL/m^2 (approximately 0.2 mL/kg body weight), but not to exceed an adult dose of 10 mL of a 3% solution (approximately 300 mg). While excessive sodium nitrite can cause methemoglobinemia, it should be noted that in the 70-year history of using the kit, the only reported fatality of such toxicity from using the kit involved a child without serious cyanide poisoning who was given two adult doses of sodium nitrite (Berlin, 1970; Hall and Rumack, 1986). In fact, the scientific literature recommends pediatric dosing based on monitoring hemoglobin levels. The next

part of the cyanide antidote kit is sodium thiosulfate, which is administered intravenously (Hall and Rumack, 1986; Baskin and Brewer, 1997; Anon, 1998; Rotenberg, 2003a). The sodium thiosulfate and cyanmethemoglobin become thiocyanate, releasing hemoglobin; thiocyanate is excreted by the kidneys. Table 68.8 provides a dosing chart for the safe dosing of sodium nitrite and sodium thiosulfate, with continuous monitoring of hemoglobin levels. Before treating pediatric patients with nitrites, it is imperative that prescribers inquire about conditions that may predispose a victim to anemia and, if there are concerns, doses should be decreased. Methemoglobin levels must be monitored sequentially in children and should not exceed 20% (Rotenberg, 2003a). Due to concerns about the excessive methemoglobinemia, along with the complicated administration procedures associated with the cyanide antidote kit, experts have suggested that alternative therapies, such as hydroxocobalamin, may be preferable to use in children (Geller et al., 2006).

Alternative Strategies

Alternative methods of treating cyanide intoxication are used in other countries. For example, the antidote used primarily in France is hydroxocobalamin (a form of vitamin B_{12}), which combines with cyanide to form the harmless vitamin B_{12a} cyanocobalamin (Baskin and Brewer, 1997; Rotenberg, 2003a). In France, this medication is used for children at a dose of 70 mg/kg. A study of 41 French children with fire smoke inhalation showed a prehospital mortality rate of 4% for those given hydroxocobalamin and not found in cardiac arrest (Geller et al., 2006). The authors of the study noted that for those children found in cardiac arrest by paramedics, administration of hydroxocobalmin did not prevent mortality. Another case series detailed 8 pediatric patients exposed to cassava, where 4 of the most severely affected children were given the cyanide antidote kit, while the others were given 500 mg of hydroxocobalamin. All the children improved regardless of which therapy they were given and were discharged from the hospital with no sequelae. This medication appears to have a good safety profile; adverse effects reported such as transient reddish-brown discoloration of the urine and mucous membranes. Some elevations in blood pressure and rash have also been reported (Geller et al., 2006). The FDA approved hydroxocobalamin for use in the United States in December 2006 to treat cyanide exposure victims in a product called Cyanokit, manufactured by EMD Pharmaceuticals, Inc. The package insert for this medication provides adult dosing and a statement that the safety and effectiveness of Cyanokit has not been established in the pediatric population. However, there is a reference to the 70 mg/kg dose that is used in Europe (Anon, 2006).

Summary

Cyanide is found in a wide variety of industrial processes and has been explored by Al Qaeda for use as a weapon of terror (Rotenberg, 2003a). Whether ingested or inhaled, cyanide is very lethal. Cyanide produces toxicity through impairment of mitochondrial enzymes, disrupting the electron transport chain, and preventing their utilization of oxygen. The mainstay of treatment of cyanide toxicity consists of the use of a multistage antidote kit. The management of children with cyanide toxicity should include appropriate antidote dose adjustments and proper monitoring to prevent fatal methemoglobinemia. Another antidote, hydroxocobalamin, may gain favor over time as the treatment of choice for pediatric cyanide exposures, due to its preferable safety profile and its ease of administration (Geller et al., 2006).

DECONTAMINATION OF CHILDREN

Decontamination after a chemical terrorist attack needs to be well-planned, efficient, and cognizant of the special needs of children. It is well-recognized that the unique vulnerabilities of children may lead to a disproportionate number of pediatric victims after a chemical attack. Without proper planning and consideration as to how children will be decontaminated, the potential for preventable pediatric casualties is increased due to time loss and confusion. It is highly recommended for pediatricians to be involved in the development of each hospital's plans for decontamination. Over the last several years, many advances have been made in the management of the critically injured child. In fact, studies have shown that children managed in a PICU have better

outcomes than children managed in an adult intensive care unit (ICU; Wheeler and Poss, 2003). Not all hospitals have the resources to have their own PICU, but they need to be able to provide the initial resuscitation and stabilization of pediatric victims of a terrorist attack. It is highly recommended that predetermined, written transfer agreements exist between emergency departments in community hospitals and centers that specialize in pediatric care. These agreements will allow the rapid transport of critically injured children to the sites that can ensure the best outcomes.

The first step in the decontamination process is the appropriate triage of patients (Burklow et al., 2003). If this step is done quickly and accurately, patients will be appropriately managed and outcomes will improve. The key to triage is the ability to ration care when resources are limited. Victims are usually classified into tiered categories. The classic categories that have been used on the battlefield include minimal, delayed, immediate, and expectant. Patients in the minimal category have minor injuries that may not require medical care or can be managed with self-care. However, it should be noted that it is difficult for children to manage themselves, in addition to the fact that the category they are placed within can change more rapidly than for adults. The delayed category describes patients who have injuries that will require medical intervention, but the injuries are not immediately life-threatening. Logically, the immediate category describes patients who are critically injured and need medical intervention to save life or limb. Finally, the expectant category describes those patients who are so critically injured that they are not expected to survive. The expectant category poses a special challenge to civilian healthcare workers, who are used to expending vast resources and personnel to maximize survival.

In a mass casualty event, clinicians need to come to grips with the fact that the most ill may not be treated. Although the classic categories of triage are fairly well known, they are not consistently used among hospitals. Some categories are developed specific to chemical attacks. An example of this are triage categories that separate patients as "exposed" and "not exposed." At the University of Maryland Medical Center, the biochemical response triage categories differentiate between exposed and not exposed individuals. Furthermore, recognizing that not all exposed individuals will necessarily be symptomatic but may still need to be isolated, the categories differentiate between those who are exposed and symptomatic, exposed and asymptomatic, and those with unrelated emergent conditions. Regardless of what categories get utilized, triage must focus on the fact that the best outcome is achieved for the greatest number of victims. To achieve this outcome, appropriate identification of the causative agent is critical. This can be a challenge because often, full identification is delayed. To protect those involved in triage, full personal protective equipment is highly recommended. Working in full personal equipment can be cumbersome and uncomfortable, but when triage is done correctly, unnecessary decontamination can be avoided.

After triage, the decontamination process should begin (Wheeler and Poss, 2003). All workers who are involved in this process must be appropriately protected with butyl rubber aprons and gloves, double layers of latex gloves, waterproof aprons, and chemical-resistant jumpsuits. Personal protective equipment should also include an appropriately selected air-purifying or atmosphere-supplying respirator, depending upon how well the threat environment has been categorized. It is important to note that this equipment often needs to be changed to prevent healthcare worker exposure.

The setup and use of the decontamination area must be carefully thought out. Often, the area is split into different zones (Rotenberg et al., 2003). At a minimum, there must be a dirty contaminated zone and a clean decontaminated zone. It is critical to emphasize that traffic must go one way between zones. This will eliminate the possibility of a cleaned patient becoming cross-contaminated or an exposed patient entering a healthcare facility before being decontaminated. Security personnel must be utilized to make sure that patients do not consciously or unconsciously violate the rules. A secondary triage will be needed as patients enter the clean zone to allow patients to receive antidotes or be referred for further care. Keep in mind that for severely ill patients, antidote administration may precede decontamination.

The selection of the appropriate decontamination agent is important. The gold standard for decontamination is plain water (Rotenberg et al., 2003). Other agents that have been used for decontamination include carbonaceous adsorbent powder, dilute (0.5%) hypochlorite solution, water with soap, and dry decontaminants such as flour or talcum powder. For children, the use of water or water with soap is preferred. In addition to agents used to decontaminate, other cornerstones to management include exposure to fresh air (when patients have been exposed to chemicals in the gaseous form), a change of clothing, and showers.

Conducting decontamination in children can be especially difficult. At every step of the process, special considerations need to be addressed (Rotenberg et al., 2003). Starting at triage, clinicians need to understand how chemical toxicities manifest in children; also, an understanding of what normal vital signs should be for a child will be critical. Pediatric-specific triage tools often consider different vital signs, such as heart rate

and respiratory rate parameters and the varying ability of patients to communicate. It is important for the triage to include the examination of a child's mouth and eyes because of frequent hand-to-mouth and hand-to-eye activity. If antidote administration is needed, pediatric references should be readily available, and an understanding of pediatric doses will be needed. When there is a lack of experience with managing children, the otherwise efficient decontamination process can get bogged down. Some hospitals have decided to set up pediatric-specific areas to address the specific needs of children.

Clinicians may need to handle uncooperative or nonverbal children. This becomes especially challenging when an IV line needs to be started. Placing a line in a child while in full protective equipment is no small feat. Also, keep in mind that the unfamiliar presence of a clinician in full personal protective equipment can cause fear and distress in a child. Children undergoing decontamination will benefit from a parent or guardian to guide them through and reassure them. For those children who present alone, a guardian will need to be appointed and a system for parental identification will be needed. Hospitals will need to plan for this extra resource. In fact, one Israeli hospital has employed social workers to participate in their disaster preparation to help manage patient/family needs and psychological distress (Rosenbaum, 1993). It is recommended not to separate parents and children during a time of crisis. Plans should be made for the decontamination and treatment of parent–child pairs (Rotenberg et al., 2003).

A range of specially sized supplies is needed to appropriately manage children, which range from pediatric-sized emergency equipment to basic needs, such as formula for feeding and diapers. Since decontamination often includes disrobing, child-sized clothing would be needed. For children who may need to be observed for hours, toys will be needed.

Also, the agents used to decontaminate children should be carefully selected. Bleach or hypochlorite solutions are not recommended for use with children due to the possibility of skin irritation or damage (Rotenberg et al., 2003). Water is the gold standard for decontamination. When employing water in decontamination, the temperature of the water must be considered. Children, especially newborns and infants, are prone to hypothermia and hemodynamic instability from cold water. Water at a comfortable temperature is recommended, along with a good supply of blankets that can be used to quickly warm up pediatric patients after water decontamination. In some situations, indoor sprinkler systems have been used when outdoor conditions were inhospitable.

PREPARATION FOR A CHEMICAL EVENT

Understanding chemical agents used for terrorism and knowing how to manage toxicity is just the first step in preparing for a chemical event. Appropriate training on how to manage pediatric patients in these scenarios is critical. Pediatricians are uniquely trained to participate in the management of pediatric casualties and to advocate for children so that their needs are addressed in emergency planning (Bradley et al., 2003). Many hospitals have held emergency exercises to see how prepared they are for these situations. Beyond this, the assessments should identify deficits and should be used to forge partnerships and relationships and share assets in the community to manage every possible scenario (Blaschke et al., 2003). Healthcare facilities responsible for treating pediatric victims in a chemical–biological event could be easily strained and overwhelmed. Often large-scale chemical–biological incidents necessitate the use of alternative areas to triage patients such as auditoriums and arenas. These alternative triage areas need to know how to manage pediatric victims (CEH/CID, 2000). Planning for an attack begins with the development of local health resources. Unfortunately, with chemical releases, clinical effects can occur extremely quickly, limiting the amount of time available to borrow resources from nearby communities. First-responders must be educated to recognize pediatric signs and symptoms from each chemical agent, how to wear protective gear in the face of persistent agents, handle pediatric patients, and be able to manage field decontamination. It is critical that adequate supplies of protective gear are available. When planning for decontamination procedures, pediatric vulnerabilities and challenges need to be considered, such as the temperature of the water and the ability of children to follow directions.

Since children spend the majority of the day at school, community preparation for a threat must include the local educational system. Development of a rapid evacuation plan and the establishment of in-school shelters are critical. Schools can play a valuable role for the management of pediatric casualties.

Another key element to appropriate preparedness is the development of a pharmaceutical cache of antidotes, antibiotics, and vaccines. This cache will play a key role in the initial management of a chemical attack. Even though the SNS is now in place throughout the United States, it may be several hours before it reaches a hospital and the supply is divided among several sites. The SNS has made efforts to include pediatric-ready medications, such as suspensions and solutions. Efforts must be made for local pharmaceutical caches to address pediatric needs. An example of a pediatric pharmaceutical cache is displayed in Table 68.9.

TABLE 68.9 Example Pediatric-Specific Hospital Emergency Drug Cache

Drug	Strength	Dosage Form	Pediatric Dosing	Therapy or Prophylaxis	Disease
Albuterol MDI	17 gm	INH	2–4 puffs q4h	Respiratory distress from chemical agents	Chemical exposure
Amoxicillin oral suspension	400 mg/5 mL 100 mL	Oral suspension	15 mg/kg q8h—up to 40 kg, >40 kg 500 mg q8h	Chemoprophylaxis	Anthrax
Atropine	1 mg/mL	Injection	See dosing table	Chemotherapy	Nerve agent exposure
Ciprofloxacin oral suspension	250 mg/5 mL 100 mL	Oral suspension	20–30 mg/kg/day divided q12h for 60 days	Chemoprophylaxis	Anthrax, plaque
Clindamycin	600 mg/NS 50 mL	IVPB	30 mg/kg/day q8h (max 4.8 g/day)	Chemotherapy	Anthrax
Cyanide antidote package	1 kit	Kit	See dosing table	Chemotherapy	Cyanide poisoning
Diazepam IV	5 mg/mL × 2 mL	Injection	See dosing table	Seizures post chemical exposure	SZ postchemical exposure
Doxycycline oral suspension	25 mg/5 mL 60 mL	Oral suspension	2.5 mg/kg q12h—up to 40 kg, >40 kg 100 mg q12 h for 60 days	Chemoprophylaxis	Anthrax, cholera, brucellosis, plague
Oseltamivir suspension	12 mg/mL 25 mL	Suspension	For children ≥1–12 yrs: ≤15 kg: 2 mg/kg/dose (max 30 mg) BID × 5 days, >15–23 kg: 45 mg/dose BID × 5 days, >23–40 kg: 60 mg/dose BID × 5 days, >40 kg 75 mg/dose BID × 5 days	Chemotherapy	Avian influenza
Potassium iodide	65 mg	Tablet	4–18 yrs: 65 mg, 1 mo–3 yrs: 32.5 mg, <1 mo: 16.25 mg	Chemotherapy	Radiation emergency
Pralidoxime	1 gm/20 mL SDV	Powder for injection	See dosing table	Chemotherapy	Nerve agent exposure
Ribavirin solution	40 mg/mL 100 mL	Solution	LD 30 mg/kg followed by 15 mg/kg/day BID × 10 days	Chemotherapy	Viral hemorrhagic fever

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Much progress has been made in understanding how pediatric patients need to be managed when they are affected by chemical agents. Several pediatric organizations, such as the AAP, have given guidance on how best to handle these situations. It is a special challenge to gather information regarding pediatric chemical casualties because our experience is so limited. Further research and resources are needed to fully understand all the physical and psychological effects that a terror attack has on children. The intention of this chapter is to provide a framework from which local and national efforts can be developed. In the event of a chemical attack, prior preparation and planning will make the difference to whether lives are saved or further lives are lost. Efforts to improve upon current recommendations for managing pediatric chemical casualties must continue in order to better protect this vulnerable population.

CHAPTER

69

Physiologically Based Pharmacokinetic/ Pharmacodynamic Modeling of Countermeasures to Nerve Agents

Elaine Merrill, Chris Ruark, Jeffery Gearhart and Peter Robinson

INTRODUCTION

Physiologically based pharmacokinetic/pharmacodynamic (PBPK/PD) modeling has proven useful in many areas of toxicology and therapeutics. This quantitative, mechanism-based approach has allowed limited experimental *in vivo* and *in vitro* data to be quantitatively integrated with physiological data to facilitate predictions of the behavior of organisms under different exposure conditions. Specifically, it has been used for:

- Extrapolation across species (particularly experimental animals to humans)
- Extrapolation across dosing scenarios (such as high to low doses)
- Extrapolation across routes of exposure

Models have been developed for a number of chemical warfare (CW) agents (Langenberg et al., 1997; Worek et al., 2005; Aurbek et al., 2006; Sweeney et al., 2006; van der Merwe et al., 2006; see also Chapter 58) and surrogates, including diisopropyl fluorophosphate (DFP) (Gearhart et al., 1990; 1994), diazinon (Poet et al., 2004), and chlorpyrifos (Timchalk et al., 2002a,b). In the case of agent countermeasures, PBPK/PD modeling also allows the prediction of therapeutic efficacy under varying exposure scenarios. Specifically, it may allow therapeutic regimens to be optimized to particular exposure scenarios (routes, exposure times, concentrations). To do so, PBPK/PD models of individual agents and countermeasures must be combined to take into account their interactions, whether they are pharmacokinetic or pharmacodynamic. Such modeling of agent or (multiple) counteragent combinations is an example of mixtures modeling (Krishnan et al., 1994).

There is little in literature approaching a complete model of the kinetic and dynamic interaction of nerve agent (NA) and its current (multiagent) or potential countermeasures. There have been, however, a number of important steps in that direction, both on the level of model development and in the experimental generation of data useful for the development and validation of such models.

We restrict our discussion here to countermeasures of NAs and do not discuss other chemical agents such as mustards and cyanide and their antidotes. However, the modeling ideas outlined here can also apply to other agents.

BACKGROUND

Organophosphate compounds (OPs), such as the NAs, sarin (GB), soman (GD), tabun (GA), and VX, exert their toxicity via inhibiting acetylcholinesterase (AChE). As a result, Acetylcholine (ACh) accumulates in the synapses and neuromuscular junctions, resulting in hyperstimulation of muscarinic and nicotinic cholinergic receptors. Clinical symptoms include salivation, lacrimation, urination, defecation, and possibly convulsions (Myhrer et al., 2007). At moderate to high doses, seizures rapidly progress to *status epilepticus* (SE), which can lead to irreversible brain damage or death (Filliat et al., 1999; Carpentier et al., 2001). Survivors suffer long-lasting cognitive deficits and behavioral changes (McDonough et al., 1995) largely attributable to neuronal degeneration of hippocampal structures. Under acute high-level

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00069-5

exposures, the focus of countermeasure treatment is the prevention of seizures, respiratory failure, and bradycardia due to convulsive spasms. For low-level exposures, and for the survivors of high exposures, the concern shifts to minimizing the cognitive impact of the agent that may or may not be related to the degree of seizure activity.

McDonough and Shih (1997) hypothesized that NA-induced seizures follow three main phases. Initially, approximately 5 min after exposure, hypercholinergic activity triggers the seizure. A transitional phase of cholinergic and glutamatergic hyperactivity follows as a self-sustaining glutamate–NMDA receptor (NMDAR)-mediated positive feedback loop begins to develop. After approximately 40 min, a predominantly glutamatergic phase sustains seizures, leading to neuronal damage predominantly in the hippocampus, amygdala, piriform cortex, thalamus, and entorhinal cortex across species (Olney et al., 1983; Wade et al., 1987; Carpentier et al., 1990; Fosbraey et al., 1990; Lallement et al., 1992; Solberg and Belkin, 1997).

High levels of glutamate are directly neurotoxic because overstimulation of glutamate ionotropic receptors allows excessive influxes of Na^{2+} and Ca^{2+}, causing prolonged depolarization of postsynaptic membranes (Bittigau and Ikonomidou, 1997). A cascade of events results from the delayed Ca^{2+} overload, leading to excitotoxic cell necrosis (McDonough and Shih, 1997; Solberg and Belkin, 1997). In addition, as the time lapse before anticonvulsant treatments increases, the Ca^{2+} influx induces transcription factors that mediate significant increases in damaging pro-inflammatory peptides, such as IL-1β, IL-6, and mRNA of TNF-α (Chapman et al., 2006).

The content of this chapter is not inclusive in the sense of taking one through the complete development and validation of a complex PBPK/PD model, which would describe the kinetics of each component, together with the pharmacodynamic interactions between selected NAs and countermeasures. Rather, this chapter briefly describes some examples of progress made in quantitative modeling and exploring how specific countermeasures interfere in this NA-induced cascade of events, and how such quantitative approaches could be used to develop improved treatment regimens.

CURRENT COUNTERMEASURES

Conventionally, NA poisoning is treated by a combination of prophylactic and post-exposure therapy, which target the three post-exposure phases of neurotransmitter systems described. Prophylactic treatments are designed to circumvent aging of the NA–AChE complex and consist of carbamate anticholinesterases (e.g., pyridostigmine) to bind AChE reversibly. Current carbamate pretreatment regimes bind 30% to 40% of available red blood cell (RBC) AChE, thereby protecting some of the enzyme from irreversible OP binding (McDonough and Shih, 1997). Carbamates, however, are not without side effects. Partial AChE blockage by pyridostigmine results in a transient overstimulation of the AChR, mimicking mild NA poisoning with nausea, diarrhea, shortness of breath, and dizziness (Abraham et al., 2002). Moreover, repeated prophylactic administration of carbamates is associated with detrimental and debilitating changes in nerve and muscles function (Hudson et al., 1986).

Standard post-exposure treatments include concurrent administration of anticholinergics, such as the muscarinic cholinergic blocker atropine sulfate, and AChE reactivators, such as obidoxime and pyridine-2-aldoxime methylchloride (also known as 2-PAM). Oximes cannot reactivate OP-inhibited AChE that has already "aged." Therefore, traditional oxime treatment is considered to be less effective for those agents such as soman, for which aging is rapid (Worek et al., 2005).

If seizures develop, then treatments that attempt to attenuate the hyperglutamatergic phase are required. Anticonvulsants, such as the benzodiazepine, diazepam, may be used. Diazepam is a lipophilic agonist of the γ-aminobutyric acid A ($GABA_A$) receptor, the most predominant inhibitory receptor of the CNS. The $GABA_A$ receptor is ubiquitously distributed. Therefore, its activation or inactivation affects virtually all brain regions, making dosage critical. Treatments with traditional benzodiazepines depend on administration within a very narrow time span to be effective because profound neuropathological changes are usually detected within 20 min of the onset of seizures (Lallement et al., 1994; Leadbeater et al., 1985; McDonough et al. 1995; Shih et al., 1999). By themselves, benzodiazepine anticonvulsants provide limited protection, and seizures recur with desensitization of $GABA_A$ receptors (Goodkin et al., 2005). In addition, diazepam has consistently failed to eliminate the neuropathological changes resulting from NA-induced seizures (McDonough and Shih, 1997). Furthermore, in many battlefield and civilian exposure scenarios for NAs, pretreatments are unrealistic and post-exposure anticonvulsants are likely to be delayed. Epidemiological studies have shown that time to seizure treatment in the United States varies broadly, with only approximately 41% of all patients receiving their first antiepileptic drug within 30 min (Pellock et al., 2004).

NOVEL COUNTERMEASURES

Because of the undesirable side effects of the standard treatment regimes, and because of limitations of traditional benzodiazepines to adequately control seizures, the

need for alternative therapeutics still exists. The focus of OP intoxication treatment is also expanding from immediate survival to include the prevention of long-term cognitive deficits. Other antidotes have been proposed that demonstrate promise in reducing excessive glutamatergic activity and/or prevent destabilization of Ca^{2+} homeostasis, because excitotoxic mechanisms of seizure activity ultimately result in Ca^{2+} overload and activate various enzymes that lead to necrosis of the cell. Attempts have been made by blocking the *N*-methyl-D-aspartate (NMDA) or alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, two subtypes of CNS glutamate receptors (Braitman, 1989; Lallement et al., 1994; McDonough and Shih, 1995; Raveh et al., 2003). NMDA-type glutamate receptors are glutamate-gated cation channels whose permeability to Ca^{2+} underlies aspects of normal synaptic plasticity. Excess Ca^{2+} influx through NMDARs mediates cell death in certain neurodegenerative pathologies. Therefore, neurons must precisely control NMDAR synaptic density, which is negatively regulated by global neuronal activity.

A number of glutamate receptor antagonists have demonstrated neuroprotective and anticonvulsive effects in animals (Urbanska et al., 1998). The high-affinity NMDAR antagonist, ketamine, has shown promise when administered intramuscularly with atropine sulfate up to 30 min after poisoning (Dorandeu et al., 2005). Other noncompetitive NMDA antagonists, like dizocilpine (MK-801) and N-(1-[2-thienyl]cyclohexyl)3,4-piperidine (TCP), display the ability to terminate seizures when treatment is delayed by 40 min but seriously decrease respiration (Carpentier et al., 1990; Shih, 1990; Shih et al., 1991; McDonough and Shih, 1997; Shih and McDonough, 1997).

An unusual NMDAR antagonist that recently demonstrated potent neuroprotection against GD-induced seizure-related brain damage in rats is dexanabinol. Dexanabinol is a nonpsychoactive synthetic cannabinoid that acts as a highly selective, low-affinity NMDAR antagonist (Feigenbaum et al., 1989; Eshhar et al., 1993). In GD-exposed rats ($1.6 \times LD_{50}$ subcutaneous), dexanabinol administered intraperitonealy at either 5 or 40 min after the onset of seizures reduced median brain lesion volume 86% and 81%, respectively (as assessed by microtubule-associated protein 2 [MAP2]-negative staining) (Filbert et al., 1999). When administered 5 min after seizure onset and repeated every 6 h up to 24 h, 98% reduction was seen. However, it is not known if the same degree of protection would be afforded if measurements were taken later than 24 h after seizure onset. Dexanabinol did not diminish seizure activity in any of the GD-treated rats, suggesting that its neuroprotective effects may be due to its properties as a potent antioxidant and free radical scavenger, as well as its ability to inhibit the production of tumor necrosis factor-alpha (TNF-α) (Shohami et al., 1997), thus also blocking the signal transduction pathway that activates nuclear factor B (NFB).

Data to date also indicate that enzyme-based bioscavengers show much promise for the next generation of pretreatments or antidotes, with potentially no observable side effects. Candidate bioscavenger proteins either bind and sequester toxic OPs (such as serum cholinesterases and carboxylesterases) or catalytically break down the OP into nontoxic products (such as human serum organophophorus acid anhydride hydrolases [OPAH] or paraoxonase [HuPON]). These scavengers, as well as carboxylesterase (CarbE), are each capable of providing protection against 2–16 × LD_{50}s of GD, GB, or VX, depending on the scavenger and the test species (rat, mouse, rabbit, guinea pig, or rhesus monkey), with little to no deficits in behavioral testing (Li et al., 2005). Human clinical trials of several bioscavengers are now underway that could lead to FDA licensure.

Human serum paraoxonase (HuPON1) is a Ca^{2+}-dependent enzyme that effectively hydrolyzes many toxic AChE-inhibiting organophosphates (Blum et al., 2008). HuPON1 is present in high-density lipoproteins of human plasma and plays an important role in protecting lipoproteins and cell membranes from oxidative damage. Because it is a human enzyme (Li et al., 2005), it could potentially be used as either a prophylaxis or medical post-treatment for NA exposure, without causing adverse immune reactions (Draganov and LaDu, 2004). Human PON1 has catalytic activity against the pesticide paraoxon and the NAs sarin (GB), soman (GD), and cyclosarin (GF), but shows only minimal activity against the nerve agent VX (Blum et al., 2008). The advantage of catalytic scavengers is the very small amount of the exogenous enzyme needed to hydrolyze and detoxify large amounts of NA.

PBPK/PD MODELING

For obvious ethical reasons, only animal experiments can be used to evaluate new NA antidotes. However, the extrapolation of data from animals to humans is hampered by marked species differences. Currently, quantitative analyses addressing the co-treatment of countermeasures and medicinal treatments simultaneous with or immediately preceding or after NA exposures have been very limited. The current paradigm thus relies on experimentation in various animal models to determine efficacy and then, following the classical model for pharmaceutics, scales the animal results to the human exposure scenario. In the case of NA countermeasures, short of controlled human experimental studies, this leaves a large uncertainty factor regarding the protection of military personnel from NA threats and may severely limit or compromise operational risk

management (ORM). One solution to this dilemma is to develop validated mathematical models to predict the biological impact of simultaneous and sequential low-level exposures to specific NAs, together with specific countermeasures, countermeasure combinations, and dosing regimens.

PBPK/PD models can be used to explore the interactions between agents, countermeasures, and the organism to integrate multiple animal (*in vivo* and *in vitro*) and human (typically *in vitro*) data sets and to develop tools for countermeasure design and dosing regimen selection to maximize countermeasure administration efficacy. The models make quantitative use of differences in physiological parameters between test animals and humans, such as organ blood flow. The result of this approach is the development of an interaction model quantifying competition for AChE binding sites between specific agents and countermeasures, as well as other relevant pharmacodynamic and pharmacokinetic modes of interaction and the development of methods to optimize countermeasure therapies for specific NA exposure scenarios in humans.

The process of applying mathematical constructs to describe experimental results often reveals patterns in the agent's pharmacokinetics or dynamics that might not otherwise be discernable. Failure of a model's simulations to predict experimental measurements sometimes prompts questioning of the data, such as the reliability of the quantitative methods, sample collection, or exposure techniques. More often, it may indicate that greater complexity in the structure of the model is required to capture the behavior of the data. This is another primary reason for developing models, that is, to create hypotheses (model structures) that are falsifiable, leading to improved models and improved predictions in an iterative process.

There are currently a number of critical toxicological data gaps related to NA exposure at both acute high levels and repeated low levels. Many of these gaps are due to the impossibility of conducting controlled human experiments involving NA exposure. Filling these data gaps for exposure to NAs is essential for predicting performance degradation of personnel, enhancing risk assessment modeling tools, and defining detection thresholds that are physiologically relevant. The purposes of filling such data gaps are to develop a valid method for predicting dose–response effects for exposures to low NA agent concentrations/doses over long durations, and to identify threshold exposure conditions at which toxicologically significant effects occur. PBPK/PD modeling provides a means to fill these gaps. Because of the physiologically based nature of these models, simulations of experimental data can be performed by one exposure route in a particular species to develop and validate the PBPK model, and then that model can be used to simulate and predict the kinetics and pharmacodynamics in another species, such as the human exposed via another exposure route. The power of PBPK/PD models thus lies in aiding the ability of scientists and decision-makers to make reliable quantitative predictions concerning the potential health effects of real-life human exposures. In addition, this modeling approach can be useful for the development of meaningful therapeutic animal models. After all, therapeutics that have been successfully tested in animals can ultimately be tested in human clinical trials. However, their therapeutic efficacy against NAs can only be tested in animals.

DEVELOPMENT OF PBPK/PD MODELS

Critical components to PBPK models include species-specific physiological parameters and chemical-specific parameters. Species-specific physiological parameters include the organ weights and blood flow rates for

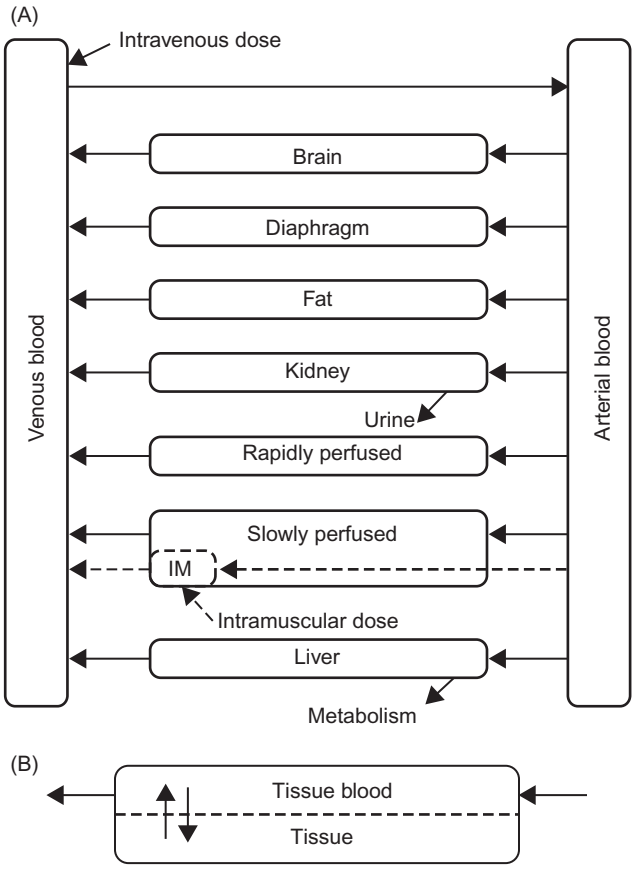

FIGURE 69.1 PBPK model schematic of the distribution of the oxime TMB-4 in rats and humans. Each tissue compartment depicted in schematic A includes diffusion limitation as shown in schematic B (Sterner et al., 2013).

the defined compartments in the PBPK model. These values are most often available in the published literature (Brown et al., 1997; Peeters et al., 1980) and, when lacking, can be derived by appropriate scaling factors from similar species. Chemical-specific parameters may include tissue to blood partition coefficients and metabolic rate constants, which may be measured experimentally or predicted, as described in the next section on quantitative structure–activity relationship (QSAR) methods. The basic structure of a PBPK model used to describe pharmacokinetics and pharmacodynamics of a compound is similar to the model presented in Figure 69.1, which predicts the absorption, distribution, metabolism, and excretion (ADME) of the oxime, TMB-4 (Sterner et al., 2013).

Although PBPK models can be used to predict ADME, they can be expanded to quantitatively describe the compounds pharmacological mechanism(s). Figure 69.2 shows a schematic representation of the pharmacodynamic processes involved in the interactions between NAs such as sarin with the organism (via AChE inhibition), together with interactions with pretreatments (pyridostigmine bromide [PB]) and countermeasures (oxime, atropine, and diazepam). When this PD submodel is linked to the PBPK model via the simulated concentration of a particular NA or therapeutic in a selected target tissue (i.e., plasma, RBCs, diaphragm, and brain), it provides a framework for describing these biochemical processes quantitatively. Linking it with the PBPK model also puts the biochemical processes into a physiological context. This allows extrapolation of results to multiple species, to description of relevant exposure scenarios to address potential health effects, and to optimization of pretreatment and countermeasure delivery.

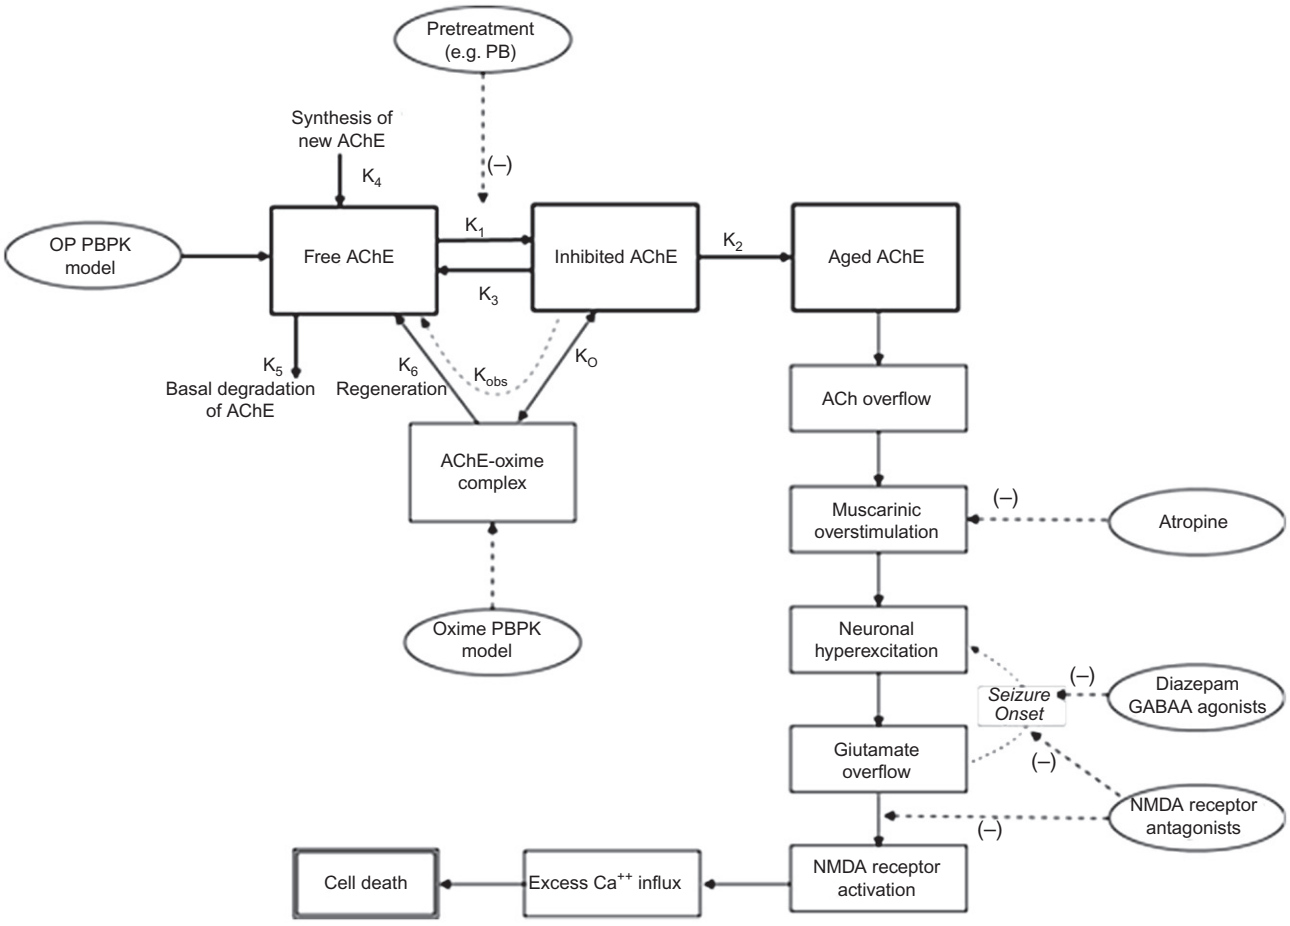

FIGURE 69.2 Schematic for a PD model of AChE inhibition and aging by OPs such as sarin, together with the interaction of pretreatment (pyridostigmine bromide [PB]), and countermeasure treatment (oxime). Pyridostigmine acts as a reversible cholinesterase inhibitor, oxime acts as an AChE regenerator. k_{obs} is an "effective" first-order rate that can be derived as: $k_{obs} = (k_r * [Ox])/(K_D + [Ox])$, when [Ox]≫[Inhibited AChE]. Potential links for the countermeasures atropine, a muscarinic receptor antagonist, and diazepam, a positive allosteric modulator of the $GABA_A$ receptor and NMDA antagonists, are shown without detailed kinetic interactions.

EXPERIMENTAL AND QSAR METHODOLOGIES TO PREDICT BLOOD AND TISSUE PARTITION COEFFICIENTS

As shown in Figure 69.1, PBPK modeling utilizes mathematical compartments that conceptually represent the physiology of an organism to depict the pharmacokinetics of chemicals exposed to the body. Traditional PBPK models depend on knowing the partitioning of the agent in key tissues of the organism. The distribution of a chemical within a tissue/compartment is most commonly represented by the following Eq. (69.1) (Krishnan and Andersen, 2001):

$$\frac{dA_t}{dt} = PA\left(CV_t - \frac{C_t}{P_t}\right) \tag{69.1}$$

where A = amount of chemical in the tissue, PA = permeation area cross product for the tissue, CV_t = concentration in venous blood emerging from the tissue, C_t = concentration in tissue, and P_t = tissue–blood partition coefficient. Note that $A = C_t \times V_t$, where V_t is the volume of the tissue.

PBPK modeling relies heavily on a proper definition of the partition coefficient because this parameter drives chemical uptake into the tissue. It is generally identified for PBPK modeling as the concentration ratio of the fraction in the tissue to the fraction in the blood at equilibrium (Schmitt, 2008), as shown in Eq. (69.2).

$$P_t = \frac{C_{\text{Tissue}}}{C_{\text{Venous}}} \tag{69.2}$$

The vial equilibration method is the most common *in vitro* method for determining partition coefficients for volatile or semivolatile materials and has been used most successfully for volatile organic solvents (Gargas et al., 1988). Tissues are harvested from the species of interest and incubated with the test compound until equilibrium is reached between the tissue and the headspace in the vial. The blood/air or tissue/air partition coefficients are given by the ratio of the concentrations of the chemical in the blood or tissue relative to its concentration in the headspace. Tissue–blood partition coefficients are calculated from the respective tissue/air and blood/air values. A number of operational equations have been derived to calculate these ratios under specific experimental conditions. Time to steady state is critical and should be optimized for the test compound. Metabolism of the compound in exposed tissue samples must be controlled. Analysis is performed by gas chromatography in a verified linear range. Human tissues can be obtained from tissue bank organizations to provide species specificity to models developed with human data. To estimate partitions for compounds of low volatility or nonvolatility, the *in vitro* filtration method of Jepson et al. (1994) can be used. Limitations of all such *in vitro* methods include issues of how representative the tissue sample is of the often quite heterogeneous tissue in the animal, and how closely the *in vitro* tissue preparation approximates the *in vivo* state. In addition, for highly lipophilic compounds, issues related to adsorption of the material onto glass and other surfaces need to be addressed.

Identifying the partition coefficient of a chemical for PBPK modeling is difficult because of the fact that most experimental methods fail to address this proper definition. *In vivo* methods most commonly track the kinetics of the chemical (radio-labeled or not). However, if enzymes are not properly inhibited, then metabolites can also be tracked instead of the parent compound, leading to contamination of the measured partition coefficient by the more water-soluble metabolite. Experiments are most commonly performed via a single dose at different routes of exposure, rarely leading to the steady state. To reach steady state, a critical point at which measurements should be made, a constant intravenous infusion of a chemical over an extended period of time until the concentration in the blood and tissue becomes constant must be made. Finally, protein binding is most commonly not accounted for, leading to a total concentration measured instead of the available free fraction. Compounds bound to proteins such as albumin, globulin, and lipoproteins reduce a chemical's tendency to partition into or out of tissues. This can be an extremely important issue depending on the chemical because some are upwards of 90–95% bound in the blood (Poulin and Krishnan, 1996a). These *in vivo* experimental issues are rarely addressed, which leads to utilization of *in vitro* measurements where there is greater control of the system.

Because experimental determinations of partition coefficients are slow and expensive, and are fraught with difficulties, particularly for NAs, an alternative is to predict tissue partitioning from more readily available chemical properties (particularly chemical structure), together with key biological properties of the tissue itself, such as its lipid composition, by means of QSAR (Ruark et al., 2008; Sterner et al., 2008). The pharmaceutical industry has utilized QSAR to obtain information of new drug candidates rapidly to help alleviate bottlenecks in the discovery process. A drawback to these models is that they have limited predictive power for scaling across species and to other compounds. However, by utilizing novel mechanistically based methods specifically suited to PBPK modeling, estimations of chemical warfare nerve agent partition coefficient properties can be developed.

Tissue distribution is predicted utilizing a variety of descriptors that range from both chemical-specific to tissue-specific, allowing for universal application of the methods across all species, tissues, and chemicals. A compound's

structure and their physiochemical properties, such as the log of the octanol:water distribution (LogP) and the octanol:water distribution mixture of different ionic forms (LogD), are commonly utilized in partition coefficient QSAR, or quantitative structure–property relationships (QSPR) models because they describe the relative affinity for a chemical between hydrophilic and hydrophobic phases. Octanol, being amphiphilic, represents the phospholipid bilayer, which provides a barrier for the cell, separating the extracellular from its intracellular components. However, many studies have shown that octanol is not a perfect surrogate for all lipids within organisms and many are beginning to pursue other surrogates such as vegetable oil and specific phospholipid membranes (Poulin et al., 1999; Schmitt, 2008). Other relevant properties include a wide range of descriptors predicted from *ab initio* calculations such as H-bonding acidity and basicity parameters, polarity, polarizability, molar refraction, McGowan volume, energies of the lowest unoccupied molecular orbital (E_{lumo}) and the highest occupied molecular orbit (E_{homo}), the maximum positive and negative atomic charge ($\sum Q$), the solvation of free energy (ΔG), as well as many others (Zhang and Zhang, 2006).

As far as tissue characterization is concerned, the fractions of lipid and water tend to be the dominating factors that influence partitioning into or out of the tissue. Some QSPR studies have included proteins that account for an electrostatic interaction with the amino or carboxyl terminal ends of an ionized chemical at physiological pH, as well as some nonspecific binding for neutral compounds. However, a recent QSPR model developed by Schmitt (2008) identified that nonspecific binding to proteins is approximately 40-fold weaker than to lipids. Therefore, proteins may only become of importance for tissues such as muscle and lung that contain a greater fraction of proteins than that of lipids. There have also been attempts at differentiating between phospholipids and neutral lipids (Poulin and Krishnan, 1995a,b; 1996a–c; Poulin and Theil, 2000, 2002; Poulin et al., 2001). Rodgers and Rowland (2006, 2007) later differentiated between acidic and neutral phospholipids to account for another electrostatic interaction with ionized chemicals within the tissue. There is also a need to distinguish between tissue and interstitial space, because the interstitial space is highly representative of blood plasma. Other tissue components that may be of interest include DNA, RNA, and intracellular organelles. Binding to DNA appears to be highly correlated with β-blockers; however, the fraction of DNA in tissue is too low to make a substantial difference in the current predictions (Rodgers et al., 2005a,b). Some authors have also suggested differences in intracellular organelle pH as another means of accounting for differences in tissue partitioning for ionized chemicals (MacIntyre and Cutler, 1988; Ishizaki et al.,1996; Daniel and Wojcikowski, 1999; Siebert et al., 2004); however, the overall volume of these organelles in relation to the cytoplasm is very low, most likely not resulting in substantial differences.

