Although extremely rare, gastrointestinal anthrax has a high estimated mortality rate (25–60%). Symptoms occur 1–7 days after ingestion, presenting as either oropharyngeal or intestinal anthrax. Oropharyngeal anthrax presents as tongue lesions, lymphadenopathy, fever, and dysphagia. Intestinal anthrax presents 2–5 days after infection with abdominal pain, fever, nausea, emesis, and diarrhea. Abdominal pain and diarrhea are a direct result of ulceration, edema, and hemorrhaging of the gastrointestinal tract due to EF and LF (Friedlander, 1997). Therefore, diarrhea may be bloody with extensive fluid loss and circulatory collapse. If treatment is not started early, then toxemia and shock may develop, resulting in death. Oropharyngeal anthrax produces a milder infection than the intestinal form and leads to a better outcome. Treatment for either form reduces symptoms and typically leads to full recovery 10–14 days after infection.

Meningitis

Meningitis is a complication of all anthrax infections and is associated with high mortality. Anthrax meningitis occurs through either a hematogenous or lymphatic spread from the infection site to the central nervous system (CNS) (Sejvar et al., 2005). High bacterial counts from anthrax bacteremia allow for *B. anthracis* to cross the blood–brain barrier into the CNS to infect the meninges and cerebrospinal fluid (CSF). Anthrax meningitis is most common with inhalational anthrax and is seen in ~50% of those cases. Development of anthrax-associated meningitis is a very grave sign and invariably fatal. Even with antibiotic treatment, death occurs approximately 1–6 days after signs and symptoms of meningitis appear (Dixon et al., 1999), and the mortality rate is estimated to be 94% (Sejvar et al., 2005).

Symptoms at the onset of anthrax meningitis include fever, headaches, nausea, vomiting, chills, malaise, agitation, and nuchal rigidity (Sejvar et al., 2005). Delirium, coma, refractory seizures, and neurological degeneration occur within 2–4 days (Sejvar et al., 2005). Neurological degeneration can be seen with signs that include cranial nerve palsies, myoclonus, fasciculations, decerebrate posturing, and papilloedema (Sejvar et al., 2005). A notable feature of anthrax meningitis infection includes subarachnoid and intraparenchymal hemorrhages. Hemorrhage can be observed in the CSF, as well as polymorphonuclear pleocytosis, an increase in protein concentration, and a decrease in glucose concentration. *B. anthracis* can be observed in the CSF, meninges, subarachnoid space, and brain parenchyma.

DETECTION AND DIAGNOSIS

Detection

Detection and diagnosis of anthrax infection can be difficult. Diagnosis is made predominantly on a positive history of exposure to contaminated animal products and a physical examination of the presenting signs and symptoms. Tests to detect *B. anthracis* are typically never ordered unless there is evidence of exposure. The disease typically progresses to an advanced stage before initiating appropriate treatment. The formation of a black eschar with

hyperemic and edematous borders is a hallmark of cutaneous anthrax infection. Unfortunately, the black eschar occurs in the later stages of infection. The appearance of painless, pruritic papules with edematous borders is suggestive of possible cutaneous anthrax infection. Further tests to identify *B. anthracis* as the infectious agent should be attempted but should not delay initiation of antibiotic treatment. Evidence of pulmonary involvement on chest X-ray can provide suspicion of inhalational anthrax. The common triad of findings is mediastinal widening, pulmonary infiltrates, and/or pleural effusions (Friedlander, 1997; Dixon et al., 1999). Without a proper diagnosis, progression of some forms (i.e., inhalational anthrax) to the second stage of infection is nearly 100% fatal.

Depending on the form of disease suspected, certain specimens should be collected. If cutaneous anthrax is suspected, then swabs of the lesion are warranted. A sterile, dry swab should be used to collect vesicular fluid if the lesion is in the vesicular stage. If the lesion is in the eschar stage, then the edge of the eschar should be lifted and the swab should rotate underneath for 2–3 s. However, if the lesion is not in either the vesicular or eschar stage, the base of the ulcer can be swabbed with a sterile swab moistened with saline. Blood cultures should be collected regardless of the route of exposure or signs of disease (Beatty et al., 2003). If gastrointestinal anthrax is suspected, then ascitic fluid should be taken, and if oropharyngeal anthrax is suspected, then swabs from oropharyngeal lesions should be taken (Beatty et al., 2003). If pleural effusions are seen, then pleural fluid should be collected, and if meningeal signs/symptoms are present, then CSF should be collected.

Diagnostics

Laboratory tests for anthrax can include Gram staining, differential plating, γ-bacteriophage plaque assay, blood cultures, motility tests, enzyme-linked immunosorbent assays (ELISAs), and fluorescent covalent microsphere immunoassay (FCMIA). Although microbial tests take 24 h to perform, often delaying the diagnosis, these tests may be necessary to confirm a diagnosis of anthrax. If there is a high index of suspicion for anthrax, then initiation of therapy should not be delayed for results of these confirmatory tests.

Microbiological Tests

Simple tests to rule out anthrax infection are Gram staining of cultured bacteria, differential plating, and a γ-bacteriophage plaque assay. Gram staining is nearly always used in the identification of bacteria (CDC, ASM, APHL, 2002). *B. anthracis* will appear as large, Gram-positive rods in short chains. The size of the bacterium is approximately 1–1.5 by 3–5 μm. *B. anthracis* capsules will not absorb India ink stain and will cause the bacilli to appear as clear zones on a black, stained background. *B. anthracis* can be distinguished from other *Bacillus* species by culturing the organism on blood agar plates. It is the only *Bacillus* species that does not cause hemolysis. In addition, *B. anthracis* cells are lysed by the bacterial virus γ-bacteriophage to form small plaques on nutrient agar plates.

Blood cultures should follow normal laboratory protocol. Specimens collected for cutaneous anthrax can be plated on 5% sheep blood agar (SBA), MacConkey agar (MAC), or any media normally used for surface wounds (CDC, ASM, APHL, 2002). Stool specimens from gastrointestinal anthrax cases should be plated on phenylethyl alcohol agar, MAC, and SBA. Sputum specimens from inhalational anthrax patients should be plated on chocolate agar, SBA, and MAC. Cultures will show isolated *B. anthracis* colonies 2–5 mm in diameter, flat or slightly curved, with a wavy border after 15–24 h. *B. anthracis* shows growth on SBA and not on MAC. Colonies of *B. anthracis* plated on SBA will appear as a "beaten egg white" when teased with a loop (basic diagnostic testing). These blood cultures are useful, especially in the differential diagnosis of anthrax, and should be completed before antibiotic treatment is administered.

A motility test is useful because *B. anthracis* is a nonmotile bacterium. Two motility tests available are the wet mount and motility medium variety. In a wet-mount preparation, organisms with Brownian movement or no movement will support the presence of *B. anthracis*. The presence of *B. anthracis* in a motility medium preparation would be a single line of growth along the original inoculum stab (CDC, ASM, APHL, 2002).

Molecular Tests

Acute and convalescent serum samples for serological ELISA testing should be collected for diagnosis. The CDC developed an ELISA for the detection of *B. anthracis* PA using immunoglobulin G (IgG) antibodies in response to the bioterrorist anthrax plot in 2001. ELISA proved extremely useful in the detection of cutaneous and inhalational anthrax (Quinn et al., 2002). The diagnostic sensitivity and diagnostic specificity for this test are 97.6% and 94.2%, respectively.

A more recent study reports another tool that detects anthrax better than ELISA detection of PA (Biagini et al., 2004). The FCMIA can be multiplexed, meaning that numerous analytes can be measured simultaneously. In anthrax cases, anti-PA and anti-LF can be examined in serum samples at the same time. FCMIA is more sensitive, rapid, and reliable than ELISA.

Histopathology

Punch biopsies can confirm cutaneous anthrax if Gram stain and culture results are negative, due to antibiotic treatment (Godyn et al., 2005), and a suspicion of cutaneous anthrax remains. The center of the eschar, the

erythematous region, and the skin margin should all be included in the biopsy when an eschar is present (Godyn et al., 2005).

Radiology

Radiological tests are available to narrow the differential diagnosis for anthrax. A chest radiograph will almost always exhibit a widened mediastinal contour that includes unilateral or bilateral hilar enlargement, as well as prominent periobronchovascular markings and pleural effusions (Frazier et al., 2006). The size of the widened mediastinum contours and pleural effusion can increase rapidly over hours or days. However, findings from the radiograph might be subtle and even appear normal in the early stages of infection (Frazier et al., 2006). Noncontrast CT will exhibit high-density mediastinal and hilar lymphadenopathy, which can rapidly increase in size over days (Friedlander, 1997; Frazier et al., 2006). This indicates both hemorrhage and edema in the mediastinal lymph nodes. In addition, contrast-enhanced CT on mediastinal nodes can display rim enhancement and central hypodensity (Frazier et al., 2006). The role of radiological tests has not been identified in the diagnosis of gastrointestinal/oropharyngeal anthrax (Beatty et al., 2003). Radiographs of patients with gastrointestinal anthrax displayed findings indicative of obstruction; however, further studies need to be completed to determine if radiology can be used to help diagnose gastrointestinal anthrax (Beatty et al., 2003). Patients with anthrax disease can also acquire complications of anthrax meningitis. CT or magnetic resonance imaging shows hemorrhages in the deep gray matter, subarachnoid space, and ventricles (Sejvar et al., 2005).

RISK ASSESSMENT

The risks posed by an intentional outbreak of anthrax cannot be minimized because the potential effects go beyond merely the medical. The primary costs of a biological terrorism-related anthrax event in terms of lives lost, medical resources required to treat affected individuals, and economic burden to decontaminate spores are significant. Certainly, the subsequent psychological and societal costs could be as high or higher, based on the US Federal government experience with the 2001 anthrax letters. "On a collective level, a major epidemic of anthrax can destroy the social order" (Guillemin, 1999).

The distribution of *B. anthracis* endospores in mailings through the US Postal Service in the fall of 2001 served to ignite public awareness concerning anthrax as a weapon of mass destruction. Deliberate contamination of the mail resulted in 22 cases of anthrax (11 inhalational and 11 cutaneous). These mailings led to five deaths among the inhalational anthrax cases and an enormous economic burden associated with decontamination. The media coverage and public fallout unveiled the deficiencies in our current risk assessment of anthrax.

The effects on public order, as well as economic and social effects, should be considered in an assessment of weaponized anthrax risk. Decontamination of the Hart Senate Office Building in Washington, DC, required 7 months at a cost of $23 million. Decontamination of the postal facilities that processed the "anthrax letters" in Brentwood, DC, and Hamilton Township, NJ, required more than 1 year at a cost in excess of $100 million (Fernandez, 2002). The psychological effects of an anthrax attack could exceed the medical or economic effects, especially in the short term. Panic caused by seemingly random outbreaks of symptoms in apparently unrelated persons or events "could degenerate into panic, flight, communications breakdown, general societal dysfunction" (Wein et al., 2003).

A comprehensive risk assessment is dependent, in part, on determining the health risk posed to the individual by this biological agent. Animal models play a critical role by providing key sources of information for predicting consequences of human exposure because comparable naturally occurring human indices are rare. These animal models have been reviewed in previous sections throughout this chapter. Another method to assess risk is to use an anthrax stimulant. The Defense Research Establishment Suffield in Canada undertook a series of experiments to assess the risk of envelopes filled with anthrax spores (Kournikakis et al., 2001). In their experiments, envelopes containing spores of the nonpathogenic *Bacillus globigii* were opened in a mock mail room inside an aerosol test chamber to estimate aerosol release from the envelopes. Investigators showed that dispersal by passive letter opening was far more effective than initially thought. A lethal dose (LD) could be inhaled within seconds of opening the content (Kournikakis et al., 2001). Not only would the mail handler opening the envelope receive an LD of between 500 and 3,000 LD_{50}s but also other workers in the room would inhale lethal numbers of spores.

In silico models of anthrax release can be used to bridge the gap to help predict consequences of human exposure in the event of an outbreak or biological attack scenario. Several modeling studies have been published (Wein et al., 2003) in attempts to assess anthrax risk. The model of Wein et al. (2003) assumes a point-release of 1 kg of spores at a height of 100 m over a city of 10 million inhabitants. The effects on mortality of different antibiotic treatment strategies in an urbanized anthrax release are examined. This *in silico* biological weapon attack results in more than 100,000 deaths, given that both symptomatic and asymptomatic persons receive antibiotics and the model incorporates availability and distribution parameters. In the base case, an approximation of

current treatment and distribution strategies, deaths are estimated at more than 1% (Wein et al., 2003). The model predicts significantly higher death rates (≥7 times) in cases with less aggressive distribution or administration being modeled (Webb, 2003).

One of the greatest fears of a scenario involving anthrax is the application of genetic engineering to enhance its pathogenicity. Several studies have demonstrated the ability to generate antibiotic-resistant anthrax (Pomerantsev et al., 1993). In addition to developing multiple antibiotic-resistant strains of *B. anthracis*, biotechnology offers a highly likely scenario that the very nature of *B. anthracis* could be altered. It is possible that *B. anthracis* can be engineered to produce novel toxin activity (Sirard et al., 1997a,b). Other approaches may focus on the modification of PA such that it remains functional but immunologically distinct from the PA used in current vaccines.

TREATMENT

Overview

Treatment of any form of anthrax infection is generally the same: aggressive antibiotics and supportive care. Rapid definitive diagnosis of anthrax is critical for effective treatment, although in cases in which anthrax is suspected before confirmation, antibiotic therapy should not be withheld pending test results. Postexposure treatment should be administered in cases of putative exposure to anthrax spores to prevent systemic disease. Antibiotics and supportive management are the mainstays of treatment to prevent septic shock, fluid and electrolyte imbalance, and dyspnea associated with systemic anthrax disease. Initial administration of ciprofloxacin or doxycyclin is recommended (USFDA, 2001; CDC, 2001a–c). A duration of 60 days has been recommended for prophylaxis, although the most efficacious duration has not been determined (Brook, 2002).

Intravenous ciprofloxacin or doxycycline is recommended for treatment of anthrax, usually as part of a cocktail of antibiotics (CDC, 2001a,b). Multiple antibiotics are usually indicated in anthrax cases with signs of septicemia, extensive edema, or for cases with cutaneous lesions in the head and neck (Brook, 2002). Penicillin may be included in the antibiotic cocktail but is not recommended as a stand-alone therapy due to *B. anthracis* β-lactamase production. *B. anthracis* can express β-lactamase variants, penicillinases and cephalosporinases, which would undermine a lone-penicillin therapy (Lightfoot et al., 1990). *B. anthracis* has shown *in vitro* resistance to cephaloporins and trimethoprim-sulfamethoxazole (Inglesby et al., 2002). Corticosteroid therapy may help treat edema from head and neck lesions or prevent airway obstruction. Table 29.3 contains therapeutic guidelines based on CDC recommendations (CDC, 2001a–c) for pharmacologic management of *B. anthracis* infection.

Inhalational, Oral, and Gastrointestinal Anthrax

At the time of writing, the recommended initial therapy for inhalational, oral, and gastrointestinal anthrax in adults is 400 mg of ciprofloxacin every 12 h or 100 mg of doxycycline every 12 h, administered intravenously (Inglesby et al., 2002). In addition to these treatments, one or two additional antimicrobials should be administered (list mentioned) (Inglesby et al., 2002). These guidelines should be followed until the condition of the patient improves. The treatment should then be switched to either 500 mg of ciprofloxacin twice per day or 100 mg of doxycycline twice per day (Inglesby et al., 2002). This stage of treatment should begin intravenously and switch to oral dosing when appropriate. Treatment should continue for 60 days. Oral amoxicillin can be used as an alternative in adults and children for completion of therapy only after clinical improvement (CDC, 2001a,b; Inglesby et al., 2002). Pediatric guidelines for medical management of anthrax are provided in Table 29.3, in addition to recommendations for pregnant women and immunocompromised patients.

Cutaneous Anthrax

The recommended initial therapy for adults with cutaneous anthrax is either 500 mg of ciprofloxacin orally administered twice per day, or 100 mg of doxycycline orally administrated twice per day (Inglesby et al., 2002). The duration of therapy is suggested to be 60 days (CDC, 2001a,b), although previous guidelines recommend 7–10 days (Inglesby et al., 2002). Intravenous therapy and a multidrug regimen approach are recommended for patients with signs of extensive edema or head/neck lesions (CDC, 2001c). The guidelines for pharmacologic management of cutaneous anthrax in pediatric patients and pregnant women are also provided (Table 29.3). With early treatment, systemic disease does not occur, and laboratory cultures will yield negative results for *B. anthracis*; however, treatment will not curtail formation of the black eschar and progression of the edematous skin ulcer (CDC, 2001c).

Bacteremia

Bacteremia often occurs with anthrax infection, especially with gastrointestinal/oropharyngeal and inhalational anthrax. A multidrug approach consisting of ciprofloxacin or doxycycline, along with one or two other antimicrobials, is suggested when bacteremia is suspected (CDC, 2001c). Other drugs that are

TABLE 29.3 Anthrax Therapeutic Guidelines[a]

		Adults		Children		Pregnant Women	
Therapy		**Initial Therapy[b] (Intravenous Dosing)**	**Oral Dosing**	**Initial Therapy (Intravenous)**	**Oral Dosing**	**Initial Therapy**	**Duration**
Recommended first line treatment—inhalational, GI, and oropharyngeal anthrax[c]	Ciprofloxacin (use in combination with one or two additional antimicrobials listed below)	Intravenous treatment initially (400 mg q 12 h) in combination with one or two additional antimicrobials[d]	Switch to oral dosing when appropriate (500 mg PO BID)	Intravenous treatment initially (10–15 mg/kg q 12 h)[e] in combination with one or two additional antimicrobials	Switch to oral when appropriate (500 mg PO BID)	Same for adults	
		Duration: Continue for 60 days total (i.v. and p.o. combined)[f]					
	Doxycycline[g] (use in combination with one or two additional antimicrobials listed below)	Intravenous treatment initially (100 mg q 12 h) in combination with one or two additional antimicrobials[d]	Switch to oral when appropriate (100 mg PO BID)	Intravenous treatment initially >8 years and >45 kg (100 mg q 12 h) >8 years and <45 kg (2.2 mg/kg q 12 h) <8 years (2.2 mg/kg q 12 h)	Switch to oral therapy when appropriate >8 years and >45 kg (100 mg PO BID) >8 years and <45 kg (2.2 mg/kg PO BID) <8 years (2.2 mg/kg PO BID)		
		Duration: Continue for 60 days total (i.v. and p.o. combined)[f]					

	Adults		Children		Pregnant Women		
Therapy	**Initial Therapy (Oral)[h]**	**Duration**	**Initial Therapy (Oral)**	**Duration**	**Initial Therapy**	**Duration**	
Recommended first line treatment—cutaneous anthrax[c]	Ciprofloxacin	500 mg BID	60 days[f]	10–15 mg/kg q 12 h (not to exceed 1 g/day)	60 days[f]	500 mg BID	60 days[f]
	Doxycycline[g]	100 mg BID		>8 years and >45 kg (100 mg q 12 h) >8 years and <45 kg (2.2 mg/kg q 12 h) <8 years (2.2 mg/kg q 12 h)		100 mg BID	
Alternative option in cutaneous anthrax[i]	Amoxicillin		500 mg PO TID		80 mg/kg/day divided every 8 h		

[a] *Therapeutic treatment protocol for immunocompromised persons is the same for immunocompromised adults and children.*
[b] *Steroids may be considered in as adjunct therapy for patients with severe edema and for meningitis. (Dexamethosone: Adults (0.75–0.90 mg/kg/day orally, i.v., or i.m. in divided doses every 6 h); Children (0.25–0.50 mg/kg every 6 h)) (Prednisone: Adults (1–2 mg/kg or 5–60 mg orally/day); Children (0.5–2 mg/kg/day).)*
[c] *Ciprofloxacin or doxycycline are first line therapeutics for all forms of anthrax.*
[d] *Other agents with in vitro activity include rifampin, vamcomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, and clarithromycin. Because of concerns for beta-lactamases in B. anthracis, penicillin and ampicillin should not be used alone. Consultation with an infectious disease specialist is advised.*
[e] *In children, ciprofloxacin dosage should not exceed 1 g/day.*
[f] *Due to the potential for spores to persist after an aerosol exposure, antimicrobial therapy should be continued for 60 days.*
[g] *If meningitis is suspected, doxycycline may be less optimal due to poor CNS penetration.*
[h] *Cutaneous anthrax with signs of systemic involvement, extensive edema, or lesions of the head or neck require intravenous therapy, and a multidrug therapeutic approach.*
[i] *Amoxicillin is an alternative option in adults and children for completion of therapy only after clinical improvement.*

recommended for use with ciprofloxacin or doxycycline include rifampin, vancomycin, imipenem, chloramphenicol, penicillin/ampicillin, clindamycin, and clarithromycin (CDC, 2001c).

Anthrax Meningitis

There is limited clinical experience for treating patients with anthrax meningitis (Sejvar et al., 2005). However,

the recommended therapy is also a multidrug treatment, including the use of a fluoroquinolone and two additional drugs with excellent CNS penetration. The fluoroquinolone that is recommended for use is ciprofloxacin. The ciprofloxacin level in CSF is 26–50% of serum levels. Other fluoroquinolones include levofloxacin, gatifloxacin, moxfloxacin, and ofloxacin. Doxycycline is not recommended as a first-line agent for anthrax meningitis. Although doxycycline has a low minimum inhibitory concentration (MIC) (0.03 mg/L), it has low CNS penetration and a lower percentage of serum levels in the CSF than ciprofloxacin (10–26%). These drugs have been shown to work against *B. anthracis*; however, these drugs have not been observed in humans and have not been tested in animal models. Drugs with significant CNS penetration include ampicillin, meropenem, rifampicin, or vancomycin. Although penicillin is a beta-lactam, like ampicilin and meropenem, it is not suggested for use against anthrax meningitis for the reasons stated. Similar to the treatment suggestions, the recommended duration of therapy is 60 days. Even with the effectiveness of antibiotic treatment, there is no guarantee that anthrax will be diagnosed in time to initiate therapy. Therefore, anthrax represents a significant risk to the public because it is lethal, potent, and induces public anxiety.

Vaccines

Although vaccines are promising, further research needs to be conducted with the goal of updating vaccine technology. Conclusive demonstration of seroconversion against an anthrax infection was demonstrated in animals previously immunized with an active anti-PA vaccine and later administered postexposure antibiotic therapy (Friedlander et al., 1993). Therefore, other therapies, such as injection of anthrax-specific monoclonal antibodies (Maynard et al., 2002), may lead to a promising treatment after exposure to *B. anthracis*. Both of the current anthrax vaccines, *anthrax vaccine adsorbed* (AVA) and a newer one based on recombinant PA (rPA), offer long-lasting protection against an aerosol challenge of *B. anthracis* in rhesus macaques. Efficacy of both vaccines is primarily attributable to the PA. The AVA vaccine offers similar protection from challenge in rabbits; however, the duration of immunity is unknown (Phipps et al., 2004). Various negative side effects have been reported after administration of the current anthrax vaccine to humans, and it would be beneficial to develop a vaccine that has fewer side effects before instituting a massive vaccination plan. Recent reports suggest that the addition of CpG oligonucleotides may offer an improved response. These CpG motifs interact with various receptors on B cells and dendritic cells, which improve antigen presentation and upregulate pro-inflammatory cytokine expression. After co-administration of CpG oligonucleotides with the AVA vaccine, this combination triggered a fast and higher-titer immune response in comparison with the vaccine alone (Klinman et al., 2004). These findings suggest a potential for using oligonucleotides as an adjuvant in a postexposure vaccine.

Other studies have used an adenoviral delivery system to invoke a protective immune response in mice (Tan et al., 2003). Immunization with this form of vaccine demonstrated a rapid anti-PA antibody response at a higher level than that of the current vaccine. Further, this method of delivery offered a longer protection time in comparison with that of the rPA vaccine. However, current public fears of using a virus as an immunization vector, coupled with the lack of similar findings with other model systems, make it imperative to further research this potential area of vaccine technology.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The fear of *B. anthracis* has only been heightened in recent years as a result of the terrorist events in 2001 and the increase in acts of terrorism worldwide. There are few infectious agents that are more feared or notorious than *B. anthracis*, the causative agent of the zoonotic disease anthrax. *B. anthracis* would be an ideal weapon for a terrorist attack not only because of the disease pathology, but also because this organism can sustain desiccation and survive long-term outside of its host as a dormant spore. Moreover, infection of humans by inhalation of spores has been reported. Thus, *B. anthracis* disseminated in an aerosol could be a feasible means for targeting and infecting a large population.

The processes of *B. anthracis* infection and pathogenesis have been studied in various animal models. During the initial phases of infection, regardless of the route of infection (i.e., inhalational, dermal, or oral), the host animal may display general symptoms that are characteristic of numerous infections or disease states, making a positive diagnosis difficult. Pathogenesis involves initial uptake of dormant spores by phagocytes. Germination takes place soon afterwards either at the site of inoculation or later after transport to the lymph nodes. It is the vegetative cell that moves through the circulatory system and lymphatics to infect other target organs. Lungs and gastrointestinal tract are major targets for vegetative bacilli. Later the spleen, brain, liver, and almost every other organ in the body can be colonized. In systemic anthrax, there is overwhelming septicemia. Although septicemia is important, lethality from *B. anthracis* is believed to be mediated by the actions of anthrax toxins (LT and ET). The toxins are thought to be primarily responsible for causing immune system suppression, necrosis of critical cells, vascular leakage, hemorrhage, shock, and death.

There are numerous gaps in our understanding of anthrax. Although the general pathogenesis of *B. anthracis* has been studied in a variety of animals, a number of important questions still remain unanswered. Although spore uptake has been demonstrated in macrophages and dendritic cells, the molecular interactions involving uptake, spore germination, and escape require additional research. Further *in vitro* and *in vivo* studies will help to elucidate these mechanisms. Understanding of the molecular mechanisms of TLR signaling and its relationship to LT-mediated apoptosis may lead to new therapies. The inhibition of TLR-mediated signaling of apoptosis may inhibit macrophage cell death and assist in controlling the pathogen.

Several studies have shown bacilli in many organs of the body after various routes of exposure. However, the time course of transit to target organs and the targeting order of these organs may be helpful in further defining therapeutic windows of opportunity. Finally, the molecular mechanisms of toxicity and death caused by LT and ET remain unclear. There is no direct evidence that proves the importance of macrophage apoptosis in the course of disease progression. Recent reports suggest that LT may induce apoptosis of endothelial cells, which suggest that macrophages are not the sole cell type affected by LT (Kirby, 2004). In addition, reports that demonstrate LT reduces cytokine expression (Pellizzari et al., 1999; Moayeri and Leppla, 2004) suggest that death may not be due to an inflammatory reaction.

Several animal model studies have focused on the immune response to infection and also to vaccination. Most studies identify antibody titer, but some also show cytokine production or possible mechanisms of bacterial evasion. A focus on immune response studies will help to further define *B. anthracis* pathogenesis and provide insight into the design of future vaccines and therapeutics. Most countermeasure studies have been conducted on vaccines, because antibiotic studies have typically been performed *in vitro*. Primary concerns are the length of required treatment, efficient prophylaxis methods, and less complicated dosing regimens for vaccines. In a theoretical bioterrorist attack scenario, it will be essential to distribute effective treatment and prophylaxis to infected or potentially exposed persons in an expedient manner.

The choice of an appropriate animal model system that most closely mimics the human response to *B. anthracis* infection is crucial to the development of improved treatments and more effective vaccines. Such development relies on testing in appropriate animal models in which disease, infection, and progression mimic that seen in humans. The importance of selecting an appropriate animal model for human anthrax is magnified by the potential of a genetically engineered *B. anthracis* bacterium made more virulent than its predecessor. The addition of antibiotic resistance genes would render prophylactic treatment against infection by modified organisms difficult, if not futile. Further, the inclusion of genes that encode toxins not naturally found in *B. anthracis* may assist the bacterium in escaping host immunosurveillance. Therefore, defining the pathogenesis of *B. anthracis* and designing appropriate countermeasures is a critical necessity for treatment of those exposed in occupational settings, national security, and the global community. Whether medical systems would be able to provide treatment early enough to prevent widespread disease in the event of a bioterrorist attack involving anthrax remains questionable.

Onchidal and Fasciculins

Arturo Anadón, Maria Rosa Martínez-Larrañaga and Luis G. Valerio Jr.

INTRODUCTION

Onchidal and fasciculins are natural toxins that produce their toxicity in mammalian systems primarily by virtue of acetylcholinesterase (AChE) inhibition. AChE hydrolyzes acetylcholine (ACh) and inactivates AChE, thereby regulating the concentration of the transmitter at the synapse. Termination of activation normally depends on dissociation of ACh from the receptor and its subsequent diffusion and hydrolysis, except in diseases where ACh levels are limited or under AChE inhibition, conditions that increase the duration of receptor activation (Silver, 1963).

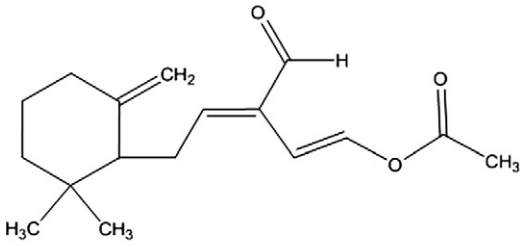
The toxins that inhibit the AChE are called *anticholinesterase (anti-ChE)* agents. They cause accumulation of ACh in the vicinity of cholinergic nerve terminals and thus are potentially capable of producing effects equivalent to excessive stimulation of cholinergic receptors throughout the central nervous system (CNS) and peripheral nervous system (Long, 1963). Nevertheless, several members of this class of compounds are widely used as therapeutic agents; others that cross the blood–brain barrier (BBB) have been approved or are in clinical trial for the treatment of Alzheimer's disease. The treatment approaches in the neurodegenerative pathology of Alzheimer's disease continue to be primarily symptomatic, with the therapeutic strategies based on the cholinergic hypothesis, and specifically on AChE inhibition (Lane et al., 2004).

AChE can be classified in several ways. Mechanistically, it is a serine hydrolase. Its catalytic site contains a catalytic triad—serine, histidine and an acidic residue—as do the catalytic sites of the serine proteases (such as trypsin), several blood clotting factors, and others. However, the acidic group in AChE is a glutamate, whereas in most other cases, it is an aspartate residue. The nucleophilic nature of the carboxylate is transferred through the imidazole ring of histidine to the hydroxyl group of serine, allowing it to displace the choline moiety from the substrate, forming an acetyl-enzyme intermediate. A subsequent hydrolysis step frees the acetate group. Understanding of the catalytic properties of the protein has assisted in our understanding of its inhibition by organophosphate (OP) and carbamate (CM) inhibitors. However, several questions remain to be answered regarding AChE catalysis, such as the mechanism behind the extremely fast turnover rate of the enzyme (Fair et al., 1994). Despite the fact that the substrate has to navigate a relatively long distance to reach the active site, AChE is one of the fastest-reacting enzymes (Nair et al., 1994). One theory to explain this phenomenon has to do with the unusually strong electric field of AChE. It has been argued that this field assists catalysis by attracting the cationic substrate and expelling the anionic acetate product (Ripoll et al., 1993). Site-directed mutagenesis, however, has indicated that reducing the electric field has no effect on catalysis. However, the same approach has indicated an effect on the rate of association of fasciculin, a peptide that can inhibit AChE (Schafferman et al., 1994).

Naturally occurring irreversible inhibitors of AChE are toxins that are often selective inhibitors of protein function, and this property can often be exploited for a variety of purposes (Pita et al., 2003). For instance, physostigmine (also called eserine), is a naturally occurring alkaloid reversible inhibitor of AChE that has been used in understanding the kinetic mechanism of AChE. Through its action at both the central and peripheral cholinergic receptors, physostigmine reverses anticholinergic activity and ameliorates the coma, delirium, and seizures that accompany severe toxicity. Antidotes for such poisoning have been developed to accelerate enzyme regeneration.

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00030-0

The slow reactivation of AChE is the basis of the use of physostigmine and pyridostigmine (a physostigmine derivative) as a prophylactic in anticipation of the use of these toxins. It is argued that the psychological stress associated with warfare impaired the integrity of the BBB, allowing the peripheral-acting inhibitor of AChE to penetrate the brain, where it activated AChE transcription (Kaufer et al., 1998). For further details on toxins/toxicants and the BBB, see Chapter 49.



Onchidal

FIGURE 30.1 The chemical structure of onchidal.

BACKGROUND

This chapter covers natural agents that prolong the existence of ACh after it is released from cholinergic nerve terminals. Natural toxins are chemical agents of biological origin (including chemical agents and proteins), and can be produced by all types of organisms; such is the case for onchidal and fasciculins. Although a chemical and a protein, respectively, onchidal and fasciculins share the same toxic effect of inhibiting AChE, which is concentrated in synaptic regions and is responsible for the rapid catalysis of the hydrolysis of ACh. As such, the natural toxins onchidal and fasciculins can produce disorders of neuromuscular transmission that are clinically categorized as either presynaptic or postsynaptic; some toxins simultaneously affect both sites. Chemical agents associated with neuromuscular transmission syndromes include the fasciculins, crotoxin, taipoxin, tubocurarine, and OP compounds (Anadón and Martínez-Larrañaga, 1985).

These aforementioned natural anti-ChE agents can be developed for a different purpose, including extensive application as toxic agents (i.e., potential chemical weapons). One of the first interesting structures with cholinergic properties isolated from a marine source is onchidal. This compound was first isolated from the mollusk *Onchidella binneyi* and has an acetate ester similar to ACh. Upon isolation, onchidal was discovered as being an active, site-directed, and irreversible inhibitor of AChE (Abramson et al., 1989).

Neurotoxins from snake venoms have proved to be valuable tools for the understanding of synaptic transmission mechanisms. Likewise, the powerful inhibitory action of fasciculins against mammalian AChE makes them potentially useful for pharmacological and neurochemical research. Studies of their biochemical and electrophysiological effects on the CNS and biochemical characterization are now being carried out.

Natural toxins can be extremely potent, and many of them are effective at far lower dosages than conventional chemical agents. Natural toxins, as compounds of biological origin, are often classed as biological agents, but they are not infectious and are more similar to chemicals with respect to their military potential for tactical use; therefore, they should be considered to be chemical agents. The Chemical Weapons Convention (CWC 2003) (available at www.fas.harvard.edu/~hsp/cwc/cwcbyart.html) also includes natural toxins as chemical agents, specifically including the onchidal and fasciculin toxins in its control regime, along with other highly toxic chemicals.

Onchidal

Onchidal is a toxic component of a poisonous marine opisthobranch mollusk. Like other opisthobranchs, the Onchidiacea family of mollusks does not have the protection of a hard external shell as most mollusks do. They rely instead on the production of a defensive secretion. When the animal is disturbed, it emits a viscous fluid from specialized glands. In two species of Onchidella (*Onchidella floridanun* and *Onchidella borealis*), this defensive secretion has been shown to act as a deterrent to potential predators, including fish and crabs. Chemically, it is a simple lipophilic acetate ester (Figure 30.1).

Onchidal has been identified as the major lipid-soluble component of the defensive secretion of *O. binneyi*, and it has been proposed as the compound responsible for the chemical protection of *Onchidella* species. *O. binneyi* is an opisthobranch mollusk that inhabits the rocky intertidal zone near the area of Baja California, Mexico. The defensive secretion was obtained in the field by squeezing the mollusk and collecting the mucus discharge in capillary tubes. Large quantities of this material could be obtained after the extraction of intact animals with acetone (Ireland and Faulkner, 1978). However, the distribution of onchidal in different species of *Onchidella* was not reported and, apart from inhibiting the growth of *Staphylococcus aureus* (the IC_{50}value was between 0.21 and 0.63 µg/mL), which implies that onchidal is a potent inhibitor of Gram-positive microorganisms, no biological activity of onchidal was described. Additional studies demonstrated that onchidal is contained in several different species of *Onchidella* and that, once purified, it is toxic to fish (Abramson et al., 1989). Onchidal can be found in four of the eight known species of *Onchidella*

TABLE 30.1 Concentration of Onchidal in Different Species of *Onchidella* (Abramson et al., 1989)

Organism	Collection Site	Onchidal Concentration (μg/Animal)
O. binneyi	Baja California, Mexico	230
O. borealis	Central California, USA	33
O. nigricans	New Zealand	18
O. patelloides	Australia	42

TABLE 30.2 Types of Fasciculin Identified

Fasciculins Characterized	From the Mamba Snake Venoms (Elapidae Family) (*Dendroapsis* genus)
Fas1	*D. angusticeps* (green mamba)
Fas2 (formally F_7 toxin)	*D. angusticeps* (green mamba)
Fas3 (formally Toxin C)	*D. polylepis* (black mamba)
Fas4	*D. viridis* (Western green mamba)

collected from different countries (Table 30.1). In addition, the Abramson study found onchidal to be toxic to goldfish. Although goldfish are not potential predators of *Onchidella*, these results demonstrate that onchidal has a distribution and a biological activity consistent with its proposed role in the chemical defense of *Onchidella*.

Fasciculin

The venom of the mamba snake (*Dendroaspis angusticeps*, *Dendroaspis polylepis*, *Dendroaspis viridis*, *Dendroaspis jamesoni*) contains a mixture of neurotoxic compounds, including postsynaptic cholinoreceptor α–neurotoxins, dendrotoxins, fasciculins, and muscarinic toxins (Hawgood and Bon, 1991). Effects at the NMJ include AChE inhibition by fasciculins and increased presynaptic release of ACh by dendrotoxins (polypeptides that facilitate ACh release in response to nerve stimulation); together with the high ACh content of mamba toxin (6–24 mg/g), these effects are synergistic and enhance neurotoxicity and lethality. Moreover, the venom may contain other components that have a synergistic action with dendrotoxin.

Toxins that facilitate neuromuscular transmission are a characteristic component of mamba venom. The four known fasciculins bind to a peripheral regulatory anionic site of AChE in a noncompetitive and irreversible manner (Hawgood and Bon, 1991). The dendrotoxins comprise the second group of facilitatory neurotoxins and are present in most mamba venom (with the exception of *D. jamesoni*); they inhibit voltage-dependent K^+ channels in motor nerve terminals and facilitate ACh release at the NMJ. Postsynaptic toxins present in mamba venom bind to and block nicotinic acetylcholine receptors (nAChRs). The muscarinic toxins present in mamba venom are small proteins (7 kDa) that selectively bind to muscarinic cholinergic receptors and may constitute up to 1% of the venom protein (Adem and Karlsson, 1985; Jerusalinsky and Harvey, 1994). About 12 muscarinic toxins have been isolated. M1 toxin binds noncompetitively and with high affinity to the M_1 muscarinic receptor subtype. MTx1 and MTx2 show high affinity for both muscarinic M_1 and M_3 receptors; little is known about the receptor selectivity of MTx3 and MTx4. Dpα and Dpβ are also muscarinic agonists, displaying similar affinity for both the M_1 and M_2 receptor subtypes. The last two agonists, DpMTx and DvMTX, are selective muscarinic agonists present in the venom of some mamba species; these agonists also show affinity for the M_1 muscarinic receptor subtype.

The fasciculins are a family of closely related ~6,750-Da peptides isolated from the venom of mambas (genus *Dendroaspis*), and are named after the long-lasting muscle fasciculations they produce in mice (Rodriguez-Ithurralde et al., 1983). They are potent and selective inhibitors of AChE. Fasciculins are 61-residue-long polypeptides. They share a three-looped structural motif with other toxins, such as α-neurotoxins, cytotoxins, and muscarinic toxins, directed to diverse specific targets. Four fasciculins are known (Table 30.2), which differ only by 1–3 residues and show selective and potent anti-AChE activity: Fas1 and Fas2 from the venom of *D. angusticeps* (the Eastern green mamba) contains 61-amino-acid residues, including eight half-cystines (Rodriguez-Ithurralde et al., 1983), ToxC from the venom of *D. polylepis polylepis* (the black mamba) (Joubert and Taljaard, 1978), and Fas3, which was isolated from a particular batch of *D. viridis* (the Western green mamba) venom and found to have the same primary structure as ToxC (Marchot et al., 1993). No fasciculin has been found in other *D. viridis* venoms (Marchot et al., 1993), or in *D. jamesoni* (Jameson's mamba).

Angusticeps-type toxins constitute a group of toxins typical for mamba venoms. They consist of 59–61 amino acids residues and four disulfides, and show sequence homology with short-chain postsynaptic toxins and cardiotoxins, but they are immunochemically distinct from these toxins. Eight toxins of this type have been sequenced and structurally classified into four subgroups (Joubert and Taljaard, 1978). Pharmacological studies on these *angusticeps*-type toxins have revealed that only toxins F_7 and C, which belong to subgroup I, exhibit a potent inhibition of cholinesterase (ChE) of various tissues, except for that of chick skeletal muscle. Both F_7 and C stimulate mouse and toad skeletal muscles by their anti-ChE activity, as well as possibly by facilitating ACh release from nerve terminals (Lee et al., 1985).

Fasciculins account for 3–6% of the venom protein, and the relative proportions between Fas1 and Fas2 is about one-third (Cerveñanský et al., 1994).

The structural similarity between onchidal (an acetate ester) and ACh suggested that the toxicity of onchidal could result from inhibition of either nAChRs or AChE. Although onchidal (1.0 mM) did not prevent the binding of ^{125}I-α-bungarotoxin to nAChRs, it inhibited AChE in a progressive, apparently irreversible manner. The apparent affinity of onchidal for the initial reversible binding to AChE (K_d) was approximately 300 μM, and the apparent rate constant for the subsequent irreversible inhibition of enzyme activity (K_{inact}) was approximately 0.1 min^{-1}.

Fasciculins are a family of closely related peptides that are isolated from the venom of mambas and exert their toxic action by inhibiting AChE. The crystal structure of Fas2 from green mamba (*D. angusticeps*) snake venom was first resolved in 1992 (Le Du et al., 1992). The three-dimensional structure of Fas1, obtained from the US National Library of Medicine, National Center for Biotechnology Information, Molecular Modeling Database 3-D Structure Database (MMDB), is illustrated in Figure 30.2.

Fasciculins belong to the structural family of three-fingered toxins from Elapidae snake venoms, which include the α-neurotoxins that block the nAChR and the cardiotoxins that interact with cell membranes. The features unique to the known primary and tertiary structures of the fasciculin molecule were analyzed by Harald et al. (1995). Loop I contains an arginine at position 11, which is found only in the fasciculins and could form a pivotal anchoring point to AChE. Loop II contains five cationic residues near its tip, which are partly charge-compensated by anionic side chains in loop III.

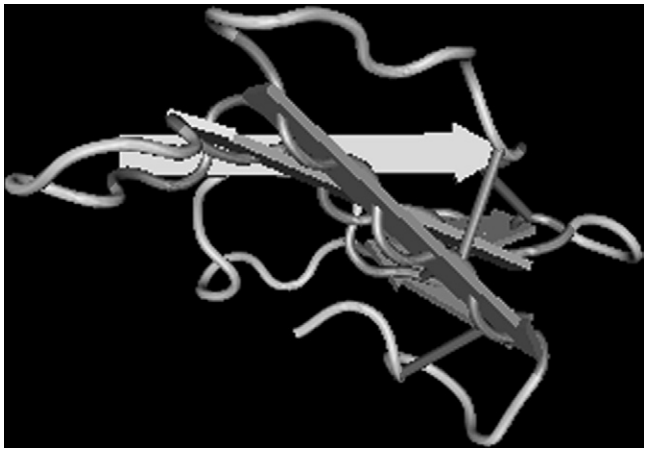


FIGURE 30.2 The 3-D protein structure of Fas1 derived from green mamba (*D. angusticeps*) snake venom. *Source: Image obtained from the public domain at the US National Library of Medicine, National Center for Biotechnology Information, MMDB.*

By contrast, the other three-fingered toxins show full charge compensation within loop II. The interaction of fasciculin with the recognition site on AChE was investigated by estimating a precollision orientation, followed by the determination of the buried surface area of the most probable complexes formed, the electrostatic field contours, and the detailed topography of the interaction surface. This approach has led to testable models for the orientation and site of bound fasciculin.

MECHANISM OF ACTION AND BIOLOGICAL EFFECTS

Onchidal

Onchidal belongs to the group of natural nonprotein neurotoxins and is an irreversible inhibitor of the AChE enzyme, with a novel mechanism of action. It has been suggested, however, that its toxicity could be a consequence of the inhibition of either nAChRs or the AChE enzyme.

Incubation of AChE with onchidal resulted in the production of acetate, demonstrating that onchidal was a substrate for AChE, and approximately 3,250 mol of onchidal were hydrolyzed/mol of enzyme irreversibly inhibited. OP and CM inhibitors of AChE have partition ratios (mol of toxin hydrolyzed/mol of enzyme irreversible inhibited) that approach unit. Therefore, the relatively high partition ratio for onchidal suggests that the mechanism of inhibition utilized by onchidal may be distinctly different from other irreversible inhibitors (Walsh, 1984). The rate of hydrolysis of onchidal (K_{cat}) was 325 min^{-1}; this value is relatively slow, suggesting that onchidal is not a very good substrate. The ability of AChE to hydrolyze onchidal raised the question of whether inhibition of enzyme activity resulted from onchidal itself, or from a product of the enzymatic hydrolysis of onchidal. Enzyme kinetics revealed that onchidal was unable to completely inhibit higher concentrations of AChE. From the experiments performed by Abramson et al. (1989), onchidal was in molar excess and completely hydrolyzed. Thus, irreversible inhibition of enzyme activity resulted either from onchidal itself, or from a reactive intermediate produced during the hydrolysis of onchidal (Walsh, 1984).

In another investigation, irreversible inhibition of enzyme activity was prevented by co-incubation with reversible agents that either sterically block (edrophonium and decamethonium) or allosterically modify (propidium) the ACh site (Barnett and Rosenberry, 1977). Enzyme activity was not regenerated by incubation with oxime reactivators; therefore, the mechanism of irreversible inhibition does not appear to involve acylation of the active site serine.

Because onchidal is an acetate ester similar to ACh, and because cholinergic neurotransmission is often the site of action of natural products involved in chemical defense, Abramson et al. (1989) investigated the ability of onchidal to inhibit AChE and the nAChR. Although onchidal did not prevent the binding of ^{125}I-α-bungarotoxin to nAChRs, it was shown to be an active site-directed irreversible inhibitor AChE. The structure and pharmacology of onchidal suggest that inhibition of AChE results from a novel covalent reaction between onchidal and an amino acid within the ACh binding site. The onchidal could potentially be exploited in the design of a new class of natural anti-ChE agents and in the identification of amino acids that contribute to the binding and hydrolysis of ACh.

Fasciculin

Various toxins in snake venoms exhibit a high degree of specificity in the cholinergic nervous system. The α-neurotoxins from the Elapidae family interact with the agonist binding site on the nicotinic receptor. α-Bungarotoxin is selective for the muscle receptor and interacts with only certain neuronal receptors, such as those containing α7 through α9 subunits. Neuronal bungarotoxin shows a wider range of inhibition of neuronal receptors. A second group of toxins, the fasciculins, inhibits AChE. A third group of toxins, termed the *muscarinic toxins* (MT_1–MT_4), are partial agonists and antagonists for the muscarinic receptor. Venoms from the Viperaridae family of snakes and the fish-hunting cone snails also have relatively selective toxins for nicotinic receptors.

Other reversible inhibitors, such as propidium and fasciculin, bind to the peripheral anionic site on AChE. This site resides at the lip of the gorge and is defined by tryptophan 286 and tyrosines 72 and 124 (Taylor, 2001).

A large number of organic compounds reversible or irreversibly inhibits AChE (Long, 1963), which bind either to the esteratic or the anionic subsite of AChE catalytic site or to the peripheral site of the enzymes. Most of them are synthetic substances, sometimes with insecticidal properties. Few natural inhibitors of AChE are known and, to date, fasciculins are the only known proteinic AChE inhibitors. They have been shown to display a powerful inhibitory activity toward mammalian AChE. Iodination of Fas3 provided a fully active and specific probe of fasciculin-binding sites on rat brain AChE (Marchot et al., 1993). These authors demonstrate that fasciculins bind on a peripheral site of AChE, distinct from the catalytic site and, at least partly, common with the sites on which some cationic inhibitors and the substrate in excess bind; since phosphorylation of the catalytic serine (esteratic subsite) by [1,3-^{3}H]diisopropyl fluorophosphate can still occur on the Fas3. In the AChE complex, the structural modification induced by fasciculins may affect the anionic subsite of the AChE catalytic site.