Optimization of predictions can be made utilizing linear as well as nonlinear relationships by means of statistical methods to correlate chemical and physiological descriptors to experimental data sets. These statistical methods include multilinear partial least-square analysis, principal component analysis, and neural networking. Many of these tools are included in QSPR/QSAR packages through companies such as Advanced Chemistry Development, SemiChem, EduSoft, BioByte, TOPKAT, MDL, ChemSilico, Pallas, Pharma Algorithms, and others.

A review of the literature will reveal that several QSPR equations have been developed to predict PCs of drugs for use in PBPK models and many are suitable for a wide variety of chemicals. It appears that the greatest deviations in predicted versus experimental measurements of PCs are largely due to an experimental uncertainty or misinterpretations of the data rather than incorrectness of the models. Strategies still need to be developed for other macromolecular binding (ά-acid glycoprotein) and processes such as blood–brain barrier (BBB) permeation and active transport, but it appears that the methods thus developed are suitable for preliminary PBPK modeling.

INTERACTION PBPK/PD MODEL FOR NAS AND COUNTERMEASURES

As stated, a number of PBPK/PD models have been developed for individual nerve agents (sarin, VX, soman, and cyclosarin) in multiple species. Chapter 58 in the current volume discusses the development of such models. Standalone PBPK or compartmental models have also been developed that describe the pharmacokinetics of certain countermeasures, such as diazepam (Igari et al., 1983; Gueorguieva et al., 2004) and oximes (Stemler et al., 1990; Sterner et al., 2013). However, to date, few models for specific countermeasures have been harmonized and linked to NA PBPK/PD models to be able to quantitatively describe their pharmacokinetic and pharmacodynamic interactions. This is partly due to the fact that most PBPK/PD models developed for NAs and other OPs focus on the inhibition of ChEs as the critical endpoint. The lack of a mathematical description of the disruption of other complex biochemical pathways presents a problem for linking these NA models to those of many countermeasures. For example, the conventional NA countermeasures, atropine and diazepam, as well as many novel countermeasures, do not directly impact ChE kinetics because they act at sites distinct from the active site of the esterases, such as muscarinic, $GABA_A$, or NMDARs (Figure 69.2).

Interactive models that have been developed and validated exist for countermeasures that compete with

NA inhibition of ChE or the regeneration of the free enzyme from its inhibited state, such as pyridostigmine and oximes, respectively. Numerous data in the literature describe the kinetics of interaction between nerve agents (and other OPs) and specific countermeasures at active enzyme sites of concern. For example, Davies and Green (1956) have measured the rate of reactivation of inhibited erythrocyte ChE by various oximes (Table 69.1). More recently, Worek et al. (2004) determined kinetic rate constants of inhibition, reactivation, and aging for different NAs, pesticides, and oximes with human erythrocyte AChE (see Figure 69.2 and Table 69.2), as described by the reactions listed here:

$$[E] + [OP] \xrightarrow{k1} [EP]$$
$$[EP] + H_2O \xrightarrow{k2} [EA]$$
$$[EP] + H_2O \xrightarrow{k3} [E] + [OP]$$
$$[EP] + [OX] \xleftrightarrow{k_D} [EPOX] \xrightarrow{k_r} [E] + [POX]$$

where [E] is the active enzyme (i.e., AChE), [OP] is the organophosphorus compound, [EP] is the reversibly phosphylated AChE, [EPOX] is the Michaelis–Menten-type phosphyl-AChE-oxime complex [EPOX], [OX] is the oxime, [POX] is the phosphylated oxime, and [EA] is the dealkylated, "aged" AChE. The reaction rates used describe the bimolecular inhibition (k_1), aging (k_2), spontaneous (k_3), and oxime-induced reactivation. The dissociation rate, K_D, is equal to the ratio [EP] × [OX]/[EPOX] and (k_r) represents a first-order rate constant for the displacement of the phosphyl residue from [EPOX], resulting in regenerated enzyme and a phosphorylated oxime.

Hence, both a high affinity of the oxime to the "inhibited" or phosphylated AChE and a high regeneration rate (k_r) are critical for oxime efficacy. Using *in vitro* enzyme kinetic constants and *in vivo* inhibitor and oxime concentrations, Worek et al. (2005) were able to extrapolate the percent of AChE inhibition in humans after sarin or cyclosarin (intravenous) and a simultaneous intramuscular injection of various oximes. Similarly, kinetic models have been developed to predict a dose range of human butyrylcholinesterase (HuBChE) required to maintain an adequate residual RBC AChE level after exposure to sarin, soman, or VX (Ashani and Pistinner, 2004). These and other data sets can be readily integrated into the full PBPK/PD modeling framework, as shown in Figures 69.1 and 69.2. For example, Figure 69.3 shows a simulation of RBC AChE inhibition and regeneration in the Rhesus monkey after exposure to sarin, followed by 2-PAM administered at 9 min after sarin and produced using the PBPK/PD model for sarin presented in Chapter 58. The lower simulation represents AChE inhibition after sarin exposure alone, whereas the upper simulation was generated by fitting an effective first-order rate constant (k_3^{eff}), which can be derived as shown in Eqs. (69.3) and (69.4). Improved simulation of the early time points of AChE regeneration may be achieved through linking the sarin model with a PBPK for 2-PAM, which would capture the distribution phase of the countermeasure as well taking into account its affinity.

$$k_{\text{obs}} = \frac{k_r^*[Ox]}{K_D + [Ox]} \tag{69.3}$$

$$k_3^{\text{eff}} = k_3 + k_{\text{obs}} \tag{69.4}$$

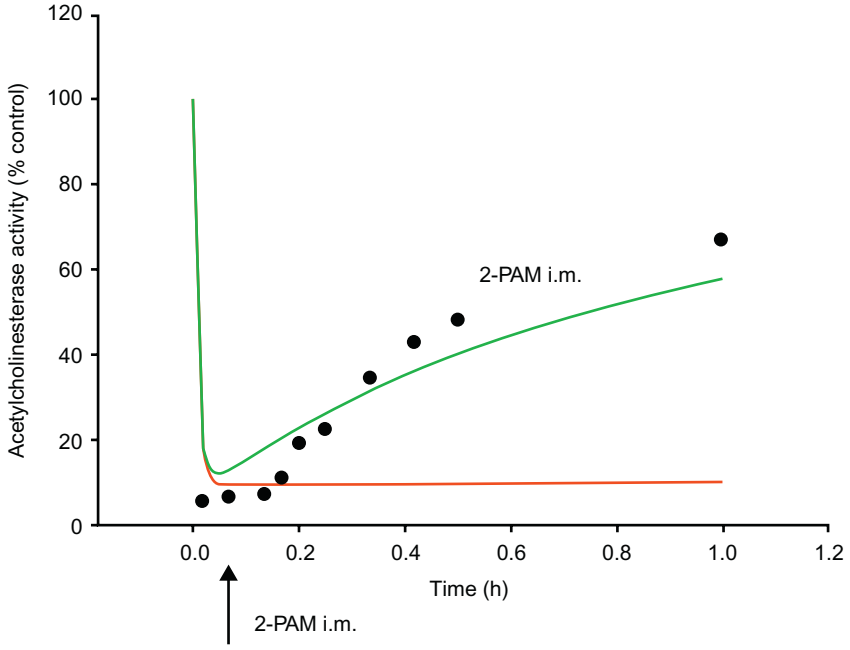

FIGURE 69.3 RBC AChE inhibition in Rhesus monkey after administration of sarin 0.75 LD_{50} (15 µg/kg) intravenous, and with 2-PAM (25.8 mg/kg) administered intramuscularly at 9 min after sarin intravenous administration. Atropine was administered (0.4 mg/kg) intramuscularly 15 min before sarin administration. The filled circles indicate experimental data (Woodard et al., 1994); the curves show our PBPK model simulations of AChE activity after sarin, both with (upper curve) and without (lower curve) 2-PAM administration.

Specific model features relevant to the agent's route of exposure and its biological effect can be incorporated when appropriate, for example, quantitative models for ciliary removal of NAs in the upper respiratory tract during inhalation exposure. In addition, it is important to take into account (and incorporate into the model) the limitations of the analytical methods used to quantify circulating and tissue levels of NA, such as the regeneration of NA from its binding sites. For example, it is desirable to model competition for AChE binding sites at erythrocytes and at target sites in the brain; the former because this regenerated NA from RBCs can be interpreted to calculate a measure NA systemic exposure and the latter, of course, because of the health impact. In general, the PBPK models can be linked via interaction processes at target sites.

Pharmacokinetic/PD models have been developed and used to predict the pharmacological effect of seizure activity for several anticonvulsants for which drug receptor kinetics were available from either *in vitro* or *ex vivo* binding studies. Diazepam, an agonist of the $GABA_A$ receptor, is among the NA antidotes, for which pharmacodynamic impact on electroencephalogram (EEG) activity has been modeled. Dunhof et al. (2007) have developed compartmental kinetic models for various anticonvulsants and modeled their ligand receptor pharmacodynamics. EEG parameters have been used as pharmacodynamic endpoints (Tuk et al., 1999; van der Graaf et al., 1999; Bueters et al., 2003; Dunhof et al., 2007). These receptor binding models predict changes in receptor binding and pharmacodynamics as a function of changes in the pharmacokinetics of the ligand as described in Eq. (69.5):

$$E(C) = E_{maxA} \cdot \left(\frac{C_A^N}{K_A + C_A} \right) \tag{69.5}$$

When E(C) is the observed effect at concentration C, E_{max} is the maximal effect (based on EEG components), K is the concentration at half-maximal effect, and N is the Hill factor, a constant expressing the sigmoidicity of the concentration–effect relationship. Subscripts A refer to the specific ligand of a ligand-gated ionotropic receptor.

Unfortunately, the impact of anticonvulsants on NA-induced seizures has not been modeled in this way. Given that many countermeasures have different ligand receptor interactions, such an approach would need to be expanded to the other excitatory and inhibitory neurotransmitters and their respective receptors, which are involved in seizure induction and sustainment. However, validation of such an approach, using components of gross EEG recordings, may not be plausible because of the large number of ionotropic channels represented. An endpoint such as sustained elevated glutamate may be more appropriate.

In addition, many target receptors undergo rapid changes in their level of expression during status

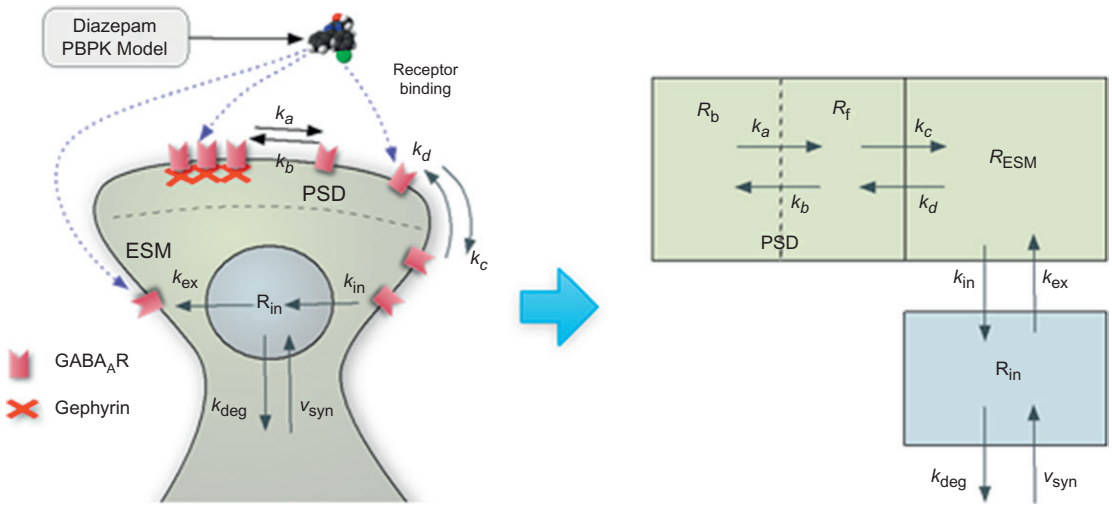

FIGURE 69.4 Simplified model of GABA$_A$R trafficking. *Rb* and R_f represent surface GABA$_A$ *Rs* within the PSD that are either bound to scaffolding proteins or free, respectively. R_{ESM} represents extrasynaptic GABA$_A$Rs and R_{in} represent internalized receptors. First-order rates are used to describe binding (k_b) and unbinding (k_a) of receptors to scaffolding proteins within the PSD, lateral movement between the synaptic and extrasynaptic membrane (k_c and k_d), internalization (k_{in}), recycling and membrane insertion (k_{ex}), and degradation (k_{deg}). Synthesis of nascent receptors is described with a zero-order rate, V_{syn}. *Adapted from Merrill (2012).*

epilepticus. GABA$_A$ receptors are undergoing rapid internalization, whereas AMPA and NMDARs are increasing at excitatory synapses, aggravating the loss of inhibitory tone (Naylor et al., 2005; Naylor, 2010). Figure 69.4 illustrates a basic model of GABA$_A$ receptor trafficking that can be developed into a full PBPK/PD model to include time-critical changes in target receptor activity (Merrill, 2012), leading to benzodiazepine pharmacoresistance. Such a model could be expanded to include other therapeutic targets, such as the NMDAR; when linked with PBPK models for the corresponding therapeutics, they can be used to optimize dosing based on the time from onset of status epilepticus.

Although the receptor targets of various NA countermeasures vary distinctly, be they ion channel-linked, G-protein-linked or enzyme-linked, their pharmacodynamic effects often converge on the final steps leading to the disruption of intracellular Ca^{2+}, beyond which cell death is inevitable. Hence, ultimately, a systems biology approach may provide the best predictions of countermeasure efficacy, especially for modeling long-term low-level effects. The Systems Biology Markup Language (SBML) project is an effort to create a machine-readable format for representing computational models in biology. SBML provides an input and output format, so that different software tools can operate on the same representation of a model, removing chances for errors in translation. SBML also provides convenient model databases, such as Biomodels (www.biomodels.net) for sharing these models. Neural Open Markup Language (NeuroML) similarly facilitates building, simulating, testing, and publishing of models describing channels, neurons, and networks of neurons. Future integration, via a common computational language, of these molecular and cellular level models with PBPK models will permit the development of multiscale models that will link external exposure and tissue dosimetry with NA-induced neurotoxicity. This multiscale approach is necessary for quantitative assessments of the health risks associated with NA exposure.

HEALTH EFFECTS ASSESSMENT AND COUNTERMEASURE OPTIMIZATION

Once validated, PBPK/PD models can be used to predict efficacy of specific countermeasures, countermeasure combinations, and dosing regimens for specific NAs and combinations thereof. To do so, appropriate measures of efficacy need to be defined. Perhaps the simplest way to estimate the effectiveness of a particular countermeasure is to determine the degree of a receptor activation *at the target site of concern* (e.g., brain or brain region) at a certain time or period of time after the administration of the countermeasure(s), compared with the situation in which no countermeasure is administered. Expressed as a simple ratio, countermeasure effectiveness (CE) may be written in terms of the time-weighted average concentration (from time $t = T_1$ to $t = T_2$) of receptor occupancy (obtained from the PBPK/PD model):

$$CE = \frac{\int_{T_1}^{T_2} [E]_c \, dt}{\int_{T_1}^{T_2} [E] dt}$$

Here, the numerator is calculated by running the model in the presence of the countermeasure, whereas the numerator is obtained in the absence of countermeasures. The ratio CE can be calculated under a variety of countermeasure dosing regimens to determine an optimum for each specific NA exposure scenario. Clearly, if such an exploration of countermeasure effectiveness were to be conducted experimentally, without the benefit of modeling, then it would be prohibitively expensive and time-consuming, thus demonstrating the usefulness of the modeling. The information obtained in this way would provide a rational basis for designing countermeasure delivery systems for optimized effectiveness. Ultimately, such an approach would also aid in the design of novel countermeasures, either to be used alone or to be integrated into an optimized countermeasure delivery "package."

A separate, although related, application of the proposed modeling approach is the development of meaningful therapeutic animal models based on rational animal to human scale-up. In such an application, dosing regimens for existing countermeasures and countermeasure combinations, and particularly novel countermeasures, can be tested in experimental animals with the knowledge that the results obtained can be extrapolated to humans by taking into account the appropriate species differences incorporated into the models.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

It can be expected that, in the near future, PBPK/PD models will be developed that can predict the interaction between mixtures of NAs and countermeasures and their opposing pharmacodynamic effects. Validation of such complex modeling efforts is data-intensive and will rely on compilation of existing *in vitro*, *in vivo*, and *ex vivo* data. Unfortunately, the majority of toxicological studies of NAs measure lethality, with little or no additional collection of time-course data of pharmacodynamic endpoints. Similarly, interaction studies between NAs and antidotes often measure only efficacy in terms of a reduction in cell death. This is understandable because of the difficulty and cost in measuring these NAs in biological matrixes and the large number of animals involved in collecting time-course data. Measurements of neurotransmitter changes after OP and countermeasure exposures are very difficult, and often there is uncertainty in deciding which biomarker is most predictive of an effect that is not easily quantifiable, such as cognitive deficits. PK/PD analyses may not always be possible if the relationships between the input (the concentrations of the NA and countermeasure) and the output become too indirect. However, it should always be remembered that even without formal concentration–effect analyses, there is always much to be gained if a pharmacological countermeasure test is performed with intensive sampling of PK and PD parameters. Differences in PK/PD parameters give quantitative information about different neurotransmitter systems in the central and peripheral nervous systems, which cannot be distinguished by pure statistical group comparisons. PK/PD analyses largely eliminate pharmacokinetic variability and provide detailed and functional characteristics of pharmacological systems in the brain or other target organs.

With specific regard to finding novel therapeutics for preventing or ameliorating NA-induced brain damage, PBPK/PD modeling provides a means to extrapolate experimental findings in animals to humans. Differences seen in the efficacy of different therapeutics may sometimes be explained by pharmacokinetics. Perhaps the therapeutic dose reaching a critical tissue, such as the diaphragm, heart, or brainstem is too little, too late, or not long enough. In addition, many of the animal toxicity studies performed to assess the efficacy of a therapeutic against NA measure a biomarker, such as cell death within 24 h from NA exposure. Biomarkers measured at 24 h may not always be indicative of outcome. Whether any protection seen at that point would still remain if the biomarker (e.g., cell death) were measured days, weeks, or months later then remains unknown. For example, damage seen in thalamus at 24 h might later extend to areas with which it has strong reciprocal connections, such as the cerebral cortex. Finally, in the quest for antidotes that may rescue one from cognitive deficits later, when realistically administered beyond the time when the glutamatergic phase takes control of seizure activity (i.e., > 40 min after NA exposure), predicting biomarkers that indicate the promotion of physiological balance in the brain, rather than the attenuation of seizure activity, may become the most important endpoints for predicting the efficacy of novel countermeasures.

Given the unsustainable cost and time involved in bringing novel therapeutics to market, the use of quantitative techniques to improve countermeasure development are being used increasingly more. Several opportunities exist in drug development, which could lead us on a more direct path toward finding suitable countermeasures, for example, more complete integration of the available knowledge of therapeutic candidates early in their development using PBPK/PD model(s) for NAs and countermeasures together. This should be started early, in the preclinical phases of drug development. Extrapolation of animal PBPK/PD models to humans for simulating initial clinical trials should be preformed to evaluate the design of proposed clinical trials of a drug development plan, and to provide proof of concept. This ability to mathematically explore various exposure–response relationships of NA(s) and

countermeasure(s) is useful for designing optimal countermeasure regimens and identifying the limits of the therapeutic window after NA exposure. Uncertainty analysis of the parameters of the model may identify biomarkers that may be critical in describing the data. Ways of defining and decreasing the uncertainty in efficacy and safety (risk assessment) in the drug and disease model are needed.

Finally, the mechanisms (e.g., diffusion-limited transport, receptor binding, protein upregulation or desensitization) described in a particular NA countermeasure model should be updated as new information is generated, thereby using the models as knowledge management tools. Thus, modeling the PK/PD of neuroprotectants in the presence of NA may provide direction and guidance early during clinical development, when there is opportunity to change direction and plans.

Strategies to Enhance Medical Countermeasures After the Use of Chemical Warfare Agents on Civilians

David A. Jett and David T. Yeung

INTRODUCTION

Chemical warfare agents (CWAs) are highly toxic chemicals that have been used in military conflicts, beginning in World War I and continuing in more recent conflicts in the Middle East, specifically during the Iran–Iraq war in the 1980s. However, ever since the 2001 terrorist attacks in the United States, there has been a heightened awareness of the potential deployment of biological, radiation/nuclear, and chemical threats against the civilian population as well. Underscoring these concerns are events surrounding the use of the CWAs sarin and *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX) by the terrorist organization Aum Shinrikyo against Japanese civilians in the 1990s (Vale, 2005; Yanagisawa, 2006). These concerns were highlighted again when sarin was deployed against civilians in the suburbs of Damascus, Syria, in 2013, during the Syrian civil war (Dolgin, 2013). Divisions within the US Department of Health and Human Services (HHS) and other federal agencies have sustained a highly focused effort to assess, and if necessary, improve current emergency response capabilities in the event of a terrorist event. These efforts include both nonmedical countermeasures, such as personal protective equipment (PPE) for first-responders who must enter a contaminated site, and medical capabilities, such as safe and effective antidotes and diagnostic tools to reduce mortality and morbidity after a chemical attack. These countermeasures are also important for large scale industrial accidents involving toxic chemicals.

OVERALL STRATEGIC APPROACH

The strategic research plan and research agenda for civilians aims to improve the nation's ability to diagnose, prevent, and treat injuries resulting from chemical attacks or accidents. Medical interventions must be appropriate for a diverse civilian population, and treatment strategies must take into account how a toxic chemical enters the body and the time window for possible medical intervention, which is often very short. Thus, treatments must be administered easily and rapidly in a situation involving mass casualties. Both immediate and long-term effects of exposure to chemicals must be understood to ascertain whether treatments are needed and whether they can be developed. Drugs should be chemically and physically stable so that they are amenable to prepositioning and stockpiling, and pretreatments for first-responders to a contaminated site should be considered, especially when decontamination is impossible.

In 2006, the US Congress appropriated funds to the National Institutes of Health (NIH) to implement the National Strategic Plan and Research Agenda for Medical Chemical Countermeasures (http://www.niaid.nih.gov/topics/BiodefenseRelated/ChemicalCountermeasures/Documents/nihstrategicplanchem.pdf). This program, led by the National Institute of Neurological Disorders and Stroke (NINDS) and coordinated by the National Institute of Allergy and Infectious Diseases (NIAID) with participation from several other NIH institutes and centers, is called Countermeasures

Handbook of Toxicology of Chemical Warfare Agents.

Against Chemical Threats (CounterACT; http://www.ninds.nih.gov/counteract). This program has two important goals. First, it supports basic research to learn information about the toxicology of chemical threat agents so that novel therapeutic targets and approaches can be identified. In this regard, the program serves as a science and technology base for the larger federal research enterprise. Second, CounterACT supports more advanced translational research with promising lead compounds that would be eligible for transfer to the HHS Biomedical Advanced Research and Development Authority (BARDA; http://www.phe.gov/ABOUT/BARDA/) for more advanced studies that are required to obtain approval from the US Food and Drug Administration (FDA). The CounterACT and BARDA programs operate within a highly collaborative environment that includes similar research agencies within the US Department of Defense (DOD).

COUNTERACT PROGRAM STRUCTURE

From its inception, the CounterACT program has employed a strategy of building partnerships among laboratories within industry, academic, and federal sectors. CounterACT has specifically relied on the vast experience and resources within the DOD, as it had been the primary federal agency responsible for CWA research, including countermeasure development. The program has used the expertise of researchers in chemical warfare and engaged a vast pool of NIH-funded experts in scientific areas that are very relevant to some of the central questions being posed in this field. For example, if untreated, chemical nerve agents can cause seizures and possibly neuropathological sequelae, conditions that share molecular mechanisms and phenotypes with many neurological illnesses such as epilepsy and stroke. These disorders are research areas that the NIH has supported for decades, and this has provided an unprecedented opportunity for CounterACT to engage researchers and neurologists from these fields. Similarly, the partnership between HHS and DOD facilitated by CounterACT has also led to excellent collaborations among scientists who otherwise would rarely interact. These efforts have already produced promising, novel approaches in the development of medical chemical countermeasures. Research within CounterACT has already resulted in over 600 publications in some of the most prestigious scientific journals (see www.ninds.nih.gov/counteract for more information).

The CounterACT program has supported over 60 individual research projects, multiple contracts, and at least eight different Research Centers of Excellence located at many of the top laboratories across the United States thus far. Most, if not all, of these programs have collaborations with other domestic and foreign laboratories, resulting in a large interdisciplinary and vibrant collaborative research network. This network of researchers maintains collaborative interaction by sharing new and exciting results at scientific meetings sponsored by both the NIH and international research societies, such as the Society of Toxicology, American Thoracic Society, and Society for Neuroscience. As a result, new collaborations among scientists in disciplines such as neuroscience, dermatology, and pulmonary research are formed at these meetings each year.

SCOPE OF RESEARCH

The CounterACT program focuses on basic and translational research on the development of novel therapeutics that will enhance medical response capabilities against chemical threats during an emergency. *Chemical threats* are defined as highly toxic chemicals that could be used intentionally in a terrorist attack or could be released from transportation and storage facilities after an accident or a natural disaster, causing mass casualties. The civilian threat spectrum includes not only traditional CWAs, but also thousands of other highly toxic industrial compounds and materials (TICs/TIMs). However, based on availability and the feasibility of mass exposure, the number of chemicals posing a serious threat is smaller (Figure 70.1). Some TICs/TIMs are stored at large industrial facilities and transported by rail and other means across the United States. Accidents and resulting fatalities involving human exposures to these chemicals are not uncommon (Figure 70.2). In fact, the number of annual incidents involving exposure to hazardous substances is in the thousands within the United States alone (Mannassaram et al., 2003; Broughton, 2005; Buckley et al., 2007). While CWAs are rarely implicated outside military facilities or off the battlefield, there are major exceptions, such as the terrorist attacks in Japan and the recent use of sarin in Syria.

The scope of research supported by the CounterACT program includes mechanistic research to identify targets for therapeutic development. If targets are known, the program supports the creation and development of screening assays that must be validated with appropriate pharmacology, biological activity, and other factors that increase the likelihood that candidate therapeutics emerging from the *in vitro* screening activity will be effective *in vivo*. As such, creation and validation of animal models of chemical effects on humans is a critical component of the program. The primary goal of this effort is to develop models of lethality and serious morbidity that are based on the best available data in humans. Using these models, the program supports preliminary proof-of-principle data on the efficacy of candidate

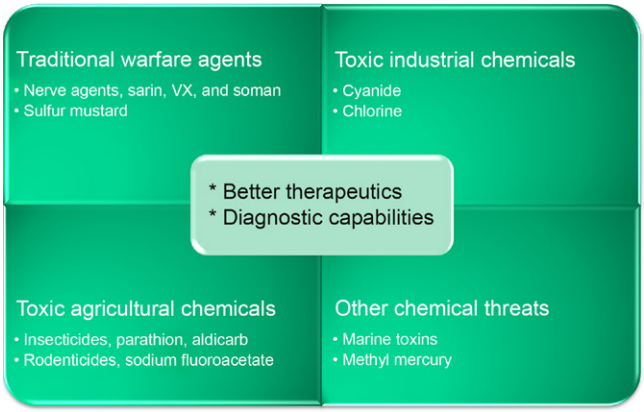

FIGURE 70.1 The civilian chemical threat spectrum, including general categories of chemical threats and some examples of chemicals within each category.

FIGURE 70.2 Train wreck and chlorine spill in Graniteville, SC, in 2005; *Source: accessed from www.cen.online.org, June 23, 2008.*

therapeutics, as well as more advanced efficacy studies and preclinical research, including safety and pharmacokinetic/pharmacodynamic studies that are necessary to obtain regulatory approval and licensure.

CounterACT not only supports the discovery of novel compounds with requisite therapeutic activity and acceptable safety profiles, but also alternate routes of administration for FDA-approved therapeutics that would be safe and effective and may be easy to administer during a mass casualty scenario [e.g., intramuscular injection (Rebmann et al., 2009)]. Although antidotes that are specific to a chemical agent are supported, the program is also very interested in developing countermeasures that can be effective against the acute effects and pathologies common to multiple chemical threat agents. This latter approach would allow the development of a therapy that can be used to treat injuries caused by a spectrum of chemical threats with common mechanisms and pathologies. Special consideration is given to research that is relevant to populations who are particularly vulnerable, including the young, the elderly, pregnant women, and individuals with preexisting medical conditions. Children and pregnant women, for example, have been shown to be much more sensitive to the toxicity of some CWAs and thus may require specialized medical management after exposure (Baker, 2007). Consequently, animal models and studies that address these vulnerabilities, as well as long-term effects after an acute exposure, are of keen interest.

THE CIVILIAN VERSUS MILITARY THREAT SPECTRUM

CWAs can generally be divided into four broad categories: traditional nerve agents, such as sarin and VX; vesicating agents, such as sulfur mustard; pulmonary agents, such as chlorine and phosgene; and metabolic poisons, such as cyanide and hydrogen sulfide. Detailed descriptions of medical interventions for each of these CWAs can be found elsewhere in this book, so they will be discussed only briefly here to illustrate the different approaches undertaken by the NIH research community to develop medical countermeasures for treating civilians.

Military research on the effects of the organophosphorus (OP) nerve agents and mustard gases has been ongoing for several decades since their discovery and use in past wars. This work, along with efforts in the nonmilitary research community, has led to the development of useful therapeutics and diagnostic tools primarily for use to protect the soldiers on the battlefield. Of particular note are the development of more effective PPE, prophylactic drugs such as pyridostigmine bromide (PB) that reversibly binds to acetylcholinesterase (AChE; Gordon et al., 2005), and portable antidote kits like the MARK-1, Antidote Treatment Nerve Agent Autoinjector (ATNAA), and Duodote autoinjectors (Henretig et al., 2002). Key differences between the civilian and military populations pose some unique challenges to researchers in this field (Figure 70.3). First, the typical soldier is fit and healthy and between the ages of 18–45, whereas the civilian demographic is much broader, including pediatric and elderly people, pregnant women, and individuals with preexisting medical conditions such as asthma, heart disease, and diabetes. These factors will be extremely important when deciding the specific type and dosage of medical countermeasures that can be administered during a civilian chemical emergency. Fortunately, some military countermeasures can be adapted to special populations such as children (Rotenberg and Newmark, 2003; Baker, 2007). However, the development and validation of good animal models

Military focus:
- Warfighter: 18–45 and healthy
- Open air environment
- High number of casualties is the goal
- Prophylactic measures is focus

Civilian focus:
- Pediatric - elderly
- Preexisting medical conditions
- Could happen in closed environment
- No need for high casualties
- Post-exposure therapies is focus
- First responders and DeCon personnel

FIGURE 70.3 Civilian and military challenges in countermeasure development.

to simulate these special segments of the population are still urgently needed.

Another important difference between the military and civilian sectors is that military officials may be able to predict with some degree of certainty when CWAs could be used, and thus equip the warfighter with pre- and post-exposure countermeasures, such as PB and Duodote kits. However, since it is nearly impossible to predict when a civilian attack may occur, the NIH has been primarily focused on treating victims after exposure to CWAs. The exception to this approach is that there is some current research into prophylactic treatments that could be administered to first-responders who must enter a contaminated site or those who must treat victims that may still be contaminated, such as healthcare providers in the emergency department.

BASIC/MECHANISTIC RESEARCH AND TARGET IDENTIFICATION

Support of basic or fundamental research efforts is an important component of the NIH mission statement (http://www.nih.gov/about/mission.htm). To that end, the CounterACT program supports basic research efforts to identify molecular mechanisms of toxicity exerted by chemical threat agents for the purpose of identifying novel therapeutic targets. For example, the program supports research into the mechanisms of nerve agent-induced seizures with respect to temporal and regional changes, roles of cardiac versus neuronal mitochondria in cyanide toxicity, or the cellular and molecular basis for agent-induced pulmonary edema. Similarly, understanding the toxicokinetics related to the different routes of exposure to chemical agents is also critical to the development of novel medical countermeasures.

Some of the most toxic chemical threat agents selectively target molecular sites and processes within the nervous system. They may bind directly to receptors or ion channel proteins, while others target metabolic enzymes. Some chemical threat agents can inhibit neuronal respiration, leading to anoxia, whereas others may produce oxidative stress, leading to cell death and neuropathological lesions. These molecular effects and the resulting signs and symptoms of toxicity depend on the level of and duration of exposure to the dose which, in the case of a terrorist attack or industrial accident, will likely be a high dose during a short period of time. Lethal exposures to the neurotoxic chemicals usually result in disruptions of critical neurological functions, such as central and peripheral control of cardiac and respiratory functions. Other serious but nonlethal effects can include seizure activity, including *status epilepticus*, paralysis, and loss of consciousness. Neurologic sequelae, sometimes occurring years after an exposure incident, may include emotional and cognitive abnormalities and weakness in the limbs (Yamasue et al., 2007).

IN VITRO AND *IN VIVO* MODELS FOR EFFICACY SCREENING

Development and validation of *in vitro* and/or animal models for rapid screening of molecular libraries to identify potential medical countermeasures is another priority of the CounterACT program. These models include nerve agent-induced seizures in small mammals, models of direct pulmonary injury from an inhaled chemical source such as sulfur mustard, animal models of cellular intoxication in the case of cyanide and sodium azide, and medium-throughput models of dermal or ocular injuries caused by vesicants like lewisite. To accelerate scientific progress and the development of new therapies, these models must also be rigorously designed (Landis et al., 2012) and be amenable to use under Good Laboratory Practice (GLP) methodology to allow regulatory review by the FDA. Since strict adherence to GLP standards may be expensive, earlier efficacy screens to identify potential hits are usually performed under non-GLP conditions.

For specialized efficacy testing, CounterACT investigators are encouraged to utilize the centralized testing facilities that the NIH has provided. One such facility is the NINDS Anticonvulsant Screening Program (ASP) at the University of Utah (http://www.ninds.nih.gov/funding/research/asp/index.htm). The NINDS ASP has screened compounds for potential therapeutic activity in the treatment of epilepsy for decades. Capitalizing on this considerable experience and the medium-throughput screening models that are already in place within the ASP, the CounterACT program has developed an additional testing arm at the ASP devoted to seizures induced by OP chemicals. This CounterACT arm aims to identify compounds for efficacy in alleviating OP-induced

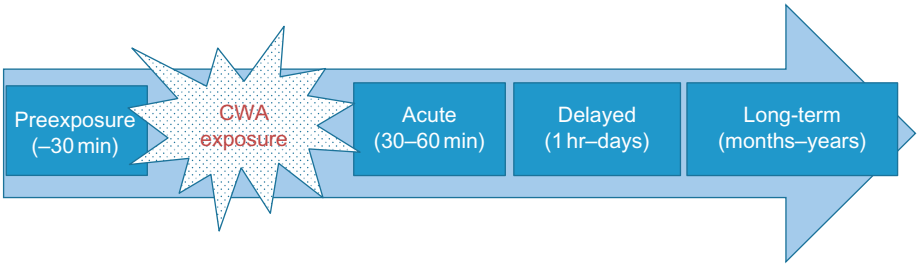

FIGURE 70.4 Timeline of morbidity progression after CWA exposure and opportunities to intervene.

seizures, as well as those that may be capable of preventing the neuropathology that could occur after nerve agent exposure.

One of the major challenges of developing an NIH program on medical chemical countermeasures is that many of the highest-priority chemical threat agents (such as OP nerve agents) are highly toxic and can be used only in approved, usually military, research facilities. Consequently, the NIH has partnered with the US Army Medical Research Institute of Chemical Defense (USAMRICD; http://chemdef.apgea.army.mil/) to conduct chemical countermeasure research against CWAs that cannot be done outside DOD laboratories and that takes advantage of the CWA research expertise within DOD.

One particular challenge for the program is to define the effects of chemical agents that are nonlethal but still represent serious morbidity, both in the short term, immediately in the aftermath of CWA exposure, and in the long term. These long-term effects could manifest immediately after the incident and last chronically for months to years afterward, or they may not develop until much later (see Figure 70.4). It is important to define these endpoints so that potential therapeutics can be tested to determine if these often-debilitating illnesses and disabilities can be prevented. As such, animal models that are predictive of these long-term effects in humans are needed to assess the efficacy of potential therapies. These models must also clearly define treatment modalities that are consistent with the context of intended use in humans, and thus should be based on the best available human data. Data from terrorist attacks is rare, fortunately, but much can still be learned from exposures that occur from industrial accidents and occupational situations.

ADVANCED PRECLINICAL DEVELOPMENT AND CLINICAL STUDIES

Once a lead compound is identified, optimization of that compound into a viable drug candidate is crucial. Using medicinal chemistry, it may be possible to optimize a compound to exhibit the best possible pharmacokinetic profile for a desired formulation and preferred route of administration. This is an iterative process that is coupled to biological assays of efficacy, safety, and pharmacokinetics. General chemistry and manufacturing support is critical once a lead compound is identified. These support activities include current Good Manufacturing Principle (cGMP)–compliant stability studies to support regulatory submission. Manufacturing processes and procedures under cGMP conditions must be developed, and reagent and clinical grade drugs must be synthesized in amounts sufficient for preclinical evaluation and Phase I and II clinical trials. The CounterACT program uses several core NIH resources, including the CounterACT Preclinical Development Facility (CPDF) discussed next, to support these preclinical activities.

The CPDF provides researchers with access to state-of-the-art resources to conduct pharmacokinetic, safety, chemistry, and formulation studies under both GLP and cGMP conditions when a lead compound is ready for Investigational New Drug (IND)–enabling studies. Alternatively, the CPDF may conduct smaller pilot studies for promising compounds that require additional characterization before further efficacy or preclinical testing. This facility and other programs under development may also support regulatory affairs on an individual basis for CounterACT investigators. For clinical trials, the CounterACT program takes advantage of other established resources at the NIH, such as the NINDS Neurological Emergency Treatment Trials (NETT) Network (http://www.nett.umich.edu/nett/welcome). The NETT conducted a Phase II/III double-blind, randomized, noninferiority clinical trial to compare the efficacy of intramuscular midazolam with that of intravenous (IV) lorazepam for children and adults in *status epilepticus* treated by paramedics (Silbergleit et al., 2011, 2012). Results of this study are of interest because they suggest that this drug may also be effective in treating seizures caused by nerve agents in adults and children.

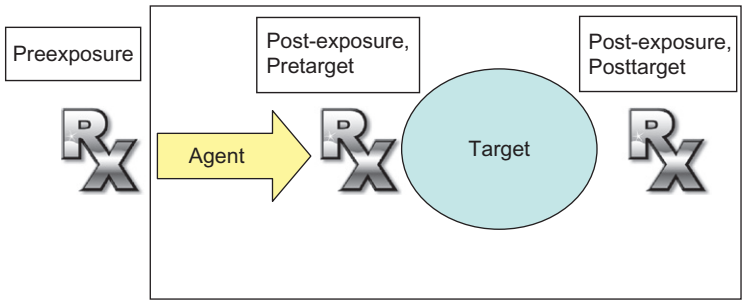

FIGURE 70.5 Different opportunities for medical intervention to reduce mortality and morbidity caused by CWAs.

PRETREATMENTS

For the purpose of this chapter, we define *pretreatments* as those medical countermeasures to be administered before CWA exposure (see Figure 70.5). Personnel who would be pretreated with medical countermeasures include first-responders, such as emergency medical technicians (EMTs) and persons responsible for site decontamination. Emergency department medical personnel, who are likely to treat individuals shortly after a chemical incident, may also require pretreatment to prevent incapacitation from exposure to residue and off-gassing of CWAs from patients. These secondary exposures could be deadly and lead to more loss of life, both during and after an event. In theory, prophylactic drugs would be administered in conjunction with proper PPE to first-responders before they enter a CWA "hot zone." However, depending on the possible adverse effects and pharmacokinetics of the proposed drugs, there may be some operational difficulties in the implementation of a prophylaxis program. For example, compliance by otherwise healthy individuals may present an issue if there are potential side effects. These potential side effects that may occur when a countermeasure is administered to otherwise normal and unexposed individuals illustrates the importance of favorable safety profiles, especially if the intended indication is for prophylaxis use. Side effects in first-responders and care providers could compromise their ability to respond effectively to chemical events involving civilians.

Another challenge for the prophylaxis approach is the time needed for the proposed drugs to achieve or maintain maximal therapeutic levels when a first-responder arrives at the contaminated site. Similarly, the half-life of the drugs must ensure lasting therapeutic efficacy to protect first-responders during the window of potential exposure. However, if these challenges can be overcome, pretreatments against the toxic effects of chemical agents for emergency first-responders would represent a significant advancement. In addition to prophylactic drugs, better dermal and ocular medical protectants should be considered for inclusion as preexposure treatments, especially for medical personnel who may have to work in areas where off-gassing may occur by individuals exposed to CWAs.

The only pretreatment currently approved by the FDA for nerve agents is PB, which was first approved for treating myasthenia gravis and is now approved for treating intoxication by soman only. It is to be used by military troops at high risk of exposure to soman on the battlefield. PB is a reversible inhibitor of AChE and protects it from permanent inhibition by soman. Since it is itself an inhibitor of the target enzyme in nerve agent toxicity, it is contraindicated after exposure, and AChE inhibition has already occurred. The US military has led the efforts to explore other potential pretreatments. One effort involves the use of serum-derived or recombinant butyrylcholinesterase (BChE) as a stoichiometric scavenger of nerve agents that could be administered as a prophylactic treatment (Lenz et al., 2007). Previous studies have shown that administering the exogenous human BChE enzyme can protect guinea pigs and cynomolgus macaques from death against extremely high doses of soman or VX (Saxena et al., 2011). The challenge with this stoichiometric approach is rapidly reaching and maintaining an effective dose when each protein molecule binds only 1 molecule of nerve agent, so another approach is being explored that adds a catalytic function to scavenger molecules (Gupta et al., 2011; Cherny et al., 2013).

POST-EXPOSURE (PRETARGET) PROPHYLACTIC THERAPIES

Most CWAs reach their physiological targets at toxic levels to cause serious illness and even fatality in only minutes after exposure. The medical intervention in this case is to reverse the toxic action at the target site immediately or treat the physiological response (symptoms) as soon as possible. Another possibility is that some CWAs may exert their toxic effects more slowly and not

reach the target site at critical levels until after a period of time. This may be due to the route of exposure, such as the relatively slower dermal route versus more rapid inhalation, or due to slower toxicokinetics and toxicodynamics. In this instance, the opportunity for medical intervention may be greater, and a post-exposure, pretarget or post-exposure prophylaxis approach would be beneficial (Figure 70.5). Under this paradigm for treating CWA intoxication, reversible cholinesterase inhibitors and scavengers may be utilized to protect peripheral AChE before the systemic concentration of irreversibly inhibited OP nerve agent–AChE reaches a critical and toxic level. Thus, higher success rates with potential therapeutics may be expected after dermal exposures to lower-volatility CWAs such as VX since there would be time to protect AChE before all the VX enters the systemic circulation (Mumford et al., 2011).

Consequently, therapeutics that detoxify or remove chemical agents from systemic circulation, such as protein scavengers of nerve agents or newer cobalamine-based molecules that bind and scavenge cyanide, show promise as well. For cyanide intoxication, the Cyanide Antidote Kit has been used for several years to remove cyanide from circulation by forming cyanomethemoglobin (using nitrites) or thiocyanate (using sulfur donors) complexes that are less toxic and more readily excreted. Hydroxocobalamin marketed as the Cyanokit is a relatively new FDA-approved product for IV treatment of cyanide poisoning. An even more effective scavenger is cobinamide, a related compound under development (Chan et al., 2010). This drug binds cyanide with very high affinity and can be administered by intramuscular injection, which would be very suitable for a chemical attack or an emergency scenario with mass casualties (Brenner et al., 2010). These drugs can be effective if they can remove cyanide before it reaches critical targets that regulate cellular respiration. Next-generation cyanide antidotes may include drugs that could preserve mitochondrial respiration via direct interaction with the targets, sulfur donors with longer half-lives, or novel nitric oxide-based approaches.

POST-EXPOSURE POSTTARGET TREATMENT

For many CWAs, there is little opportunity to medically intervene when the dose is high and rapidly delivered to the target site. In these situations, high doses of CWAs are almost always fatal. If the action at the target site does not cause immediate death, there are several strategies that can be employed to reduce the impending morbidity and lethal effects. At the molecular level, AChE reactivators such as oximes can be administered during a nerve agent exposure incident to remove the agent from the active site of AChE. Administration of oxime therapy will succeed only if irreversible covalent modification of the nerve agent–AChE complex has not occurred (a process called *aging*). Un-aged AChE enzyme is thus restored to the active state and can continue the hydrolysis of the neurotransmitter acetylcholine (ACh). This intervention was developed through an intimate knowledge of the molecular mechanism of nerve agent toxicity. CounterACT researchers are using this knowledge to develop AChE reactivators that are more effective in removing nerve agents from AChE (Topczewski et al., 2013), and also possess chemical characteristics that allow them to cross the blood–brain barrier (BBB) and enter the CNS (Kovarik et al., 2013). For further details on CWAs, AChE reactivators, and the BBB, see Chapter 49.

In cases where intricate knowledge at the molecular level is not yet available to allow reversal of the toxic action on the target, the intervention is to treat the effects of target site activation (or inactivation). For example, at sublethal doses of nerve agents, medical intervention primarily involves combating the effects of nervous system activation and cholinergic crisis. As discussed in other chapters, atropine is used to block the overstimulation of cholinergic receptors, and anticonvulsants such as diazepam are used to prevent or treat seizures. Similarly, victims exposed to a sublethal concentration of the fast-acting poison cyanide are treated with ventilation and supportive care to delay mortality and morbidity until they can be taken to medical facilities. Another important area of research is to identify new approaches to mitigate the pulmonary edema that typically develops after lung injury caused by agents such as chlorine and phosgene.

Whether there is sufficient time after an exposure to the CWA for a therapy to be beneficial depends on the initial effective dose. This determination is based on several factors, including the initial level of the agent released, proximity to the point of release, route of exposure, and duration of exposure. If the effective cumulative dose is low, the risk of an acute, life-threatening intoxication will likely not be an issue, but there is evidence that acute sublethal exposures to chemical nerve agents may be associated with long-term neurological sequelae (Yanagisawa, 2006 and chapter 4). Some agents, such as chlorine and sulfur mustard, may also cause delayed toxicity after initial exposure or long-term pulmonary effects (such as fibrosis) years later (Chen et al., 2013; Mo et al., 2013; Veress et al., 2013 and chapter 5). Therefore, medical interventions aimed at improving the long-term health outcomes of nonlethal exposures are critical. Since the immune responses observed in the pulmonary system after sulfur mustard or TIC exposure share similar characteristics, it is likely that therapeutic drugs that prevent, slow, or halt the processes of

inflammation and subsequent cellular degeneration will probably have great utility across many different types of chemical agents. Drugs such as anti-inflammatory, antioxidant, anti-necrotic/apoptotic compounds, or those that promote cell survival such as growth factors may be effective against various chemical threats that cause these pathologies.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

With the increasing threat of terrorism, the development of medical products for use in the event of a chemical attack on civilians has become a high priority. Civilian-focused research resides within the HHS, which established a program in 2006 to develop and stockpile medical products for chemical threats. This NIH strategic plan takes into account the ongoing efforts with the DOD, and it partners with laboratories already working in this area of study. Strategies for enhancing medical preparedness in civilian locations are similar to those of the military. At NIH, a broad research community that otherwise would not be involved in CWA research is being engaged to take advantage of its critical expertise in areas of scientific endeavor relevant to the civilian and military CWA research programs. The scientific approach seeks opportunities to medically intervene during the course of exposure through acute and long-term responses. Understanding long-term chronic effects after a chemical exposure is critical, especially if better acute treatments can increase survivability from an otherwise lethal exposure. With regard to these nonlethal effects, it will be critical to study the human condition of survivors of chemical exposures in order to develop animal models and other techniques for predicting the efficacy of candidate therapeutics in humans. Finally, a major focus of future research strategies will be to address the large number of chemical threats that pose a threat to national security, especially for those where little is known about their toxicity and potential therapeutic interventions.

CHAPTER

71

Pyridinium Oximes in the Treatment of Poisoning with Organophosphorus Compounds

Milan Jokanović

INTRODUCTION

Organophosphorus (OP) compounds have long been used as pesticides and have been developed into warfare nerve agents such as tabun, soman, sarin, VX, and others. Exposure to even small amounts of an OP compound can be fatal. Death is usually caused by respiratory failure resulting from the paralysis of the diaphragm and intercostal muscles, depression of the brain respiratory center, bronchospasm, and excessive bronchial secretions. The mechanism of OP poisoning involves phosphorylation of the serine hydroxyl group in the active site of acetylcholinesterase (AChE), which leads to the inactivation of this essential enzyme. As the result of AChE inhibition, the accumulation of acetylcholine (ACh) at cholinergic receptor sites produces continuous stimulation of cholinergic nerves throughout the central and peripheral nervous systems, motor convulsions, and epileptic seizures. Accumulating evidence indicates that seizure events are linked to irreversible long-term compromise of cognitive functions and alteration of CNS electrical excitability (Terry et al., 2014). Presently, therapy of acute OP poisoning includes administration of atropine as a muscarinic ACh receptor antagonist, together with an oxime, pralidoxime (2-PAM), HI-6, or congeneric bisquaternary pyridinium compounds such as TMB-4 or LüH-6 and CNS depressants such as diazepam. When administered *in vivo*, quaternary oxime reactivators largely remain in blood and peripheral tissue capable of crossing the blood–brain barrier (BBB) in small amounts and reactivating OP-inhibited brain AChE. This chapter describes the mechanisms of OP actions and the role of pyridinium oximes as AChE reactivators in the treatment of OP poisonings.

INTERACTION OF CHOLINESTERASES WITH OP INHIBITORS

The different types of cholinesterases (ChEs) in the human body are characterized by their location in tissues, substrate affinity, and physiological function. The principal ones are AChE (EC 3.1.1.7), predominantly found in the nervous system and also present in the outer membrane of red blood cells (RBC). Plasma ChEs (EC 3.1.1.8, ChE) are another group of enzymes present in plasma, liver, cerebrospinal fluid, and glial cells. Under normal physiological conditions, AChE breaksdown ACh, which is the chemical mediator responsible for conduction of nerve impulses at the sites of cholinergic transmission. Its physiological role in blood is not understood. However, ChE is also an esterase that can react in a similar way with most of the compounds that react with AChE. Although the effects of inhibition of AChE can be fatal, depending on the dose used, inhibition of ChE does not have any known consequences on normal body functions (Jokanović and Maksimović, 1997). ChE is a circulating plasma glycoprotein synthesized in the liver and does not serve any known physiological function. Recent evidence indicates that ChE may have roles in cholinergic neurotransmission, other nervous system functions such as cellular proliferation and neurite growth during the development of the nervous

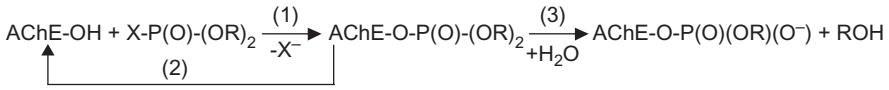

FIGURE 71.1 Interaction of acetylcholinesterase (AChE-OH) with OP compounds. Reaction 1 shows interaction of organophosphate molecule with the serine hydroxyl group at the active site of AChE. Inhibited AChE cannot further serve its physiological function, which causes the accumulation of ACh at the nerve endings. Reaction 2 is spontaneous reactivation of inhibited AChE, which occurs very slowly for most OP compounds. Reaction 3, called "aging," represents nonenzymatic time-dependent loss of one alkyl group (R) bound to the phosphorus. The aging reaction depends on the chemical structure of the inhibitor and leads to a stable nonreactivatable form of phosphorylated AChE. X indicates acyl radical (i.e., Cl^-, F^-, CN^-, *p*-nitrophenol).

system, and processes in neurodegenerative disorders (Darvesh et al., 2003).

AChE terminates the action of ACh at the junctions of the various cholinergic nerve endings with their effector organs or postsynaptic sites. In the presence of OP inhibitors, AChE becomes progressively inhibited and is not further capable of hydrolyzing ACh to choline and acetic acid (Jokanović and Maksimović, 1997). Consequently, ACh accumulates at cholinergic receptor sites and produces effects equivalent to excessive stimulation of cholinergic receptors throughout the central and peripheral nervous systems.

Both substrate and inhibitors react covalently with the esterases in essentially the same manner because of the fact that acetylation of the serine residue at AChE catalytic site is analogous to phosphorylation. In contrast to the acetylated enzyme that rapidly separates acetic acid and restores the catalytic site, the phosphorylated enzyme is stable (Figure 71.1). Inhibited enzymes can be spontaneously reactivated at different rates depending on the inhibitor; for organophosphates with branched alkyl groups such as warfare nerve agents, it may occur at a very slow rate.

The variations in the acute toxicity of OPs are the result of their different chemical structures, rates of spontaneous reactivation, and aging. An aged form of phosphorylated AChE is resistant to both spontaneous and oxime-induced reactivation. For example, when inhibited with VX, AChE in red blood cells spontaneously reactivates at a rate of approximately 1% per hour for approximately the first 48 h, whereas the VX–AChE complex ages very little during this period. The soman–AChE complex does not spontaneously reactivate because the half-time for aging is approximately 2–4 min. The half-time for aging of the sarin–AChE complex is between 5 and 12 h, depending on experimental conditions, and only approximately 5% of the enzyme undergoes spontaneous reactivation. The half-time for aging of the tabun–AChE complex is approximately 46 h (Karczmar, 1984; Sidell, 1997; Stojiljković et al., 2001; Milatović and Jokanović, 2009). For OP pesticides containing dimethyl phosphate groups, the half-time of spontaneous reactivation of phosphorylated AChE *in vitro* is approximately 1 h and the half-time of aging is 3.7 h, whereas these for diethyl phosphates are slower—approximately 31–57 h and 31 h, respectively (Worek et al., 1999; Mason et al., 2000; Eyer, 2003).

Although it has many phosphorylated AChE complexes, the aging reaction has major clinical importance and is an imperative problem, particularly in the treatment of soman poisoning. Aging with soman occurs so fast that no clinically relevant spontaneous reactivation of AChE can occur before aging has taken place. Hence, recovery of function depends on the resynthesis of AChE, which is a relatively slow process. After soman exposure, it is important to immediately administer atropine and oximes so that some extent of AChE reactivation occurs before the entire AChE has aged. Even though aging occurs slowly in the case of other warfare nerve agents and OPs, early oxime administration is of high clinical importance for treatment efficiency.

CLINICAL ASPECTS OF ACUTE OP POISONING

Signs and symptoms of acute poisoning with OPs are predictable from their biochemical mechanism of action and are directly related to the levels of AChE activity (Table 71.1). The types of effects manifested in these poisonings are muscarinic, nicotinic, and central signs and symptoms. The duration of effects is determined mainly by the properties of the compound: its liposolubility, the stability of the OP–AChE complex, and whether it is reactivatable after the use of ChE reactivators, such as oximes. It is important to note that only OPs containing the P═O bond, known as direct inhibitors, are potent AChE inhibitors, whereas those with a P═S group, indirect inhibitors, must be metabolically activated to the P═O group (Jokanović, 2001). The signs and symptoms of poisoning with direct inhibitors appear quickly during or after exposure, whereas those with indirect inhibitors appear slower and last longer, even up to several days after cessation of exposure.

TABLE 71.1 Signs and Symptoms of Poisoning with OP Compounds (Milatović and Jokanović, 2009)

Signs and Symptoms			Severity of Poisoning	Red Blood Cell AChE (% of Control)
Muscarinic	**Nicotinic**	**Central**		
Nausea, vomiting, diarrhea, salivation, lacrimation, bradycardia and arrhythmia, bronchoconstriction, bronchosecretion		Headache, dizziness, drowsiness, anxiety	Mild	>40
As above plus miotic pupils (unreactive to light), involuntary defecation and urination	Twitching of fine muscles, hyperreflexia, fasciculations	As above plus ataxia, psychosis, tremor, dysarthria, slurred speech	Moderate	20–40
	As above plus muscle weakness, reduced tendinous reflexes, paralysis affecting diaphragm and respiratory muscles	As above plus coma, convulsions, respiratory depression	Severe	<20

Clinical diagnosis is relatively simple and is based on medical history, circumstances of exposure, and the presence of clinical symptoms of poisoning. Confirmation of diagnosis can be made by measurement of red blood cell AChE or plasma ChE. Activities of these enzymes are accepted as biomarkers of exposure and/or toxicity of OPs. Red blood cell AChE is identical to the enzyme present in the target synapses and its levels are assumed to reflect the effects in target organs. Thus, RBC AChE is regarded as a biomarker of toxicity of these compounds. AChE in the brain is restored by *de novo* synthesis more rapidly than in erythrocytes, where AChE activity is recovered via erythropoiesis. The level of activity of ChE should be carefully interpreted because the normal range in healthy subjects is relatively wide, rendering interpretation in individual patients difficult unless the results of previous estimations in the patient are available. Inhibition of ChE does not provide accurate information related to the clinical severity of the poisoning. Many OP insecticides, for example, chlorpyrifos, demeton, and malathion, are apparently more potent inhibitors of ChE than they are of erythrocyte AChE and, consequently, ChE inhibition might occur to a greater extent than AChE inhibition (Jokanović, 2009).

The first 4–6 h are the most critical in acute poisoning with OP pesticides. If there is improvement in symptoms after initial treatment, then the patient is very likely to survive if adequate treatment is continued (IPCS, 1998; Jokanović, 2009). The duration of effects is determined mainly by the properties of the compound: its liposolubility, the stability of the OP–AChE complex, and whether it is reactivatable after the use of ChE reactivators such as pyridinium oximes.

The rate of spontaneous reactivation (Figure 71.1, Reaction 2) can be accelerated by pyridinium oximes that have a chemical structure that "fits" the structure of the inhibited AChE. The oximes can only be of benefit as long as inhibited AChE is not completely converted to the aged form.

ANTIDOTES IN THE TREATMENT OF OP POISONING

Atropine

Atropine acts by blocking the effects of excess concentrations of ACh at muscarinic cholinergic synapses after OP inhibition of AChE. Atropine is the initial drug of choice in acute OP poisoning that can relieve the following symptoms of OP poisoning: sweating; salivation; rhinorrhea; lacrimation; nausea; vomiting; and diarrhea. It can also help control bradycardia and circulatory depressions and dilating of the bronchi, and it can abolish bronchorrhea. Atropine does not bind to nicotinic receptors and cannot relieve nicotinic effects of OP compounds. In addition, there is evidence regarding the anticonvulsant properties of atropine in poisoning with soman and VX (McDonough et al., 1987; Zilker, 2005).

The standard dosing of atropine depends on the severity of OP poisoning. The initial dose is usually 2 mg in an adult (0.02 mg/kg in a child) administered every 5–10 min until hyperatropinization (flushing, dryness of the mouth, nose, lungs, and the skin, heart rate 80–100/min, normal blood pressure, mydriasis). The dose may be increased as required. Patients poisoned with OPs appear to be resistant to the toxic effects of atropine and may require relatively large doses of atropine administered during prolonged period of time. According to IPCS (2002) in severe OP poisoning, the total dose of atropine given during 5 weeks of treatment can be as high as 30,000 mg.

In an open-label, randomized clinical trial, Abedin et al. (2012) compared the efficacy and safety of conventional

bolus doses of atropine with individual incremental doses for atropinization followed by atropine infusion for management of OP poisoning. It was concluded that rapid incremental dose atropinization, followed by atropine infusion reduced mortality and morbidity from OP poisoning and shortened the length of the total hospital stay and recovery. They recommended that incremental atropine and infusion should become the treatment of choice for OP poisoning.

Diazepam

Benzodiazepines are CNS depressants, anxiolytics, and muscle relaxants. Their main site of action is at the gamma-aminobutyric acid (GABA) receptor. The $GABA_A$ receptor is a ligand-gated chloride ion channel and is part of a superfamily of receptors that also includes the nicotinic ACh receptor and the glycine receptor. GABA is the major inhibitory neurotransmitter in the mammalian CNS. Benzodiazepines, including diazepam, alter GABA binding at the $GABA_A$ receptor site in an allosteric fashion, but these drugs do not directly activate the receptors (Sellström, 1992; Marrs, 2004).

Currently, the most important anticonvulsant is diazepam. The combination of atropine and diazepam is more effective in reducing mortality than atropine or oxime alone. It was also shown that diazepam enhanced the efficacy of low doses of atropine. In the cholinergic nervous system, diazepam appears to decrease the synaptic release of ACh. The main consequence of the action of benzodiazepines in CNS is the hyperpolarization of neurons. This makes neurons significantly less susceptible to cholinergically induced depolarization. The ultimate result is cessation of convulsions propagation (Sellström, 1992; Marrs, 2004; Jokanović, 2009).

In patients poisoned with OPs, benzodiazepines may have a beneficial effect in reducing anxiety and restlessness, reducing muscle fasciculation, arresting seizures, convulsions, controlling apprehension and agitation, and possibly reducing morbidity and mortality when used in conjunction with atropine and an oxime. Diazepam should be given to patients poisoned with OPs whenever convulsions or pronounced muscle fasciculation are present. In severe poisoning, diazepam administration should be considered even before these complications develop. The recommended dose of diazepam in cases of OP poisoning is 5–10 mg intravenous in the absence of convulsions and 10–20 mg intravenous in cases with convulsions, which may be repeated as required (Johnson and Vale, 1992).

It appears that other anticonvulsant benzodiazepines, such as midazolam, avizafone, and lorazepam, are just as effective in stopping nerve agent–induced seizure as diazepam in a hospital setting. In animal studies, midazolam was even more effective than diazepam (Bokonjić and Rosić, 1991). FDA and the French army are considering approval of midazolam as treatment of nerve agent–induced seizures (Sidell et al., 2009; Masson, 2011; Jokanović, 2012). In addition to diazepam, Delacour and Dorandeu (2014) recommended administration of clonazepam in the management of severe OP poisoning.

Detailed therapeutic protocols used in the treatment of poisoning with OPs are presented in several excellent reviews (World Health Organization, 1986; Lotti, 1991; Bismuth et al., 1992; Johnson and Vale, 1992; Johnson et al., 2000; Marrs and Vale, 2006; Jokanović, 2009; Jokanović and Prostran, 2009; Jokanović et al., 2010; Jokanović, 2012; Balali-Mood and Saber, 2012).

Oximes

Extensive studies over the past decades have investigated the mechanism of oxime action. There is convincing evidence that the antidotal potency of oximes is primarily attributed to their abilities to reactivate the phosphorylated ChEs. Oximes reactivate phosphorylated ChEs by displacing the phosphoryl moiety from the enzyme because of their high affinity for the enzyme and powerful nucleophilicity. The rate of reactivation depends on the structure of the phosphoryl moiety bound to the enzyme, the source of the enzyme, the structure and concentration of oxime that is present at the active site, the rate of postinhibitory dealkylation known as aging, and the steric hindrance effects between oxime molecule and phosphoryl moiety attached to the active site of AChE (Jokanović and Stojiljković, 2006; Maxwell et al., 2008). Phosphorylated oximes are formed during reactivation reaction and some of them appear to be potent inhibitors of AChE (Luo et al., 1999; Ashani et al., 2003; Worek et al., 2007). It was shown that phosphorylated oximes of 2-substituted pyridinium compounds (e.g., 2-PAM, HI-6) are unstable, whereas those of 4-pyridinium aldoximes are markedly stable (Worek et al., 2000; Ashani et al., 2003; Kiderlen et al., 2005) (Figure 71.2).

Oximes bind to AChE as reversible inhibitors and form complexes with AChE at the acylation (catalytic) site, at the allosteric site, or at both sites of the enzyme and protect AChE from phosphorylation. When the reversible inhibitor binds to the catalytic site, the protection is due to direct competition between OP and reversible inhibitor. Binding of a reversible inhibitor to the allosteric site induces indirect protection of the active site. Differences in the mechanisms of enzyme reactivation and protection demonstrate how stereochemical arrangements of oximes can play a role in the potency of their therapeutic efficacy. Direct pharmacological effects, such as direct reaction with OPs (van Helden et al., 1996; Jokanović and Prostran, 2009; Jokanović, 2012) and anticholinergic and sympathomimetic effects may also be relevant for the interpretation of antidotal potency of oximes.

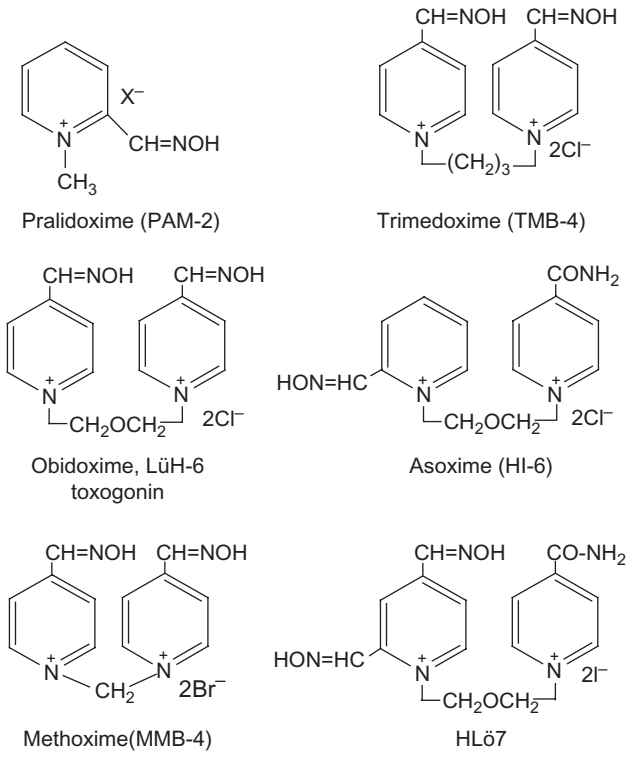

FIGURE 71.2 Chemical structure of pyridinium oximes used in treatment of OP compound poisoning. X indicates an anion (in PAM-2 it can be Cl^-, I^-, or methanesulfonate).

Mono-pyridinium and bis-pyridinium oximes are effective against OP-inhibited AChE in the peripheral nervous system (PNS) but have a limited penetration across the BBB. Limited penetration of HI-6 is due to its pharmacokinetic profile and the two quaternary nitrogen atoms in its structure. However, it appears that oxime penetration through the BBB is underestimated because soman can cause a seizure-related opening of the BBB (Carpentier et al., 1990; Grange-Messent et al., 1999) and thus enable the passage of higher oxime concentrations into the brain. Abdel-Rahman et al. (2002) have shown that 0.5–1.0x LD_{50} of sarin caused a dose-dependent increase in permeability of BBB in midbrain, brainstem, cerebrum, and cerebellum in rats 24h after poisoning. Sakurada et al. (2003) have determined the amount of 2-PAM passing across the BBB at approximately 10% of the given dose, which may be effective in reactivation of OP-inhibited AChE in brain. Obidoxime concentrations in brain were estimated to be 3–5% of plasma levels in rodents (Falb and Erdmann, 1969), and those of HI-6 were estimated to be up to 10% of the serum highest concentration (Cassel et al., 1997). Several studies (Kassa, 2002; Shrot et al., 2009) suggested that such oxime concentrations in the brain are apparently sufficient to produce biochemical and physiological effects in soman poisoning, particularly in specific brain regions, such as the medulla oblongata. These effects can contribute to survival after OP intoxication. Others claim that it is uncertain whether this amount is sufficient to reactivate nerve agent–inhibited AChE (Shih et al., 2011). When AChE reactivation was achieved in the pontomedullar region, good therapeutic effects of oximes were observed and survival of poisoned animals correlated with the AChE activity in this region (Bajgar et al., 2007). In addition, it was suggested that in pralidoxime and obidoxime penetration through the BBB, a carrier-mediated transport mechanism might be involved (Lorke et al., 2008). For further details on oximes crossing the BBB, see chapter 49.

PYRIDINIUM OXIMES IN MANAGEMENT OF POISONING WITH WARFARE NERVE AGENTS

Pralidoxime (2-PAM)

Pralidoxime was synthesized in the United States in 1955 (Wilson and Ginsburg, 1955). Its four salts, chloride (2-PAM Cl), methiodide, methylsulfate, and mesylate (P2S), were investigated and introduced into practice. 2-PAM is very effective in reactivating AChE inhibited with sarin or VX (Johnson and Stewart, 1970; Sidell and Groff, 1974; Harris and Stitcher, 1983; Mesić et al., 1991; Masuda et al., 1995; Nozaki and Aikawa, 1995), but it was not successful in the reactivation of the tabun-inhibited or soman-inhibited enzyme (Inns and Leadbeater, 1983; Koplovitz and Stewart, 1994).

Because 2-PAM, as quaternary pyridinium salt, penetrates the BBB only to approximately 10% of its blood concentration, its pro-drug pro-2-PAM (*N*-methyl-1,6-dihydropyridine-2-carbaldoxime hydrochloride), which apparently rapidly oxidizes in brain to 2-PAM, was synthesized and tested in experimental animals. Pro-2-PAM provided some reactivation of sarin-inhibited and VX-inhibited AChE in the brain, blood, and peripheral tissues of the guinea pigs, which was reflected by a limited ability to block or terminate seizures elicited by these agents. Pro-2-PAM provided marginal reactivation of blood, heart, and spinal cord AChE inhibited by cyclosarin, but it was not effective against cyclosarin-induced seizures (Shih et al., 2011). Pro-2-PAM was effective in suppression and elimination of seizures/status epilepticus in DFP-treated guinea pigs. In addition, pro-2-PAM provided a significant reduction of neurological damage in DFP-poisoned guinea pigs. In both cases, 2-PAM was ineffective (DeMar et al., 2010). Clement (1979) reported that pro-2-PAM was effective in protecting mice poisoned with DFP and sarin, but only very slightly effective against soman in guinea pigs. In summary, pro-2-PAM was not a significant improvement

over 2-PAM with regard to prophylaxis against noted OP compound. However, pro-2-PAM was less effective than 2-PAM in experimental poisoning with paraoxon in mice (Bošković et al., 1980).

When given together, atropine and 2-PAM act synergistically, involving different mechanisms; the net effect is protection/treatment of animals poisoned with very high doses of certain OPs. Studies with nonhuman primates proved that the combination of atropine and 2-PAM provided protection up to five-times the LD_{50} of all known nerve agents except soman (Stojiljković et al., 2001) and against 128x LD_{50} of paraoxon (Murphy, 1986).

2-PAM may be given by slow intravenous injection over 5–10 min, by intravenous infusion over 15–30 min, or by subcutaneous or intramuscular injection; it has also been given orally (Pralidoxime, 2009). The minimum therapeutic concentration of 2-PAM in plasma is 4 μg/mL, and this level is reached in approximately 16 min after a single injection of 600 mg 2-PAM Cl (Pralidoxime, 2007).

In the treatment of OP poisoning, atropine and 2-PAM should be given as soon as possible and maintained as long as needed. When the effects of atropine become apparent, 1–2 g of 2-PAM chloride, iodide, or mesylate should be given intramuscularly or intravenously and repeated after 1 h and then every 8–12 h if necessary. Alternatively, 2-PAM Cl may be given in an initial dose of 30 mg/kg by intravenous infusion over 20 min, or by intravenous injection over at least 5 min if pulmonary edema is present or if infusion cannot be given; the initial dose is then followed by intravenous infusion at a rate of 8 mg/kg/h (IPCS, 1998; Milatović and Jokanović, 2009; Pralidoxime, 2009). 2-PAM is relatively short-acting (the apparent half-life of 2-PAM Cl is 74–77 min) and repeated doses may be needed, especially when there is any evidence of continuous absorption of the OP compound (Pralidoxime, 2007). The treatment should be continued until no longer needed. This decision can be made on the basis of the clinical status of the patient, relatively high AChE activity in erythrocytes when compared with control values, and the absence of OP compounds and/or OP metabolites in urine (Jokanović, 2009).

In some countries, autoinjectors are available for emergency use containing 2-PAM, either alone or combined with atropine and/or avizafone, a water-soluble prodrug of diazepam (Pralidoxime, 2009). The French army is considering including water-soluble benzodiazepine midazolam in its autoinjector (Masson, 2011). Typical doses are 600 mg of 2-PAM Cl or 500 mg of 2-PAM mesylate given intramuscularly up to three times, depending on symptoms. In severe poisoning, 2-PAM may be given as a continuous infusion of 200–500 mg/h, titrated against response. A maximum dose of 12 g in 24 h has been suggested (Pralidoxime, 2009).

2-PAM has been very well-tolerated in most cases (Pralidoxime, 2007). Adverse effects of 2-PAM in volunteers include dizziness, drowsiness, blurred vision, occasional diplopia, impaired accommodation, nausea, headache, tachycardia, hyperventilation, increased systolic and diastolic blood pressures, and muscular weakness. Tachycardia, laryngospasm, and muscle rigidity have been attributed to giving pralidoxime intravenously too quickly. Large doses of pralidoxime may cause transient neuromuscular blockade (Jager and Stagg, 1958; Sidell and Groff, 1971; Eyer, 2003; Pralidoxime, 2007; Pralidoxime, 2009). Forty to 60 min after intramuscular injection, mild to moderate pain may be experienced at the site of injection. Elevations in AST and/or ALT enzyme levels in blood were observed in one out of six normal volunteers given 1,200 mg of 2-PAM Cl intramuscularly, and in four out of six normal volunteers given 1,800 mg intramuscularly. Levels returned to normal in approximately 2 weeks (Pralidoxime, 2007). 2-PAM should be used cautiously in patients with renal impairment and a reduction in dosage may be necessary. Caution is also required in giving pralidoxime to patients with myasthenia gravis because it may precipitate a myasthenic crisis (Pralidoxime, 2009).

The clinical experience with the use of 2-PAM iodide, given with atropine and diazepam, in the treatment of the victims of Tokyo sarin attack in 1995 was very favorable (Sidell et al., 2009). However, 2-PAM should not be recommended as the drug of choice for the management of poisoning with all OPs due to its lack of efficacy against tabun and soman.

Trimedoxime (TMB-4)

TMB-4 Cl_2 was synthesized in the United States in 1957 (Poziomek et al., 1958). It is the only one of the major bispyridinium oximes with a propylene bridge between the two pyridinium rings. It was shown that TMB-4 is a more potent reactivator of the DFP-inhibited AChE than 2-PAM (Hobbiger and Sadler, 1958) and better reactivator than LüH-6 in the case of the tabun-inhibited enzyme (Hobbiger and Vojvodić, 1966). TMB-4 was the first oxime that was efficient in the treatment of the animals intoxicated with tabun (Schoene and Oldiges, 1973; Maksimović et al., 1980; Bokonjić et al., 1993). It could also protect the animals poisoned with sarin or VX, but not the ones intoxicated with soman (Maksimović et al., 1980; Inns and Leadbeater, 1983; Binenfeld, 1986). Although TMB-4 was the most toxic oxime among the "great four," it was shown in mice that its LD_{50} is three-times, four-times, and eight-times less than that for LüH-6, 2-PAM, and HI-6, respectively (Clement, 1981).

Obidoxime (LüH-6, Toxogonin)

After being introduced into medical practice in 1964, obidoxime showed significant potential as an antidote

in poisonings with OPs (Erdmann and Engelhard, 1964). Given with atropine, obidoxime efficiently protected experimental animals against poisoning with tabun (Inns and Leadbeater, 1983; Maksimović et al., 1989), sarin (Inns and Leadbeater, 1983; Maksimović et al., 1989), and VX (Maksimović et al., 1989). Obidoxime was more effective than TMB-4 as an antidote against intoxication with tabun (Heilbronn and Tolagen, 1965). Similarly to 2-PAM and TMB-4, obidoxime was also inefficient in soman poisoning in mice (Maksimović et al., 1980), guinea pigs (Inns and Leadbeater, 1983), and primates (Hamilton and Lundy, 1989). Obidoxime was more efficient than HI-6 against tabun intoxication. Similarly, obidoxime was more effective as a medical countermeasure after intoxication with most ChE-inhibiting insecticides, whereas HI-6 was considered to be a better drug against soman-inhibited AChE (Aas, 2003). However, LüH6 was not a potent reactivator of tabun-inhibited human AChE (Worek et al., 2004; Lundy et al., 2011). In contrast to TMB-4, obidoxime, when administered with atropine in guinea pigs pretreated with pyridostigmine, could provide some protection against soman as well (Inns and Leadbeater, 1983).

When administered to human volunteers by intramuscular route, 5 mg/kg of LüH-6 produced a plasma concentration more than 4 mg/L, from 5 min after injection to 3 h (Sidell and Groff, 1970). Adverse effects of LüH-6 in male volunteers were described as pallor, nausea, burning sensation, headache, generalized weakness, sore throat, and paresthesia of the face (Simon and Pickering, 1976; Eyer, 2003; Marrs and Vale, 2006). Transient hepatotoxic effects of LüH-6 were reported in approximately 10% of severely poisoned patients (Marrs, 1991; Eyer, 2003).

Obidoxime can be given with atropine in the treatment of OP poisoning in a usual initial dose of 250 mg (4 mg/kg) by slow intravenous injection. This may be followed by intravenous infusion of 750 mg over 24 h, continued until the concentration of OP is below critical levels; alternatively, repeated doses of 4–8 mg/kg may be given at intervals of 2–4 h. It has also been given by intramuscular injection (Obidoxime Chloride, 2009).

Asoxime (HI-6)

The first oxime that could reactivate soman-inhibited AChE and provide at least some protection of the animals experimentally poisoned with this nerve agent was synthesized in 1966. It has been shown that HI-6 is more potent than LüH-6 and HS-6 (1-(4-hydroxyiminomethylpyridinium)-3-(4-carbamoylpyridinium)-2-oxapropane dichloride) in the protection of various rodent species from intoxication with soman (Oldiges and Schoene, 1970; Inns and Leadbeater, 1983; Mesić et al., 1991; Lundy et al., 2011), as well as sarin and particularly VX (Maksimović et al., 1980; Inns and Leadbeater, 1983). HI-6 could not reactivate tabun-inhibited AChE (Clement, 1982; Ćetković et al., 1984; Kassa et al., 2008), and it was inefficient when used as the only oxime against poisoning with tabun (Maksimović et al., 1980; Inns and Leadbeater, 1983; Mesić et al., 1991; Bajgar, 2010). However, other studies found that HI-6 can provide a similar degree of protection against tabun and soman intoxication in primates (Hamilton and Lundy, 1989). It is also suggested that sufficiently high doses of HI-6 could even protect rats from the multiple lethal doses of tabun (Lundy et al., 1989). HI-6 given with atropine protected guinea pigs from poisoning against 5x LD_{50} of soman or cyclosarin (Lundy et al., 2005). It was suggested that HI-6 is superior to the other oximes in treatment of cyclosarin-poisoned animals (Kassa, 2002).

The acute toxicity of HI-6 is the lowest among the six oximes (HI-6, 2-PAM, TMB-4, LüH-6, HLö-7, MMB-4) (Maksimović et al., 1980; Clement, 1981; Rousseaux and Dua, 1989; Bartošova et al., 2006) with LD_{50} value after intramuscular administration of 781 mg/kg in rats.

HI-6 was introduced into clinical practice in Serbia in the early 1980s. It was administered to more than 200 patients poisoned with OP insecticides and to volunteers. A clinical study with HI-6 administered intramuscularly at doses up to 500 mg in 22 healthy volunteers revealed no adverse effects. However, with patients poisoned by several OP insecticides, HI-6 provided rapid reactivation of AChE in almost all cases except in dimethoate and phosphamidon poisoning (Kušić et al., 1985; Jovanović et al., 1990; Kušić et al., 1991; Jokanović and Maksimović, 1995; Jokanović et al., 2010). Similar results regarding HI-6 tolerance were later found in a double-blind, placebo-controlled, single-dose study in 24 volunteers (Clement et al., 1995). Safety of HI-6 administration was in correlation with the recent report of Pohanka et al. (2011), who found that therapeutic doses of HI-6 are safe in dogs but 10-fold therapeutic doses can cause hyperglycemia.

Clinical studies have shown that HI-6 dosed at either 250 or 500 mg by intramuscular route reached plasma concentrations more than 4 mg/L in 4–6 min. This concentration was maintained for 125 min after the lower dose of 250 mg and 200 min after the higher dose of 500 mg (Kušić et al., 1985; Jokanović and Maksimović, 1995).

HI-6 is considered to be a very promising bispyridinium oxime in medical treatment after exposure to most nerve agents. For these reasons, HI-6 is involved in the equipment of the Czech, Slovak, Swedish, and Canadian Armies as an antidote against nerve agent intoxication (Bajgar, 2010; Masson, 2011) and is under development in other countries (Lundy et al., 2011; Masson, 2011; Jokanović, 2012). A disadvantage of HI-6 compared with

other available oximes is the lack of stability in aqueous solutions (Kušić et al., 1985; Aas, 2003).

In addition to the four pyridinium oximes that were introduced to clinical practice, the oximes HLö-7 and MMB-4 require attention after proving to be efficient against warfare nerve agents in animal studies.

HLö-7

Another important "Hagedorn oxime" (after LüH-6, HS-6 and HI-6), HLö-7, was also synthesized in Freiburg, Germany, in 1986 (Löffler, 1986). Only HLö-7 could reactivate AChE inhibited by any of the four major nerve agents *in vitro* and *in vivo* (DeJong et al., 1989; Worek et al., 1994a,b, 1995), as well as AChE inhibited by cyclosarin (Lundy et al., 1992). In addition, HLö-7 more efficiently restored the neuromuscular transmission impaired by *in vitro* superfusion of the neuromuscular preparation with tabun, sarin, soman, or cyclosarin compared with 2-PAM, LüH-6, and HI-6 (Alberts, 1990). It was found that HLö-7 induced a significant reactivation of AChE in mice diaphragms inhibited with tabun, sarin, soman, and cyclosarin (Clement et al., 1992). Both HI-6 and HLö-7 can antagonize sarin-induced hypothermia, proving that, when given with atropine, they can pass the BBB and gain access to the CNS (Clement, 1992; Clement et al., 1992). The toxicity of HLö-7 was 2.5-times higher than that of HI-6 (Clement et al., 1992). The cardiovascular tolerability of HLö-7 was similar but still not as good as HI-6, at least in anesthetized guinea pigs (Worek and Szinicz, 1993). HLö-7 appears to be more effective than HI-6 against tabun and VX poisoning and less effective against sarin, soman, and cyclosarin intoxication (Eyer et al., 1992; Lundy et al., 1992). HLö-7-induced protection against tabun poisoning in guinea pigs was significantly better compared with HI-6, whereas HI-6 was only slightly more efficient than HLö-7 in soman poisoning (Melchers et al., 1994a,b). However, Kuča et al. (2005, 2011) reported that HLö-7 was not a good reactivator of tabun-inhibited AChE *in vitro*, possibly due to the presence of the lone electron pair on the tabun amide group.

The pharmacokinetic profile of HLö-7 was similar to that of HI-6. The mean absorption half-time of HLö-7 was approximately 14 min after intramuscular administration. Maximum HLö-7 concentration in plasma was reached after 30 min, and the half-time of elimination was approximately 45 min (Eyer et al., 1992).

Methoxime (MMB-4)

MMB-4 is a structural analog of toxogonin showing potent antimuscarinic activity (Amitai et al., 1980). It is a bis-pyridinium 4,4′-bis-aldoxime first described by Hobbiger and Sadler (1959). MMB-4 is currently being proposed as a leading candidate for the replacement of 2-PAM as an oxime reactivator of nerve agent–inhibited AChE activity that can prevent lethality after warfare nerve agent exposure (Worek et al., 2010; Lundy et al., 2011; Masson, 2011). So far, the oxime MMB-4 has not undergone any clinical trials (Lundy et al., 2011).

MMB-4 was less toxic in mice (LD_{50} = 441 mg/kg, intramuscular) than obidoxime (188 mg/kg, intramuscular) but more toxic compared with HI-6 (671 mg/kg, intramuscular) (Bartošova et al., 2006). It was shown that MMB-4 was inferior to HI-6 in reactivation of peripheral AChE from soman-poisoned animals, although both oximes were better than 2-PAM. In soman-poisoned rats MMB-4 was not successful in protection or reactivation of soman-inhibited AChE (Shih, 1993). Luo et al. (2008) found that MMB-4 was not a good reactivator of soman-inhibited AChE obtained from human and three monkey species, in which it was found to be less effective compared with HI-6. This is consistent with the findings reported in other studies (Lundy et al., 2011).

MMB-4 was also less effective in reactivation of cyclosarin-inhibited rat brain AChE and sarin-inhibited human or monkey AChE compared with HI-6 (Kuča and Patočka, 2004; Lundy et al., 2011). MMB-4 was found to be a weak reactivator of tabun-inhibited human AChE (Worek et al., 2004). However, experimental data indicate that MMB-4 was superior to PAM-2 in reactivating OP-inhibited AChE and in preventing lethality in OP-poisoned animals (Worek et al., 2010). It was also reported that MMB-4 was the most effective oxime in reactivation of ChE in blood and peripheral tissues in guinea pigs poisoned by sarin, cyclosarin, VX, and VR (Shih et al., 2010). In addition, MMB-4 was reported to be a better AChE reactivator than PAM-2 in paraoxon-poisoned and methylparaoxon-poisoned rats (Petroianu et al., 2006, 2007).

PYRIDINIUM OXIMES IN MANAGEMENT OF POISONING WITH OP PESTICIDES

The efficacy of pyridinium oximes has been demonstrated in experimental conditions and in many cases of patients poisoned with OP insecticides who have been treated in European clinics. In those cases, the recommendations for 2-PAM dosing proposed by the WHO were followed (IPCS, 1998).

Contrary to these findings, reports from Asia indicate that 2-PAM treatment was not sufficiently effective in their patients. However, in their studies 2-PAM was not used as recommended by the WHO (de Silva et al., 1992; Singh et al., 1995; Johnson et al., 1996; Cherian et al., 1997, 2005). In addition, these studies were apparently poorly designed due to suboptimal dose, short duration of treatment, long delay between patient exposure, and

2-PAM administration, and with the chemical structure of OP pesticides not being taken in account (Jokanović, 2009; Jokanović et al., 2010).

A particular problem in interpreting the beneficial role and efficacy of pyridinium oximes in clinical practice is a relative lack of published data, especially those evaluated in controlled clinical trials. Studies related to the efficacy of oximes in a clinical setting showed the heterogeneity of therapeutic approaches (i.e., dose regimen, oxime choice, and final outcome of the treatment) (Jokanović, 2009).

Jokanović et al. (2010) reviewed the experience gained in clinical management of 296 patients poisoned with OP insecticides at Clinic of Toxicology of the National Poison Control Center in Military Medical Academy in Belgrade during the period from 1998 to 2007. Poisoning with dimethyl OP was confirmed in 246 patients (malathion, 153; dimethoate, 69; dichlorvos, 4; fenitrothion, 6; monocrotophos, 8), with diethyl OP in 38 patients (diazinon, 21; parathion, 9; phorate, 1; phoxim, 1; phosalone, 3; chlorpyriphos, 2; quinalphos, 1) and 12 patients in whom OP was not fully identified. The majority of poisonings (92%) was due to deliberate ingestion of OP insecticides. Accidental inhalational poisonings were registered in 3.8% patients, accidental ingestion in 4.1% patients, and there were two cases of deliberate intramuscular and intravenous application of OP. Suicidal poisonings were usually oral, and the severity of poisonings depended on the toxicity, the amount of OP insecticides taken, and the time from exposure to admission to the Clinic of Toxicology and initiation of treatment. In this study, 15.9% of OP-poisoned patients died, which was consistent with the findings of other authors (Eddleston et al., 2009) who reported case fatality generally more than 15%. Approximately 42% of the deceased patients died within 7 days, and lethal outcome occurred within hours in 18% patients due to the severity of poisoning.

In this study, 74 patients were treated with pralidoxime methylsulfate (Contrathion®). The dosage regimen for severely poisoned patients included a loading dose of 400 mg by slow intravenous infusion, subsequently 200 mg/h continuous intravenous infusion administered the first day, and continued as long as clinical signs of poisoning and OP insecticide and/or its metabolite were present in urine and blood. In moderate poisoning, 400 mg of Contrathion® was followed by 400 mg every 3–4 h. However, due to the economic crisis in Serbia, the Clinic of Toxicology did not have oxime available for several years and the patients were treated with atropine and diazepam only. In patients treated with atropine and oxime or atropine only, there were no differences in mortality. Atropine consumption was lower in the group of patients treated with an oxime, but the difference was significant only in the group of severely poisoned patients in whom it was reduced by 30%.

Eddleston et al. (2005) conducted a prospective study on 802 patients self-poisoned with chlorpyrifos, dimethoate, or fenthion. Compared with chlorpyrifos (8.0%), the proportion of fatalities was significantly higher with dimethoate (23.1%) or fenthion (16.2%) than was the proportion requiring endotracheal intubation (chlorpyrifos, 15.0%; dimethoate, 35.2%; fenthion, 31.3%). Patients poisoned by the diethyl OP pesticide (chlorpyrifos) responded well to pralidoxime, whereas those exposed to the two-dimethyl OP pesticides (dimethoate, fenthion) responded poorly. The poor efficacy of 2-PAM in the treatment of human dimethoate and fenthion poisonings was in agreement with experimental studies reported by Jokanović and Maksimović (1995), who found that the antidotal efficacy of obidoxime, trimedoxime, 2-PAM, and HI-6, when given with atropine and diazepam, in rats dosed with 2x LD_{50} of dimethoate was low. However, there was a discrepancy between fenthion-poisoned patients and animals in that 2-PAM was ineffective as an antidote in patients, whereas the four oximes showed considerable efficacy in rats.

In a randomized controlled trial, Pawar et al. (2006) studied the effects of very high doses of 2-PAM iodide (2-g loading dose, then 1 g either every hour or every 4 h for 48 h, then 1 g every 4 h until recovery) in 200 patients with moderate OP poisoning (excluding severely ill patients). The OP pesticides involved were chlorpyrifos (diethyl OP) and dimethoate (dimethyl OP). The dosing regimen was associated with reduced case fatality, fewer cases of pneumonia, and reduced time on mechanical ventilation. This study suggests that large doses of 2-PAM could have a positive effect on patients if they are treated early and have good supportive care.