Cholinesterases have a very different sensitivity toward fasciculins. AChEs from rat brain, human erythrocytes, and electroplax of electric eel (*Electrophorus electricus*) are inhibited by fasciculins with a K*i* of about 10^{-11} M and pseudocholinesterases as human serum ChE are inhibited by fasciculins with a K*i* of about 0.5 μM. A second group of enzymes is partially (10–30%) inhibited by low concentrations (<0.5 nM) of fasciculin. Increasing the concentration of fasciculins to a toxic level of about 1 nM inactivates the enzymes to 90–110% of their initial activity. AChEs from guinea pig ileum, ventricle, and uterus behave similarly. A third group consists of enzymes insensitive to fasciculin; AChEs from chick *biventer cervicis* muscle and brain and from insects, heads of *Musca domestica* (common housefly) and cobra (*Naja naja*) venom. The biochemical mechanism of fasciculins involves displacement of propidium from its binding site on AChE. Since propidium is a probe from a peripheral anionic site, it is concluded that fasciculins also bind to the same site. The different sensitivity of ChE to fasciculin should depend on the nature of their peripheral sites. Fasciculins are basic proteins of 61 amino acid residues and 4 disulfides, highly homologous to short α-neurotoxins and cardiotoxins. Indeed, a large number of AChE inhibitors are cations (e.g., neostigmine, physostigmine, and propidium).

The binding between fasciculin and AChE is strong, as indicated by a K*i* of about 10^{-11} M. This should result from interaction of several amino acid residues in the toxin with the enzyme. A modification of one of these residues should not abolish the activity, but it should significantly decrease it. But the decrease in activity can also depend on structural perturbations caused by the modification. Chemical modification and structural data suggest that Lys32 and Lys51 have a functional role (Cerveñanský et al., 1994). This author acetylated the amino groups of Fas2 with acetic anhydride. The monoacetyl derivatives of the ε-amino acids (Lys25, Lys32, Lys51 and Lys58) retained between 28% and 43% of the initial activity, and that of the α-amino group retained 72%. Acetylation of Lys25 that has the most reactive amino group decreased the activity by 65%, apparently without producing structural perturbation since the circular dichroism spectrum was not affected. The three-dimensional structure shows a cationic cluster formed by Lys32, Lys51, Arg24, and Arg28. A comparison of 175 sequences of homologous toxins shows that Lys32 is unique for fasciculin. Acetylation of lysine residues in the cluster had a large effect and reduced the activity by 72% (Lys32) and 57% (Lys51).

Fasciculins inhibit AChE from mammals, electric fish, and some snake venoms with K*i* values in the picomolar

to nanomolar range; in contrast, the AChEs of avian, insect, and some other snake venoms are relatively resistant, and high micromolar concentrations are required to inhibit mammalian butyrylcholinesterases (Marchot et al., 1993). Dissociation constants of Fas1 and Fas3 are twofold and 60-fold lower, respectively, than that of Fas2 for synaptosomal rat brain.

An examination of fasciculin association with several mutant forms of recombinant deoxyribonucleic acid (DNA)–derivated AChE from mice shows that it interacts with a cluster of residues near the rim of the gorge on the enzymes; the aromatic residues, Trp286, Tyr72, and Tyr124, have the most marked influence on fasciculin binding, whereas Asp74, a charged residue in the vicinity of the binding site that affects the binding of low-molecular-weight inhibitors, has little influence on fasciculin binding. The three aromatic residues are unique to the susceptible AChE and, along with Asp74, constitute part of the peripheral anionic site. Fasciculin falls into the family of three-loop toxins that include the receptor blocking α-toxins and cardiotoxins. A binding site has evolved on fasciculin to be highly specific for the peripheral site on AChE. Acetylthiocholine affects rates of fasciculin binding at concentrations that cause substrate inhibition. In the case of the mutant ChE, where rates of fasciculin dissociation are more rapid, steady-state kinetic parameters also show ACh-fasciculin competition to be consistent with occupation at a peripheral or substrate inhibition site rather than the active center (Radic et al., 1994).

Fasciculin inhibition of AChE is prevented by chemical modification of the enzyme at a peripheral site (Durán et al., 1994). The specific interaction of Fas2 with peripheral sites present in *E. electricus* AChE (K*i*; 0.04 nM fasciculin) was investigated by chemical modification with *N*,*N*-dimethyl-2-phenylaziridium (DPA) in the presence of active or peripheral anionic site protective agents. An enzyme was obtained that compared to the native AChE and was 10^6 times less sensitive to Fas2. This enzyme was fully inhibited by edrophonium and tacrine and was 25–170 times less sensitive to several peripheral site ligands. It seems Fas2 binding to an AChE peripheral site partially overlaps the site of other peripheral site ligands, including ACh.

EXPERIMENTAL AND HUMAN TOXICITY

Administration of Fas1 and Fas2 to mice at doses of 1–3 mg/kg and 0.05–2.0 mg/kg, respectively after intraperitoneal (i.p.) injection caused severe, generalized, and long-lasting fasciculations (5–7 h), followed by gradual recovery to normal behavior. *In vitro* preincubation with fasciculins at concentrations of 0.01 μg/mL inhibited brain and muscle AChE up to 80%. Histochemical assay for AChE showed an almost complete disappearance of the black-brown precipitate at the neuromuscular endplate after *in vitro* incubation with fasciculins. Fasciculins represent a new type of AChE inhibitors exerting muscle fasciculations through a powerful inhibition of enzyme activity at the neuromuscular endplate, interfering with the normal hydrolysis of ACh molecules. Fasciculins have also been demonstrated to be powerful inhibitors of brain AChE (Rodriguez-Ithurralde et al., 1983).

The cause of death due to toxin F_7, an *angusticeps*-type toxin isolated from the venom of *D. angusticeps*, was studied in anesthetized mice (Lee et al., 1986). The carotid arterial blood pressure, electrocardiography, and the respiratory movements were recorded. Within a few minutes after intravenous (i.v.) injection of F_7 (1 mg/kg), both the rate and amplitude of the respiratory movements decreased, and respiratory arrest took place within 15 min in most cases. Before respiratory arrest, marked bradycardia with various types of arrhythmia and oscillation of blood pressure were observed. Artificial ventilation could abolish these cardiovascular changes and maintain the blood pressure for a long period. Toxin F_7 caused a transient and slight increase of arterial blood pressure, which could be prevented by hexamethonium. Intracisternal application of toxin F_7 (1 mg/kg) caused a long-lasting hypertension and bradycardia and the respiratory arrest time was significantly longer than after i.v. injection. A large dose (50 mg/kg, i.p.) of atropine, but not smaller doses (5–10 mg/kg), protected mice against respiratory failure induced by toxin F_7.

In rats, the phrenic nerve discharge was prolonged during respiratory depression. Since the toxin F_7 has a potent anti-ChE activity, it is concluded that the respiratory failure induced by toxin F_7 is peripheral in origin; this was chiefly, if not entirely, due to its anti-ChE activity.

Strydom (1976) performed the purification of *D. polylepis polylepis* venom and found 12 low-molecular-weight proteins, of which 11 have subcutaneous LD_{50} values of less than 40 μg/g in the mouse. Clinically, mamba bites may not provoke a major local reaction. If neurotoxins are injected by the bite, clinical symptoms appear within minutes to hours. Clinical signs of impairment of neuromuscular transmission (ptosis, ophthalmoplegia, bulbar symptoms, or generalized weakness) dictate administration of antivenom (Ludolfph, 2000). The venom of Elapidae (coral snakes) is known to be a potential neurotoxin and may cause paresthesias, weakness, cranial nerve dysfunction, confusion, fasciculations, and lethargy. Often mild local findings, diplopia, ptosis, and dysarthria are common early symptoms. Patients die because of respiratory paralysis. In these cases, early and aggressive airway management is vital. Symptoms may be delayed by 8–12 h (Cameron, 2006).

COMPUTATIONAL TOXICOLOGY ASSESSMENT

Toxicity databases and computer-assisted (*in silico*) computational predictive toxicology modeling are now becoming increasingly important to risk assessors. This is especially true when risk assessment of a chemical using experimental animal toxicological studies is unclear because the data are equivocal or even absent (Bailey et al., 2005; Arvidson et al., 2008; Valerio, 2009). Furthermore, a law passed by the European Union called Registration, Evaluation, Authorization, and restriction of Chemicals (REACH), entered into force on June 1, 2007. The goal of the regulation was to identify and more effectively avoid the risks that the toxic properties of chemicals pose to humans and the environment (Lahl and Gundert-Remy, 2008). Under REACH, firms that manufacture or import more than 1 ton of a chemical substance per year in the European Union are required to assess the chemical's potential toxicological or environmental adverse effects, and to register this information in a central database (Saiakhov and Klopman, 2008). REACH has had an impact on the widespread use of computational predictive modeling because it rules that no animal test should be used if it can be replaced with other techniques, such as reliable computer-based predictions (Lahl and Gundert-Remy, 2008; Saiakhov and Klopman, 2008). Therefore, the use of computer-assisted computational predictive toxicology software has attracted considerable attention worldwide because it may not only reduce, but eliminate the need for animal testing under certain circumstances. Since the acute and chronic toxic potential of onchidal in experimental animal studies are rather limited, strategies using *in silico* assessment of its toxic potential could be envisioned. Computational-based strategies with pharmaceuticals and natural product toxins have already been developed for use in safety evaluation and risk assessment at US government agencies (Bailey et al., 2005; Valerio et al., 2007; Demchuk et al., 2008; Valerio, 2009; Arvidson et al., 2010; Valerio and Cross, 2012; Choi et al., 2013; Valencia et al., 2013; Valerio et al., 2013; Valerio, 2013). These strategies can be considered for an *in silico* risk assessment of onchidal. One approach is to combine different predictive models for the same toxicological endpoint to determine if a consensus prediction regarding the effect is possible. Another approach is to combine computational software that employs human rule-based approaches with software that utilizes statistical algorithm-based predictions using quantitative structure-activity relationship (QSAR) models for the toxic potential of the compound of interest. Consistent with this notion, the current version of (M7) guidance from the International Conference of Harmonisation (ICH) on hazard assessment of DNA-reactive mutagenic pharmaceutical impurities recommends, in the absence of data, the use of a statistical QSAR model and human rule-based structure-activity relationship (SAR) approach to assess if there is a structural concern that an impurity identified in drug substances or drug products is mutagenic. According to ICH M7, this analysis from the *in silico* assessment of the molecular structure of impurities should be focused on predicting the outcome of bacterial mutagenicity (i.e., Ames assay). If the outcome from a QSAR and SAR structural assessment with expert interpretation is negative, then the M7 guidance indicates that the assessment is sufficient to conclude there is no concern and to treat the impurities as nonmutagenic. If the outcome from the complementary *in silico* QSAR/SAR assessments is positive, then the impurity would need to be controlled to safe levels or qualified according to regulatory protocols (ICH S2(R1) and OECD 471). Thus, as evident from the ICH M7 guidance, the use of *in silico* toxicology methods has taken a real practical role and utility as a tool in facilitating regulatory decisions in a risk assessment setting to ensure the safety and quality of pharmaceutical products. There are a variety of computational toxicology predictive software and data mining databases available at either no cost or commercially for a fee (Richard et al., 2008; Marchant et al., 2008; Saiakhov and Klopman, 2008; Shi et al., 2008; Mostrag-Szlichtyng et al., 2010; Choi et al., 2013; Valencia et al., 2013). However, the information obtained from a predictive and data mining *in silico* assessment must be used judiciously in order to serve a true purpose in risk assessment and management regarding the safety of a chemical (Arvidson et al., 2010; Valerio, 2012).

In order to assess the potential toxicological effects of onchidal from a predictive standpoint, the author subjected the two-dimensional molecular structure of onchidal (1) to an *in silico* QSAR computational analysis. Details regarding the approach of the software, including procedures and model building methods, have been described in recent publications (e.g., Choi et al., 2013; Valencia et al., 2013). The *in silico* analysis of the molecular structure of onchidal produced predictive information on nonclinical toxicities. The computational QSAR models included bacterial mutagenicity (*Salmonella typhymurium* mutagenicity (Ames) assay), and phospholipidosis (Table 30.3).

These computational prediction results show that onchidal is not flagged to be of concern for bacterial mutagenicity, but it might be expected to induce phospholipidosis in animals despite not possessing a traditional cationic amphiphilic molecular structure (Choi et al., 2013). Predictions were also made using the QSAR approach regarding clinical cardiac adverse events related to proarrhythmia. The *in silico* predictions are presented in Table 30.4. The predictions show that onchidal's molecular structure is associated with QT

TABLE 30.3 The Molecular Structure of Onchidal Analyzed by a Statistical QSAR Method

Salmonella t. reverse mutation assay (Ames test)	0.225	0.227	0.189	–
Phospholipidosis	0.650	0.875	0.851	+

The data shown in the table indicate onchidal is predicted negative in the Ames test and positive to induce phospholipidosis in animals.

TABLE 30.4 Predictions of the Onchidal Molecule Using Symmetry QSAR Models for QT/QTc Prolongation and Torsade de Pointes

End-Point	Score (Probability)	Std. Dist. AD+	Std. Dist. AD−	Prediction Result
QT/QTc prolongation	0.932	0.315	1.136	+
Torsade de Pointes	0.389	0.195	0.177	–

The QSAR models were built using molecular descriptors M0102 in a risk-based approach (Valerio et al., 2013). A strong positive prediction for QT prolongation resulted from the *in silico* analysis, but onchidal was not predicted by the QSAR model to induce the potentially fatal cardiac arrhythmia Torsade de Pointes.

prolongers in the training set of the QSAR model, but it is not predicted to be a risk for torsade de pointes, a potentially fatal cardiac arrhythmia. Onchidal has anticholinergic effects (Anadón and Martínez-Larrañaga, 1985). Tachycardia as a result of anticholinergic has been suggested to increase or lead to arrhythmias (e.g., with low-potency antiphsychotics; Huffman and Stern, 2003), and this might explain the positive prediction of onchidal as a QT prolonger. However, the negative prediction for torsade de pointes mitigates this theoretical risk.

Overall, these *in silico*/computational toxicology models, as well as many others, have been developed at regulatory agencies, to help inform regulatory science. These models represent structure-based assessments using statistical QSARs to predict with an intended precision the toxicological and adverse human effects of many classes of organic substances (Valerio, 2009; Valerio et al., 2013). As with all methods, these models have some limitations, and in this regard, the main consideration with predictive modeling is the quality of the data used to build it. Advanced efforts have been focused on data integration techniques to combine empirical data with theoretical predictions (Nigsch et al., 2011; Valerio, 2012, 2013). Clearly, building *in silico* tools directed at understanding human adverse effects can be helpful for assessing safety parameters that are difficult to determine in animals or acquire from well-controlled human studies. Thus, if properly validated, described, interpretable and made available for broad consumption, the *in silico* approach should have a bright future, especially in the area of chemical risk assessment (Valerio, 2013). Programs in advancing regulatory science and modernizing toxicology with predictive models are underway (Valerio, 2011; Valerio and Choudhuri, 2012). We anticipate that as capabilities expand, the use of new informatics tools, standards, and predictive technologies via these enabling methods will help build groundbreaking efforts to transform the way that regulated products are developed and evaluated, including therapies for the toxic effects of at-risk substances such as onchidal and fasciculins.

TREATMENT

Antidotal therapy for the toxic effects of ChE inhibitors, such as onchidal and fasciculins used as potential chemical warfare agents, is directed toward blocking the effects of excessive ACh stimulation and reactivating the inhibited enzyme. Atropine in sufficient dosages effectively antagonizes the actions at muscarinic receptor sites (Taylor, 2001). Atropine is used in adults at doses of 1–2 mg i.v. and in pediatrics at a dose of 0.05 mg/kg i.v.; doubling this dose every 5 min (DeLisle, 2006). Larger doses are required to get appreciable concentrations of atropine into the CNS. Atropine is virtually without effect against peripheral neuromuscular compromise. The aforementioned action of the anti-ChE agents, as well as all other peripheral effects, probably can be reversed by reactivators of ChE such as pralidoxime (2-PAM) in the treatment of onchidal and fasciculin poisonings. The usual dosages are as follows:

- In adults, 1–2 g i.v. over 15–30 min, may repeat in 1 h if necessary or start a drip at 500 mg/h.
- In pediatrics, 25 mg/kg i.v. over 15–30 min, follow with continuous infusion of 10–20 mg/kg i.v. (DeLisle, 2006).

On the other hand, the antivenom is indicated for all confirmed eastern coral snake bites (western, no antivenom) (Cameron, 2006).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The natural toxins onchidal and fasciculins behave as anti-ChE agents. Onchidal is an active, site-directed irreversible inhibitor of AChE, and fasciculins are proteinic AChE inhibitors that bind to a peripheral regulatory anionic site of AChE in a noncompetitive, irreversible manner.

There is limited information about the toxicity, toxicokinetics, and toxicological properties of onchidal, and additional data are needed to make a health-effect-based

risk assessment of the natural compound. Although fasciculins are much better known, data on toxicological properties and toxicokinetics will be of interest and useful for risk assessments. This is the case even though it is generally accepted that the toxicity of this proteinic poison occurs at very low doses.

Onchidal and fasciculins are interesting natural compounds, and it is difficult to predict their toxicity. As demonstrated in this chapter, predictive *in silico* approaches using computational models can be used to help assess both the nonclinical and clinical adverse effects of chemical agents. The quality of computational toxicology assessments relates to the quality of data used to derive predictions and appropriate expert interpretation of the data. It is possible to make predictions for human clinical adverse effects using computational models built upon human clinical trial data. Because the *in silico* approach is tailored toward filling data gaps, the paucity of human data on onchidal and fasciculins makes a clear case for the use of *in silico* predictive technologies. The future of computational assessments seems to be in enabling techniques that would facilitate integrating theoretical predictions with empirical evidence in order to strengthen contemporary decision analysis. A major challenge will be to predict the military potential and overall human impact of these natural toxins since their biochemical affinity for enzyme inhibition depend upon the amount and duration of human exposure, and data about human exposure are lacking.

CHAPTER

31

Cyanobacterial (Blue-Green Algae) Toxins

Deon van der Merwe

INTRODUCTION

Cyanobacteria, commonly referred to as blue-green algae, are photosynthesizing prokaryotic bacteria. They are important primary producers in most freshwater and marine environments that are close enough to the surface to receive sunlight. Cyanobacteria perform photosynthesis through the green pigment, chlorophyll-a. They often produce accessory photosynthetic blue pigments, called phycobilins or phycocyanins. Red to brown accessory photosynthetic pigments, called phycoerythrins, may also be produced. Colony colors vary depending on the relative pigment levels and range between shades of blue and green and, less commonly, brown and red (Adhikary, 1996). Cyanobacteria may be benthic or pelagic and are morphologically diverse. Five morphologically distinct sections have been recognized: unicellular colonies with binary fission, unicellular colonies with multiple fission, multicellular colonies, multicellular colonies with differentiated cells, and branched multicellular colonies with differentiated cells (Schirrmeister et al., 2011). Colonies are often large enough to be seen with the naked eye and, when numerous, may change the color of the water or form scums at the water surface. Dense proliferations of cyanobacteria are referred to as algal blooms. When blooms have the potential to cause harmful effects, they are called harmful algal blooms (HABs). The incidence of HABs is increasing in most regions and is usually linked to excess nutrient inflow into surface water from agricultural and industrial sources (Paerl et al., 2001; de Figueiredo et al., 2004; Hudnell, 2010; Gkelis and Zaoutsos, 2014).

Several genera of cyanobacteria are able to produce toxins (Briand et al., 2003). The production of toxins is influenced by genetic and environmental factors. Cyanobacteria known to have the genetic potential to produce toxins do not always do so or may not produce toxins at concentrations that are high enough to result in a significant poisoning risk. Certain environmental factors, including nutrient concentrations, water temperature, and pH, may play a role in triggering toxin production. The critical parameter values that trigger toxin production are, however, not fully known or predictable. Toxin production is generally more common during warm weather and abundant sunlight but can occur at any time of the year (Downing et al., 2001; Kanoshina et al., 2003; Graham et al., 2004; Dodds et al., 2009). Toxin production during HABs can be extremely high. For example, a HAB formed by microcystin-LR-producing *Microcystis aeruginosa* in a Kansas lake in 2011, produced toxin concentrations in the water of 126,000 ng/mL (van der Merwe et al., 2012). Such concentrations are highly significant considering that hepatotoxic effects in humans are possible after ingestion of 100 mL of water containing 20 ng/mL microcystin-LR (WHO, 2003). The spontaneous production of high concentrations of toxins in a natural environment, although it is somewhat sporadic, could make them accessible to harvesting for use as chemical weapons, requiring only simple equipment and low levels of technical expertise. Deriving toxins from cyanobacteria produced in bioreactors is also possible but requires a greater level of equipment investment and technical expertise. Only one cyanotoxin, the neurotoxin known as saxitoxin or paralytic shellfish poison (PSP), is listed as a Schedule 1 substance in the Chemical Weapons Convention. Other cyanotoxins may also pose credible threats based on their potency, environmental persistence, and widespread production in surface waters where they may be easily accessible.

The toxins produced by freshwater cyanobacteria can be classified based on their toxic effects, their molecular

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00031-2

structure, or their origins. A classification based on toxic effects is used in this discussion.

HEPATOTOXINS

Microcystins and Nodularins

Introduction

Microcystins are cyclic heptapeptides produced by several genera, including *Microcystis*, *Anabaena*, *Planktothrix*, *Nostoc*, *Oscillatoria*, and *Anabaenopsis*. The frequency of microcystin-producing HABs appears to be increasing in most regions in association with the expansion of intensive agriculture, industrial development, and urbanization. Because of their widespread and frequent occurrence, their high potency, and environmental persistence, microcystins are a significant public health risk. Nodularins are mainly produced by *Nodularia spumigena* in brackish waters. They are similar to microcystins in structure and mechanism of toxicity and, for the purposes of this discussion, are considered equivalent to microcystins (Namikoshi et al., 1994; Chen et al., 2013). Microcystin concentrations are generally correlated with cell density, although the correlation is not consistent and high cell densities without toxin production are possible. People are most often exposed when swimming, skiing, or boating in contaminated waters. Other routes of exposure include drinking water, contaminated foods or nutritional supplements, and, in at least one lethal and tragic incident, contaminated water used in dialysis (Azevedo et al., 2002).

Chemistry

Microcystins have a cyclic heptapeptide structure (Figure 31.1). More than 80 naturally occurring structural variants have been described (Welker and Von Dohren, 2006). Six amino acids, including four nonprotein amino acids and two protein amino acids, form a ring structure. One nonprotein amino acid, referred to as ADDA (3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca;4,6-dienoic acid), forms a side chain. The ADDA side chain is consistent between microcystin variants and can be used to quantify microcystins independent of the variant type. The two protein amino acids, at positions 2 and 4 in the ring structure, contribute most to the structural variability. Microcystin variants are named based on the protein amino acids at the variable positions. One of the most common variants, for example, contains leucine and arginine at the protein amino acid positions and is referred to as microcystin-LR.

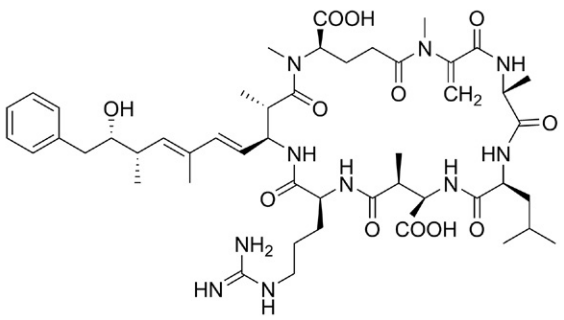

FIGURE 31.1 Microcystin chemical structure.

Microcystins are not produced by cyanobacterial cells and therefore are strongly associated with cyanobacterial cells as long as the cells remain intact. However, microcystins may be released into the surrounding water when cyanobacterial cells disintegrate. Microcystins are stable, with a typical environmental half-life of 10 weeks. The rate of breakdown is increased under direct sunlight, at high environmental temperatures (>40ºC), and extremely low pH (<1) or high pH (>9) (Tsuji et al., 1994; Harada et al., 1996). Microcystin concentrations may be reduced by boiling or heating in a microwave oven (Gutierrez-Praena et al., 2013). However, the concentration of free microcystins in muscle tissue from exposed fish may increase after boiling because of the release of phosphatase-bound microcystins (Zhang et al., 2010).

Toxic Effects

Most of the available toxicological data on microcystins have been based on microcystin-LR. Other microcystin variants appear to be similar to microcystin-LR in their toxicological effects, but they differ in potency. Other factors that need to be taken into account when interpreting available data are that much of the data have been derived from experiments in rodents and rabbits using intraperitoneal injection as the route of exposure, and the extracts used in studies may consist of complex, crude mixtures of components derived from toxic algal blooms, or more or less purified and characterized components (Zhao et al., 2008, 2009). Extrapolation between routes of exposure and between the toxicities of different complex mixtures can make the comparison of data from different studies challenging.

The clinical effects of microcystin poisoning depend on the route of exposure, the level of exposure, and the mixture of components involved in the exposure. In typical exposures of mammals to toxic blooms, low to mild exposure levels are associated with irritant effects, resulting in inflammatory responses in the skin, respiratory system, and gastrointestinal system. Higher exposure levels, particularly oral exposures, result in liver damage and, if the liver damage is severe, liver failure (Briand et al., 2003). The earliest detectable signs of liver damage include increased concentrations of liver enzymes in the blood and liver swelling. Early symptoms typically appear within minutes to hours of exposure and include inappetance, depression, and vomiting,

followed by diarrhea, which may become extreme and hemorrhagic. Inappetance and depression become progressively worse. The final stages of lethal poisoning may be associated with variable central nervous system (CNS) dysfunction, recumbency, and coma (DeVries et al., 1993; van der Merwe et al., 2012). Exposure to microcystins may be a contributing factor to the development of hepatocellular cancer and colorectal cancer in humans (Meneely and Elliot, 2013).

An important difference between exposures in aquatic organisms and terrestrial organisms is that exposures in aquatic environments often involve exposures to sub-lethal doses over days or weeks. In fish, exposures to microcystins cause cellular damage, particularly liver damage, similar to the effects seen in mammals (Tencalla and Dietrich, 1997). Microcystins also inhibit fish embryo development (Gotz et al., 2000), and toxic effects in fish embryos may be seen at relatively low microcystin concentrations (Pietsch et al., 2001). Mature fish are generally more resistant to microcystin toxicosis compared with juvenile fish and mammals (Malbrouck and Kestemont, 2006). Although fish may have the ability to avoid areas of accumulation of toxic algae, sub-lethal liver damage in fish is associated with algal blooms because of the accumulation of microcystins in fish food items such as mussels, snails, and zooplankton (Liu et al., 2002; Malbrouck and Kestemont, 2006). Fish are also susceptible to decreased water oxygen levels associated with the decay of algal scum (Ibelings and Havens, 2008), and this effect may play a role in fish kills associated with microcystin-producing algal blooms.

Mechanism of Action

After ingestion, microcystins are released from cyanobacterial cells and are absorbed into the portal circulation from the small intestine via bile acid transporters in the intestinal wall. Microcystins are then accumulated in hepatocytes via similar bile acid transporters on hepatocyte membranes (Hooser et al., 1991). Microcystins irreversibly inhibit serine/threonine protein phosphatases 1 and 2A (Yoshizawa et al., 1990). Microcystin-LR may also bind to AP synthase, leading to hepatocyte apoptosis (Mikhailov et al., 2003).

Protein phosphatases are ubiquitous. They are found in all tissues and across species as diverse as mammals, plants, and bacteria, and they play a critical role in the regulation of multiple cellular metabolic pathways. Protein phosphatases reverse the active state of kinases through the hydrolytic removal of the phosphoryl group from kinases. The protein phosphatases inhibited by microcystins have broad substrate specificity and play roles in the regulation of a wide range of cellular functions. Protein phosphatase 2A is highly conserved and is a major downregulator of active protein kinases in eukaryotic cells. Toxic effects in hepatocytes and other living cells are therefore multifaceted and include disruption of the cytoskeleton, DNA damage, apoptosis related to mitochondrial damage, and oxidative stress attributable to the formation of free oxygen radicals (Zegura et al., 2004; Ding and Nam Ong, 2006).

Chemical Warfare Potential

Microcystins are commonly produced in freshwaters when nutrient levels and weather conditions are suitable for HAB formation. Toxin concentrations can reach extremely high levels (van der Merwe et al., 2012) and, coupled with the persistence of microcystins (Harada et al., 1996), represent an opportunity for the collection and storage of microcystins using widely available equipment and minimal technical skill. Contamination of water and food supplies represents a significant health risk. However, the major impact of such an event will be the cost associated with avoidance of exposure, including testing, water purification, and the procurement of alternative water and food. Contamination of medical supplies represents a particularly dangerous potential use of microcystins, as demonstrated by the lethal consequences of accidental contamination of dialysis water supplies (Azevedo et al., 2002). There are no specific antidotes for microcystin-poisoning.

Cylindrospermopsin

Introduction

Cylindrospermopsin is an alkaloid cyanotoxin produced by several freshwater cyanobacteria genera, including *Cylindrospermopsis*, *Aphanizomenon*, *Anabaena*, *Lyngbya*, *Umezakia*, and *Raphidiopsis* (Guzman-Guillen et al., 2013). It is found worldwide in surface freshwaters (de la Cruz et al., 2013).

Chemistry

Cylindrospermopsin is an alkaloid consisting of a tricyclic guanidine coupled with hydroxymethyluracil (Figure 31.2). It is a zwitterionic, highly water-soluble molecule (Ohtani et al., 1992). There are two known structural variants: deoxycylindrospermopsin (Norris et al., 1999), which is relatively less toxic, and 7-epicylindrospermopsin (Banker et al., 2001), which is relatively

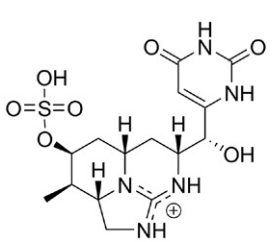

FIGURE 31.2 Cylindrospermopsin chemical structure.

more toxic. Cylindrospermopsin is resistant to high temperatures, sunlight, and pH extremes (Chiswell et al., 1999). Unlike microcystins, cylindrospermopsin is often released from the cells into the surrounding water (Rucker et al., 2007). It bioaccumulates, particularly in organisms low in the food chain such as gastropods, bivalves, and crustaceans (Kinnear et al., 2009).

Toxic Effects

A major outbreak of poisoning in humans, including 148 cases, occurred in 1979, associated with a reservoir on Palm Island, Queensland, Australia (Griffiths and Saker, 2003). The reservoir produced a dense bloom of cylindrospermopsin-producing *Cylindrospermopsis raciborskii*. People living close to the reservoir and using the water were affected with a syndrome that included liver and kidney damage, as well as severe gastroenteritis. Symptoms included hemorrhagic diarrhea, vomiting, fever, hepatomegaly, dehydration, electrolyte imbalances, acidosis, and hypovolemic shock. However, the potential role that a copper sulfate water treatment soon before the start of the poisoning outbreak could have played in the disease process remained uncertain. Intraperitoneal injection of extracts from *C. raciborskii* collected from the reservoir produced liver and kidney damage in mice (Hawkins et al., 1985).

Cylindrospermopsin was isolated from water used in dialysis in Brazil that caused liver failure in dialysis patients. However, the role of cylindrospermopsin in the disease process was not clear because the water was also contaminated with toxic concentrations of microcystin (Azevedo et al., 2002).

C. raciborskii can cause mild skin irritation in some individuals, but the role of cylindrospermopsin in the reaction, if any, is not clear (Pilotto et al., 2004).

Pure cylindrospermopsin injected into tilapia caused progressive tissue damage over a period of 5 days in the liver, kidney, heart, and gills (Gutierrez-Praena et al., 2013). Liver and kidney damage are consistently caused in laboratory rodents after exposure to acutely toxic doses of cylindrospermopsin-containing extracts. Typical liver pathology includes lipid infiltration and necrosis, mostly in the periacinar region (Shaw et al., 2000).

Mechanism of Action

The main target tissue of purified cylindrospermopsin toxicosis is the liver, but several other tissues are also affected, including the kidneys, thymus, and heart (Terao et al., 1994). Cylindrospermopsin is a potent inhibitor of protein synthesis, but the exact mechanism of action has not been elucidated. Four sequential phases of hepatocyte damage were identified by time-series analysis, including protein synthesis inhibition, membrane proliferation, lipid infiltration, and necrosis. Cylindrospermopsin has been shown to cause DNA fragmentation *in vitro*, and metabolic activation by a P-450 enzyme appears to be necessary for this effect to occur (Bazin et al., 2010). Kidney pathology includes necrosis of the proximal tubules and protein accumulation in distal tubules (Falconer et al., 1999).

Studies using crude extracts report higher potency and a wider range of effects compared with studies using purified cylindrospermopsin, indicating the components other than cylindrospermopsin contribute to the toxic effects (Shaw et al., 2000; Seifert et al., 2007).

Chemical Warfare Potential

The mechanisms of toxicity of cylindrospermopsin are not yet fully understood, but ample evidence of its potential impact on human health exists, based on clinical cases, *in vitro* studies, and animal model studies (Poniedziałek et al., 2012). Its relatively infrequent natural occurrence, compared with more common cyanotoxins such as microcystis, make it generally less accessible. The primary threats include contamination of drinking water supplies and food supplies.

NEUROTOXINS

Anatoxin-a

Introduction

Anatoxin-a is a potent, fast-acting neurotoxin. It occurs worldwide in freshwaters and is produced by several genera of cyanobacteria, including *Anabaena*, *Aphanizomenon*, *Microcystis*, *Planktothrix*, *Raphidiopsis*, *Arthrospira*, *Cylindrospermum*, *Phormidium*, *Nostoc*, and *Oscillatoria* (Osswald et al., 2007). Exposures occur mainly through consumption of contaminated drinking water but have also occurred from recreational use of lakes and through contaminated dietary supplements (Rogers et al., 2005).

Chemistry

Anatoxin-a is a bicyclic amine alkaloid (Figure 31.3). It contains a homotropane scaffold that is derived from glutamic acid. It is chiral, with two symmetric centers (Wonnacott and Gallagher, 2006). Only the (+)-anatoxin-a enantiomeric form is naturally produced, and the pK_a of this form, at 9.4, indicates that it is mostly in the protonated form under typical environmental pH conditions

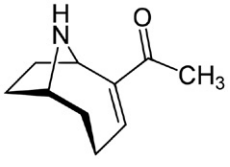

FIGURE 31.3 Anatoxin-a chemical structure.

(Valentine et al., 1991). Anatoxin-a is stable under sterile conditions but is susceptible to microbial biodegradation (Rapala et al., 1994). Breakdown is also accelerated by high temperature, UV light, and alkaline conditions (Kaminski et al., 2013; Stevens and Krieger, 1991). The half-life in a reservoir was reported to be 5 days under typical environmental pH conditions (Smith and Sutton, 1993). A structural analog, called homoanatoxin-a or methylene-anatoxin-a, has been isolated from *Oscillatoria formosa* (Skulberg et al., 1992). Small quantities of anatoxin-a are produced synthetically for use in acetylcholine (ACh) receptor research (Aronstam and Witkop, 1981).

Toxic Effects

Anatoxin-a was originally called very fast death factor because of its rapid lethal effects within 2–7 min in laboratory mice after intraperitoneal injection of cell culture extracts from anatoxin-a producing algal blooms (Carmichael and Gorham, 1978). Acute deaths after exposure to anatoxin-a have been recorded in multiple species, including dogs (Edwards et al., 1992), cattle (Carmichael and Gorham, 1978), and wildlife (Carmichael, 1981). There are species differences in susceptibility to anatoxin-a. Mallard ducks, for example, are more sensitive compared with ring-necked pheasants (Carmichael and Biggs, 1978). Anatoxin-a is rapidly absorbed from the gastrointestinal tract, as indicated by the rapidity of clinical effects after oral exposure. Clinical effects of poisoning may appear within minutes to hours after exposure and may include loss of muscle coordination, muscle tremors and fasciculations, convulsions, and respiratory distress. The principal lethal effect is respiratory failure after loss of control over respiratory muscles (Osswald et al., 2007).

Anatoxin-a was implicated in the death of a 17-year-old boy who swallowed water from a lake containing a bloom of *Anabaena flos-aquae*. The boy died 2 days after exposure. Terminal clinical signs included convulsions, shock, and heart failure. However, uncertainty regarding the identity of the toxin and the unusual clinical course compared with confirmed cases in animals have cast some doubt on the diagnosis of anatoxin-a poisoning in this case (Carmichael et al., 2004).

Mechanism of Action

Anatoxin-a appears to be a pure neurotoxin, with no characteristic blood chemistry changes and no gross or histological lesions associated with poisoning (Rogers et al., 2005).

It is an agonist of peripheral and central ACh receptors, with a 100-fold selectivity for nicotinic receptors over muscarinic receptors (Aronstam and Witkop, 1981). It binds to the ACh receptor at the same position as ACh, causing sodium/potassium ion channels to open and inducing a depolarizing blockade. Anatoxin-a is more potent than ACh or nicotine (Swanson et al., 1986), with a high nicotinic receptor affinity (Aronstam and Witkop, 1981). It also has the ability to modulate dopamine release through agonistic binding to $\alpha4\beta_2$-receptors and α_7-receptors (Sharples et al., 2000). Binding of anatoxin-a to the nicotinic ACh receptors at neuromuscular junctions results in uncontrolled action potential propagation that manifests clinically as uncoordinated muscle contraction, muscle fatigue, and paralysis (Stevens and Krieger, 1991). Cholinesterase does not break-down anatoxin-a, leading to persistent muscle stimulation (Spivak et al., 1980; Wonnacott and Gallagher, 2006). Stimulation of nicotinic receptors in the cardiovascular system causes increased heart rate and blood pressure (Siren and Feurstein, 1990). Stimulation of presynaptic nicotinic receptors in the CNS by anatoxin-a may also cause the release of neurotransmitters such as dopamine, which could further increase the susceptibility of postsynaptic receptors to overstimulation (Wonnacott and Gallagher, 2006). CNS receptors are, however, less sensitive to anatoxin-a compared with peripheral receptors (Aracava et al., 1987).

Chemical Warfare Potential

Anatoxin-a is potentially dangerous as a chemical warfare agent because of its high potency, fast action, and occasional availability of highly lethal concentrations of toxin during natural cyanobacterial blooms. However, it is susceptible to rapid bacterial breakdown under nonsterile storage conditions, making its intentional use challenging without relatively sophisticated extraction and storage procedures.

Anatoxin-a(s)

Introduction

Anatoxin-a(s) is a natural organophosphate analogue produced by cyanobacteria in the genus *Anabaena* (Molica et al., 2005; Patocka et al., 2011). The "(s)" in the name "anatoxin-a(s)" refers to salivation, which is a characteristic sign of poisoning observed in laboratory rodents after exposure (Mahmood and Carmichael, 1986; Carmichael et al., 1990).

Chemistry

Anatoxin-a(s) is a cyclic *N*-hydroxyguanine with a phosphate ester moiety (Figure 31.4) similar to typical

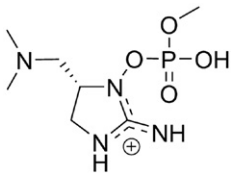

FIGURE 31.4 Anatoxin-a(s) chemical structure.

synthetic organophosphate insecticides and chemical warfare nerve agents. No structural variants have been described. It is susceptible to rapid degradation in alkaline conditions (Matsunaga et al., 1989).

Toxic Effects

Clinical signs are indistinguishable from organophosphate poisoning. Muscarinic signs include salivation, lacrimation, urinary incontinence, and defecation. Nicotinic signs include muscle tremors and fasciculations, convulsions, and respiratory failure (Mahmood and Carmichael, 1986). The muscarinic effects of anatoxin-a(s) can be suppressed by atropine (Cook et al., 1990), but it is relatively resistant to oxime reactivation, compared with typical organophosphate insecticides, because of the formation of an enzyme-adduct (Hyde and Carmichael, 1991).

Mechanism of Action

Anatoxin-a(s) is a noncompetitive inhibitor of acetylcholinesterase (AChE). Similar to other organophosphate poisons, anatoxin-a(s) is activated via oxidative metabolism. AChE is necessary for the inactivation of ACh at nicotinic and muscarinic receptor sites. Inhibition of the enzyme therefore causes ACh level to build-up at receptor sites, triggering excessive nicotinic and muscarinic receptor stimulation, resulting in persistent postsynaptic membrane depolarization (Cook et al., 1990). In this regard, the mechanism of action is similar to that of anatoxin-a, except that it is less selective for nicotinic effects. Anatoxin-a(s) has a high potency, with an LD_{50} of 20–50 μg/kg body weight when administered by intraperitoneal injection in mice (Mahmood and Carmichael, 1986). For further details, readers are referred to Patocka et al. (2011).

Chemical Warfare Potential

Anatoxin-a(s), similar to anatoxin-a, is a potential threat but will require relatively sophisticated procedures and equipment to implement.

Saxitoxins

Introduction

Saxitoxins are produced in freshwater and marine environments. In marine environments, they are often referred to as PSPs. Most human saxitoxin toxicoses have been associated with the ingestion of marine shellfish, which accumulate saxitoxins produced by marine dinoflagellates (Cusick and Sayler, 2013). In freshwaters, saxitoxins are produced by cyanobacteria in the genera *Anabaena*, *Aphanizomenon*, *Planktothrix*, *Cylindrospermopsis*, *Lyngbya*, and *Scytonema* (Smith et al., 2012; Wiese et al., 2012). Saxitoxins can accumulate in freshwater fish such as tilapia (Galvao et al., 2009).

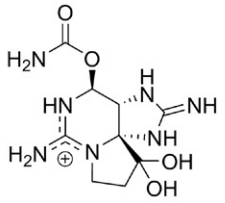

FIGURE 31.5 Saxitoxin chemical structure.

Chemistry

Saxitoxins are nonvolatile, tricyclic, perhydropurine alkaloids (Figure 31.5) (Schantz et al., 1975). Various structural substitutions produce at least 57 analogues. Activity is mediated through positively charged guanidinium groups (Wiese et al., 2012). Saxitoxins are heat-stable, particularly in slightly acidic environments, and are highly water-soluble. They are tasteless and odorless and are not destroyed by normal food preparation methods (Trevino, 1998). Methods of synthetic saxitoxin production have been published (Akimoto et al., 2013).

Toxic Effects

The clinical presentation of saxitoxin-poisoning varies depending on the level of exposure. High levels of exposure are usually related to ingestion of toxin-accumulating shellfish or fish, in association with toxin-producing dinoflagellate blooms (marine environments) or cyanobacterial blooms (freshwater environments). The lag time between exposure and the appearance of clinical signs is highly variable and can range from minutes to as long as 72 h (Montebruno, 1993). At relatively low exposure levels, moderate paresthesia, often described as a tingling sensation, are experienced around the mouth and extremities. Larger exposures lead to a spreading numbness of the mouth, throat, and extremities. High exposure levels may cause acute muscle paralysis and respiratory failure (Garcia et al., 2004).

Mechanism of Action

Saxitoxins are selective, reversible, voltage-gated sodium channel blockers (Huot et al., 1989; Tarnawa et al., 2007; Walker et al., 2013). Saxitoxins cross the blood–brain barrier, and sodium channel blockade in the CNS contributes to its paralytic effects (Borison and McCarthy, 1977). Saxitoxins are extremely potent, with mouse LD_{50} values of 263 μg/kg (oral), 10 μg/kg (intraperitoneal), and 3.4 μg/kg (intravenous) (Wiberg and Stephenson, 1960).

Chemical Warfare Potential

Saxitoxins are the only cyanotoxins listed in the Chemical Weapons Convention Schedule 1, where it is referred to as Agent TZ. Saxitoxins are also listed in the

War Weapons List of the German War Weapons Control Act. Reasons for the relatively high level of concern regarding saxitoxins include that they are potent and stable, they can be produced synthetically, and they have been shown to be suitable for incorporation into ammunition. A factor that complicates the regulatory control of saxitoxins is the ongoing need for its availability as an analytical standard in paralytic shellfish poisoning monitoring and risk management programs, and its use in medical research on voltage-gated sodium channels. Because of these needs, saxitoxins are subjected to lower levels of restriction under the Chemical Weapons Convention when small quantities (5 mg or less) are to be used for diagnostic or medical purposes.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Some cyanotoxins, particularly microcystins, can reach extremely high concentrations during HABs and could be collected and placed in storage with minimal equipment and technical sophistication. Use of such material to intentionally contaminate water, food, and medical supplies represents a significant health and economic risk. Other cyanotoxins, such as cylindrospermopsin, anatoxin-a, and anatoxin-a(s) are potentially dangerous because of their high potency and occasional availability during HABs but are less likely to be used intentionally because of unpredictable and sporadic availability and the need for complex extraction and storage procedures. Saxitoxins are an exception because they are listed in the Chemical Weapons Convention as a Schedule 1 compound. The listing is justified relative to other cyanotoxins based on its high potency, stability, availability of synthetic production methods, and suitability for incorporation into ammunition.

CHAPTER

32

Radiation and Health Effects

Kausik Ray and Melissa Stick

INTRODUCTION

Exposure to ionizing radiation occurs throughout our lives, with beneficial and detrimental consequences. The majority of ionizing radiation exposure occurs as a result of natural sources; however, industrial, medical, and consumer sources also account for exposure (http://www.world-nuclear.org/info/Safety-and-Security/Radiation-and-Health/Nuclear-Radiation-and-Health-Effects/). Ionizing radiation cannot be detected without the use of specialized devices; therefore, the effects of exposure to humans have been extensively explored in large, retrospective population studies. These studies were conducted after large populations were exposed to harmful levels of radiation (for example, survivors of the Hiroshima and Nagasaki atomic bomb explosion and workers and residents around Chernobyl). In individuals from Hiroshima and Nagasaki, the major health effect observed at the lowest doses of exposure has been cancer, while heart, digestive, and other systemic complications have been noted at higher doses of exposure (Harley, 2001, 2008).

For many years, deliberate or accidental releases of ionizing radiation have been universally feared. Alternatively, ionizing radiation has been used in controlled, defined amounts as radiation therapy for certain tumors in both pet animals and man. Acute radiation toxicity responses, often known as *acute radiation syndrome (ARS)*, occur with high amounts of radiation and become apparent within 24 h after exposure. Because ARS can present with hematopoietic, gastrointestinal, and neurological/vascular symptoms, history is an important criterion in determining whether the radiation is related to the cause of a particular complication or adverse effect. Chronic radiation exposure may appear months to years after the exposure; complications may be associated with the bone marrow, kidneys, liver, or central nervous system (CNS) (Center for Drug Evaluation, 2005). The presentation of these symptoms assumes whole-body exposure and is not valid if the entire body has not been exposed. The speed with which symptoms manifest, as well as the difference in sensitivity of organs, is related to the absorbed dose of radiation, with greater doses resulting in a shorter period of time before the onset of symptoms.

Natural resources account for most radiation exposure. Attempts to determine if there are subtle effects from background irradiation have only begun to yield information about these widely dispersed effects. Advent of new techniques for such estimation has increased the sensitivity and reliability of detection. The objectives of this chapter are to describe common types of ionizing radiation, discuss radiation toxicity in humans, and provide information on the possible benefits and risks associated with ionizing radiation.

HISTORICAL PERSPECTIVE

Human understanding of ionizing radiation began with the pioneering work of individuals like Wilhelm Conrad Roentgen, Henri Becquerel, and Marie and Pierre Curie just before the turn of the twentieth century. In 1895, Roentgen observed that the external effects of an electric discharge tube covered with black paper caused a dye outside the tube to fluoresce. Although the term *Roentgen rays* is used in many countries, the more common term for these electromagnetic waves is *x-rays*, the name given to them by Roentgen himself. A year later, an Austrian surgeon named Leopold Freund demonstrated that this invisible energy source could be used therapeutically to treat a hairy mole. In the same year, Becquerel discovered radioactivity when a photographic plate protected from visible light was exposed to a uranium salt. In 1898, Marie and Pierre Curie published their findings of the isolation of a new compound that they

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00032-4

suggested be named *polonium* after Marie Curie's homeland of Poland. They introduced the term *radioactivity* to describe the properties of the newly discovered element. A few months later, they published a paper about another radioactive element they had discovered, which they named *radium*. These early discoveries encouraged additional research on the uses of radiation.