An interesting clinical trial in which 2-PAM chloride was investigated in 235 patients self-poisoned with OP insecticides was reported by Eddleston et al. (2009). The patients were randomized to receive 2-PAM ($n = 121$) or saline placebo ($n = 114$). 2-PAM produced substantial and moderate erythrocyte AChE reactivation in patients poisoned by diethyl and dimethyl compounds, respectively. Mortality was insignificantly higher in patients receiving 2-PAM: 30 out of 121 (24.8%) receiving 2-PAM died compared with 18 out of 114 (15.8%) receiving placebo. The authors concluded that, despite clear reactivation of erythrocyte AChE in diethyl OP insecticide-poisoned patients, they found no evidence that treatment with 2-PAM improves survival or reduces the need for intubation in patients with OP insecticide poisoning. However, this study has a major methodological problem of randomization; the authors wrote that "more severely poisoned patients were allocated to pralidoxime" than to the placebo treatment. Based on this statement, it is expected that more patients would die in the group treated with 2-PAM. This was supported by another sentence present in this report indicating that "patients died sooner

in the pralidoxime group." In addition, there are other problems with this study, such as the lack of atropine inclusion in both groups. The World Health Organization (1986) recommends treatment of OP-poisoned patients with atropine, 2-PAM, and diazepam, and not just with 2-PAM. There also were a relatively small number of patients included in the study, relatively long and variable periods between self-poisoning and administration of 2-PAM (mean, 4.3 h; intervals, 2.9–7.8 h), which probably had an impact on aging of phosphorylated AChE, and ethical issues such as why the patients in the placebo group were allowed to die without the best possible treatment according to the WHO recommendations. Because of these and other problems, the results of this study shall be considered with caution.

Kušić et al. (1991) tested the oxime HI-6 in OP pesticide poisoning in 60 patients. HI-6 was administered four times per day as a single 500-mg intramuscular injection with atropine and diazepam treatment. Oxime therapy was started on admission and continued for 2–7 days. Most patients were treated with HI-6 and nine severely poisoned patients with quinalphos were treated with 2-PAM chloride (1,000 mg four times per day). HI-6 rapidly reactivated human RBC AChE inhibited by diethoxy OPs (phorate, pyridaphenthion, quinalphos) as well as that inhibited by dichlorvos, a dimethoxy OP. AChE inhibited with other dimethoxy OPs, dimethoate and phosphamidon, was reported to be resistant to HI-6 treatment, whereas reactivation with malathion was slow, with reactivation half-time of 10 h. Both HI-6 and 2-PAM successfully reactivated AChE in quinalphos-poisoned patients, with HI-6 acting as a faster AChE reactivator than 2-PAM.

Willems et al. (1993) reported that ethyl parathion and methyl parathion poisoning could be effectively treated with 2-PAM methylsulfate (plasma concentrations 4 mg/L) and atropine when pesticide concentrations in plasma were relatively low. In severe poisoning with pesticide levels in plasma more than 30 µg/L, high 2-PAM concentrations in plasma (14.6 mg/L) did not provide any improvement. In addition, 2-PAM at concentrations of 6.3 mg/L was not effective in AChE reactivation in dimethoate poisoning when AChE was inhibited with its active metabolite omethoate.

It was reported that in parathion poisoning, an obidoxime dose of 250 mg intravenously administered as a bolus followed by infusion of 750 mg/day was effective, but AChE reactivation after severe poisoning did not occur until the concentration of paraoxon in plasma became low (Thiermann et al., 1997, 1999). Oxydemeton methyl poisoning responded to obidoxime therapy only when the oxime was instituted soon after poisoning. In cases when obidoxime treatment was started too late, there was no reactivation of erythrocyte AChE and one out of six patients died.

Nine patients intoxicated with OP pesticides were treated with 2-PAM methylsulfate using a dose of 4.42 mg/kg as a bolus injection followed by continuous infusion of 1.14 mg/kg/h. In patients poisoned with ethyl parathion or methyl parathion, AChE reactivation could be obtained at low oxime concentrations (2.88 mg/L). In others, however, an oxime concentration as high as 14.6 mg/L was ineffective. The therapeutic effect of the oxime apparently depended on the plasma concentrations of the OP pesticides. Due to AChE reinhibition, reactivation was absent as long as these concentrations remained above 30 µg/L (Aragao et al., 1996).

In a clinical study involving 63 patients poisoned with OP insecticides, patients were divided into three groups: one was treated with atropine only and the other two received atropine and either 2-PAM or obidoxime. Initial and maintenance intravenous doses for 2-PAM were 30 mg/kg and 8 mg/kg/h, respectively; and 8 mg/kg and 2 mg/kg/h, respectively, for obidoxime. The major clinical findings or AChE activities at the time of admission did not show statistically significant differences among the groups. Although the severity of intoxications, based on respiratory complications and duration of hospitalization, was higher in the atropine plus oxime groups, 12% and 50% of patients in the atropine and atropine plus obidoxime groups died, respectively. No mortality was found in the 2-PAM plus atropine group. Incidences of recurrent twitching and convulsions, repeated respiratory arrest, requiring mechanical respiration, requiring intensive care unit therapy, and duration of hospitalization were smaller in the atropine plus obidoxime group than in the atropine plus 2-PAM group. Three of the patients who received the obidoxime combination therapy developed hepatitis and two of them died due to hepatic failure, which may indicate overdosage of obidoxime (Balali-Mood and Shariat, 1998).

In the study reported by Tsai et al. (2007), 2-PAM was administered to 56 patients within 48 h of OP pesticides poisoning. The average duration of 2-PAM treatment was 5.5 ± 4.9 days and the mean total dose was 16.4 ± 12.4 g. The mortality and length of stay did not improve with 2-PAM treatment. Days spent on ventilator support were decreased in patients treated with 2-PAM (6.7 ± 1.9 days) compared with those who were not (23.0 ± 4.8 days). However, there are many limitations in this study. For example, a relatively small number of treated patients, lack of data regarding the OP pesticides involved, dose taken, and AChE inhibition.

AChE inhibited by several OP pesticides, including dimethoate, demethon, triamiphos, ethoprophos, profenofos, fenamiphos, and pyridafenthion, was resistant to any attempt of reactivation with any oxime, probably because of the variations in phosphoryl moiety and distribution of electron charge (Bismuth et al., 1992; Jokanović and Maksimović, 1995; Jokanović, 2009; Jokanović et al., 2010; Jokanović, 2012).

Jokanović and Maksimović (1995) have studied the acute oral toxicity of 25 OP insecticides and one OP fungicide (pyrazophos) in the rat, and the efficacy of antidotal treatment involving TMB-4, LüH-6, 2-PAM, or HI-6 (given with atropine and diazepam 1 min after poisoning) in animals dosed with 2x LD_{50} of the OP insecticides. The success of therapy was dependent on the chemical structure of OPs. The oximes were potent antidotes in poisoning with the insecticides with phosphate structure and provided some extent of antidotal protection in poisoning with phosphonates, phosphorothiolates, phosphorothionates, and phosphorodithioates. However, none of them was an effective antidote against dimethoate and pyridafenthion. The study has shown that TMB-4 was the most effective pyridinium oxime in the treatment of OP insecticide poisoning.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Despite the enormous efforts devoted to synthesis and development of new pyridinium oximes as potential antidotes against poisoning with OPs in the past several decades, there were no major advances in designing compounds that would be effective against the nerve agents and other OPs. Only four compounds so far are applicable in human medicine. However, they differ in their activity in poisoning with warfare nerve agents and OP insecticides. There is still no universal broad-spectrum oxime capable of protecting against all known OP compounds.

HI-6 seems to be a promising choice for nerve agent poisoning because it was able to protect experimental animals from toxic effects and improve survival of animals poisoned with sublethal doses, especially in the cases of soman and cyclosarin. HI-6 was also effective against poisoning with OP insecticides. MMB-4 is currently being proposed as a leading candidate for replacement of 2-PAM as an oxime reactivator of nerve agent-inhibited AChE activity, that can prevent lethality after warfare nerve agent exposure. Available experimental evidence suggests that there are no clinically important differences between pralidoxime, obidoxime, and HI-6 in the treatment of nerve agent poisoning. However, obidoxime appears to be a good choice for the treatment of poisoning with OP insecticides, but it is necessary to rigorously test these statements in properly designed randomized clinical trials.

CHAPTER

72

Novel Cholinesterase Reactivators

Kamil Musilek, Jan Korabecny, Daniel Jun, Jiri Kassa and Kamil Kuca

INTRODUCTION

The continuous threat of organophosphorus (OP) nerve agent misuse supports the development of antidotes with enhanced potency. In this chapter, we are focusing on antidotal therapy with acetylcholinesterase (AChE) reactivators. Although this group of compounds has been known for more than a half-century, there is no single compound that might counteract every nerve agent's lethal effects. This chapter describes in detail the design and synthesis of the AChE reactivators that have been developed within the last two decades. Within the design of novel molecules, special emphasis is placed on the structural requirements (structure–activity relationship) of these compounds. Finally, several new trends in the development of new reactivators are discussed.

OP AChE INHIBITORS

OP compounds are widely used in agriculture as pesticides (e.g., dichlorvos, diazinon, chlorpyrifos, and parathion), industry and technology as softening agents and lubricant additives, and in the medical and veterinary fields as therapeutic agents (Gupta, 2006). Some OPs are declared as chemical warfare agents (CWAs), nerve agents, or both. Sarin, cyclosarin, soman, tabun, *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX), and Russian VX are well-known members of the OP nerve agent family (Table 72.1; Marrs, 1993; Bajgar, 2004, Gupta, 2006).

The history of nerve agents began prior to World War II in Germany. The first-known nerve agent, tabun (*O*-ethyl-*N*,*N*-dimethylphosphoramidocyanidate), was synthesized in the laboratories of IG Farben in Germany by Dr. Gerhard Schrader in 1936. Although the original aim of Schrader's studies was synthesizing pesticides, German authorities identified the deadly potential of OPs, and subsequently, many nerve agents, such as sarin, cyclosarin, and soman, were developed. A few decades later, the nerve agent VX was developed in the United Kingdom. Further-developed nerve agents include intermediate volatile agents, an example of which is Agent GP; and novichok (Figure 72.1; Halamek et al., 2007).

During the Cold War, nerve agents were stored and prepared for potential military use, but were not used in military conflicts. However, they were misused by Saddam Hussein in Iraq in the Kurdish village of Birjinni (1988) and by the Japanese Aum Shinrikyo sect in Matsumoto (1994) and Tokyo (1995; Tu, 2000).

Nerve agents phosphonylate serine Ser203 at the esteratic part of the active site of enzyme AChE (EC 3.1.1.7). AChE plays a key role in the termination of action of a neurotransmitter acetylcholine (ACh) in the peripheral nervous system and central nervous system, and persistent inhibition of AChE can lead to life-threatening consequences (Marrs, 1993).

Depending on the particular nerve agent, AChE is further irreversibly phosphorylated via a time-dependent process called *aging*, defined as dealkylation of the phosphoryl adduct to give a negatively charged adduct that is stabilized by interaction with catalytic His440 (Millard et al., 1999; Carletti et al., 2010). Aged enzymes cannot be restored by any nucleophilic reactivators. Because of the irreversible inhibition of AChE, the enzyme is not able to fulfill its physiological role in the organism—namely, splitting the neuromediator ACh at the synaptic clefts. Subsequently, ACh accumulates at the cholinergic synaptic junctions and persistently stimulates cholinergic receptors (Marrs, 1993).

The acute toxicity of nerve agents is usually attributed to excessive cholinergic stimulation caused by

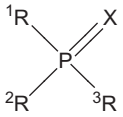
TABLE 72.1 Selected AChE Inhibiting OP Nerve Agents, Pesticides, and Prototype Compounds



Compound	1R	2R	3R	X	Class
Tabun	*O*-Et	N-Me2	CN	O	NA
Sarin	*O*-isopropyl	Me	F	O	NA
Soman	*O*-(3,3-dimethylbut-2-yl)	Me	F	O	NA
Cyclosarin	*O*-cyclohexyl	Me	F	O	NA
VX	*S*-[(2-diisopropyl)aminoethyl]	Me	*O*-Et	O	NA
Russian VX	*S*-[(2-diethyl)aminoethyl]	Me	O-isobutyl		NA
DFP	*O*-isopropyl	*O*-isopropyl	F	O	Pesticide
DDVP	*O*-(2,2-dichloroethenyl)	*O*-Me	*O*-Me	O	Pesticide
Paraoxon	*O*-(4-nitrophenyl)	*O*-Et	*O*-Et	O	Pesticide
Parathion	*O*-(4-nitrophenyl)	*O*-Et	*O*-Et	S	Pesticide

Et, ethyl; Me, methyl.

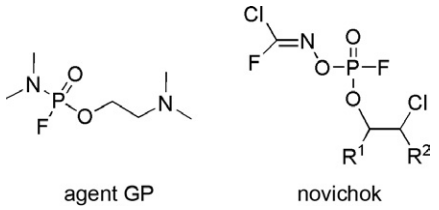


FIGURE 72.1 Proposed structure of new nerve agents (Halamek et al., 2007).

excess accumulation of ACh, followed by subsequent overstimulation of cholinergic pathways and desensitization of cholinergic peripheral and central receptor sites (Bajgar, 2004).

Symptoms of intoxication are as follows: when an individual is exposed to low amounts of a nerve agent, the initial symptoms include runny nose, contraction of the pupils, miosis, deterioration of visual accommodation, headache, slurred speech, nausea, hallucination, pronounced chest pain, and an increase in the production of saliva (muscarinic central and peripheral symptoms). At higher doses, the aforementioned symptoms are more pronounced, and coughing and breathing problems also occur. The individual may then begin to have convulsions (nicotinic symptoms) and may experience impaired ventilation, coma, and death. At even higher doses, an exposed individual would almost immediately go into convulsions and die from respiratory and cardiovascular failure. The initial stages of symptoms of an individual exposed to a nerve agent may vary depending on the particular nerve agent and amount of agent the individual was exposed to (Bajgar, 2004).

ACETYLCHOLINESTERASE (AChE; EC 3.1.1.7)

AChE is a serine hydrolase enzyme that belongs to the esterase family within higher eukaryotes. Enzymes of this family act on different types of carboxylic esters. The biological role of AChE is termination of transmission impulses at cholinergic synapses within the nervous system by rapid hydrolysis of neurotransmitter ACh. The monomer of AChE, with a molecular weight around 60,000, is an ellipsoidal molecule whose size is approximately 45 × 60 × 65 angstrom (Å), consisting of a 12-strand, central, mixed β-sheet surrounded by 14 α-helices (Sussman et al., 1991). Each monomer contains one catalytic center composed of two compartments: the esteratic subsite containing the catalytic triad and the anionic subsite that accommodates the positive quaternary compartment of ACh. In human AChE, the esteratic subsite contains the catalytic machinery of the enzyme: a catalytic triad of Ser203, His447, and Glu334. The anionic subsite is defined by Trp86, Tyr337, and Phe338. Its role is to orient the charged part of ACh that enters the active center. This role is the main function of Trp and Tyr residues (Bourne et al., 2003). The recent rendition of the X-ray structure for AChE places the active catalytic site deep within a gorgelike fold of the protein. The aromatic gorge in the protein is approximately 20 Å deep and penetrates halfway into the enzyme. The active site lies at the base of this gorge only 4 Å above the base, leading some to label this the "active gorge." The aromatic gorge is a more appropriate term because 40% of its content is composed of 14 aromatic residues, which is

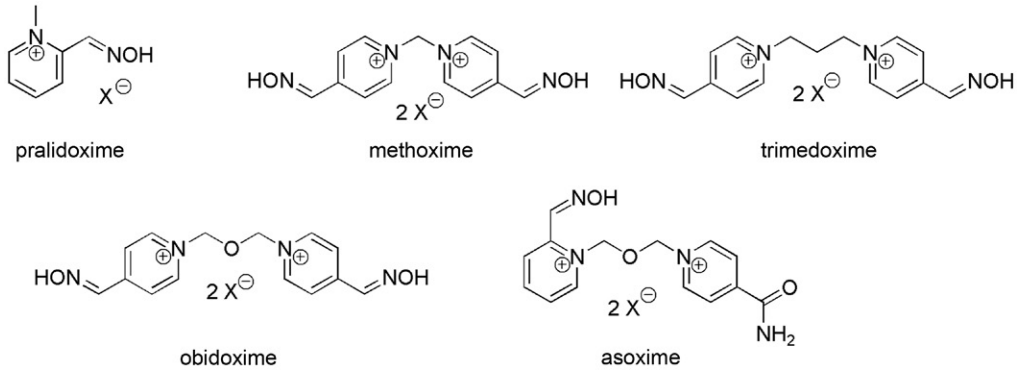

FIGURE 72.2 Standard AChE reactivators (Musilek et al., 2011a).

highly conserved from different species of AChE (Harel et al., 1993). The high aromatic content may explain studies that have proposed hydrophobic and anionic binding sites independently on the active site. Only a few acidic residues are present within the gorge. The aromatic residues play an important role in stabilization of the enzyme–substrate complex. Both electrostatic and hydrophobic effects are important here. The electrostatic potential map of AChE suggests that this enzyme, like the other enzymes with charged substrates, steers its substrate toward its gorge and into the active site.

The second anionic site of AChE, the so-called peripheral anionic site, is located at the active center gorge entry and encompasses overlapping binding sites for different activators and inhibitors. The peripheral anionic site consists of residues Tyr72, Trp286, and Tyr341. Binding of ligands to these residues may be key to the allosteric modulation of AChE catalytic activity (Bourne et al., 2003).

ANTIDOTES FOR AChE INHIBITED BY OP COMPOUNDS

Antidotes developed for treatment of nerve agent intoxication can be divided into two types: prophylaxis, as preexposure administration of antidotes; and post-exposure treatment, consisting of anticholinergic drugs, AChE reactivators, and anticonvulsants. The best-known prophylactic means are carbamates (e.g., pyridostigmine and physostigmine), oximes (e.g., asoxime and the TRANSANT patch), and scavengers (e.g., butyrylcholinesterase, paraoxonase, and phosphotriesterase). The main drugs used for post-exposure treatment are anticholinergic agents (functional antidotes) that antagonize the effects of accumulated ACh at cholinergic synapses, and AChE reactivators (called *oximes* after the functional oxime group) which restore AChE inhibited by the OP inhibitor (causal antidotes). Their effects are synergistic. Centrally active drugs such as benzodiazepines (e.g., diazepam and avizafone) are also used as anticonvulsants (Bajgar, 2004).

Pralidoxime (2-PAM; 2-hydroxyiminomethyl-1-methylpyridinium chloride), obidoxime (1,3-bis(4-hydroxyiminomethylpyridinium)-2-oxapropane chloride), methoxime (MMC-4; MMB-4; 1,1-bis(4-hydroxyiminomethylpyridinium)-methane bromide or chloride), trimedoxime (TMB-4; 1,3-bis(4-hydroxyiminomethylpyridinium)-propane bromide), and asoxime (oxime HI-6; 1-(2-hydroxyiminomethylpyridinium)-3-(4-carbamoylpyridinium)-2-oxapropane chloride) are considered the most important commercially available AChE reactivators (Figure 72.2). Other AChE reactivators are currently under development in different countries, including HLö-7 (1-[2,4-bis(hydroxyiminomethylpyridinium)]-3-(4-carbamoylpyridinium)–2-oxapropane chloride) and K027 [1-(4-hydroxyiminomethylpyridinium)-3-(4-carbamoylpyridinium)–propane bromide] (Figure 72.3).

From a chemical point of view, standard AChE reactivators are monoquaternary or bisquaternary pyridinium salts bearing a functional oxime group in their molecules. The oxime is able to split the bond between the OP and enzyme. Consequently, free-functioning AChE is released. Unfortunately, none of the abovementioned AChE reactivators is effective against all known nerve agents and OP pesticides (Table 72.2; Kuca et al., 2007a).

DESIGN AND SYNTHESIS OF NEW AChE REACTIVATORS

Nowadays, many scientific institutions around the world are interested in design, synthesis, and improvement of new antidotes against CWAs, especially nerve agents. This is because of the continuous threat of nerve agent misuse by terrorists. Finding a suitable oxime that is sufficiently effective against OP-inhibited AChE (regardless of

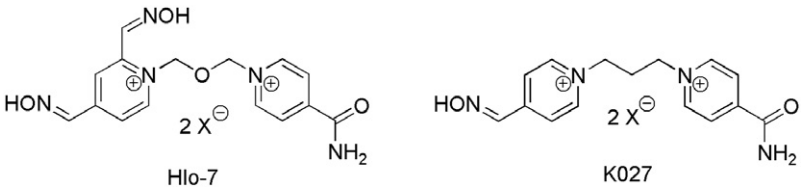

FIGURE 72.3 Selected AChE reactivators that are under development.

TABLE 72.2 Reactivation Potencies of Five Commercially Available Oximes (Kuca et al., 2007a)

	Pralidoxime	Trimedoxime	Obidoxime	Methoxime	Asoxime
VX	34/0	66/10	79/8	59/0	28/13

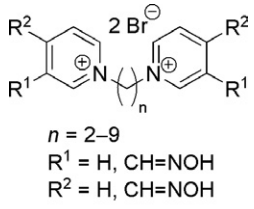
Reactivation (%) at oxime concentration 10 − 3M/10 − 5M.

the type of OP compound) is a very important task. There are several reviews dealing with the synthesis of new cholinesterase reactivators (e.g., Musilek et al., 2007a, 2011a; Mercey et al., 2012a). Several studies related to developments since 2003 in the synthesis of novel reactivators are discussed next.

Pang et al. (2003) prepared bispyridinium dicarbaldoximes (**1**; Figure 72.4) and found a new, efficient method for synthesis of bis-2-hydroxyiminomethylpyridinium salts using bistriflates as alkylating agents. Human erythrocyte AChE inhibited by echothiophate was used for *in vitro* reactivation screening. A compound with three-membered carbon linkers was the most effective from the *p*-series, and a compound with seven carbon connecting chains (called *Ortho-7*) seemed to be the most effective from the *o*-series. These results were demonstrated in the study using 3-D structures.

Kuca et al. (2003a) tried to find a reactivator K048 (**2**; Figure 72.5) with good efficacy against tabun. The *in vitro* test on rat brain homogenate showed that K048 oxime has greater reactivation ability for tabun-inhibited



1

FIGURE 72.4 Bispyridinium dicarbaldoximes (Pang et al., 2003).

AChE than pralidoxime or asoxime, and is comparable to obidoxime.

Kuca et al. (2003b) prepared a similar potential reactivator of AChE 1-(4-hydroxyiminomethylpyridinium)-3-(carbamoylpyridinium)-propane dibromide (K027; **3**; Figure 72.5) that differs from K048 in length of the connecting chain. Two synthetic pathways were used to reach the proposed structure. The activity of K027 was tested *in vitro* on sarin-inhibited AChE, with promising results.

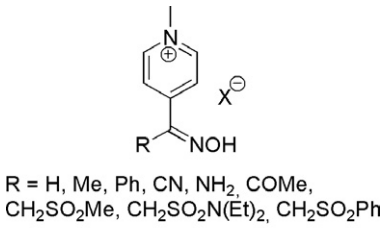

FIGURE 72.9 Structure of compounds prepared by Picha et al. (2005).

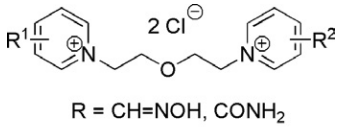

FIGURE 72.10 Structure of reactivators synthesized by Kim et al. (2006).

Kuca et al. (2004a) also synthesized and tested activity of symmetrical bispyridinium dicarbaldoximes (**4–5**; Figure 72.6) *in vitro* against cyclosarin-inhibited AChE. The compound 1,4-bis(2-hydroxyiminomethylpyridinium)butane dibromide (**4**; K033) gave promising results in *in vitro* reactivation of cyclosarin-inhibited AChE compared to commonly used pralidoxime.

In the same laboratory, a new series of four monoquaternary compounds (**6**; Figure 72.7), using the original synthetic strategy was prepared (Kuca et al., 2004b). The reactivation potency was examined *in vitro* on rat brain AChE. All tested compounds were less effective reactivators of sarin, cyclosarin, VX, and tabun-inhibited AChE than pralidoxime.

Chennamaneni et al. (2005) repeated the synthesis of oximes K027 and K048 in experiments conducted in India; moreover, they added four new reactivators derived from these compounds (**7**; Figure 72.8). Consequently, they tested their reactivation activity on tetraethylpyrophosphate-inhibited mouse brain cholinesterases. Their activities were compared to pralidoxime, and all compounds (except the one with a pentylene linker) were found to be more effective. Bispyridinium monooximes with a 3-carbamoyl group were found to be more potent reactivators than corresponding 4-carbamoyl compounds.

Picha et al., (2005) returned to monopyridinium compounds (**8**; Figure 72.9) having a hydroxyiminomethyl group with modified side-chaining, with the aim to improve the nucleophilicity of this group. From the eight oximes prepared and tested, none achieved better reactivation potency compared to pralidoxime, obidoxime, or asoxime (Picha et al., 2005; Jun et al., 2008).

In 2006, a new group of 3-oxapentane linker-containing reactivators (**9**; Figure 72.10) was prepared in South Korea (Kim et al., 2005). Among them, several analogues

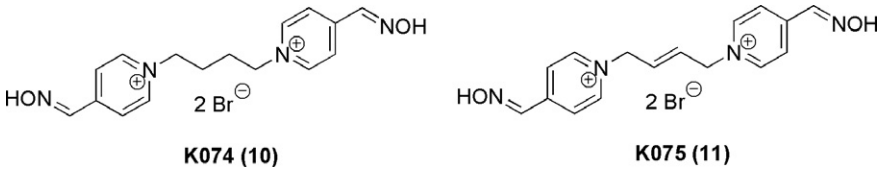

FIGURE 72.11 Structure of oximes K074 and K075 (Kuca et al., 2005a).

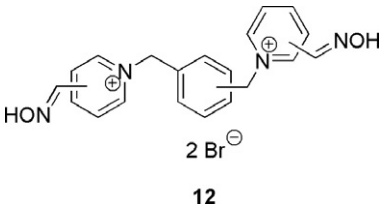

FIGURE 72.12 Structure of xylene containing linker reactivators (Musilek et al., 2005, 2007b).

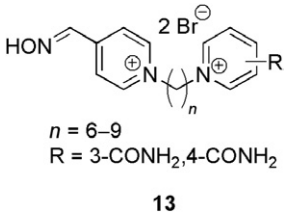

FIGURE 72.13 Structure of monooxime-carbamoyl reactivators (Srinivas Rao et al., 2006).

were found to be promising in cases of paraoxon, diisopropylfluorophosphate (DFP), and tabun-inhibited cholinesterase reactivation (Kuca et al., 2006; Kim et al., 2006).

Very promising compounds (K074-K075; **10-11**; Figure 72.11), which are being tested in many laboratories around the world, were resynthesized in 2005 in the Czech Republic (Kuca et al., 2005a). They showed very promising reactivation activity in the case of tabun and OP pesticide treatment (Musilek et al., 2007c; Lorke et al., 2008a); and this will be discussed more thoroughly later in this chapter.

A new xylene linker connecting two pyridinium rings was studied. In this investigation, 18 new oximes (**12**; Figure 72.12) were prepared and tested for their ability to reactivate tabun and pesticide-inhibited rat brain AChE (Musilek et al., 2005, 2007b; Hrabinova et al., 2006). Several compounds were found to be more promising against tabun, VX, and chlorpyrifos than five commercially available reactivators *in vitro*.

Srinivas Rao et al. (2006) prepared four new series of nonsymmetrical bisquaternary monooximes (**13**; Figure 72.13) with the aldoxime group in position 4 at the pyridinium ring and carbamoyl group in positions 3 and 4 at the second pyridinium ring. This was a follow-up to a similar study done by this group in 2005. The main difference from their previous results was change in the length of the connection chain between two pyridinium rings. Length consisted of six to nine methylene groups. The ability of tested compound to reactivate tetraethylpyrophosphate-inhibited AChE on mouse brain was compared to pralidoxime, and it was found that reactivators with increased linker lengths (from seven to nine methylene groups) potentiated the inhibitory effect of OP.

Musilek and colleagues changed regular connection chains between two pyridinium rings (*n*-methylene or 2-oxapropane) and but-2-ene. When considering steric rearrangement of the but-2-ene linker, there could be two possible geometrical isomers (*E* and *Z*). Both linkers in bisoxime reactivators were used (**14–15**; Figure 72.14). They were tested for reactivation of tabun- and OP pesticide–inhibited AChE. From obtained results, several candidates were considered promising for further evaluation of their reactivation ability (Musilek et al., 2006a–c, 2007e).

Monoquaternary pyridinium compounds with the oxime group in various positions (**16**; Figure 72.15) were prepared with bisquaternary ones (**17**; Figure 72.15) connected via a propane linker. Their reactivation ability was tested on tabun- and OP pesticide–inhibited cholinesterases. As predicted, trimedoxime reached the best activity compared with other oximes synthesized throughout the study (Musilek et al., 2006b,c).

A group of South Korean scientists prepared new oximes with a novel linker having two oxygen atoms in its structure (**18**; Figure 72.16). Their reactivation ability was tested on rat brain homogenate inhibited by agent VX. 1,6-bis(4-hydroxyiminomethylpyridinium)-2,5-dioxahexane dichloride was the most potent and appeared to be the most promising compound as a potential reactivator for AChE inhibited by VX agent. Prepared oximes were tested on housefly AChE and bovine red blood cell AChE inhibited by DFP and paraoxon. In the case of OP pesticide–induced AChE inhibition, the abovementioned oxime achieved promising results (Oh et al., 2006; Yang et al., 2007). Acharya et al. (2008) prepared many other compounds with similar structure. The whole set consisted of 11 compounds that differ in the lengths of their connection chains and positions of oxime groups. They were tested on electric eel AChE inhibited by sarin. Two promising oximes were found that should be considered for further investigation.

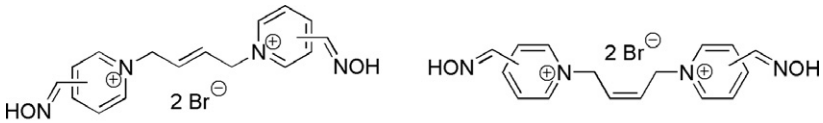

FIGURE 72.14 Oximes with but-2-ene linker in their structure (Musilek et al., 2006a–c, 2007d).

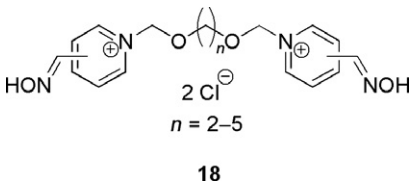

FIGURE 72.16 Structure of oximes prepared in South Korea and India (Oh et al., 2006; Yang et al., 2007; Acharya et al., 2008).

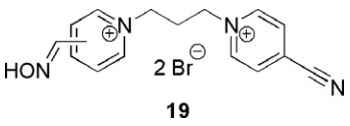

FIGURE 72.17 Structure of oximes with nitril moiety (Musilek et al., 2006d).

Musilek et al. (2006d) prepared bisquaternary reactivators with a carbonitril group instead of the carbamoyl group (**19**; Figure 72.17), which is present in the structure of asoxime, K027, or K048. Only one analogue seemed to be promising against paraoxon-inhibited AChE. None of the tested compounds were able to satisfactorily reactivate tabun-inhibited AChE.

Because asoxime is considered the first choice reactivator, there have been many efforts to improve the way it works. One approach is the choice of the right counteranion in the molecule of reactivator. The anion could influence solubility and stability of the reactivator in solution. In 2007, 12 different salts of asoxime (acetate, bromide, chloride, iodide, maleinate, malonate, mesylate, phosphate, salicylate, sulfate, tartarate, and tosylate) were prepared and tested to evaluate how the anion influences the reactivation process. It was found that there is no difference in reactivation of cyclosarin-inhibited AChE by varying the counteranion (Kuca et al., 2007b).

Because of the presence of promising oximes among those with but-2-ene linker, this pharmacophore was introduced into several other compounds with an oxime group in position 4. Other functional groups were introduced in position 4 at the second pyridinium ring (**20**; Figure 72.18). Thanks to this structural combination, many new promising oximes were found (Musilek et al., 2007f). Among them, oxime K203 (**21**; Figure 72.18) seemed to be the best choice for tabun poisoning. According to the current body of knowledge, it is considered best in terms of reactivating tabun-inhibited AChE (Musilek et al., 2007g).

Because of this promising efficacy, many other compounds with the oxime group on the first pyridinium ring and the carbamoyl group on the other ring were prepared (**22**; Figure 72.19). Among them, no better reactivator of tabun-inhibited AChE was found compared to K203. However, many other promising oximes for treatment of paraoxon-inhibited AChE were investigated (Musilek et al., 2008).

Another five monoquaternary oximes were prepared and tested in Croatia by Odzak et al. (2007) (**23**; Figure 72.20). All oximes reversibly inhibited human AChE. All prepared oximes achieved reactivation of tabun-inhibited AChE within 24 h from 30% to 80% (Odzak et al., 2007).

A South Korean group published a study of synthesis and *in vitro* evaluation of several structurally different cholinesterase reactivators (**24–26**; Figure 72.21). Two from this series (**24**) had already been explored (Pang et al., 2003; Oh et al., 2008). Two other oximes (**25–26**) are very interesting when blood–brain barrier (BBB) penetration is considered. They have either no quaternary nitrogen or only one, where the second ring possesses the tertiary nitrogen without charge. Unfortunately, this structure modification decreased reactivation potency (Oh et al., 2008).

Ohta et al. (2006) published a study of a large group of monoquaternary reactivators (**27**; Figure 72.22) differing in positions of the oxime group and lengths and shapes of their alkylating moiety. Subsequently, Okuno et al. (2008) examined BBB penetration of selected reactivators using *in vivo* rat brain microdialysis with liquid chromatography–tandem mass spectrometry (LC–MS/MS). Increased BBB permeability of modified reactivators was proven, but increased toxicity based on LD_{50} was also found.

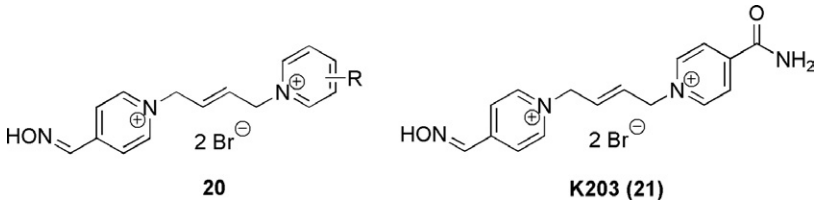

FIGURE 72.18 Structure of promising oximes with but-2-ene linker (Musilek et al., 2007e,f).

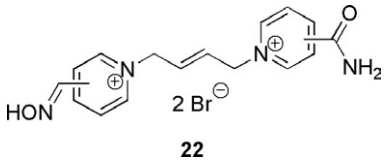

FIGURE 72.19 Analogues of oxime K203 (Musilek et al., 2008).

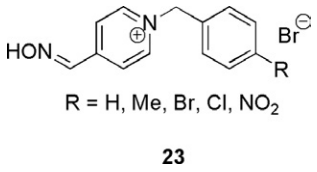

FIGURE 72.20 Monoquaternary reactivators synthesized in Croatia (Odzak et al., 2007).

Other, more recent synthetic results were achieved by Acharya et al. (2008, 2009a,b). The findings of Acharya et al. (2009a) focused on the same topic previously studied by other investigators (Musilek et al., 2005, 2007b; Hrabinova et al., 2006; Acharya, 2008)—namely, a synthesis of series of bispyridinium oximes connected by a xylene linker (**12**; Figure 72.12). The synthesized compounds were tested for their reactivation of sarin-inhibited electric eel AChE. Acharya et al. (2009b) described the synthesis of unique compounds (**28**; Figure 72.23) having *para* and *meta*-xylene, *E*-but-2-ene, and but-2-yne structural motifs in their structure. All these compounds were tested on electric eel AChE inhibited by DFP. Unfortunately, none of the newly prepared compounds could surpass pralidoxime activity.

Jeong et al. (2009) synthesized fluorinated reactivators (**29–30**; Figure 72.24) to increase their BBB penetration. For housefly AChE, some fluorinated compounds turned out to be potent reactivators of paraoxon-inhibited enzyme. BBB penetration was examined only via quantum mechanical calculations that supposed increased lipophilicity of prepared compounds.

Monooxime-monocarbamoyl bispyridinium xylene-linked reactivators (**31**; Figure 72.25) were prepared by Musilek et al. (2010). The compounds were evaluated on the tabun- and paraoxon-inhibited AChE. Compounds did not exceed previously known data for tabun reactivation, but they showed some promising results for paraoxon inhibition. The molecular modeling studies were used to rationalize their binding with active sites of OP-inhibited AChE. Decreased toxicity of prepared compounds (based on LD_{50}) compared to similar bisoximes was proven.

Monooxime bisquaternary reactivators with prop-1,3-diyl linkage and varying moiety on a non-oxime aromatic ring (**32**; Figure 72.26) were prepared by Musilek et al. (2011b). The compounds were examined on tabun- and paraoxon-inhibited AChE. Some of them showed promising reactivation ability for both used OPs. *In vitro* and molecular modeling studies highlighted the previously known oxime K027.

An experiment by de Koning et al. (2011a,b) pioneered a new approach to reactivator development. The chosen peripheral site ligand (PSL) was attached to quaternary pyridinium oxime or non-quaternary keto-aldoxime via an oligo-ethylene glycol linker (**33–34**; Figure 72.27). The prepared compounds did not show promising reactivation ability in case of sarin-, VX-, and tabun-inhibited human AChE compared to commercial standards.

A library of novel AChE reactivators based on imidazole aldoximes and *N*-substituted 2-hydroxyiminoacetamides (**35–36**; Figure 72.28) was screened by Sit et al. (2011). Compounds were screened for reactivation of sarin-, cyclosarin-, VX-, and paraoxon-inhibited human AChE. Reactivators exhibited reactivation activity that was comparable or greater than that of pralidoxime, monoisonitrosoacetone (MINA), and 2,3-butanedione monooxime. Unfortunately, standard substances used in this field (i.e., obidoxime and asoxime) were not compared in this study. More recently, some oximes from this library were tested against tabun-inhibited human AChE (Kovarik et al., 2013). Some selected compounds were able to reactivate tabun inhibition with a performance comparable to pralidoxime, but they were not as effective as the bisquaternary standards trimedoxime and obidoxime. Radic et al. (2012) published presented pyridinium and non-pyridinium oxime reactivators derived from pralidoxime and edrophonium (**37–39**; Figure 72.29). Compounds were tested on cyclosarin-, VX-, and paraoxon-inhibited human AChE and BChE and compared to pralidoxime and asoxime. Some novel compounds were found to be better reactivators than

pralidoxime, but none of them had better reactivation than asoxime. Some reactivators, together with hBChE injection, improved survival rate of mice intoxicated by sarin and paraoxon.

Kalisiak et al. (2011) introduced amidine oximes (**40**; Figure 72.30) as non-quaternary reactivators. Prepared compounds were tested on human AChE or BChE inhibited by nerve agent– and OP-pesticide model compounds. Novel molecules responded better to non-quaternary oxime MINA, but were worse reactivators than pralidoxime. Kalisiak et al. (2011) prepared cyclic amidine oximes (**41**; Figure 72.30) in a study meant to be an improvement of the previous investigation. The prepared compounds were tested on human AChE- or BChE-inhibited by nerve agent– and OP-pesticide model compounds. Some compounds performed better than MINA or pralidoxime, but bisquaternary standards were not compared in this research. Ongoing research efforts are focused on searching for more convenient PSLs attached to 3-hydroxy-2-pyridinealdoxime moiety that could serve as possible nucleophilic agents and allow preparation of non-quaternary reactivators (Dale and Rebek, 2009; Louise-Leriche et al., 2010; Saint-Andre et al., 2011).

Mercey et al. (2011) prepared two reactivators with 3-hydroxy-2-pyridinealdoxime moiety attached to phenyltetrahydroisoquinoline PSL (**42**; Figure 72.31). Both compounds were tested on human AChE inhibited by VX or tabun, and they were compared to asoxime, obidoxime, and trimedoxime. Reactivation of novel non-quaternary compounds was found to be comparable to existing standards for both nerve agents. Mercey et al. (2012b) broadened the oxime pool with nine phenyltetrahydroisoquinoline conjugates (**43**; Figure 72.32). These novel compounds were tested on tabun-, VX-, and paraoxon-inhibited human AChE. The prepared compound showed increased reactivation potency that was better than or comparable to pralidoxime, asoxime, obidoxime, and trimedoxime.

A series of seven novel, uncharged compounds (Renou et al., 2013) combining 3-hydroxy-2-pyridinealdoxime with different PSLs was prepared and examined for VX- and tabun-inhibited human AChE (**44**; Figure 72.33). Concerning *in vitro* reactivation of VX-hAChE, they were more efficient than pralidoxime, but less efficient than obidoxime and asoxime. Regarding tabun-inhibited AChE, only one compound reached a reactivation potency comparable to pralidoxime.

IN VITRO EVALUATION OF SELECTED AChE REACTIVATORS

There are many available techniques to evaluate the reactivation activity of structurally different AChE reactivators (Holas et al., 2012). Probably the most frequent are Ellmann's method (Ellman et al., 1961) and the potentiostatic method (Kuca and Kassa, 2003). Each of these has its advantages and disadvantages. For instance, Ellmann's method uses acetylthiocholine, rather than natural substrate ACh, while the potentiostatic method takes a lot of time and materials.

Although results obtained by both methods are proportionally comparable, due to the influence of structural moieties on final reactivator activity, only one method should be used. Among various scientific groups focused on ChE reactivation, both methods are extensively used. Moreover, species differences in reactivation should be taken into account (Kuca et al., 2005b; Worek et al., 2011). It is difficult or impossible to compare all results among various scientific groups.

TABLE 72.3 Reactivation Ability Influenced by Oxime Group Number and Position

Structure	Reactivation Potency (%)		Structural Factors			
	10^{-5} M	10^{-3} M	No. oxime Groups	Oxime Group Position	Linker Length	No. Quaternary Nitrogen
	9	80	1	2	–	1
	3	0	1	3	–	1
	0	7	1	4	–	1
	6	19	2	2,2′	3	2
	1	16	2	3,3′	3	2

	10	24	2	2,2′	4	2
	0	6	2	3,3′	4	2
	30	50	2	4,4′	4	2

Source: Source of enzyme—rat brain homogenate; OP inhibitor—chlorpyrifos; time of inhibition—30 min; time of reactivation—10 min; pH 7.6; 25°C; oxime concentrations 10 − 5 M and 10 − 3 M (Racakova et al., 2006).

All results considered in the structure–activity relationship discussed next are trying to compare results obtained in different groups with different methods on different cholinesterase species.

THE STRUCTURE–ACTIVITY RELATIONSHIP OF ACHE REACTIVATORS

Five important structural factors influence the affinity of AChE reactivators toward inhibited AChE: (a) presence of the oxime group; (b) position of the oxime group at the aromatic ring; (c) number of oxime groups in reactivator structure; (d) length and shape of the linker between aromatic rings; and (e) presence of quaternary nitrogen in reactivator molecule.

Presence of the Oxime Group in Reactivator Structure

The presence of the oxime group in the structure of the reactivator is a substantial structural factor. Hydroxyiminoacetones, hydroxamic acids, geminal dioles, and ketoximes used to be prepared as potential nucleophilic agents for breaking the bond between inhibitor and enzyme (Heath, 1961; Picha et al., 2005). The aldoxime group seems to be used predominantly these days, and it is involved in all newly synthesized AChE reactivators (see the section "Design and Synthesis of New AChE Reactivators," earlier in this chapter).

The oxime group in the human body dissociates to oximate anion, which acts as a nucleophilic agent and cleaves the bond between the enzyme and phosphorus atom of the OP inhibitor (Heath, 1961; Bajgar, 2004).

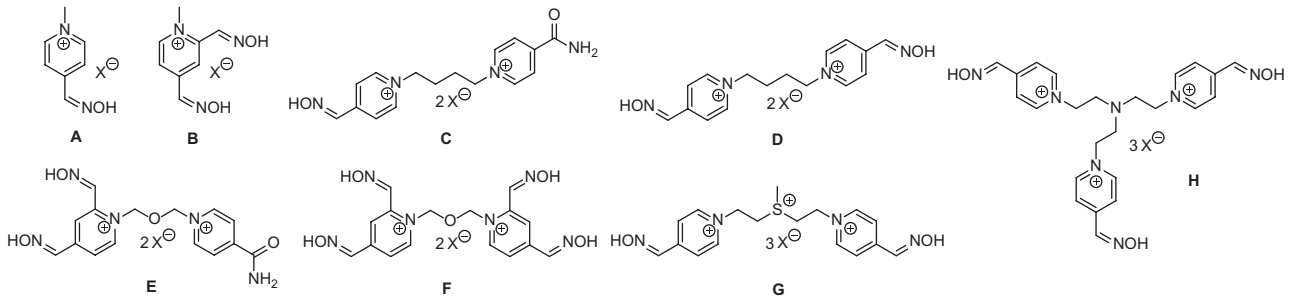
Position of the Oxime Functional Group

The other important structural factor is the position of the oxime group at the aromatic ring. As can be seen in Table 72.3, there are significant differences in reactivation potency of oximes regarding the oxime group position.

There is no applicable rule for oxime position in terms of the ability to reactivate all OP-caused AChE inhibitions. The general finding is that reactivators containing the oxime group in positions 2 and 4 are more effective compared to oximes in position 3, and the reason for that is the difference in pK_a between the number of oximes in positions 2 and 4 (usually between 7 and 9) versus those in position 3 (usually over 9).