BASIC RADIATION CONCEPTS

The nucleus of an atom contains one or more protons and (with the exception of hydrogen) neutrons, while any associated electrons, frequently equal in number to the protons, move around the nucleus in specific orbitals. Each element is defined by the number of protons in the nucleus, its atomic number (Z); for instance, $Z = 1$ for hydrogen, $Z = 6$ for carbon, and $Z = 8$ for oxygen. Although the number of protons defines the element, the number of neutrons defines the different isotopes of that element. For example, hydrogen has no neutrons in its nucleus, but there are two additional isotopes of hydrogen: deuterium, with one neutron, and tritium, with two neutrons. The atomic mass of an isotope is determined by the total number of nucleons (protons and neutrons); electrons with a mass that is 1/1,838th that of a proton or neutron contribute little to the total atomic mass. The shorthands for hydrogen, deuterium, and tritium are ^{1}H, ^{2}H, and ^{3}H (or H-1, H-2, and H-3), respectively. Most isotopes are stable (that is, the number of protons and neutrons remains unchanged indefinitely), but some isotopes have unstable nuclei, making them radioactive. For example, hydrogen and deuterium are stable isotopes, while tritium is a radioactive isotope that is commonly used in biomedical research.

Radioactive isotopes go through a process of radioactive decay that involves emitting ionizing radiation in the form of subatomic particles, electromagnetic radiation, or both. The source of radiation is the nucleus, and the decay continues until the nucleus is converted to a stable isotope. Tritium decays by emitting only one particle, becoming a stable isotope of helium (He-3, as opposed to the more common form of helium, He-4), while uranium (U-238) emits a total of 14 particles before becoming a stable isotope of lead (Pb-206). There are four naturally occurring radioactive families on Earth. Two of these have almost disappeared because their half-lives are relatively short in comparison to the age of the Earth (Table 32.1), leaving only the thorium and the uranium–radium series.

Each decay event on the way to becoming a stable isotope is known as a *disintegration*, and the rate of decay is given in disintegrations per minute (dpm) or disintegrations per second (measured in becquerels, abbreviated Bq); see Table 32.2 for a list of units and magnitudes.

TABLE 32.1 Naturally Occurring Radioactive Families

Series	Half-Life of Parent (Years)	Parent Radioisotope	Stable Decay Product
Thorium	1.41×10^{10}	Th-232	Pb-208
Uranium–radium	4.47×10^{9}	U-238	Pb-206
Uranium–actinium	7.04×10^{8}	U-235	Pb-207
Neptunium	2.14×10^{6}	Np-237	Bi-209

The particles emitted during radioactive decay include alpha and beta particles and neutrons. In addition to ionizing particles, radioactive decay can also produce a form of ionizing shortwave electromagnetic radiation known as *gamma rays*. Important information about the steps involved in the decay of a radioactive isotope is contained in its decay scheme. An example for iodine (I-131), an important radioisotope with regard to nuclear power plant accidents, is given in Figure 32.1.

The four main types of irradiation are alpha particles; beta particles, which can be electrons (negatively charged) or positrons (positively charged); gamma rays; and x-rays. An atom can decay by the loss of mass (protons and neutrons), or the loss of charged electrons (beta particles or positrons). Gamma irradiation occurs when excess energy is released from the nucleus, usually after an alpha, beta, or positron transition. Ionizing radiation can also originate from outside the atomic nucleus. Examples include x-rays and extreme ultraviolet radiation (EUV). Historical observation demonstrated that radioisotopes emitted three unique types of radiation, which were differentiated based on the way they behaved when subjected to a magnetic field. Two types of radiation followed a curved path in a magnetic field, but in opposite directions, indicating that they had opposite charges. The positively charged radiation is called *alpha rays*, while the negatively charge radiation is referred to as *beta rays.* The third type of radiation, not deflected by a magnetic field, is referred to as *gamma rays*. Other atomic particles qualifying as ionizing radiation, but not discussed in this chapter, include a variety of particles generated in particle accelerators and particles, other than alpha and beta particles, which are produced in nuclear fission and fusion reactions.

Alpha and Beta Particles

In 1903, Ernest Rutherford discovered that alpha particles were equivalent to a helium nucleus (2 protons and 2 neutrons) and contained an overall charge of +2. Alpha particles are also given off by decaying radionuclides,

TABLE 32.2 Abbreviations for Units and Orders of Magnitude

Abbreviation	Parameter
UNITS	
Bq	becquerel
C	coulomb
erg	erg (10^{-7} J)
eV	electron volt
g	gram
Gy	gray
J	joule
m	meters
R	roentgen
rad	radiation absorbed dose
rem	roentgen equivalent in man (or mammals)
sec	seconds
Sv	sievert
MAGNITUDES	
a	atto (10^{-18})
f	femto (10^{-15})
p	pico (10^{-12})
n	nano (10^{-9})
Î¼	micro (10^{-6})
m	milli (10^{-3})
c	centi (10^{-2})
k	kilo (10^{3})
M	mega or million (10^{6})
G	giga (10^{9})
T	tera (10^{12})
P	peta (10^{15})
E	exa (10^{18})

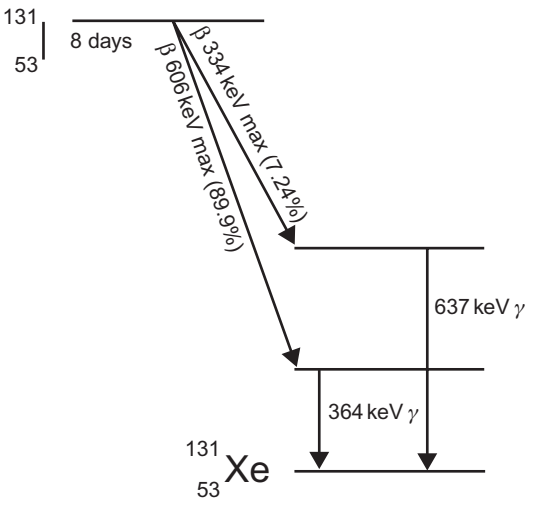

FIGURE 32.1 Decay scheme for ^{131}I, showing beta particle emissions that lead to the formation of a stable isotope of xenon (Xe-131). The decay occurs mostly in two ways: 7.24% of the time, a beta particle with maximum energy of 334 keV is emitted with subsequent emission of a 637-keV gamma ray; and 89.9% of the time, the decay occurs by the emission of a beta particle with a maximum energy of 606 keV and the subsequent emission of a 364-keV gamma ray. *Source: This image has been reprinted from Rebois and Ray, 2012. Copyright 2012, with permission from Elsevier.*

such as radium, and are present as a natural source of radiation. For example, $^{226}Radium_{86}$ decomposes to $^{222}Radon_{84}$ and an alpha particle ($^{2}He_{2}^{++}$) + energy (5.2 MeV). Most alpha particles are in the energy range of 4–8 MeV. Henri Becquerel was credited with the discovery of the beta particle in 1900, and he showed that beta particles were identical to electrons, which were discovered by Sir Joseph J. Thomson in 1897. Beta particles are emitted when a neutron is converted to a proton plus an electron, and the electron is lost. Unlike the discrete energy emissions from the decay of alpha particles, beta particles are emitted along a spectrum of energies because energies are shared between positive and negative electrons. A positron is emitted when a proton becomes a neutron and decays by beta emission or an electron is captured. Unlike the other particles (electron, proton, and neutron), positrons were detected as particles in cosmic rays by C. D. Anderson in 1932, were not found in "ordinary matter," and were formed only during interconversion of free elementary particles. Beta particles have the mass (9.1×10^{-31} kg) and the negative charge (1.6×10^{-19} coulombs) of an electron. A positron contains the same mass as a beta particle and has a +1 electric charge (whereas an electron has a −1 charge), but are equal in magnitude to an electron and may also be referred to as a *beta particle.*

The kinetic energy imparted to nonrelativistic alpha and beta particles when they are ejected from the nucleus is given by the following formula:

$$E = \tfrac{1}{2}mv^2,$$

where E is the energy of the particle in joules, m is its mass in kilograms, and v its velocity in m/s. The unit of energy for this equation is the joule (J), but the energy of ionizing particles is usually given in electron volts (eV), where 1 eV is the amount of energy imparted to an electron when it is accelerated by a potential difference of 1 volt. The factor for converting joules (kg m^2/s^2) to eV is:

$$1\text{eV} = 1\text{V} \times 1.6 \times 10^{-19}\text{C} = 1.6 \times 10^{-19}\text{J}.$$

Ionizing particles have energies in the thousands or millions of electron volts (keV or MeV, respectively):

$$1\text{KeV} = 1\text{eV} \times 10^3 \text{ and } 1\text{MeV} = 1\text{eV} \times 10^6.$$

Alpha particles emitted by a particular radioisotope all have the same energy. For example, U-238 emits an alpha particle with an initial energy of 4.19 MeV, but the energies of alpha particles from different isotopes vary. The energy of alpha particles ranges from 3 to 7 MeV, while beta particles have energies ranging from 20 keV to a few MeV. Beta particles from the same isotopic source vary in their energy. The value given in decay schemes represents the maximum energy (Figure 32.1). As a rule of thumb, the average energy is one-third of the maximum. The additional energy lost when lower-energy beta particles are emitted is contained in a neutrino that is also emitted.

Gamma Rays (Photon) Emission

Gamma ray emission is mostly secondary to alpha, beta, or positron emission or electron capture. When all of the energy is not used by the emission, the nucleus is in an excited state with energy available for emission. This excitation energy is emitted as a photon when the particle is emitted. In many cases, the photon will not be emitted; rather, it binds to an electron, which is ejected as a monoenergetic particle that equals the photon energy minus the binding energy. This latter process is called *internal conversion* (Harley, 2001, 2008). The wavelength (λ) of electromagnetic radiation varies from more than 10^8 m in length to less than 10^{-16} m. The energy of electromagnetic waves is given by the following equation:

$$E = hc/\lambda,$$

where h is Planck's constant (6.626×10^{-34} J.s or 4.136×10^{-15} eV.s) and c is the speed of light (3.0×10^8 m/s). Only electromagnetic waves with λ of less than approximately 10^{-8} m have sufficient energy to qualify as ionizing radiation. Electromagnetic radiation with λ between 1.2×10^{-7} and 10^{-8} m are referred to as *EUV rays*, while x-rays generally range from 10^{-8} to 10^{-11} m, and gamma rays are any electromagnetic radiation with λ of less than 10^{-11} m (Table 32.2). Plugging these values into the preceding equation gives a range of energy of 0.01–0.12 keV for EUV, 0.12–120 keV for x-rays, and greater than 120 keV for gamma rays. Electromagnetic radiation interacts with matter in three ways: (i) the photoelectric effect, (ii) Compton scattering, and (iii) pair formation. The photoelectric effect results in the complete absorption of a gamma photon's energy by an electron in the inner K and L shells of an atom. The electron escapes with energy (Ee) approximately equal to that of the photon (Eγ) minus the binding energy of the electron (Eb).

TABLE 32.3 Comparison of Biodosimetry Methods for Ionizing Radiation Exposure

Assay/Biomarkers	Detection Limit (Gy)	Postexposure Duration	Advantages/Disadvantages
Physical measurement/ESR	0.1	Indefinite (years)	No chemical analysis/large equipment required
Blood counts	0.5–1	Weeks, months	Simple, rapid
Tooth, enamel, fingernails	0.1	Weeks, months	Dose estimated even after years/low detection limit
Cytogenetic biomarkers			
Dicentric (unstable)	0.5–1	Several years	Radiation-specific/technical expertise
Micronuclei	0.1–0.3	1 year	Fast, simple/specific technique
PCC	0.1–0.5	Days, weeks	Cheap, fast, simple
FISH (stable)	0.1–0.25	Years	Rapid/technical expertise
SOMATIC CELL BIOMARKER			
GPA mutation	1–2	Indefinite (years)	Fast, simple, detected after years
HPRT mutation	1–2	Transient (<1 year)	Simple/longer length of time
Nucleic acid biomarkers (DNA, RNA)	0.2–1	2 days or more	Reliable markers/specific techniques
Protein Biomarkers	1–2	Within a day or more	Reliable/lacks amplification
Metabolite biomarkers	0.2–1	Within 24 h or more	Within 24 h or more
Microbiome biomarker	0.2–1	Undetermined	Noninvasive/instruments needed

ESR, electron-spin resonance; PCC, premature chromosome condensation.

Eb varies with the atomic number (Z) but is generally much less than $E\gamma$, so the energy carried away by the electron is close to that of the incident gamma photon. Gamma photons can also be scattered by an encounter with an electron. This is known as *Compton scattering*, and it results in the deflected gamma photon continuing in a new direction, with reduced energy, while the electron carries off the balance of the energy in another direction. Pair formation occurs when a gamma photon is converted into an electron–positron pair. The energy represented by an electron (or positron) with resting mass m_o (9.1×10^{-31} kg) is given by $m_o c^2$. Since $c = 3 \times 10^8$ m/s and 1 MeV = 1.6×10^{-13} J (kg m^2/s^2),

$$m_o c^2 = 0.51 \text{ MeV}.$$

Because both an electron and a positron are formed, the photon's energy must be at least 1.02 MeV. Any energy in excess of this amount is shared by the particles as kinetic energy. Positrons are unstable and, after coming to rest, will quickly recombine with resting electrons, producing a pair of gamma photons each of 0.51 MeV moving in opposite directions.

X-Rays

When a beam of electrons hits a heavy metal target, their rapid deceleration by positively charged atomic nuclei within the target causes some of the electron energy to be converted to electromagnetic radiation in the form of x-rays. Radiation produced in this way is also known as *bremsstrahlung* (which means "braking" in German). The beam of electrons originates at the negatively charged cathode within an evacuated tube and is accelerated toward the metal target (the anode) by a voltage difference between the two electrodes. The energy of the x-rays depends upon the magnitude of this voltage difference. X-rays generated by voltage differences of 100–300 kV have enough energy to ionize molecules in the target tissue by Compton scattering. The electrons that are stripped from molecules are known as *secondary electrons*, and if they have sufficient energy to produce additional ionizations, then they are known as *delta rays*. X-rays produced with high voltages have important diagnostic and therapeutic applications. The energy of x-rays produced by x-ray tubes is limited by the potential difference that can be applied to the electrodes. The practical limit for conventional x-ray tubes is 300 kV. By definition, the electrons produced by this voltage would have a maximum energy of 300 keV and are capable of producing x-rays with the same maximum energy. Only about 1% of the electrons striking the anode generate x-rays, and their average energy is one-third of the maximum. The energy of the remainder of the electrons is converted to heat. Generating x-rays with energies on the order of 10 MeV requires a linear accelerator. An x-ray with energy of 10 MeV would correspond to a wavelength on the order of 10^{-3} m or 0.0001 nm. This overlaps extensively with gamma rays (Table 32.1). What distinguishes gamma rays from x-rays is not wavelength, but the source of the radiation. Gamma rays originate in the nucleus of an atom, while x-rays arise from sources outside the nucleus. X-ray tube voltages between 25 and 50 kV are used to generate "soft" x-rays (Table 32.1), which are absorbed completely after producing a single ionization by the photoelectric effect described previously. Soft x-rays are important for medical diagnostic procedures such as mammography because they produce better contrast between tissues that do not differ greatly in electron density, making it easier to distinguish between tumor tissue and normal tissue.

INTERACTION OF RADIATION WITH MATTER

The interactions of radiation with matter generate ionized and excited atoms and molecules in the irradiated material and result in changes in its physical, chemical, and biological behavior. Kinetic energy transfer from alpha, beta, or gamma photons to atoms and molecules of matter leads to ionization or excitation of these atoms and molecules. Ionizing radiation loses energy by producing ion pairs (an electron and a positively charged atom). Radiation energy with about 33.85 eV is needed to produce an ion pair (ionization) by ejecting one or more orbital electrons from an atom. Ion pairs themselves can interact with surrounding matter, producing more ion pairs or secondary ionization. If the energy transfer is not sufficient to cause ionization, excitation occurs, and electrons in an excited state may break or form molecular bonds or can revert to the original energy level by emitting electromagnetic radiation.

Alpha Particles

An alpha particle, with a mass equal to 7,300 times that of an electron, loses its energy over a relatively short distance. Since 33.85 eV is required to produce an electron pair, an alpha particle (typically 5 MeV of energy) can produce approximately 7,400 electron pairs within 1 micron (μm) of the decay. Penetration by alpha particles can easily be stopped by a sheet of paper (100 μm thick) or the protective (dead) layers of skin. Most damage caused by alpha particles occurs when they are ingested or inhaled because they end up in close proximity to living cells. The effects of ingested or inhaled alpha particles will be discussed in greater detail later in this chapter.

The rate at which an electron transfers energy to a material is known as *linear energy transfer (LET).* LET is used to describe the local concentration of energy in human tissue resulting from ionization by charged particles passing through human tissue. The actual relationship of the efficiency in producing damage to LET values (keV per μm-keV/μm) depends on the biological effect considered. For a biological effect, there is a LET value that produces an optimum energy concentration within the tissue. Radiation with lower LET values does not produce an adequate concentration of energy, but radiation with higher LET values tends to deposit more energy than is needed to produce the effect. Inhaled or ingested alpha particles that do not escape the body lose all their energy over a relatively short distance. This energy is deposited in the tissue over the space of a few millimeters, resulting in a high LET. In addition to tissue damage, cellular changes, including deoxyribonucleic acid (DNA) strand breakage, are also associated with high LET activity; this topic will be discussed further later in the chapter.

Beta Particles

Beta particles with small mass, high velocity, and a single negative charge can travel through matter farther than alpha particles before producing ionization; therefore, their energy loss in matter is calculated differently. Even low-energy beta emitters travel near the speed of light and must be corrected for mass increase by the term 0.511 (1 − particle velocity^2/light velocity^2) + 0.511. When traveling through matter, electrons of beta particles interact with the negative charge of orbital electrons, ejecting them from their orbits, thus producing ion pairs or causing excitation. When approaching the nucleus of the atom within the target, the velocity of beta particle increases and then decreases as it moves away due to electrostatic interaction (positively charged protons in the nucleus). This type of emission, referred to as *bremstrahlung radiation*, increases with the atom number of the target atom, increasing electrostatic attraction. Products with a low Z value (Z = number of protons in the nucleus), such as aluminum or plexiglass, can serve as a shield and protect from high-energy beta emitters. Beta particles of 1 MeV will penetrate to about 0.5 cm in water for soft tissue and have much less LET than alpha particles. Because damage to tissue is related to LET, exposure to beta particles results in less damage than exposure to alpha particles.

Gamma and X-Rays

Gamma and x-rays are both electromagnetic radiation but differ in their origin. As stated earlier, gamma rays originate in the nucleus of an atom, while x-rays arise from sources outside the nucleus. Because gamma rays possess more energy that alpha and beta particles, they are able to penetrate much farther into tissue and deposit their energy over larger distances. If lead shielding is used, the density would be much greater, and penetration beyond the lead shield would be much less. If energy emitted is sufficiently low, penetration of the rays is negligible. While lead shielding confers protection, some fraction of energetic gamma-emitters (e.g., ^{60}Cobalt) irradiation can penetrate even lead, and added earth shielding is required. Radiation leakage, which means the penetration of radiation, is usually measured to determine the amount of external radiation that is still present in spite of the presence of a source and shielding. If therapeutic gamma radiation is used instead of x-irradiation, radiation leakage may become as high as 1–10% of the source strength depending on the amount of shielding. Because both gamma rays and x-rays have low LET, travel at a low rate along their path, emerge from the body and continue on their way, x-rays can be used to generate images on a photographic plate.

ABSORBED DOSE

Total Dose and Dose Rate

The term *absorbed dose* (total ionizing dose) describes the amount of radiation absorbed by an object or person. The units for absorbed dose are gray (Gy) and rad. Absorbed dose is a function of the mass and density of the media. Sometimes absorbed dose is called *kerma* (kinetic energy released in matter). Because exposure and dose are often used interchangeably, dose is often confused with exposure level. The absorbed dose depends not only on the radiation incident, but also on the absorbing material; a soft x-ray beam may deposit a dose four times greater in bone than in air, and none at all in a vacuum.

If the dose is delivered quickly in a single exposure at a high dose rate, there is almost no time to repair radiation damage, and the damage/unit of dose absorbed is high. Alternatively, if the total dose is delivered slowly, at a lower dose rate, or in divided dose fractions, over the life span of the subject, there is more time to repair radiation damage and the damage/unit of dose is much lower. For example, if multiple fractionated doses are delivered per hour, the damage/unit of total dose decreases significantly. In this situation, the radiation therapist can deliver higher doses to the area, but less total rem/h from the source or x-radiation machine.

Dose Equivalent and Cancer Risk

Dose equivalent (or effective dose) takes into consideration the amount of radiation absorbed and the medical effects of the type of radiation. Alpha particles, with

large mass, produce intense ionization tracks per unit distance relative to beta particles, whereas beta particles produce more intense ionization than gamma rays. As stated earlier, LET measures this transfer of energy per unit distance traveled by the emission from the radiation particle. In situations where dose is considered to be proportional to response, that dose must be normalized for LET. For a particular end point (e.g., cell death in mouse fibroblasts), the relative biological effectiveness (RBE), which is equal to the dose of radiation under study relative to the dose of gamma rays needed to achieve the same effect, is calculated. Radiation with high LET will be expected to have an RBE of greater than 1. For beta and gamma radiation, the dose equivalent (1 rem or 1,000 mrem) is the same as 1 rad of the absorbed dose, but is larger than the absorbed dose for alpha and neutron radiation, as these types of radiation are more damaging to the human body.

Dose equivalent (or effective dose) is calculated as follows: Dose equivalent = (Absorbed dose) × (weighting factor or RBE). Recommended weighting factors are approximately 1 for x-rays, gamma rays, beta particles, and electrons, and 20 for conventional neutrons (>0.1–2 MeV), protons, alpha particles and charged particles of unknown energy. As an example, the weighting factor or RBE of plutonium-238 (^{238}Pu) is between 10 and 30; thus, the roentgen equivalent in humans (rem) is 10–30 roentgens in air (rad). Similarly, the dose equivalent following alpha emission is larger than the absorbed dose, which is confined to an immensely small area in human tissue because alpha irradiation travels only a short distance in tissue and has a high LET.

The term *effective dose* allows the comparison of cancer and genetic risks from different partial-body and whole-body doses to be integrated for the purposes of estimating a whole-body response. Complicating the matter, different organs vary in their sensitivity to the effects of radiation. This is taken into account by using a tissue-weighing factor that varies for different organs. Some tissues, like gonads, are more sensitive than others, such as bone marrow, colon, stomach, and lung. Similarly, bone marrow, colon, stomach, and lung are more sensitive than bladder, breast, liver, esophagus, and thyroid. Skin and bone surface are the least sensitive. Other tissues not specified are taken to have a weighting factor of 0.05 as a conservative estimate (Harley, 2001, 2008). Effective dose is calculated by multiplying the tissue-weighting factor in protracted exposures (exposures over significant periods of time) by the dose equivalent.

Committed Dose Equivalent

The *committed dose equivalent* is the dose of radiation that a specific organ or tissue receives from an intake of radioactive material over a specified period of time. Once radioactivity is placed internally in the body, it becomes an internal emitter. Internal emitters can be used therapeutically (actually implanted in a tumor) or result from accidental exposure via ingestion or inhalation or penetration through skin. Usually, internal emitters cannot be removed simply or easily, and an irreversible committed dose equivalent is said to exist. For radionuclides with a half-life of 0–3 months, the dose equivalent or effective dose is equal to the annual dose of the year of intake. After 12 months of exposure, a radionuclide with a half-life of 3 months will have undergone the passage of four half-lives; the fraction of dose delivered will be $(1 - ½^4)$ (or approximately 94% of the total dose) for all time. Thus, 94% of the possible dose will have been delivered, and only 6% will remain to be delivered. Radionuclides with a shorter half-life deliver almost 100% of the dose within a year of exposure [half-life of 1 month $(1 - ½^{12})$, or approximately 99.98% of the total dose for all time]; therefore, any effort to remove an internal emitter will reduce the internal dose only minimally. Alternatively, if the half-life of the radionuclide is 1, 10, or even 5,000 years, considerably less radioactive decay will occur, and much more of the total dose will remain to be delivered: $(1 - ½)$, or approximately 50%, $(1 - ½^{1/10})$, greater than 50%, and $(1 - ½^{1/5,000})$, significantly greater than 50%, respectively, at the end of 1 year. So, for elements with longer half-lives, it is more advantageous to remove the particulates than to allow the natural process of decay and the risks associated with it to continue. It is a good idea to perform such analyses with each radionuclide to see how much of the dose remains to be delivered; this way, the effort associated with removing the remaining dose can be weighed against the risks of not removing the remaining dose.

Negligible Individual Risk Level (Negligible Dose)

The concept of linear, nonthreshold cancer induction from ionizing radiation is an accepted fact, and this allows calculation of cancer risk regardless of how small or large the dose may be. Calculating very low risk enables us to calculate a risk below the ability to detect a response. In 1987, the National Council for Radiation Protection (NCRP) defined the *negligible individual risk level (NIRL)* as the level of average annual excess risk of fatal health effects attributable to irradiation below which efforts to reduce radiation exposure to the individual is unwarranted. The NCRP emphasized that this level should not be confused with *acceptable risk level*, a level of significance or a standard. The NCRP recommended a level of about half the natural background radiation level, which is approximately 2 mrem; the final recommended NIRL level is 1 mrem or 0.01 mSv. This level is now called the *negligible individual dose (NID)* level.

CONSEQUENCES OF RADIATION-INDUCED DNA DAMAGE

Chromosomal Aberrations and Radiation-Induced Genomic Instability

The cytogenetic effects of x-rays were first documented in plants irradiated during the G1 cell cycle phase and included the production of dicentrics, centric rings, and deletions (Sax, 1940). The current view is that the majority of radiation-induced chromosome aberrations are produced by mispairing of DNA double-strand breaks (DSBs), possibly due to damage to multiple DNA sites and complex exchanges of DNA lesions. While repair of DSBs is performed by nonhomologous end-joining and homologous recombination mechanisms in mammalian cells, in some cases, the pairs of DSBs required for the formation of chromosomal aberrations are produced by one or more electron tracks from the single photon and in others by two or more tracks of different photons (Charlton et al., 1989). The prevailing view is that chromosomal aberrations of all types result from the interactions of multiple pairs of DNA lesions, and that these lesions can be induced by a single track or by combinations of two or more radiation tracks. Ionizing radiation can induce a wide range of unique DNA lesions, both double-stranded and single-stranded breaks can be expressed as chromosomal aberrations (Price and D'Andrea, 2013). DNA DSBs are particularly lethal, and a complex cascade of signal transduction pathways respond to the radiation-induced cell damage in an attempt to restore the integrity of the damaged DNA molecules (Kavanagh et al., 2013). Based on the complexity of DNA damage (such as defects in sister chromatid exchanges, chromosome aberrations, and micronucleation), DNA lesions can also lead to cell cycle arrest. Many cytogenetic assays are now available to measure chromosomal aberrations along with cell death markers, but these tests are slow in detecting the circulating markers and are not always useful for predictive, prognostic, and diagnostic purposes. There is increasing interest in developing automated, noninvasive DNA and chromosome-based tests for radiation exposure (Amundson et al., 2001; Varga et al., 2004; Martin et al., 2007; Pinto et al., 2010a,b).

Chromosomal changes are the best-described phenomenon associated with radiation-induced instability. Radiation-induced genomic instability is observed at delayed times after irradiation and is manifest in the progeny of exposed cells many generations after the initial insult. Among the instabilities described in a number of reviews are chromosomal alterations, micronucleus formation, gene mutations, gene amplifications, and changes in ploidy (Seizer and Hebar, 2012). Multiple molecular pathways have been shown to initiate and promote instability; the contributions of these different pathways also depend on the genetic background of the target cells or organisms (Klarer and McGregor, 2011; Jacquet, 2012; Vijg and Suh, 2013; Mukherjee et al., 2014).

In previous studies, delayed responses associated with radiation exposure have included the loss of reproductive potential and cell death among the clonal progeny of irradiated cells (Puck and Marcus, 1956; Trott and Hug, 1970; Seymour et al., 1986) and chromosomal instability in skin fibroblast cultures obtained from mouse fetuses derived from irradiated zygotes (Pampfer and Streffer, 1989). More definitive studies of chromosomal instability were obtained using an *in vitro* clonogenic assay to obtain clonal bone marrow cell populations derived from irradiated hematopoietic stem cell populations from both murine and human bone marrow (Kadhim et al., 1992, 1994). In these studies, cytogenetic analysis revealed nonclonal aberrations with a high frequency of *de novo* chromatid-type aberrations. Comparable ongoing chromosomal instability in bone marrow has been demonstrated *in vivo* (Watson et al., 1996, 2001; Zyuzikov et al., 2011). While some investigators describe chromosomal gaps or breaks as the primary observed aberration, it is unlikely these contribute to the instability process since gaps have no known phenotype and breaks are generally lethal events. Of more significance are gross chromosomal rearrangements, particularly chromosomal duplications, partial trisomies, or both, which appear to involve the amplification and recombination of large chromosomal regions by a currently unknown mechanism (Marder and Morgan, 1993; Limoli et al., 2000; Savage, 2004).

Radiation-Induced Bystander Effect

The term *bystander effect* describes the ability of cells affected by irradiation to convey manifestations of damage to other cells not directly targeted for irradiation. An irradiated cell can send out a signal and induce a response in a cell whose nucleus was not directly hit by radiation. This amplification can cause similar radiation-induced effects and may result in genetic damage or instability. Some radiation-induced bystander effects can be detrimental, while others are not, depending on the type of cell producing the bystander signal after irradiation and the type of cells receiving these signals. The first indications of radiation-induced bystander effects were reported in 1992, when in two independent studies of α-particle irradiations, cytogenetic responses were noted in more cells than were actually irradiated (Kadhim et al., 1992; Nagasawa and Little, 1992). In these studies, low fluencies of α-particles were used, resulting in a situation where many cells were not actually "hit" by a particle; however, the number of cells expressing responses was greater than the number of cells actually

irradiated. The phenomenon of more cells than were actually irradiated expressing responses has been confirmed by a number of investigators (Deshpande et al., 1996; Azzam et al., 1998; Nagasawa and Little, 1999; Zhou et al., 2000; Prise et al., 2002). In unrelated studies, significant decreases in cloning efficiency were observed in nonirradiated cells exposed to medium from irradiated cell cultures (Mothersill et al., 1997; Mothersill and Seymour, 1998). Radiation-induced bystander effects have also been demonstrated in the coculture of irradiated and nonirradiated cells (Pinto et al., 2006, 2010a,b). These indirect effects of radiation may result in genetic damage or instability and may be lethal to nonirradiated cells. Although the majority of bystander studies have focused on end points associated with genomic damage, the effects are not necessarily always detrimental. Favorable bystander effects on cells include enhanced cell differentiation (Belyakov et al., 2002), increased cell proliferation (Iyer et al., 2000; Gerashchenko and Howell, 2004, 2005), and a radioprotective adaptive response.

Our understanding of these nontargeted bystander effects is still in its infancy. Because much of the data to date has been obtained from *in vitro* studies, the significance of these indirect effects on human health has yet to be elucidated. It would seem prudent to consider the implications of nontargeted delayed effects of radiation exposure when considering models of radiation carcinogenesis, particularly at low doses.

HUMAN EXPOSURES AND RADIATION TOXICITY

Different doses of irradiation produce a variety of radiation-induced toxicity in humans and as stated before, different organs vary in their sensitivity to the effects of radiation (Figure 32.2). Biological effects of radiation are typically divided into two categories. The first category consists of exposure to high doses of radiation over short periods of time producing acute or short-term effects. The second category represents exposure to low doses of radiation over an extended period of time, producing chronic or long-term effects. High doses tend to kill cells, while low doses tend to damage or change

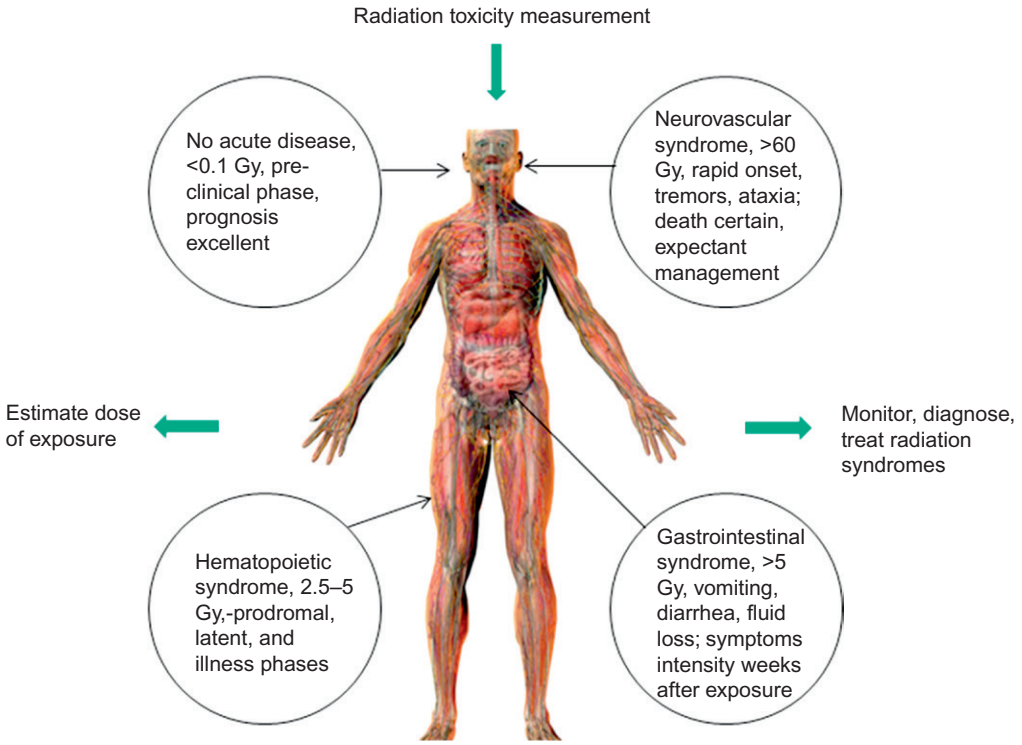

FIGURE 32.2 Radiation dose ranges and health impacts in humans after total body exposure. Health effects are categorized by time of appearance after irradiation as *early* and *late effects*. Two major variables needed to predict outcomes in humans are the amount of radiation dose and its distribution in time; that is, dose rate and fractionation. Health impacts of uniform irradiation of the whole body include three ARSs—the hematopoietic (bone marrow), GI, and neurovascular syndromes, with thresholds of about 2, 5, and 50 Gy. When total body exposure occurs, a series of events takes place. Within a few days to weeks, the prodromal symptoms occur, which vary based on the dose magnitude and length of time of the exposure. In total body exposures of about 100 Gy, cerebrovascular syndrome results in rapid death as a result of blood leaking through vessels in the brain. GI syndrome results in days and weeks after 5–10 Gy of exposure due to the destruction of the epithelial lining of the GI tract. Hematopoietic syndrome results days to weeks after total body radiation exposure ranging from 2.5–5 Gy. That syndrome leads to bone marrow depletion and a reduction in circulating red blood cells, white blood cells, and platelets.

cells. High doses affect many cells, can cause tissue/organ damage, and ultimately yield ARS. Even normally radio-resistant cells, such as those in the brain, cannot withstand the cell destruction capability of very high doses of radiation. The initial signs and symptoms of the ARS are nausea, vomiting, fatigue, and loss of appetite. Below 0.1 Gy, these symptoms, which are no different than those produced by a common viral infection, may be the only outward indication of radiation exposure. Depending on the level of the dose above 1 Gy, the presentation of one of three radiation syndromes (neurovascular, gastrointestinal, and hematopoietic) may begin.

Radiation levels greater than 60 Gy produce CNS changes, also known as *neurovascular syndrome*, characterized by agitation, apathy, disorientation, disturbed equilibrium, vomiting, opisthotonus, convulsions, prostration, coma, and death usually occurs within 24–48 h after exposure (NCRP, 1989). Prior to 1970, the human brain was thought to be radio-resistant to lower doses of radiation, with acute CNS syndrome occurring after a single dose of greater than 30 Gy and white matter necrosis occurring at fractionated doses greater than 60 Gy. During the 1980s–1990s, late radiation-induced brain injury, characterized by vascular abnormalities, demyelination, and ultimately white matter necrosis, was recognized as a dose-limiting morbidity presenting more than 6 months after irradiation (Schultheiss et al., 1995). Extensive preclinical studies in rodents revealed dose-dependent changes in these histopathological lesions (Calvo and Hanks, 1988). Classically, late radiation-induced brain injury was viewed as solely attributable to a reduction in the proliferative capacity of glial or vascular endothelial cells in rodents (van den Maazen, et al., 1993). Of importance, these late effects were viewed as progressive and irreversible. Although white matter necrosis is uncommon with modern-day radiation therapy technologies, there has been a growing belief that patients receiving fractionated partial or whole-brain irradiation can develop significant cognitive impairment more than 6 months after irradiation, even in the absence of detectable anatomic abnormalities (Fike, 2011; Greene-Schloesser and Robbins, 2012).

Gastrointestinal (GI) syndrome can result after acute exposure to 10 Gy or less. The radiation exposure causes destruction of the epithelial lining of the GI tract, and GI syndrome is characterized by lethargy, diarrhea, dehydration, degeneration of bowel epithelium, and death in 10–14 days (NCRP, 1989). The other syndrome associated with acute exposure is hematopoietic syndrome, which may present days to weeks after total body radiation exposure ranging from 2.5 to 5 Gy. The hematopoietic syndrome is characterized by granulocytopenia, thrombocytopenia, hemorrhage, infection, and electrolyte imbalance. Even lower doses (1–5 Gy) can cause hematopoietic syndrome, which results in what is commonly termed *bone marrow death.* Death resulting from hematopoietic syndrome is usually associated with higher dose exposure and typically occurs within 2–3 months after exposure; at lower doses (1–3 Gy), survival may be much longer (Fliedner and Graessle, 2008).

HUMAN POPULATION AND HEALTH RISKS

Radium Exposures

In the mid- to late-1920s, many young women in the United States who were watch-dial painters accidentally ingested radium through the practice of "pointing" (touching) their paintbrush tips to their lips while painting the hands and faces of clocks and watches with radium paint. The cohort studies of cancer risk among radium watch-dial painters were initially carried out at the Massachusetts Institute of Technology and the Argonne National Laboratory (Stebbings et al., 1984; Stehney, 1994). The survival times of women radium dial workers first exposed before 1930 showed definite life-shortening, radium-induced malignancies. Effects that emerged later were osteogenic sarcoma and head carcinoma, primarily in the sinuses.

Radium exists in several different forms depending on the parent radioactive element. Ra-226, the most common form, is created during the decay of uranium (specifically U-238), an element with a half-life of approximately 4.5×10^9 years. In contrast, Ra-228 has a half-life of 6.7 years. Once taken into the human body, radium acts somewhat similar to calcium. It is incorporated on the surface of the bone into the bone matrix. Raabe et al. (1980) modeled dose and risk and defined the level at which bone cancer will not appear from radium exposure to be 0.04 Gy (4 rad/day), or a total dose of 0.8 Gy (80 rad). A multivariate analyses of the dose–response relationship of the two radium isotopes (Ra-226 and Ra-228) found in the body of a dial painter determined that both isotopes of radium contributed significantly and independently to the rate of mortality from bone sarcomas. The ability of Ra-228 to induce bone sarcomas, per microcurie (μCi) of intake, is two and a half times greater than Ra-226. The term *initial systemic intake* may be used to define the risk of the induction of a bone sarcoma in a dial painter. It is the sum of the activity of Ra-226 (in μCi) that entered the body, plus two and a half times the activity of Ra-228 (in μCi) that entered the body. In another study, British dial painters who were exposed to lower doses of radium and did not ingest radium by brush pointing showed no evidence of bone sarcomas (Baverstock and Papworth, 1985). Bone sarcomas also were observed in patients with tuberculosis, ankylosing spondylitis (AS), and other diseases in

which high doses of ^{224}radium exposure were part of the treatment (Nekolla et al., 2000).

Atomic Bomb Survivors

The greatest number of war-related acute-radiation syndrome deaths occurred when nuclear bombs were detonated over Hiroshima and Nagasaki in August 1945. Within 1–2 km of the epicenter, people received radiation doses as high as several Sv. At distances greater than 2.5 km, irradiation was not significantly above the background. Risk estimates are important because they are used for occupational exposure guidelines. Based on more than 60 years of collected data and a follow-up study of atomic bomb survivors, the Life Span Study (LSS) investigated the radiation effects on human health (Sakata et al., 2012). The LSS cohort consisted of 93,741 atomic bomb survivors and another 26,580 age and sex-matched subjects who were not in either city at the time of the bombing. Radiation doses were computed based on individual location and shielding status at the time of the bombings. Radiation exposure significantly increases the risks of death (22% at 1 Gy), cancer incidence (47% at 1 Gy), death due to leukemia (310% at 1 Gy), and incidence of several noncancer diseases (e.g., thyroid nodules, chronic liver disease and cirrhosis, uterine myoma, and hypertension). Significant effects on maturity (e.g., growth reduction and early menopause) were also observed, as was an increased incidence and mortality of diseases other than cancer. Another similar long-term follow-up study of atomic bomb survivors has provided reliable information on health risks for the survivors and was helpful in establishing radiation protection standards for workers and the public (Fujiwara et al., 2008; Grant et al., 2012; Semmens et al., 2013).

Children Treated with X-Irradiation for Ringworm of the Scalp (*Tinea Capitis*)

Between the 1940s and the 1950s, more than 2,200 children between the ages of 1 and 15 years received x-ray treatment for ringworm of the scalp at New York University Medical Center. When compared to 1,400 control children with essentially the same disease, but treated with other methods, a striking temporal pattern of radiation-induced skin cancer was observed (Shore et al., 1984). No excess risk of skin cancer was noted 20 years postirradiation, but thereafter, the excess risk became pronounced. The risk increased with time, and the excess rates for 20–24, 25–29, and 30–35 years postirradiation were 79, 200, and 420/10^5 person-years (PY) at risk, respectively. The risk for basal cell carcinoma of the skin was highest, and females had a greater mortality rate than males. Also noted was that the risk of skin cancer occurring on the face increased, and lightness of skin complexion was an important risk factor. This suggests that ultraviolet (UV) ray exposure or sensitivity, along with exposure to ionizing radiation, may have a cumulative effect in defining skin cancer risks in these children (Roy et al., 1984; Shore et al., 1984).

Chernobyl, Three Mile Island, and Fukushima Dai-ichi Nuclear Reactor Accidents

The Chernobyl nuclear accident in 1986 resulted in the largest radiation exposure in recent history. The radioactive materials released contained high levels of radioactive iodine (particularly, ^{131}I, with a half-life of 8 days), an element that accumulates in the thyroid gland as a component of thyroid hormone. Following the explosion, people were exposed to deadly radioactive materials estimated to be 100 times greater than that associated with the detonation of the atomic bomb over Hiroshima. In Belarus, thyroid cancer in children under 18 increased from an incidence of 0.03–0.05 cases per 100,000 (1986–1988 data) to more than 10 times that level (5–8 cases per 100,000) in the period 1993–2002. Increases in thyroid cancer also were noted in Ukraine, with rates going from 0.02 per 100,000 (1986–1988 data) to 5–10 times that level (1–2.2 per 100,000) over the period from 1993–2002 (Reiners et al., 2013). There is little doubt that Chernobyl radiation exposure caused thyroid cancer among children in the affected area.

It is worth mentioning that potassium iodide (KI) is a compound that blocks the uptake of ^{131}I. If KI had been available and use of the contaminated milk been discontinued in favor of other sources, it is doubtful that large numbers of thyroid cancers would have occurred after the Chernobyl disaster.

The human health consequences of the accident at the Three Mile Island Unit 2 (TMI-2) nuclear reactor in Pennsylvania in 1979 were minimal. The small radioactive releases at Three Mile Island have had no detectable health effects on plant workers or the public, and a recent study determined that the actual release had negligible effects on the physical health of individuals or the environment (World Nuclear Association report, January 2012).

While it is still too early to determine the long-term health consequences of the Fukushima Dai-ichi accident in 2011, France's Institute for Radiological Protection and Nuclear Safety (IRSN) estimated the maximum external doses to people living around the plant were unlikely to exceed 30 mSv/yr in the first year. People living in Fukushima prefecture are expected to be exposed to around 10 mSv over their entire lifetimes, while for those living farther away, the dose would be 0.2 mSv per year. The findings from several international reports to date (Becker, 2011, 2013; Sugimoto et al., 2014), including a health risk assessment report from the World Health Organization (WHO) in 2011 (http://apps.who.int/iris/

bitstream/10665/78218/1/9789241505130_eng.pdf), concluded that long-term health risks for those individuals with the greatest exposure are possible.

Patients Irradiated with X-Rays for AS

AS patients diagnosed between 1935 and 1957 in the United Kingdom were exposed to x-rays to relieve and/or cure them. Patients received a total body dose of 2.64 Gy during several courses of treatment over a 5-year period; vertebrae received the highest dose. Cancer mortality was significantly higher compared to the expected national rates, and significant increases in leukemia, non-Hodgkin's lymphoma, multiple myeloma, and cancers of the esophagus, colon, lungs, pancreas, bones, bladder, kidney, and prostate, relative to a control population, were observed 6–20 years after exposure. A linear dose–response model for all cancers except leukemia gave a higher relative risk in the period 5–24.9 years after first radiation treatment, but decreased significantly in the period more than 25 years after the first treatment (Weiss et al., 1994).

Miners Exposed to Radon

An increased risk of lung cancer has been demonstrated in miners exposed to radon, including uranium, tin, silver, and coal miners and those mining other substances in radon-contaminated mines. Most cancers from radon are produced by radon daughter decay products (polonium, 3 isotopes; bismuth, 1 isotope; and lead, 3 isotopes) adhering to the delicate cell lining and passageways leading to the lungs. The increase in the excessive relative risks (ERRs) of lung cancers is approximately linear to the exposure, as estimated by cumulative working level months (WLMs) and ranges from 0.002 to 0.08 per WLM of 170 h of exposure. 1 WLM is about 200 picocurie (pCi) per liter of air in a home and 300 pCi/L in an underground mine. Excess lung cancer risk diminishes with time from exposure, and some data show the excess risk may disappear completely 30–40 years after a single exposure (Roscoe et al., 1989; Smigel, 1989). While cigarette smoking is the most common cause of lung cancer and radon represents a far smaller risk for this disease, it is important to note that radon is the second-leading cause of lung cancer in the United States. Scientists estimate that radon exposure is responsible for about 21,000 lung cancer deaths per year in the United States (NCI, 2004; EPA, 2007).

Natural Radioactivity and Background Radiation

Occupational, accidental, and wartime experiences have provided the basis for the estimation of risk to humans following radiation exposure; however, cosmic, cosmogenic, inhaled, and in-body radiation account for total body effective doses of 3 Bq per year. Thus, both natural and artificial sources of ionizing radiation contribute to human exposure and consequently pose a possible risk to human health. Much of this is unavoidable (e.g., natural background radiation), but as the use of radiation increases, so do the potential health risk and the public's concerns (Morgan and Bair, 2013). One such example of exposure to natural radioactivity is exposure to indoor radon gas, which usually is not sufficiently high enough to produce clinical signs. Two main sources for radon in the home are the soil and water supply. Research has shown that the risk of lung cancer from breathing radon in the air is much larger than the risk of stomach cancer from swallowing water with radon in it. If the average indoor radon concentration in a house exceeds 4 pCi/L, a passive system should be activated, including a vent fan to help reduce indoor radon levels. It is interesting to note that indoor air pollution is responsible for most of our total effective radon and total effective radiation dose from natural radioactivity and background radiation. Radon levels are specific to each indoor dwelling; therefore, the average indoor radon concentration level may vary considerably. This variation has led to measuring radon concentration in houses to ensure safety. As stated earlier, radon gas decays into radioactive particles that can get trapped in the lungs during breathing. As they break down, these particles release small bursts of energy, which can damage lung tissue and lead to lung cancer. Not everyone exposed to elevated levels of radon will develop lung cancer, and the amount of time between exposure and the onset of the disease may be many years (Truta et al., 2014). Like other environmental pollutants, there is some uncertainty about the magnitude of radon health risks; however, we know more about the risks of radon because this information is based on studies of miners exposed to radon.

RADIATION HORMESIS

Hormesis is defined as a phenomenon in which a harmful substance gives stimulating and beneficial effects to living organisms when the quantity of the harmful substance is small (Sakai, 2006). Although radiation has been thought to be harmful no matter how low the dose exposure, accumulating evidence suggests that hormesis is a real phenomenon and that bioprotective functions including antioxidant capacity, DNA repair, apoptosis, and immune responses are induced by low doses of radiation (Sakai, 2006; Sanders, 2010; Hamada et al., 2011).