Although the rule governing the oxime position for all nerve agents is unrealistic, position of the oxime group and nerve agent being counteracted are related in many ways. It means that the position of the oxime group depends on the nerve agent in question, as well as the length of connecting chain between aromatic rings. For example, cyclosarin-inhibited AChE is properly reactivated by compounds with oxime in position 2 (Kuca and Patocka, 2004). Very good reactivation ability of sarin- and VX-inhibited AChE has been found with oxime groups in positions 2 and 4 (Kuca et al., 2005c,d). On the other hand, reactivators with the oxime group in position 4 are currently considered the most potent for reactivation of tabun-inhibited AChE (Musilek et al., 2007g). Also, OP pesticide–induced poisonings are best treated with AChE reactivators with an oxime at position 4 (Worek et al., 1996; Musilek et al., 2011a). In contrast, uncharged reactivators with oxime in position 2 (Mercey et al., 2011, 2012b) seem to overcome their dependence on tabun- and OP-pesticide reactivation on four-positioned oxime.

TABLE 72.4 Structurally Different Reactivators with Different Amount of Oxime Groups



Compound Type	Reactivation Potency (%)		Structural Factors	
	10^{-5} M	10^{-3} M	No. Oxime Groups	No. Quaternary Nitrogen
A	0	6	1	1
B	0	2	2	1
C	6	25	1	2
D	15	45	2	2
E	2	3	2	2
F	0	1	4	2
G	0	9	2	3
H	0	2	3	3

Source: Source of enzyme—rat brain homogenate; OP inhibitor—tabun; time of inhibition—30 min; time of reactivation—10 min; pH 7.6; 25°C; oxime concentrations 10 − 5 M and 10 − 3 M (Cabal et al., 2004).

Number of Oxime Groups in the Reactivator Molecule

The number of oxime groups in the reactivator molecule is the other structural requirement that needs to be discussed. One molecule of AChE reactivator can contain one, two, three, or four oxime groups with none, one, two, or three quaternary nitrogen in one molecule. Examples of different structures with one, two, three, or four oxime groups are shown in Table 72.4.

As can be seen from Table 72.4, the number of oxime groups does not increase reactivation ability of the potential AChE reactivator. This fact could be connected to increased size of reactivator molecule and limited binding in the AChE active site. Based on this finding, the main role in the reactivation process appears to involve just the first oxime group (with the proper pK_a). Presence of the second or additional oxime group is not necessary for quaternary or uncharged reactivators (Mercey et al., 2011; Musilek et al., 2011a).

Length and Shape of the Linker Between Aromatic Rings

The length of connecting chain between both aromatic rings (for bisquaternary pyridinium as well as uncharged reactivators) plays an important role in potency to reactivate nerve agent–inhibited AChE (Kuca et al., 2003c; Pang et al., 2003; Renou et al., 2013). For *n*-methylene linkage chains, there exists a dependence between length of the connection chain and nerve agent used for inhibition, as shown in Figure 72.34 (Kuca et al., 2003c).

As the figure shows, ideal length of the reactivator linker in bisquaternary oximes for satisfactory activity of tabun-, sarin-, or VX-inhibited AChE is three or four methylene units. On the other hand, one methylene group seems to be the most potent reactivator of cyclosarin-inhibited AChE.

Unfortunately, this rule is satisfied just in the case of *n*-methylene linkage chains and oxime groups in position 4 at the pyridinium ring. Compounds with oxygen, sulfur, and other structural fragments incorporated into the connection chain and with different positions of oxime groups do not fulfill these criteria (Pang et al., 2003; Musilek et al., 2005, 2006a; Oh et al., 2006; Acharya et al., 2008). These variances could be caused by presence of π-electrons or free electron pairs in the connection chain, and subsequent interactions of reactivator molecule with enzyme amino acid residues taking place.

An important structural factor influencing the reactivation process could also be rigidity of the linking chain. Owing to rigidity of the connection chain, the spatial

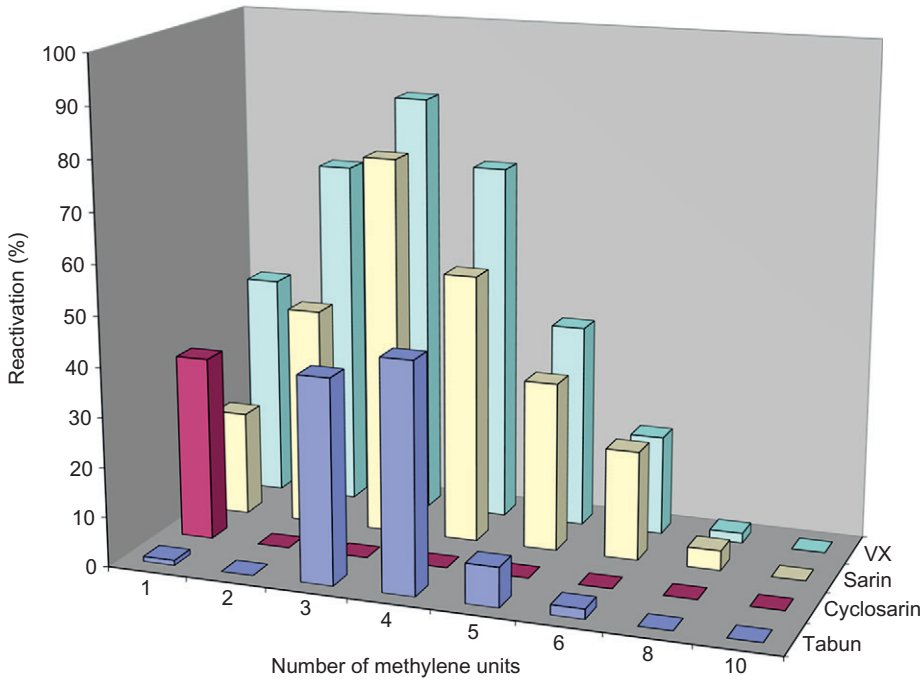


FIGURE 72.34 Dependence of reactivation ability on methylene linker length (Kuca et al., 2003c).

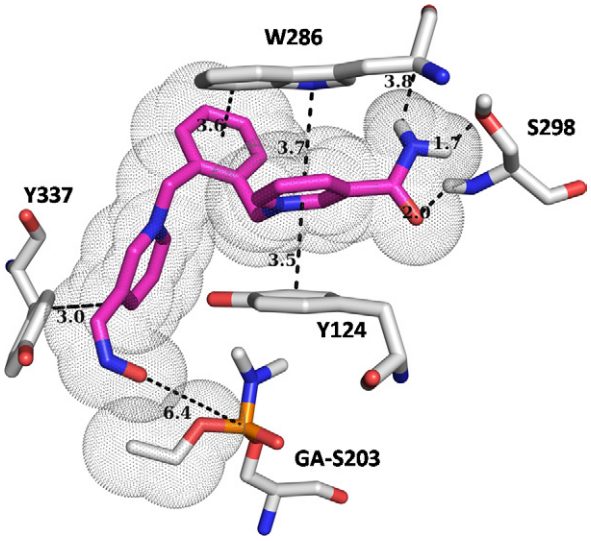

FIGURE 72.35 A spatially rigid linker in the reactivator molecule (Musilek et al., 2010).

orientation of pyridinium rings in the enzyme cavity is limited. Compounds with a certain level of rigidity in the connection chain were synthesized with the aim of elucidating the influence of rigidity on reactivation ability. *Z*- and *E*-but-2-ene and *ortho*-, *meta*-, *para*-xylene moieties were inserted into the linker (Musilek et al., 2005, 2006a, 2007d, 2010). In Figure 72.35, spatial orientation of the reactivator with the rigid linker is shown (Musilek et al., 2010).

Presence of Quaternary Nitrogen in the Reactivator Structure

It is generally known that the anionic center of AChE binds the charged quaternary group of choline moiety of ACh, bisquaternary AChE reactivators (Kuca et al., 2004c), as well as other uncharged ligands, including nonquaternary reactivators (de Koning et al., 2011a,b). Owing to the presence of quaternary nitrogen in the structure of AChE reactivator, quaternary oximes have an increased affinity for both intact and inhibited AChE. In fact, this structural feature allows the molecule of AChE reactivator to enter the enzyme cavity. In contrast, it has been shown that uncharged reactivators with PSL in their molecule may also have an increased affinity for inhibited AChE (Mercey et al., 2011, 2012b).

There has been some interest in the penetration of the quaternary charged compounds (especially AChE reactivators) through the BBB. The partial ability of monoquaternary (Sakurada et al., 2003; Petroianu et al., 2007a) and bisquaternary (Lorke et al., 2007) oximes to penetrate the BBB was published. *In vivo* reactivation of nerve agent–inhibited brain AChE has been determined many times in the past, and this topic is well described in Bajgar et al. (2007) and Lorke et al. (2008b). Commonly used AChE reactivators have one or two quaternary nitrogen in their molecules (e.g., pralidoxime or asoxime). According to our results, affinity of bisquaternary oximes for intact and inhibited AChE is generally higher than monoquaternary ones (Kuca and Kassa, 2004).

Uncharged reactivators were proven to cross BBB more readily than quaternary oximes (Okolotowicz et al., 2014). However, most of them also had poor reactivation ability, increased AChE inhibitory ability, low solubility, and questionable toxicity. The lack of quaternary moiety is responsible for these failings. These findings limit practical use of these compounds and need to be clarified by further development of uncharged oximes. Nevertheless, these uncharged oximes have great potential, so they merit future investigation.

PROMISING OXIMES

Along with those AChE reactivators that are commercially available (namely, pralidoxime, trimedoxime, methoxime, obidoxime, and asoxime), there are several oximes that are seen as promising.

We can also consider development of the new reactivator salt (the known reactivator with a novel counteranion) as the new compound. Asoxime dimethanesulfonate is probably the leading oxime under development in many countries because of its superior stability and solubility compared to asoxime dichloride. It is well known to be a broad-spectrum reactivator for all nerve agents except tabun (Lundy et al., 2006).

In the Czech Republic, great efforts have been focused on the development of new reactivators for use in cases of tabun poisoning. During the last 5 years, three new generations have been prepared. The best reactivators of the first generation (i.e., K027 and K048) are currently being tested in many countries because of their extraordinary potency and low toxicity (Calic et al., 2006; Benko et al., 2007). Subsequently, the second generation of these drugs was developed; among tested compounds, oximes K074 and K075 were recommended as the best. However, their excellent reactivation activity was counteracted by their increased toxicity, so they were excluded from further investigation (Kuca et al., 2007c; Kassa and Humlicek, 2008). Currently, the best third-generation oxime for tabun-inhibited AChE seems to be K203 (Musilek et al., 2007g; Kassa et al., 2008). Except for the promising results of developed oximes obtained with tabun, these oximes seem to be satisfactory in case of OP pesticide poisoning as well (Petroianu et al., 2006a,b). Among them, K027 was tested in the United Arab Emirates as the best oxime (compared with obidoxime, trimedoxime, pralidoxime, and HI-6) against pesticides (paraoxon, methylparaoxon, and DFP) both *in vitro* and *in vivo* (Petroianu et al., 2007b).

Efforts are still being made to compare oxime HLö-7 with asoxime to see if its activity is comparable or better. The structures of both compounds are similar (differing slightly in one added oxime group, at position 4 on the pyridinium ring of asoxime). However, the reactivation potency of HLö-7 is not much better compared to asoxime to perform all steps, which are needed for introduction to the market.

In the United States, methoxime is going to replace pralidoxime, which is now considered an old-fashioned and ineffective antidote. There are many studies focused on this topic (Singh et al., 2007). According to recent research, several laboratories are also focusing on Ortho-7, which has been described by many investigators (e.g., Pang et al., 2003; Ekström et al., 2006; Oh et al., 2008).

The novel classes of uncharged reactivators have been thoroughly investigated in the last decade. Although some potent reactivators were described *in vitro*, there is only limited knowledge on their activity *in vivo*; namely, their increased AChE inhibitory ability, low solubility, and questionable toxicity have to be further improved and clarified.

RECENT TRENDS IN DEVELOPMENT OF NEW ACHE REACTIVATORS

New trends to improve potency of reactivators have various purposes. There are many directions to consider.

The most discussed factor is probably the possibility of a broad-spectrum reactivator. Every new oxime could be tested for its broad-spectrum ability. However, the probability of finding such an oxime is low. Alternatively, a combination of two oximes can be used. Such an approach was originally applied decades ago by Kovacevic et al. (1989). Candidates for this approach include asoxime and various other oximes, which are applicable in case of tabun- or OP-pesticide poisoning.

Another factor that needs to be discussed is BBB penetration, which could be addressed by chemical modification of the reactivator's structure. Examples of this include nonquaternary reactivators and connection of quaternary moiety with lipophilic compounds, which can serve as carriers (e.g., amino acids, steroids, drugs to treat Alzheimer's disease, and saccharides), or the use of special carriers (e.g., nanoparticles and complex systems). However, do we really need to increase oxime levels in the brain? If there are higher concentrations of oxime in the brain, its toxicity could be increased. The uncharged reactivators might have great potential, but these effects should be taken into account and verified. For further details, see Chapter 49.

A new nucleophilic group, instead of the oxime group, could also be considered as a promising approach. However, during the last 50 years, no better nucleophilic group has been found.

New techniques currently used for drug design could be used for this purpose as well. Among them are molecular modeling studies, prediction of new structures using chemometric tools, click chemistry, or random chemistry

approaches, all of which could be applied to achieve the desired goals.

Finally, oximes could be applied for reactivation of AChE as life-endangering enzymes, and their use as butyrylcholinestrase (BChE) reactivators could contribute to finding a pseudocatalytic scavenger. Such a scavenger could neutralize the nerve agent via BChE (as a stoichiometric scavenger) and then inhibited BCHE could be renewed by oxime to be available repeatedly for nerve agent binding.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

As discussed in this chapter, the threat of misuse of OP nerve agents continues. The requirements of agricultural production also demand the use of pesticides, so deaths from these compounds in agricultural workers is increasing. There is no universal oxime that could be applied in every situation of nerve agent or OP pesticide intoxication. The development of new, effective and safe reactivators is necessary.

Acknowledgments

The financial support from Ministry of Education, Youth, and Sports of the Czech Republic (LH13009), Ministry of Health of the Czech Republic (NT12062), University Hospital in Hradec Kralove (MH CZ-DRO No. 00179906), and the University of Defense of the Czech Republic (Long-term Development Plan No. 1011) is greatly appreciated.

Paraoxonase (PON1) and Detoxication of Nerve Agents

Lucio G. Costa, Toby B. Cole and Clement E. Furlong

INTRODUCTION

More than 60 years ago, it was discovered that certain organophosphorus (OP) insecticides could be enzymatically hydrolyzed by plasma, and it was determined that this hydrolysis was catalyzed by enzymes that were designated A-esterases (Mazur, 1946; Aldridge, 1953). Aldridge's proposal that an A-esterase hydrolyzed both phenylacetate and paraoxon (the active metabolite of the OP insecticide parathion) was conclusively proven several decades later, when it was shown that recombinant paraoxonase/arylesterase catalyzed both activities (Gan et al., 1991). Studies in the late 1970s and early 1980s indicated that the plasma hydrolytic activity toward paraoxon was polymorphically distributed in human populations (Playfer et al., 1976; Eckerson et al., 1983; Mueller et al., 1983), suggesting a genetically based differential susceptibility to OP toxicity. The molecular basis of the paraoxonase (PON1) activity polymorphisms (Adkins et al., 1993; Humbert et al., 1993) and its role in the toxicity of OP compounds (Davies et al., 1996; Li et al., 2000; Costa et al., 2003a, 2006, 2013) have been elucidated. Furthermore, novel important roles of PON1 in the metabolism of oxidized lipids, in the bioactivation or detoxication of certain drugs and in the hydrolysis of quorum-sensing factor, have also emerged, highlighting the multifaceted roles and importance of this enzyme. These latter aspects of PON1 are not discussed in this chapter, but the reader can refer to other publications (Costa and Furlong, 2002; Mackness et al., 2002; Costa et al., 2003b; Draganov and La Du, 2004; Ozer et al., 2005; Ng et al., 2005; Camps et al., 2009).

PON1 POLYMORPHISMS: DEFINING PON1 STATUS

PON1 is a member of a family of proteins that also includes PON2 and PON3; the genes for these are clustered in tandem on the long arms of human chromosome 7 (q21.22). PON1 is synthesized primarily in the liver and a portion is secreted into the plasma, where it is associated with high-density lipoproteins (HDLs) (Sorenson et al., 1999; Deakin et al., 2002). PON1, which received its name from its ability to hydrolyze paraoxon, its first and most studied OP substrate, hydrolyzes the active metabolites of other OP insecticides (e.g., chlorpyrifos oxon, diazoxon) as well as nerve agents such as sarin or soman. However, many other OPs are not hydrolyzed by PON1. Of the three PONs, only PON1 has OP-esterase activity, whereas all three are lactonases, displaying overlapping but distinct substrate specificities for lactone hydrolysis (Draganov et al., 2005). The crystal structure for a recombinant chimeric PON1 indicates that it is a six-bladed β-propeller with two calcium ions in the central tunnel, one of which is essential for enzyme activity and the other is essential for structural stability (Harel et al., 2004). However, recombinant PON1 differs from human PON1 in amino acid sequence and OP-esterase activity (Otto et al., 2009; Trovaslet-Leroy et al., 2011); thus, the tertiary structure of native PON1 remains to be elucidated.

Plasma paraoxonase activity in human populations is polymorphically distributed and individuals with high, intermediate, or low paraoxonase activity can be identified (Eckerson et al., 1983; Mueller et al.,

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00073-7

1983; Geldmacher-von Mallinckrodt and Diepgen, 1988; Ginsberg et al., 2009), although, as shown later, the resolution of the three phenotypes are not revealed by single substrate assays (Davies et al., 1996; Richter and Furlong, 1999). Studies in the early 1990s led to the purification, cloning, and sequencing of human PON1 (Furlong et al., 1991; Gan et al., 1991; Hassett et al., 1991), and in the molecular characterization of its polymorphisms (Adkins et al., 1993; Humbert et al., 1993). Two common polymorphisms were observed in the PON1 coding sequence: a Gln(Q)/Arg(R) substitution at position 192 and a Leu(L)/Met(M) substitution at position 55 (Adkins et al., 1993; Humbert et al., 1993). The gene frequencies of $PON1_{Q192}$ range from 0.75 for Caucasians of Northern European origin to 0.31 for some Asian populations (Brophy et al., 2002). In addition to these two polymorphisms in the coding region of PON1, several polymorphisms have been found in the noncoding 5 Disease: Basic and Clinical PON1 gene, with the most significant one being the C108T polymorphism at an Sp1 binding site, and with the –108C allele providing levels of PON1 approximately twice as high, on average, as the –108T allele (Leviev and James, 2000; Suehiro et al., 2000; Brophy et al., 2001a,b). Complete resequencing of PON1 from 47 individuals (24 African-Americans and 23 Europeans) has revealed more than 160 single nucleotide polymorphisms (SNPs) (Furlong et al., 2008). Some of the few that have been characterized so far have allowed reconciliation of discrepancies between PCR analysis of codon 192 and determination of PON1 status (Jarvik et al., 2003)

The L/M polymorphism at position 55 does not affect catalytic activity but has been associated with plasma PON1 protein levels, with $PON1_{M55}$ being associated with low-plasma PON1 (Blatter Garin et al., 1997; Mackness et al., 1998); this appears to primarily result from linkage disequilibrium with the low efficiency of the T-108 promoter allele (Brophy et al., 2002), although some data indicate that $PON1_{M55}$ may be somewhat less stable than $PON1_{L55}$ (Leviev et al., 2001; Roest et al., 2007). In contrast, the Q/R polymorphism at position 192 significantly affects the catalytic efficiency of PON1. This polymorphism is substrate-dependent, because the $PON1_{R192}$ alloform hydrolyzes chlorpyrifos oxon and paraoxon more rapidly than $PON1_{Q192}$ *in vitro* (Li et al., 2000), whereas both PON1 alloforms hydrolyze diazoxon (Li et al., 2000) and phenylacetate (Furlong et al., 2006) with the same efficiency.

Although most studies investigating the association of PON1 polymorphisms with diseases have examined only the nucleotide polymorphisms (Q192R, L55M, C-108T) with PCR-based assays, it has been argued that measurements of PON1 function (plasma activity) are of greater relevance, because they measure the plasma activity of PON1, which is the most important factor that determines rates of detoxication of both endogenous and xenobiotic substrates. This functional genomics analysis is accomplished through the use of a high-throughput enzyme assay involving two PON1 substrates (either diazoxon and paraoxon or a pair of nontoxic substrates) (Richter et al., 2004, 2008, 2009). This approach, which has been referred to as the determination of the "PON1 status" for an individual (Richter and Furlong, 1999), in addition to providing a functional assessment of the plasma PON_{192} alloforms, also provides the plasma level of PON1 for each individual, thus encompassing the two factors that affect rates at which PON1 detoxifies endogenous and exogenous substrates. Rates of detoxication of compounds that are not affected by the Q192R polymorphism are determined by plasma PON1 concentrations. Rates of detoxication of other compounds for which rates are affected by the Q192R polymorphism are determined both by plasma PON1 levels and the-PON1 alloform(s) in plasma. In all cases, it is important to determine PON1 plasma levels and, for some compounds, the Q192R polymorphism as well. For this reason, many epidemiological studies that have analyzed SNPs alone have not provided useful data.

Thus, for adequate risk assessment, it is important to know PON1 levels and activity. In a given population, plasma PON1 activity can vary up to 40-fold (Eckerson et al., 1983; Mueller et al., 1983; Davies et al., 1996; Richter and Furlong, 1999; Jarvik et al., 2000), and differences in PON1 protein levels up to 13-fold are also present within a single $PON1_{192}$ phenotype (QQ, QR, RR) in adults (Davies et al., 1996). Ample evidence is now available from studies investigating the role of PON1 in cardiovascular disease that PON1 status (encompassing genotype and activity levels) is a much better predictor of disease than PON1 genotype alone (Jarvik et al., 2000; Mackness et al., 2001; Bayrak et al., 2012; Zhao et al., 2012).

PON1 AND THE TOXICITY OF OP INSECTICIDES

Evidence that PON1 plays a role in modulating the *in vivo* toxicity of OPs has emerged over the past 20 years, although it had already been noted that species differences in PON1 activity correlated with susceptibility to OP toxicity (Costa et al., 1987; Furlong et al., 2000). A previous study by Main (1956) showed that intravenous administration of partially purified PON1 from rabbit serum would protect rats from the toxicity of paraoxon; therefore, several initial studies followed a similar approach. Administration (by the intravenous route) of purified rabbit PON1 to rats protected the animals from acetylcholinesterase (AChE) inhibition by chlorpyrifos oxon and paraoxon (Costa et al., 1990). Further studies in mice provided evidence that intravenous administration

of pure rabbit PON1 increased serum chlorpyrifos oxonase activity by 30-fold to 40-fold and protected animals against AChE inhibition by dermally applied chlorpyrifos oxon (Li et al., 1993). Because intravenous administration of PON1 increased serum PON1 activity for a short duration ($t_{1/2}$ = ~6 h), additional experiments aimed at investigating other routes of administration for PON1 that would extend its plasma half-life. When PON1 was given by the intravenous and intraperitoneal routes, plasma enzyme activity toward chlorpyrifos oxon increased by 35-fold and the half-life was extended to 30 h. An even longer half-life, albeit with lower peak activity levels, was found when PON1 was administered by the intravenous plus intramuscular route (Li et al., 1993). These studies also showed that rabbit PON1 could confer protection toward the parent compound, chlorpyrifos, and that protection was also present when the enzyme was given 30 min to 3 h after exposure (Li et al., 1995), suggesting a therapeutic potential for exogenous PON1 in cases of OP poisoning, possibly in combination with other conventional treatments.

More recently, *PON1* knockout (*PON1*$^{-/-}$) and *PON1* transgenic mice have provided important new tools to investigate the role of PON1 in modulating OP toxicity. Plasma and liver from *PON1*$^{-/-}$ mice have no detectable hydrolytic activity toward paraoxon and diazoxon, and have very limited chlorpyrifos-oxonase activity (Shih et al., 1998; Li et al., 2000). *PON1*$^{-/-}$ mice do not differ from wild-type animals in their sensitivity to demeton-*S*-methyl, an OP insecticide with a structure similar to malathion and that is not a substrate for PON1 (Li et al., 2000). In contrast, *PON*$^{-/-}$ mice have a dramatically increased sensitivity to chlorpyrifos oxon and diazoxon, and a slightly increased sensitivity to the toxicity of the parent compounds chlorpyrifos and diazinon (Shih et al., 1998; Li et al., 2000). A surprising finding is that the lack of PON1 did not affect the sensitivity of mice to paraoxon, the substrate for which the enzyme was named, despite the absence of any paraoxonase activity in plasma and liver (Li et al., 2000).

When *PON1*$^{-/-}$ mice were given exogenous PON1, resistance to OP toxicity was also restored (Li et al., 2000). In these studies, purified human $PON1_{Q192}$ or $PON1_{R192}$ was injected, by the intravenous route, into *PON1*$^{-/-}$ mice, and the effects of various OPs on brain and diaphragm AChE activity were determined (Li et al., 2000). $PON1_{R192}$ provided significantly better protection than $PON1_{Q192}$ toward chlorpyrifos oxon, a finding also confirmed by a study by Cowan et al. (2001), who administered recombinant adenoviruses containing *PON1*-LQ or *PON1*-LR genes to BALB/c mice before challenge with chlorpyrifos oxon. Li et al. (2000) also showed that $PON1_{R192}$ and $PON1_{Q192}$ were equally effective in protecting against the toxicity of diazoxon, but neither alloform afforded protection against paraoxon toxicity.

Kinetic analyses of substrate hydrolysis by purified human $PON1_{R192}$ or $PON1_{Q192}$ provided an explanation for the *in vivo* finding. The catalytic efficiency of both PON1 alloforms toward chlorpyrifos oxon was very high, with the $PON1_{R192}$ alloform having the highest catalytic efficiency. In the case of diazoxon, catalytic efficiency was still high, although lower; however, there was little difference between the two $PON1_{192}$ alloforms. The $PON1_{R192}$ alloform was also much more efficient than the $PON1_{Q192}$ alloform in hydrolyzing paraoxon; however, its overall catalytic efficiency was too low to protect against exposure (Li et al., 2000). This latter finding confirms the hypothesis that PON1 may not degrade paraoxon efficiently at low concentrations *in vivo* (Chambers et al., 1994; Pond et al., 1995).

Further experiments were performed in *PON1* transgenic mice (i.e., mice expressing either human PON_{Q192} or human $PON1_{R192}$) on the knockout background (*Tg-hPON1*$_{R192}$ and *Tg-hPON1*$_{Q192}$) or mice expressing the human $PON1_{R192}$ on top of murine PON1. The latter mice, whose serum paraoxonase activity was 3.5-fold higher than that of wild-type mice, showed similar sensitivity to paraoxon as wild-type mice (Li et al., 2000), further confirming the inefficacy of PON1 for detoxifying paraoxon *in vivo*. *Tg-hPON1*$_{R192}$ mice were significantly less sensitive to the toxicity of chlorpyrifos oxon and of chlorpyrifos than *Tg-hPON1*$_{Q192}$ mice, despite having the same level of PON1 protein in liver and plasma (Cole et al., 2005). Thus, these further experiments in transgenic mice confirmed all previous observations. In addition, administration of a recombinant human PON1 to *PON1*$^{-/-}$ mice protected them against the toxicity of diazoxon when given either after or before the enzyme (Stevens et al., 2008).

Altogether, these animal experiments indicate that PON1 can modulate the acute toxicity of OPs in a compound-specific manner. Thus, in the case of chlorpyrifos oxon, both the level of expression and the Q192R genotype are important determinants of susceptibility, highlighting the importance of assessing PON1 status in potentially exposed individuals. With regard to diazoxon, protection or susceptibility is dictated primarily by the level of expression of PON1, independently of the Q192R genotype, stressing the importance of knowing PON1 levels. Perhaps ironically, PON1 status does not appear to play a role in modulating sensitivity to paraoxon toxicity due to the low catalytic efficiency of paraoxon hydrolysis.

There is limited evidence that PON1 status may affect susceptibility to OP insecticides in humans. A series of studies has investigated the role of PON1 in modulating chronic central and/or peripheral nervous system abnormalities, at times referred to as "dipper's flu," associated with exposure of sheep dippers to diazinon. Diazoxonase activity was initially found to be lower

in cases than referents (Cherry et al., 2002); however, in a follow-up study in the same populations, serum PON1 activity toward diazoxon did not differ between cases and controls. Although when the two groups were divided into quintiles according to serum diazoxonase activity, sheep dippers in the lowest quintile had a greater risk of reporting ill health than those in the other quintiles (Mackness et al., 2003). Additional investigations suggested that the risk associated with PON1 polymorphisms may vary with genotypes of CYP2D6 (which bio-activates diazinon) (Povey et al., 2007). On the basis of these and of similar findings (O'Leary et al., 2005; Mackenzie Ross et al., 2010; Cherry et al., 2011), it would appear that ill health in sheep dippers was more pronounced in individuals who had a lower ability to detoxify diazoxon.

A few other studies are suggestive of a role of PON1 status in modulating susceptibility to various effects of OPs (Lee et al., 2003; da Silva et al., 2008; Lacasana et al., 2010; Singh et al., 2011). However, these studies lack detailed information on exposures, which hampers interpretation of the findings. Exposure to diazinon and to chlorpyrifos, but not to parathion, was found to be associated with an increased risk of Parkinson disease in carriers of the $PON1_{M55}$ variant (low PON1 activity) (Manthripragada et al., 2010). Exposure to diazinon and chlorpyrifos was also associated with an increased risk of brain tumor in children with low PON1 activity (Searles Nielsen et al., 2005). Finally, a study of pesticide handlers in Washington State, exposed to various OPs (most notably chlorpyrifos), low PON1 catalytic efficiency (Q192), and low plasma activity were associated with increased degrees of plasma butyrylcholinesterase (BChE) inhibition from baseline levels (Hoffman et al., 2009).

Overall, human studies available to date provide limited initial evidence that low PON1 status may increase susceptibility to adverse effects of certain OP insecticides. However, further studies are certainly warranted.

PON1 AND THE TOXICITY OF NERVE AGENTS

Several OP nerve agents, such as soman, sarin, tabun, and VX, have been shown to be metabolized *in vitro* by PON1 (Davies et al., 1996; Rochu et al., 2007; Valiyaveettil et al., 2010). Information is scarce regarding VX (Peterson et al., 2011), but more information is available regarding the other compounds, particularly soman and sarin. Both sarin and soman are hydrolyzed to a higher degree by $PON1_{Q192}$ than by $PON1_{R192}$ (Davies et al., 1996), and plasma somanase activity and sarinase activity (both in U/L) were found to be 2,143 and 335 for QQ homozygotes and 992 and 38 for RR homozygotes, respectively (Davies et al., 1996). Thus, homozygotes for the $PON1_{Q192}$ allele hydrolyze sarin approximately 10-times better than individuals homozygous for the $PON1_{R192}$ allele, whereas the ratio is approximately two for soman (Davies et al., 1996). Results of a kinetic study confirmed these findings; catalytic efficiency for sarin was determined as 0.91 and 0.07 (ratio = 13) for $PON1_{Q192}$ and $PON1_{R192}$ homozygotes, respectively, whereas values for soman were 2.8 and 2.1 (ratio = 1.3) (Rochu et al., 2007). Soman exists as four stereoisomers (C+P+, C+P−, C−P+, C−P−) (Beschop and deJong, 1988), with both P− isomers displaying the highest *in vivo* toxicity; wild-type recombinant human PON1 was shown to stereo-selectively hydrolyze soman, with a sixfold overall difference in catalytic efficiency (P+ > P−) (Yeung et al., 2007). Further evidence that purified human PON1 and recombinant PON1 can hydrolyze soman and sarin has been provided by Valiyaveettil et al. (2010), who also reported hydrolysis of tabun.

In vivo studies in animals have shown that intravenous administration of naked DNA bearing the human $PON1_{Q192}$ cDNA to mice could elevate plasma somanase activity by approximately twofold (Fu et al., 2005). The pcDNA/PON1-treated mice survived in greater number with a pcDNA/PON1 dose-dependence and for a longer period after an acute dose of soman (0.2 mg/kg, subcutaneous) (Fu et al., 2005). More recently, Valiyaveettil et al. (2011a,b) have reported that PON1 could protect guinea pigs from the acute toxicity of sarin and soman. In one study, small quantities of purified human or rabbit PON1 were administered intravenously to guinea pigs 30 min before exposure to sarin or soman by microinstillation inhalation (846 and 841 mg/m^3, respectively, equivalent to 1.2 × LC_{t50}) (Valiyaveettil et al., 2011a). Although there was only a modest increase in plasma PON1 activity, PON1 from both species significantly increased survival time and antagonized several effects of the nerve agents, including AChE inhibition in brain. In a companion study, human recombinant PON1 expressed in *Trichoplusia ni* larvae was given intravenously to guinea pigs 30 min before exposure to sarin or soman (Valiyaveettil et al., 2011b). Protective effects were essentially identical to those of the other study. In apparent contrast to these findings, a more detailed study by Hodgins et al. (2013) reported that administration of wild-type human PON1 purified from *T. ni* larvae (Otto et al., 2010) or induced via adenoviral infection in mice protected against the toxicity of the OP insecticides diazoxon and chlorpyrifos oxon, but not of several nerve agents (tabun, soman, sarin, cyclosarin). These findings re-emphasize the fact that human PON1 has a low catalytic activity toward nerve agents and suggest that there is a need for developing novel human PON1 mutants with enhanced nerve agent–hydrolyzing activity. These studies also suggest that the $PON1^{-/-}$ mouse may be a much better model than the guinea pig for two

reasons. First, is no background OP hydrolase activity in the plasma of *PON1*$^{-/-}$ mice, allowing for the pharmacokinetics to be clearly delineated. Second, much less PON1 (purified or recombinant) is required to increase the plasma level of mice to quite high levels of activity (Li et al., 1993, 1995, 2000; Stevens et al., 2008). Once the efficacy of a given PON1 variant has been demonstrated in the mouse model and protocols have been developed to produce large quantities of rPON1, it will be feasible to study the efficacy of the variants in other animal models. The toxicity of exogenous PON1 described by some workers is most likely due to residual detergent or other toxins in the PON1 preparations. Removal of such contamination should allow for the injection of much higher quantities of rPON1.

There are currently two quite different approaches underway for engineering recombinant PON1 variants with higher catalytic efficiency for treating OP exposures. One initiated by Tawfik et al. begins with the chimeric PON1 that they engineered for solubility and the determination of the crystal structure (Harel et al., 2004). The goal of this approach is to make the sequence of variants with high catalytic efficiency of agent hydrolysis (Aharoni et al., 2004) more "human-like" to minimize immunogenicity (Sarkar et al., 2012). A second approach is to begin with the native human rPON1 and introduce the minimal number of mutations required for the desired catalytic efficiency (Stevens et al., 2008). These two approaches are complementary and inform each other.

The 1995 terrorist attack in the Tokyo subway system that left 12 people dead and more than 5,000 injured (Suzuki et al., 1995; Nagao et al., 1997) provided the opportunity to investigate the role of PON1 in modulating the toxicity of sarin in humans. The prevalence of the $PON1_{R192}$ genotype in the Japanese population is 0.66 compared with 0.25–0.30 in the Caucasian population (Yamasaki et al., 1997; Brophy et al., 2002). Thus, Japanese individuals may have been more prone to sarin toxicity because of the low sarin-hydrolyzing ability of the $PON1_{R192}$ allozyme. However, among 10 of the victims of the Tokyo attack, seven expressed the $PON1_{192Q}$ genotype, with six Q/R heterozygotes and one Q/Q homozygote (Yamada et al., 2001). Thus, the genotype that confers high hydrolyzing activity toward sarin did not appear to provide protection from acute sarin poisoning. However, several issues need to be considered. First, only the Q192R genotype of those 10 individuals was analyzed, with no information regarding their PON1 status. In a Caucasian population, the range of sarinase activity among individuals with the QQ or QR genotype ranged from approximately 0–758 U/L (Davies et al., 1996). Second, exposure to sarin in these seven QQ or QR individuals was indeed massive, because it caused death instantly or, with one exception, in less than 48 h (Yamada et al., 2001). Such high-dose exposure would be expected to overcome any potential protection afforded by the $PON1_{Q192}$ genotype. Third, and most importantly, the catalytic efficiency of sarin hydrolysis by PON1, even in QQ homozygotes, is low; the situation is thus similar (albeit reversed) to that of paraoxon, with one $PON1_{192}$ alloform hydrolyzing sarin with better efficiency, but still not sufficiently high enough catalytic efficiency to provide protection against nerve agent exposure.

A few studies have also investigated PON1 polymorphisms in US and UK troops that were deployed in the Persian Gulf area during 1990 and 1991. Individuals who served in the Gulf War were potentially exposed to a wide range of biological and chemical agents, including sand, smoke from oil well fires, solvents, petroleum fuels, depleted uranium, anthrax and botulinum toxoid vaccinations, insecticides, pyridostigimine bromide, and nerve agents (IOM, 2000, 2003). A large number of these veterans have reported a range of unexplained illnesses, including chronic fatigue, muscle and joint pain, loss of concentration, forgetfulness, and headache, symptoms that are often referred to as Gulf War syndrome (IOM, 2000, 2003). PON1 genotypes and plasma enzyme activity were investigated in a group of 25 ill US Gulf War veterans and 20 controls (Haley et al., 2000). $PON1_{R192}$ homozygotes or $PON1_{Q/R192}$ heterozygotes were more likely to have neurologic symptoms than individuals homozygous for PON_{Q192}. Furthermore, low activity of the plasma $PON1_{Q192}$ isoform appeared to correlate better with illness than the PON1 genotype or the activity levels of the $PON1_{R192}$ genotype (Haley et al., 2000). This study would suggest that low PON1 status may represent a risk factor for illness in Gulf War veterans, although such findings necessitate further confirmation in a larger population (Furlong, 2000).

A similar study of a group of 152 UK Gulf War veterans, who self-reported the presence of symptoms associated with the Gulf War syndrome, yielded somewhat different results (Mackness et al., 2000). Plasma paraoxonase activity and levels of PON1 protein were lower in veterans than in a control group, and these decreases were independent of the *PON1* genotype (Mackness et al., 2000). Thus, although in both studies a reduced plasma paraoxonase activity was found, in one case it was attributed to an over-representation of the low-activity PON1 isozyme (Haley et al., 2000), and in the other it was common to all *PON1* genotypes (Mackness et al., 2000). Although the latter study suggests that this group of veterans may have a decreased capacity to hydrolyze some OP insecticides, such as chlorpyrifos oxon, its significance is hampered by the lack of information regarding the extent of exposure to such compounds among veterans (Costa et al., 2003a). An additional study compared *PON1* genotypes and plasma paraoxonase activity in groups of UK veterans

from the Persian Gulf War who were symptomatic by self-reporting ($n = 115$), healthy Persian Gulf War veterans ($n = 95$), symptomatic Bosnia peacekeeping veterans ($n = 52$), and symptomatic nondeployed military controls ($n = 85$) (Hotopf et al., 2003). No differences in genotype distribution or PON1 activity were found between healthy and ill Gulf War veterans. However, individuals who were deployed to the Gulf had 25–35% lower median PON1 values than the other two groups, and these differences were not explained by differences in $PON1_{192}$ genotypes between groups. Thus, $PON1_{192}$ genotype and activity were not associated with Gulf War syndrome but appeared to be the results of deployment in the Persian Gulf. Possible explanations suggested for such findings were the potential exposure of those who served in the Gulf to yet unknown agents that led to a long-term decrease in PON1 activity, and/or an overrepresentation in those two groups of individuals with the –108T allele, which is associated with lower PON1 levels (Hotopf et al., 2003).

PON1 AS A THERAPEUTIC AGENT

In recent years there has been much interest in developing new means of antagonizing the toxicity of OPs, particularly of nerve agents (Masson and Rochu, 2009; Nachon et al., 2013). Current therapy for OP poisoning relies on the use of atropine, a cholinergic muscarinic antagonist, and on oximes, such as pralidoxime (2-PAM), to reactivate phosphorylated AChE before "aging occurs" (Lotti, 2000; Eyer et al., 2007). Anticonvulsant drugs such as diazepam may also be utilized to control OP-induced convulsions (Lotti, 2000). More efficacious pyridinium 4-aldoximes, such as obidoxime and trimedoxime, have also been developed; however, their ability to reactivate phosphorylated AChE is not fully exploited because of the formation of phosphoryloximes, which have very high anticholinesterase activity. Interestingly, phosphoryloximes are rapidly hydrolyzed by PON1, with the $PON1_{Q192}$ allozyme being approximately 50-fold more active than $PON1_{R192}$ (Stenzel et al., 2007), suggesting that PON1 status would also influence the effectiveness and safety of these oximes (Eyer et al., 2007).

Although current therapies are effective in preventing lethality, it has been suggested that they may not prevent behavioral deficits, incapacitation, loss of consciousness, or the potential for permanent brain damage caused in particular by OP nerve agents (Lenz et al., 2007). Complementary approaches have thus focused on the use of human proteins that would act as biological scavengers for OP compounds. Such biological scavengers should have no effects on their own, should not present an antigenic challenge to the immune system, should act rapidly and specifically, and should remain in circulation for a prolonged period of time (Lenz et al., 2007; Suzuki et al., 2010). Out of this general concept two parallel approaches have emerged, one relying on stoichiometric bioscavengers and the other relying on catalytic bioscavengers. Among stochiometric bioscavengers, B-esterases, such as AChE and BChE, which react with OPs but do not catalyze their hydrolysis, have been utilized in several studies. Administration of these two proteins to rodents has been shown to afford protection toward twofold to fivefold LD_{50} doses of sarin, soman, or VX (Wolfe et al., 1987; Doctor and Saxena, 2005; Lenz et al., 2007; Saxena et al., 2011). Of particular interest in this regard is human BChE, either isolated from human plasma or recombinant (Cerasoli et al., 2005).

Although stoichiometric scavengers may offer some protection toward OP toxicity, high doses are needed to neutralize an equimolar amount of nerve agent (Ashani and Pistinner, 2004; Valiyaveettil et al., 2012). In contrast, a catalytic scavenger would afford similar or even higher protection at relatively low doses, because one molecule of a catalytic scavenger can hydrolyze a very large number of molecules of an OP (Sweeney and Maxwell, 2003; Stevens et al., 2008; Valiyaveettil et al., 2012). For example, it has been estimated that 3 μM sarin would be neutralized by 765 mg of human BChE, but only 120–550 mg of $huPON1_{Q192}$ (depending on time) (Rochu et al., 2007), or a much lower dose of engineered recombinant human PON1 with significantly increased catalytic efficiency of agent hydrolysis. A number of arguments would support the use of PON1 as a catalytic bioscavenger (Nachon et al., 2013). PON1 is a human protein, suggesting the possible absence of immunological response. However, reports of PON1-induced cytotoxicity in macrophages needs to be further investigated (Mackness and Mackness, 2010). Experiments using mice and guinea pigs have clearly shown that administration of purified human PON1 or of recombinant PON1 protects animals against the toxicity of specific OP compounds, provided that the catalytic efficiency is sufficient (Li et al., 2000; Cowan et al., 2001; Stevens et al., 2008; Duysen et al., 2011; Valiyaveettil et al., 2011a,b; Hodgins et al., 2013). In this regard, novel ways to deliver PON1 are being investigated in addition to administration of purified enzyme (Li et al., 2000) or of an adenoviral vector (Cowan et al., 2001; Duysen et al., 2011; Hodgins et al., 2013). For example, Gaidukov et al. (2009) showed that administration of BL-3050, a highly stable engineered human PON1-HDL complex, protected mice against the toxicity of chlorpyrifos oxon and did not cause any apparent adverse effect on its own. In another study, human PON1 was re-engineered as an IgG-PON1 fusion protein in which the 355-amino-acid human PON1 was fused to the carboxyl terminus of the heavy chain of a chimeric monoclonal antibody against the human insulin receptor (Boado et al., 2011).

This fusion protein, designated as HIR-Mab-PON1, was able to enter the brain when injected intravenously into nonhuman primates. This would be of much interest because PON1 is basically absent from brain cells (Giordano et al., 2011), whereas OPs easily penetrate the blood–brain barrier.

PON1 has been shown to hydrolyze soman, sarin, and tabun, although its catalytic efficiency toward OP nerve agents, in particular sarin, is low. It has been calculated that, to provide a valuable medical countermeasure against intoxication by nerve agents, the catalytic efficiency of PON1 will need to be enhanced by one or two orders of magnitude (Rochu et al., 2007). Some direct evolution variants of a recombinant PON1 were found to exhibit a 10-fold faster detoxication of cyclosarin and soman (Amitai et al., 2006). Other huPON1 mutants with enhanced catalytic activity have also been described, although not in relationship to OP nerve agents (Yeung et al., 2004). Directed evolution of a chimeric PON1 made via mammalian gene shuffling, combined with high-throughput screening, led to an evolved variant of chimeric PON1 with a 100,000-fold higher catalytic efficiency toward the most toxic enantiomer of a coumarin analog of cyclosarin (Gupta et al., 2011). However, chimeric PON1 is expected to be immunogenic; hence, its practical application is doubtful. Nevertheless, further efforts to develop human PON1 variants with increased catalytic efficiency toward nerve agents are warranted.