Experimental data support the concept of radiation hormesis, and several review articles provide detailed evidence of this (Ren, 2006; Hoffman and Stempsev,

2008; Liu, 2010; Morgan and Bair, 2013). The effect of low-dose irradiation on the immune system was investigated in mice (Ren et al., 2006). When a 0.2-Gy (20-rad) dose of x-irradiation was administered every other day for a total of four times, the number of lymphocytes yielded by the liver, spleen, and thymus decreased over the first 10 days, but increased above the level of the control mice by day 28. In the same study, the population of natural killer (NK) T cells dramatically increased, especially in the liver, where primordial lymphocytes were present. Functional and phenotypic activation of these cells occurred at the recovery stage, raising the possibility that an initial activation of macrophages by low-dose irradiation mediated the innate immune system (Ren et al., 2006). While data suggested that the low-dose radiation preexposure could induce adaptive responses or bioprotective responses, how low doses of radiation similar to background levels influence human health is still a matter of debate. A number of studies compared natural radiation levels and cancer risk with cancer risk in high-background radiation areas (HBRAs) (Tao et al., 2000; Hendry et al., 2009; Jaworowski, 2010). Interestingly, data from HBRA studies in China, India, Brazil, and the United States showed a decrease in the incidence of cancer and mortality (Wei et al., 1997; Tao, 2000; Sanders, 2010) in these high-risk areas. Future research is needed to assess this issue more completely.

BIOMONITORING AND BIOMARKERS OF RADIATION

The possibility of a radiation disaster from a nuclear detonation or accident has existed for over 45 years. In recent years, national security experts have expressed increasing concern about the threats of radiological and nuclear terrorism. The scenarios by which overt dispersion of radioactive materials, attacks on nuclear power plants, or the detonation of stolen or improvised nuclear weapons might be deployed have been discussed in some detail (Graham et al., 2008). Thousands of victims might not initially show signs and symptoms of radiation toxicity, even if exposed to substantial doses of radiation, or individuals could display signs and symptoms of radiation toxicity despite minimal evidence of exposure. In addition, due to person-to-person variation in response to a given radiation dose, estimates of radiation exposure dose alone will not necessarily predict the extent of radiation injury to organs and tissues.

The U.S. Homeland Security Council and the Office of Science and Technology Policy created the Weapons of Mass Destruction Medical Countermeasure Subcommittee to oversee the research and development of improved countermeasures. This subcommittee listed the development of biomarkers and devices for biodosimetry as one of the highest-priority areas of research (Pellmar and Rockwell, 2005). *Biodosimetry* can be defined as individual dose evaluation based on biological end points induced by ionizing radiation (so-called biomarkers).

There is a critical need for rapid, accurate, and sensitive assays and techniques and diagnostic platforms that can confirm exposure and predict acute and delayed radiation injury to different organs and tissues in victims of radiation incidents. Table 32.3 lists some of the common methods of biodosimetry comparison for radiation exposure. Knowledge about dose levels in radiation protection is an important step in risk assessment; however, in most cases of real or suspected accidental exposures to ionizing radiation, physical dosimetry cannot be performed for retrospective estimates. Because the relationship between biological end points (such as vomiting and diarrhea) and the absorbed dose is not always straightforward, a precise correlation between symptoms and absorbed dose is rarely achieved. In such situations, biodosimetry has been proposed as an alternative for investigation (Ainsbury et al., 2011). The scoring of unstable chromosomal-type aberrations (such as dicentrics, rings, and micronuclei) in mitogen-stimulated peripheral blood is the most extensively used biodosimetry assay to detect radiation exposure. The dicentric assay is the gold standard in biodosimetry since the presence of dicentrics is generally considered to be specific to radiation exposure; however, the scoring of micronuclei is easier and faster than that of dicentrics for dose assessment (Blakely et al., 2001). While biodosimetry techniques and devices can be useful in determining whether radiation exposure occurred, these methods cannot assess interindividual differences to radiation sensitivity, which are influenced by an individual's genotypic composition and heterogeneity in the dose of radiation received. Furthermore, these techniques and devices do not predict the severity of injury sustained by specific organs and tissues and thus do not allow for the prompt organ- and tissue-directed medical treatment. There is a critical need to develop radiation-specific biomarkers and devices to predict acute and delayed damage to specific organs and tissues. Such developments are underway and should facilitate precise and timely medical intervention, reduce morbidity, and save lives.

Protein biomarker-based dosimetry multiparameter approaches are able to provide dose assessment over extended time ranges. The levels of a number of proteins are up- or down-regulated, and enzymatic modifications occur as a consequence to irradiation. Such changes can be identified in cells, tissues, urine, and blood samples using a range of biochemical methods. High-throughput, antibody-based assays have also been developed to identify and quantify radiation-responsive protein biomarkers (Partridge et al., 2010). Proteomic

approaches to detect global changes in protein expression and composition are promising for the discovery of clinical biomarkers of radiation, but they warrant further study.

Another diagnostic instrument is a metabolomics biomarker, which is a noninvasive tool that studies small-molecular-weight molecules and metabolites. Radiation metabolomics seeks to define patterns of metabolic changes that are associated with exposure to radiation (Coy et al., 2011). An interesting approach is underway that utilizes information from microbiomes. The human microbiome consists of a population of more than 100 trillion microorganisms that live in the mouth, nasal cavities, GI tract, urogenital tract, skin, and other places in the human body. Several studies in the 1950s and 1960s, prompted by the development of atomic bombs, attempted to identify specific bacteria in the feces that were sensitive to radiation. Along with animal studies, a recent study provided some evidence of a decrease in *Escherichia coli* in the feces of cancer patients in the first days after undergoing radiotherapy (Packey and Ciorba, 2010). In this study, a PhyloChip assay developed by Second Genome, Inc., identified changes in the levels of 212 bacteria. The microbial changes seen after exposure persisted for 3 weeks and also showed significant increases in the number of the proteobacteria. If similar microbial signatures are identified in radiation-exposed patients, this assay may become a noninvasive and cost-effective way to triage and treat a large number of the population with potential radiation exposure.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Radiation has existed for more than 3 billion years. Radiation is of concern because it cannot be seen, and although exposure is frequently not painful, it can cause significant physiological damage. Ionizing radiation has both positive and negative aspects; when released by nuclear weapons, it can cause agonizing death, but treatment with it (for certain diseases) can save lives. Appreciation of the potentially devastating effects of radiation arose in the early twentieth century with the plight of the radium dial workers, but widespread fear of radiation was not established until nuclear weapons were used to destroy Hiroshima and Nagasaki in 1945. Today, the choices made with regard to the use of radiation require careful consideration. Nuclear power stations carry immense risk, as shown by the accidents at Three Mile Island, Chernobyl, and Fukushima Dai-ichi and the future possibility of a radiation disaster from a nuclear detonation or accident remains high. In recent years, national security experts have expressed increasing concern about the threats of radiological and nuclear terrorism. Overt dispersion of radioactive materials, attacks on nuclear power plants, or the detonation of stolen or improvised nuclear weapons are real concerns. During emergencies, there need to be multiple technologies that can be used to monitor radiation exposure levels. The current gold standard for biodosimetry radiation exposure is chromosomal aberration analysis, which involves a team of skilled personnel, expensive equipment, and several days to complete; however, these requirements make the technique not readily applicable for triage in the case of a nuclear detonation. There are complementary, blood-based methodologies that measure the biological processes affected by ionizing radiation. The advantages of these methods are that they yield immediate information and that they measure cellular damage rather than the dose received; however, the disadvantages are that the measurements may not be specific to radiation damage. There are also physically based dosimetry methods that estimate radiation dose by changes to the teeth and nails. With these methods, there is no complex variation by time or response, but the disadvantages include the relatively low sensitivity and with no internal control, the heterogeneity of the reporting signal is always there, and the resolution is low. The most useful markers are those that are most specific and quantitatively predictive of radiation-induced severity. This chapter addressed the need for the development of new biomarkers, including protein products, physiological markers, and metabolites. Research and development on biomarkers to monitor radiation tolerance and advances in the field of radiation markers of tissue toxicity are expected in the next decade.

Acknowledgments

The authors would like to acknowledge the excellent contribution of Dr. John Pickrell, Kansas State University, in writing the first edition of this chapter. The views expressed here are the authors' own and do not represent any institution, organization, or funding body.

CHAPTER

33

Depleted Uranium

George C-T Jiang and Michael Aschner

INTRODUCTION

Uranium (U) is a naturally occurring heavy metal that is radioactive and ubiquitous (ATSDR, 1999; Harley, 1999; Jiang and Aschner, 2006). Depleted uranium (DU) is the by-product of the enrichment process of uranium for its more radioactive isotopes. Enriched uranium (EU) is used for nuclear energy, whereas DU is used in other applications that require a heavy metal, such as aviation counterweights and naval ballasts. Because of its pyrophoric and dense metallic properties, DU is used primarily by the military in armor and ammunitions. DU retains 60% of its natural radioactivity and, as such, there are health hazards associated with exposure to the retained inherent radioactivity, but the radiological risks are less than those of natural uranium. However, the chemical toxicity of DU cannot be overlooked and the possibility that it exerts specific chemical toxicological effects separate from its radiological effects has been a subject of intense investigation.

There has been significant public concern regarding the use of DU by the military. For instance, it has been hypothesized that DU may be a cause of Gulf War Syndrome. The public concern also stems from the lack of awareness regarding the specific physical chemistry and hazards of DU, and the belief that DU is still a form of uranium and therefore radiologically hazardous. These concerns have given rise to the belief that DU may be used as a weapon of mass destruction in the form of a dirty bomb, or as an agent of bioterrorism.

BACKGROUND

Small amounts of uranium are found in rock, soil, air, water, and food, and it is estimated that total annual intake of uranium by human adults approximates 460 μg by ingestion of food and water and 0.6 μg by inhalation (Fisenne et al., 1983; UNSCEAR, 2000a,b; Pietrzak-Flis et al., 2001). Natural uranium is composed of three isotopes, ^{234}U, ^{235}U, and ^{238}U, in the proportions shown in Table 33.1.

DU is formed as a by-product of the enrichment of naturally occurring uranium for its most radioactive isotope ^{235}U. As such, DU contains significantly less ^{235}U and more ^{238}U. EU contains much greater levels of ^{235}U, ranging from 3% to more than 90%, whereas its ^{238}U content is decreased from less than 10–97%. For every 1 kg of uranium enriched to 3% ^{235}U during the enrichment process, approximately 5 kg of DU (as a fluoride, UF_6) is produced (Bem and Bou-Rabee, 2004; Jiang and Aschner, 2006). It is estimated that 700,000 tons of UF_6 are stored in the United States, and that each year the mass of accumulated DU increases by 30,000 tons (Hartmann et al., 2000; Bem and Bou-Rabee, 2004; Jiang and Aschner, 2006).

DU has 40% less radioactivity than natural uranium but may contain trace levels of plutonium, neptunium, americium, technetium, and ^{236}U, which increase the radioactivity by 1% but are insignificant with respect to chemical and radiological toxicity (WHO, 2001; Sztajnkrycer and Otten, 2004). Because of the decreased radioactivity of DU, it is believed that DU is a safer form than natural uranium while maintaining the same chemical properties. As the heaviest occurring element, uranium is extremely dense, and both uranium and DU

TABLE 33.1 Forms of Uranium and Their Respective Isotope Percentages

	Forms of Uranium		
Isotope	**Natural**	**Depleted**	**Enriched**
^{238}U	99.275%	99.8%	<10% to 97%
^{235}U	0.720%	0.2%	3% to >90%
^{234}U	0.0055%	0.001%	0.03%

are often used in applications that require such dense metals.

This chapter describes DU and its applications in weapons of mass destruction. The DU exposure pathways, pharmacokinetics, health effects, toxicity, and available treatments are also reported.

Civilian Uses of DU

DU in civilian applications is marginal compared with its use in military applications (Cantaluppi and Degetto, 2000; Betti, 2003; Bem and Bou-Rabee, 2004; Jiang and Aschner, 2006). As a heavy metal, DU is used as ballasts in yachts, counterbalances in commercial jets, shielding in radiation therapy, and as containers for transportation of radioactive materials (Mould, 2001; Betti, 2003; Sztajnkrycer and Otten, 2004; Jiang and Aschner, 2006). DU has also been used in glassware and ceramics, and even historically in dentistry as parts of dental porcelain (Betti, 2003). Considering ingestion, inhalation, and dermal exposure as the typical routes of exposure, typical civilian exposure to uranium from food, water, and air is considered minimal under normal circumstances (Fisenne et al., 1988). These exposures are well below the daily tolerable intake levels for soluble uranium (0.5 μg/kg body weight), insoluble uranium (5 μg/kg body weight), and inhaled uranium (1 $\mu g/m^3$ in the respirable fraction), as set forth by both the World Health Organization (WHO) and Agency for Toxic Substances and Disease Registry (ATSDR) (ATSDR, 1999; WHO, 2001). Because uranium is present in greater levels in war-ravaged regions, it is believed that uranium may pose a potentially greater exposure danger to civilians in these regions (Bleise et al., 2003; Bem and Bou-Rabee, 2004).

Military Uses of DU

The major use of DU is by the military as an alloy in armor and ammunition. These applications take advantage of the unique metallic properties of DU, specifically the density and pyrophoric properties. Uranium is the heaviest naturally occurring element and is extremely dense. Uranium has a density 1.7-times the density of lead, and rods made of uranium are resistant to deformation (Bem and Bou-Rabee, 2004). Uranium shielding is therefore used in the armor of military armored vehicles, allowing the deflection of enemy projectiles. Furthermore, alloys of uranium that contain 2% molybdenum or 0.75% tungsten have a unique attribute such that they will sharpen themselves on impact with a hard target, which allows for greater penetration of uranium-based projectiles compared with traditional tungsten-based alloys (Jiang and Aschner, 2006). DU is also pyrophoric, such that particles will ignite at relatively low temperatures. Fine particles will burn rapidly at relatively low temperatures (150–175°C), whereas particles will spontaneously burn violently with air hotter than 600°C, releasing heat and uranium oxide aerosols (Harley, 1999; Bem and Bou-Rabee, 2004). These unique properties of uranium make it an excellent material for military applications.

It is estimated that 300 tons of DU were used in the aircraft rounds and tank-fired shells in Kuwait and southern Iraq over an area of 20,000 km^3 during the 1991 Gulf War (Operation Desert Storm) (Bem and Bou-Rabee, 2004). Studies have shown that DU penetrators hitting armored targets convert 17–28% of a projectile's mass into DU aerosols (Harley, 1999; Parkhurst, 2003; Bem and Bou-Rabee, 2004). Of these aerosols, 83% are S-type (S for slow dissolution) oxides, whereas 17% are M-type (M for medium dissolution) oxides, and the respirable fraction (diameter <10 μm) may be 50% of the total mass of the aerosol (Harley, 1999; Jiang and Aschner, 2006). This would mean that of 50 tons of tank-fired and 25 tons of aircraft-fired DU munitions, 10 tons of uranium oxides, would have been released into the air in the form of respirable uranium (Jiang and Aschner, 2006).

The US Department of Defense (DOD) has conducted studies to evaluate distribution of aerosolized DU after destruction of an armored tank to assist in determining DU health risk (Harley, 1999). The concentration of uranium inside a tank can reach hundreds or thousands of mg/m^3 just after an explosion caused by a DU penetrator (Harley, 1999). Because uranium has such a high density, the aerosolized DU particles fall within 10 m of a burning tank. The US DOD estimates that the DU intake of a person in the vicinity of a tank hit by a single 120-mm DU-containing projectile is 0.1-mg uranium, and the maximum intake in traversing a cloud of smoke plume that is 200 m in length is 0.8 μg of uranium (Harley, 1999; Parkhurst, 2003; Bem and Bou-Rabee, 2004). These US DOD studies demonstrate that the risks of uranium inhalation are greatest for crews of damaged tanks and rescue teams (Jiang and Aschner, 2006).

Because the DU particulate matter can be carried by winds and deposited in soil and water, there are concerns that both civilian and military units may be exposed to DU dust, vapors, and aerosols, particularly as military conflicts continue. The concerns regarding the unknown exposure data of these individuals have spurred recent studies of war veterans and civilians living in war-ravaged regions to try to determine if DU has human health and environmental impacts. These studies are often general survey studies that look for any signs of adverse human health effects, either radiological or chemical (Bleise et al., 2003; Danesi et al., 2003a; Durakovic, 2003; Milacic et al., 2004; Hindin et al., 2005; Oeh et al., 2007b; Carvalho and Oliveira, 2010; Alaani et al., 2011, 2012).

EXPOSURE PATHWAYS AND BODY RETENTION OF DU

The chemical toxicity of DU is only an issue if the metal is internalized. The three traditional pathways of exposure are inhalation, ingestion, and dermal contact (Figure 33.1). Typically, in nonmilitary situations, the main routes of natural uranium uptake are by inhalation and ingestion. Because of the use of DU in ammunitions and armor by the military, the more important routes of exposure are inhalation and internalization of the DU (Figure 33.1). This internalization of the DU results from embedding of DU projectile fragments (shrapnel) because of explosions of DU-containing armor and ammunitions. Follow-up studies of 1991 Gulf War veterans with embedded DU shrapnel have attempted to determine if there are adverse health effects associated with internalized DU (McDiarmid et al., 1999, 2000, 2001a,b, 2002, 2004a,b, 2006, 2007, 2009, 2011a,b, 2013; Ejnik et al., 2000, 2005; Hodge et al., 2001; Gwiazda et al., 2004; Brown, 2006; Squibb and McDiarmid, 2006; Cazoulat et al., 2008; Bakhmutsky et al., 2011, 2013; Todorov et al., 2013). Several animal studies have also been completed to mimic the effects of DU fragments in humans (Pellmar et al., 1999a,b; Arfsten et al., 2001, 2005, 2006, 2007, 2009; Hahn et al., 2002; Leggett and Pellmar, 2003; Lestaevel et al., 2005; Linares et al., 2005; Fitsanakis et al., 2006).

Inhalation

Inhalation is a likely route of intake of DU, primarily because of its use in DU munitions, whereas naturally occurring uranium dust particles are only inhaled in very small quantities (ATSDR, 1999; Jiang and Aschner, 2006). Studies of people in New York City show that approximately 1 μg of uranium is inhaled each year by each person (Fisenne and Welford, 1986; Fisenne et al., 1987; ATSDR, 1999; Harley, 1999). Inhalation risk from DU is attributable to the aerosolization after the impact of ammunitions, forming DU oxides and particles. These particles become suspended in the air by the wind or settle into the environment for later resuspension. For example, it was determined that the estimated mean annual concentration of suspended matter in ambient air in Kuwait after the 1991 Gulf War was 200 $\mu g/dm^3$, one of the highest concentrations in the world (Bem and Bou-Rabee, 2004). With the increased scrutiny of DU, several studies have looked at the air concentrations in or near conflict arenas where DU aerosols would likely be present; these studies, performed after conflict, show that uranium levels in the air are not higher than background levels because the DU particles are quickly dispersed (Jia et al., 2005; Carvalho and Oliveira, 2010; Yousefi and Najafi, 2013).

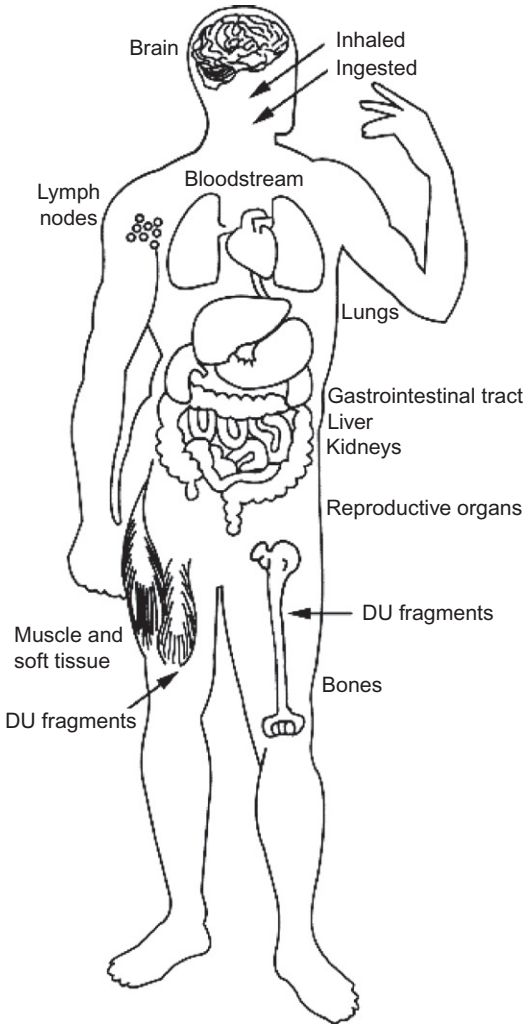

FIGURE 33.1 Routes of DU entry into the body and the corresponding target organs where DU has been shown to accumulate.

The particle size of the aerosolized DU and its correlated physical and chemical properties (e.g., solubility) have a significant impact on how far into the lungs the particles will penetrate, and if they will result in deposition in the respiratory tract (ATSDR, 1999). Only small particles less than 10 μm in diameter will reach and accumulate in the bronchioles and alveoli, whereas larger particles are effectively cleared by mucociliary clearance (Harley, 1999; WHO, 2001; Gwiazda et al., 2004). These respirable particles present a potential health hazard from uranium inhalation, but studies have shown than less than 1% of inhaled uranium actually reaches the kidneys (Spencer et al., 1990; Harley, 1999; WHO, 2001; Gwiazda et al., 2004). These studies have demonstrated that of the uranium that is inhaled, 75% is exhaled and 25% is retained in the respiratory tract and lungs. Of the retained fraction of uranium in the lungs, 80% is removed by bronchial clearance, 15% is deposited in lymph nodes, and 5% actually enters the blood (Spencer et al., 1990; Harley, 1999).

Ingestion

Soil ingestion by children is an important exposure pathway but typically, for humans, ingestion is only an important route of entry if food and drinking water are contaminated by DU (Jiang and Aschner, 2006). The average daily intake of uranium from food and water is estimated to be between 1 and 5 μg/day from uncontaminated areas (ATSDR, 1999; Harley, 1999). In uranium mining areas, ingestion has been found to range between 13 and 18 μg/day (ATSDR, 1999; Harley, 1999). Obviously, these concerns of adverse health effects from DU-contaminated food and drinking water are amplified in battlefield arenas, such as Iraq, Kuwait, the Balkans, and Afghanistan. A number of studies have demonstrated increased uranium levels in the soil in these sites several years after the conflict (Sansone et al., 2001a,b; Danesi et al., 2003a,b; Durante and Pugliese, 2003; Bem and Bou- Rabee, 2004; Di Lella et al., 2004, 2005; Jia et al., 2005, 2006; Oliver et al., 2007, 2008a,b; Zunic et al., 2008; Giovanetti et al., 2010). To date, there have been a number of studies that have attempted to link higher malignancy rates and genotoxic effects in these regions with varying degrees of correlation (Milacic et al., 2004; Obralic et al., 2004; Milacic, 2008; Milacic and Simic, 2009; Darolles et al., 2010; McDiarmid et al., 2011a; Bakhmutsky et al., 2013). Furthermore, bone ash data indicate significant baseline uranium differences across countries (Fisenne et al., 1980, 1983, 1988; Fisenne and Welford, 1986), and there is no clear indication as yet that these different levels of uranium have led to any adverse health consequences (ATSDR, 1999; Harley, 1999).

The solubility of the uranium compound is an important consideration in determining adsorption and distribution because toxicity is related to uptake efficiency of the gastrointestinal (GI) tract. Generally, absorption is increased with the increased solubility of the compound. Uranium oxides (U_3O_8 and UO_2) are relatively insoluble (types M and S; M for medium and S for slow dissolution), whereas uranium trioxide (UO_3) is more soluble (between type M and F; F for fast dissolution). These more insoluble forms are less likely to enter the bloodstream and cause toxicity. However, uranyl nitrate hexahydrate, uranium hexafluoride, or uranyl fluoride are all relatively soluble forms and tend to be absorbed through the GI epithelium. However, unlike other heavy metals, uranium is not efficiently absorbed through the intestinal lumen (Spencer et al., 1990; ATSDR, 1999; Harley, 1999). Studies in humans ingesting uranium nitrate in spiked grapefruit juice demonstrate only 0.5–5% absorption of the original dose (Karpas et al., 1998) (IARC publication). Only 0.2–2.0% of uranium in food and water is absorbed by the GI tract; of the amount that is absorbed, 67% will be filtered out by the kidneys and excreted in the urine within the first 24 h (ATSDR, 1999; Harley, 1999; WHO, 2001).

Dermal Contact and Embedded Fragments

Dermal absorption has not been characterized in human studies, and there have not been any dermal effects reported from uranium miners, millers, or processors (ATSDR, 1999). There have also been no human deaths related to dermal exposure of uranium. Dermal contact is not an important route of exposure because DU does not pass through the skin into the blood unless there are open wounds or embedded fragments (ATSDR, 1999; Harley, 1999; WHO, 2001).

Embedded DU-containing shrapnel, if not removed, is a permanent exposure source within the body and will allow the DU to enter the systemic circulation. The DU Follow-Up Program at the Baltimore Veterans Administration Medical Center has been surveying a small population of approximately 230 soldiers since the 1991 Gulf War, and reports from this program have shown that the uranium leaches into the circulation, resulting in elevated urinary uranium levels compared with those of control patients (McDiarmid et al., 1999, 2000, 2001a,b, 2002, 2004a,b, 2006, 2007, 2009, 2011a,b, 2013; Ejnik et al., 2000, 2005; Hodge et al., 2001; Gwiazda et al., 2004; Squibb et al., 2005, 2012; Brown, 2006; Squibb and McDiarmid, 2006; Cazoulat et al., 2008; Bakhmutsky et al., 2011, 2013; Todorov et al., 2013).

PHARMACOKINETICS

Adsorption

Ingestion

Uranium ingested from food and water consumption ranges from 1 to 5 μg of uranium in uncontaminated regions to 13–18 μg of uranium in uranium mining areas (ATSDR, 1999). The absorption of uranium across the GI tract is related to the solubility of the compound and generally increases with increased solubility. Only a small fraction is absorbed of even the relatively soluble uranium compounds, such as uranyl nitrate hexahydrate, uranium hexafluoride, or uranyl fluoride. For example, studies have shown that humans ingesting uranium nitrate hexahydrate or uranyl nitrate absorb only 0.5–5% of the original dose (Hursh et al., 1969; Karpas et al., 1998). In animal studies with uranyl nitrate and uranium dioxide directly intubated into the GI tract, only 0.77% and 0.11% of the total doses, respectively, were absorbed (Harrison and Stather, 1981). Studies in rats with an intragastrically applied relatively insoluble form of uranium, UO_2 (type S dissolution), showed that uranium could not be detected in liver, kidney, muscle, bone, brain, blood, and urine, and that uranium was not absorbed or retained significantly in the epithelial cells of the intestinal wall (Lang and Raunemaa, 1991).

Inhalation

Typically, uranium is present in limited concentrations in the air, and uranium particle inhalation is minimal (ATSDR, 1999; Harley, 1999). Uranium particle deposition in the respiratory tract is governed by the physical forces that effect particle behavior in the air, as well as the anatomy of the respiratory tract (ATSDR, 1999; Bleise et al., 2003; Chazel et al., 2003; Phalen and Oldham, 2006; Cheng et al., 2009; Valdes, 2009). The anatomy of the lungs is important because this affects the clearance mechanisms available to deal with deposited particles and the degree of actual uranium absorption that will occur. In addition to the aerodynamic diameter (AD) of the particle, the solubility of the inhaled uranium is an important determinant regarding how much uranium will be absorbed (Lang and Raunemaa, 1991; Eidson, 1994).

Most inhaled uranium particles have an AD that does not permit them to be carried deep in the lungs (Igarashi et al., 1987; ATSDR, 1999). Studies have shown that only small uranium particles less than 10 μm in diameter will reach and accumulate in the bronchioles and alveoli, whereas larger particles are effectively cleared by mucociliary clearance (Harley, 1999; WHO, 2001; Gwiazda et al., 2004). These inhaled respirable particles do present a potential health hazard from uranium inhalation, but studies have shown that less than 1% of inhaled uranium actually reaches the kidneys (Morris et al., 1990; Spencer et al., 1990; Lang et al., 1994; Harley, 1999; WHO, 2001; Gwiazda et al., 2004). Studies have demonstrated that of the uranium that is inhaled, 75% is exhaled and 25% is retained in the respiratory tract and lungs. Of the retained fraction of uranium in the lungs, 80% is removed by bronchial clearance, 15% is deposited in lymph nodes, and 5% actually enters the blood (Spencer et al., 1990; Harley, 1999).

Dermal

In animal studies, soluble uranium compounds have been shown to penetrate the skin of rats within 15 min of application (de Rey et al., 1983). The penetration was as high as 7 g/kg body weight for ammonium uranyl tricarbonate, whereas uranyl nitrate hexahydrate ranged from 0.5 to 7 g/kg body weight. No penetration through the skin was observed when uranium dioxide, a more insoluble form, was applied (de Rey et al., 1983). Two days after exposure, dermally absorbed uranium was no longer localized to the epithelium, and rats either had significant weight loss or had died. Other studies have demonstrated that other uranium compounds (uranium tetrafluoride, uranium tetrachloride, and uranium trioxide) are absorbed through the skin of mice, rats, and guinea pigs at a rate of 0.1% of dermally applied uranium, which is a relatively low absorption rate (Orcutt, 1949). These studies show that soluble uranium compounds can be absorbed through the skin. However, the concentrations of uranium applied to the skin were extremely high, and it is unlikely that humans would typically experience such exposures. Dermal absorption has not been characterized in humans (ATSDR, 1999).

Distribution

Once absorbed into the system circulation, uranium undergoes chemical transformations to complex with the blood. Uranium in the trivalent form will oxidize to the hexavalent species to form uranyl ions, which form soluble complexes with bicarbonate, citrate, or proteins in the plasma (Chevari and Likhner, 1968; Stevens et al., 1980; Cooper et al., 1982). The distribution of uranium in the blood is approximately 47% complexed with bicarbonate in plasma, 32% bound to plasma proteins, and 20% bound to erythrocytes (Chevari and Likhner, 1968, 1969).

Uranium is then distributed by the systemic circulation primarily to the bones and kidneys. Of the total absorbed uranium, 85% is associated with bone, where uranium replaces calcium in the hydroxyapatite complex (Donoghue et al., 1972). Of the remaining 15% uranium, more than 90% is associated with the kidneys, accumulating primarily in the proximal tubule (ATSDR, 1999). Uranium also distributes in detectable amounts to the liver, brain, testes, and spleen (Pellmar et al., 1999a; Leggett and Pellmar, 2003; Fitsanakis et al., 2006). The embedded uranium fragments continuously release uranium into the circulation, and the fragment size diminishes with time.

Less soluble uranium compounds (type M and type S dissolution), which are not effectively absorbed, are distributed in bronchial lymph nodes as well as the lung tissue itself (Leach et al., 1970, 1973).

Metabolism and Excretion

Once uranium is in the systemic circulation, it is transported as various complexes in the blood. The predominant form of uranium is as a bicarbonate complex, the stability of which is highly dependent on the pH of the solution (Chevari and Likhner, 1968; ATSDR, 1999). In the kidneys, the bicarbonate complex is filtered at the renal glomerulus and excreted in the urine (Bowman and Foulkes, 1970; Foulkes, 1971; Adams and Spoor, 1974; Blantz, 1975; Blantz et al., 1985; Brady et al., 1989; ATSDR, 1999). Protein-bound uranium will remain in the blood because little protein passes through the glomerulus.

Studies using humans have shown that approximately 66% of an intravenous injection of uranium is eliminated from the plasma within 6 min, whereas 99% of the uranium is eliminated from the plasma 20 h after injection (Luessenhop et al., 1958; ATSDR, 1999; Harley, 1999). Another study has shown that the kidneys excrete

more than 90% of intravenously injected soluble hexavalent uranium salt, with less than 1% excreted in the feces; approximately 70% of the dose is excreted within the first 24 h (Bassett et al., 1948).

Oral Exposure

The average GI uptake of uranium is limited, ranging from 1% to 5% in adult humans (Leggett and Harrison, 1995; ATSDR, 1999). Absorption generally increases with increasing solubility of the compound. It is highest for the soluble uranium compounds; nevertheless, only a small fraction of uranium is absorbed across the GI epithelium. Uranium absorption takes place predominantly in the small intestine, with no absorption from the buccal cavity, stomach, or large intestine (Dublineau et al., 2005). Measured with *ex vivo* techniques, the apparent uranium permeability was shown to be similar in various parts of the small intestine (Dublineau et al., 2005). Uranium transport across the GI epithelium likely occurs via a transcellular pathway. Approximately 90% of the ingested uranium in humans is excreted in the feces without being absorbed, whereas the remainder is excreted in the urine (Wrenn et al., 1985; Spencer et al., 1990; Oeh et al., 2007a,b). Studies using rats show similar excretion patterns to humans, of which the majority of ingested uranium (99%) is eliminated in the feces and 95% of the absorbed uranium is excreted in urine within 1 week of exposure, with a half-life of 2–6 days (Wrenn et al., 1985; La Touche et al., 1987; Dublineau et al., 2005).

Inhalation Exposure

The rate of deposition and clearance of uranium-containing particles from the lung depends on its chemical form and particle size. As previously discussed in the adsorption section, most of the larger uranium particles are transported out of the respiratory system by mucocilliary action or swallowed and eliminated in the feces. Smaller particles with higher solubility are more rapidly absorbed into the systemic circulation, but can be excreted in the urine.

The aerosol by-products of exploded DU munitions are primarily the uranium oxides with varying dissolution rates. Uranium trioxide (UO_3) is soluble like uranyl salts, and systemic absorption accounts for more than 20% of the exposure burden, with 20% of the excreted uranium being in the urine (Morrow, 1964; Morrow et al., 1964, 1972, 1982). UO_3, being soluble, has a fast dissolution rate (type F) and is rapidly removed from the lung (half-life of 4.7 days). Uranium dioxide (UO_2) and triuranium octaoxide (U_3O_8) are relatively insoluble and have slow dissolution rates (type S), resulting in pulmonary clearance rates dominated by particle size and mucocilliary transport out of the lungs. In humans, studies of these insoluble uranium compounds suggest a two-phase clearance process consisting of a short phase with a biological half-time of between 11 and 100 days and a slow phase of clearance with a biological half-time between 120 and 1,500 days (Hodge, 1973; Eidson, 1994; Taylor and Taylor, 1997).

Embedded Fragment Exposure

DU fragments from embedded shrapnel act as reservoirs to continuously release uranium into the circulation (Pellmar et al., 1999a; Leggett and Pellmar, 2003; Arfsten et al., 2006; Fitsanakis et al., 2006; Jiang and Aschner, 2006; Zhu et al., 2009). Significant percutaneous diffusion of soluble uranium through intact skin has been described (de Rey et al., 1983; Lopez et al., 2000; Petitot et al., 2007a,b). In rats, the absorption of uranium via deep wounds was shown to depend on the chemical form of uranium. On intramuscular injection of uranium nitrate, approximately 98% of the uranium was in the blood (Houpert et al., 1999). In contrast, after UO_4, 70% and 85% of instilled uranium was found in the blood after 1 and 3 days, respectively (Houpert et al., 1999).

Surgical removal of fragments attempts to remove as many fragments as possible, but often there will be residual fragments that cannot be removed because of location and/or size. Over time, the fragment sizes will decrease as the uranium leaches from these fragments; the body has no other way to effectively remove such embedded fragments.

MECHANISM OF ACTION

There have been many *in vitro* studies evaluating the toxic effects of uranium in different cell types, many of which demonstrate cytotoxicity. There is no specific mechanism that emerges to explain all the results, but the weight of evidence suggests that DU-induced cytotoxicity may result from oxidative stress and eventual cell death. Uranyl compounds have high affinity for phosphate, carboxyl, and hydroxyl groups, and they easily combine with proteins and nucleotides to form stable complexes (Weir, 2004). DU can cause oxidative DNA damage by catalyzing hydrogen peroxide and ascorbate reactions, resulting in single strand breaks in plasmid DNA *in vitro* (Miller et al., 2002a,b; Yazzie et al., 2003). Evidence for induction of oxidative stress and reactive oxygen species (ROS) by DU has been shown by increases in NO (Abou-Donia et al., 2002), lipid oxidation (Briner and Murray, 2005; Ghosh et al., 2007; Jiang et al., 2007; Periyakaruppan et al., 2007; Lestaevel et al., 2009; Daraie et al., 2012; Shaki et al., 2013), transcriptomic, and proteomic changes (Malard et al., 2005; Prat et al., 2005; Periyakaruppan et al., 2007). Moreover, some studies indicate that heat shock proteins may be involved in the cellular response to DU exposure and acquired resistance to uranium rechallenge (Furuya

et al., 1997; Mizuno et al., 1997; Tolson et al., 2005). These data strongly suggest the possibility that uranium may result in the formation of ROS, leading to cell death. An apoptotic mechanism has even been suggested after a study during which significant apoptotic events were seen in mouse macrophage cells treated with 100 μM DU (Kalinich et al., 2002).

TOXICITY OF DU EXPOSURE

Scientists in the mid nineteenth century first believed that natural uranium had homeopathic properties and could be an effective treatment for diabetes and albuminuria after promising results in animals and humans dosed with uranium (Hodge, 1973; Jiang and Aschner, 2006). However, animal studies in the early twentieth century showed that uranium was not therapeutic, and the misuse of uranium in humans was halted (Hodge, 1973). There is extensive literature regarding the toxicology of uranium, which now includes studies specifically of DU. The following section highlights a number of key *in vitro*, animal, and human studies of DU as they relate to health effects from uranium exposure. Chemical toxicity of uranium only poses a threat if the metal is internalized.

Nephrotoxicity

The kidney is the major target organ for uranium toxicity (ATSDR, 1999; Harley, 1999; Jiang and Aschner, 2006; Aschner and Jiang, 2009). Renal toxicity associated with uranium exposure results as the kidneys work to eliminate internalized uranium, and this has been known for two centuries (Goodman, 1985). In the kidneys, the site of action is the proximal tubule where proton secretion degrades the bicarbonate complex of the uranyl ion. Uranium can then react with apical cell membranes of the tubule epithelium (Goodman, 1985; Harley, 1999). Nephrotoxicity is clearly associated with uranium exposure and has been documented in animal studies at high exposure levels (Leggett, 1989; Harley, 1999; Sztajnkrycer and Otten, 2004). Recent *in vitro* studies of renal cells demonstrated a concentration-dependent uranium toxicity (L'Azou et al., 2002; Carriere et al., 2004; Thiebault et al., 2007). Any observed uranium nephrotoxicity results from acute exposure. Currently, there is no evidence that DU has any long-term effects on renal function, or that long-term renal impairments will develop if no acute effects are seen (ATSDR, 1999; Harley, 1999; Jiang and Aschner, 2006; Aschner and Jiang, 2009). There is even evidence in animals and humans that there may be repair of damaged tubular epithelial tissue (Goodman, 1985; Diamond et al., 1989; Harley, 1999).

Carcinogenicity

Bones

Bones are the secondary target organ of uranium toxicity (ATSDR, 1999). The majority of absorbed uranium is distributed to the bones and, not surprisingly, the carcinogenic potential of uranium in bones has been explored in uranium workers and personnel living in or having served in the war-ravaged regions potentially exposed to DU (Harley, 1999; Abu-Qare and Abou-Donia, 2002; Boice et al., 2003a–c, 2007; Obralic et al., 2004; Storm et al., 2006).

Animal studies to mimic injuries of Gulf War veterans and to assess the chronic effects of internalized DU have utilized rats implanted with DU and control tantalum pellets (de Rey et al., 1984; Miller et al., 1998b; Pellmar et al., 1999a,b; Hahn et al., 2002; Leggett and Pellmar, 2003; Arfsten et al., 2005, 2006, 2007, 2009; Fitsanakis et al., 2006; Zhu et al., 2009). Carcinogenicity of these surgically implanted DU fragments has been evaluated and is related to the size of the fragments—DU fragments of sufficient size can cause localized proliferative reactions and soft tissue sarcomas (Hahn et al., 2002). Urine and serum mutagenicity studies with rats implanted with DU demonstrated enhanced mutagenic activity in the *Salmonella* TA98 strain and the Ames II mixed strain (TA7001–7006) in a dose-dependent manner with excreted urinary concentration (Miller et al., 1998b). There are numerous other studies that demonstrate the deleterious effects of DU on viability, micronuclei, chromosomal instability, and sister chromatid exchanges by human bronchial, bone marrow, and Chinese hamster ovary cells (Kennedy and Saluga, 1970; Kadhim et al., 1992, 1994; Nagasawa and Little, 1992; Lin et al., 1993; Schroder et al., 2003; Stearns et al., 2005; Holmes et al., 2014). However, it is still unclear if the mutagenic and carcinogenic effects are a result of the chemical or radiological effects of DU, but it is believed that these effects are primarily due to the latter. Osteosarcoma risk has clearly been demonstrated to be related to the amount of radiation exposure, and there is a wealth of *in vitro* studies of bone cells and animal models that illustrate this (Miller et al., 1998a, 2001, 2003, 2005; Ibrulj et al., 2004, 2007; Miller and McClain, 2007). However, many scientists believe that the amount of radiation emitted by DU is insufficient to raise a significant risk in humans, but may be more of a concern for children whose bones are growing rapidly (Brugge et al., 2005; Jiang and Aschner, 2006; Aschner and Jiang, 2009).

Lungs

It is often difficult to pinpoint specific cancerous agents using epidemiological studies (Priest, 2001) but, because the lungs are the primary portal of inhaled uranium, numerous studies have examined the health

effects of inhaled uranium. It has been known since the 1940s that the most soluble uranium compounds are the most toxic (Voegtlin and Hodge, 1949a,b). Early animal studies did not reveal significant animal mortality from inhalation unless very soluble forms of uranium were used. However, most of the effects of uranium on the lungs occur because of the insoluble forms of uranium. Researchers have found that the lungs and tracheobronchial lymph nodes are the major sites of uranium accumulation for large particles and relatively insoluble forms of uranium, and fibrotic changes in the lung tissue have been observed that are suggestive of radiation injury (Leach et al., 1970, 1973). These insoluble particles deposited in the lungs have a long residual time and may result in increased risk for cancer (Houpert et al., 1999; Hartmann et al., 2000). Typical health effects seen in uranium inhalation studies are the development of pneumonia and chemically irritated passages, which are considered early signs of lung cancer (Voegtlin and Hodge, 1949a,b, 1953a,b).

The mechanisms associated with lung injury in high-level uranium exposure are not well-understood. Treatment of rat lung epithelial cells with uranyl (VI) acetate was shown to result in increased oxidative stress and decreased cell proliferation, which were attributed to the loss of cellular redox (Periyakaruppan et al., 2007). Effects of uranium on cytokine secretion and on the proteasome–ubiquitin system have also been advanced (Gazin et al., 2004; Malard et al., 2005). Several studies have also established the deleterious effects of DU on viability, micronuclei, chromosomal instability, and sister chromatid exchanges in cells (Lin et al., 1993; Prabhavathi et al., 1995; Miller et al., 1998a, 2001, 2003; Schroder et al., 2003; Ibrulj et al., 2004; Wolf et al., 2004; Krunic et al., 2005; Milacic, 2008; McDiarmid et al., 2011a). These effects are believed to be more attributable to the radiological properties of uranium than to the chemical effects (Mould, 2001; Bolton and Foster, 2002).

Reproductive/Developmental Toxicity

The reproductive effects of DU have recently been studied in various animal models (Paternain et al., 1989; Llobet et al., 1991; Arfsten et al., 2001, 2005, 2006, 2007, 2009; Domingo, 2001; Linares et al., 2005). Uranium has been shown to be a developmental toxicant when administered orally or subcutaneously, resulting in decreased fertility, embryo/fetal toxicity including teratogenicity, and reduced growth of offspring, after uranium exposure during different gestation periods (Domingo et al., 1989a,b; Ortega et al., 1989b; Paternain et al., 1989; Llobet et al., 1991; Bosque et al., 1993; Arfsten et al., 2001, 2002, 2005, 2006, 2007, 2009; Domingo, 2001). It is still unclear what the exact mechanism of action is, although *in vitro* studies in Chinese hamster ovary cells showed DU-induced genotoxicity and cytotoxicity (Lin et al., 1993). In humans, studies have evaluated the reproductive effects in male miners, uranium processors, and Gulf War veterans and show that these individuals have uranium in their semen, but they do not otherwise show any detrimental reproductive effects (Voegtlin and Hodge, 1953a,b; Llobet et al., 1991; McDiarmid et al., 2000, 2006; Arfsten et al., 2001, 2005, 2006, 2009; Domingo, 2001; Abu-Qare and Abou-Donia, 2002; Linares et al., 2005; Squibb and McDiarmid, 2006; Abu-Musa et al., 2008; Todorov et al., 2013).

Neurotoxicity

As concerns mounted regarding the cause of Gulf War syndrome, a growing body of evidence suggested that DU may affect the central nervous system (CNS). Animal studies demonstrated that uranium crosses the blood–brain barrier (BBB) and readily accumulates in the brain (Gilman et al., 1998a–c; Pellmar et al., 1999a,b; Leggett and Pellmar, 2003; Lemercier et al., 2003; Houpert et al., 2004, 2005, 2007; Lestaevel et al., 2005; Monleau et al., 2005; Fitsanakis et al., 2006). Furthermore, studies using rats and some follow-up studies using Gulf War veterans suggested that DU may cause subtle changes in CNS function without any corresponding nephrotoxicity (McDiarmid et al., 1999, 2000, 2001a,b, 2002, 2004a,b, 2006, 2007, 2009, 2011a,b, 2013; Pellmar et al., 1999a,b; McDiarmid, 2001). The public concern regarding the potential neurotoxic effects of DU has spurred recent novel scientific research to extensively evaluate if there are reasons to be concerned about DU exposure and neurotoxicity.

One of the earliest studies evaluating the specific effects of DU on the CNS demonstrated that uranyl nitrate facilitated the release of acetylcholine from the nerve terminals to potentiate muscle contraction in phrenic nerve preparations from mice (Lin et al., 1988). It was then shown that uranium could cross the BBB *in situ* using rat brain perfusions (Lemercier et al., 2003). Significant amounts of uranium accumulated in the brain after only a 2-min perfusion. Studies using rats embedded with DU and/or control tantalum pellets for 1 day and for 6, 12, and 18 months confirmed previous biodistribution data that demonstrated kidneys and bone as the primary target organs, but also identified other sites in the lymphatic, respiratory, reproductive, and central nervous systems (Pellmar et al., 1999a). High-dose (20 pellets) DU implantation resulted in significantly increased uranium levels in the skull (12.5 ng U/g skull tissue) after only 1 day compared with controls (1.41 ng U/g skull tissue) (Pellmar et al., 1999a). By 6 months, there was a significant difference in the amount of uranium in brain samples from rats that received high doses (approximately 5,000 ng U/g tissue) compared with tantalum control

samples (approximately 50 ng U/g tissue) (Pellmar et al., 1999a). Significant differences in brain region distribution of uranium were also found. Differences were also seen in electrophysiological studies in hippocampal slices of rats implanted with DU; the hippocampus is important for learning, memory consolidation, and spatial orientation functions. The 6-month and 12-month high-dose groups exhibited decreased neuronal excitability compared with controls, whereas rats in the 18-month DU treatment groups did not show significant changes in neuronal excitability, perhaps obscured by the aged rats (Pellmar et al., 1999a,b). No significant differences in hippocampal weights of DU-treated animals compared with controls were seen.

Generation of nitric oxide (NO) and evaluation of the central cholinergic system of male Sprague-Dawley rats after uranium exposure have also been studied (Abou-Donia et al., 2002). Intramuscular injection of 0.1 and 1.0 mg/kg for 7 days, followed by a 30-day observational period, resulted in sensorimotor deficits in rat behavior, differential levels of NO, and increased acetylcholinesterase activity in the cortex of animals dosed with 1 mg/kg, suggesting multiple exposures to low doses of uranyl acetate caused prolonged neurobehavioral deficits in rats after the initial exposure has ceased, similar to the exposures of Gulf War veterans (Abou-Donia et al., 2002).

Short-term and long-term differences in brain lipid oxidation and open-field behavioral differences in rats exposed to DU have been shown (Briner and Murray, 2005). After 2 weeks of DU exposure, brain lipid oxidation was increased and correlated with increases in line-crossing and rearing behavior. Although open-field behavior differences remained after 6 months of DU exposure, brain lipid oxidation could no longer be clearly correlated with the behavioral changes (Briner and Murray, 2005). Male rats were also more sensitive to the behavioral effects of DU compared with female rats (Briner and Murray, 2005). The gender differences may warrant further study to allay the fears of the public because the US armed forces deployment to Kosovo, Bosnia, and the Persian Gulf in 2000 were approximately 91% males (DOD, 2002). The results of both of these studies support previous studies that indicate that DU is a toxicant capable of crossing the BBB and producing prolonged behavioral/neurological changes.

Studies have recently addressed the cytotoxicity of uranyl acetate in primary rat cortical neuron cultures. Researchers found no evidence that uranyl acetate at concentrations less than 100 μM caused cytotoxicity (Jiang et al., 2007; Aschner and Jiang, 2009). Furthermore, there was no significant change in the levels of F_2-isoprostanes, biomarkers of oxidative stress, as well as thiol metabolite levels on treatment with uranium. 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide reduction assays and lactate dehydrogenase activity were also unchanged in neurons treated with uranyl acetate. In complementary studies in the nematode *Caenorhabditis elegans*, researchers found no evidence for neuronal degeneration using green fluorescent protein reporter strains corroborating the neuron culture results (Aschner and Jiang, 2009; Jiang et al., 2009).

With respect to human subjects, Gulf War veterans subjected to friendly fire and embedded with shrapnel from DU projectiles have been followed-up (Hooper et al., 1999; McDiarmid et al., 1999, 2000, 2002; Hodge et al., 2001; Gwiazda et al., 2004; Dorsey et al., 2009; Bakhmutsky et al., 2011, 2013). The fragments are a permanent exposure source inside the body and these veterans have demonstrated consistently higher urine levels of uranium, compared to controls without DU shrapnel, even after years of exposure (Hooper et al., 1999; Ejnik et al., 2000, 2005; McDiarmid et al., 2000, 2001a,b, 2002, 2004a,b, 2006, 2007, 2009, 2011a,b, 2013; Hodge et al., 2001; McDiarmid, 2001; Gwiazda et al., 2004; Squibb et al., 2005, 2012; Squibb and McDiarmid, 2006; Dorsey et al., 2009; Bakhmutsky et al., 2011, 2013; Hines et al., 2013). These Gulf War veterans do not show evidence of kidney damage or dysfunction, but there was an indication that increased uranium exposure may be marginally correlated with decreased neurocognitive performance, as measured by paper and pencil, and automated tests. In more recent follow-up studies, the initially identified neurological disabilities can no longer be detected. Many groups have called for further studies to examine the potential relationship between DU exposure and cognition (Harley, 1999; DOD, 2000; Durakovic, 2001, 2003; Priest, 2001; Society, 2001, 2002; WHO, 2001; Bem and Bou-Rabee, 2004; Sztajnkrycer and Otten, 2004).

TREATMENT

Currently, the treatments for uranium exposure are limited. Chelation therapy is used to prevent acute toxicity of high doses of uranium in systemic circulation, typically resulting from some sort of ingestion. Chelating agents are used to competitively compete for the uranyl ion. Numerous studies have tested the efficacy of different chelating agents, such as gallic acid, 4,5-dihydroxy-1,3-benzenedisulfonic acid (Tiron), diethylenetriaminepentaacetic acid, 5-aminosalicylic acid, catechol-3,6-bis(methyleneiminodiacetic acid) (CBMIDA), and ethane-1-hydroxy-1,1-bisphosphonate (EHBP) (Ortega et al., 1989a; Durbin et al., 1997, 2000; Fukuda, 2005; Fukuda et al., 2005, 2006a,b, 2008, 2009a,b). Recent uranium chelation therapy studies have evaluated compounds *in vitro* in cell lines (Liu et al., 2011; Zhang et al., 2011) and to treat dermal contamination (Belhomme-Henry et al., 2014). These chelating agents

can be effective in removing uranium and providing protective effects from acute uranium toxicity with differing efficacy. However, the length of time before initiating chelation therapy for acute uranium intoxication greatly influences the effectiveness of this therapy (Domingo et al., 1990).

For embedded DU fragments, surgical removal is the best option to get rid of as much of the shrapnel as possible. Because shrapnel can be of different sizes and dispersed in multiple locations, it is often difficult to remove every piece. Large fragments and fragments that are easily accessible, such as in soft tissues, are removed when possible to minimize the amount of uranium that will remain in fragments in the body.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

DU is an excellent metallic substrate for radiation shielding and for armor and ammunition by the military due to its density and pyrophoric properties. Furthermore, the unique ability of uranium-based ammunitions to sharpen themselves on impact, allowing for deeper penetration of the ammunitions, also makes DU a better substrate for weapons of mass destruction. As such, it is not surprising that the use of DU in military applications continues to grow, even while alternative metals are explored. This continued increased use has been bolstered by recent scientific studies showing that DU exposure has relatively low adverse health effects, contrary to the public backlash and belief that DU is a harmful chemical and may be the cause of Gulf War syndrome, and by the studies illustrating increased toxicity of metallic alloy alternatives.

There has also been speculation that there is a potential black market use of DU as a weapon for bioterrorism, or as part of a dirty bomb. However, a thorough evaluation of the toxicology of uranium indicates that DU is relatively inert compared with other potential materials and organisms that could be used to make an effective bioterrorism weapon or dirty bomb. The reason why DU may still be considered to be an excellent bioterrorism agent is the public perception that DU is a harmful chemical, even though the toxicology of the chemical and radiological effects are relatively mild.

Recent studies have provided a great deal of new information about DU and have narrowed the gaps in our understanding. For example, we now know that uranium will cross the BBB and accumulate in the brain, and there appear to be minimal functional changes associated with brain uranium accumulation. However, while the evidence suggests that DU is relatively inert, the controversy still remains regarding whether DU may be an agent that causes Gulf War syndrome, even though long-term follow-up studies have shown minimal chemical effects. Although there is not a great demand for pharmacological interventions, potential development of better chelating agents would be beneficial to assist in the treatment of uranium exposures, both acute and chronic.

CHAPTER

34

Chemical Warfare Agents and the Nervous System

Jing Liu, Chibuzor Uchea, Linnzi Wright and Carey Pope

INTRODUCTION

Chemical warfare has a long history. One of the earliest forms of chemical warfare involved the application of natural toxins to the tips of arrowheads and spears, used by early civilizations in Europe, Asia, South America, and Africa and described in Greek and Norse mythology (Mayer, 2008). The various types of chemical warfare agents (CWAs) are now listed as scheduled chemicals (Schedule 1, 2, and 3) in the Chemical Weapons Convention, administered by the Organization for the Prohibition of Chemical Weapons (OPCW). The use of CWAs in modern warfare began in World War I (1917–1919), during which chlorine gas, mustard gas, and phosgene (primarily dermal and pulmonary irritants) were used. Mustard gas was used again during World War II. A number of organophosphorus chemicals, primarily targeting the cholinergic nervous system, were synthesized as potential CWAs during the 1930s and 1940s and are often referred to as "nerve gases," or more appropriately, "nerve agents." There remains widespread concern for threats from CWAs, in particular the organophosphorus nerve agents, reinforced by their military use in the Iran–Iraq War of 1980–1988 and their use by terrorists in Japan in the mid-1990s.

Concern over the use of CWAs has again increased because of recent events in Syria. The Syrian government reportedly possessed a stockpile of over 1,000 tons of chemical agents and precursors including sulfur mustard (2,2′-dichlorethyl sulfide; HD), sarin, and *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX). Sarin was employed in a series of well-documented attacks in the city of Damascus in August 2013. There have also been reports of use of chlorine gas in munitions during the Syrian conflict. These concerns are being mitigated by the efforts of an OPCW–United Nations (UN) joint mission in Syria, targeting the removal or destruction of all priority chemicals in Syria which was completed by September 30, 2014.

There is some suggestion that a class of compounds could have been developed as binary CWAs; i.e., *novichoks* (which means "newcomers" in Russian). The OPCW recently concluded that there was insufficient information to comment on the existence or chemical/toxicological properties of novichoks. There is limited information, however, suggesting that their toxicity could be greater than that of the more common CWAs and that their mechanisms of action could be different, potentially rendering traditional treatments ineffective (Moshiri et al., 2012).

Different types of CWAs can affect one or multiple major organ systems. This chapter focuses on the nervous system as a potential target for CWAs. A brief overview of the nervous system, highlighting some of the special features that often contribute to its unique sensitivity to CWAs (and toxicants in general), will be provided. Specific information on the effects of selected CWAs on the nervous system will be discussed as well.

OVERVIEW OF THE NERVOUS SYSTEM

The nervous system can be divided into two major structural divisions: the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain and spinal cord, covered by three membranes—the meninges. The outermost layer is the dura mater. The PNS consists of all parts of the nervous system that lie outside the dura mater. The nervous system can also be classified based on functionality into the

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00034-8

autonomic and somatic nervous systems. The autonomic nervous system, which can be further divided into the sympathetic, parasympathetic, and enteric divisions, regulates visceral functions and various processes that are not under voluntary control, while the somatic nervous system controls voluntary skeletal muscle activity. Maintenance of homeostasis and proper communication within and among these various components of the nervous system is pivotal for physiological coordination and normal functioning of the whole organism.

There are two basic types of cells in the nervous system: neurons (accounting for about 10% of the total number of cells) and glia (the remaining 90% of the cells, including astrocytes, oligodendrocytes, NG2 cells, microglia, satellite cells, and Schwann cells). Neurons are highly specialized cells optimized for the conduction of electrical impulses to other nerve cells and to innervated tissues such as glands and muscles. In all neurons, there exists a soma (cell body), dendrites (smaller branching structures), and an axon (electrical impulse–conducting fiber) that terminates in multiple endings and gives rise to specialized areas (i.e., the presynaptic terminals). The junctional region between the presynaptic terminal and its target (innervated) cell is the synapse, where intercellular communication occurs, mediated by signal molecules (e.g., neurotransmitters) released by the presynaptic terminal. Anatomically, neurons can be classified into three basic types based on extensions of the dendrites and axon: unipolar, bipolar, and multipolar. Functionally, neurons can be characterized into afferent neurons (sensory neurons), efferent neurons (motor neurons), and interneurons. Afferent neurons conduct electrical impulses from tissues to the CNS, efferent neurons carry electrical impulses from the CNS to the tissues, and interneurons transmit information between neurons.

Despite having a markedly higher density in the nervous system, glial cells have historically been considered to provide metabolic and physical support for the neurons. For example, astrocytes aid in the maintenance of homeostatic conditions of the extracellular fluid surrounding neurons by removing excess potassium ions. Microglia participate in phagocytosis following neuronal damage/degeneration. Oligodendrocytes and Schwann cells (found in the CNS and PNS, respectively) form the lipid-rich myelin layers around axons, which effectively enhance conduction speed down the axon and prevent the spread of impulses between juxtaposed axons. It is now recognized, however, that glial cells play many important roles as key regulators of many aspects and processes associated with development, aging, and pathology, such as synaptogenesis, reactive gliosis, immunoreactivity, and homeostasis of neurotransmitters (Allen, 2013; Verkhratsky et al., 2014).

Neurons are excitable cells undergoing dynamic phases of depolarization and repolarization. As with all cells, neurons maintain a resting potential across the plasma membrane, typically −60 to −75 mV relative to the extracellular fluid. When excited, the membrane potential in a neuron exceeds a threshold voltage, which triggers a series of events that result in the initiation and propagation of an action potential along the axon. Each action potential begins with a rapid reversal of voltage from the negative resting potential to a positive potential (depolarization phase) and ends with an almost equally rapid change to a negative potential (repolarization phase). Once initiated, the action potential is self-propagated to the end of the axon in an all-or-none fashion. When an action potential reaches the presynaptic terminal, voltage-gated Ca^{2+} channels open in response to depolarization, resulting in extensive influx of Ca^{2+} ions, which then trigger exocytosis. The synaptic vesicles in the presynaptic terminal fuse with the plasma membrane and release their contents (neurotransmitters and other signals) into the synaptic cleft. Electrical impulses are thus transformed into chemical signals and thereby conducted from one neuron (presynaptic) to another (postsynaptic) through synaptic transmission.

Intercellular communication in the nervous system is typically mediated through synaptic transmission via the release of neurotransmitters and their subsequent binding to specific receptors. The transmitter-receptor interaction then elicits changes in ion channel permeability and/or second messenger formation in the innervated cell. Neurotransmitters can also interact with receptors located on the presynaptic terminal (either *autoreceptors*, which are activated by the same transmitter, or *heteroreceptors*, which are activated by a different transmitter released by a different neuron) to regulate the presynaptic function, often by influencing neurotransmitter release. Termination of synaptic neurotransmission depends upon the removal of neurotransmitter molecules from the synaptic cleft by either enzymatic degradation or by reuptake into the presynaptic terminal.

Classical neurotransmitters in the nervous system can be classified into amino acids (e.g., glutamate, aspartate, gamma-aminobutyric acid (GABA), glycine), monoamines (e.g., catecholamines, serotonin, histamine), and acetylcholine (ACh). Adenosine triphosphate (ATP) and nitric oxide (NO) are nonclassic neurotransmitters that often mediate co-transmission with other classical transmitters (e.g., norepinephrine or ACh). Neurotransmitters typically mediate synaptic transmission in an anterograde fashion; i.e., the transmitter molecules are released from presynaptic terminals and then diffuse through the synaptic cleft to bind to receptors on postsynaptic neurons or cells.

In the last 20 years or so, another group of signals termed *endocannabinoids (eCBs)* have gained more attention as neuromodulators with the potential to modulate numerous physiological and pathological processes

(see review of Pacher and Kunos, 2013). The eCBs are endogenous signal molecules derived from membrane lipids that modulate synaptic function in a retrograde fashion, i.e., they are released by a postsynaptic cell to influence the presynaptic neuron activity. Anandamide (AEA) and 2-arachidonylglycerol (2-AG) are the two most studied eCBs. In the CNS, eCB signaling is mediated by cannabinoid (CB1) receptors, a putative membrane transporter of eCBs, and enzymes involved in both synthesis (diacylglycerol lipase and *N*-acylphosphatidylethanolamine-specific phospholipase D) and inactivation (fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MAGL)) of eCBs. Unlike other neurotransmitters, which are synthesized and stored in synaptic vesicles, the eCBs are synthesized on demand from arachidonic acid in membrane lipids of postsynaptic neurons. Upon depolarization, the eCBs are released from the postsynaptic neuron, and they then diffuse through the synapse to bind and activate CB1 receptors on the presynaptic terminal. eCB synthesis and release can also be stimulated in a receptor-mediated fashion by activation of the G_q protein-coupled metabotropic glutamate receptors and the muscarinic M1 and M3 receptors. Termination of eCB signaling appears to require cellular reuptake via a carrier-mediated transport process. Following cellular reuptake, eCBs are enzymatically degraded. FAAH is distributed throughout the brain and appears to be primarily responsible for AEA hydrolysis, while MAGL appears to be the primary enzyme involved in 2-AG degradation. Both FAAH and MAGL are intracellular enzymes and inhibition of either or both can lead to increases in eCB levels.

Depolarization-induced suppression of inhibition (DSI) and depolarization-induced suppression of excitation (DSE) are two forms of synaptic plasticity mediated by eCBs. In DSI, postsynaptic neurons release eCBs, which in turn decrease GABA release in presynaptic neurons and disinhibit postsynaptic cell activity. In DSE, eCBs reduce presynaptic glutamate release, leading to a net suppression of postsynaptic cell activity.

The nervous system is complex both anatomically and functionally. The extensive networks mediating intracellular and intercellular communications make it highly vulnerable to disruption by many toxicants. Moreover, the nervous system possesses additional unique features that can contribute to its higher sensitivity to toxicants, including CWAs.

Special Features of Neurons and High Energy Demand

As noted previously, neurons are composed of a cell body (or soma), extended, branching dendrites, and an elongated axon. Because of this structural complexity, most neurons have relatively large cell volumes compared to other cell types. The unique spatial features of neurons often require the synthesis of a large amount of proteins in the soma and their transport over long distance through processes of axonal transport. The Nissl substance, found exclusively in soma of neurons and formed by clusters of ribosomal complexes, synthesizes the large amount of proteins needed for these cells. Unlike other cells, neurons are excitable cells that continuously generate and transmit electrical signals along their axons and chemical signals across the intercellular synapses. The neurons, therefore, have an absolute requirement for a continuous and abundant supply of energy to support the need for synthesis of large amounts of proteins and neurotransmitters, for transport of proteins, cellular organelles, and cytoskeletal components to distant parts of the cell, and to maintain and restore ionic gradients affected by cycles of depolarization and repolarization.

The nervous system depends heavily on aerobic glycolysis to generate energy. The demand for oxygen and glucose is so high and sustained that even a brief interruption of oxygen, glucose, or both may result in severe adverse consequences, as there is essentially no reserve in the brain. The high oxygen requirement is associated with approximately 20% of the total cardiac output going to the brain. Toxic agents that interrupt the supply of oxygen (e.g., carbon monoxide) or the utilization of oxygen (e.g., cyanide), therefore, can produce catastrophic cellular damage in the nervous system.

The nervous system is a lipid-rich environment. As noted earlier, many elongated axons in the CNS and PNS are insulated by concentric layers of myelin that facilitate conduction of electrical impulses. Because of the density of the lipids, myelinated axons can be more sensitive to lipophilic neurotoxicants. Moreover, axons in adult CNS have a very limited ability to regenerate after injury, at least partially because of myelin-associated inhibitory factors from oligodendrocytes and "glial scars" from reactive astrocytes. In contrast, axons in the PNS have a greater potential to regenerate and regrow after injury under a different environment provided by Schwann cells.

Blood–Brain Barrier

Most of the adult brain and spinal cord is anatomically separated from the circulation by a continuous lining of specialized endothelial cells whose apposed surfaces form tight junctions. This, aided in part by associated glial cells, constitutes a blood–brain barrier (BBB), largely limiting passage of substances based on lipophilicity and active transport mechanisms. The BBB plays a pivotal role in protecting the CNS from various chemical challenges, especially larger, hydrophilic toxicants. In humans, this BBB is incompletely developed at birth, and even less so in premature infants. The

barrier also does not exist in certain brain regions (e.g., the area postrema, hypophysis, hypothalamic regions, pineal body, and the supraoptic crest). The deficiency of the BBB in these areas in the adult brain and the incomplete BBB in the developing brain can be important in terms of differential sensitivity to chemicals, including CWAs. With many substances, such as organophosphorus nerve agents, that are hydrophobic in nature, the BBB plays a minimal role in sensitivity. The integrity of the BBB can be compromised under certain conditions (e.g., anesthesia, stress, metabolic, and pathological disorders (such as adrenocorticoid hypertension and meningitis)), leading to higher sensitivity to some neurotoxicants (Kandel et al., 2012, for more details on all the nervous system overview topics described previously). For further details on effects of chemical and biological warfare agents on the BBB, see Chapter 49.

TYPES OF NEUROTOXICITY

Based on locations of the original "lesion" elicited by a neurotoxicant, neurotoxicity can be classified as neuronopathy, axonopathy, myelinopathy, or transmission-associated toxicity. *Neuronopathy* involves injury or death of neurons, with subsequent degeneration and loss of dendrites, axons, and myelin sheath (when present). Such neuronal degeneration is irreversible and can result in an encephalopathy with global dysfunction, dependent upon the neuronal population(s) affected. *Axonopathy* can be thought of as a "chemical transection" at some point along an axon, such that the distal segment degenerates but the soma remains intact. The critical difference between central and peripheral axonopathies is the ability of the axon to regenerate and reinnervate the target cell over time. An early clinical indicator of axonopathy is loss of sensation (e.g., glove and stocking paresthesia) and disruption in fine, distal motor control. *Myelinopathy* is chemical-induced demyelination (i.e., loss of the myelin sheath) or intramyelinic edema (i.e., separation of the concentric layers of the myelin). Remyelination typically occurs with a much thinner myelin sheath than the original condition. *Neurotransmission-associated toxicity* is typically without any overt morphological change, but related to toxicant-induced neurochemical changes within the synaptic region. Toxicants can disrupt neurotransmission by affecting presynaptic processes, including neurotransmitter synthesis, transport, and storage in synaptic vesicles, neurotransmitter release, reuptake, or degradation, by binding to presynaptic and/or postsynaptic receptors, by affecting ion flux in the presynaptic or postsynaptic cell, or by other mechanisms influencing signal transduction.

Neurotoxicity can also be classified based on the nerve-organ affected, e.g., dysautonomia when the autonomic nervous system is affected, neuromuscular disorders when somatic motor neurons or the neuromuscular junction is affected, sensory neuropathy when the sensory receptors or afferent sensory neurons are the primary targets, cognitive deficits and mood/mental disorders when higher brain/cognitive functions are affected.

SELECTED CWAS THAT AFFECT THE NERVOUS SYSTEM

As briefly reviewed earlier, the nervous system possesses some unique anatomical, biochemical, and physiological characteristics that can contribute to its relatively higher sensitivity to xenobiotics, including some CWAs. Many chemicals are potential weapons of mass destruction, including but not limited to organophosphorus (OP) nerve agents, cyanides, mustards, arsenicals, and the natural products botulinum toxin and ricin. Many CWAs adversely affect the nervous system either directly or indirectly, leading to acute and/or chronic adverse health consequences.

Organophosphorus (OP) Nerve Agents

The OP nerve agents are widely recognized as CWAs and are among the most lethal CWAs ever developed. They are classified as either "G" or "V" series agents. The G agents, including tabun (*O*-ethyl *N*,*N*-dimethylphosphoramidocyanidate; GA), soman (*O*-pinacolyl methylphosphonofluoridate; GD), sarin (isopropyl methylphosphonofluoridate; GB), and cyclosarin (cyclohexyl methylphosphonofluoridate; GF), are volatile and nonpersistent, whereas the V agents, such as VX (*O*-ethyl *S*-2-diisopropylaminoethyl methylphosphonofluoridate) are less volatile and relatively more persistent. Both the United States and the Soviet Union stockpiled many of these agents for military use during the Cold War. However, the first documented military use of nerve agents was not until the Iran–Iraq War of 1980–1988. During this conflict, Iraqi troops employed sarin munitions against both military personnel and civilians, confirmed by detection of trace amounts of a breakdown product, isopropyl methylphosphonic acid, in soil samples taken from a Kurdish village in northern Iraq (Macilwain, 1993). Subsequently, sarin was used in two separate terrorist attacks in Japan by a cult named Aum Shinrikyo (meaning "divine truth" in Japanese). The first attack, on June 27, 1994, occurred in a residential neighborhood in Matsumoto, resulting in 56 hospitalizations and 7 deaths. The second attack, on March 20, 1995, occurred in several subway cars in Tokyo, resulting in 796 hospitalizations and 12 deaths (Yanagisawa et al., 2006).

Among the victims of the sarin attack in Tokyo, Japan, 111 individuals were characterized as severely or moderately injured on admission to the hospital on the day of the attack. They exhibited miosis (99%), headache (75%), respiratory distress (63%), nausea and vomiting (60% and 37%, respectively), eye pain (45%), blurred or dim vision (40% and 38%, respectively), and seizures (approximately 3%) (Okumura et al., 1996). Changes in psychomotor functioning, visual perception and sustained attention, learning and memory, and mood (Murata et al., 1997; Yokoyama et al., 1998) were observed in 18 evaluated survivors 6–8 months later. Depressive behaviors were reported in survivors between 6 months and 7 years after the attack. This included those who had not presented with symptoms of acute toxicity at the time of the incident (Araki et al., 2005). Yamasue et al. (2007) observed smaller regional white matter volumes and diffuse bilateral disruption of white matter integrity 5–6 years after the attacks. Miyaki et al. (2005) reported deficits in attention and gross motor speed 7 years after the attacks.

More than 100,000 US military personnel participating in the Gulf War were potentially exposed to low levels of cyclosarin and sarin following the destruction of a munitions storage facility at Khamisiyah, Iraq, in March 1991 (Smith et al., 2003). Reviews of medical records for Gulf War veterans and of published field accounts revealed no clinical indications of acute OP intoxication (Riddle et al., 2003). However, thousands of veterans later reported various neurological symptoms, referred to as "Gulf War illnesses," characterized by impaired cognition, including depression and insomnia; confusion-ataxia, including problems with thinking and disorientation; and joint/muscle pain, fatigue, and extremity paresthesia (Haley et al., 1997). Deficits in motor dexterity and visuospatial abilities (Proctor et al., 2006) and a twofold increase in the incidence of brain cancer–related deaths (Bullman et al., 2005) were reported in these veterans 4 years later. In addition, a reduction in the overall volume of white matter and an enlargement of the lateral ventricles were observed in the brains of some veterans (Heaton et al., 2007). It has been suggested that exposure to anticholinesterases , including possible low-level exposure to sarin and cyclosarin, prophylactic use of the carbamate drug pyridostigmine bromide, and widespread application of pesticides such as chlorpyrifos, may have played a role in the development of the Gulf War illnesses (Brimfield, 2012).

The most recent documented use of OP nerve agents was in August 2013, in the Ghouta area of Damascus, Syria. Sarin was employed via surface-to-surface rockets, with a considerable number of casualties. Although there are conflicting reports on the numbers, at least 3,600 people went to medical facilities with neurotoxic signs and symptoms, and 588 fatalities were recorded by the Violations Documentation Centre, which reports to the UN (Dolgin, 2013; Enserink, 2013; Patrick et al., 2013).

Organophosphorus compounds, including the nerve agents, elicit acute toxicity primarily via inhibition of acetylcholinesterase (AChE), disrupting ACh-mediated cholinergic signaling in the CNS and PNS. ACh is synthesized in the presynaptic terminal by choline acetyltransferase using choline and acetyl CoA as substrates. Once synthesized, ACh molecules are stored in the synaptic vesicles. Upon depolarization, the vesicles containing ACh fuse with the presynaptic membrane and release ACh into the synapse. The diffusible ACh molecules then interact specifically with cholinergic (i.e., muscarinic and nicotinic) receptors on postsynaptic cell membranes to mediate signal transduction. Muscarinic receptors are G protein–coupled receptors that affect the formation of second messengers (e.g., cyclic adenosine monophosphate (cAMP), diacylglycerol (DAG), and inositol triphosphate (IP3)). To date, five muscarinic receptors (M1–M5) have been identified and cloned. M1, M3, and M5 subtypes are coupled to phospholipase C (PLC) via G_q and increase the formation of DAG and IP3 upon activation, whereas the M2 and M4 subtypes are coupled to adenylyl cyclase via G_i and decrease the formation of cAMP once activated. Nicotinic receptors are ligand-gated ion channels that increase Na^+ influx upon stimulation. ACh can also bind to presynaptic muscarinic and nicotinic receptors to modulate the further release of ACh in a negative "feedback" manner. ACh in the synapse is degraded very rapidly by AChE into choline and acetate. The choline molecules are transported back into the presynaptic terminal through a process known as *sodium-dependent high-affinity choline uptake*, the rate-limiting step in ACh synthesis. ACh, therefore, has only a transient opportunity to activate muscarinic or nicotinic receptors, either postsynaptically or presynaptically. Inhibition of AChE prevents the normally efficient breakdown of ACh in the synapse, leading to ACh accumulation and persistent/prolonged stimulation of cholinergic receptors, which in turn elicits signs and symptoms of cholinergic toxicity.

Many of the classical signs of cholinergic toxicity associated with OP poisoning involve the PNS. The well-recognized syndrome of excessive secretions, known as salivation, lacrimation, urination, and defecation (SLUD), and other effects (e.g., miosis) are the result of AChE inhibition and muscarinic receptor activation in peripheral tissues (Espinola et al., 1999). Other common signs of cholinergic toxicity (e.g., muscle fasciculations) involve overstimulation of nicotinic receptors in peripheral tissues (Costa, 1988). The most debilitating effects of anticholinesterase exposures involve the CNS, however (Pope, 2006). Lethality from OP intoxication is typically due to depression of brainstem respiratory control centers, compounded by excessive airway secretions

and dysfunction of diaphragm and intercostal muscles. Rickett et al. (1986) reported that one of the first signs of nerve agent–induced respiratory distress in cats was disruption of the normal firing of respiratory-related neurons in the pons medulla, followed by changes in airflow, diaphragm contraction, diaphragm electromyogram (EMG) and phrenic nerve activity. Spectral analysis of diaphragm EMG indicated that the functional integrity of the diaphragm in guinea pigs following soman exposure (15 μg/kg, s.c.) was not sufficiently compromised to produce respiratory distress despite signs of fatigue (Chang et al., 1990). These studies suggested that respiratory distress following nerve agent exposure is mainly due to disruption of central cholinergic signaling. Moreover, Bajgar et al. (2007) reported that AChE activity in the pons medulla (i.e., the site of respiratory control centers) was more extensively inhibited by soman, sarin, and VX than AChE in many other parts of the brain.

Whole body tremors can result from extensive AChE inhibition in the CNS, with activation of muscarinic receptors in the basal ganglia being of prominent importance (Espinola et al., 1999). With severe intoxications, seizures can be elicited that can lead to irreversible neuropathology (Shih et al., 1991; Kadar et al., 1995; Dekundy et al., 2001, 2007). Shih and McDonough (1999) demonstrated that all five of the classic nerve agents (i.e., cyclosarin, sarin, soman, tabun, and VX) were capable of inducing seizures at lethal dosages. In the case of VX, however, the latency of seizure development was 3–5 times longer than with the other nerve agents. Soman-induced seizures occurred in rats only when cortical AChE inhibition was over 65% (Tonduli et al., 2001). Both anticholinergics (e.g., atropine and biperiden) and benzodiazepines (e.g., diazepam and midazolam) were able to terminate nerve agent–induced seizures in guinea pigs when administered within 5 min of seizure onset, but a higher dose of each was typically required to terminate seizures induced by soman compared to other nerve agents (Shih et al., 2003).

Prolonged seizure activity (i.e., *status epilepticus*) following nerve agent exposure has been shown in several animal models to cause neuropathological lesions that are associated with long-term deficits in cognitive function and other behaviors. Moderate to severe neuropathological lesions were reported in 70% of sarin- (Kadar et al., 1995) and 98% of soman-treated (McDonough et al., 1995) rats, when the seizures lasted 20 min or longer. Pathological lesions were primarily noted in the hippocampus, piriform cortex, and thalamus, but later progressed to other brain regions (e.g., the amygdala). Soman-induced status epilepticus in rats resulted in significant neuronal loss and neurodegeneration (in particular with GABAergic interneurons) in the basolateral nucleus of the amygdala. Moreover, this neuropathology was associated with increased anxiety-like behavior measured in the open-field test and the acoustic startle response 14 days later (Prager et al., 2014). Spatial memory performance in the Morris water maze was directly related to the severity of hippocampal lesions in soman-treated rats. Interestingly, no memory impairment was observed below a threshold of 15% neuronal loss (Filliat et al., 1999). Impaired contextual and cued fear conditioning (fear-based learning and memory) was observed in soman-treated rats and mice that experienced seizures and neuronal degeneration in different brain regions (Coubard et al., 2008; Moffett et al., 2011). These mice also showed anxietylike behaviors measured in unconditioned fear tests (light/dark boxes and elevated plus-maze). Deficits in cognitive function measured in a novelty test, the brightness discrimination task (Myhrer et al., 2005), and the stone maze (Raffaele et al., 1987) were reported in rats following soman-induced convulsions, associated with neuropathological lesions.

Nerve agents such as soman and other OP compounds have been shown to induce anxiety- and depressive-like behaviors in animal models at dosages that do not elicit seizures. A sublethal dosage of soman (0.6–0.8 × LD_{50}) triggered anxiety-like behavior (measured in the open field test and elevated plus maze) in guinea pigs (Mamczarz et al., 2010). Acute intoxication with diisopropylfluorophosphate (a prototype OP and structure analog of sarin) in rats resulted in depressive-like behavior (e.g., increased immobility and decreased swimming in the forced swimming test; Wright et al., 2010). Chen et al. (2011) reported serotonergic-related changes in affective behaviors measured in the elevated plus maze, the Vogel's conflict test, the novelty-suppressed feeding test, and the forced swimming test in adolescent rats exposed to chlorpyrifos (10–160 mg/kg/day for 7 days, subcutaneously). Repeated exposure to methamidophos in the drinking water at levels that did not elicit systemic toxicity induced depressive-like behavior in adult mice (Lima et al., 2009). Malathion exposure has also been reported to be associated with depressive-like behavior in rodents (Ramos et al., 2006; Brocardo et al., 2007; Acker et al., 2009).

Anxiety and depression have also been reported in humans following OP intoxication. A number of epidemiological studies have reported long-term neuropsychological or neuropsychiatric sequelae, such as anxiety and depression, with past anticholinesterase intoxication or exposure (Savage et al., 1988; Rosenstock et al., 1991; McConnell et al., 1994; Steenland et al., 1994; Yokoyama et al., 1998, 2002; Wesseling et al., 2002; Colosio et al., 2003; London et al., 2005; Roldan-Tapia et al., 2006). A cross sectional survey conducted among 761 individuals, representing 479 farms in northeastern Colorado between 1992 and 1997, found that exposure

to pesticides, in particular OPs, at levels sufficient to cause self-reported poisoning symptoms, was associated with a more than fivefold higher rate of depression, independent of other known risk factors (Stallones and Beseler, 2002). A mini-review of 11 studies on depression in relation to pesticides revealed increased odds ratios (ranging from 2 to 6) for developing depression or other psychiatric disorders (Freire and Koifman, 2013). More recently, Wesseling et al. (2010) reported an increased incidence of depression and anxiety, along with other psychological or psychiatric deficits, in workers exposed to OPs that had received medical attention 1–3 years prior to the study.

Thus, central actions of OP anticholinesterases can be critical in both acute toxic responses and long-term neurologic sequelae following acute or repeated exposures. While disruption of cholinergic neurotransmission is a hallmark of OP poisoning, substantial evidence indicates that disruption of noncholinergic signaling contributes to the ultimate outcome. Shih et al. (1991) reported that seizures elicited by soman were initially sensitive but later resistant to the antimuscarinic antidote, atropine. Activation of glutamate signaling in limbic regions (e.g., the hippocampus) appeared particularly important in OP-induced seizures (Lallement et al., 1991). These investigators observed a 78% increase in extracellular glutamate in the CA3 region of the hippocampus within 30 min of seizure onset, and a more robust early increase (180%) followed by a declined but more sustained increase in the hippocampal CA1 region after 50 min of seizure onset in soman-treated rats. Sparenborg et al. (1992) reported that MK-801 (30, 100, or 300 μg/kg, i.m.) blocked soman-induced seizures in a dose-dependent manner, suggesting that NMDA receptor activation may play a critical role in the spread and maintenance of nerve agent-induced seizures. Moreover, NMDA receptor antagonists blocked seizures elicited by OP insecticides (dichlorvos and chlorfenvinphos; Dekundy et al., 2001, 2007). In contrast, it is reported that higher striatal dopamine and GABA levels were correlated with severity of signs of soman toxicity, seizure intensity, and epileptiform bursting (Cassel and Fosbraey, 1996; Jacobsson et al., 1997). The dopamine D1-like antagonist SCH23390 completely blocked soman-induced seizures (Bourne et al., 2001). The activation of noncholinergic signaling pathways, therefore, appears to participate in the expression of OP toxicity, and brain-regional differences in activation of noncholinergic signaling may be important in the ultimate toxic outcome.

Another noncholinergic signaling pathway that may influence the ultimate expression of OP toxicity is mediated by eCBs. The eCB signaling participates in a variety of processes including thermoregulation, food intake, immune function, perception (hearing, color, vision, and taste), cognition (long-term potentiation and short-term memory), and motor function (locomotor activity, proprioception, and muscle tone). Of particular importance, eCBs inhibit the release of a number of neurotransmitters (Miller and Walker, 1995; Gifford and Ashby, 1996; Cadogan et al., 1997; Gessa et al., 1997; Levenes et al., 1998; Cheer et al., 2004). Several studies suggested that eCBs tonically inhibit ACh release in the hippocampus via CB1 receptors; i.e., agonists reduce the release of ACh, while antagonists increase it (Gifford and Ashby, 1996; Gessa et al., 1997; Gifford et al., 2000; Kathmann et al., 2001; Tzavara et. al., 2003; Degroot et al., 2006). Interestingly, ACh release in the striatum is unaffected by eCB agonists and antagonists or by deletion of the CB1 gene in mice (Gifford et al., 2000; Kathmann et al., 2001). Thus differential effects of eCBs on ACh release in different brain regions may be important.

eCB-mediated inhibition of GABA and glutamate release from presynaptic neurons via DSI and DSE may also play an important role in the expression of OP toxicity. As mentioned above, higher levels of striatal GABA and limbic glutamate levels have been correlated with more severe signs of OP toxicity (Lallement et al., 1991, 1992; Cassel and Fosbraey, 1996; Jacobsson et al., 1997). Furthermore, the $GABA_A$ receptor antagonist bicuculline is proconvulsant when directly administered into limbic regions but is anticonvulsant when microinjected into the striatum (Turski et al., 1989, 1991). Thus, changes in GABAergic and glutamatergic signaling and their modulation by eCBs could have regional-specific effects on neurological function after OP intoxication.

While eCBs can regulate the release of ACh and other neurotransmitters, OP toxicants may also affect eCB signaling either indirectly, through AChE inhibition (and neuronal depolarization/activation of M1/M3 receptors), or directly, through binding to cannabinoid receptors, inhibiting cannabinoid metabolizing enzymes, or both (Quistad et al., 2001, 2002, 2006; Segall et al., 2003; Nallapaneni et al., 2006, 2008). Chlorpyrifos oxon, paraoxon, and diisopropylfluorophosphate (DFP) inhibit CB1 receptor binding and the activities of FAAH and MAGL *in vitro*, with chlorpyrifos oxon being more potent. *In vivo*, DFP inhibited FAAH but had little effect on MAGL or CB1 binding (Nallapaneni et al., 2008). More recently, Liu et al. (2013) reported that both chlorpyrifos and parathion (the parent compounds of chlorpyrifos oxon and paraoxon, respectively) inhibited FAAH and MAGL *in vivo*, with more extensive inhibition seen with FAAH by both compounds. Extracellular levels of eCBs in the rat hippocampus were increased by both chlorpyrifos and parathion at dosages that inhibited more than 80% of hippocampal AChE activity.

Pharmacological manipulation of eCB signaling has been shown to affect both acute and long-term toxicity of OPs. The CB1 receptor agonist WIN 55,212-2 (1.5 mg/kg, i.p.) reduced acute paraoxon toxicity with a

single dose, but increased toxicity if paraoxon was given after repeated WIN 55,212-2 dosing (Nallapaneni et al., 2006). Acute DFP toxicity was reduced by WIN 55,212-2, as well as by inhibitors of FAAH and MAGL (URB597 and URB602, respectively) and the eCB reuptake inhibitor (AM404; Nallapaneni et al., 2008). As noted before, acute DFP exposure induced depressive-like behavior in rats. The combination of URB597 and URB602 was shown to have antidepressant-like effects, reversing DFP-induced changes in the forced swimming test (Wright et al., 2010). Interestingly, the CB1 receptor antagonist/inverse agonist AM251 markedly decreased parathion-induced toxicity in rats, while having no influence on functional signs of chlorpyrifos (Liu et al., 2013). Thus, eCB signaling may play differential roles in toxic outcome of OPs based on the modulation of different neurotransmitter systems, possibly related to the time of onset and the duration of the neurotoxic response.

OP anticholinesterases have the potential to markedly disrupt nervous system function, eliciting a broad range of acute and long-term effects. While AChE has been considered the primary target, and downstream changes in cholinergic signaling have been the main focus in understanding mechanisms and exploring countermeasures, noncholinergic pathways following AChE inhibition may play a prominent role in the ultimate outcome following OP exposure.

Cyanides

Cyanides have been used for their toxic potential since ancient Roman times. Cyanogen chloride, cyanogen bromide, and hydrogen cyanide are important cyanide-containing compounds of potential used as CWAs. The use of cyanides in warfare was not implemented until World War I. Due to their high volatility, however, these compounds rarely achieve lethal atmospheric concentrations except in enclosed spaces (Lee, 1997). Hydrogen cyanide was used for mass extermination of prisoners in concentration camps by the Nazis during World War II. Other forms of cyanide-containing compounds have also been used for malicious purposes. For example, potassium cyanide was illicitly placed in capsules of Extra-Strength Tylenol, leading to 7 deaths in the Chicago area in 1982 (Dunea, 1983).

Signs of cyanide exposure include agitation, dizziness, headache, and mental confusion, followed by cardiac disturbances, loss of consciousness, respiratory distress, seizures, and death. While cyanide exposure is often fatal, there are reports of long-term effects with sublethal intoxications. Finelli (1981) described a 30-year-old male who developed choreiform movements in his extremities and impairment in the movement of his left hand one year after he attempted suicide with cyanide. Similarly, Carella et al. (1988) reported a 46-year-old woman who drank a beverage poisoned with cyanide and later developed a dystonic posture of the mouth and tongue that was deviated to the right and twisted. Computed tomography scans showed that both individuals had lesions in the basal ganglia.

Although there are a number of reports on the neuropathological consequences of cyanide exposure, including necrotic lesions in the cerebellar gray matter of dogs (Haymaker et al., 1952) and demyelinating lesions in the corpus callosum and optic nerves of rats (Lessell, 1971), its neurobehavioral sequelae have received relatively little attention. D'Mello (1986) reported that a single exposure to sodium cyanide (4 mg/kg, subcutaneously) impaired swimming ability in guinea pigs. Mathangi and Namasivayam (2000) demonstrated that repeated exposure to sodium cyanide (2 mg/kg/day × 30 days, intraperitoneally) impaired T-maze performance in rats, along with a reduction in dopamine and 5-hydroxytryptamine levels in the hippocampus.

The primary mode of action for cyanide-induced toxicity is inhibition of cytochrome oxidase, the terminal enzyme of the electron transport chain. Inhibition of cytochrome oxidase leads to cytotoxic hypoxia, with a shift from aerobic to anaerobic metabolism, a decrease in ATP synthesis, and an increase in lactic acid production (Way, 1984). The CNS is particularly sensitive to the toxic effects of cyanide due to both extremely limited anaerobic metabolic capacity and high energy dependence. Ikegaya et al. (2001) showed that the inhibition of cytochrome oxidase activity following oral administration of potassium cyanide (10 mg/kg) in rats was higher in the brain than in other organs. Thus, not only is the CNS particularly sensitive to cyanide-induced hypoxia and energy deficit, but the target enzyme itself in the CNS may be more sensitive to inhibition by cyanide compared to enzymes in other tissues.

Oxidative stress may also play a critical role in cyanide-induced toxicity. Potassium cyanide (7 mg/kg, administered subcutaneously) decreased the activities of catalase, glutathione peroxidase, and superoxide dismutase in mouse brain (Ardelt et al., 1989). Potassium cyanide also stimulated the formation of reactive oxygen species (ROS) and increased levels of malondialdehyde in a number of neuronal cell types, including cerebellar granule cells (Gunasekar et al., 1996), primary cortical cells (Li et al., 2002) and rat pheochromocytoma (PC-12) cells (Kanthasamy et al., 1997). Johnson et al. (1986) proposed that a rise in intracellular Ca^{2+} levels following potassium cyanide exposure was responsible for the formation of ROS. In support of this, Gunasekar et al. (1996) reported that removal of Ca^{2+} from the culture medium blocked the formation of ROS in cerebellar granule cells exposed to potassium cyanide (100 µM). Moreover, antioxidants (Muller and Krieglstein, 1995), Ca^{2+} channel blockers (Johnson et al., 1987), cyclooxygenase-2 (COX-2)

inhibitors (Li et al., 2002), as well as the NMDA receptor antagonists (Gunasekar et al., 1996) and phospholipase A2 inhibitors (Kanthasamy et al., 1997), all blocked the formation of ROS in neuronal cell lines exposed to potassium cyanide.

Cyanide-induced cell death may involve selective activation of apoptosis or necrosis in different brain regions or neuronal populations. Mills et al. (1999) reported that cyanide induced cell death in mouse brain via apoptosis in the cortex, but through necrosis in the substantia nigra. Similarly, Prabhakaran et al. (2002) reported that cyanide-induced cell death occurs via apoptosis in primary cortical cells, but by necrosis in primary mesencephalic cells. While potassium cyanide (400 μM) increased the formation of ROS in both cell types, the rates of formation and the nature of the ROS varied. Furthermore, catalase and superoxide dismutase decreased the formation of ROS in cortical cells, but not in mesencephalic cells. These findings suggest that the selective vulnerability of different neuronal populations to cyanide may be related to differences in their susceptibility to oxidative stress.

Dopaminergic neurons are highly sensitive to oxidative stress, possibly due to dopamine autoxidation to quinones and other ROS (Basma et al., 1995; Ben-Shachar et al., 1995). Kanthasamy et al. (1994) reported that mice repeatedly exposed to potassium cyanide (6 mg/kg, twice a day for 7 days, subcutaneously) had a reduced number of TH-positive cells, indicating a loss of dopaminergic neurons in the substantia nigra. Approximately 30% of the cyanide-treated mice exhibited decreased locomotor activity and akinesia, which were alleviated by the administration of L-DOPA (100 mg/kg, intraperitoneally). Cassel and Persson (1992) reported that levels of striatal dopamine and its metabolite homovanillic acid (HVA) were rapidly decreased in rats exposed to sodium cyanide (20 mg/kg, intraperitoneally). However, the *in vivo* synthesis of dopamine, measured as the rate of L-DOPA accumulation after neuronal decarboxylase inhibition, increased in these rats. Kiuchi et al. (1992) noted that perfusion of sodium cyanide (2 mM) into rat striatum produced a transient but marked increase in DA release. In addition, dopamine D1 and D2 receptor binding in the striatum was decreased in rats after the administration of sodium cyanide (2 mg/kg, intraperitoneally) (Cassel et al., 1993). Given that Parkinson's disease is a condition characterized by the selective loss of dopaminergic neurons in substantia nigra and the depletion of striatal dopamine levels (German et al., 1989), these findings suggest that cyanide exposure may lead to the development of signs or symptoms that resemble that disease.

Both glutamatergic and GABAergic neurons may be involved in the development of seizures after cyanide exposure. There is a strong correlation between whole-brain Ca^{2+} levels and cyanide-induced seizures in mice (Johnson et al., 1986). Patel et al. (1992) demonstrated that NMDA receptor activation was responsible for the rise in intracellular Ca^{2+} levels, contributing to cyanide-induced toxicity in cultured hippocampal neurons. Yamamoto and Tang (1996, 1998) reported that cyanide-induced seizures in mice were blocked by MK-801 (2 mg/kg, subcutaneously) and the morphological changes observed in cerebrocortical neurons exposed to potassium cyanide (1 mM) were blocked by 2-amino-7-phosphonoheptanoic acid (AP7; 1 mM): both are selective NMDA receptor antagonists. Persson et al. (1985) reported that striatal GABA levels were decreased in rats exposed to sodium cyanide (20 mg/kg, intraperitoneally), and these decrements were associated with an increased susceptibility to seizures (Cassel et al., 1991). Similarly, Yamamoto (1990) reported that whole-brain GABA levels were markedly decreased and Ca^{2+} levels were increased in cyanide-treated mice exhibiting seizures. All these findings suggested that increased glutamatergic activity, decreased GABAergic activity, or both may contribute to the development of seizures following cyanide exposure.

Sulfur Mustard

Sulfur mustard, also known as HD, is a classic blister agent and an effective incapacitating chemical. It was first used as a CWA in World War I during a German attack on British troops at Ypres, Belgium, in 1915. Subsequently, it has been used in a number of military conflicts, including the Iran–Iraq War of 1980–1988 (Marshall, 1984). During this conflict, Iraqi troops employed sulfur mustard against both military personnel and civilians. Approximately 40,000 victims of sulfur mustard have been documented among the Iranian and Kurdish populations (Hay, 2000; Khateri et al., 2003).

Sulfur mustard exerts local actions on the eyes, respiratory tract, and skin, followed by systemic actions on the nervous, cardiac, gastrointestinal, and hematopoietic systems (Dacre and Goldman, 1996). A moderate exposure to sulfur mustard can cause blisters, conjunctivitis, erythema, lacrimation, nausea, and respiratory inflammation, whereas a severe exposure can cause blindness, bronchitis, bronchopneumonia, corneal damage, leucopenia, seizures, and death. Sulfur mustard is a strong alkylating agent that reacts with thiol, amino, carboxyl, hydroxyl, and primary phosphate groups in DNA and other macromolecules. Alkylation of DNA activates chromosomal poly(ADP-ribose) polymerase, reducing the intracellular supply of NAD^+ and thus inhibiting glycolysis and causing cell death (Papirmeister et al., 1985). More recently, it was suggested that oxidative stress may play a critical role in sulfur mustard-induced toxicity as well (Naghii, 2002). Jafari (2007) demonstrated that

high dosages of sulfur mustard (>10 mg/kg, intraperitoneally) decreased the activities of catalase, glutathione peroxidase, glutathione *S*-transferase, and superoxide dismutase in rat liver and brain, leading to the impairment of antioxidant defense systems.