An additional approach would be that of stimulating the biosynthesis of natural PON1. Several compounds have been shown to stimulate the expression of PON1 (Costa et al., 2005, 2011), among them being low doses of ethanol, some fibrates, statins, or dietary polyphenols such as quercetin (Gouedard et al., 2004a). The red wine ingredient resveratrol has been shown to increase PON1 activity nearly threefold *in vivo* (Gouedard et al., 2004b) and less than twofold in liver cells *in vitro* (Curtin et al., 2008). Interestingly, in the latter study, the increased PON1 afforded protection of cells against the toxicity of soman and sarin (Curtin et al., 2008). Modulation of PON1 activity by drugs or dietary agents is of interest; however, more information of the regulation of the PON1 gene is needed to devise approaches that would offer substantially larger increases in PON1. However, it also has been argued (Valiyaveettil et al., 2012) that a moderate increase of PON1 (less than twofold) may perhaps be sufficient to provide some protection against some of the symptoms of OP exposures, as shown by the protection seen against sarin and soman in guinea pigs (Valiyaveettil et al., 2011a,b). Nevertheless, the low catalytic efficiency of nerve agent hydrolysis by native human PON1 may not be adequate to provide efficient protection against nerve agent exposure. The recent report by Hodgins et al. (2013) supports the point that the catalytic efficiency for hydrolysis of a specific OP must be sufficiently high to protect against exposure to that specific OP.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Evidence from *in vitro* studies shows that PON1 can hydrolyze a number of OP compounds, including nerve agents. *In vivo* studies using rodents have also indicated that PON1 status can influence the acute toxicity of certain OPs, and that administration of exogenous PON1 can protect animals from OP toxicity. In case of nerve agents, the catalytic efficiency of PON1 is relatively low, and PON1 status does not greatly influence an individual's susceptibility to toxicity. However, recombinant variants can be engineered with enhanced catalytic activity toward nerve agents. The nonglycosylated, engineered recombinant PON1s with high catalytic efficiency for OP hydrolysis should be excellent candidates for use as catalytic biological scavengers, with both prophylactic and therapeutic applications. As previously suggested (Suzuki et al., 2010; Costa et al., 2011; Hodgins et al., 2013) efforts in this direction and in attempting to increase endogenous PON1 should proceed in parallel, because a combined strategy may prove successful. The increase in endogenous PON1 levels should be efficacious for exposures to the OPs known to be hydrolyzed at rates sufficient to provide protection (Li et al., 2000; Hodgins et al., 2013).

CHAPTER

74

The Role of Carboxylesterases in Therapeutic Intervention of Nerve Gases Poisoning

Sigrun Hanne Sterri and Frode Fonnum

INTRODUCTION

Carboxylesterases (CarbEs or CEs) constitute an important group of enzymes that plays a major role in the hydrolytic biotransformation of a large number of drugs. In the present context, we discuss their ability to act as scavengers toward the highly toxic organophosphorus (OP) nerve agents. The scavenger function of CarbE in blood plasma is the main reason for the variation in nerve gas toxicity among the species, both in the presence and absence of carbamate prophylaxis and oxime treatment. The various effects of CarbE proteins in plasmas of different species are due to their content, not necessarily their apparent enzymatic activity. The fact that plasma CarbE in rodents is a natural scavenger toward nerve gases allows for explaining the species differences between the toxicities of nerve agents. This is of vital importance when comparing and analyzing OP toxicity data for experimental animals, such as rodents, and species that do not have this specific blood protein, such as rhesus monkeys and humans. The plasma CarbE scavenger function in rodents allows for estimating the protection factor of therapeutic intervention of nerve gas poisoning in humans. Although experimental protection factors with such interventions in rodents may be relatively low due to their natural scavenger content in plasma, it is worth noting that the estimated factors appear to be high for species (including humans) that do not have endogenous plasma CarbE. Treatment of nerve gas poisoning, therefore, might strongly benefit from further exploration of the use of CarbE and other scavengers.

ENZYMOLOGY

Classification

Aldridge (1953) separated esterases into two groups. The first was A-esterases, which are capable of hydrolyzing OP compounds, and the second was B-esterases, which could bind the OP compounds. This group includes other esterases as well, such as CarbE, acetylcholinesterase (AChE), butyrylcholinesterase (BuChE), and chymotrypsin. They all have an active group with serine that binds to the OP compounds. CarbEs are also connected to the alpha/beta hydrolase fold, which is common to several hydrolytic enzymes of widely differing phylogenetic origins and catalytic functions. The core of each enzyme is similar: an alpha/beta-sheet, not barrel, of eight beta-sheets connected by alpha-helices. These enzymes have diverged from a common ancestor and comprise a large family of proteins. They are important in hydrolyzing substrates containing ester or amide groups to free acids and alcohols. They are found in several tissues, including the liver, small intestine, kidney, lung, and plasma. At present, the database for this family contains over 450 orthologous or homologous members with 44 distinctive functions. Mammalian liver CarbEs belong to a family of proteins encoded by multiple genes. The isoenzymes were initially classified by their substrate specificity and isoelectric point (pI; Mentlein et al., 1987). However, this classification is now ambiguous because of overlapping substrate specificities, and it is imprecise because CarbEs as glycoproteins exhibit multiple bands with different pI values upon

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00074-9

electrophoresis. They are very difficult to classify due to their wide substrate specificity. Satoh and Hosokawa (1998) separated all mammalian CarbEs into five main groups based on their molecular properties. The two most important groups are CES1 and CES2. CES1 is the largest group, comprising members that have more than 60% homology to human liver CarbE. It contains the liver enzymes of humans, monkeys, rats, and mice. CES1 enzymes preferentially hydrolyze substrates with lower alcohol groups esterified to a large acyl group. Examples of substrates are cocaine, meperidine, methylphenidate, and temocapril (Zhang et al., 1999), which contain methanol or ethanol linked to a large acyl group. CES2 includes human, monkey, mouse, rat, and hamster intestinal CarbE. In contrast to CES1, CES2 enzymes hydrolyze esters with a higher alcohol group and a relatively small acyl group. Examples of substrates are heroin, 6-acetylmorphine, and methylprednisolone, which contains acetate or succinate as acyl groups. Other categories are CES3, which includes ES-male and human hCE3 and is expressed at low levels in the liver and the gastrointestinal tract; CES4, which includes a protein excreted in cat urine with Mol.wt. 70 kD (Miyazaki et al., 2003); and CES5, which contains protein with a much lower Mol.wt., (namely, 46.5 kD) and a different structure.

Active Site

Cohen et al. (1955) demonstrated that all the esterases in Aldrige group B contain an active serine that binds to the OP group or participates in ester hydrolysis. Further, comparison of the structure of a large number of esterases and lipases confirmed that they all contained a catalytic triad consisting of Ser, His, and Glu (and sometimes Asp instead of Glu). This catalytic triad were preserved in AChE, BuChE, a series of lipases, and CarbE (Cygler et al., 1993). Two adjacent Gly molecules formed an oxyanion hole. Frey et al. (1994) showed for chymotrypsin that the formation of a low-barrier hydrogen bonds facilitates a nucleophilic attack of the serine-OH group on the acyl carbonyl group of peptide. In the same way, these substances allow reactions between substrate esters or OP esters and the serine-OH of ChEs or CarbEs. When the catalytic triad consisting of Ser203, Glu336, and His450 in CarbE was transferred to The 203, Als 336, and Ala 450, respectively, the mutant reduced CarbE activity (Satoh and Hosokawa, 1998). The specificity of CarbE differs from AChE and BuChE in active site volume, electrostatic character, and cation-pI binding. The active site gorge of the enzymes has different sizes. For torpedo AChE, it is 296 D3; for BuChE, it is 496 D3; and for CarbE, it is 3014 D3. This explains why diisopropylfluorophosphate (DFP) cannot inhibit AChE, but it can inhibit BuChE and CarbE. In cholinesterase (ChE), there are 7 anionic groups to establish catioinic substrates, whereas CarbE has only 2. Further, AChE has 14 aromatic residues lining the active site gorge, BuChE has 7, and CarbE has only 2 (Ripoll et al., 1993; Shafferman et al., 1994). This explains the attraction of AChE and VX for ChE and not for CarbE.

The steps for CarbE interacting with substrate or soman (as an example of an OP inhibitor) are the following:

1. The ester bond or the P—F bond is attacked by the serine-OH.
2. The hydrogen bond between the negatively charged oxygen of a tetrahedral complex and the NH groups of glycine stabilize the charged carbonyl oxygen or phosphate oxygen of the substrate or inhibitor.
3. The ester bond or P—F bond breaks and the leaving group (alcohol or F) diffuses away.
4. A water molecule attacks the serine-O-acyl or O-phosphoryl group on the enzyme. Then, histidine delivers a hydrogen atom to the serine-O-acyl, which releases the acyl or phosphoryl group.

This reaction is fast for esters, but slow for soman. In human CarbE1, replacement of histidine for V1466 and glutamate for L363 leads to an enzyme with the same binding to OPs, but with an increased spontaneous reactivation of the enzyme (Hemmert et al., 2011). The two residues are positioned on different sides of the active site and are in an ideal position to direct a water molecule to the serine-OH. This results in an enzyme that is a significantly better scavenger for sarin, cyclosarin, and soman.

In the case of AChE, there is an intermediate step where serine-O-phosphoryl is dealkylated or aged. This is a process where the alkoxy group of the soman residue on the enzyme is hydrolyzed and the soman residue is resistant to the last hydrolysis step. The orientation of the sequence in CarbE allows the alkoxy group in soman residue and other nerve agents to be farther from the His group (7 Å instead of 3.5 in AChE), and therefore, it is not dealkylated (Maxwell and Brecht, 2001).

Substrate Specificity

Several different carboxylic esters may be hydrolyzed by CarbEs; among them, several may also be hydrolyzed by BuChE and A-esterases. For CarbEs, the aromatic butyryl esters are better substrates than the acetyl esters, whereas the opposite holds for A-esterase (Augustinsson, 1959; Aldridge 1953; Ecobichon, 1970). The hydrolysis of two simple aliphatic and aromatic butyryl esters (namely, methyl butyrate and 4-nitrophenyl butyrate) is catalyzed by CarbE, with only minimal contributions by ChE and A-esterase in a series of rat tissues, except

for duodenum, based on the use of specific inhibitors of the three enzymes (Sterri et al., 1985b). The two substrates, therefore, are appropriate to use for comparative evaluation of rat tissue CarbEs with respect to both inter- and intra-tissue diversity. Thus, the ratio between activities toward the two substrates in different tissues correlated to the plasma ratio seem to separate CarbEs of rat tissues into two main groups. The CarbEs of cerebrum, kidney, and duodenum display similar relative activity as plasma, with a preference for 4-nitrophenyl butyrate. In contrast, liver, lung, heart, and diaphragm constitute the other group with a far higher (13- to 17-fold) relative preference for methyl butyrate (Sterri et al., 1985b). This may indicate that the two groups are predominantly constituted by CES1 and CES2 CarbEs (as described in the section "Classification," earlier in this chapter), with preference for a substrate with lower (methanol) or higher (4-nitrophenol) alcohol esterified to the butyric acid. Also, the two CarbE isoenzymes of rat plasma and the three isoenzymes of guinea-pig plasma seem to differ with respect to their relative specificity for methyl butyrate and 4-nitrophenyl butyrate. For each species, the ratio between substrate activities of the plasma isoenzymes differs fivefold to sevenfold in favor of 4-nitrophenyl butyrate, as measured in the top fraction of activity peaks separated by chromatofocusing (Sterri and Fonnum, 1987, 1989).

Inhibition of CarbE with OP Compounds

Paraoxon, sarin, and soman inhibit AChE, BuChE, and CarbE almost to the same extent. DFP inhibits BuChE and CarbE to the same extent and 1,000-fold more than AChE. Diphenyl p-nitrophenyl phosphinate inhibit CarbEs over 1,000-fold more than the ChEs. This explains why bis-p-nitrophenylphosphate is a specific inhibitor of CarbEs.

A problem for CarbE as a scavenger for nerve gases is that VX and echothiophate are both 10,000-fold better inhibitors of AChE than CarbE. This is due to the anion attraction of ChE as described in the section "Active site," earlier in this chapter. OP-inhibited CarbE differ from OP-AChE in that they do not age. Instead, they spontaneously reactivate similar to a slow substrate. The half-life for spontaneous reactivation of sarin-inhibited CarbE is 2 h, whereas for soman or paraoxon, it is 20 h and for DFP, it is 40 h (Maxwell and Brecht, 2001). This agrees with results from a series of experiments with repetitive injection of 0.5x LD_{50} of soman in guinea pigs at different intervals, which demonstrated that soman was completely removed within 24 h and plasma CarbE (tributyrinase) activity was fully recovered (Sterri et al., 1981). The slow reactivation of DFP from CarbE explains its low tolerance to repetitive administration.

Reactivation by Oxime of Nerve Gas-Inhibited CarbE

The original finding by Askew (1956) that diacetylmonoxime (DAM) has an antidotal effect for sarin poisoning in several species, including guinea pigs, was due to the reactivation by DAM of sarin-inhibited CarbE in plasma (Myers, 1959; Polak and Cohen, 1970a; Cohen et al., 1971). In addition, they found that DAM reactivation had less of an effect on sarin-inhibited erythrocyte, brain, and lung CarbEs than on plasma CarbE of both rat and mouse (Myers, 1959).

Similar different sensitivities to DAM reactivation are reported for various soman-inhibited CarbEs. Following *in vitro* inhibition by soman, the CarbE isoenzymes with low pI in plasma of both rats and guinea pigs are partially reactivated (50–60%) by DAM within 5 min. and are not further reactivated during the next 30 min. (Sterri and Fonnum, 1987; Sterri and Fonnum 1989). The two isoenzymes in rat plasma cannot be discriminated based on DAM reactivatability (Sterri, 1989), whereas the one with high pI (6.1) in guinea-pig plasma is about half as sensitive to DAM reactivation than the other two (Sterri and Fonnum, 1987). Also, two out of three CarbE isoenzymes in rat small intestine display similar reactivatability as the plasma CarbEs (Sterri, 1989), whereas none of the three CarbE isoenzymes in guinea-pig liver can be reactivated by this oxime after soman inhibition (Sterri and Fonnum, 1987). The latter results correspond well with the poor effect of DAM on soman-inhibited commercial CarbEs from porcine liver (Fonnum et al., 1985).

ORIGIN OF PLASMA CARBE

It follows from the role of CarbE in nerve gas poisoning that the regulation of plasma CarbE is of great interest. Possible tissues of origin may include the liver (Yan et al., 1995) or the intestine (Sterri, 1989).

Interestingly, based on the results from immunoblots with hydrolase S antibody and messenger RNA (mRNA) levels detected by Northern blot, the 67- and 71-kDa proteins in the liver and serum, respectively, seem to be coregulated by the treatment of rats with various xenobiotics, including phenobarbital (approximately 1.7-fold induction; Yan et al., 1995). Such coregulation are not supported by the results obtained on plasma and liver CarbE activities with methyl butyrate or 4-nitrophenyl butyrate following phenobarbital treatment of rats by Sterri et al. (1985b). In this study, the induction was 1.5-fold to 1.8-fold in liver and maximally 1.2-fold in plasma. However, phenobarbital induction of CarbE in mice led to similar enhanced activities in both liver and plasma (Clement, 1983).

Some interesting results on soman toxicity, thyroid deficiency, and plasma CarbE were reported by Swisher

et al. (1986), which observed reduced effects of soman intoxication in hypothyroid rats with respect to both seizure activity and lethality. The resistance to soman was ascribed to increased binding of soman to plasma proteins since both ChE and CarbE (tributyrinase) of plasma displayed nearly twofold higher activity in hypothyroid than euthyroid rats. We therefore investigated hypothyroid rats with respect to the possible parallel coregulation of CarbE and ChE in plasma and liver. Plasma ChE is undoubtedly synthesized in liver (Augustinsson, 1948; Koelle, 1963), and the ChE activity in rat plasma and liver is known to differ between males and females (Leeuwin, 1966; Andersen et al., 1983; Edwards and Brimijoin, 1983; Sterri et al., 1985a) and to respond upon thyroidectomy (Leeuwin, 1966). When male and female rats received rat chow supplemented with 0.05% thiouracil for 22, 30, or 38 days, they became hypothyroid within 3 weeks (Stakkestad and Bremer, 1983). The results of CarbE activities in rat plasma and liver are presented in Figure 74.1. The activities with methyl butyrate increased significantly in liver but did not change in plasma of both males and females after 22 and 38 days of thiouracil feeding, whereas the hydrolysis of 4-nitrophenyl butyrate varied only slightly and inconsistently. At the same time, the ChE activities of plasma and liver decreased in females and increased in males.

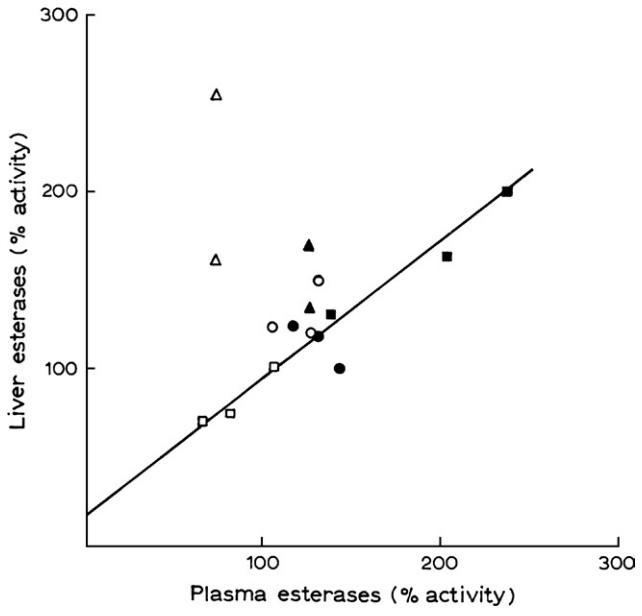

FIGURE 74.1 CarbE and ChE activities in liver versus blood plasma of thiouracil-fed rats. The animals received rat chow supplemented with 0.05% thiouracil for 22, 30, or 38 days. Methyl butyrate hydrolysis (▲△) and 4-nitrophenyl butyrate hydrolysis (●○) were measured in liver homogenate and plasma in accordance with Sterri et al. (1985b), and AChE hydrolysis (■□) by the method of Sterri and Fonnum (1978). The activities are percent of corresponding control (= 100%) activities in male (closed symbols) and female (open symbols) animals fed standard rat chow.

The results show that the ChE activities in plasma and liver of both male and female rats are strongly coregulated, whereas the CarbE activities of the two tissues are definitely not coregulated (methyl butyrate hydrolysis) or are only marginally influenced by thyroid deficiency (4-nitrophenyl butyrat hydrolysis). This investigation, therefore, does not indicate that rat plasma CarbE may be synthesized in the liver.

Results concerning the various CarbE isoenzymes with respect to reactivatability by DAM after soman inhibition (see the section "Reactivation by oxime of nerve gas-inhibited CarbE," earlier in this chapter) might suggest that plasma CarbE has an intestinal origin. Two isoenzymes in plasma of both rat and guinea pig are reactivated to a similar degree as two isoenzymes in the rat small intestine, and quite different from the three liver isoenzymes of guinea pig, which are not sensitive to DAM (Sterri and Fonnum, 1987; Sterri, 1989). Since the results from rat plasma and the small intestine are obtained with the same nerve gas and the same oxime under the same conditions, they may reflect similarities or differences, respectively, in enzymatic properties. It is interesting in this context that the DAM-sensitive isoenzymes of rat plasma and small intestine display correspondingly low isoelectric points (4.0–4.8; Sterri, 1989), whereas higher pI values (5.0–6.4) are reported for 6 CarbE isoenzymes of rat liver (Mentlein et al., 1987). The conclusion, therefore, may be that depending on the species, the plasma CarbE may come from the intestine or the liver.

ROLE OF PLASMA CARBE

Scavenger Function

The early results by Myers (1959) concerning prophylactic action of DAM against sarin poisoning in rats suggested that most of the sarin required to kill a rat actually may be used up by the inhibition of plasma CarbE, and the sarin may be destroyed in the bloodstream before it reaches target AChE levels in the vital organs of the rat. The importance of plasma CarbE for detoxification of sarin in the blood was also suggested by results from 32p-sarin injection and its distribution in the rat (Polak and Cohen, 1969, 1970a,b). Similar conclusions with respect to the function of plasma CarbE were based on results from a series of experiments with acute or repetitive injection of soman in rodents (Sterri et al., 1980, 1983, 1985a; Fonnum and Sterri, 1981; Sterri, 1981; Sterri and Fonnum, 1984; Fonnum et al., 1985). The results showed that the reaction rate between plasma CarbE and soman or sarin was rapid enough to inactivate a large proportion of the OP compound before it leaves the blood. Also, the plasma CarbE seemed to

be spontaneously and sufficiently recovered within 24 h and is then ready to detoxify another dose of soman or sarin—a point that is especially relevant in cases of repetitive exposure.

A scavenger function of plasma CarbE that is able to prevent highly toxic OP compounds from reaching AChE in the brain and diaphragm requires that an adequate amount of CarbE is present in the plasma. This is fulfilled for rodents since CarbEs have been found by several studies to be especially abundant in rodent plasma (Myers, 1952; Aldridge, 1953; Goutier, 1956; Augustinsson, 1959; Christen and Cohen, 1969; Polak and Cohen, 1970a). In fact, rat and guinea-pig plasma may contain as much as 2.8–3.0 μM or 0.5–0.6 μM of CarbE catalytic centers, respectively, as found with 32p-sarin binding to plasma proteins and subsequent polyacrylamide gel electrophoresis or reactivation of CarbE by lowering the pH (Christen and Cohen, 1969; Christen et al., 1969; Cohen et al., 1971). CarbE, therefore, is able to bind and detoxify the highly toxic OP compounds at the active site in equimolar proportions.

The various isoenzymes of plasma CarbE might have different importance with respect to their scavenger function, and it is not possible to predict the scavenger effect from assaying of substrate activities. But results from comparing male and female rat isoenzyme activity and developing of isoenzyme activities with age in rats showed a better correlation to soman toxicity for 4-nitrophenyl butyrate than for methyl butyrate as substrate (Sterri and Fonnum, 1989)

Toxicity of Nerve Gases

Several investigations have demonstrated that the concentration of CarbE protein in rodent plasma is critical for tolerance to acute exposure to highly toxic ChE inhibitors such as soman. For example, a strong correlation exists between the LD_{50} of soman and the plasma CarbE content in developing young rats (Fonnum et al., 1985; Sterri et al., 1985a). In these rats, the plasma CarbE activities with 4-nitrophenyl butyrate increased from negligible (5 days old) to adult (31 days old); and in the same period, the acute LD_{50} of soman increased eightfold to tenfold (while toxicity decreased) and reached adult value in the 31-day-old rats. In addition, young rats (14 days old) with low content of their own plasma CarbE, displayed strongly reduced mortality to soman poisoning when a partly purified CarbE protein from rat liver was prophylactically supplied by intravenous (IV) injection into the rats' blood before the exposure to soman (Fonnum et al., 1985). Also, a linear correlation between soman toxicity and changes in plasma content of CarbE in aging rats is reported by Maxwell et al. (1988).

The specific CarbE inhibitors tri-O-cresyl-phosphate (TOCP) (Mendel and Myers, 1953) and 2-[O-cresyl]-4H-1,2,3-benzodioxa-phosphorin-2-oxide (CBDP; Casida et al., 1961) have been used by several investigators to evaluate the effect on LD_{50} of highly toxic OP compounds. In mice, the LD_{50} of soman was reduced to about 1/18 by pretreatment with 35–50 mg/kg CBDP (McKay et al., 1971; Boskovic, 1979), whereas pretreatment with 100 mg/kg TOCP reduced the LD50 of soman to one-third in guinea pigs and rats (Fonnum and Sterri, 1981; Sterri, 1981; Sterri et al., 1981). In rats, the LD_{50} of sarin was reduced to about 1/5 by pretreatment with 40–50 mg/kg TOCP (Myers, 1959; Polak and Cohen, 1969). Inhibition of CarbE with CBDP showed that soman displayed the same toxicity with different species (Maxwell et al., 1988). Interestingly, for malathion, a more than 100-fold increase in acute toxicity by pretreatment with CarbE inhibitor tri-o-tolyl-phosphate was reported by Murphy et al. (1976). However, malathion is a less toxic OP compound that will be hydrolytically detoxified by the enzymatic activity of CarbE due to its content of carboxylic ester group.

The scavenger function of plasma CarbE may explain various aspects of soman toxicity and soman inactivation in rodents, but it also may be of value for an adequate understanding of soman toxicity in other species. Rats, guinea pigs, and primates (including humans) are species with high, medium, and minor (marmosets), or zero (rhesus monkeys and humans) concentrations of plasma CarbE, respectively (Myers, 1952; Aldridge, 1953; Christen et al., 1969; Christen and Cohen, 1969; Cohen et al., 1971). Sterri and Fonnum (1989) presented a concept based on the presence of CarbE, which in principle could explain the differences in LD_{50} of soman among the species. The predicted LD_{50} values of soman for rats, guinea pigs, marmosets, and rhesus monkeys (or humans) agreed well with the experimental values for subcutaneous LD_{50} of soman in rats (Sterri et al., 1980, 1985a), guinea pigs (Sterri et al., 1981), marmosets, and rhesus monkeys (Dirnhuber et al., 1979). General knowledge of the experimental LD_{50}s of soman suggests that rodent plasma CarbE may be a main scavenger for soman during inhalation, IV, and subccutaneous administration, whereas additional dermal or hepatic factors may influence the LD_{50} of soman by percutane or intraperitoneal administration (Sterri, 1989).

The CarbE concept described by Sterri and Fonnum (1989) assumes that the concentration of target AChE in the nervous tissue is small, so it can be regarded as constant in the different species, whereas the concentration of CarbE in plasma differs. A strongly simplified visual representation of their proportional contribition to LD_{50} of soman in rats is shown in Figure 74.2. The concentrations of target AChE and plasma CarbE in rats is represented in the figure by the quadrangles 1 and 2, respectively, and their proportions are similar to those previously presented in the CarbE concept (Sterri and

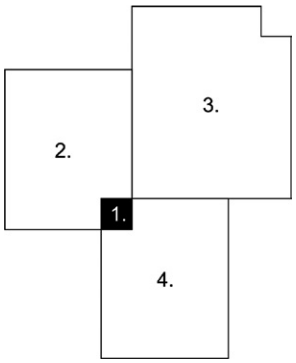

FIGURE 74.2 Visual representation of soman LD_{50} in rats as proportionally influenced by (1) target AChE, (2) plasma CarbE, (3) carbamate prophylaxis, and (4) other therapeutic regimen (at rat plasma CarbE conc.). The concentration of target AChE (1) or its enhancement by carbamate prophylaxis (3) is constant among the species, whereas the concentration of plasma CarbE (2) varies. The representation is based on the CarbE concept outlined by Sterri and Fonnum (1989) and Sterri (1989). LD_{50} decreases (and toxicity increases) when plasma CarbE (2) is decreased or absent.

Fonnum, 1989). At a glance, one can see from Figure 74.2 that without therapeutic intervention, the LD_{50} of soman as represented by (1 + 2) is strongly influenced by the concentration of plasma CarbE (2). Also, it is reduced in species with lower CarbE concentrations than rats, until it is exclusively represented by the target AChE concentration (1) in species such as rhesus monkeys and humans, which do not have CarbE in their plasma.

This concept works well with OPs that are very toxic, such as sarin, soman, and paraoxon. It does not work for less toxic OPs such as DFP because their toxicity is so low that the level of OP in plasma overwhelms the level of CarbE (Dettbarn et al., 1999). It does not work for VX and echothiophate because they are very good inhibitors of AChE and poor inhibitors of CarbE

Therapeutic Intervention

The effect on soman toxicity by pyridostigmine prophylaxis in different species could in principle also be explained by the CarbE concept of Sterri and Fonnum (1989). This means that the protection factors of carbamate prophylaxis, as calculated for the different species, were similar to the experimental protection factors of pyridostigmine prophylaxis against soman as observed with rats and guinea pigs (Gordon et al., 1978), as well as marmosets and rhesus monkeys (Dirnhuber et al., 1979). Thus, due to the CarbE concept, we were fairly convinced that the human species would achieve similar protection by pyridostigmine prophylaxis as rhesus monkeys, since both species lack the plasma CarbE. The proportional contribution by pyridostigmine prophylaxis to the LD_{50} of soman in rats is displayed in Figure 74.2, as represented by quadrangle 3. Since this prophylaxis leads to protection of a constant factor (namely, target AChE), the contribution to LD_{50} by pyridostigmine is regarded to be constant in the species (30× target AChE concentration) in accordance with the CarbE concept (Sterri and Fonnum, 1989). At a glance, one can see from Figure 74.2 that the protection factor of carbamate prophylaxis, which is the LD_{50} with prophylaxis (1 + 2 + 3) divided by that without prophylaxis (1 + 2), is relatively low in rats due to the large concentration of plasma CarbE (2), whereas in species such as rhesus monkeys and humans, the factor would be equal to 30 (see Figure 74.2, 1 + 3) divided by (1) since plasma CarbE is not present. Any other form of therapeutic regimen can be treated in a similar way to obtain the protection factor in humans.

This concept was later confirmed by studies by Maxwell and Brecht (1991) and Maxwell et al. (1993). When animals such as rats, guinea pigs, and rabbits with widely different levels of CarbE were poisoned with soman, therapeutic regimens gave the same level of protection in all the animals pretreated with CBDP.

Since plasma CarbE is established as a functional scavenger for highly toxic OP compounds, this has inspired other investigators to use artificially supplied scavengers to improve human protection against nerve gases. Efficient protection has been observed against OP poisoning by prophylactic injection of CarbE, AChE, or BuChE into the bloodstream of rodents and primates (Fonnum et al., 1985; Wolfe et al., 1987; Raveh et al., 1989, 1997; Broomfield et al., 1991; Maxwell et al., 1991, 1992; Doctor et al., 1993). In the future, new scavengers that could mimic the function of plasma CarbE might hopefully be developed. The consequence of this concept is that for evaluating toxic doses in humans, one should use animals with no plasma CarbE. This can be achieved by using plasma CarbE knockout mice, as described by Duysen et al. (2012), or rodents whose plasma CarbE is inhibited by TOCP or CBDP (Sterri et al., 1981; Fonnum and Sterri, 1981; Maxwell and Brecht, 1991; Maxwell et al., 1993; Boskovic, 1979).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Plasma CarbE has proved to play an important role in nerve gas poisoning, both with and without therapeutic intervention, and it has been shown in nature that an effective scavenger of nerve gases can be present in the blood. In accordance, both CarbE and other B-esterases have proved to be effective as artificially supplied scavengers, but since they are highly molecular proteins, some problems may be difficult to overcome for practical use. It is tempting to speculate, as has been

done previously (Sterri 1989), that a low-molecular scavenger associated with the large amount of albumin in human plasma would be a better alternative. Perhaps resources should be directed toward investigating these possibilities.

CHAPTER

75

Catalytic Bioscavengers: The New Generation of Bioscavenger-Based Medical Countermeasures

Patrick Masson

INTRODUCTION

Organophosphate thioesters/oxoesters (OPs) were discovered in the middle of the nineteenth century. They are mostly pesticides (parathion, malathion, chlorpyriphos, dichlorvos), and some of them have been used as drugs or pro-drugs (echothiophate, métrifonate, cyclophosphamide), flame retardants, and antiwear agents (tricresyl phosphate [TCP]). Other OPs are potent chemical warfare agents (G agents: tabun, sarin, soman, cylclohexyl-sarin; and V agents: VX, VR, CVX). The mysterious nerve agents (NAs) called "novichoks" (A-230, A-232, A-234) are also OPs (Tucker, 2006). Highly toxic OPs may be formed by cytochrome P450-mediated metabolic oxidation of thionophosphoesters, such as paraoxon from parent compound parathion (Foxenberg et al., 2007), or 2-(o-cresyl)-4H-1,3,2-benzodioxaphosphoran-2-one (CBDP or cresyl-saligenin phosphate [CSP]) by cyclization of tri-*ortho*-cresyl phosphate (TOCP), a TCP isomer (Eto et al., 1962). High-temperature pyrolysis of synthetic oils may lead to toxic OP such as trimethylolpropane phosphate (TMPP) (Masson et al., 2012). Most of these compounds are potent irreversible inhibitors of cholinesterases (ChEs) (Figure 75.1) (Costa, 2006) and of many other serine hydrolases. However, TMPP is not an inhibitor of ChEs; it is a gamma aminobutyric acid (GABA) antagonist so toxic that it has been called "the poor man's nerve agent."

There are two types of ChEs, acetylcholinesterase (AChE; EC 3.1.1.7) and butyrylcholinesterase (BChE; EC.3.1.1.8). AChE plays a major role in the cholinergic system terminating the action of the neurotransmitter acetylcholine (ACh). Inhibition of AChE leads to accumulation of ACh in synapses and blockade of cholinergic transmissions in peripheral and central nervous systems. Inhibition of peripheral and central AChEs is the main cause of acute toxicity of OPs (Maxwell et al., 2006). Irreversible inhibition of other enzymes, including various serine hydrolases, plays a role in subacute toxicity and noncholinergic toxicity of OPs (Casida and Quistad, 2004, 2005).

Significant progress has been made in the past 25 years in emergency treatments of acute poisoning and management of poisoned casualties (Eyer et al., 2007; Thiermann et al., 2007; Wetherell et al., 2007; Eddelston et al., 2008; Masson, 2011; Moshiri et al., 2012). However, classical pharmacological approaches are reaching their optimum limit. Recent attacks in Syria, where nerve agents (NAs) were used, revealed the limitations of current medical treatments (Dolgin, 2013). In addition, due to accumulation of OP in depot sites and subsequent slow release from these sites, blood and tissue ChEs may remain inhibited for long periods of time. Therefore, persistence of certain OPs in the body after initial exposure complicates treatments. This is particularly well-documented for severe intoxications by parathion (Willems and de Bisschop, 1993).

Endogenous enzymes are involved in natural defenses against OP toxicity. The presence of detoxifying enzymes in skin contributes to reduce the OP dose that penetrates into the body (Schallreuter et al., 2007). Numerous secondary targets of OPs found in various tissues are detoxifying enzymes and they certainly play a role in the natural defenses against OPs (Wang et al., 1998; Nomura et al., 2005, 2008). Liver enzymes play an essential role in detoxification. In particular, oxidases, such as glutathione *S*-transferases (GSTs), play a role in degradation of

Handbook of Toxicology of Chemical Warfare Agents.

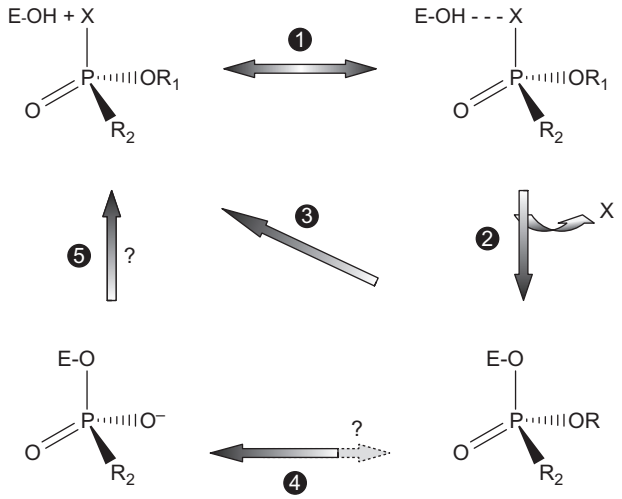

FIGURE 75.1 Mechanism of inhibition of cholinesterases by OPs. After formation of reversible complex between ChE and OP (step 1), the active serine (esteratic site, E-OH) is phosphylated; the reaction leads to release of leaving group X (step 2). The phosphylated enzyme can be reactivated by nucleophilic agents, such as quaternary oximes (2-PAM [Contrathion or pralidoxime], TMB-4, MMB-4 [methoxime], Obidoxime [toxogonin], HI-6, Karboxim), used as antidotes in emergency treatment of OP poisoning (Lundy et al., 2006; Worek et al., 2007; Worek and Thiermann, 2013) (reaction 3). Water is a nucleophile that is too weak for fast spontaneous reactivation of phosphylated ChE. The phosphyl–ChE conjugate may undergo spontaneous dealkylation through alkyl-oxygen bond scission ("aging") (Kovach 2004; Masson et al., 2010), resulting in irreversibly inactivated ("aged") enzymes (step 4). The dealkylation reaction can be very fast ($t_{1/2}$ = 3 min at 37°C for human AChE phosphonylated by soman). At the moment, drug-mediated reactivation to E-OH through realkylation (R_1) of aged ChE (reverse reaction 4 and subsequent reaction 3) or direct displacement of the aged adduct (reaction 5) are not possible.

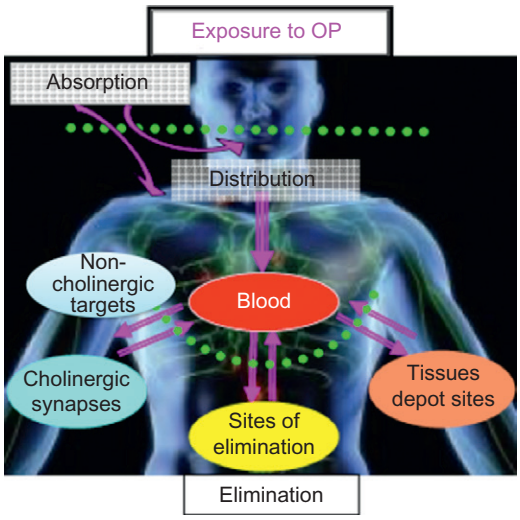

FIGURE 75.2 Biological fate of organophosphorus compounds in humans. Routes of penetration of OPs are absorption through the skin, eyes, and/or respiratory tract (nerve agents, pesticides), or ingestion (self-poisoning). OP molecules distribute from the blood compartment into tissues, including depot sites, biophases (cholinergic synapses and secondary targets), and sites of elimination (liver and kidneys). Cholinesterases are the main biological targets (acute toxicity); reaction with secondary targets (carboxylesterases, serine-amidases, peptidases, and other proteins) may be responsible for non-cholinergic sublethal effects of OPs and chronic toxicity at low-dose exposure (Casida and Quistad, 2004; Costa, 2006).

alkyl/aryl chains (Casida and Durkin, 2013). However, as mentioned, liver cytochrome P450 enzymes activate phosphorothioates and lead to oxon forms much more toxic than parent compounds, but cytochrome P450 also dearylate aryl-containing OPs and participate in detoxification of OPs (Furlong, 2007; Ellison et al., 2012). Natural blood bioscavengers significantly contribute to reduce the amount of OP molecules reaching physiological targets. It has been shown that animal species in which the concentrations in paraoxonase-1 (PON-1; EC 3.1.8.1) or in carboxylesterase (CarbE; EC 3.1.1.1) are high are relatively resistant to OPs (Kaliste-Korhonen et al., 1996). Conversely, *knockout* mice for PON1 are very sensitive to OPs (Shih et al., 1998). Albumin displays low esterase activity and slowly reacts with carbamyl-esters and phosphoryl-esters. However, its concentration in blood and lymph is so high (≈0.6 mM) that it likely plays a role in detoxification of carbaryl at toxicologically relevant concentrations (Sogorb et al., 2007). Thus, plasma albumin could also play a role in detoxification of certain OPs (Li et al., 2008; Tahroni et al., 2007).

Toxicity of OPs can be countered by reducing skin absorption and lowering OP concentrations in the blood compartment, thus preventing the transfer of OP molecules toward cholinergic synapses and other biological targets (Figure 75.2). Neutralization of toxicant molecules can be achieved by using stoichiometric traps or catalysts acting on exposed surfaces (e.g., active TSPs) or in the bloodstream (bioscavengers). The concepts of bioscavenger and development of this approach in prophylaxis and post-exposure treatment of OP poisoning have been exposed in several recent reviews (Masson and Rochu, 2009; Masson and Lockridge, 2010; Nachon et al., 2013).

STOICHIOMETRIC SCAVENGERS

The first molecules that have been studied with the purpose of making stoichiometric scavengers were cyclodextrins (Désiré and Saint-André, 1986), neutralizing antibodies (Glikson et al., 1992), and activated charcoal. Although the interest of charcoal is much debated, hemodialysis on a charcoal cartridge was successfully used in a Tokyo casualty who was resistant to the classical treatment for sarin poisoning (Yokoyama et al., 1995). Transfusion of human plasma has been used for treating OP poisoning. The effects of fresh-frozen plasma (plasmapheresis) on ChE levels and outcomes in OP-poisoned

patients have been evaluated (Güven et al., 2004; Qiu et al., 2011). An *in vitro* study also suggests that plasma (freshly prepared and fresh-frozen plasma) therapy may be an effective adjunctive treatment method against G agents (Wille et al., 2013). Plasma BChE and possibly other abundant OP scavenging proteins in plasma (e.g., albumin, PON-1) may have contributed to these results. At this point, it must be noted that unlike plasma of most model animals, human plasma does not contain CarbE (Li et al., 2005).

At the end of the 1980s, research of scavengers mostly focused on enzymes that specifically react with OPs. ChEs (Wolfe et al., 1987) and CarbE (Redinbo and Potter, 2005; Fleming et al., 2007; Hemmert et al., 2010) have been proposed as stoichiometric scavengers. Human BChE has been proven to be an effective stoichiometric bioscavenger for pretreatment and post-exposure treatment of NA and OP pesticide poisoning (Allon et al., 1998; Doctor and Saxena, 2005; Lenz et al., 2007; Saxena et al., 2008a,b; Mumford et al., 2013; Rosenberg et al., 2013, 2014). Human plasma-derived BChE was granted Investigational New Drug (IND) status by the FDA in 2006 for protection against NAs (Lenz et al., 2007). Clinical trials using volunteers (phase I) started a few years ago. However, enzymatic stoichiometric neutralization of several OP LD_{50} needs administration of huge amounts of enzymes, approximately 3 mg/kg of highly purified plasma BChE (i.e., 200–300 mg for humans against 2× LD_{50} of soman) (Ashani and Pistinner, 2004). Large-scale production of enzymes under good manufacturing practices (GMP) conditions at a reasonable cost was the subject of intense research during the past 10 years. However, although several thousand tons of outdated human plasma are available in the United States for preparing the enzyme, 1 L of human plasma provides less than 1 mg of GMP BChE.

Several industrial GMP processes have been proposed for mass production of human BChE. The first one is purification of the natural enzyme from human plasma (Cohn Fraction IV). This process has been developed by Saxena et al. (2008a,b), Lockridge et al. (unpublished), and Baxter Healthcare Corporation (www.baxter.com). The second method has been developed by Nexia (www.nexiabiotech.com); it uses the recombinant human enzyme produced in milk of transgenic goats. Several grams of enzyme can be secreted in 1 L of milk. This enzyme has been named Protexia™. Since 2005, Pharmatheme (www.pharmathene.com) developed Protexia™ PEGylated derivatives of this enzyme (Huang et al., 2007) and fusion proteins (Huang et al., 2008). However, production of recombinant human BChE in milk of transgenic mammals has been discontinued due to high coast and pharmacokinetics problems. Therefore, Pharmatheme and other companies are working on large-scale production of recombinant human BChE expressed in human cells or in Chinese hamster ovary (CHO) cells (Rosenberg et al., 2010). Production of human BChE in transgenic tobacco has also been made possible (Geyer et al., 2010; Larrimore et al., 2013). PlantForm in Canada (www.plantformcorp.com) has been engaged in development of recombinant human BChE in tobacco that mimics stability and pharmacokinetics of plasma-derived enzyme.

Certain secondary targets of OPs are potential bioscavengers. In particular, because of the high number of amino acid residues in human serum albumin that covalently bind OP molecules (five tyrosines and two serines) (Ding et al., 2008), it may be hypothesized that reactivity of these residues could be enhanced by genetic engineering and/or on specific chemical modification. However, direct tyrosine nitration (to lower pK_a of tyrosine) did not lead to expected improvement in reactivity, possibly because of steric hindrance (Masson et al., unpublished). Engineered albumins could lead to a new generation of stoichiometric bioscavengers. However, conversion of albumin into a catalytic bioscavenger would need to increase its catalytic efficiency by several orders of magnitude, a challenge that seems to be unrealistic (Li et al., 2008).

Low molecular stoichiometric scavengers could be an economic alternative to enzyme-based stoichiometric scavengers. Several serine-containing and tyrosine-containing hexapeptides from a random library of peptides have been selected because they form phosphoester bond with a fluorescent analog of sarin (Landry and Deng, 2008; Zhu et al., 2008). Finally, a way to increase the endogenous stoichiometric bioscavenger capacity could be to enhance the endogenous expression of BChE and AChE. This could be achieved by administration of proline-rich polypeptides derived from ChE collagenic tail peptide (ColQ PRAD) or peptides derived from transmembrane anchor (PRIMA) that promote folding, tetrameric assembly, and exportation of the enzymes from cells (Rotundo, 2011).

PSEUDOCATALYTIC BIOSCAVENGERS

Because the main limitation of the stoichiometric bioscavenger approach is the cost of the huge dose of enzyme to be administered for challenging the OP molecules, a way to circumvent this problem is to *in vivo* reactivate the administered enzyme, turning the stoichiometric bioscavenger into a pseudocatalytic bioscavenger.