There is limited information available on the effects of sulfur mustard on the CNS. The majority of the victims exposed to sulfur mustard during the Iran–Iraq War seeking medical treatment at European hospitals suffered from anxiety, confusion, headache, and lethargy (Balali-Mood and Hefazi, 2006). A cohort study conducted on 495 Iranian civilians revealed that individuals exposed to sulfur mustard exhibited a significantly higher incidence of depression, anxiety, hostility, and obsessive-compulsive behavior compared to age-matched counterparts 20 years after exposure (Roshan et al., 2013). Lethal dosages of sulfur mustard (>10 mg/kg, subcutaneously) caused hyperexcitability followed by unsteadiness of gait, muscular weakness, and seizures in dogs (Lynch et al., 1918). Philips and Thiersch (1950) reported that lethal dosages of 2,4,6-tris(ethylenimino)-*S*-triazine (>125 mg/kg, intraperitoneally), which has an ethylenimine moiety analogous to sulfur mustard, caused similar effects in mice. Although the mechanism responsible for these effects is unknown, it is interesting to notice sulfur mustard-induced AChE activity in neuroblastoma cell cultures, suggesting that cholinergic signaling may play a role in its effects on the CNS (Lanks et al., 1975). Thus, while sulfur mustard is typically thought of as a blister agent, clinical and experimental data suggest that it has the potential for eliciting both acute and long-term neurotoxic effects.

3-Quinuclidinyl Benzilate

3-quinuclidinyl benzilate (QNB, also known as BZ,1-azabicyclo[2.2.2]oct-3-yl hydroxy(diphenyl)acetate) is a potent, atropine-like glycolic acid ester that blocks muscarinic receptors in the CNS and PNS (Spencer, 2000). During the 1950s, QNB was explored by both the United States and the Soviet Union as a potential antidote for OP anticholinesterases. However, the marked hallucinogenic actions of QNB led to its potential use as a CWA (Marshall, 1979). In July 1995, the Yugoslav People's Army allegedly used an incapacitating agent that caused hallucinations and irrational behavior against Bosnian refugees fleeing the town of Srebrenica (Hay, 1998). While many believe that this incapacitating agent was QNB, there is no evidence to support this allegation.

QNB acts as a potent, competitive inhibitor of ACh at muscarinic receptors located in the brain, heart, exocrine glands, and smooth muscles in various organs, resulting in a confusional mental state with delusions, hallucinations, mental slowing, erratic behavior, a decrease in intestinal motility and tone, inhibition of bronchial and salivary secretions, sweating, mydriasis, and tachycardia (Ketchum, 1963). Early studies demonstrated QNB was a potent and selective ligand for muscarinic receptors. Yamamura and Snyder (1974) showed that the inhibition of [^{3}H]-QNB binding to homogenates of rat brain by muscarinic drugs correlated with their pharmacological potencies, whereas nicotinic and noncholinergic drugs had negligible affinity. Kuhar and Yamamura (1976) reported that the injection of [^{3}H-]QNB into rat brain led to its localization to muscarinic receptors in the cerebral cortex, hippocampus, nucleus accumbens, and striatum. In addition, Jovic and Zupanc (1973) reported that the subcutaneous administration of QNB (5–20 mg/kg) to rats decreased oxygen consumption in the cerebral cortex and medulla oblongata. Interestingly, while QNB as a radioligand appears to bind to all known subtypes of muscarinic receptors, some evidence suggests that it has higher affinity for the M2 subtype of muscarinic receptors when administered *in vivo* (McRee et al., 1995). QNB thus can produce a variety of neurological effects, presumably through the antagonism of cholinergic muscarinic receptor signaling in the CNS and PNS.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The nervous system has a number of biochemical, physiological, and anatomical characteristics that can make it particularly sensitive to CWAs. Indeed, many CWAs (particularly the nerve agents) can elicit debilitating and devastating neurotoxic responses. In some cases, these neurotoxic effects are elicited by direct interaction with specific target molecules within the nervous system, while in other cases, actions on other organ systems can lead to indirect impairments of neurologic functions. The global importance of the continuous neuronal regulation of vital physiological processes throughout the body makes the nervous system an effective target for disruption by CWAs. Thus, knowledge of mechanisms by which CWAs elicit neurotoxicity can aid in seeking and designing effective countermeasures against CWA exposures.

Behavioral Toxicity of Nerve Agents

Jiri Kassa, Jiri Bajgar, Kamil Kuca and Daniel Jun

INTRODUCTION

Behavioral changes in humans exposed to highly toxic organophosphorus (OP) compounds, called nerve agents, have been discussed in numerous reports. The incidence of behavioral effects is higher in individuals who have been severely exposed to nerve agents, but they may occur in individuals who have received low-level exposure below those producing convulsions and other severe clinical signs of toxicity. The behavioral effects usually start within a few hours and last from several days to several weeks or months. The most frequent symptoms include feelings of uneasiness, tenseness, and fatigue. Exposed individuals may be forgetful and generally display impaired memory and learning, poor comprehension, decreased ability to communicate, or occasional mild confusion.

There are a few reports describing behavioral changes in subjects accidentally exposed to nerve agents. They reported sleep disturbance, mood changes, fatigue, jitteriness or tenseness, an inability to read with comprehension, difficulties with thinking and expression, forgetfulness, a feeling of being mentally slow, depression, irritability, giddiness, poor performance in arithmetic tests, minor difficulties in orientation, and frightening dreams. It was observed that the complex of central nervous system (CNS) symptoms may not fully develop until 24 h after exposure. In addition, no correlations between the presence or severity of symptoms and the degree of acetylcholinesterase (AChE) inhibition were seen. Most of the effects of exposure disappear within 3 days. It was concluded that not only severe but also mild intoxication of nerve agents may cause behavioral and psychological disturbances. In general, the behavioral effects have not been permanent but have lasted from weeks to several months, or possibly several years. Long-term behavioral effects after poisoning with nerve agents or OP insecticides have been reported (Levin and Rodnitzki, 1976; Karczmar, 1984; Loh et al., 2010). These reports are based on clinical observations, which are occasionally supported by psychological studies.

METHODS USED TO EVALUATE BEHAVIORAL EFFECTS OF NERVE AGENTS

Functional Observatory Battery

The functional observatory battery (FOB) is a noninvasive and relatively sensitive type of neurobehavioral examination of 40 sensory, motor, and autonomic nervous functions. Some of them are scored (Table 35.1), and the others are measured in absolute units (Frantik and Hornychova, 1995). The first evaluation is performed when nerve agent–exposed or control rats are in the home cage. The observer evaluates each animal's posture, palpebral closure, and gait, and the presence or absence of convulsions is noted. Each rat is then removed from the home cage and briefly held in the hand. The presence or absence of spontaneous vocalization, piloerection, and other fur and skin abnormalities as well as irritability is noted. Lacrimation and salivation are also observed. Other signs such as exophthalmus, crustiness around the eyes, or emaciation are also recorded. The rats are then placed on a flat surface that serves as an open field. A timer is started for 3 min, during which the frequency of rearing responses is recorded. At the same time, gait characteristics are noted and ranked, and activity, tremor, convulsions, and abnormal posture are evaluated. At the end of the third minute, the number of fecal boluses and urine pools on the absorbent pad is registered. Then, a reflex test that consists of recording each rat's response to the frontal approach of the blunt end of a pen, a touch of the pen to the posterior flank, and an auditory click stimulus is used.

TABLE 35.1 Functional Observational Battery

	Scored Values Only									
Marker	**−2**	**−1**	**0**	**1**	**2**	**3**	**4**	**5**	**6**	**7**
Posture				Sitting or standing	*Rearing*	*Asleep*	Flattened	Lying on side	Crouched over	Head bobbing
Catch difficulty				Passive	*Normal*	Defense	Flight	Escape	Aggression	
Ease of handling				Very easy	Easy	Moderately difficult	Difficult			
Muscular tonus	Atonia	Hypotonia	*Normal*	Hypertonia	Rigidity	Fasciculations				
Lacrimation			*None*	Slight	Severe	Crusta	Colored crusta			
Palpebral closure				*Open*	Slightly	Half-way	Completely shut	Ptosis		
Endoexophthalmus		Endo	*Normal*	Exo						
Piloerection			*No*	Yes						
Skin abnormalities			*Normal*	Pale	Erythema	Cyanosis	Pigmented	Cold	Injury	
Salivation			*None*	Slight	Severe					
Nose secretion			*None*	Slight	Severe	Colored				
Clonic movements			*Normal*	Repetitive	Nonrhythmic	Mild tremors	Severe tremors	Myoclonic	Clonic	
Tonic movements			*Normal*	Contraction of extensors	Opisthotonus	Emprosthotonus	Explosive jumps	Tonic convulsions		
Gait			*Normal*	Ataxia	Overcompensation of hindlimb movement	Feet point outwards from body	Forelimbs are extended	Walks on tiptoes	Hunched body	Body is flattened against surface
Gait score				*Normal*	Slightly impaired	Somewhat impaired	Totally impaired			
Mobility score				*Normal*	Slightly impaired	Somewhat impaired	Totally impaired			
Arousal (level of unprovoked activity)				Very low	Sporadic	Reduced	*Normal*	Enhanced	Permanent	
Tension			*None*	Partial (ears)	Stupor					
Stereotypy			*None*	Head weaving	Body weaving	Grooming	Circling	Others		
Bizarre behavior			*None*	Head	Body	Self-mutilation	Abnormal movements	Others		
Approach response				No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction		
Touch response				No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction		
Click response				No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction		
Tail-pinch response				No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction		
Pupil size		Miosis	*Normal*	Mydriasis						
Pupil response			No reaction	*Normal reaction*						
Righting reflex				*Normal*	Slightly uncoordinated	Lands on side	Lands on back			

The responsiveness to a pinch on the tail and the ability of pupils to constrict in response to light are then assessed. These measurements are followed by a test for the aerial righting reflex, then by measurements of forelimb and hindlimb grip strength, body weight, rectal temperature, and, finally, hindlimb landing foot splay. The whole battery of tests requires approximately 6–8 min per rat. Motor activity data are collected using an apparatus for testing a spontaneous motor activity of laboratory animals. The animals are placed for a short period (10 min) in the measuring cage and their movement (total horizontal activity, stereotypical activity, rearing, jumping, scratching, and total vertical activity) is recorded.

Performance on the RAM Task

Radial arm maze (RAM) sessions are conducted using an eight-arm commercially available radial maze measuring 137.2 cm in diameter. The center of the maze is a plastic octagon hub measuring 26.67 cm across, with a Plexiglass lid and wire grid-floor. A Plexiglass arm with a wire mesh floor is attached to each of the eight sides of the hub. The entrance to each arm contains a motorized guillotine door allowing access to and from the hub. Each arm's runway contains two floor-mounted switches that are depressed by the weight of the rat when present in the proximal and distal portion of the runway, respectively. The terminal portion of each arm contains a food dispenser for delivering food pellets that is connected to a trough that is outfitted with the photoemitter/detector unit that can detect access by the rats. Experiments are controlled and monitored using a commercial hardware interface and a microcomputer using the L2T2S software control system (Coulbourn Instruments). For the RAM task, four of eight arms are "baited." That is, a single food pellet is available with a nose-poke into the food trough at the terminal portion of four arms. Each rat is randomly assigned a maze configuration of four baited arms from 37 possible configurations that exclude more than two consecutive baited arms. Thus, the same configuration of baited arms is used for a particular rat for each of the sessions, but different configurations can be used for different rats. Sessions begin with the rat placed in the center hub compartment and the doors to the eight arms are raised. The rat is then free to explore the maze to obtain the food rewards available from the four baited arms. The session is terminated when a rat obtains all four food rewards or when 15 min have elapsed. If a rat does not complete the maze within 15 min, then a completion time of 15 min is assigned and errors are analyzed. Failure to complete the maze, however, is infrequent and only occurs during the initial few sessions in the maze. No familiarity training with the maze is conducted before the first session. The major dependent variables characterizing performance on the RAM task are the time to complete the maze and the number of errors made. Errors are designated as occurring when a rat chooses an unbaited arm (reference memory error) or when a rat returns to a baited arm after obtaining the food reward (working memory error) (Genovese et al., 2006).

Acoustic Startle Response and Prepulse Inhibition

The animals are tested for acoustic startle response (ASR) and prepulse inhibition (PPI) in the SM100 Startle Monitor system. The system is usually programmed for six types of white-noise burst stimulus trials: no stimulus (background, 60 dB), prepulse (70 dB), pulse (100 and 120 dB), and prepulse plus pulse (70 dB + 100 dB and 70 dB + 120 dB). Each trial type is presented 10 times in 10 blocks. Stimuli are presented in random order to avoid order effects and habituation. The inter-trial interval can vary from 9 to 16 s. All animals are regularly handled before individual tests to minimize handling-related stress. Animals are pair-matched according to baseline values into the experimental groups using the average of the response to 100 and 120 dB. The tested animals are restrained loosely in holders that are placed on a sensing plate transforming movements of the body (jerks) into an analog signal through an interface. Finally, the percentage PPI measures are calculated as the difference between the pulses alone and multiplied by 100. Percentage scores are typically used to minimize the effect of individual variation of startle amplitude on PPI (Mach et al., 2008).

Performance on Y-Maze

Cognitive functioning can be tested using a Y-maze with averse motivation by a strong electric footshock evaluating learning and spatial memory (Koupilova et al., 1995). The Y-maze is a fully automated apparatus used for the study of behavior of laboratory rats. It is a plastic box consisting of a square start area (285 × 480 mm^2) separated by a Plexiglass sliding door from two trapezoid, black and white arms—choice area (140 × 324 mm^2). The grid-floor at the start and in the choice area is electrifiable. The animal (usually rat) is placed on the start area and after 48 s, electric footshocks (60 V, 50 Hz, duration 0.5 s) are applied at 5-s intervals. The rats try to avoid the shock by escaping to one of two arms. In the case of a rat moving to the wrong (dark) arm, the rat fails to avoid further footshock. The animals are taught spatial discrimination with the preference of the black or white arm in the Y-maze. The latency to enter the correct arm is measured and the number of wrong entries is counted. Before exposure to nerve agent, the rats are trained to avoid footshock by moving to the correct (white) arm

in the Y-maze. It usually takes 4 weeks of training to reach the criterion, which was 80% or more correct averse behavior (moving to the correct arm) within less than 1.5 s. During the training, 10 sessions (two trials/session) per week lasting 4 min are completed. The exposure starts the day after the animals reached this criterion. The latency time to enter the correct arm by nerve agent–exposed rats and the number of entry errors are compared with the values obtained from the control rats exposed to the pure air instead of nerve agent.

Performance on T-Maze

Cognitive functioning can be also tested using a T-maze consisting of five segments, a starting, and a goal compartment to evaluate learning, spatial memory, and spatial orientation (Koupilova and Herink, 1995). The rats are trained, with the food reward, to run through the maze in less than 10 s without entering the side arm. The time necessary to reach the goal box is recorded. Before exposure to nerve agent, the rats are trained to reach the goal box as soon as possible by moving to the correct segment in the T-maze. It usually takes 4–6 weeks of training to reach the criterion, which was 80% or more correct behavior. The exposure starts the day after the animals reaches this criterion. The time of reaching the goal box by rats exposed to nerve agent is compared with the values obtained from the same rats immediately before nerve agent exposure and from control rats exposed to pure air instead of nerve agent.

Performance on Morris Water Maze

The water maze (WM) is often used for the evaluation of effects of various compounds on memory functions, e.g., memory formation, consolidation, and retrieval effects due to its advantages and broad utilization. The Morris WM is a widely used measurement of visuospatial learning that has been demonstrated to have high validity in identifying cognitive effects of various brain lesions and the effects of drugs used to treat cognitive deficits (Morris, 1984; Myhrer, 2003). Special motivation such as food and water deprivation is not required for the WM performance. The effect of odor cue is eliminated in the WM. In addition, rats are forced to swim in the WM. They cannot choose whether to move, so failure to respond is not a confounding issue (Shukitt-Hale et al., 2004). The place-learning version with submerged platform can be used for working memory tests (Myhrer, 2003). The WM can be used to measure spatial learning and memory in the case of the evaluation of cognitive impairment in rats because of the aforementioned advantages.

The rats perform cognitive tasks that require spatial learning and memory—the ability to acquire a cognitive representation of location in space and the ability to effectively navigate the environment in the WM (Shukitt-Hale et al., 2004). Memory alterations appear to occur mostly in secondary memory systems and are reflected in the storage of newly acquired information (Bartus et al., 1989; Joseph, 1992). It is thought that hippocampus mediates allocentric spatial navigation (i.e., place learning) and prefrontal cortex is critical in acquiring the rules that govern performance in particular tasks (i.e., procedural knowledge), whereas the dorsomedial striatum mediates egocentric spatial orientation (i.e., response and cue learning) (McDonald and White, 1994; Oliviera et al., 1997).

The WM consists of a black circular pool (180 cm diameter × 80 cm high) filled to a depth of 25 cm with water at room temperature (Raveh et al., 2002). The pool is imaginarily divided into four equal compartments numbered 1–4 (clockwise). The black antireflective circular escape platform (15-cm diameter) is placed into compartment number 1 or 4, 20 cm off the pool wall. The platform is sunk 2 cm below the water surface so it is not visible to the rats because of the water mirror effect. The yellow rectangle ($30 \times 40\,cm^2$) is fixed on the pool wall that is closest to the platform as the spatial conditional cue (Robinson et al., 2004). Its place is variable according to the platform. Another dark rectangle is randomly fixed on the pool wall in different compartments (without platform) as the negative conditional cue. Around the pool there are several stable extramaze cues in the room that the rat could use to navigate the maze (Morris, 1984). However, the impact of extramaze cues is not significant because of high maze walls.

Performance on Passive Avoidance Test

Passive avoidance is a fear-motivated test classically used to assess short-term or long-term memory on small laboratory animals (rats, mice). Basically, passive avoidance working protocols involve timing of transitions, e.g., time that the animal takes to move from the white compartment to the black one after a conditioning session—during which the entry into the black compartment is punished with a mild inescapable electrical shock—is performed. The animal's position is detected by using high-sensitivity weight transducers providing more effective and reliable detection of animal responses (zones entries) than systems based on photocells beams or on grid-floor displacements. The measured parameter is a latency to enter into the black compartment. A two-compartment step-through passive avoidance apparatus is usually used. The apparatus ($430 \times 220 \times 190\,mm^3$) is divided into bright and dark compartments by a removable divider. The divider is a tunnel with an automatic door. Using a software-controlled magnetic switch, this door can be closed automatically. The gate has to be

opened manually at the start of the experiment. Each compartment is equipped with a light (2.2 W each). The ceiling also contains a common loudspeaker to deliver a sound signal (10 kHz fixed, maximum 100 dB). The animal's position inside the cage is monitored with the help of infrared light barriers. After a specified time interval after drug administration, passive avoidance training is performed. The animals are placed in the bright compartment and allowed to explore for 30 s, at which point the guillotine door was raised to allow the rat to enter the dark compartment. When the animal enters the dark compartment, the guillotine door is closed and an electrical foot shock (0.1–3.0 mA) is delivered. Training sessions are conducted twice (double trainings) during the light phase of the 12-h day/night cycle. The second double-training session is performed immediately after the first session. The animals are placed in the bright compartment and allowed to explore for 30 s, and then the guillotine door will raise. The latency to enter the dark compartment is recorded for up to 300 s (Gacar et al., 2011).

LONG-TERM BEHAVIORAL EFFECTS OF ACUTE HIGH-LEVEL EXPOSURE TO NERVE AGENTS

Many of the data regarding long-term neurological sequelae to exposures to cholinesterase inhibitors in humans have been gathered after accidental exposures to OP compounds (pesticides as well as nerve agents). Nevertheless, the extrapolation from these exposures to prediction of effects from nerve agent is difficult because:

- The cholinergic crisis caused by acute, severe intoxication with the OP pesticides is generally much longer than that caused by OP nerve agents.
- OP pesticides-induced delayed peripheral neuropathy can be caused by nerve agents only at doses many times greater than that of the LD_{50} (Davis et al., 1960).
- A delayed manifestation of OP poisoning has not been described after administration of nerve agents to animals or in instances of nerve agent poisoning in humans (Sidell, 1997).

There have been descriptions of the acute effects in humans that follow high-dose exposure ($\geq LD_{50}$) to nerve agents soman, sarin, and VX (Inoue, 1995; Nozaki et al., 1995; Nakajima et al., 1997). The similar cluster of behavioral symptoms (anxiety, psychomotor depression, intellectual impairment, and sleep disturbance) was observed in the immediate period after resolution of the acute signs of intoxication and then slowly faded with time, sometimes taking months to be fully resolved. The CNS symptoms noted after short-term exposure of humans to diisopropyl fluorophosphate (DFP) were excessive dreaming, insomnia, jitteriness and restlessness, increased tension, emotional lability, subjective tremulousness, nightmares, giddiness, drowsiness, and mental confusion. CNS symptoms were correlated with the depression of red blood cell AChE (EC 3.1.1.7) to 60–70% of original activity and they disappeared within 1–4 days (Grob et al., 1947). It was also noted that more severely exposed individuals and those with multiple exposures tended to display persistent symptoms that included forgetfulness, irritability, and confused thinking, although the duration of these persistent symptoms was never clearly defined (Holmes and Gaon, 1956). These CNS symptoms are virtually identical to those that have been reported to occur after high-level exposure to nerve agents. It was shown in the study of human sarin poisoning that sarin-induced behavioral effects were virtually identical to those reported for DFP. These effects coincided with the depression of plasma ChE and red blood cell AChE activity to approximately 50–60% of original activity (Grob and Harvey, 1958). The behavioral symptoms such as anxiety, psychomotor depression, general intellectual impairment consisting of difficulties in concentration and retention, and sleep impairment generally involving insomnia because of excessive dreaming were also described during human poisoning with nerve agent VX (Bowers et al., 1976).

The exposure to high doses of OP compounds including nerve agents has been demonstrated to result in severe brain neuropathology that involves not only neuronal degeneration and necrosis of various brain regions (Petras, 1981; McLeod et al., 1982; Lemercier et al., 1983) but also persistent severe alteration in behavior and cognitive incapacitation, especially impairments of learning and memory (McDonald et al., 1988; Bushnell et al., 1991). The most significant injury caused by OP poisoning is neuronal degeneration of the hippocampus that is associated with spatial learning and memory. Therefore, impairment of cognitive functions, especially incapacitation of learning and memory, belongs to the most frequent central signs of acute OP poisoning (McDonald et al., 1988; Marrs, 1993). In addition, the adverse effects of OP compounds on cognition functions, such as learning and memory, may persist for quite some time after termination of toxicant exposure. The results from several studies have demonstrated the presence of OP compound-induced learning impairments several days after the classic signs of OP toxicity have subsided (McDonald et al., 1988; Buccafusco et al., 1990; Bushnell et al., 1991). Behavioral effects are typically evident before the occurrence of physical symptoms. These effects were associated with whole-blood ChE inhibitions of more than 60%. It was also found that severe poisoning with OP compounds causing general tonic–clonic convulsions altered Ca^{2+} dynamics that could underlie some of the long-term plasticity changes

associated with OP compound toxicity. These changes demonstrated in hippocampal neurons can be responsible for long-term behavioral toxicity of OP compounds (Deshpande et al., 2010).

Several studies of the long-term effects in victims of sarin exposure in Japan have been published. Exposure to nerve agents in humans was found to produce effects that include cognitive deficits and memory loss (Hatta et al., 1996; Hood, 2001; Okudera, 2002). Eighteen victims of the Tokyo subway incident were evaluated at 6–8 months after exposure (Yokoyama et al., 1998). Individuals exposed to sarin scored significantly lower than controls on a digit symbol substitution test and scored significantly higher than controls on a general health questionnaire (GHQ; psychiatric symptoms) and a profile of mood states (POMS; fatigue). The elevated scores on the GHQ and POMS were positively related to the increased posttraumatic stress disorder (PTSD) scores and were considered to be attributable to PTSD (Yokoyama et al., 1998). There have been two brief reports of individuals severely poisoned with nerve agents (one sarin and one VX) in Japan who experienced retrograde amnesia, possibly because of prolonged periods of seizures and/or hypoxia (Nozaki et al., 1995; Hatta et al., 1996). Symptoms related to sarin exposure in Japan still exist 1–3 years after the incident and include fatigue, asthenia, shoulder stiffness, and blurred vision (Abu-Qare and Abou-Donia, 2002).

The existence of long-term behavioral effects after acute exposure to high doses of nerve agents was verified many times with the help of laboratory experiments on animals. There are numerous studies using animals that show that survivors of high-level OP exposure can experience subtle but significant long-term neurological and neuropsychological outcomes that are detectable months or even years after recovery from acute poisoning (Brown and Kelley, 1998). Exposure of animals to nerve agents was shown to produce neurotoxicity in the CNS areas associated with cognition and memory functions (Koplovitz et al., 1992; Petras, 1994). There are a few studies that revealed changes in the brain after sublethal nerve agent exposure that involve not only the cholinergic system but also the glutamatergic system (Lallement et al., 1992; McDonough and Shih, 1997). Excitotoxic injury caused by increased levels of glutamate has repeatedly been shown to cause cognitive dysfunction (O'Dell et al., 2000). Therefore, the disruption of cognitive functions, especially spatial and working memory, seems to be the most frequent and the most observable behavioral effect of nerve agent poisoning. In addition, acute and repeated administration of OP compounds induced anxiogenic and depression-like responses. This fact was assessed on elevated plus-maze and forced-swim test, which are validated animal models for observing anxiety and depression-like behavior (Assissi et al., 2005). The studies show changes in the brain after sublethal nerve agent exposure that leads to memory and attention deficits that normally involve the hippocampus (Hatta et al., 1996; Nishikawi et al., 2001; Miyaki et al., 2005). The role of hippocampus in complex visuospatial learning and memory has been well established. The high concentration of N-methyl-D-aspartate (NMDA) and alpha-amino-3 hydroxy-5 methyl-4-isoxazolepropionic acid (AMPA) glutamate receptors, which play a key role in hippocampal-mediated learning and memory, also makes the hippocampus highly vulnerable to glutamate-induced excitotoxic injury from nerve agent poisoning (Shih et al., 1990; Lallement et al., 1992; Filliat et al., 2007).

After a high-dose exposure (more than 0.5 × LD_{50}), seizures are a prominent sign of nerve agent intoxication and these prolonged seizures can produce neural lesions (McDonough and Shih, 1997). Thus, neurological and behavioral deficits are predictable long-term effects after exposure to such doses of nerve agents. Animals exposed to high (convulsive) doses of nerve agent can develop spontaneous seizures and display hyperactive and aggressive behavior and profound deficits in learning and/or performance of a variety of behavioral tasks. Animal studies have demonstrated deficits in acquisition of several types of operant tasks, performance of serial probe recognition task, maze learning, and passive avoidance learning after acute poisoning with nerve agents (McDonough et al., 1986; Raffaele et al., 1987; Modrow and Jaax, 1989).

The inhalation exposure to high-level sarin induced in rats impaired memory processes seen at 1 month after exposure with no recovery of cognitive function during the 6-month follow-up period. In the open field, sarin-exposed rats showed a significant increase in overall activity with no habituation over days. In a working memory paradigm in the WM, the same rats showed impaired working and reference memory processes with no recovery. These data suggest long-lasting impairment of brain functions in surviving rats after a single exposure to sarin. Animals that seem to fully recover from the exposure, and even animals that initially show no toxicity signs, develop some adverse neurobehavioral changes with time (Grauer et al., 2008). These findings are in accord with reports of long-term behavioral impairment after exposure to OP pesticides used in agriculture (Wesseling et al., 2002). Similarly, long-term follow-up of victims of the sarin attacks in Japan demonstrated neurological as well as emotional and cognitive changes up to 7 years after exposure (Ohbu et al., 1997; Yokoyama et al., 1998; Miyaki et al., 2005).

Generally, according to high-dose exposure studies, animals exposed to nerve agents that exhibit seizures that are not promptly controlled develop brain damage and subsequent neurobehavioral problems. Animals

that do not develop seizures or those that are rapidly and effectively treated with drugs that stop the seizures suffer no brain lesion and display no long-term neurobehavioral deficits. Besides classic antidotes (atropine, oximes, benzodiazepines), other drugs such as centrally acting anticholinergic drug scopolamine and a new anticonvulsant drug imidazenil are effective to eliminate or at least reduce behavioral toxicity of nerve agents (Che et al., 2011; Wang et al., 2012).

CHRONIC BEHAVIORAL EFFECTS OF SINGLE OR REPEATED LOW-LEVEL EXPOSURE TO NERVE AGENTS

Anticholinesterase compounds such as nerve agents can alter behavioral functions even after small subtoxic doses. There are very few data regarding human exposures. Based on the data describing the signs and symptoms in accidentally exposed humans, some long-term health effects, including behavioral effects of repeated subclinical exposures to OP compounds, were observed (Wesseling et al., 2002). When the workers were exposed to small amounts of nerve agents they showed mild toxic signs of exposure, including CNS effects such as insomnia, excessive dreaming, restlessness, drowsiness, and weakness (Craig and Freeman, 1953). It was shown that psychological symptoms are probably more common than usually recognized and may persist in more subtle forms for much longer (days, weeks) than physical symptoms (Sidell and Hurst, 1997). Recently, a dose–response association was found between low-dose exposure to sarin and cyclosarin inhalation during the 1991 Gulf War and impaired neurobehavioral functioning as well as subtle CNS pathology, as revealed by MRI study (Proctor et al., 2006; Heaton et al., 2007). It is interesting that functional impairments were detected even in people who initially developed only mild or no signs of sarin or cyclosarin toxicity. These data correspond to the published epidemiological studies showing alterations in cognitive functions, impaired memory, and concentrations in humans after chronic low-dosage occupational exposure to OP insecticides (Stephens et al., 1995; Parrón et al., 1996). Increased reports of forgetfulness and difficulties in thinking, exposure-related increases in work-related tension, sleep disturbance, restlessness, and nervousness have been documented among sheep farmers exposed to OP pesticides (Stephens et al., 1995; Beach et al., 1996).

Based on the experimental animal data, the progression of signs, their neuropharmacological basis, and toxic consequence elicited from acute high-dose exposures have been well characterized (McDonough and Shih, 1993; Shih et al., 2003). However, much less is known about the long-term effects of repeated low-dose nerve agent exposure. Several comprehensive reviews of the long-term health effects of exposure to low-level nerve agent exposure have been published (Moore, 1998; Romano et al., 2001).

It is known that a significant, clinically manifested AChE inhibition in CNS leading to the neuronal degeneration of some brain regions, including the hippocampus, which is associated with spatial learning and memory, is not necessary for clinically manifested cognitive impairments. This fact corresponds with previously published data about neurological and neurophysiological outcomes detectable months or even years after recovery from acute OP poisoning (Savage et al., 1988; Yokoyama et al., 1998). It is very difficult to find the real reason for the memory impairments in the case of low-level nerve agent exposure. Recently, a temporal relationship has been demonstrated between OP-induced impairment in performance of a spatial memory task and the protracted decrease in the expression of cholinergic receptors in specific brain regions (including the hippocampus) after the asymptomatic exposure to OP compounds (Stone et al., 2000). Nerve agent–induced impairment of cognitive functions is probably caused by subsequent desensitization and internalization of cholinergic receptors as a reaction of nerve agent–exposed organisms on hyperstimulation of cholinergic receptors, especially in parts of the brain with a high density of cholinergic synapses such as the hippocampus (McDonald et al., 1988; Stone et al., 2000). This means that a decrease in the number of cholinergic receptors in the hippocampus after low-level exposure to OPs without significant AChE inhibition could cause memory impairments. It was also found that OP compound–induced cognitive deficits may be related to persistent functional changes in brain neurotrophin and cholinergic pathways (Terry et al., 2011, 2014). In addition, the influence of diet on the behavioral toxicity of nerve agents has been demonstrated (Langston and Myer, 2011). It was found that diet composition exacerbates or attenuates behavioral toxicity of nerve agents in exposed rodents. The exacerbated behavioral toxicity of nerve agents in the animals fed with glucose-enriched diet could be due to inactivation of esterases including AChE, BuChE, CaE, and PON by glycation or glycooxidation or by increased acetylcholine (ACh) synthesis and/or utilization. However, ketogenic diet attenuates behavioral toxicity of nerve agents. The mechanism responsible for this effect is unknown, but there is considerable evidence that the ketogenic diet has neuroprotectant and anticonvulsant properties by altered energy or altered neurotransmitter (gamma aminobutyric acid – GABA) synthesis (Bough and Rho, 2007). In addition, moderate benefit of choline supplementation against behavioral toxicity of nerve agents was observed (Langston and Myer, 2011).

In the available literature regarding repeated low-dose exposure to nerve agents, soman is the nerve agent

studied most often. Mice, rats, guinea pigs, and primates were used to investigate repeated low-dose soman exposure. The effects of repeated soman exposures ranged from performance decrements on a well-learned compensatory tracking task (Blick et al., 1994b) to development of attention deficits (Gause et al., 1985) and hyperreactive responses to handling (Shih et al., 1990). In addition, a single subcutaneous exposure of guinea pigs to sublethal doses of soman triggers long-lasting anxiogenesis and decreased locomotor activity (Mamczarz et al., 2010).

Unlike soman, the amount of literature regarding the effects of repeated low-level exposure to sarin is rather sparse and sometimes conflicting. Rhesus monkeys exposed to low levels of intramuscular sarin showed no signs of adverse health or long-term behavioral effects (Burchfiel et al., 1976). In contrast, it has been observed in rats and mice that intraperitoneal injections of subtoxic doses of sarin or soman decreased locomotor activity and altered behavior on the plus-maze and elevated horizontal bridge tests (Nieminen et al., 1990; Sirkka et al., 1990; Baille et al., 2001). Single as well as repeated low-level inhalation exposure of rats to sarin produced a deficit on RAM spatial memory task. The deficit was resolved during the first 3 weeks of acquisition (Genovese et al., 2009). It was also shown that repeated low-level sarin inhalation in rats at clinically asymptomatic doses was disruptive to neurophysiological function and caused long-term memory impairments (Kassa et al., 2001a,b). The results of the study related to the measurement of sarin-induced alteration of behavioral and neurophysiological functions at 3 months after low-level sarin inhalation exposure of rats showed a significant alteration of mobile activity and gait characterized by ataxia and an increase in stereotypical behavior. These signs were observed in rats repeatedly exposed to sarin at clinically asymptomatic doses or singly exposed to sarin at doses causing mild muscarinic signs of exposure. These animals had awkward hindlimbs and their mobility was markedly diminished (Kassa et al., 2001d). Spatial discrimination in the Y-maze was also altered in rats exposed to low levels of sarin. Although spatial orientation of rats singly exposed to clinically asymptomatic doses of sarin was significantly influenced for only a short time (1 or 2 h after exposure), the rats repeatedly exposed to clinically asymptomatic doses of sarin showed a decrease in Y-maze performance for a relatively long time (until the third week after exposure) (Kassa et al., 2004). The significant impairment of spatial memory of rats exposed to clinically asymptomatic concentrations of sarin was also observed when cognitive functions were evaluated with the help of T-maze performance. Rats exposed to low-level sarin showed a significant decrease in T-maze performance for a short time (until the first day after exposure). In addition, the effects of low-level sarin inhalation exposure were dose-dependent. When the rats were exposed to low-level sarin causing moderate signs of poisoning, their time of passage through the maze was longer at 1 and 2 h after the inhalation exposure compared with the rats exposed to clinically asymptomatic levels of sarin (Kassa et al., 2001c).

Single exposure to another nerve agent, cyclosarin, at concentrations that do not produce convulsions or severe clinical signs of toxicity can also produce performance deficits on learned behavioral tasks. However, with repeated exposure, the deficits are not persistent and recovery is complete. In addition, exposure concentrations not producing any evaluated clinical signs of toxicity, other than temporary miosis (in the case of inhalation exposure), do not produce performance deficits on the behavioral tasks (Genovese et al., 2006). Asymptomatic exposure of rats to VX vapors can produce only minor performance effects on previously learned behavioral tasks and on the acquisition of new behavioral tasks (Genovese et al., 2007).

Reports in the literature of animal studies show that nerve agents can be administered repeatedly with minimal overt neurobehavioral effects if care is taken in choosing the dose and the time between doses (Sterri et al., 1980, 1981). The repeated low-level nerve agent exposure made the cognitive impairments longer and higher compared with the single nerve agent exposure. The repeated exposure to low doses of soman can produce small, transient performance decrements only, probably because of the development of a physiological and behavioral tolerance to low levels of ChE activity (Blick et al., 1994a,b). Nevertheless, progressive and long-lasting inhibition of ChE in CNS after repeated administration of low doses of nerve agent soman was demonstrated (Hartgraves and Murphy, 1992). This study was corroborated by using nerve agent sarin (Olson et al., 2000). Generally, repeated or long-term exposure to low levels of nerve agents can cause neurophysiological and behavioral alterations (Abu-Quare and Abou-Donia, 2002).

The rats repeatedly exposed to sarin at doses corresponding to $0.5 \times LD_{50}$ (three times per week, subcutaneous) showed an increase in acoustic startle and a decrease in distance explored in the open field 2 weeks after sarin exposure. However, no effect of sarin exposure on passive avoidance was noted at the same time after sarin poisoning. Brain regional AChE was not affected at any time after sarin exposure, but muscarinic receptors were downregulated in the hippocampus, caudate putamen, and mesencephalon in the sarin group at 2 weeks after sarin exposure. Thus, downregulation of muscarinic receptors in the hippocampus as a reaction to ACh accumulation at muscarinic receptor sites based on AChE inhibition can be considered a cause of behavior performance deficits, especially disruption of cognitive functions (Scremin et al., 2003). In addition,

protracted impairment of cognitive functions in rats exposed repeatedly to low-level OP compounds may be associated with a decreased rate of AChE recovery in the hippocampus (Prendergast et al., 1997).

The results from several studies have demonstrated the presence of OP-induced learning impairments several days after the behavioral signs of OP toxicity have subsided (McDonald et al., 1988; Bushnell et al., 1991). Chronic exposure to OP compounds can also result in specific long-term cognitive deficits even when signs and symptoms of excessive cholinergic activity are not present (Prendergast et al., 1998). Thus, the significant, clinically manifested AChE inhibition in the CNS leading to the neuronal degeneration of some brain regions, including the hippocampus, is not necessary for the clinically manifested cognitive impairments. This conclusion corresponds with previously published data about neurological and neurophysiological outcomes detectable months or even years after recovery from acute OP poisoning (Savage et al., 1988; Yokoyama et al., 1998). A current study attempts to show a temporal relationship between OP-induced impairment in performance of a spatial memory task and the protracted decrease in the expression of cholinergic receptors in specific brain regions caused by asymptomatic exposure to an OP compound (Stone et al., 2000). In addition, low-level OP-induced memory impairment may be associated with a decreased AChE recovery in the hippocampus relative to the cortex. This decreased rate of enzyme recovery may contribute to hippocampal toxicity underlying protracted impairment of working memory and other cognitive functions (Prendergast et al., 1997).

Repeated or chronic low-level nerve agent exposure can cause a prolonged inhibition of extracellular AChE, leading to a prolonged increase in extracellular ACh. The prolonged availability of ACh in the synaptic clefts results in feedback inhibition on muscarinic, presynaptic receptors to decrease further ACh release (Russell et al., 1985). The greater ACh release in the nerve agent–exposed group may be due to the known downregulation of muscarinic receptors in response to chronic nerve agent exposure (Churchill et al., 1984). Neurochemical analyses showed that the normal brain neurotransmitter and receptor homeostasis is disrupted even at 10–12 days after 2 weeks of chronic nerve agent exposure, at least in the striatum, but probably throughout the whole cholinergic system in the brain (Shih et al., 2006).

CONCLUDING REMARKS AND FUTURE DIRECTION

Exposure to high doses of nerve agents has been demonstrated to result in severe brain neuropathology that involves not only neuronal degeneration and necrosis of various brain regions but also persistent severe alterations in behavior and cognitive functions, especially impairment of learning and memory. The most significant injury caused by nerve agent poisoning is neuronal degeneration of the hippocampus, which is associated with spatial learning and memory. Therefore, impairment of cognitive functions, especially incapacitation of learning and memory, belongs to the most frequent central signs of acute nerve agent poisoning. In addition, the adverse effects of nerve agents on cognitive functions, such as learning and memory, may persist for a relatively long time after the termination of nerve agent exposure.

Behavioral alterations and impairments of cognitive functions were found after acute exposure to nerve agents with the absence of any classic signs of cholinergic toxicity. It was shown based on the experimental results that not only convulsive doses but also clinically asymptomatic doses of nerve agents can cause subtle long-term neurophysiological and neurobehavioral dysfunctions. The neurological and neurophysiological outcomes are detectable months or even years after the recovery from acute poisoning. It probably means that systems other than the cholinergic nervous system can be involved in nerve agent–induced long-term signs of alteration of neurological and neurophysiological functions. Thus, it is necessary to find new markers describing noncholinergic outcomes of low-level nerve agent exposure.

The long-term behavioral toxicity of nerve agents, especially the alteration of cognitive functions (T-maze, Y-maze, Morris maze test) due to nerve agent-induced delayed toxicity, seems to be connected with the neuropathological damage observed in the hippocampus. Thus, neuropathology of the hippocampus connected with the alteration of cognitive functions can occur after high-level as well as repeated or long-term low-level nerve agent exposure.

Neurochemical analysis of repeated or low-level nerve agent exposure provokes the suggestion that the prolonged nerve agent-induced alteration in brain chemistry may be a pharmacological basis for neurobehavioral changes. Thus, it is necessary to follow brain homeostasis during acute as well as chronic nerve agent exposure.

Repeated or long-term exposure to low levels of nerve agents can cause neurophysiological and behavioral alterations attributable to downregulation of muscarinic receptors in the hippocampus as a reaction to ACh accumulation at muscarinic receptor sites based on AChE inhibition. This phenomenon is considered the cause of behavior performance deficits, especially disruption of cognitive functions.

CHAPTER

36

The Respiratory Toxicity of Chemical Warfare Agents

Alfred M. Sciuto and Urmila P. Kodavanti

INTRODUCTION

Chemical warfare agents (CWAs) play a significant role in the defense preparation plans of major military organizations worldwide. Human CWA exposure produces unique pulmonary and systemic health effects. The exposure/response relationships have been characterized to some extent, but many of the precise mechanisms are extremely complex and unknown. The physiology, biochemistry, and toxicology of CWA exposure has been studied for decades, but more recently, the interest in this topic has been rejuvenated due to increased threat for potential use of CWAs and development of countermeasures. The health studies involve acute and chronic exposure effects to high or low doses of various agents. The landscape for the administration of medical therapies has evolved from these studies. However, recent history has shown that some of the focus of chemical defense has shifted to the biological agents that have attracted much attention with the deadly anthrax attacks in the early part of this century. While many of these agents pose a different kind of threat with regard to their potential use, this chapter deals specifically with the more common CWAs, including traditional nerve agents such as sarin, soman, and tabun; vesicants such as sulfur mustard; riot control agents (RCAs); metabolic poisons such as cyanide; and choking agents such as phosgene and chlorine. Many of the agents discussed here, while not necessarily regarded as valid CWAs in current plans and scenarios, remain legitimate terrorist weapons.

In an attempt to elucidate the site-specific targets of toxicity and to define the physiological, biochemical, and toxicological mechanisms of an inhalation exposure, rodent models have been extensively utilized. This has been the case with practically all studies that investigate the adverse effects of an inhalation challenge. While these models are extremely useful as a first attempt to identify exposure/response effects, rodents do not accurately represent humans in terms of respiratory structure and function. Therefore, the extrapolation of rodent data to humans should be made carefully with regard to the toxicity of CWAs. The agents discussed herein manifest their toxicities based on the capability of the exposed animal to distribute, detoxify, metabolize, excrete, and override the deleterious effects of an agent challenge, regardless of route of exposure. However, when the toxic load overwhelms the system, potentially adverse outcomes are imminent.

HISTORY OF CWA USE

The use of CWAs on the battlefield gained significant recognition during and after World War I. An excellent and comprehensive history of the use of CWAs is presented by Hilmas et al. (2008) and Salem (2008). The historical use of CWAs stems from work with plant poisons by the ancient Egyptians and Indian civilizations nearly 5000 years ago. One of the earliest recorded uses of chemical warfare was that of Greek fire, as noted in the Ebers Papyrus 3500 years ago. Greek fire may have consisted of pitch, quicklime, and sulfur naptha. Arsenic-based and phosgene-like toxic smokes and "flaming concoctions" were used throughout history by the Greeks, Chinese, and Romans before the common era (BCE) to achieve victories in such settings as the Peloponnesian Wars (431–404 BCE) against tribal mountain rebels, and the Turks over 2000 years ago, respectively. During the fifteenth century, Leonardo da Vinci proposed the use of shells filled with copper acetate, sulfur, and arsenic as a weapon to be

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00036-1

fired against enemy ships to disable the crew by directly affecting their lung. Similar toxic smokes were used during the Thirty Years War (1618–1648). The use of chlorine gas was suggested during the U.S. Civil War (1861–1865), but it was not actually manifested under battlefield conditions until World War I. By far, the most extensive use of CWAs on the battlefield occurred during World War I. Both Germany and the Allies used projectiles filled with chlorine, phosgene, diphosgene, and sulfur mustard. These were used singly or in combinations, such as chlorine used with phosgene. These agents were well suited for use, as they generally tended to be heavier than air, and as such, caused extensive mortality and morbidity. In the mid-1930s, during the Italian-Ethiopian War, sulfur mustard (and possibly chloropicrin (PS) and phosgene) were used. In the intervening years between World War I (1914–1918) and World War II (1939–1945), significant effort was put into developing therapies and physical barrier protection, such as masks and suits, for the possibility of the chemical warfare attack by warring nations in future conflicts. Although CWAs were stockpiled during World War II, none were used. The development of more deadly chemical agents—namely those of the organophosphorus nerve agents—occurred during this period.

In the 1960s, during the Vietnam War, the United States used defoliating agents such as Agent Orange to uncloak the enemy. While the planned use of sulfur mustard was not applied on the battlefield, the United States implemented the use of nonlethal RCAs. In the Yemen Civil War, the Egyptians used mustard gas, phosgene, nerve agents, and RCAs on a regular basis from 1963 to 1967. In the mid-1980s, sulfur mustard and nerve agents were used by the Iraqis on Iranian troops, causing massive casualties and deaths. Over 35 years later, the survivors of these gas attacks continue to have exposure-related health issues. More recently, in 2002, the Russians used the incapacitating agent fentanyl to subdue Chechnyan terrorists holding Russian civilians hostage in a movie theater. This attempt to defuse the situation resulted in over 118 deaths due to asphyxiation. In 2007, terrorists exploded homemade chlorine canisters, causing numerous casualties in Iraq. Even more recently, in 2013, there was the alleged use of the nerve gas sarin by the Syrian government in the Syrian Civil War that presumably killed hundreds of civilians. Virtually all these agents, regardless of their route of exposure, can injure the respiratory system.

THE RESPIRATORY SYSTEM

The structure of the respiratory system is complex, so the effects produced by inhaled CWAs can vary depending on the chemistry and deposition efficiencies of these substances. The respiratory system is comprised of the airway compartment, to transport air, and the alveolar compartment, to perform the gas-exchange function. The airway begins with the nose, which through the pharynx carries air to the trachea, divides into two main bronchi and then several small bronchioles within each lung. Epithelial cells of different types line the airways and perform cell-specific functions. The pseudostratified, columnar ciliated cells predominate in the airways, and while guiding the airflow, function to remove particles encountered through inhaled air and protect the lung from injury. Dome-shaped, secretory cells within small airways (known as *Clara cells*) secrete uteroglobin, possess drug-metabolizing enzymes, and function as stem cells to replenish lost ciliated epithelial cells. In addition, goblet cells produce and secrete mucus at the apical surface of the airway epithelium. The mucous layer helps remove particulates and pathogens via mucociliary clearance and modulates the innate immune response. The thickness of the mucous layer is proportional to the diameter of the airway and the density of goblet cells in a given area. At the basal sector of the airway epithelial cells is the basement membrane, which supports the epithelial cells and interstitial space and allows communication to the smooth muscle layer. Dendritic cells that project between airway epithelial cells function as antigen-presenting cells which, upon recognition of antigens (particulate, microbial, or soluble substances), produce innate and humoral responses (Cook and Bottomly, 2007). Sensory, vagal C-fibers innervate the airways at the airway epithelium and evoke a classical reflex reaction when stimulated, leading to bronchoconstriction and coughing, which in turn enhances parasympathetic tone, causing bradycardia and hypotension (Pisi et al., 2009). The airway surface layer is the first to encounter inhaled soluble and insoluble respirable toxicants that pass through the nose after inhalation.

The terminal airways, called *respiratory bronchioles* in humans, lead into small alveolar sacs, which are lined with type 1 and type 2 alveolar epithelial cells. Thin type 1 epithelial cells cover the alveolar surface, while cuboidal type 2 cells function to secrete proteins and surfactant material that is stored in lamellar bodies. The pulmonary arteries, which bring blood from the heart to the lung for oxygenation, form a capillary network surrounding the alveolar sacs. Type 1 cells are close to the capillary walls, allowing the diffusion of carbon dioxide from the blood to the air and oxygen from the air to the blood to occur (Galambos and Demello, 2008; Herzog et al., 2008). Myofibroblasts are found within the interstitial tissue supporting the alveolar compartments and capillary network and are involved in various functions, including synthesis of collagen, elastin, and other extracellular matrix proteins. The alveolar sacs, interstitial matrix, and capillary network are encapsulated by the

pleural mesothelial layer, which provides anatomical structure to each lung.

The surfactant material produced within type II cells is composed of about 80% phospholipids and about 20% neutral lipids and proteins. Once secreted, it layers thinly over the entire alveolar epithelial surface and provides stability to the alveoli, prevents collapse, and preserves patency. In addition to maintaining surface tension, surfactants play an important role in host defense. Of the four surfactant proteins (SPs), SP-A, SP-B, SP-C, and SP-D, SP-A and SP-D play a role in host defense, whereas hydrophobic SP-B and SP-C are involved in the adsorption and spreading of the surfactant material along the alveolar lining (Griese, 1999; Enhorning, 2008). Alveolar macrophages within the alveoli protect the lung from inhaled pathogens by engulfing bacteria, particles, damaged surfactants, and dead neutrophils or other cells after an acute lung injury. In addition, macrophages perform important innate immune functions by expressing cytokines that are involved in mounting an inflammatory response, as well as in the resolution of inflammation. A variety of warfare agents and pathogens can produce acute lung injury and alveolar edema and lead to respiratory collapse when exposures are encountered at high levels.

PULMONARY AGENTS

Practically all CWAs can be classified as airway and lung toxicants. When inhaled, CWAs can penetrate to various levels of the respiratory system, from the nasal passages to the lung periphery, and cause toxicities specific to lung cells. More importantly, the development of many CWAs were specifically designed to cause significant mortality and morbidity due to compromised respiratory function. These include phosgene, chlorine, diphosgene, and chloropicrin, all of which were used either singly or in combination during World War I and other conflicts worldwide. While, these compounds may be found in old agent stockpiles, both phosgene and chlorine pose industrial and occupational hazards because they are also employed in many industrial chemical manufacturing processes. They are also toxic combustion by-products. Their heavy industrial usage classifies them as toxic industrial compounds (TICs), with the significant potential to affect large residential or rural areas if exploited. In this chapter, we describe the respiratory toxicity of the known warfare agents for which inhalation is the primary route of exposure.

Arsine

Arsine (also known as *arsenic trihydride*, *arsenous hydride*, and *hydrogen arsenide*) has been described as the most toxic form of arsenic. Its chemical formula is AsH_3, and it has a molecular weight of 77.95. It is 2.5 times as dense as air, which makes it highly suitable for a "state-of-the-art" trench-type warfare agent. Arsine most likely would now be classified as a low toxicity and high persistence CWA, at a level equivalent to chlorine (Table 36.1). However, due to its low toxicity (10 times less toxic than phosgene), its battlefield usage was halted during World War I. It is colorless and can have the mild odor of garlic. AsH_3 is soluble in chloroform and benzene, but only slightly soluble in water. Currently, arsine gas is used in the microchip industry to plate semiconductors with arsenic. Other workplace activities where arsine is used are for galvanizing, soldering, etching, and lead plating. Arsine is a strong reducing agent and can be formed through the following arsenide, Zn_3As_2, and acid hydrolysis reaction (Eq. (36.1)):

TABLE 36.1 Classification of CWAs and Their Military Symbols Based on Environmental Persistence and Lethality

Potency	High Persistence	Low Persistence
Low lethality	Sulfur mustard (HD), lewisite (L), mustard-lewisite (HL), nitrogen mustard (HN1–3), cyanogen chloride (CK), diphenylchloroarsine (DA), arsine (AsH_3), chlorine (Cl_2)	*o*-Chlorobenzylmalonitrile (CS), dibenz(*b*,*f*)-1,4-oxazepine (CR), chloracetophenone (CN), chloropicrin (PS)
High lethality	Soman (GB), cyclosarin (GF), VX	Phosgene (CG), sarin (GB), tabun (GA), hydrogen cyanide (AC)

$$Zn_3As_2 + 6H^+ \rightarrow 2AsH_3 + 3Zn^{2+} \qquad (36.1)$$

Exposure Physiology

The single most important route of exposure to arsine is through inhalation. Generally, no discomfort occurs from exposure to arsine, as it is a nonirritating compound. The extent and nature of the symptoms depend largely upon the concentration and duration of exposure. Romeo et al. (1997) report that exposure levels of 10–32 mg/m^3 for up to several hours may produce symptoms consistent with arsine toxicity (described next). An earlier study (Morse and Setterlind, 1950) indicated that exposures ranging from 23 to 970 mg/m^3 may be linked to lethal results in people. Many symptoms are latent in nature. Within 1–24 h after inhalation at a high concentration, persons become ill and may experience hematuria (the voiding of dark, bloody urine). Massive hematuria may lead to anuria, which can become fatal. Within 24 h, symptoms may also include headache, vomiting, muscle weakness, dyspnea, nausea, confusion, wheezing, and jaundice. Fowler and Weissberg (1974) have shown that arsine

causes tachycardia, tachypnea, hepatic enlargement, and abdominal rigidity and tenderness. In severe cases, acute respiratory distress syndrome (ARDS) could become evident along with hyperthermia, hypotension, and paresthesias in the extremities. According to the Centers for Disease Control and Prevention (CDC), high levels of inhaled arsine can also produce convulsions, loss of consciousness, paralysis, and respiratory failure, ultimately leading to death. Pulmonary edema and circulatory collapse may also result in a fatal outcome. However, at low concentrations of 10 ppm for 6 h/day for 4 days, arsine exposure to pregnant mice and rats resulted in no developmental effects (Morrissey et al., 1990). The chronic aftereffects of arsine poisoning include renal injury, polyneuritis, memory loss, and agitation. The most significant finding of arsine toxicity is the fulminant lysis of erythrocytes. It has been reported that arsine at estimated concentrations of 750–1,500 ppm × min will cause extensive hemolysis (Caravati, 2004). The LCt_{50} for arsine gas is estimated to be 5,000 mg × min/m^3 (Seto, 2011).

Exposure Biochemistry

The effect of arsine on the blood has been studied in several animal inhalation exposure models. Blair et al. (1990a,b) exposed male and female mice to arsine at concentrations totaling 9–900 ppm administered for 6 h/day for 5 days over 13 weeks. Pathophysiological results at the highest total dose showed significant decreases in hematocrit (HCT) and hemoglobin (HGB) with increases in mean corpuscular hemoglobin at 5 days post-exposure. Between 15 and 90 days, a regenerative process appeared to have been activated by elevated reticulocytes and mean corpuscular volume. At 90 days, denatured proteins such as Heinz bodies were present. Also at 90 days, the formation of methemoglobin suggests that the oxidation of ferrous heme iron (Fe^{2+}) to ferric heme iron (Fe^{3+}) had occurred. When red blood cells (RBCs) were exposed to arsine gas *in vitro*, reduced glutathione (GSH) levels were diminished by 60% after a 4-h exposure (Blair et al., 1990a,b). The authors concluded that an enhanced oxidative environment may be the source of the oxidation of membrane-bound sulfhydryl groups on the HGB molecule. This conclusion was corroborated to some extent by the addition of the sulfhydryl inhibitor N-ethylmaleimide, 2 h after arsine exposure, which resulted in less hemolysis (Rael et al., 2000). Ionic gradient hemostasis is also affected by arsine exposure in RBCs. Rael et al. (2000) have shown that intracellular K^+ and Mg^{2+} decreased, whereas Na^+, Cl^-, and Ca^{2+} increased. Based on these data, the increase in Ca^{2+} influx may be responsible for arsine-induced hemolysis of RBCs. However, the role of oxidized GSH and an amplified oxidizing environment has been questioned by some investigators as the primary reason for arsine-induced hemolysis (Hatlelid et al., 1995; Winski et al., 1997). Pulmonary toxicity of arsine has not been reported, although inhalation exposures have been used in many studies, except for one where intraperitoneal (i.p.) injections of dimethylarsine and trimethylarsine have resulted in lung tumor formation (Yamanaka et al., 2009).

Exposure Histopathology

A search of literature did not reveal any lung pathological reports for arsine gas toxicity. As stated earlier, the most prominent event following an inhalation challenge is erythrocyte hemolysis.

Chlorine

Similar to phosgene, chlorine is considered a "choking" agent. Under ambient conditions, chlorine, also known as *dichlorine* (molecular weight/MW = 71), is a pungent, noncombustible, yellow-green gas. Chlorine is heavier than air, which enables it to settle in low-lying areas, making it a possible persistent agent, and yet it does not have the toxicity of phosgene (Table 36.1). It is slightly soluble in water in which it can form hydrochloric and hypochlorous acids (HOCl). Chlorine can also bind with alkenes, alcohols, and ammonia. Due to high electronegativity, chlorine can react with numerous biomolecules present in cells and tissues. Reactions with Cl_2 can occur by either radical or ionic processes that form one or two chlorine atom bioproducts. As a nonmetal halogen, Cl_2 is not formed in nature due to its high reactivity. After fluorine and oxygen, it is the third most electronegative element. It was one of the first widely used CWAs, having been employed early in World War I. Presently, the majority of exposures to chlorine occur through accidental occurrences such as train derailments, industrial process failures, and recently, the intentional use of these substances by terrorists in Iraq in 2007 (Weill, et al., 1969; Hilmas, et al., 2008; Van Sickel et al., 2009).

Exposure Physiology

The principal route of exposure to chlorine is through respiration. Chlorine is classified as a pulmonary irritant that can affect both the central and peripheral airway compartments. Unlike phosgene, chlorine does not obey Haber's rule; i.e., that a constant concentration × time ([*C*] × *t*) product leads to a consistent physiological/toxicological outcome (Hoyle, et al., 2010). Acute lung injury is not necessarily caused by chlorine itself, but by the aqueous reaction products formed in the mucus membrane of the airways. These include chlorine dioxide, chloramine, and HOCl. General sequelae include, but are not limited to, lacrimation, rhinorrhea, conjunctival irritation, cough, sore throat, laryngeal edema, dyspnea, stridor, pulmonary edema, and ARDS, all of which can lead to respiratory collapse. Furthermore, inhalation

leads to abrupt airway bronchoconstriction, increased airway resistance along with decreased compliance, epithelial cell necrosis, and microvascular permeability. Chlorine exposure has also been linked to irritant-induced asthma, or what is commonly known as *reactive airways dysfunction syndrome (RADS)*. RADS is characterized by airway hyperreactivity, fibrosis, and airway obstruction. Thus, the responses to chlorine are generally nonspecific, as they are with most irritant compounds. The LCt_{50}, the amount of chlorine inhalation needed to cause 50% mortality in exposed animals or humans, is estimated to be 19,000 mg × min/m^3 (Seto, 2011).

To understand the physiological and mechanistic responses to chlorine inhalation, exposure-response studies have been conducted in rodents. Acute respiratory responses following exposure of female mice to chlorine were examined by Morris et al. (2005). In this study, mice were exposed for 15 min at total chlorine concentrations ranging from 12 to 57 ppm × min. It is not surprising that in obligate nose-breathers, the results indicate that chlorine was scrubbed with excellent efficiency in the upper respiratory tract (URT) at 97%. Resistance in the URT beginning at 15–17 days after exposure was also significantly higher with chlorine than with deep lung irritants. The RD_{50} (the 50% reduction in respiration rate as measured by frequency), at 57 ppm/min of chlorine was significantly increased from baseline to twofold during the last 6 min of 15 min total exposure. Mo et al. (2013) reported an impairment of lung antimicrobial activity in male mice exposed to a total concentration of 14,400 ppm × min chlorine and then challenged with *Aspergillus fumigatus* 24 h post-exposure. In these mice, significant increases in the recruitment of lymphocytes, monocytes, and neutrophils were measured compared to chlorine exposure alone. The authors show that increased neutrophils and concentrations of reactive oxygen species (ROS) may be responsible for the inability of exposed mice to mount an immune challenge to *A. fumigatus*.

Exposure Biochemistry

Chlorine inhalational damage is not restricted to particular cell types, such as epithelial cells. Injury caused by inhaled chlorine can be complex and involves multiple pathways (Figure 36.1). The loss of vascular tone following chlorine exposure has been linked to dysfunctional nitric oxide (NO)–dependent mechanisms and resulting vasodilation (Honavar et al., 2011). To address the role of NO, Honavar et al. (2014) found that when rats were exposed to a total chlorine concentration of 12,000 ppm × min, isolated pulmonary artery studies showed disruption of vascular tone due to disrupted NO signaling. The balance between endothelial nitric oxide synthase (eNOS)- and inducible nitric oxide synthase (iNOS)-derived NO was disrupted by chlorine. The expression and activation of eNOS and iNOS through the interaction between p38 MAPK- and PI3/AKT-dependent pathways may also have an effect on endothelial permeability in lung injury. However, the precise mechanism by which eNOS and iNOS might be linked to functional impairment of pulmonary vascular tone, and bronchoconstriction is not well understood.

Exposure to chlorine in mice induces inflammatory pathways, resulting in the recruitment of neutrophils and the production of cytokines such as GROα/CINC/KC, IL-6, and TNFα (Tian et al., 2008; Song et al., 2011). Li, et al. (2013) have determined that exposure of mice to chlorine gas, 400 ppm × 30 min upregulates unfolded protein response (UPR) in the lung for up to 6 h post-exposure. UPR elements are regulated by a defensin-like peptide through the disruption of iron homeostasis. The authors speculate that inflammatory mediators such as TNFα, IL-6, and hepcidin might also be involved. The link between UPR elements and inflammation has been demonstrated in other studies (Xue et al., 2005). Chlorine exposure also affects regulatory Na^+ channels in epithelial lung cells (Lazrak, et al., 2012). Epithelial Na^+ channels (ENaC), which are present on the apical surface, were inhibited in mouse lung slices and Type II epithelial cells after exposure to 400 ppm × 30 min of Cl_2. The data suggests that Cl_2-activated ERK1/2 expression (extracellular signal-related kinase) in Type II cells *in vitro* and *in vivo* might be involved. The data suggests that Cl_2 exposure results in compromised Na^+ regulatory activity, partly responsible in fluid clearance mechanisms. Post-exposure treatment with reactive species scavengers ameliorated the problem (Xue et al., 2005). The common thread among these studies is that chlorine-induced inflammation produces reactive intermediates and induces cytokine release, which can ramp up destructive pathophysiological responses. Chloramine, a reactive by-product of chlorine metabolism, is also capable of initiating reactive processes. The degree of chlorine-induced injury and lung inflammation has been shown to differ between mouse strains (Tian et al., 2008).

Exposure Histopathology

In humans who have died from severe chlorine exposure, postmortem results have shown the presence of massive pulmonary edema, ulcerative bronchiolitis, and cardiotoxicity (White and Martin, 2010). In mice exposed to chlorine at 400 ppm × 15 min, profound changes in lung pathology were observed (Hoyle et al., 2010). This study looked at lung damage through a range of concentrations over various points in time that produced a constant concentration × time ([C] × *t*) product. There was significant damage to the airway epithelium. At 6 h post-exposure, the injury was more widespread, encompassing large airways and causing denudation. At 24 h post-exposure, sloughed epithelial tissue fragments were present in the airway lumen. There was

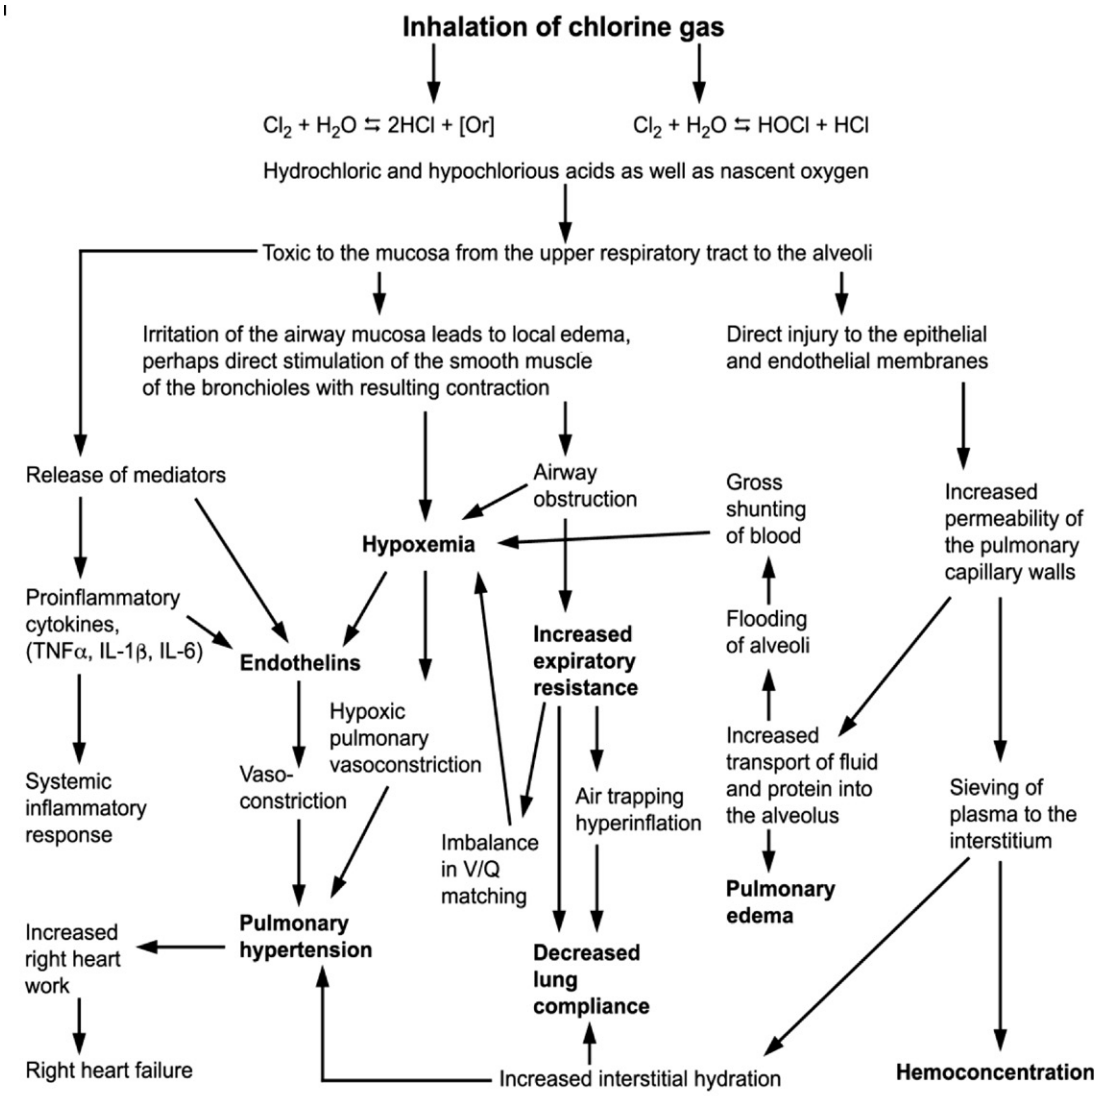

FIGURE 36.1 General mechanistic pathways involved in the toxicity of inhaled chlorine following exposure. IL: interleukin; TNF: tumor necrosis factor; V/Q: ventilation profusion ratio. *Source: Reprinted from* Textbooks of Military Medicine: Medical Aspects of Chemical Warfare, *Published in 2008 by the Office of the Surgeon General at TMM Publications.*

also evidence of neutrophilic inflammation that is consistent with inhaled chlorine toxicity. The magnitude of the histopathological response was not necessarily [*C*] × *t*-dependent. These data corroborate a comparable study by Tian et al. (2008) where similar histological responses were observed. However, at a later time point after exposure (48 h) repair processes are likely activated. Thus, exposure to high concentration of chlorine can produce profound lung injury and pathology.

Phosgene

Phosgene (also known as *carbonyl dichloride, carbon dichloride oxide, carbon oxychloride, chloroformyl chloride, dichloroformaldehyde*, and *dichloromethanone*), whose chemical formula of $COCl_2$ (MW = 98.9) was used as a CWA during World War I. In addition to its weapons applications, it has a variety of industrial uses, such as in the synthesis of pharmaceuticals and organic materials (Wyatt and Allister, 1995). Because of its potential for toxicity, phosgene is often produced and used captively in the same chemical facility to avoid potential hazard. Although it is less toxic than nerve gases such as sarin and tabun, it is still regarded as a viable CWA because it is so easy to produce. Phosgene is generally produced in industry by the interaction of carbon monoxide and chlorine gas, using activated carbon as a catalyst. It can also be produced from chloroform in the presence of oxygen and ultraviolet (UV) light. When phosgene reacts with water, it decomposes into hydrogen chloride

(HCl) and carbon dioxide. Accidental exposures to phosgene in humans at high concentrations cause pulmonary edema, sensory irritation, and associated rapid breathing (Diller, 1985a). Patients complain of dyspnea upon exertion and reduced ability to exercise for several months to years after an accidental exposure. Normalization of lung function can take several years (Diller, 1985b).

Exposure Physiology

Phosgene can be widely and easily dispersed by the wind. Being heavier than air, it tends to sink into trenches and ditches making it fairly nonpersistent on the ground (Table 36.1). Phosgene is deposited in deeper regions of the lung, as opposed to nitrogen oxide, sulfur oxide, and chlorine, which are more water-soluble and are deposited primarily in the upper airways. Inhaled phosgene causes chest pain, burning throat, and persistent cough. It affects numerous metabolic pathways critical to cell and tissue survival. The average LCt_{50} of phosgene in acutely exposed rats has been reported to be 1,741 $mg/m^3 \times$ min (Pauluhn, 2006a). The respiratory toxicity of phosgene is well studied in laboratory rodents, and large animal species such as dogs and sheep. There is a steep acute [*C*] × time mortality relationship for phosgene gas in rats (Pauluhn et al., 2007).

Exposure to phosgene was associated with early bronchoconstriction, an obstructive injury pattern, and disruption of mechanical rhythm of breathing, which were largely attributed to the progressive production of pulmonary edema in mice (Sciuto et al., 2003). Increased expiratory resistance and decreased dynamic compliance were noted in rats exposed to phosgene (Ghio et al., 2005). In pigs exposed to a high concentration of phosgene, a transient decrease in oxygen saturation and cardiac stroke volume index was observed during the exposure period, while significant decreases in arterial pH, P_aO_2, and lung compliance were noted 6 h after exposure (Brown et al., 2002). Thus, the acute physiological effects are likely mediated by sensory irritation and lung edema.

Exposure Biochemistry

Once inhaled, phosgene penetrates deep into the alveolar region, where it transits through the airway surface and is hydrolyzed to CO_2 and HCl; however, it has been shown that the concentration of HCl is not sufficient enough to produce the damage that is typically seen after an acute phosgene exposure (Pauluhn et al., 2007). In contrast to soluble gases, the less-soluble phosgene gas penetrates the lower respiratory tract without marked retention in the conducting airways. It has been hypothesized that phosgene-induced acylation of nucleophilic amino, hydroxyl, and sulfhydryl moieties of the fluid components of the alveolar lining, rather than HCl itself, results in rapid alveolar injury and inflammation (Pauluhn et al., 2007). Through this acylation reaction, phosgene instantaneously interacts with antioxidants such as GSH, resulting in its depletion (Sciuto et al., 2003; Sciuto et al., 2005). It has been proposed that surfactant destabilization and generation of reactive oxidation by-products results in rapid intra-alveolar pulmonary edema. The surfactant abnormalities have been presumed to initiate events leading to acute respiratory failure (Mautone et al., 1985).

Many experimental studies have investigated transient surfactant abnormalities soon after phosgene exposure (Jugg et al., 1999). The surfactant, a mixture of lipids and proteins, performs an important function of maintaining surface tension between air liquid interphase within the alveoli and prevents alveolar collapse. It also regulates innate immune response and host defense (Wright, 2003). Proteins leaked from the vasculature into the alveoli due to phosgene-induced damage to the surfactant and alveolar cells can further inactivate surfactant material. Upon exposure to phosgene, increases in the bronchoalveolar lavage fluid (BALF) levels of proteins are attained on day 1, while lipids increase on day 3, suggesting that these proteins are the likely cause of surfactant destabilization, leading to further vascular leakage, inducing apoptosis, and inflammatory signaling cascade via an innate immune response (Pauluhn et al., 2007). Evidence from studies using large animal models such as dogs and pigs suggests that phosgene inhalation causes a high-permeability type of lung edema brought on by high surface tension and the compensatory interstitial perimicrovascular hydrostatic pressure, resulting in alveolar flooding (Pauluhn, 2006a,b). It has been postulated that the latency between phosgene entry into the lung and edema are due to the time required for increased fluid distribution between interstitial, lymphatic, and perimicrovascular compartments within the alveoli. The alveolar epithelial and interstitial cells (but not endothelial cells) are the primary targets of phosgene-induced injury, further supporting the hypothesis that pulmonary edema results from a pressure gradient across the air liquid interphase (reviewed in Pauluhn et al., 2007).

Increased pulmonary edema induces a sequence of events that results in the release of inflammatory cytokines, apoptosis, extravasation of inflammatory cells, and inflammation that is linked to extracellular matrix remodeling and fibrosis observed in a number of studies, specifically those involving low-level, longer duration exposures. The degree of inflammation and subsequent fibrosis could be directly related to the concentration of phosgene, the longevity of exposure, and the type of laboratory animal model being exposed (Kodavanti et al., 1997; Pauluhn et al., 2007). The removal of pulmonary liquid and inflammatory cells may facilitate quick reestablishment of the homeostasis. A number of

processes, such as mucociliary clearance, fluid clearance through pulmonary circulation, and inflammatory cell signaling, are initiated within alveolar and lower airway structures. Although acute pulmonary toxicity of phosgene is fairly well established, there are no effective antidotes other than supportive management of symptoms. A number of different therapeutic approaches have been tested experimentally (Sciuto and Hurt, 2004).

Exposure Histology

Histopathological lesions have been reported after an acute exposure to phosgene, which are characterized by alveolar and interstitial edema, hemorrhage, fibrin deposition, alveolar and interstitial flooding, and inflammatory cell infiltration. Focal bronchiolar and terminal airway degeneration and necrosis have also been reported. Resolution of inflammation and edema have been noted in a number of animal studies (Gross et al., 1965; Hatch et al., 2001; Duniho et al., 2002). At relatively low concentrations and longer exposures, phosgene can induce alveolar inflammation and fibrosis in a concentration-dependent manner (Kodavanti et al., 1997). The histologic changes in the bronchioalveolar regions in rats exposed to phosgene at 0.1 ppm for 4 weeks were characterized by a small but apparent thickening and mild inflammation, which were progressive with increased concentrations. Masson's trichrome staining indicated increased collagen deposition at the terminal bronchiolar sites and increased pulmonary hydroxyproline, a measure of collagen deposition, at high concentration of 1 ppm. These lesions were also seen in animals exposed for 12 weeks and persisted after a 4-week nonexposure recovery period. Histological changes, including collagen deposition after long-term phosgene exposure, have also been reported by Pauluhn (2006a). Histopathology in pigs exposed to high concentrations of phosgene revealed areas of widespread pulmonary edema, petechial hemorrhage, and bronchial epithelial necrosis (Brown et al., 2002). Thus, phosgene-induced injury is likely to cause pulmonary fibrosis and scarring of the peripheral lung tissue, which might affect breathing.

Nerve Agents

The nerve agents consist of a family of compounds whose role in chemical warfare was to cause significant morbidity and mortality among soldiers. As such, the most likely application of nerve agents was initially for military purposes. However, as recently as 2013, nerve agents were allegedly used against civilians in conflicts in the Middle East (Sellstrom et al., 2013). The syntheses and development of nerve agents took place in Germany between World War I and World War II. Nerve agents are highly toxic and are classified as organophosphates (OPs). OPs are esters of phosphoric acid and are the most toxic of the known chemical CWAs. Members of this family also include parathion, malathion, and mipafox, which are commonly used worldwide in agriculture as well.

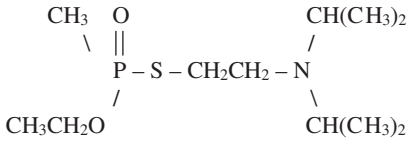
The principal chemical varieties of chemical warfare nerve agents are shown in Figure 36.2. Nerve agents are generally odorless and colorless. See Table 36.2 for physical chemical characteristics. Sarin (GB), tabun (GA), cyclosarin (GF), and soman (GD) are known as the *G agents*, where *G* denotes "Germany." These agents volatilize fairly rapidly. Whereas the *V agents* (where *V* denotes "venomous"), such as *O*-ethyl *S*-[2-(diisopropylamino) ethyl] methylphosphonothioate (VX) and VR, are classified as nonvapor hazards. VR (also known as *Russian VX*) is a close stereoisomer of VX. Classifying V agents as nonvapor threat agents may not be entirely appropriate, as these agents can penetrate the airways if they adhere to dusts, mists, and fog particles, thereby causing significant effects. As a class of threat agents, they are meant to be used as offensive weapons and can be delivered via rockets, bombshells, mortar rounds, and other devices. Usually dispersion is in the forms of sprays, aerosols, and vapor, and possibly the combination of aerosol and vapor. The toxicity response produced by a mixture of OPs can be multifaceted with respect to how these agents are absorbed and deposited in the airway. Punte et al. (1958) makes the statement that OPs in the aerosol form may be more toxic than an equivalent amount delivered by a gas exposure. Owing to their rapid uptake, nerve agents can be absorbed by inhalation, dermal, ocular, and oral routes of exposure. The neuronal effects of nerve agent intoxication include physiological, toxicological, and biochemical responses, which are well studied, but the pulmonary effects are less well examined. These effects are common to all the agents with structural similarities, as shown in Figure 36.2.

Regardless of the route of exposure, nerve agents cause a variety of physiological and toxicological effects, as discussed next. Many of these occur within minutes of exposure, especially with the more volatile G agents. Studies involving inhaled nerve agents have been conducted for many years with a range of animal models. Many factors affect the toxicity response—for example, whole-body exposure versus head-out or nose-only, animal species, agent type, time of day of exposure, duration of exposure, aerosol versus vapor (as these enter the airspaces at different rates and in different locations), dilution vehicle used, agent concentrations and particle size (in the case of an aerosol), and most important, the target tissue dose. Pulmonary toxicities of different classes of nerve agents are described next.

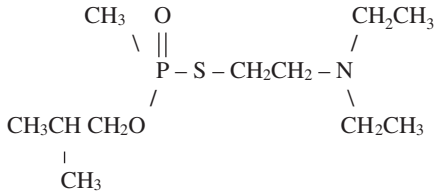
Volatile Agents

G agents include GA, also known as *ethyl dimethylamidocyanophosphate, EA1205* (tabun); GB, known as *isopropyl methylphosphonofluoridate, trilone, MFI, TL1 618, T144*, and

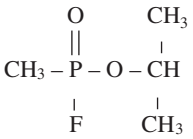
A. VX (*O*-ethyl *S*-(2-(diisopropylamino) ethyl) methlyphosphonothioate)



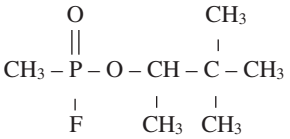
B. VR (O-isobutyl S-[2-(diethylamino)ethyl] methylphosphonothioate)



C. Sarin ([GB], isopropyl methylphosphonofluoridate)



D. Soman ([GD], pinacolyl methyl phosphonofluoridate)



E. Tabun ([GA], ethyl *N*-dimethyl phosphoroamidocyanidate)

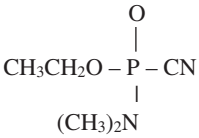


FIGURE 36.2 Chemical structures of nerve agents.

T2106 (sarin); and GD, known as *pinacolyl methylphosphonofluoridate* (soman). They are among the most toxic CWAs. Listed in descending order of ease of volatilization, it is GB, GD, and GA. GA is colorless and may have a fruity odor, which can change to bitter almonds (similar to cyanide) upon decomposition. GA is soluble in organic solvents such as ethanol, diethyl ether, and chloroform. Hydrolysis of GA can produce cyanide and hydrocyanic acid. GA has a $t_{½}$ of 8.5 h at a pH of 7 in an aqueous solution. GB is colorless and odorless, and it is the most volatile of the G agents. It is miscible in water and, like GA, is hydrolyzed in both acidic and basic conditions. This rapidly acting compound has a $t_{½}$ of about 1.5 min. at a pH of 11 and 25°C. However, one report shows an estimated $t_{½}$ to be 40 h (Garigan, 1996). GB comes in two enantiomeric forms (+) and (−), with the (+) form twice as toxic as the (−) form (Christen and Van den Muysenberg, 1965). GD is also a colorless liquid with a fruity odor. It is about 20% soluble in water at 25°C. In water at 20°C, and a pH of 7, it hydrolyzes with $t_{½}$ of about 80 h. GD has two isomers, C (±)P(−) is more toxic than C(±)P(+), each possessing different rates of hydrolysis, with C(±)P(+) being faster. GF and GA are the least studied of the G agents and will not be discussed herein. Chemical properties of the G agents are shown in Table 36.2.

Exposure Physiology

Considerable valuable and relevant data have come from many experimental models using the inhalational approach to assess G agent toxicity. The organ distribution of G agents can take on different patterns following exposure with regard to the volume of distribution. GB is distributed to the brain, kidney, liver, and blood plasma of mice (Little et al., 1986). Within the brain, both GA and GD are detected in the hypothalamus (Wolthuis

et al., 1986). GD can partition into fat, which delays the morbidity response in animals. In addition to distribution, elimination pathways of nerve agents consists of covalent binding and enzymatic hydrolysis. A number of studies have examined the toxicity of these agents. Van Helden et al. (2004) exposed marmosets and guinea pigs to low vapor concentrations of GB, 7–150 µg/m^3 over 10–300 min, to determine the earliest physical response to exposure. Results showed that GB, at levels that were undetected by the fielded alarm systems used, produced significant neuronal effects in the exposed animals. This suggested that acute effects of GB can occur at very low levels. Lung microinstillation exposures of guinea pigs for 4 min to GB caused increased weight loss, lung edema, decreased O_2 saturation, decreased peak inspiratory and expiratory flows, and increased minute volume within 4 h (Conti et al., 2009). Decreased flows are indicative of increased airway resistance. High-dose inhalation exposure to GB (a total dose of 130–150 mg/m^3 × min over 10 min) caused severe bronchoconstriction in rats (Gundavarapu et al., 2014). Che et al. (2008) showed that microinstillation exposure of GB in guinea pigs caused immediate inhibition in BALF in acetylcholinesterase (AChE) activity, followed by a reversal of this effect within an hour despite continued inhibition of blood AChE. This was likely due to the high lipophilicity and rapid absorption of GB. In a 3-month study using rats exposed to GB vapor at 33–35 µg/L for 10 min daily, Allon et al. (2005) determined that there was an increased vulnerability to cardiac arrhythmias after each challenge to GB. This study pointed to the potential of delayed effects of GB exposure; however, long-term consequences of single high-dose GB exposures are not well studied. In a limited study, Husain et al. (1993) showed that mice exposed to nebulized GB at 100 mg/m^3×min per day for 10 days developed muscular weakness of the limbs and slight ataxia on day 14. GB and GD exposure-response effects on hemodynamics and lung function were assessed in baboons following an inhalation challenge. GD at 13.14 µg/kg and GB at 30 µg/kg were vaporized into the upper airway of baboons. Both agents caused increased development of apnea due to decreased phrenic nerve signals, cardiac arrhythmias, and a decrease in mean systemic blood pressure (Anzueto et al., 1990).

In an acute *in vivo* guinea pig lung microinstillation model, Katos et al. (2009) demonstrated that exposure to GD produces prominent respiratory dynamic changes. At 24 h post-exposure, tidal volume increased along with respiratory frequency. In contrast to the study by Conti et al. (2009), peak inspiratory flow was increased, possibly suggesting agent-specific effects on lung airflow patterns. Using a head-out vapor exposure system, Perkins et al. (2013) investigated the toxicity of inhaled GD at concentrations ranging between 520 and 1,410 mg × min/m^3 in the conscious rat. All animals exposed to the higher two doses died. Significant increases in BALF protein occurred with dose-dependent inhibition of AChE activity in the lung and brain within 24 h after challenge. Cholinergic crises were evident based on dose-dependent changes in cholinergic symptoms compared to controls. It can be presumed that the systemic effects of acute nerve agent exposure may be more likely when the RBC–AChE levels drop by 75–80% (Sidell, 1992). Systemic OP-induced depletion of AChE could be directly responsible for increases in mortality resulting from heightened convulsive and seizurogenic activity. However, a number of studies have shown the effects independent of AChE inhibition. Willems (1981) demonstrated that in OP pesticide-exposed individuals, there was no correlation between AChE inhibition and the extent of neuronal symptoms. Moreover, an acute non-inhalation exposure study with sarin, VX, and soman in male and female guinea pigs demonstrated that respiratory toxicity of these compounds did not correlate with AChE activity (Fawcett et al., 2009). Mutagenicity studies with GB and GD have shown that they do not produce adverse effects in the Ames *Salmonella*, Chinese hamster ovary, and mouse lymphoma assays. However, GA was deemed slightly mutagenic in the Chinese hamster ovary and Ames bacterial system assays (Nasr et al., 1988; Goldman and Dacre, 1989).

Thus far, human data have largely come from low-dose exposure of volunteers and from nonfatal accidental exposures. Exposed humans have experienced coughing, wheezing, rhinorrhea, and nonexertional and exertional dyspnea, along with a feeling of increasing pressure in the thoracic region. Craig and Freeman (1953) provided evidence that accidental exposure to GA or GB causes behavioral changes, sleep disturbances, fatigue, and mood changes. Indeed, the concentrations of these agents required to produce mortality in humans are not precisely known. However, the estimated LCt_{50} of GA, GB, and GD are believed to be 150, 70–100, and 40–60 mg × min/m^3, respectively.

Exposure Biochemistry

The nerve agents are known to bind and functionally disable AChE regardless of the agent form (i.e., vapor or spray) or the route of exposure. The extent of AChE inhibition is a function of dose and duration of exposure, basically the product of $[C] \times t$. AChE is found at the synaptic junctions of nerve endings and is responsible for hydrolyzing excess acetylcholine (ACh), which is critical to synaptic nerve transmission. The failure to metabolize or break down ACh causes an accumulation of ACh at the nerve terminals, leading to increased cholinergic stimulation and many of the toxidromic symptoms typical of nerve agent poisoning, known medically as a *cholinergic crisis.* Increased cholinergic stimulation leads to persistent stimulation of muscarinic receptors (M_1–M_3 in the lung) within the parasympathetic neurons. In mammalian species, parasympathetic nerves innervate the airways. Muscarinic receptors belong to the G-protein coupled receptor family presenting throughout the airways. Overstimulation of muscarinic receptors initiates increased salivation, lacrimation, urination, and defecation (commonly known as *SLUD*), along with bronchoconstriction, bradycardia, increased nasal secretions, emesis, and dyspnea. Nicotinic receptors, a member of the ligand-gated ion channel family, occur in the somatic or sympathetic nervous system and are also affected by OPs. Symptoms include tachycardia, mydriasis, fasciculations, meiosis, skeletal muscle paralysis, hypertension, slurred speech, irritability, fatigue, impaired judgment, insomnia, and diaphragmatic weakness. More severe poisoning is associated with more profound CNS responses such as ataxia, convulsions, seizures, and death by asphyxiation.

Neurotransmitter pathways may be directly involved in the sequelae of G agent-induced toxicity. In the CNS, G agents can also act directly on glutamate receptors. Chebabo et al. (1999) demonstrated in an *in vitro* model that nM amounts of GB reduced the amplitude of gamma-aminobutyric acid (GABA), which is a neurotransmitter. It has been suggested that overstimulation of glutamatergic receptors by GD in the brain may be responsible for the modulation of seizure activity (Lallement et al., 1991a,b). Affected neurotransmission pathway may have far-reaching consequences on behavior and induction of convulsions. For an in-depth discussion of nerve agent exposure-response effects and case histories, refer to the excellent overview by Sidell et al. (2008). Some investigations have centered on the effects of repeated exposure to nerve agents. Kalra et al. (2002) studied the effects of subclinical repeated inhalation nose-only exposures to GB of 0.2 and 0.4 mg/m^3 on immune cell responses in rats. GB exposure suppressed T-cell mitogenesis, conconavalin A, and anti-αβ-T receptor-dependent antibody-forming cell responses. In addition, there was a reduction in glucocorticoid production. Their data indicated that repeated exposures to GB over 5–10 days caused changes in T-cell responsiveness mediated by GB's effect on the autonomic nervous system.

Inhaled G agents cause significant respiratory problems. The respiratory effects occur within minutes and clinically can resemble a severe asthmatic attack. A nerve agent-induced death is normally linked to pulmonary dysfunction. Enhanced secretions are the result of vagal efferent activity resulting from increased ACh concentration, substance P, and vasoactive intestinal peptide release. The inhalation of a high concentration of vapor will result in loss of consciousness, apnea, flaccid paralysis, and seizures (status epilepticus) within a period ranging from seconds to several minutes. Peak effects can occur within 30 min, followed by an asphyxiating death (Berkenstadt et al., 1991).

One of the major differences between the principal nerve agents GA, GB, and GD is associated with aging of the AChE enzyme. This AChE aging is basically a chemical reaction resulting in the complexation of the nerve agent with the AChE enzyme that prevents the reactivation of the enzyme. GB-complexed AChE ages over about 5 h, whereas GD takes only minutes (Garigan, 1996). Aging half-time estimates can vary depending on the experimental model used such as *in vitro* versus *in vivo* (Sidell et al., 2008).

In addition to binding with AChE, the detoxification process can lead to interaction of OPs with other cholinesterases such as butyrylcholinesterase (BuChE) and carboxylcholinesterase (CaChE) in the plasma and tissues. Levels of these enzymes can vary from organ to organ. In humans, CaChE is present in cells rather than in plasma, as is measured in other animal species. OPs can also interact with other enzymes such as paraoxonase and arylesterase. For a more comprehensive review of these secondary effects, see Casida and Quinstad (2004).

Exposure to G agents in particular GD may change the antioxidant-to-oxidant ratio by affecting free-radical scavenging pathways that are abundant in mammals. Klaidman et al. (2003) showed that an intramuscular injection of GD in rats decreased protein sulfhydryls in

the piriform cortex and the hippocampus during seizures at 1 h post-exposure, whereas at 24 h, post-exposure GSH levels decreased nearly 50% in the piriform cortex. These results suggest that free-radical formation may be contributing to seizurogenic pathophysiology. Furthermore, subcutaneous challenge to GD increased lipid peroxidation and formation of nitrogen oxides within 30 min of administration in rat brain, especially the hippocampus, thalamus, and medulla-pons (Jacobsson et al., 1999). Since the medulla-pons region controls respiration, it is likely that neuronal mechanisms might also contribute to respiratory effects of OPs. Despite the fact that the two models cited here do not involve the inhalation route of exposure, it is clear that once the agent crosses into the systemic circulation, similar physiological responses occur regardless of the route of exposure.

Exposure to G agents can also cause changes in transcriptional pathways. For instance, RamaRao et al. (2011) showed that GD caused perturbations in the phosphorylation levels of cAMP response element binding protein (CREB), c-Jun, and NF-κB, all of which control a variety of pathological processes. Dillman et al. (2009) demonstrated using microarrays that GD markedly modulated p38 mitogen-activated protein kinase (MAPK) and extracellular receptor kinase (ERK) signaling pathways. While these were not inhalation studies, it should be noted that once the agent enters the systemic circulation, multiple comparable side effects are initiated and propagated. Exposure to G agents causes perturbations in calcium regulatory signaling pathways, which can affect a variety of physiological responses. Destabilization of protein kinase C, which is responsible for brain ion fluxes and eventual neurotransmitter release at different rates in various brain regions, suggests that brain regions respond differently to nerve agent challenges. Exposure to GB also induces inflammatory gene expression within the lung. GB increases lung tissue expression of IL-2, TNFα, IL-1β, hypoxia-induced factor HIF-α, and eotaxin 24 h following exposure, suggesting a cytokine surge resulting from highly active inflammatory processes (Gundavarapu et al., 2014). For these and other nerve agent-induced expression changes in inflammatory processes, see RamaRao and Bhattacharya (2012).

Exposure Histopathology

Inhalational effects of G agents on lung tissue following exposure can range from basically none to severe based on the $[C] \times t$ of exposure. In rats exposed to 768 mg × min/m^3 aerosolized GB, major changes in the pathology at 4 days after exposure were observed. Primary changes were seen in the epithelial lining of the lobar bronchi. Lung histology showed increases in interstitial mononuclear cells and thickening of the alveolar septa. Masses of exudate, inflammatory cell infiltration, and bronchial epithelial damage were also seen (Pant et al., 1993). In a study featuring 10-day repeated exposure to GB, on day 14 post-exposure spinal cord pathology showed clear evidence of degenerative axons (Husain et al., 1993). Brain lesions and cardiomyopathy were observed in rats exposed to GD or GB in a subcutaneous injection model (Singer et al., 1987; Tryphonas and Clement, 1995). In Perkins et al. (2013), rats exposed to 4–6 min GD vapor at 600 mg × min/m^3 had compromised lung tissue pathology compared with controls. At 24 h after exposure, alveolar hemorrhage, inflammation, and histiocytosis scored twofold higher than controls. Neutrophilic exudate and alveolar destruction were also observed. An intramuscular challenge with GD showed astrocytic degeneration, neuronal necrosis, and liquefaction necrosis of the CNS. The cerebral cortex, limbic system, thalamus, and substantia nigra appeared to be targets of toxicity in the rat (Tryphonas and Clement, 1995). Pulmonary pathology changes after systemic administration of nerve agents are not well characterized.

Nonvolatile Agents

Nonvolatile agents, such as VX and its structural isomer VR, have the same molecular weight (as shown in Table 36.2) and are not considered to be vapor hazards. As a result, they are judged to be low inhalational threats to humans (the agents, listed in order of volatility are GB, GD, GA, VX, and VR). Most research on V agents have centered on VX, which is considered the "gold standard" against which the toxicities of all other agents (GA, GB, and GD) are compared.

VX is an odorless and colorless compound when in pure form. It is an oily liquid that is slightly soluble in water. These characteristics are largely responsible for its capacity to be classified as a persistent agent (Table 36.1). Although VX and VR are similar in structure, Collins et al. (2013) demonstrated in a rat aerosol exposure model that after a single 10-min exposure to VX or VR, the VR lethal concentration was nearly half that of VX (367 versus 632 mg × min/m^3) making it more toxic. These data support results from an earlier study by Chang et al. (2002), where they conclude that it may take higher doses of atropine to treat those exposed to VR. While there may be differences between VR and VX in terms of lethality, the physiological, biochemical, histopathological, and toxicological outcomes are very similar. Therefore, unless specifically pointed out, mostly VX data are reported. The reported estimates of lethality for VX is 40 mg × min/m^3 (Seto, 2011).

Exposure Physiology

While VX and VR pose more of a percutaneous threat, exposure by inhalation should be given more serious consideration, as the agent can directly come into contact

with airway surfaces when bound to mists, dust particles, fog, and other substances. As a result, entry into the airspaces can be accelerated. Exposure of airway surface can lead to almost immediate reactions culminating in respiratory failure if the [C] × t product is sufficiently high. Bronchoconstriction, a hallmark of nerve agent exposure, in animals caused by the inhaled V agents most likely is a result of mechanisms common to those of G agents. Bronchospasms may be caused by local effects on the respiratory center of the CNS, as opposed to direct effects. It is likely that more persistent agents have a tendency to deposit in the lung compartment and are slowly released over time as previously described for GD. Exposure to VX or VR produces similar hypercholinergic effects such as SLUD, incapacitation, seizures, and cardiorespiratory depression (bradycardia, dyspnea, and convulsions).