Certain ChE mutants sensitive to OPs do not "age" after phosphylation; they are fully reactivatable (Figure 75.1, reaction 3). Such ChE mutants, such as the human AChE mutant Y337A/F338A (Cochran et al., 2011) when associated with oximes (e.g., 2-PAM, HI-6), act as pseudocatalysts in displacing the OP moiety bound to the enzyme. These enzyme reactivator-coupled systems could lead to a new family of pseudocatalytic bioscavengers (Taylor et al., 2007; Kovarik et al., 2007, 2013;

Mazor et al., 2008). Success of this approach requires implementation of new oximes displaying higher affinity for phosphylated ChEs (lower K_D), higher reactivation constant (k_r), and a long circulation time in the bloodstream. Study with wild-type human BChE showed that the geometry of oxime function access to the phosphorus atom of conjugate is an important criterion for a fast reactivation. Several libraries of positively charged and uncharged molecules have already been made by *in silico* design or click chemistry and tested with success *in vitro* against tabun and soman (Kovarik et al., 2013; Radić et al., 2013; Renou et al., 2013).

CATALYTIC SCAVENGERS

Catalytic scavengers are enzymes or artificial catalysts capable of degrading OPs. These catalysts detoxify OPs by hydrolyzing the phosphoester (organophosphorus acid anhydride hydrolase, OPAA) activity, also called "phosphotriesterase" activity, OP hydrolase (OPH, OPase) activity, or lead to less toxic compounds by degrading their alkyl/aryl chains through oxidation.

The catalytic bioscavenger concept, second-generation bioscavengers, is based on the idea of continuously trapping and degrading OPs with a turnover in the bloodstream before OP molecules reach their central and peripheral neuronal and neuromuscular targets. Then, prophylactic injection of enzymes capable of hydrolyzing OP quickly (alone or in association with current prophylactic countermeasures, i.e., pyridostigmine bromide, PANPAL, and other reversible ChE inhibitors and anticholinergic drugs) (Masson, 2011) would allow first responders, firemen, explosive ordnance disposal technicians, and medical personnel to operate safely in contaminated environments on contaminated casualties. Intravenous or intramuscular administration of bioscavengers to chemical casualties is expected to greatly improve the efficacy of implemented pharmacological countermeasures (Ashani et al., 1998; Saxena et al., 2006).

These enzymes could be used also for protection of skin (Fisher et al., 2005), and for decontamination of skin, mucosa, and open wounds (Lejeune and Russell, 1999; Gill and Ballesteros, 2000). Genetically engineered bacteria producing OPHs could be introduced in water effluents of decontamination units and could purify contaminated water before recycling or washing up in the environment (Chen and Mulchandani, 1998).

Research of catalytic antibodies has made some progress (Jovic et al., 2005; Smirnov et al., 2012). In particular, resolution of the three-dimensional structure of a "reactibody" fragment with an OP (Smirnov et al., 2011) has opened the possibility of rational design of more active catalytic antibodies (Kurkova et al., 2012). However, the turnover of catalytic antibodies remains extremely slow, and their specificity is too narrow for practical interest as medical countermeasures.

Research of artificial enzymes acting as catalytic scavengers (e.g., functionalized β-cyclodextrins) is promising. Cyclodrextrin derivatives bearing a nucleophilic group such as isodozobenzoic acid or an oxime were made (Ramaseshan et al., 2006; Estour et al., 2013; Kalakuntla et al., 2013; Bierwisch et al., 2014). These compounds display very interesting catalytic properties against certain NAs, particularly cyclosarin (Müller et al., 2013). However, engineering (computer design and/or directed evolution) of enzymes capable of degrading OPs remains the most promising short-term research field.

REQUIREMENTS

The general requirements for the use of enzyme-degrading OPs as medical countermeasures against OP poisoning are as follows. These enzymes must have a large activity spectra and, ideally, enantioselectivity for toxic stereoisomers. Their mass production under GMP conditions must be realizable at a reasonable cost. Long-term storage without activity loss (in solution, lyophilized, or adsorbed/bound on a matrix) must be possible under field conditions. Conformational stability can be optimized by chemical modification or addition of stabilizers likes polyols. Otherwise, thermostable enzymes from hyperthermophilic bacteria (Merone et al., 2005; Elias et al., 2008) and expressed in *E. coli* or mutated/evolved highly stable enzymes from mesophilic bacteria are promising alternatives.

Other conditions depend on the type of administration, delivery system, or galenic formulation of these enzymes. Enzymes can be injected intravenously or intramuscularly. Other routes have been considered, such as the intranasal route against aerosolized or gaseous NAs. For instance, pretreatment with aerosolized forms of BChE have been shown to protect against aerosolized paraoxon (Rosenberg et al., 2013). For parenteral administration, the toxicant concentration in blood has to be considered. Even in the most severe case of poisoning, this [OP] concentration is always very low. For example, the sarin concentration in serum of casualties after Matsumoto and Tokyo chemical attacks have been estimated between 1.5 and 30 nM at 14 h after exposure (Polhuijs et al., 1997). Therefore, the [OP] concentration in plasma is always well below the K_m of the enzyme for OP substrates. This determines first-order kinetics for hydrolysis of OP in blood (Masson et al., 1998, 2008) as described by Eq. (75.1):

$$v = k_{cat}/K_m \cdot [E] \cdot [OP] \tag{75.1}$$

In Eq. (75.1), the product of the bimolecular rate constant (k_{cat}/K_m) and the enzyme active site concentration ([E]) is the first-order rate constant. The amount of enzyme to be injected for degradation of toxic molecules in a very short time depends on the enzyme efficiency (i.e., k_{cat}/K_m). The higher the catalytic efficiency, the lower the enzyme dose to be administered. The enzyme concentration that reduces the OP concentration to a nontoxic concentration in time t is:

$$[E] = \frac{X}{k_{cat}/K_m \cdot t} \tag{75.2}$$

X is the factor by which [OP] is reduced ($X = \mathrm{Ln}[OP]_0/[OP]_t$) (Masson et al., 2008). In this equation, it is assumed that stability and pharmacokinetics of the administered enzyme have been optimized, and that the enzyme concentration [E] does not decrease during the time course of the reaction with OP. The efficiency and stereo-specificity of a given enzyme can be increased by several orders of magnitude by mutagenesis or chemical engineering (Griffiths and Tawfik, 2003; Hill et al., 2003; Gupta et al., 2011; Tsai et al., 2012).

The second constraint is to maintain the bioscavenger concentration [E] in the bloodstream as high as possible for a long time. [E] is controlled by the enzyme pharmacokinetics/pharmacodynamics and/or the frequency of repeated administrations. Increasing the size of the enzyme by polymerization, decreasing glycosylation microheterogeneity, and chemical modifications of solvent-exposed surface ("capping") improve the biological life of injected enzymes (Cohen et al., 2006). Fast clearance of glycoproteins is often due to glycosylation defects; fast clearance of nonglycosylated enzyme may result from their too small size (Jackson et al., 2010). Glycosylation defects can be corrected by chemical modifications such as PEGylation (Chilukuri et al., 2005), polysialylation of purified expressed enzyme (Ilyushin et al., 2013), or by selection of appropriate expression system (Chitlaru et al., 1998), including overexpression of an additional glycosylation enzyme that increases sialylation content of the expressed glycoprotein (Schneider et al., 2013). Size defects can be corrected by conjugation to polyethylene glycol, dextran, other macromolecules, or fusion to albumin (Huang et al., 2008). All these modifications reduce renal clearance and increase plasma retention.

Administration of homologous enzymes does not induce immunologic response after a second injection (Sun et al., 2009). However, immunotolerance of injected heterologous enzymes is a major issue. Bacterial enzymes and heterologous mammalian enzymes are not suitable for use in humans, but conjugation to dextran or polyethylene glycol (PEGylation) is often sufficient to reduce antigenicity and to slow clearance after multiple injections (Novikov et al., 2010; Trovaslet-Leroy et al., 2011; Sun et al., 2013).

Extracorporeal dialysis has been successfully implemented in a patient for blood decontamination after the Tokyo subway attack (Yokoyama et al., 1995). Incorporation of OP-degrading enzymes in the medical dialysis system could greatly improve the efficiency of dialysis. Enzymes can be immobilized on dialysis cartridges (Klein and Langer, 1986). Accessibility of OP molecules to an enzyme active center must not be altered by the immobilization method or by matrix effects. The enzyme concentration per surface unit has to be maximized to reduce diffusion constraints. In that case, both the reactive surface of the matrix and k_{cat}/K_m would have to be as high as possible and the flow rate would have to be reduced to increase the efficiency of the reactor. First-order degradation kinetics takes place under the particular conditions of immobilized enzymes in the continuous-flow system. Immunocompatibility problems are theoretically suppressed, thus permitting the use of unmodified nonhuman enzymes.

Finally, *in situ* transient production of enzymes, if the need arises, will be possible by gene therapy in the future. Promising results have been published using short-induction gene vectors (adenoviral systems) for human PON-1 (Cowan et al., 2001; Bradshaw et al., 2005; Fu et al., 2005; Miyoshi et al., 2007; Guns et al., 2008; Duysen et al., 2011), human AChE (Li et al., 2006), human BChE (Chilukuri et al., 2009; Parikh et al., 2011), mutated human BChE that displays high cocaine esterase (Gao et al., 2013), and human prolidase (Aleti et al., 2013).

Enzymes in skin and eye lotions, immobilized in foams and on tissues for skin and eye decontamination (Gordon et al., 2003) or in TSPs (Braue et al., 2002) act under conditions where local OP concentrations can be very high. In these cases, enzyme reaction order in OPs tends to zero, so that reaction rate is close to maximum velocity:

$$v \rightarrow V_{max} = k_{cat} \cdot [E] \tag{75.3}$$

The enzyme efficiency depends on its concentration and its catalytic constant k_{cat}. Thus, for external use, enzyme preparations have to be highly concentrated with high molecular catalytic activity. Co-immobilization of different enzymes could be an easy way to extend the spectra of agents to be degraded. This should allow simultaneous detoxification of G and V agents, as well as other potential chemical warfare agents, pesticides, and so-called "nontraditional nerve agents." Exposure to multiple agents has to be considered. In this view, it should be remembered that during the war between Iran and Iraq, tabun and other OPs have been combined with mustard gas in some attacks (UN Reports, 1984, 1987). In asymmetric conflicts and eschatological and mafia-like terrorism, the most extreme scenarios have to be taken into account.

POTENTIAL ENZYMES

Phosphotriesterases

Bacterial PTEs

Bacterial PTEs (EC 3.1.8.1) detoxify OPs (Ghanem and Raushel, 2005; Theriot and Grunden, 2011). These enzymes have been isolated from numerous sources. Four enzyme families showing different folds or topologies can be described: TIM-barrel fold, β-lactamase fold, pita bread fold, and β-propeller fold (Bigley and Raushel, 2013). They are encoded by the OP degradation (*opd*) gene found in species of *Brevundimonas diminuta* (formerly *Pseudomonas diminuta*), *Flavobacterium Sp., Agrobacterium radiobacter* (Horne et al., 2002), *Pseudomonas pseudoalcaligenes* (Gotthard et al., 2013), and genes similar to *opd* were also located in archaea (Merone et al., 2005). PTEs belong to a superfamily of amidohydrolases (Holm and Sander, 1997; Bigley and Raushel, 2013).

Brevundimonas diminuta PTE is a 72-kDa dimeric bimetallic enzyme with Zn^{2+} involved in the catalytic process (Carletti et al., 2009). Substitution of the native Zn^{2+} ions in the active site with Mn, Co, Ni, or Cd ions results in the almost full retention of catalytic activity. After the first determination of the three-dimensional structure of *P. diminuta* PTE (Benning et al., 1994), a series of crystal structures and kinetic and spectroscopic experiments were described. Nevertheless, the enzyme mechanism of bacterial PTEs is still debated and the functional roles of divalent metal cations and amino acids in the active center are not yet fully understood (Aubert et al., 2004; Jackson et al., 2006, 2008; Chen et al., 2007; Samples et al., 2007; Wong and Gao, 2007; Bigley and Raushel, 2013).

These enzymes that are primarily lactonases are now called PTE-like lactonases (PLLs). The lactonase activity plays a role in bacterial communication (*quorum* sensing) (Dickschat, 2009). Virulence and formation of biofilms are regulated by concentration of lactones (*N*-acetyl-homoserine lactones) in the medium. Thus, the lactonase activity by hydrolyzing lactones acts as a *quorum* quencher, which in turn inhibits bacterial communication (Amara et al., 2011). The PTE activity is an undiscriminating activity believed to have evolved from lactonases (Afriat et al., 2006; Elias et al., 2008; Afriat-Jurnou et al., 2012; Hiblot et al., 2012).

Whereas the catalytic efficiency of *Brevundimonas diminuta* PTE for hydrolysis of paraoxon, the best substrate identified so far, is approaching the diffusion-controlled limit, it is slow against OP NAs (Table 75.1). Meanwhile, directed evolution of *Brevundimonas diminuta* PTE showed that only three amino acid changes dramatically enhanced the catalytic efficiency for an analogue of soman by approximately three orders of magnitude (Hill et al., 2003). Further studies combining rational design and directed evolution led to randomized libraries of mutants and selection of variants with greatly improved catalytic activity against S_p enantiomers of NA chromogenic analogues, including VX and VR analogues, and racemic real NAs (Table 75.1) (Tsai et al., 2010, 2012). There have been numerous studies highlighting the potential of this enzyme for decontamination or skin protection in addition to OP detection (Lejeune and Russell, 1999; Gill and Ballesteros, 2000; Ghanem and Raushel, 2005; Létant et al., 2005; Karnati et al., 2007). Administration of PTE before or after OP exposure was shown to improve pretreatment and current treatment of OP intoxication (Doctor and Saxena, 2005). However, to prevent abnormally fast pharmacokinetics and/or immunological response due to injection of a bacterial enzyme, PTE could be PEGylated (Jun et al., 2007) or encapsulated. First attempts at using PTE encapsulated within sterically stabilized liposomes were promising, providing protection of rats from multiple LD_{50}s of OP pesticides (Petrikovics et al., 2004). An alternative route could be the blood detoxification by extracorporeal circulation through a cartridge containing PTE immobilized in hollow fibers (unpublished results). PTEs possibly could also be used for skin protection as active components of TSPs or covalently coupled to the cornified layer of epidermis (Parsa and Green, 2001).

Brevundimonas diminuta PTE was also entrapped in additives for latex coating of biodefensive surfaces. Such PTE-based additives for paints and coatings were shown to retain catalytic parameters and stability of the enzyme (McDaniel et al., 2006). For decontamination of OPs in the environment and remediation, an alternative approach, phytodegradation by transgenic plants (e.g., tobacco) expressing a bacterial PTE, has been considered as a potentially low-cost, effective, and environmentally friendly method (Wang et al., 2008). It should be mentioned that His-tagged PTE (Efremenko et al., 2007) was reported to degrade NAs, including VX, at a high rate. Because the enzyme was not genetically modified, it is suggested that the presence of His tag plays a role in this amazing activity. Although neither three-dimensional structure nor molecular dynamics studies are available for this enzyme, it can be hypothesized that the His tag may increase the enzyme flexibility, which in turn should increase the enzyme capability to accommodate numerous OP molecules and improve its catalytic activity.

Highly stable promiscuous lactonases/PTEs from hyperthermophilic archae have been isolated in hot springs and volcano *solfatare*. Their three-dimensional structures, evolution, stability, and catalytic properties of several have been determined (Elias et al., 2008; Zhang et al., 2012; Hiblot et al., 2012; 2013a,b; Gotthard et al., 2013; Porzio et al., 2013). These enzymes have

been conveniently expressed in *E. coli* and mutated (site-directed mutagenesis and directed evolution) to improve their catalytic properties against OPs (Merone et al., 2010; Hiblot et al., 2012; 2013a,b) (Table 75.1). Because of their high stability that allows long-term storage at room temperature, fieldable uses for decontamination are possible. Other extremophile PTEs have been isolated from radio-resistant bacteria, *Deinococcus radiodurans*, and *Agrobacterium radiobacter.* Three-dimensional structure and catalytic mechanism of these enzymes have been determined and used for structure-based random mutagenesis rational design to improve their catalytic

efficiency against OPs (Hawwa et al., 2009; Jackson et al., 2009; Ely et al., 2012).

Human Paraoxonase (PON-1)

The human paraoxonase-1 (PON-1) is a 45-kDa calcium-dependent enzyme bound to high-density lipoprotein (HDL) particles in association with other apolipoproteins. PON-1 shows a genetic polymorphism; the most prominent allele determines the Q192R allozyme, which can have a substantial impact on PON-1 activity against OPs and arylesters (Smolen et al., 1991) (Table 75.1). The enzyme was shown to be involved in the protection against atherosclerosis (Watson et al., 1995; Shih et al., 1998), and thus became a player in vascular physiology. Albeit its primary function is a lipophilic lactonase (Khersonsky and Tawfik, 2005; Ben-David et al., 2013), PON-1 displays two random activities, PTE and arylesterase.

Abundant biochemical, biological, and toxicological information have been collected in the past two decades, leading to partial characterization of the enzyme function (Costa and Furlong, 2002; Mackness et al., 2008), but recurrent attempts at solving the structure of human PON-1 failed. Through chemical modification and site-directed mutagenesis studies, some amino acid residues have been identified as essential for activity (Josse et al., 1999). Finally, molecular modeling (Fokine et al., 2003; Yeung et al., 2004) and crystal structure of a hybrid rPON-1 (a synthetic construct issued from shuffling of rabbit, mouse, rat, and human PON-1 genes expressed in *E. coli*) (Harel et al., 2004), showed that human PON-1 is a six-bladed β-propeller protein with a structure very similar to that of *Loligo vulgaris* DFPase (Katsemi et al., 2005). A catalytic mechanism for this eukaryotic calcium-dependent PTE was described (Blum et al., 2006). This mechanism involves a calcium-coordinated aspartate residue as the nucleophile that attacks the OP phosphorus atom. Alternatively, another more realistic mechanism was recently proposed; it involves the activation of a water molecule into a hydroxide ion that attacks the phosphorus center (Elias et al., 2013). This mechanism is consistent with the common mechanism that has been proposed for PON-1 (Ben-David et al., 2013), PTEs (Aubert et al., 2004), and PLLs (Elias et al., 2008).

As a naturally occurring enzyme present in plasma, human PON-1 is the most promising catalytic scavenger candidate for pretreatment and therapy of poisoning by OP (La Du, 1996; Rochu et al., 2007a; Worek et al., 2014). Thus, the enzyme has been the focus of intensive research to improve its efficacy and functionalization. To provide a valuable medical countermeasure against intoxication by NAs, the catalytic efficiency of PON-1 has to be enhanced by only one or two orders of magnitude. Chimeric PON-1 mutants obtained by directed evolution and exhibiting enhanced OPH activity (Amitai et al., 2006; Ashani et al., 2011; Worek et al., 2014) show that this goal could be reasonably achieved soon. However, instability of PON-1 mutants could impinge on their biotechnological development. As an HDL-bound protein, PON-1 requires association with apolipoprotein partners to retain its stable active conformation (James and Deakin, 2004; Gaidukov and Tawfik, 2005; Rochu et al., 2010) and long residence time in the bloodstream (Valiyaveettil et al., 2012). Highly purified human plasma PON-1 was found to be associated to human phosphate binding protein (HPBP) (Rochu et al., 2007b). HPBP is an apolipoprotein that binds inorganic phosphate in blood. HPBP was serendipitously discovered (Morales et al., 2006). This protein belongs to the family of DING proteins: named after their DINGGG N termini (Berna et al., 2009). Its three-dimensional structure and complete amino acid sequence were solved (Morales et al., 2006; Diemer et al., 2008). The conditions found to separate HPBP and PON1 *in vitro* indicated that HPBP is strongly associated with PON-1 (Renault et al., 2006). Moreover, the stabilization of the active form(s) of human PON-1 by HPBP suggests that HPBP could be a functional chaperone for PON1 (Rochu et al., 2007b,c; Cléry-Barraud et al., 2009).

A gene issued from HPBP amino acid sequence was synthesized (Diemer et al., 2008), and the protein was expressed in *E. coli*. However, attempts at co-crystallization of the PON-1-HPBP complex have failed so far. Yet this crucial phase is the first step of the staircase leading to the design and development of stable human PON-1 mutants with enhanced catalytic efficiency against toxic OP stereoisomers (S_p) of G NAs.

Site-directed mutagenesis of human PON-1 based on molecular modeling has led to double mutants capable of hydrolyzing G and V NAs (Kirby et al., 2013). However, the catalytic efficiency of these mutants is modest and enantioselectivity is not changed compared with the wild-type enzyme. Directed evolution strategy has been more successful in producing chimeric PON-1 capable of degrading toxic isomers of coumarinyl NA analogs as well as real G NAs. In particular, enantioselectivity of evolved PON-1 was completely reversed. For instance, the activity against S_p-cyclosarin was enhanced by 10^5-fold (Ashani et al., 2011; Gupta et al., 2011; Goldsmith et al., 2012). The most active evolved PON-1 mutant, IIG1 (Table 75.1), administered at a dose of 1 mg/kg was shown to prevent 2× LD_{50} cyclosarin systemic toxicity in guinea pigs (Worek et al., 2014). This mutant was also shown to detoxify most G NAs at high rates under first-order conditions but was ineffective against VX under second-order conditions.

Gene therapy could also be considered to challenge OPs by using a mutated PON-1 gene coding for an enzyme with high OPH activity against NAs. Several approaches with different gene delivery vectors in mice showed increased PON-1 level serum that reduced or

even prevented the entry of OP into the brain and reduced atherosclerosis signs (Cowan et al., 2001; Bradshaw et al., 2005; Fu et al., 2005; Guns et al., 2008; Duysen et al., 2011; Hodgins et al., 2013). Local delivery of PON-1 gene using Sendai virus vector inhibited neonatal hyperplasia after arterial balloon injury in rabbits fed a high-fat diet (Miyoshi et al., 2007). However, wild-type human PON-1 does not have sufficient catalytic efficiency against NAs to provide *in vivo* protection against 2× LD_{50} of G agents. Thus, enhanced expression of mutated PON-1 by gene therapy could be beneficial for the different functions of the enzyme. Meanwhile, the complex and defectively identified PON-1 activity makes it apparent that strategy for repetitive administration of high concentrations in humans must be undertaken cautiously. For further details on paraoxonase, see chapter 73.

Other Enzymes

Other enzymes are involved in biodegradation of OPs; some are hydrolases such as prolidases, senescence marker protein (SMP), and platelet-activating factor (PAF-AH); others are oxidases, such as cytochromes P450, GSTs, laccases, and peroxidases.

Other Mammalian PTEs

Prolidases (PROL; EC 3.4.13.9) were first isolated from halophilic bacteria (*Alteromonas haloplanktis* and *A. sp.* JD6.5). This bacterial metallo-enzyme (binuclear Mn^{++} center) has a "pita bread" structure (Vyas et al., 2010). Prolidase from *A. sp.* JD6.5 is an OPAA that displays high activity against soman ($k_{cat} = 3{,}100\,s^{-1}$), but it is inactive against VX (Cheng et al., 1999). Thermostable prolidases from hyperthermophilic archaes *Pyrococcus furiosus* (Theriot et al., 2010) and *Pyrococcus horikoshii* (Theriot et al., 2011) hydrolyze P-F and P-O bond in NAs. Evolved mutants of these enzymes capable of degrading OPs over wide temperature ranges, as engineered hyperthermophilic PLLs do, should have future use for biodecontamination under mild conditions. PROL was also isolated from human liver, kidney, erythrocytes, and skin, and was expressed in *E. coli* (diTargiani et al., 2010; Costance et al., 2012; Chandrasekaran et al., 2013). This enzyme displays a catalytic activity against sarin and soman (Wang et al., 1998; diTargiani et al., 2010) and exhibits sequence homology with the *Aleromonas haloplanktis* prolidase (Wang et al., 2006). Gene-delivered human liver PROL using adenovirus produced high level of active enzyme but protected mice only against 1× LD_{50} of DFP (Aleti et al., 2013).

SMP-30 was isolated first from rat liver (Kondo et al., 2004). It is a six-bladed-β-propeller metallo-lactonase structurally close to PON-1 and DFPase with random PTE activity (Chakraborty and Bahnson, 2010). The human and mouse enzymes display modest PTE against G agents (diTargiani et al., 2010; Belinskaya et al., 2012). Engineering of this enzyme is still in its beginnings.

PAF-AH is a group of 45-kDa lipoprotein (HDL and LDL)-associated phospholipase A2. In humans, they are present in plasma and in the brain. These enzymes that react with numerous OPs are structurally related to neuropathy target esterase (NTE) (Karasawa et al., 2003; Quistad et al., 2004, 2005; Epstein et al., 2009). Site-directed mutagenesis of human plasma PAF-AH for making an OPH for the purpose of NA detoxification has been undertaken (Kirby et al., 2012). However, research of these enzymes as possible catalytic bioscavengers is still in its infancy.

Oxidases

GSTs (EC 2.5.1.18) are 20- to 30-kDa enzymes that catalyze glutathione conjugation (nucleophilic attack of the thiol group) to electrophilic substrates. They are involved in cellular detoxification processes of endogenous compounds and of numerous xenobiotics, and their role in resistance to insecticides in insects is well established. OP detoxification by GSTs results from a regioselective dealkylation of alkyl or aryl side chain (Maturano et al., 1997). These enzymes exhibit wide genetic polymorphisms. Some GST allelozymes from *Drosophila melanogaste*r and *Musca domestica* flies are highly active against OP insecticides and have been cloned and expressed in *E. coli* (Fournier et al., 1992). There is evidence that GSTs contribute to OP detoxification in humans (Fujioka and Casida, 2007).

Laccases (EC 1.10.3.2) are fungal phenol oxidoreductases that have been used for detoxification of numerous xenobiotics, including dyes and pesticides (Richardt and Blum, 2008). The laccases from *Pleurotus ostreatus* and *Chaetomium thermophilium* were found to rapidly degrade VX and VR in the presence of 2,2′-azinobis(3-ethylbenzthiazoline-6-sulfonate) (ABTS) as a mediator (Amitai et al., 1998). Laccases from *Trametes versicolor* and *Coriolopsis polyzona* with ABTS display similar properties against V agents (Trovaslet et al., 2010). The heme-containing chloroperoxidase (EC 1.11.1.X) from *Caldaromyces fumago*, with peroxide as co-substrate, is another efficient VX-degrading enzyme (Amitai et al., 2003).

These enzymes are promising for destruction of chemical weapons stockpiles, soil remediation, decontamination of materials, protective equipments, and water polluted by pesticides and NAs (Russel et al., 2003). In particular, phosphorothiolates such as VX are almost resistant to PTEs. Thus, oxidative cleavage of the P-S bond could be achieved by oxidases like laccases. These enzymes could be used in association with other OP-degrading enzymes for skin decontamination or in topical skin protection formulations. Although no work has been performed on combined action of oxidases and hydrolases, oxidation of P-bonded alkyl/aryl chains by oxidases is expected to alter enantioselectivity of PTE

for parent OPs. Therefore, biopharmaceutical formulations of combined oxidases and PTEs may improve the efficiency of PTE-based catalytic bioscavengers.

Engineered ChEs and CarbEs

As seen in Figure 75.1, OPs may be regarded as pseudo-substrates of ChEs and CarbEs. When ChEs and CarbEs react with carboxyl-ester substrates, the acyl-enzyme intermediate is a transient, with the acyl group being rapidly displaced by a water molecule. On the contrary, in the case of phosphyl-esters, the stereochemistry of the phosphyl-enzyme intermediate restricts the accessibility of water to the phosphorus atom. Thus, hydrolysis of phosphylated intermediate is very slow, and the enzyme remains inhibited (Järv, 1989). It was postulated that introduction of a second nucleophile pole in the active center could activate a water molecule. This water molecule could subsequently attack the phosphorus atom on the back face, leading to breakage of the P-serine bond.

The determination of the three-dimensional structure of AChE from *Torpedo californica* (Sussman et al., 1991) opened the way to rational redesign of CarbEs. Then, the possibility to convert a ChE into an OPH was demonstrated a few years later by Millard et al. (1995). Human BChE was chosen as the model enzyme because its active center is larger (500 $Å^3$) and less stereo-specific than that of AChE (300 $Å^3$). Molecular modeling based on the structure of the *Torpedo* AChE model was used for making the first mutants of human BChE. The second nucleophile pole was created in the oxyanion hole of the active center; a glycine residue was replaced by a histidine. The first mutant, G117H, was capable of hydrolyzing paraoxon, sarin, echothiophate, and VX (Millard et al., 1995; Lockridge et al., 1997) (Figure 75.3). However, this mutant was irreversibly inhibited by soman because the "aging" process of the conjugate was faster than the dephosphonylation reaction (Figure 75.1, reaction 4). The mechanism of aging (i.e., dealkylation of an akyl chain on the phosphylated serine adduct) is almost completely elucidated. The dealkylation reaction involves a carbocationic transient that is stabilized by active site residues E197 and W82 and water molecules (Kovach, 2004; Masson et al., 2010). Mutation of E197 into D, Q, or G considerably reduced the rate of aging. As expected, the double mutant G117H/E197Q was capable of hydrolyzing soman (Millard et al., 1999). However, the catalytic activity of this mutant was too slow to be of pharmacological interest.

Construction of transgenic mice *knockout* for AChE and carrying the G117H mutant of human BChE were found to be less sensitive to OP than in wild-type animals (Wang et al., 2004). Although transgenic mice expressed G117H mutant in all organs, unlike resistance of the blow fly, their resistance to OP cannot be explained by OP hydrolysis that was too slow, but rather by hydrolysis of excess ACh in cholinergic synapses.

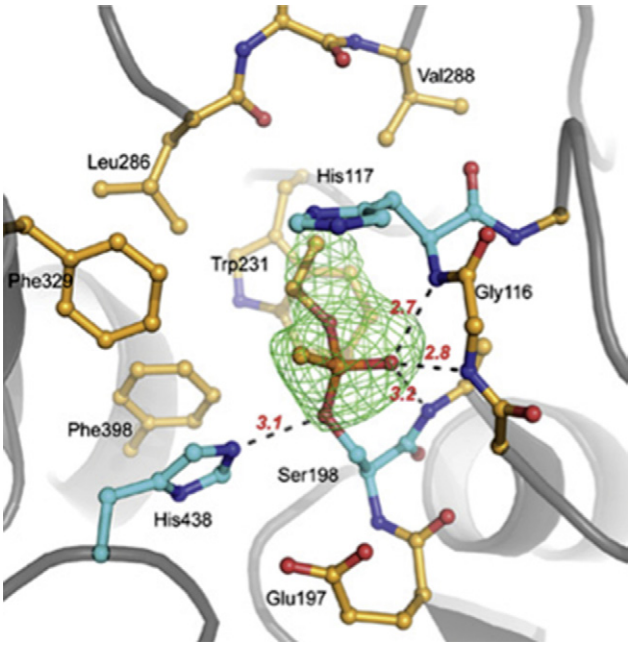

FIGURE 75.3 X-ray structure of the active center of G117H mutant of human butyrylcholinesterase conjugated with VX at 2.1 Å resolution (Nachon et al., 2011). The enzyme was phosphonylated by soaking the crystal in 1 mM VX for 2 min. X-ray data were collected at European Synchrotron Research Facility (ESRF; Grenoble, France). Two catalytic triad residues, active serine (Ser198) and histidine (His438), and the mutated residue (His117) in the oxyanion hole are shown as sticks as well as other important active center residues. His117 is mobile enough to activate a vicinal water molecule and stabilize the trigonal bipyramidal dephosphonylation transition state.

More than 60 double or triple mutants based on G117H were made (Schopfer et al., 2004), and certain mutants were eventually designed using the X-ray structure of human BChE (Nicolet et al., 2003). At the same time, mutants of human AChE and *Bungarus fasciatus* AChE were made using the same strategy (Poyot et al., 2006). Unfortunately, none of these muteins was more active than the G117H mutants. Actually, there is evidence that mutations at position G117 cause dislocation and loss of functionality of the oxyanion hole (Masson et al., 2007). For a historical review of this quest, see Masson et al. (2008).

The crystal structure of the G117H mutant conjugated to echothiophate and VX was solved (Nachon et al., 2011) (Figure 75.3). Works are in progress to understand the mechanism of dephosphorylation of this mutant (Amitay and Shurki, 2011; Lushchekina et al., 2011; Nachon et al., 2011; Yao et al., 2012). Thus, computer-assisted design of new OPH mutants of BChE is conceivable (Lushchekina et al., 2011). This new approach called "intelligent" directed mutagenesis design is based on simulation of

transition states. Simulation of activation transition state approach was already successfully applied to the design of other BChE mutants. Using the three-dimensional structure of human BChE, molecular dynamic simulations of deacylation transition state has allowed highly active mutants against (-)-cocaine to be made (Zheng and Zhang, 2008; Liu and Zhan, 2012; Zhan et al., 2014). This strategy applied to G117H-based mutant of human BChE (i.e., simulation of dephosphylation transition states) is expected to indicate how to optimize interactions favoring productive crossing of the energetic barrier for dephosphylation. Then, enzyme mutagenesis could lead to new generations of BChE mutants capable of hydrolyzing OPs at a high rate. Directed evolution of ChEs could be an alternative to computer-based methods. However, functional expression of ChEs is difficult in yeast and has failed in bacteria so far.

Bioavailability and biological stability of mutated ChEs for injection are important issues. First, pharmacokinetic studies of highly purified human BChE injected in the rat showed that the half-time ($t_{1/2}$) of enzyme in the bloodstream depends on sialylation of enzyme carbohydrate chains (Douchet et al., 1982). It is well-known that rapid elimination of asialoglycoproteins from the circulation is due to their capture by specific receptors located on the surface of hepatocytes. These receptors recognize galactosyl residue, the carbohydrate that precedes sialic acid at the terminus of complex glycans. Studies with other natural and recombinant ChEs confirmed the importance of sialic acid (*N*-acetylneuraminic acid) residues ending glycans (Kronman et al., 1995; Saxena et al., 1998; Cohen et al., 2007; Kronman et al., 2007). It was found that $t_{1/2}$ is inversely proportional to the number of unoccupied attachment sites of sialic acid (Kronman et al., 2000). To increase $t_{1/2}$ of administered recombinant ChEs, all galactosyl residues have to be sialylated. Full sialylation of recombinant enzymes can be achieved using an expression system capable of synthesizing glycans similar to natural human glycoprotein glycans and adding inhibitors of sialidase in the cell culture medium. Co-expression of the enzyme of interest and sialyltransferase in HEK 293 cells was found to lead to fully sialylated recombinant human AChE (Kronman et al., 2000). Alternatively, *in vitro* sialylation of purified enzymes is possible with a sialyltransferase or using a chemical method (Gregoriadis et al., 1999) and even by cross-linking polysialic acid chains (Ilyushin et al., 2013). PEGylation has also been proven to be an effective chemical modification for increasing circulatory half-life of administered recombinant ChE (Cohen et al., 2007; Huang et al., 2007; Kronman et al., 2007). Recently, a 150-kDa recombinant fusion protein human albumin–human BChE showed a substantially improved pharmacokinetics when administered to juvenile pigs: $t_{1/2}$ ≈32 h against ≈3 h for recombinant 70% tetrameric BChE (Huang et al., 2008).

Engineering of CarbEs to make enzymes capable of hydrolyzing NAs has made recent progress. In fact, the discovery of a blowfly (*Lucilia cuprina*) resistant to OPs because it carries a mutated CarbE (CarbE: LcαE7), G137D, at a position homologous to G117, stimulated research of G117H-based mutants of BChE. Although the OPH activity of the G137D is low, it is balanced by the abundance of the enzyme in the insect organs (Newcomb et al., 1997). The three-dimensional structure of this enzyme was recently solved (Jackson et al., 2013). Knowledge of this structure is a good starting point for engineering of mutants of LcαE7 with improved catalytic activity against OPs. Another interesting CarbE is the human CarbE1. The three-dimensional structure of human CarbE1-NA conjugates (with soman, tabun, sarin, cyclosarin) was solved (Fleming et al., 2007; Hemmert et al., 2010). The enzyme was shown to reactivate spontaneously after phosphonylation by the most toxic P_s stereoisomer of sarin (Hemmert et al., 2010). These results guided the computer-modeling design of the first CarbE1 mutants displaying OPH activity against soman and cyclosarin (Table 75.1) and enhanced the rate of spontaneous dephosphonylation after sarin inhibition (Hemmert et al., 2011). Thus, CarbEs can be reasonably considered as novel catalytic bioscavenger candidates.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Enzymes that neutralize or degrade OPs can be purified from natural sources, such as human plasma. Recombinant enzymes can be produced using procaryotic expression systems (*E. coli*), eucaryotic expression systems (yeast, insect, mammalian cell cultures), transgenic animals (worm, rabbit, goat), or transgenic plants (tomato, potato, tobacco), and also acellular biosynthetic systems. The goal of current research regarding protein engineering is to improve mass production of stable muteins at low cost. OPH improvement of *in vitro* and *in vivo* catalytic properties toward NAs and pesticides is still the main issue. In addition, improvement of thermodynamic stability (storage stability in solution or in dry forms) and *in vivo* operational stability, improvement of immunotolerance, and bioavailability are other goals. For this purpose, the different strategies of enzyme engineering have been implemented. They consist of research of new natural enzymes, particularly in collections of bacterial strains (Otto et al., 2013) and in extreme environments (Feerer et al., 2007), or identification of such enzymes from genomic sequences of extremophiles, followed by expression of the synthetic gene in a mesophilic bacterial host, characterization of catalytic properties, and X-ray structure determination (Hiblot et al., 2013a,b). Potential extremozymes, PLL and

PROL, have been discovered in halophilic, hyperthermophilic, piezophilic, and radio-resistant bacteria, and archaes. Other enzymes of interest are in insects resistant to OP pesticides and among secondary targets of OPs in human. Site-directed mutagenesis and directed evolution approaches in combination with chemical modifications and medium manipulations have been used with success to improve the desired properties, particularly stereo-selectivity, high k_{cat}/K_m, and broad-spectrum activity of selected enzymes (Bershtein and Tawfik, 2008; Goldsmith et al., 2012; Bigley et al., 2013). Computational redesign (molecular modeling and transition state simulations) of known enzymes is another promising strategy. It has already been successfully implemented: the active site of mouse adenosine deaminase, a zinc enzyme, was redesigned for hydrolysis of OPs. After maturation using directed evolution, the novel enzyme displayed a k_{cat}/K_m activity more than 10^7-fold the activity of the wild-type enzyme against R_p model OP (Khare et al., 2012). Finally, pharmacokinetic, toxicokinetic, and immunological studies of animal models allow validation of enzymes of interest.

Catalytic bioscavengers will be part of the arsenal of medical countermeasures for prophylaxis and post-exposure treatments of OP poisoning in the near future. Multiple enzyme associations (enzyme cocktails) will extend the activity spectrum of injected catalytic bioscavengers as well as the efficacy of active components in TSPs, chemical-protective clothing suits, and decontamination tools.

Gene therapy will offer the possibility of transitory production of human or humanized OP-degrading enzymes in the body. However, the road to gene therapy is still long. Regardless of ethical issues, further works are needed to engineer safe vectors that do not produce toxic viral proteins and/or induce immune response.

CHAPTER

76

Rapid Decontamination of Chemical Warfare Agents from the Skin

Edward D. Clarkson and Richard K. Gordon

BACKGROUND: THE NATURE OF HUMAN SKIN

Human skin, the largest organ in humans, developed as a physical barrier to the environment (keeping things out); however, it also maintains the aqueous nature of the human body (keeping things in). Mammalian skin consists of three major layers: the stratum corneum, epidermis, and dermis. The stratum corneum, the thin outer layer of keratin-filled dead cells (corneocytes) bounded by densely cross-linked protein and embedded in crystalline lamellar lipids, represents the major barrier protecting the body from loss of internal components and entry of undesirable external materials. The epidermis, the layer underneath the stratum corneum, contains cells that change from viable keratinocytes to corneocytes (which are anucleated cells without cytoplasmic organelles) as they migrate from the dermis to the stratum corneum. It also contains a large number of specialized dendritic cells. Smaller amounts of specialized cells are integral to the epidermis, including the pigmentation melanocytes, the immunological Langerhans cells, and the sensory Merkel cells. Throughout the epidermis, sebaceous glands, sweat glands, and hair can be found. The next inward layer, the dermis, contains hair follicles with associated sebaceous glands, ecrine sweat glands and ducts, dendritic cells, and a vascular network, including subepidermal capillaries, vascular plexi associated with the sweat glands, and dermal papillae associated with the hair follicles. Capillaries are responsible for transporting any chemicals that enter the skin systemically. Recent reviews of the skin structure and permeation are available (Menon, 2002; Hadgraft and Lane, 2005; Godin and Touitou, 2007; Wester and Maibach, 2000).

The stratum corneum, composed of keratinized dead cells that are continually being replaced, is the first major barrier to chemical agents. The barrier qualities of the stratum corneum depend on a number of factors, including its location on the body, its thickness, and how much hair is present. Thus, hair follicles and sweat glands can either provide channels through the stratum corneum, and thereby bypass its barrier attributes, or at least provide increased surface area for compounds to penetrate, since a number of compounds were shown to penetrate faster in hair follicle–rich areas (Illel et al., 1991). Maibach et al. (1971) studied three radiolabeled pesticides, parathion, malathion, and carbaryl, for their permeability at 13 different anatomical sites in humans. Variations in percutaneous penetration were observed; greater penetration of pesticides occurred at the abdomen and the dorsum of the hand.

Because it is often difficult to determine which specific nerve agent was used, most poisoning from pesticides or chemical warfare agents (CWAs) will initially be treated in a generally supportive manner, not by administering a specific antidote. Thus, decontamination is the most important early intervention (Simpson and Schuman, 2002). Although Maibach et al. (1971) present relatively recent human *in vivo* studies, most testing of decontamination products is performed either *in vivo* with animal models (Braue et al., 2011a,b; Clarkson et al., 2012) or *in vitro* using human skin samples (Mircioiu et al., 2013).

The lipid matrix is another important feature for barrier function in the epidermis. The arrangement of lamellarlike sheets yields a barrier to hydrophilic compounds and transcutaneous water transport. Extraction of those lipids from skin with organic solvents reduces barrier function (Hadgraft, 2001). The lamellae, which

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00076-2

have little phospholipids as they are catabolized, ultimately contain mainly ceramides, cholesterol, and fatty acids (Wertz and Downing, 1989; Bouwstra and Ponec, 2006). The resulting matrix is composed of nonpolar compounds enriched in cholesterol, which are adapted to protect the dermis from water loss. While extracting these lipids may increase the penetration of aqueous moieties, in the case of organophosphates (OPs—note the organic nature of the CWAs, as described later in this chapter), the hydrophobic nature of skin likely facilitates the partition of these chemical agents through the lipid matrix, which then enter the subepidermal capillaries for dissemination throughout the body. Further insight into the barrier properties of skin can be observed in some disease states, including psoriasis, where an increase in epidermal cell replication yields an irregularly stacked stratum corneum and abnormal capillaries in the dermis. This leads to an increase in drug penetration such as hydrocortisone (Kranz et al., 1977). No studies have evaluated pesticide or CWA penetration in people with psoriasis.

Aging contributes to decreased lipid barrier protection, decreased intercellular cohesion, and increased absorption of toxic material. This barrier is also complicated by environmental effects such as exposure to sun, disease, and other aging processes that include many changes to the structure of the skin. Examples of such changes are decreased amounts of collagen, loss of melanocytes, decreased number of glands and hair follicles, reduced blood flow (Yates and Hiley, 1979), and the loss of lipid content in the stratum corneum (Elias and Ghadially, 2002). Another study found that 11 of 14 pesticides showed different rates of skin penetration in aged rats compared to young rats (Shah et al., 1987). Generally, decreased absorption occurred in studies of aged skin (Fisher et al., 1992; Farage et al., 2007).

Percutaneous absorption *in vivo* leads to the delivery of the chemical or drug to the microcirculation in the dermis. The period of time necessary for entrance to the blood supply and circulation throughout the body depends on the diffusion parameters and the interaction with the lipid matrix (Roberts, 1997). Thus, chemicals exhibiting a longer lag time to pass through the skin should be less toxic if quickly removed, as opposed to rapidly penetrating compounds. Another aspect of percutaneous absorption is the number of exposures to the chemical. Some chemicals, such as azone (1-dodecylazacylohepan-2-one), alter the organization of the skin so that an increase in absorption or a synergistic effect is observed with each exposure (Ademola et al., 1993). Chemicals that don't alter the skin's structure would not be likely to increase their bioavailability and absorption; rather, they provide an additive response (Bucks et al., 1985).

BACKGROUND: NERVE AGENTS

Nerve agents are among the most toxic of the known chemical agents. Nerve agents are OPs that bind irreversibly to acetylcholinesterase (AChE; Taylor et al., 1999) and to the bioscavenger butyrylcholinesterase (BChE; Wolfe et al., 1992) in both the peripheral nervous system (PNS) and central nervous system (CNS). AChE is responsible for terminating the action of the neurotransmitter acetylcholine (ACh) by hydrolysis. OP-inhibited AChE results in an excess of ACh and overstimulation of muscarinic and nicotinic receptors. Characteristic signs of nerve agent poisoning and cholinergic overload include hypersecretion and respiratory distress. When the nerve agent is transported past the blood–brain barrier (BBB), convulsions can lead to coma and death. OPs pose a hazard in both their vapor and liquid states. Notably, AChE inhibitors are used not only as a therapy for treating glaucoma, myasthenia gravis, Alzheimer's disease, and atropine poisoning, but also in potentially hazardous ways, as pesticides to kill insects and as CWAs by terrorists and in warfare to kill humans (Sidell, 1997; Leikin et al., 2002; Martin and Lobert, 2003).

The nerve agents include the G-type agents tabun (GA; ethyl *N,N*-dimethyl-phosphoramidocyanidate), sarin (GB; isopropyl-methylphosphonofluoridate), and soman (GD; 1,2,2-trimethylpropyl methylphosphonofluoridate), and V-type agents such as *O*-ethyl *S*-[2-(diisopropylamino) ethyl] methylphosphonothiolate (VX). The V-type nerve agents are several orders of magnitude less volatile than the G-type agents and act primarily as a liquid via the percutaneous route; for example, VX is several orders of magnitude more lethal percutaneously than GB (Reutter, 1999; Braue et al., 2011a) or GD (Braue et al., 2011b; Clarkson et al., 2012).

Log *P* data (octanol:water partition coefficients and a reflection of lipid solubility) of nerve agents were used to both predict absorption through the skin and determine the distribution of OP compounds in tissues. Then, the data were correlated with toxicity as measured by the onset of fasciculation in guinea pigs. An excellent correlation (r=0.95) was established between the measured log *P* value and the rate of onset of local fasciculations, reflecting absorption in the skin, penetration to blood, and dissemination to muscle tissue throughout the animal (Czerwinski et al., 2006).

Maxwell and Lenz (1992) reported that, in general, AChE and BChE are more reactive with cationic nerve agents such as VX, while neutral agents that contain less than two bulky groups (e.g., GA, GB, and GD) were equally reactive with the cholinesterase (ChE) enzymes (Maxwell and Lenz, 1992). In general, since AChE has a smaller active site than BChE, the size and ionic character of the active sites determine the specificity of these

esterases for the agents. The estimated ranked percutaneous nerve agent LD_{50}, listed in descending order, are VX, GD, GA, and GB, and this reflects their volatility. The ranked volatility for these agents, in ascending order, is VX, GA, GD, and GB.

Using parathion as a model simulant for the nerve agent VX, the *in vitro* percutaneous absorption through unprotected human skin and clothed and uniformed skin was determined. The percent of a parathion dose that is absorbed through the unprotected skin was significantly greater than that observed through dry, uniformed skin, while absorption was higher through the wet (sweaty) uniform. These results suggested that military uniforms and other clothing worn in public places provide protection to this simulant (and by analogy to VX); but absorption through cloth and skin quantitatively occurred more readily with wet clothing than dry. Thus, even with clothing, an immediate response and decontamination of skin and clothing are required (Wester et al., 2000).

In conclusion, because of the extreme toxicity of nerve agents, the search for medical decontamination countermeasures to OPs is of paramount importance. Rapid removal from the skin would prevent penetration to the general circulation and the resulting decrements of cholinergic toxicity, which ultimately leads to seizure, death, or both in untreated individuals. In the development of medical decontamination countermeasures to nerve agent poisoning, different nerve agent administration routes likely will have different requirements for effective treatment. The window of opportunity for decontamination treatment following agent exposure is limited. The signs of poisoning develop within minutes, and if decontamination is delayed, toxic levels of the nerve agents are likely to be disseminated via the bloodstream after the agent has been absorbed. Decontamination will prevent continued absorption of the agent, reducing the need for further medical management (Table 76.1; Hamilton et al., 2004; Clarkson et al., 2004, 2012).

[a]*Delay in decontamination (Hamilton et al., 2004).*

BACKGROUND: VESICATING AGENTS (DISTILLED SULFUR MUSTARD, HD; IMPURE SULFUR MUSTARD, H; LEWISITE, L)

Sulfur mustard (HD), a synthetic vesicating agent, was a major CWA during World War I and continues to be a threat today (Reutter, 1999; Bismuth et al., 2004; Ghanei and Harandi, 2007). Its simple and cheap chemical synthesis makes it readily accessible to terrorists, as well as for use by the military. Sulfur mustard is an alkylating agent that causes damage by disrupting nucleic acids and proteins, impairing cell homeostasis and eventually causing cell death, although the significance of the multiple pathways is unclear (Smith et al., 1995). Whole-body exposure results in cutaneous (liquefaction necrosis of the epidermis), respiratory (injury to the laryngeal and tracheobronchial mucosa), and ocular effects (severe conjunctivitis). In contrast to HD agents, there is no delay with lewisite, which produces immediate burning of the skin and eyes. Compared with the G-nerve agents, sulfur mustard has a relatively low acute lethal toxicity; that is, its toxicity as an incapacitating agent is of much greater concern than its capacity to kill. Furthermore, HD persists in the soil and other materials for hours to weeks (Devereaux et al., 2002).

The skin is an important port of entry for vesicating agents. The agent's lipophilic nature and the propensity of skin to exclude aqueous compounds, but not lipophilic substances, make the skin an unwitting transport system. An increase in ambient temperature causes increased penetration (which was used effectively in World War I, where mustard was mostly disseminated at night and warmed by the early-morning sun). It has been estimated that 80% of liquid mustard evaporates and 20% penetrates the skin. Of that 20%, 12% is retained in the skin matrix, while 8% is absorbed systemically, so only large dosages of mustard will produce significant systemic toxicities (Cullumbine, 1947; Dacre and Goldman, 1996).

Mustard skin lesions first present as erythema followed by blisters (Somani and Babu, 1989). Erythema usually begins 2–24 h after contact, followed by acute itching, which diminishes as the characteristic blisters appear. These blisters initially appear as small vesicles within the area of erythema 18 h after contamination; these vesicles then coalesce to form the characteristic pendulous blisters containing large volumes of clear yellow fluid. Blisters are not painful *per se*, but they may be uncomfortable and may feel tense. Warm, moist areas, such as genitalia and axilla, are more likely to exhibit bullous lesions. By 48 h post-exposure, blistering is clearly evident, and a new round of blisters appears.

As the skin layer is disrupted, the large blisters break, leading to erosion, full-thickness skin loss (in which subcutaneous fat may be visible, but bone, tendon, and muscle are not exposed), ulceration, necrosis, and (72 h post-exposure) formation of an eschar. The eschar sloughs in a 4- to 6-day time period, finally leaving a pigmented scar (Reid et al., 2000, 2007). A burn caused by a blister agent is much slower to heal than a thermal burn, likely because of the multiple mechanisms by which the agent affects biological tissue, as discovered during World War I and reestablished in Iranian casualties from the Iran–Iraq war (1980–1988). The site of healed mustard burns is hypersensitive to mechanical trauma. In a comparison of cutaneous lesions in 500 mustard-exposed Iranian veterans and 500 unexposed veterans, a correlation was observed between exposure and severe dry skin, hyperpigmentation and hypopigmentation, local hair loss, eczema, chronic urticaria, and other skin lesions. Histopathological examination of skin biopsies has revealed nonspecific findings, including epidermal atrophy, keratosis, and basal membrane hyperpigmentation (Balali-Mood and Hefazi, 2006).

MODEL SYSTEMS TO MEASURE ABSORPTION, REMOVAL, AND DECONTAMINATION

Rats

Many different animal models have been used to assess the percutaneous absorption of toxic chemicals. There is little question that while *in vivo* human studies are best for predicting the absorption of percutaneously applied CWAs, ethics preclude conducting such studies. Rats have been widely used in the study of skin contamination, wounds, and healing and the efficacy of different decontamination modalities (Shah et al., 1987; Baynes et al., 1997; Wester and Maibach, 2000).

Guinea Pigs

While rats are often selected for their availability, low cost, small size, and thorough biological characterization, rats are not the ideal CWA model because they contain a high amount of carboxylesterase (CarbE), a potential hydrolytic enzyme for OPs (Sweeney and Maxwell, 2003). Unlike rats, humans have small amounts of this enzyme relative to AChE and BChE. To overcome this limitation, the guinea pig, which exhibits low CarbE, has been developed as a model for CWA exposure (Fonnum et al., 1985). Guinea pigs have been evaluated for skin damage from burns and are often used as a wound-healing model for sulfur mustard (Ramos et al., 2008), as well as for skin irritation to toxic industrial chemicals (TIC) (Weaver et al., 2003; Kennedy, 2007). Guinea pigs have also been used to study absorption of CWAs through the skin (Wormser et al., 2002; Dalton et al., 2006) and uptake of radioactive sulfur mustard through the skin (Logan et al., 1999), as well as an animal model for evaluating pretreatment regimens to protect against CWAs (Wetherell et al., 2006) and for assessing ChE activity responses (Haigh et al., 2005) to GD exposure and OP-induced seizure (Harrison et al., 2004).

For evaluating the decontamination of guinea pig skin, Clarkson et al. (2012) sedated and clipped guinea pigs. The animals were clipped with Oster brand clippers (model: Golden A5) with a #40 CryogenX blade instead of being shaved with shaving cream and a razor blade, as previous work showed that shaving caused razor burn and increased the rate and amount of agent that was absorbed (Snider et al., 2003). Guinea pigs were cutaneously exposed to neat nerve agents on their sides. A sponge wrapped around a pair of forceps was moved across the guinea pig's side 1 min after the exposure; then the forceps were rotated 180° so that the clean surface of the sponge was pointed at the animal. Three more passes were taken from the rear toward the front. An identical procedure was used when the protocol required an additional second sponge to decontaminate the animal. Similarly, guinea pigs were used for studies on the decontamination of sulfur mustard. In this case, 24 h after neat HD exposure and decontamination, animals were injected with trypan blue and then euthanized. The skin covering the backs of the animals was removed. In addition, skin punches were taken from each of the exposure sites (control, exposed, and decontaminated; Gordon et al., 1999; Gordon and Doctor, 2003).

Swine

Pig skin has long been a valuable model for human skin (Meyer et al., 1978; Riviere and Monteiro-Riviere, 1991) since it has a sparse hair covering, epidermis, and an arrangement of dermal collagen and elastic fibers similar to that of human skin. Again, many investigations have used the porcine skin model to study cutaneous toxicology of HD (Gold et al., 1994). Pig skin, because of its similarity to human skin with respect to hair covering, apocrine sweat glands, and other morphological features (Reifenrath et al., 1991), is an attractive model for cutaneous absorption and toxicology studies of OP CWAs (Hamilton et al., 2004). Cutaneous absorption studies show that pig skin permeability, compared to that of the rat and rabbit, most closely resembles that of human skin (Bartek et al., 1972) with a variety of test agents. Therefore, the pig is a good model with which to assess the effects of extraneous material or chemicals during early exposure. The downside is that pigs are large animals, are difficult to house, are more costly

to maintain than rodents, and require special cages to maintain them. Their size creates a serious caging issue when neat CWAs are applied to skin, and the animals may spend days in a chemical fume hood. This caging issue also occurs with nonhuman primates.

DECONTAMINATION REQUIREMENTS

Medical decontamination requires removal or neutralization of CWAs, which upon penetration of the skin produce vesication or, with OPs, enter the systemic circulation and inactivate ChEs. The most important process for the exposed soldier or civilian is to remove the chemical agent from the skin as quickly as possible. The soldier, under harsh conditions, must use the treatment product quickly to minimize transdermal penetration. A decontaminant that inactivates the chemical agent prevents its penetration through the skin and potentially protects a medical worker or colleague from suffering a secondhand exposure.

Another criterion for the decontaminating system and reagents is that they be as universal as possible and protect against the various classes of chemical agents (as well as radiochemicals and biological agents, although the latter compounds will not be discussed in this chapter). In other words, soldiers have a limited amount of space and can bear only a limited amount of weight, so they cannot carry multiple decontamination products. Furthermore, soldiers are unlikely to be able to determine the type of agent with which they are contaminated in the absence of symptoms.

In addition, the proven efficacy of a decontamination product would have to meet US Food and Drug Administration (FDA) guidelines and approval, assuring the safety of the product for soldiers. The product should be environmentally safe to use by itself and render the chemical or biological agent environmentally safe to prevent cross-contamination. Logistics would preclude decontamination products that require freezing or refrigeration since those services would not be available in the field. Finally, application of the product needs to be simple so that soldiers can easily use the product under stressful conditions, thereby reducing the probability of failure. Products like the M291 Skin Decontamination Kit (SDK), discussed next, are used by simply wiping the contaminated skin and do not require significant training. However, the M291 SDK has some drawbacks, such as a black offensive dust that is precluded from the eye. The ideal decontaminating product should be nonirritating and nonallergenic and should not have an offensive odor, as some potential mercapto compounds exhibit (Shi et al., 2008); otherwise, people will be reluctant to use it.

Methods for decontamination, neutralization, and removal of chemicals, such as OP and organosulfur compounds, herbicides, and insecticides, are known in literature (Hurst, 1997; Baker, 2004; Houston and Hendrickson, 2005; Rosenberg, 2005). The compositions and devices utilized for medical purposes are markedly different from nonmedical devices; the latter are not compatible with the skin or other sensitive tissues because they can be corrosive, flammable, toxic, difficult to make and store, composed of two component systems, and have a limited shelf life. For example, DS2, a standard decontamination agent, is comprised of 70% diethylenetriamine, 28% ethylene glycol monomethyl ether, and 2% NaOH by weight (Modec, 2003). Although DS2 is effective, it is corrosive upon exposure to air. DS2 and any matter resulting from its use is classified and regulated as hazardous material. After an application, the DS2 must stand for 30 min before rinsing the treated area with water. Additionally, DS2 comprises a teratogen. Clearly, this is not a better method for neutralizing, detoxifying, decontaminating and cleaning personnel exposed to CWAs.

DECONTAMINATION SCHEMES

OP nerve agents are a serious threat to military and civilian personnel, but not just from exposure during warfare or a terrorist event. With these agents, the possibility exists that exposed individuals could cross-contaminate the medical personnel treating them. Several medical decontamination schemes, each exhibiting advantages and disadvantages, are described next. While the ideal candidate does not exist, the final product must be fieldable for the individual—that is, for personal use in a rapid, and deployable manner. Simple materials, such as bleach, and complex products, such as OP-degrading immobilized enzyme sponges, are described. Inexpensive and readily available household materials were tested for pesticide decontamination of fabric materials over 20 years ago (Easter and DeJonge, 1985). The household products provided only marginal decontamination efficacy.

Classical Liquid: Sodium Hypochlorite (Bleach)

Decontamination methods employing hypochlorite formulations have some corrosive and toxic side effects. A Clorox (hypochlorite) solution is composed of household bleach, which is about 5% sodium hypochlorite. Thus, for a 0.5% solution, bleach is mixed with 9 parts water, although even this diluted solution is contraindicated for use in or on a number of anatomical areas including the eye.

Undiluted bleach is not used because it is toxic to the skin and may create more damage than no decontaminant. Hairless guinea pigs were exposed to sulfur

mustard in wounds and the surrounding intact skin, and then decontaminated with water, 0.5% or 2.5% bleach. No significant differences were observed among wounds decontaminated with the three solutions. Unexpectedly, the skin surrounding nondecontaminated (but exposed) control animals showed the least visual pathology. The lesions observed after decontamination might be due to the mechanical flushing of sulfur mustard onto the perilesional skin, by chemical damage of the skin induced by the solution, enhanced penetration of the agent, or interaction of sulfur mustard with the decontaminating solutions (Gold et al., 1994). In a study evaluating decontamination of GB from skin, rabbits that received GB but were not decontaminated were observed to neither convulse nor die. In contrast, when decontaminated with 5% bleach, symptoms and death increased, suggesting that 5% bleach perturbed the protective barrier of the skin or facilitated GB transport through the skin (Kondritzer et al., 1959). Since diluted bleach (0.5%) is a nonirritant to human skin, it is preferred (Racioppi et al., 1994).

In contrast, the effectiveness of diluted bleach has been demonstrated. This study measured the rate of sulfur mustard disappearance from the skin after topical application of the vesicant, which rapidly penetrates the skin because of its hydrophobicity. Three swabbing treatments of undiluted HD-exposed skin with gauze pads soaked in 0.5% hypochlorite caused 68% reduction in skin HD content and a 64% reduction when hypochlorite was replaced by water (Wormser et al., 2002). The effectiveness of 0.5% hypochlorite with water for decontaminating sulfur mustard on guinea pigs was also evaluated. However, the gauze pads soaked with the bleach contained microgram quantities of HD when water was used, but no detectable HD levels when 0.5% bleach was used. Thus, the neutralizing effect of 0.5% bleach occurred after the agent was removed from the skin and away from the lipophilic structures of the skin, where the 0.5% hypochlorite could react with and reduce the levels of the agent.

Similar to bleach's oxidative properties, topical povidone-iodine at 15 and 30 min post-exposure to sulfur mustard exhibited protective effects. Severity of the dermal parameters, acute inflammation, and dermal necrosis were significantly reduced, and reduced skin damage was observed in areas adjacent to treated sites (Brodsky and Wormser, 2007).

The impact of using 0.5% bleach as a CWA decontaminant has been significant. US Navy warships are equipped to operate in a chemical, biological, or radiological warfare environment where their exterior surfaces may become contaminated while the interior is kept clean. Most of these ships have decontamination facilities accessible from the ship's deck. Thus, in a contaminated environment, sailors or other personnel would be brought to the ship's facilities by personnel wearing protective gear. Next, contaminated clothing would be removed and contaminated skin washed with 0.5% bleach. This bleach solution is made from Navy High Test Hypochlorite (65–70%). After washing with 0.5%, the patients are rinsed with warm water and monitored to determine if it is safe to bring them into the ship for treatment (National Academy of Sciences, 2004).

Powder Decontamination Material: M291 SDK

In the 1990s, the product provided to the US soldier for field use was the M291 SDK (Figure 76.1). For 15 years, the US military fielded the M291 SDK, but in the late 2000s, the United States began to replace it with the Reactive Skin Decontamination Lotion (RSDL). However, throughout the world, many decontamination facilities continue to use the M291 SDK; therefore, it is important to discuss it in detail here. In this product, three main components are incorporated into individual pouches: a fiber pad (six to a pouch), an absorbent activated charcoal, and a reactive resin (Ambergard XE-555). Each component serves a unique purpose. The cotton pad provides structural integrity for use on a finger; the carbon incorporated into the pad absorbs organic material such as OPs and HD; and the ion-exchange resin binds chemical agents and very slowly detoxifies them. The soldier takes the M291 SDK pad and rubs the area that needs to be decontaminated. The goal is to rapidly bind chemical agents still on the surface of the skin and prevent their penetration through the stratum corneum. The M291 SDK is precluded from use in the eye because its particulate nature is irritating, but otherwise, it can be used on the face and anywhere else on the body. Much of the black powder from the M291 SDK remains on the

FIGURE 76.1 The M291 SDK, a powdered decontamination material.

skin, which has been a deterrent to its use. The presence of the black powder is an indication to the soldier that the area has been decontaminated. However, since ion-exchange resin binds chemical agents and very slowly detoxifies them, for maximum effectiveness it is best to brush off excess black powder, which may contain agents that have not been inactivated.

Efficacy of the M291 SDK has been evaluated in a number of animal models for OP poisoning (DO49 Technical Report, 1987). In an early report, rabbit skin was shaved (to mimic human skin without fur) and then exposed to GD and VX for 2 min. Decontamination with the M291 SDK yielded higher LD_{50} values (of more than 10-fold and 20-fold, respectively (Hobson et al., 1985)), in comparison to control animals that were not decontaminated. In another study, with rabbits under similar conditions, the penetration of the OP VX was measured by red blood cell (RBC) AChE inhibition. The M291 SDK increased the amount of VX required to inhibit AChE by 50% (Joiner et al., 1988). Thus, the M291 SDK neutralized or removed VX so that less of it penetrated the skin, as indicated by RBC AChE inhibition.

Three recent reports examined the effectiveness of the M291 SDK in treating GD and VX on animal models of anesthetized, clipped guinea pigs (Braue et al., 2011a,b; Clarkson et al., 2012); the LD_{50} was determined to be 24 h. Clarkson et al. (2012) reported that decontamination with the M291 SDK 1 min after neat (undiluted) exposure to GD increased the LD_{50} from 11.6 to 76.9 mg/kg, yielding a protective ratio of 6.6. Decontamination with the M291 SDK 1 min after neat exposure to VX increased the LD_{50} from 0.10 to 0.87 mg/kg, yielding a protective ratio of 8.7. In contrast, Braue et al. (2011a,b) reported that decontamination with the M291 SDK 2 min after neat exposure to GD increased the LD_{50} from 11.0 to 30.0 mg/kg, yielding a protective ratio of 2.7, and decontamination after neat exposure to VX increased the LD_{50} from 0.13 to 0.14 mg/kg, yielding a protective ratio of 1.1. The untreated LD_{50} in the studies discussed here were similar, while the difference in protective ratio for GD can be explained by the time difference in decontamination (1 versus 2 min). GD penetrates skin faster, so the additional time delay can have a significant impact on systemic dissemination of the nerve agent compared to the slower-penetrating VX, which is reflected in the decreased protective ratio. The difference in protective ratios for VX is more difficult to explain, as VX does not penetrate the systemic circulation as rapidly as GD.

The M291 SDK is also efficacious in rabbits against the vesicating agents HD and L. Thus, clipped dorsal skin of rabbits was exposed to neat HD and then decontaminated after 1 min. Vesicant-induced histopathology determined after tissue staining was reduced over 20-fold compared to nondecontaminated control rabbits.

Liquid Decontamination Material: Sandia Foam

Sandia National Laboratories decontaminating foam (licensed to Modec Inc., Denver, CO; Figure 76.2) is a solution (MDF-100) composed of two parts. The first is a solution of 6.6% *N,N,N,N′,N′*-penta-methyl,-*N′*-tallow alkyl 1,3-propanamine diammonium, 2.6% tallow pentamethyl propane quaternary ammonium compounds, benzyl-C12-18 alkyl dimethyl, and 1% isopropyl alcohol. The second is a solution of 8% hydrogen peroxide. Mixing the two parts results in a foamlike product that lasts for up to 30 min. The mixture was tested in the guinea pig model, where fur was clipped on the side of the animal 1 day before exposing the skin of the anesthetized animals to neat GD or VX (Lukey et al., 2004; Clarkson et al., 2012). The animals were decontaminated 1 min later with sterile gauze soaked in the combined solution in a defined manner: that is, the contaminated side was wiped across the exposure site in the direction of the shaved fur once and then rotated so that a clean surface of the gauze could be used to wipe the skin three additional times. Next, the OP-exposed area was similarly dried with a second piece of gauze. The exposed area was wiped a total of eight times. Then survival was determined 24 h later. Control nondecontaminated animals yielded an LD_{50} of 11.6 mg/kg for GD, while animals decontaminated with the mixture yielded an LD_{50} of 412 mg/kg, a 36-fold protective ratio. For VX, cutaneous neat exposure and decontamination with Sandia foam yielded an LD_{50} of 10.4 mg/kg compared to the control animals' LD_{50} of 0.10 mg/kg, a 104-fold protective ratio.

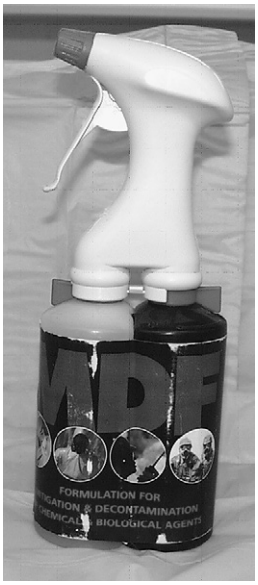

FIGURE 76.2 Sandia decontamination foam for mitigation and decontamination of CWA.

Despite its efficacy, Sandia foam has a number of drawbacks for field use by the soldier. First, it must be stored as its separate components, which would require a rapid, personal, on-site mixing chamber for combining the two solutions. Second, the presence of hydrogen peroxide, a strong oxidizing agent, precludes its use near the eye and would create much discomfort if used in a wound (Watt et al., 2004). To address these concerns, at least in part, Sandia developed the formulation DF-200, which contains less hydrogen peroxide and surfactant.

Liquid Decontamination Material: Diphoterine

Diphoterine is a product for chemical spatters on the eye and skin. Prevor Laboratory in France manufactures this odorless, colorless liquid dispensed as an eye wash or skin decontamination spray. It is composed of an aqueous solution to wash many chemical families and pull hydrophilic chemical agents away from the surface of tissues, an amphoteric solution that acts on acids and bases and restores the tissue physiological pH, and a hypertonic solution that stops penetration of corrosive chemicals into tissues. The pH is slightly alkaline (pH 7.2–7.7) and is sterile. Although not classified as a medical device in the United States, it is classified as such in Europe, Canada, Australia, and Brazil (www.prevor.com).

Diphoterine's action on more than 600 chemical compounds was reviewed by Hall et al. (2002). These chemicals included acids, alkalis, oxidizing and reducing agents, irritants, lacrimators, solvents, alkylating agents, and radionuclides. In the literature, there is one abstract describing the decontamination of sulfur mustard (Gerasimo et al., 2000). In this report, radiolabeled sulfur mustard was placed on human skin for 5 min *in vitro*. The skin was then treated with Diphoterine, water and soap, or saline at different time periods after sulfur mustard exposure, and Diphoterine was reported to be significantly better at removing sulfur mustard. No reports could be found in the literature for OP decontamination, although Hall et al. (2002) also state that Diphoterine is suitable for the decontamination of OP pesticides.

Evaluation of Diphoterine has occurred mainly in the European workplace, where it has been reported to be nonirritating to normal human eyes or skin. No adverse effects have been observed in ongoing post-marketing surveillance in European industrial facilities (Hall et al., 2009). It is nontoxic in guinea pigs and does not sensitize their skin (Mathieu et al., 2007). The product has prevented or decreased the severity of chemical eye and skin burns from 96% sulfuric acid, 100% acrylic acid, 50% acrylamide, solid sodium hydroxide flakes, and dimethylethylamine; 24 workers in a German metallurgy facility who were exposed to weak or strong acids and bases and obtained immediate Diphoterine decontamination did not require further medical or surgical burn treatment, nor did eye or skin burns develop (Nehles et al., 2006). Clearly, Diphoterine's potential is intriguing and needs to be critically evaluated for the purpose of decontaminating and detoxifying CWAs.

Liquid and Sponges: RSDL

RSDL (Figure 76.3) was developed for the cutaneous decontamination of CWAs. It was developed for topical use by the Defence Research Establishment Canada in Suffield, with broad spectrum decontamination properties for chemical agent cutaneous threats. The RSDL solution is composed of 1.25 M potassium 2,3-butanedione monoximate in polyethylene glycol monoethyl ethers with an average molecular weight of 550 daltons ($MPEG_{550}$) with 10% w/w water (pH 10.6). The pads consist of a spongelike plastic foam, Opcell, which is lightweight and easy to store. It is used instead of a cotton pad, and the Opcell holds more of the decontaminating solution for spreading on the skin.

The toxicological profile of this formulation was determined by the US military prior to FDA clearance (Tonucci et al., 2004). The army tested the product's safety by conducting skin irritation, sensitization, and photoirritation studies in more than 300 people. Its effectiveness was also tested by treating animals that had been exposed to chemical agents. On March 28, 2003, the FDA approved the product to remove or neutralize CWAs and T-2 fungal toxin (but not other biological threat agents or radiological contaminants) from the skin.

The efficacy of RSDL has been demonstrated. It was selected as the Joint Service Personnel Decontamination

FIGURE 76.3 RSDL used to decontaminate skin exposed to CWA.

System in March 2007 for use in the US Army, Navy and Air Force. It is also an approved medical device for nerve agent decontamination in the European Union, Australia, and Canada. The efficacy of RSDL to remove and decontaminate CWAs was demonstrated *in vivo* with guinea pigs and *in vitro* with chick embryos.

The *in vitro* work by Sawyer et al. (1991) involved primary cultures of chick embryo neurons to test the efficacy of the RSDL. By relating the anticholinesterase (anti-AChE) activity in these cultures of the OP/RSDL mixture to that of pure OP standards, a sensitive measure of the value of the RSD in inactivating tabun, sarin, soman, and VX was obtained. Data from experiments with all four nerve agents in this *in vitro* system correlated well with the *in vivo* data, and also indicated that the inactivation process was time- and agent-dependent and was related to the ratio of OP to RSDL. The authors showed that RSDL is also effective in decontaminating GD and VX in cutaneously exposed guinea pigs (Table 76.2; also see Gordon, unpublished observations). The protective ratios reported in Table 76.2 are in agreement with the protective ratios reported by Braue et al. (2011a,b).

The product was also compared to Fuller's earth in a pig model. The potency of the RSDL sponge was statistically better than Fuller's earth against skin injury induced by sulfur mustard, according to observations made 3 days post-exposure. In addition, RSDL was more efficient than Fuller's earth in reducing the formation of perinuclear vacuoles and inflammation processes in the epidermis and dermis. The potencies of the RSDL sponge and Fuller's earth were similar to severe inhibition of plasma ChEs induced by VX poisoning. Both systems completely prevented ChE inhibition, which indirectly indicates a prevention of toxic absorption through the skin (Taysse et al., 2007).

TABLE 76.2 Decontamination of Organophosphate-Exposed Guinea Pigs

Agent/Treatment	LD_{50} (mg/kg)	PR[a]
SOMAN		
M291 SDK	17.7	1.8
RSDL	240	24
Sponge	290	29
None	9.9	n/a
VX		
M291 SDK	0.14	n/a
RSDL	19.1	137
Sponge	21.0	150
None	0.14	n/a

[a]*Protective ratio.*

However, there are some caveats to RSDL use. The application of RSDL directly to open wounds impaired wound strength and decreased collagen content in the early phases of wound healing. This may have clinical implications for the treatment and outcomes of chemical casualty combat trauma (Walters et al., 2007). RSDL is also reported to be flammable.

Polyurethane Sponge

At the Walter Reed Army Institute of Research in Silver Spring, MD, an enzyme-immobilized polyurethane foam sponge (Figure 76.4) for decontaminating the skin of CWAs in a wide variety of environmental conditions is being developed (Munnecke, 1979; Wood et al., 1982; Havens and Rase, 1993). A porous polyurethane foam formed *in situ* from water-miscible hydrophilic urethane prepolymers has been combined with enzymes such as ChEs to produce immobilized enzyme sponges (Ember, 1997; Medlin, 1998; Gordon et al., 1999; Gordon and Doctor, 2003). In this method, the enzyme becomes an integral part of the solid support. Some of the advantages of this technique include retention of similar kinetic characteristics as the soluble form of the enzyme. Most important, the immobilized enzyme retains high activity after prolonged storage and is resistant to the detrimental effects of low and high temperatures and to prolonged exposure to the environment. In addition, the enzymes are covalently attached to the polyurethane, so they will not leach from this polymer support.

To increase the OP/enzyme stoichiometry, polyurethane-immobilized enzymes were combined with oximes (enzyme reactivators such as HI-6; Peter et al., 2007) so that the catalytic activity of OP-inhibited AChE (or BChE) is rapidly and continuously restored before irreversible aging of the enzyme–OP complex can occur. Thus, the OP is continuously detoxified. A reusable immobilized-enzyme sponge of ChEs and oximes for OP decontamination is the envisioned product. Next, it

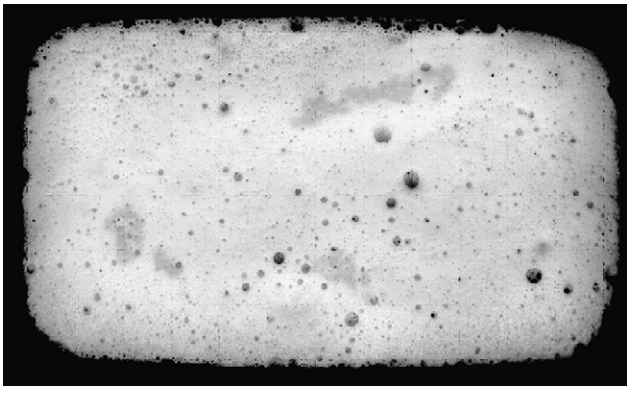

FIGURE 76.4 An enzyme-immobilized polyurethane foam sponge used to remove and decontaminate skin of CWA material.

was demonstrated that the OPs diisopropyl fluorophosphate and 7-(methyl-ethoxyphosphinyloxy)-1-methylquinolinium iodide (MEPQ) inhibited the activity of ChE sponges, as was observed for nonimmobilized ChE in solution. The oxime HI-6 restored activity of the AChE sponge until the molar concentration of MEPQ reached approximately 1,000 times that of the ChE active site. However, the AChE-sponge can be recycled many times by rinsing the sponge with HI-6 in the absence of OP. In this case, most of the original ChE activity would be restored to the sponge. Therefore, the bioscavenger approach could be used externally: the sponge would soak up OP, decontaminating the contaminated skin (Caranto et al., 1994). Then the ChE sponge and oxime would detoxify the OP in the sponge. We found that the ability of the immobilized enzymes and HI-6 to detoxify the OP MEPQ depended upon the efficiency of the sponge to decontaminate particular surfaces, including plastic and guinea pig skin.

Characteristics of polyurethane immobilized enzymes include the following: The longevity of sponges composed of immobilized ChEs is greater than 5 years at room temperature (according to unpublished observations). The immobilized enzymes are also very stable in aqueous environments. One significant difference (and advantage) that immobilized enzymes have compared to soluble ChEs is that immobilized enzymes do not dissociate (leach) from the sponge. Therefore, they can be left in liquid or other environments. For instance, the AChE activity in the immobilized sponge was stable for more than 60 days of continuous immersion in aqueous samples, including Allegheny River fresh water and brackish water (Gordon et al., 2002). Since the results were identical for autoclaved and untreated water, the immobilized enzymes were also resistant to microbial-induced proteolytic degradation. Also, note that the same sponge was assayed multiple times over many days, so it is evident that the immobilization process confers dramatic stability to covalently coupled ChEs, and that the enzymes do not leach from the polyurethane matrix.

The capacity of sponges to remove GD or OPs from guinea pig skin was determined using a back-titration method, where removed OP in the sponge was added to a known amount of ChE. Inhibition of the exogenously added ChE permits quantitation of the OP concentration. From these studies, it was determined that other components added to the sponge improved its efficacy by leaching out the CWAs. In this case, we settled on tetraglyme, which has a propensity to dissolve hydrophobiclike materials, including OPs (and sulfur mustard, as discussed later in this chapter). In part, the inability of tetraglyme sponge to remove all the GD likely reflects the rapid penetration of GD into skin and the inability of tetraglyme to extract this fraction of the poison. This further highlights the importance of decontaminating as rapidly as possible. These results clearly demonstrate that the sponge not only removed OP from the skin of the guinea pigs, but also, in the presence of oxime, effectively and completely detoxified the OPs within hours. Thus, these sponges would not pose any additional cross-contamination hazard.

It proved to be impossible to modify the prepolymer since there is currently no formulation with an increased hydrophobic nature that might be expected to absorb the OPs more effectively. Instead, we utilized the additives described previously to provide the additional ability to remove soman from the skin, protecting guinea pigs significantly better than the M291 SDK (Table 76.2). A comparison with RSDL is also shown in this table. Compared to the LD_{50} values of 9.9 and 17.7 mg/kg for untreated (not decontaminated) animals and the M291 SDK, respectively, the sponge provided an LD_{50} of 290. This combination is also effective against VX-contaminated guinea pigs: the sponge increased the LD_{50} from 0.14 to 21 mg/kg, yielding a protective ratio of 150 (comparable to that provided by RSDL).

In sulfur mustard decontamination and formulation, the sponge was used to wipe guinea pig skin contaminated with neat sulfur mustard. The following day, the animals were injected with trypan blue. Those areas representing vesicant injury take up the dye, hence becoming clearly visible. It was observed that the neat HD-exposed tissue (positive control) had a significant dye uptake, while the area decontaminated by the sponge had only a slight uptake of dye. The control, meanwhile, had no dye uptake. In addition, the amount of HD taken up and removed by the sponge was measured over time. While neat mustard remained after 15 min in water, the corresponding amounts were destroyed in the matrix of the sponge and additives. Histopathology of the HD-exposed skin specimens after 24 h demonstrated microvesicles, coagulation at the dermal interface, and, in the most severe cases, dermal coagulation. Overall, HD-exposed areas decontaminated with the sponge exhibited characteristics associated with reduced exposure (microvesicles). Thus, these sponges could reduce the damage that HD produces. ChEs may provide sinks as alkylation sites for the sulfur mustard and account for some of the reduced toxicity of the agent upon sponge decontamination. Another feature demonstrated was that the tetraglyme leaches from skin not only exposed to OPs, but also the hydrophobiclike sulfur mustard, thereby reducing its ability to alkylate skin proteins. Finally, the formulation of the sponge was modified to include nucleophilic additives acting as a reactive moiety for the sulfur mustard in the place of skin proteins. Taken together, the polyurethane sponge was shown to decontaminate and detoxify guinea pig skin exposed to two classes of CWAs: OPs, such as GD; and alkylating compounds, such as HD.

Immobilized Enzyme Badges

The sponge can incorporate a detection system for OPs and alkylating agents—a unique attribute not present in current decontamination methods (Gordon et al., 2002). The immobilized enzymes provide a detector and a rapid field system capable of identifying the type of OP. In addition to OP detection, a coupled enzyme reaction provides a rapid colorimetric or electrochemical indication of mustard. With the constant threat of chemical warfare or terrorist acts, the development of alternative means of protecting and decontaminating individuals from exposure to CWAs is critical.

Like Diphoterine, which has been evaluated only for sulfur mustard decontamination, the polyurethane enzyme-immobilized sponge is a novel technology that has demonstrated efficacy for OP and sulfur mustard cutaneous poisoning, but it is only now being evaluated for decontamination of biological warfare agents (such as T-2 mycotoxin and botulinum toxin) and radionucleotides (Gordon et al., 2006). Another advantage of ChEs over general reacting additives is that the ChEs are the direct target for current or future warfare agents, so countermeasures that incorporate ChEs should not require major reformulation. These new technologies likely will provide more efficacious solutions for the soldier in the future.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

OP nerve agents pose a serious threat to military and civilian personnel. The recent use of sarin by Syria against rebels was confirmed by the United Nations in 2013. These chemicals are some of the most potent toxic agents and are specific inhibitors of ChEs. OP nerve agents can be inhaled as a vapor, absorbed by the skin as a liquid, or ingested if food or water is contaminated. Vesicating agents such as sulfur mustard cause irreversible cell damage as a result of rapid alkylation, and they were terroristic weapons used during World War I and more recently in Iran and Iraq. Another serious problem that may be encountered while treating personnel contaminated with CWAs is the possibility of cross-contamination to the medical providers. In addition, during combat or terrorist acts, individuals might be exposed to chemical toxins before they don protective gear. Decontamination post-exposure has the potential to be an important, integral, and therefore necessary step for medical countermeasures against CWAs. The products described in this chapter must meet several criteria to be effective personal decontaminants and detoxifiers of CWAs for soldiers, although there is room for improvement; thus, novel technologies have been discussed. However, any product must be lightweight for individual use and remain shelf-stable under the environmental conditions found in the field. Decontamination and detoxification products must be readily available and work quickly because of the rapidity with which CWAs cause damage: for instance, OPs penetrate skin in less than 5 min, and mustard produces irreversible cell damage as a result of alkylation equally rapidly. The product should also be environmentally friendly. In the future, one product should incorporate chemical, biological, and radiological decontamination (and, when possible, detoxification). With the constant threat of chemical warfare, terrorist acts, and spilling of pesticides, the development of alternative means of protecting and decontaminating individuals from exposure is critical.

Phosphorylated AChE, 27, 1094
Phosphoryloximes, 1094
Phosphotriesterases (PTEs), 828–830
administration of, 1112
amino acid changes, 1112
bacterial, 1112–1114
Brevundimonas diminuta, 1112
catalytic efficiency, 1113*t*
eukaryotic calcium-dependent, 1114
His-tagged, 1112
from hyperthermophilic archae, 1112–1114
mammalian, 1115
PTE-like lactonases (PLLs), 1112
Phosphylated CarbEs, 971
Phosphylated nonapeptide (FGESAGAAS), 916–920, 953, 955, 955*f*
Photoionization spectrometer (PID), 902–903
Photon emission, 434–435
Photophobia, sulfur mustard-induced, 76
Phthalates, reproductive toxicity, 609
Phycoerythrins, 421
PhyloChip assay, 444
Physiologically based pharmacokinetic (PBPK) models of CWAs, 875
as analytical tools, 875–876
basic structure of, 878–879
binding capacity of AChE receptors associated with RBCs, 878
Chen and Seng's model, 876–877
critical components to, 877
development of, 876–877, 876*f*
guinea pig, 877
inhibition of AChE and BuChE, 876
for measuring CWNA exposures, 877–878
parameters for individual organ weights, 879
power of, 875–876
regenerated sarin from RBCs, 878
simulation of cholinesterase inhibition and regenerated GB, 879–881
soman metabolism, 876
Physiologically based pharmacokinetic/pharmacodynamic (PBPK/PD) models
of AChE inhibition and aging by OPs, 1041*f*
application of mathematical constructs, 1038
background for developing, 1035–1036
basic structure of, 1038
countermeasure effectiveness (CE), 1044
development of, 1038
distribution of oxime TMB-4, 1039*f*
exposure route, 1038
future directions, 1045–1046
health effects assessment and countermeasure optimization, 1044–1045
impact of anticonvulsants on NA-induced seizures, 1043
need for, 1037–1038
nerve agents/countermeasure interactions, 1036, 1041–1044, 1042*t*
novel, 1036–1037
pharmacodynamic processes, 1038
prediction of therapeutic efficacy, role in, 1035
absorption, distribution, metabolism, and excretion (ADME), 1038
pharmacological effect of seizure activity, 1043
regenerated NA from RBCs, 1043
simulation of RBC AChE inhibition and regeneration, 1042, 1043*f*
tissue–blood partition coefficients, determinations of, 1039–1041
uses, 1035, 1038
Physostigma venenosum, 770
Physostigmine, 152*t*, 411–412, 770, 967, 980–981, 983*t*, 990
antagonize receptor blocking effects, 992–993
anticonvulsant effects of, 991*f*
combination with procyclidine, 990–991
combination with scopolamine, 990
half-life of, 992–993
Phytodegradation, 1112
Phytolacca Americana antiviral protein (PAP), 351
Phytolaccaceae, 351–352
Phytonadione, 233
Picric acid–filled shells, 7–8
Pig ear skin permeation model, 842
Pigmentiphaga kullae (ECPB08), 193–194
Pigs
CarbE toxicity and, 801
decontamination model systems, 1130
nerve agent toxicity and, 103
radioactivity levels, 374
sulfur mustard dermatotoxicity and, 561
type A toxin, 374
Piloerection, 17
Pinacolyl methylphosphonic acid, 800
Pinacolyl methylphosphonofluoridate, 496–497
Pine Bluff Arsenal, 22
Piranha solution, 948
Pit cells, 616–617
Pitch, as incapacitant, 3
Placenta, 136, 181, 294, 602, 607, 610, 796, 889
CO toxicity and, 277
Placental barrier, 602
Plague of Athens, 387
Plagues, anthrax, 387
Planck's constant, 434
Planktothrix sp., 422, 424, 426
Plaque-forming cells (PFCs), 645–646
Plasma cells, 641
Plasma proteins, pediatric levels, 1008
Plastic, burning, hydrogen cyanide from, 301–302
Platelet-activating factor (PAF-AH), 1115
site-directed mutagenesis of, 1115
P300 latencies, sarin poisoning, 32
Pleurotus ostreatus, 1115
Plutonium, 447–448
Plutonium-238, 437
Pneumomediastinum, 1025
P-nitrophenol, 971
PNPLA6, 937–938
Pocket gophers, 219
Point detection, 900
Poison bullets, 7
Poison Control Centers, superwarfarin exposure monitoring, 225
The Poisoner's Handbook, 61
Poisonous plants, 784
Pollender, Franz Aloys Antoine, 388
Poly(ADP-ribose) polymerase (PARP), 74–75, 471–472, 559
Poly(ADP-ribose) polymerase (PARP) inhibitors, for sulfur mustard lesions, 471–472
Polybrominated biphenyls (PBBs), 4, 787–788
in feedstuffs, 635–636
Polybrominated dibenzofurans (PBDFs), 239
Polybrominated dibenzo-*p*-dioxins (PBDDs), 239
toxicity, 243–245
toxicity level of, 242–243
Polybrominated diphenyl ethers (PBDEs), 96, 240–241, 608
Polychlorinated biphenyls (PCBs), 98, 239
analytical methods, 243
congeners, 243–245
congener-specific determination, 243
generalized structures, 240*f*
historical background, 239–241
human exposure to, 241–242
mechanism of action, 243–245
mixture formulations, 239–240
physical and chemical properties, 242–243
structures of highly toxic, 241*f*
toxicity, 243–245

Polychlorinated biphenyls (PCBs) (*Continued*)
Ah receptor–mediated, 245
cytochrome-P-450–associated aryl hydrocarbon hydroxylase (AHH) activity, 243–245
Polychlorinated dibenzodioxins (PCDDs), 787
Polychlorinated dibenzofurans (PCDFs), 239, 787
congeners, 241
human exposure to, 241–242
Polychlorinated dibenzo-*p*-dioxins (PCDDs), 239
human exposure to, 241–242
toxicity, 243–245
toxicity level of, 242–243
Polychlorinated diphenyl ethers, 240–241
Polychlorinated naphthalenes, 240–241
Polycyclic aromatic hydrocarbons (PAHs)
airborne, 249
B(a)P-induced behavioral effects, 257–258
experimental model systems, 254–258
B(a)P aerosol, 254