Lung exposure studies in animals using microinstilled VX have provided evidence of the nature of pulmonary effects. In guinea pigs exposed for 5 min to VX doses ranging between 50 and 90 μg/m^3, acute effects varied from an increase in lung wet/dry weight ratio with increases in the numbers of macrophages/monocytes in BALF at 24 h post-exposure (Wright et al., 2006). In a similar exposure model of local pulmonary instillation of VX, Graham et al. (2006) demonstrated that BuChE activity, although inhibited at 5 min post exposure, was quantifiably present in BALF at 24 h post-exposure even at the highest dose of VX. The authors speculate that the presence of BuChE, which is synthesized in the liver and circulates in the plasma, may be a marker of damaged air–blood barrier integrity at later time points. Katos et al. (2007) found a significant inhibition of AChE in the esophagus and intestine following microinstilled VX in the lung. From these studies, it is apparent that VX can localize to the gastrointestinal tract, causing an "irritable bowel-like" condition as a result of its likely clearance through the gut. In guinea pig studies investigating the long-term effects of a 10 min. VX exposure on changes in pulmonary respiratory dynamics, Rezk et al. (2007) demonstrated that end-expiratory pause (EEP); i.e., the length of time between the end of expiration and the beginning of the inspiratory cycle was increased at 48 h post-exposure. This study also indicated that most of the altered respiratory function returned to near control levels by day 7, except for EEP. EEP did return to normal levels by day 18. These data suggest that VX can persist in the body due to tissue-specific compartmentalization and produce long-term effects.

A direct 10-min intratracheal VX exposure of anesthetized rats, bypassing the nose (preventing neuronal translocation to brain through nose), resulted in acute lung injury and tissue damage, suggesting direct tissue-specific effect. In this work, VX aerosol was administered at 514 mg/min/m^3 and produced significant increases in BALF protein concentrations at 6 and 24 h after exposure, suggesting the prevalence of pulmonary edema. Airway resistance was significantly increased at 20 min and 6 h post-exposure at all VX concentrations tested and at the two highest doses, 343 and 514 mg × min/m^3, 24 h post-exposure (Peng et al., 2014). The authors concluded that VX inhalation impairs pulmonary function through an obstruction associated with increased pause, expiration time, and nearly a 50% decrease in expired flow rate, decreased respiratory rate and tidal volume, leading to a drop in minute ventilation. These are all indicators of airway flow obstruction. VX inhalation could transiently disturb lung function through airway smooth muscle spasm, paralysis, or both, and when combined with mucus oversecretion, could result in respiratory failure; however, the precise mechanisms are not well understood.

Additionally, a preliminary assessment of the VX exposure effects on cellular profiles in BALF was undertaken. Study time points were 3, 6, 24 h, and 1 and 2 weeks post-exposure. Blood analyses indicated that VX exposure at 343 mg × min/m^3 increased circulating white blood cells (WBCs), erythrocytes (RBCs), HCT, HGB, neutrophils, platelets (PLTs), and eosinophils at 6 h post-VX inhalation compared with naïve controls. Lymphocytes, basophils, monocytes (MONO), HCTs, and RBCs remained elevated at 1 week. Monocytes and PLTs continued to be elevated at 2 weeks after exposure compared to naïve controls (Sciuto, 2014). While further work is needed in this area to determine how these changes are associated with pulmonary pathology and the chronicity of the damage, these data indicate that variable effects of V agent inhalation on cell populations are not limited to acute effects. This substantiates the fact that V agents may deposit in tissues and get released over a long period of time after a single exposure. It is also possible that there may be a lag-time in the immune response induced by V agent exposure as part of a compensatory mechanism.

Exposure Biochemistry

Limited published studies are available investigating the effects of V agent exposure on biochemical pathways. Similar to G agents, V agents likewise inhibit blood and lung tissue AChE activity. In the aerosolized VX rat exposure model of Peng et al. (2014), blood AChE activity was decreased 41% at 343 and 52% at 514 mg × min/m^3 24 h post-exposure. Lung tissue AChE activity was also inhibited by VX. However, using a similar exposure model testing the effects of VR, AChE mRNA transcription in the lungs was up-regulated by 19% for 143 and 30% for the 286 mg × min/m^3 VR groups compared to vehicle at 24 h (Sciuto, 2014). Up-regulation of lung tissue AChE mRNA may indicate the cellular response to accumulation of nonfunctional enzyme. In

addition, we observed by immunohistochemistry a positive staining for iNOS in alveolar epithelial cells together with decreased staining of surfactant D in lung tissue 24 h post-inhalation exposure to 514 mg × min/m^3 VX.

In these VX aerosol inhalation studies, Western blot analyses showed that xanthine oxidoreductase, an enzyme-producing superoxide, is activated in response to VX inhalation exposure at 343 mg × min/m^3. VX inhalation also triggered IL-6 expression in rat lung tissue. In VR-exposed rats, lung lavage assays showed decreased GSH concentration and superoxide dismutase (SOD) activity, which indicates a local oxidative stress environment. Western blot analyses of lung tissue 6 h post-exposure demonstrated an increased expression of xanthine oxidase, increased IL-1β expression, and activation of phosphorylation of p38 and Akt suggesting stimulation of inflammatory mechanisms.

Exposure Histopathology

There is minimal if any lung damage within 24 h after VX exposure in rats. Lung and tracheal lesions were generally less severe in the 3- and 6-h VX post-exposure groups than in the 24-h VX post-exposure groups consistent with its delayed effects. This delay could be due to the time it takes for extravasation of inflammatory cells, such as neutrophils and macrophages (Peng et al., 2014). The tracheal lesions in these animals showed evidence of ulceration accompanied by neutrophilic inflammation and necrotic epithelial lining (necrotic membrane). Similar findings were observed in a VX-exposed guinea pig inhalation model (Nambiar et al., 2007). Peng et al. (2014) also showed that at high levels of inhaled aerosolized VX, exposure produced prominent alterations in airway and lung pathology at 24 h in the rat. A 10-min exposure to 514 mg × min/m^3 VX-induced architectural changes in the trachea and lung. The most significant findings were perivascular inflammation, histiocytosis, alveolar exudate, alveolar epithelial necrosis, septal edema, and bronchiolar inflammatory infiltrates.

VX exposure also causes lung parenchymal pathology. VX-induced histological changes are persistent for 1–2 weeks post-exposure. In general, the pulmonary histologic changes described are likely secondary to nebulized agents. The prevalence of lesions suggest that VX, when administered by inhalation at concentrations of 171 and 343 mg × min/m^3, can induce mild but persistent pulmonary changes over several days post exposure. Wright et al. (2006) showed similar patterns in the lungs of guinea pigs microinstilled with VX for 5 min.

Cyanides

Cyanides were used as CWAs and are potential terrorist agents (Magnum and Skipper, 1942; NRC, 1999). Cyanides are also used industrially for electroplating and the extraction of gold and silver. They can be released into the atmosphere from volcanoes, fungi, and bacteria. Common food items such as pears, peach, sweet potatoes, peas, apples, and lima beans are sources of cyanogenic compounds.

Exposure Physiology

The cyanides, formerly known as "blood agents," consist of hydrogen cyanide (NATO code designation AC, HCN: MW 27.04) and cyanogen chloride (CK, ClCN: MW 61.5). The common metabolic by-product is the toxic CN^- anion, which is largely a systemic toxicant. Vapors from these agents are heavier than air and spread across the ground like phosgene and can pose a problem in low-lying, confined areas (Table 36.1). A mild exposure to these agents through the inhalation route can cause headache, loss of consciousness, ataxia, and confusion. Palpitations and respiratory tract irritation with labored breathing (dyspnea) can lead to hyperpnea in some cases. For exposures classified as severe, serious CNS effects may occur. These include coma, seizures, and mydriasis. Dysrhythmias, low blood pressure, and eventual life-threatening cardiac arrest may follow. The occurrence of pulmonary edema followed by respiratory insufficiency can be a late manifestation following a severe inhalation exposure episode. The toxic load of inhaled HCN can be enhanced through its effect on increased minute volume (Purser et al., 1984).

Animal studies have provided evidence of the tissue distribution of inhaled cyanide. These studies have indicated that the target organs are the lung and heart, followed by the brain; all highly perfused. For example, in the rat following an acute inhalation exposure to HCN, the highest concentrations were measured in the blood, brain, heart, and lung with very little in the liver (Ballantyne, 1994). The estimated human inhaled 50% lethal concentration of HCN is 2,500–5,000 mg × min/m^3 and for cyanogen chloride, it is approximately 11,000 mg × min/m^3. These data indicate that via the inhalation route, the cyanides are less toxic compared to their effects as systemic poisons (McNamara, 1976).

Exposure Biochemistry

It is well known that HCN vapor readily penetrates the epithelium with little difficulty due to its low ionization and low molecular weight. This allows for the rapid absorption through pulmonary alveolar membrane during exposure. The basic metabolic chemical reactions involving CN^- have been studied for decades (Sykes, 1981). CN^- binds to and inactivates enzymes involved in oxidative phosphorylation within mitochondria. The mitochondria are the primary target organelles involved in HCN poisoning. Lethal cytotoxic anoxia results from the interaction of CN^- with cytochrome c-oxidase, which is an important regulator of cellular respiration. This

reaction, which occurs within minutes, inhibits aerobic metabolism by binding to the binuclear heme center. Additionally, there is loss of the formation of ATP, which is critical to supplying cells with the energy required for normal cellular processes (Keilin, 1929; Klein and Olsen, 1947). This adverse reaction prevents the binding of electrons to the molecular oxygen. As such, aerobic cell metabolism is halted even in the presence of well-oxygenated blood. In a futile attempt to regain the loss of ATP, cells increase glycolysis, especially in organs rich in mitochondria, such as the brain and heart. This results in metabolic acidosis characterized by increase in lactic acid. This, along with severely decreased ATP production, is responsible for dampened neurotransmission and altered perceptive abilities (Lindahl et al., 2004). In the brains of mice exposed to cyanides, lactic acid increases, and accumulation of adenosine diphosphate (ADP) and phosphates also lead to overall CNS metabolic impairment (Estler, 1965; Isom et al., 1975). CN^- can be removed through metal-complexing interactions with cobalt, molybdenum, and organic compounds prior to cell entry. Cyanide also forms cyanomethemoglobin as a result of its interaction with methemoglobin within erythrocytes. This process can remove cyanide from the plasma. Detoxification of CN^- occurs through the formation of the less acutely toxic thiocyanate (SCN) via the mitochondrial enzyme rhodanese which catalyzes the transfer of a sulfane sulfur atom from sulfur donors to sulfur acceptors (Eq. (36.2) and Figure 36.3). The end reaction with the formation of SCN^- is generally irreversible.

$$CN^- + S_2O_3^{2-} \rightarrow SCN^- + SO_3^{2-} \qquad (36.2)$$

β-mercaptopyruvate-cyanide transulfurases, which are present in the liver, kidney, and blood are also capable of detoxifying cyanides forming SCN^- (Westley, 1981; Westley et al., 1983). A third enzymatic system present in the kidney may likewise play a role in the detoxification of CN^-. The sulfotransferase, called *cystathionine γ-lyase*, has been shown to be effective in cyanide-clearing processes (Wrobel et al., 2004) (Figure 36.3).

Exposure Histopathology

Inhalation exposure to cyanide-forming agents leave scant identifiable markers of tissue or cellular damage in target organs such as the lung, heart, and brain following challenge. This is mostly because once in the body, it diffuses rapidly into the bloodstream and acts essentially as a systemic toxicant, regardless of route of exposure. Several earlier animal studies showed that acute or repeated exposure to CN^- causes neuropathological changes, such as gray matter necrosis and degenerative changes in ganglion and Purkinje cells, in dogs (Haymaker et al., 1952). Encephalopathy and optic nerve neuropathy are other sites of toxicity following inhalational exposure (Hirano et al., 1967; Lessel, 1971). Thus, inhalational exposure might result in more severe neuronal impact, since the brain is rich in mitochondria. Systemic administration of cyanides, however, has been shown to affect the heart, and lung in addition to brain (Ballantyne and Salem, 2008).

Riot Control Agents

RCAs, also known as *sternutators* (from the Latin term meaning "sneezing") and *lacrimators*, consist of a specific class of irritant compounds. Agents (and NATO codes) in this class are 2 chlorobenzylidene malononitrile (CS: MW 188.6), dibenz (*b,f*)–1:4-oxazepine (CR: MW 195.3), oleoresin capscicum (OC: MW 305.4), 10-chloro-5,10-diphenylaminochlorarsine (DM: MW 277.6), chloropicrin (PS: MW 164.4), and 1-chlorocaetophenone (CN, also known as MACE: MW 154.6). Some of these agents, such as PS, DM, and CN, are CWAs (Figure 36.4).

RCAs have the general characteristics of causing rapid incapacitation, ease of dissemination, and relative low toxicity. They are usually disseminated as mists, aerosols, smoke, or volatilized M18 thermal grenades. They have been used widely as CWAs (Hilmas et al., 2008; Salem et al., 2008). CN was the original tear gas, which eventually was replaced by CS. In general, these agents possess actions that are short-lived, with the exposed becoming adapted to the effects within about 30 min of exposure. However, death has been known to occur with high doses and in confined spaces. Pharmacologically, they fall across classes that include emetics, hypnotics, serotonin antagonists, neuromuscular blockers, and sedatives. The toxicological effects of RCAs are readily apparent in various anatomical areas, such as the eye, gastrointestinal tract, nasal, oral and neuronal tissues, lung, and skin. Complex interactions among the sites described make RCAs potent candidates for crowd dispersion and control. Even though all of these anatomical sites are critical with regard to aftereffects, we will focus primarily on inhalation toxicology. For an outstanding and extensive review of RCA toxicity, see Olajos and Salem (2001).

2-Chlorobenzylidene Malononitrile (CS)

CS is a white crystalline solid with a relatively low solubility in water, but a rapid rate of hydrolysis. It is soluble in most polar organic solvents. Harris (1993) describes RCAs as nonlethal, making them most effective as crowd dispersants on unprotected personnel. RCAs can enter the respiratory tract in the form of vapor or aerosol.

Exposure Physiology

When inhaled, these agents are capable of sensory nerve receptor irritation, causing the Kratschmer reflex,

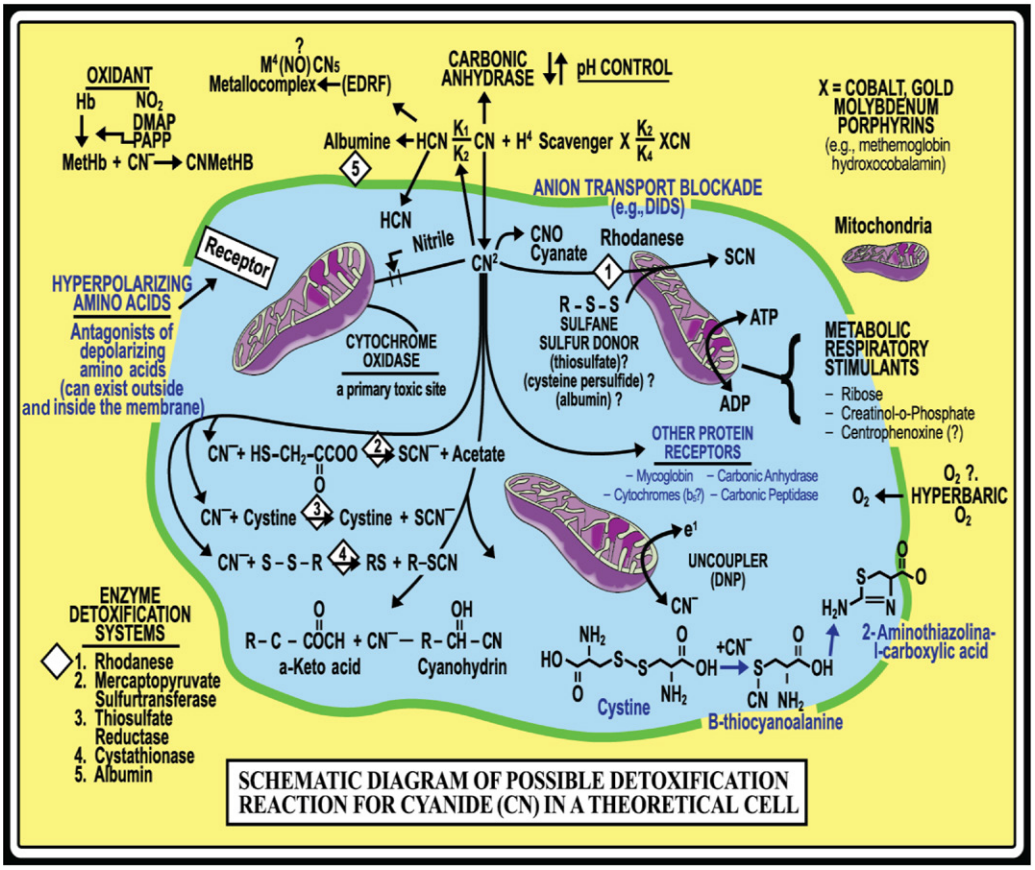

FIGURE 36.3 Likely detoxification reactions for cyanide within a cell. The enzyme detoxification systems are as follows: (1) Rhodanese: an intra-mitochondrial enzyme that catalyzes the transfer of sulfur from a donor molecule to cyanide to form thiocyanate. Rhodanese is a key regulator of cyanide detoxification. (2) Mercaptopyruvate sulfurtransferases: a group of enzymes widely distributed in the body that catalyze the transfer of a sulfane sulfur atom from a donor molecule to a thiophilic acceptor substrate for the limitation of cyanide. (3) Thiosulfate reductase: enzymes found in the liver, kidney, heart, brain, intestine, and testis that use electrons from thiols to reduce the sulfane sulfur atoms of inorganic thiosulfate and organic thiosulfonate anions to sulfide. Sulfide production from these thiol-dependent reductases is thought to be used in the synthesis of Fe-S proteins. (4) Cystathionase: enzymes widely distributed in the body that can transfer sulfur from one cysteine to another, generating thiocysteine and pyruvate. (5) Albumin: molecules that act like an enzyme in the detoxification of cyanide. Albumin contains sulfur moieties that bind to and limit cyanide formation. ADP: adenosine diphosphate; ATP: adenosine triphosphate; ATCA: 2-aminothiazoline-4-carboxylic acid; CN: cyanide ion; CNMetHb: cyanomethemoglobin; CNO: cyanide; DIDS: 4,4′-diisothiocyano-2,2′-disulfonic stilbene; DMAP: dimethylaminophenol; DNP: deoxyribonucleoprotein; EDRF: endothelium-derived relaxing factor; Hb: hemoglobin; MetHb: methemoglobin; PAPP: p-aminopropiophenone; R: reduction factor; S: substrate. *Source: Reprinted from* Textbooks of Military Medicine: Medical Aspects of Chemical Warfare, *Published in 2008 by the Office of the Surgeon General, TMM Publications.*

which may result in cessation of respiratory function. Initial responses include sneezing, coughing, a burning sensation, and excessive rhinorrhea. Additional responses can also include dizziness and disorientation. While these are protective mechanisms to reduce the effects of inhalation, they may be accompanied by bradycardia and biphasic changes in aortic blood pressure. The half-life of CS following inhalation is less than 30 seconds (Olajos and Salem, 2001). Because of its low water solubility CS is environmentally persistent (Table 36.1). To further increase environmental persistence for up to 2 weeks, two hydrophobic forms were synthesized, CS1 and CS2, which are rapidly absorbed from the respiratory tract. In rat inhalation studies, repeated exposure to CS1 caused aggressive behavior and hyperreactivity. In other studies with concentrations reaching 25,000–68,000 mg × min/m^3, there were no changes in blood electrolyte levels; however, pulmonary edema and necrosis of the respiratory and gastrointestinal tracts were observed in the rats that died after CS exposure. Death most likely consisted of the combined result of hypoxia, circulatory failure, and obstructed airways (Salem, et al., 2006). In human volunteers, exposures to a range of CS concentrations showed no evidence of deleterious changes in airway resistance, vital capacity, or tidal volume (Beswick, et al., 1972). The LCt_{50} values for humans have been estimated to range between 25,000 and 100,000 mg × min/m^3 (WHO, 1970).

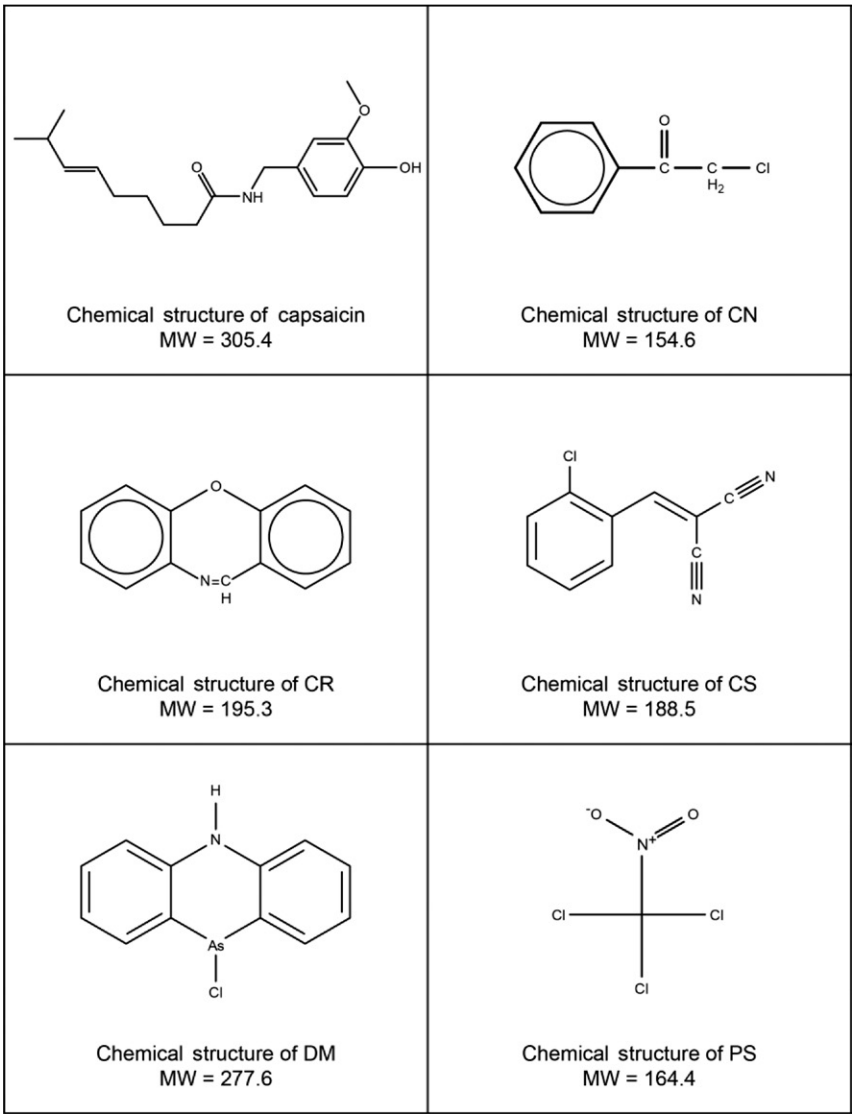

FIGURE 36.4 Chemical structures and formula weights of the most commonly studied RCAs.

However, there have been no reported human mortalities due to CS exposure. The high levels of estimated concentrations of CS required to be lethal in humans clearly places it in the low lethality category (Table 36.1). While lethality is not measured during the course of human exposure, CS exposure has been linked to RADS, which can result from a single intentional exposure (Hu and Christiani, 1992). The respiratory irritation effects of CS exposure may be linked to the release of bradykinin (McNamara et al., 1969: Cucinell et al., 1971).

Exposure Biochemistry

As noted previously, CS is rapidly absorbed during inhalation. It has a very short half-life and is metabolized and detoxified in the blood and other organs. Its disappearance follows first-order kinetics, and it spontaneously hydrolyzes to form malononitrile, which is then metabolized to thiocyanide (Nash et al., 1950). However, it is believed that in the case of inhalation exposure, the amount of formed thiocyanide may have little if any role in human toxicity (Ballantyne, 2006). Metabolites can be found in the blood only after high exposures. CS is an SN_2-alkylating agent with active halogens, which react with nucleophilic sites. A common metabolite 2-chlorobenzaldehyde was found in the blood of rodents and humans after exposure. CS reacts rapidly with plasma proteins and GSH, all of which are possible cofactors responsible for detoxification (Cucinell et al., 1971). Sulfhydryl-containing enzymes, such as lactic dehydrogenase, pyruvic decarboxylase, and glutamic dehydrogenase, are targets of the alkylating effects of CS (Lovre and Cucinell, 1970). The i.p. administration of CS to rats results in its excretion in the urine as mercapturic acid (Rietveld et al., 1983). It is not known if

this occurs following inhalation. On the other hand, it has been reported that aerosol exposure to CS leads to an excretion of thiocyanate. The release of cyanide has also been shown to occur following i.p. injection in the rat (Frankenburg and Sorbo, 1973).

Exposure Histopathology

Overall, CS does not produce significant respiratory tract or systemic lesions. In mice and rats, exposure to CS caused squamous metaplasia of the olfactory epithelium and hyperplasia and metaplasia in the respiratory epithelium. In 1990, the National Toxicology Program (NTP) tested CS for genotoxicity and carcinogenicity and found no evidence of either effect in rodents (NIH, NTP, 1990). In inhalation experiments using rats and hamsters, with CS concentrations ranging between 150 and 750 mg/m^3 and lasting from 30 to 120 min, a small degree of lung pathology was seen for up to 28 days post-exposure. The hallmark of exposure at high levels in the lung was congested alveolar capillaries, pulmonary edema, and hemorrhagic lesions. Secondary effects in extrapulmonary organs were renal tubular and hepatic cellular necrosis (Salem et al., 2006). In 120-day inhalation studies using guinea pigs, acute alveolitis was observed (Ballantyne and Callaway, 1972; Ballantyne and Swanston, 1978).

Dibenz (b,f)-1:4-oxazepine (CR)

CR is a pale yellow solid with a strong, pepperlike odor. Exposure-effect responses of CR are similar to CS. CR is the most potent lacrimator with the least toxicity. It is the parent compound of the antipsychotic drug loxapine (Blaine, 2003).

Exposure Physiology

Upon inhalation, CR is rapidly absorbed through the lung and into the bloodstream. It has a plasma half-life of about 5 min. (Upshall, 1977). CR can be dispersed as an aerosol or as grenade-generated smoke. For the most part, animals exposed to CR exhibit physical dysfunctions such as ataxia, loss of coordination, tachypnea, and convulsions. In human volunteers, low-level CR aerosol exposure produced bronchoconstriction and increased pulmonary blood flow within about 20 min. (Ashton, et al., 1978). These effects are believed to be due to the stimulation of irritant receptors, the effects of which usually subside within an hour after exposure. Ballantyne studied the effects of inhaled CR aerosol and CR smoke in rats. Concentrations ranged between 13,050 and 428,000 mg × min/m^3. Excessive nasal discharge and blepharospasms occurred, which also subsided in about 60 min. (Ballantyne, 1977). No mortalities were recorded. Investigations involving the effects of CR exposure on teratogenicity (specifically, embryo toxicity) revealed no adverse developmental toxicology (Upshall, 1974). Carcinogenicity and genotoxicity assessment using various strains of *Salmonella typhimurium* reverse mutation tests, CHO gene mutation system (V79/HGPRT), mouse lymphoma assay (L5178Y/TK+/TK−), and micronucleus testing also indicated no toxicity (Colgrave et al., 1979). Data from Kumar et al. (1995, 2006) provides evidence that CN is much more toxic than CR at the 5% LC_{50} level and upon repeated exposure in rats and mice.

Exposure Biochemistry

In rat tissue, CR is metabolized to 4-, 7-, and 9-hydroxylactams via oxidative processes, followed by ring hydroxylation and sulfate conjugation, and then excreted via urine (French et al., 1983). Metabolites and excretion profiles of CR are similar among many species regardless of exposure route. Intravascularly dosed mice suggested rapid uptake of CR from the blood and into the kidney, small intestine, bile, and liver, which was in line with data from rats indicating rapid absorption, hepatic metabolism, and renal excretion (French et al., 1983).

Exposure Histopathology

CR administered by aerosol inhalation at 68,400 mg × min/m^3 did not cause lethality in mice, rabbits, or guinea pigs (Ballantyne, 1977). However, congestion in the capillaries and alveolar hemorrhaging were noted. Pattle et al. (1974) exposed rats to CR at a concentration of 115,000 mg × min/m^3 to determine whether a high concentration produced adverse effects on cell organelles such as lamellar bodies. Electron microscopy indicated no effects of inhaled CR on lamellar bodies. Colgrave et al. (1979) exposed animals to a range of CR aerosols at dosages from 78,200 to 161,300 mg × min/m^3 and reported no abnormalities in the lung. However, subsequent assessment after microscopic examination revealed mild lung congestion, hemorrhage, and emphysema. Long-term effects of inhaled CR aerosol were conducted in hamsters and mice using dosages of 204 ppm (5 min), 236 ppm (8.6 min), and 267 ppm (15.8 min) 5 days/week for 18 weeks. Survivors were sacrificed and dissected 1 year after exposure, with the only pathology being chronic laryngeal inflammation (Marrs et al., 1983).

10-Chloro-5,10-diphenylaminochlorarsine (DM-Adamsite)

DM, an organoarsenical compound, is a yellowish-green crystalline solid with low volatility. DM and other compounds, such as PS, diphenylchloroarsine (DA), and diphenylcyanoarsine (DC), are known as *vomiting agents.* DM is considered odorless, but it can contain a faint odor of bitter almonds. It is more soluble in organic solvents, such as benzene, toluene, and alcohols, than in water. It can be released as a dry powder using thermal or explosive techniques.

Exposure Physiology

Respiratory effects of inhaled DM include increased nasal congestion, salivation, coughing, and sneezing. Irritation of the mucous membranes of the eyes and airway lining can occur. Persistent vomiting and headaches are also exhibited after DM exposure. Compared to other RCAs, the effects of inhaled DM can take as long as 3 min and last up to several hours (BMOD, 1972). Punte et al. (1962) studied the effects of a number of RCAs in animals that were exposed for periods ranging from 5 to 90 min. With DM, there were no abnormalities observed below concentrations of 500 mg × min/m^3. Estimated LCt_{50} values were as follows: for mouse, 22,400 mg × min/m^3; rat, 3,700 mg × min/m^3; and guinea pig, 7,900 mg × min/m^3.

Striker et al. (1967) exposed nonhuman primates to various [C] × *t* levels of DM. An inhaled dose of 2,565 mg × min/m^3 was well tolerated except for one animal that exhibited nasal discharge. At a dose level of [C] × *t* of 8,540 mg × min/m^3, nasal discharge and facial erythema were noted, but these symptoms were resolved by 24 h post-exposure. When the exposure dose was increased to 28,765 mg × min/m^3, hyperactivity ensued, with significant nasal discharge and respiratory distress in all animals. Striker et al. (1967) concluded that death in some animals was caused by respiratory failure. In human volunteers, doses thought to cause adverse physiological responses such as nausea and vomiting were tested. Some studies found that humans can tolerate DM in the range of 22–92 mg/m^3 for at least 1 min with a 50% tolerance level of up to 220 mg/m^3 (Punte et al., 1962). In this study, the definition of tolerability was the desire to vacate the exposure space as quickly as possible. From these studies and others, it was shown that exposure to inhaled DM produced a range of effects including pain in the eyes, throat, nose, and upper airway; coughing; and salivation similar to a cholinergic response seen with nerve agent exposure. If the exposure is severe enough and sufficient in duration, death may ensue. There is one known human death caused by inhaled DM (Owens et al., 1967). Exposure times of 5–30 min at concentrations of 1,130–2,260 mg/m^3 ([C] × *t* of 5,650 to 67,800 mg × min/m^3) were estimated. For the most part, this is well above the estimated LCt_{50} of 11,000 mg × min/m^3 for humans reported by Sidell (1997).

Exposure Biochemistry

There is only one study that suggests the possible metabolic and detoxification fate of DM (Hass et al., 2004). As an organoarsenical compound, it would seem likely that its toxicity may be linked to the metabolism of arsenic. Through the oxidation of As (III) by manganese peroxide, DM is broken down into As (V). This reaction releases chloride with the subsequent incorporation of two oxygen molecules into the parent compound (Haas et al., 2004). Arsenic released in the metabolic process with a specific valance state could inhibit succinic dehydrogenase activity and cause the uncoupling of oxidative phosphorylation and reduced ATP levels.

Exposure Histopathology

As stated previously, there remains little doubt that the target organ showing significant and consistent debilitating effects of inhaled DM is the lung. In DM-exposed nonhuman primates, gross postmortem examination showed evidence of edematous and severely congested lungs, whereas microscopic evaluation revealed ulceration of the tracheobronchial tree and alveolar edema (Striker et al., 1967). In the human death mentioned previously, postmortem analysis revealed edema of the subcutaneous tissue of the neck, mediastinum, pleura, and pericardium, along with emphysematous bullae widespread in the lung. Histologically, bronchopneumonia, hemorrhage, pseudomembrane formation in the trachea and bronchi, and congestion were observed throughout the entire respiratory tract (Owens et al., 1967).

Oleoresin of Capsicum (OC—Pepper Spray)

OC is a reddish-brown, oily resin derived from capsicum plants, commonly known as nightshade (Figure 36.5). Capsaicinoids can exist in several derivative forms such as dihydrocapsaicin, homocapsaicin, and nordihydrocapsaicins. Capsaicinoids are isolated through volatile extraction of the dried, ripened fruit of chili peppers. Once dried, the OCs are predominantly capsaicin, followed by nordihydrocapsaicin and homocapsaicin (Salem et al., 2006). However, other potentially irritating components are present, such as acids, esters, and phenolic agents. Capsaicins at high concentrations can cause a variety of potent effects such as dermatitis, nasal, ocular, pulmonary, and gastrointestinal tissue injury. The active ingredient of capsaicin is 8-methyl-*N*-vanillyl 1,6, nonenamide.

Exposure Physiology

Like all other RCAs, aerosol-dispersed OC causes erythema; burning of the eyes, nose, and throat; sneezing; coughing; and blepharospasm. Acute exposure to inhaled OCs results in pulmonary edema, bronchospasm, respiratory arrest, hypertensive crises, and hyperthermia. OC causes excitement, convulsions, dyspnea, and death due to respiratory failure. While pepper spray is considered relatively safe, fatalities have been reported due to airway obstruction (Synman et al., 2001). Inhalation of capsaicin activates the Kratschmer reflex, as mentioned earlier, accompanied by bradycardia, apnea, and a biphasic rise and fall of aortic blood pressure. The pulmonary effects of capsaicin may be species-related. In guinea pigs exposed to capsaicin via aerosol, bronchoconstriction occurred, suggesting both a

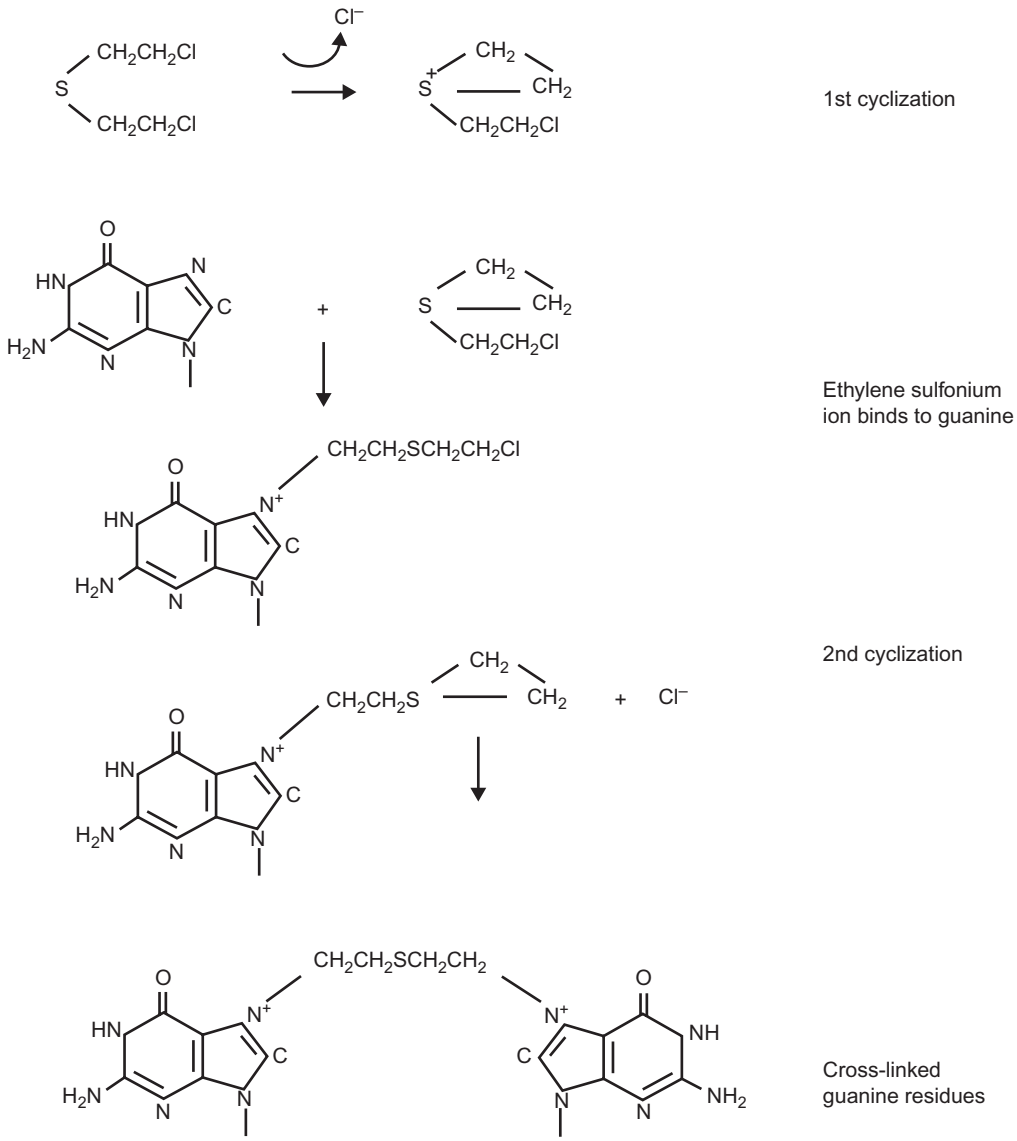

FIGURE 36.5 Reactive chemical mechanisms involved in HD hydrolysis, formation of sulfonium ion, and the alkylation of DNA through guanine cross-linked residues.

vagal-cholinergic as well as a noncholinergic local axonal reflex (Buchan and Adcock, 1992), whereas in cats using a similar exposure method, bronchoconstriction was determined to be due to a direct vagal-cholinergic response (Adcock and Smith, 1989). Glinsukon et al. (1980) determined the LD_{50} in several animal species using various routes of delivery. The concentrations ranged from 0.56 mg/kg intravenously (i.v.) to 1.6 mg/kg by intratracheal instillation. An LCt_{50} value for capsaicin of 13,000 mg/m^3×min has been published by Seto (2011).

Exposure Biochemistry

One of the mechanisms responsible for capsaicin toxicity is the stimulation of neurons consisting of neuropeptide-containing afferent nerves that are capable of activating specific vanilloid receptors (Szallasi and Blumberg, 1999). Stimulated nerves are of the Aδ and C fiber-unmyelinated types. The activation through ligand-gated mechanisms opens cation channels (Marsh et al., 1987) and increases the influx of Ca^{2+} and Na^+ in cells, which leads to depolarization and the release of neuropeptides such as substance P. Protective reflexes are activated via autonomic motor neurons. Other transmitters of biological responses to capsaicin included calcitonin gene-related peptide (CGRP) and neurokinin A (a tachykinin), both of which are released from neurons and are responsible for pain transmission and neurogenic inflammation. For an extensive list of capsaicin-sensitive markers, see Holzer (1991).

Mediator-induced inflammatory processes can lead to increased vascular permeability, neurogenic inflammation of airways and blood vessels, chemotaxis, and bronchospasm (Smith and Topford, 1999). Furthermore, capsaicin activates the vanilloid receptor family TRPV1 (transient receptor potential cation channel subfamily V) within sensory neurons. Activation of these receptors leads to prolonged refractory periods and to a nonconducting desensitization. One study suggests that TRPV pathways may not be entirely responsible for all of the adverse reactions caused by capsaicin (Holzer, 1991).

Exposure Histopathology

There have been no reports or reviews assessing the histopathology results from an inhalation challenge to capsaicins or OCs. The only data from toxicity studies was from Glinsukon et al. (1980), who found visceral organ hyperemia without hemorrhage, gastric desquamation, and increased mucus.

Chloropicrin (PS)

PS produces many of the effects consistent with RCAs. In addition, it has been classed with choking agents such as phosgene and chlorine due to its effect on the upper airways. PS is an oil ranging from colorless to light green, with a stinging odor classified as aniselike. It has low solubility in water, but it is readily soluble in most solvents such as acetone and chloroform. At high temperatures, PS decomposes to phosgene, nitrogen dioxide, and other irritants. During World War I, it was labeled as a choking agent and mixed with sulfur mustard to lower its freezing point. PS is a lung irritant and is used as a soil fumigant for its biocidal and fungicidal properties. As a result of commercial usage, exposure threats are by way of the inhalation and dermal routes in persons living and working within the operational area (O'Malley et al., 2004).

Exposure Physiology

Mechanisms of PS toxicity are not that well understood. Largely, PS is irritating to the respiratory system, mucous membrane, gastrointestinal tract, skin, and eyes. Airway inflammation, lacrimation, nausea, and vomiting are the hallmarks of exposure. In severe respiratory exposures, pulmonary edema can ensue, ultimately causing death. In mice inhalation studies, Buckley et al. (1984) assessed the RD_{50} (the dose of material required to cause a 50% reduction in respiration rate), which was 8 ppm with exposures of 6 h/day over 5 days. Exfoliation, ulceration, and necrosis of the respiratory epithelium were observed. The estimated LCt_{50} is 2,000 mg × min/m^3. A 20-min exposure to PS in pigs and cats resulted in an LD_{50} value of 800 mg/m^3 or 16,000 mg × min/m^3, respectively; and for mice, 15,840 mg × min/m^3 over a 4-h exposure (NIOSH, 2007). For humans, the permissible exposure limit (PEL) established by the National Institute of Occupational Safety and Health (NIOSH)/Occupational Safety and Health Administration (OSHA) for a work-related, time-weighted average is 0.7 mg/m^3 (1 ppm = 6.72 mg/m^3). With regard to the capacity of PS to be genotoxic, carcinogenic, or both, studies have shown mixed results.

Exposure Biochemistry

As with several RCAs, the absorption, distribution, metabolism, and excretion of PS are not well elucidated. However, in two studies by Sparks et al. (1997, 2000), data indicated that PS can form adducts with thiol groups. After oral or i.p. injection in mice, PS is rapidly absorbed and distributed to the blood, liver, and kidneys. Metabolites identified include thiophosgene dichloronitromethane, chloronitromethane, and nitromethane. Castro et al. (1988) and Sparks et al. (1997, 2000) both suggest that enzymatic reactions may be driven by β-lyase, cytochrome P-450s, and GSH-S-transferases. Additional evidence suggests that PS may be converted to raphanusamic acid (Sparks et al. 1997).

Exposure Histopathology

In postmortem assessment of exposure to inhaled PS, Buckley et al. (1984), recorded that PS was only one of several inhalants that produced lower respiratory tract lesions. In a case of homicidal poisoning resulting in an exposure to PS, spotty discoloration and pulmonary edema were found in the postmortem examination (Gonmori et al., 1987). Death in this case occurred within 3–4 h of exposure.

1-Chloroacetophenone (CN)

CN is a gray, crystalline solid compound with the odor of apple blossoms. Known also as Mace, it was specifically developed as an RCA. A potent lacrimator, it was developed just after World War I. As a vapor, it is 5 times heavier than air. Dissemination of CN can be achieved by grenade, steam dispensers, projectile cartridges, and aerosols.

Exposure Physiology

CN is a much more effective lacrimator than either CS or CR, causing serious injury to the ocular targets. Blepharospasm, corneal edema, erosion, and ulceration, as well as focal hemorrhages, can occur. As a potent skin toxicant it produces severe skin edema. Irritation of the airway, including sneezing, coughing, nasal secretions, and congestion, may persist for up to 20 min. after a challenge. The primary cause of death is from damage to the lung.

Exposure Biochemistry

The LCt_{50} for several species using the aerosol delivery method are as follows: dog, 7,033 mg × min/m^3; rat,

8,878 mg × min/m^3; and guinea pig, 7,984 mg × min/m^3. Multiple exposures using nonhuman primates and guinea pigs demonstrated that lethality decreases with repeated exposures over days or weeks, suggesting adaptation to CN toxicity. Using guinea pigs, dogs, and nonhuman primates in a similar experimental design, with a 10-day concentration totaling 88,000 mg × min/m^3, mortality was observed in animals. In one of the few comparative inhalation studies, Ballantyne and Swanston (1978) performed acute toxicity testing on rats, mice, guinea pigs, and rabbits using CN and CS aerosols. The duration of exposure ranged from 15 to 60 min, with lethality occurring within 14 days. The respective LCt_{50} values for these animals were 8,750, 18,200, 13,140, and 11,480 mg × min/m^3. For all species, CN was much more toxic than CS. Equitoxic doses of CN and CS produced similar findings using the i.v. and i.p. challenge routes. These data suggests that for appropriate toxicity screening, multispecies and multiagent comparisons are critical. For further toxicological reviews, see McNamara et al. (1969).

CN has been shown to increase lung sphingomyelin and decrease phosphatidylcholine and ethanolamine in rats (Kumar et al., 1995). Based on the increased bacterial retention in the lung in mice exposed to CN, the authors concluded that CN might increase susceptibility to infection. This may be attributed to the immunotoxic effects of CN through altered, T-cell-mediated macrophage functions (Kumar et al., 1992).

Exposure Histopathology

Animals exposed to high concentrations of CN that resulted in mortality at 48 h showed evidence of tracheal congestion and pulmonary edema (Ballantyne and Swanston (1978). Histopathology revealed congestion of alveolar capillaries and intrapulmonary veins, inter- and intra-alveolar hemorrhages, and excessive secretions in the bronchioles. CN was reported to produce degeneration in the epithelium of the bronchiole and alveolar septal-wall thickening and the presence of an increased number of mononuclear cells in rats (Kumar et al., 1995). Necrosis of the liver, kidney, small intestine, and spleen were also observed.

DA and DC

As previously stated, DA and DC are known as *vomiting agents.* Like other RCAs, they manifest their toxicity by irritating the airway mucous membranes, as well as the eyes. Irritation results in sneezing, coughing, vomiting, and headache. They have a bond between trivalent arsenic and chlorine (in the case of DA) or cyanide (in the case of DC) and are less toxic than CN.

DA, a sternutator, is a white crystalline solid with a MW of 265. As was noted for DM, the toxicity of these compounds is attributable to the presence of arsenic in the form of As (III). The general, physiological outcome of exposure to organoarsenicals can be manifested as severe conjunctival membrane irritation, swelling of the cornea, and sloughing of respiratory mucosa forming mucus plugs in the lower airways. DA can produce these effects, and it leads to death if exposure occurs in unventilated and confined spaces (Ochi et al., 2004). Studies by Ishi et al. (2004) postulated that metabolic byproducts of DA and DC, such as diphenylarsenic acid, might be associated with developmental abnormalities in humans. The estimated LCt_{50} values for DA and DC are 15,000 and 10,000 mg × min/m^3, respectively (Seto, 2011). It should be noted, however, that the toxicity of DA as a CWA is lower than the vesicants discussed next. Limited information is available on the pulmonary toxicity of these agents.

Vesicating Agents

Sulfur mustard was used extensively in World War I and was responsible for thousands of casualties. The most recent significant intentional use of vesicants was that of sulfur mustard (HD) during the Iran-Iraq war (1984–1988). Vesicants are compounds that produce chemical burns. Members of this group of vesicating agents include HD, lewisite (also known as *Agent L*) (an arsenical) and phosgene oxime (CG). CG exposure produces hivelike, urticarial skin reactions on contact. HD is a persistent agent as it can remain on the soil for more than a day (Table 36.1). Persistence is dependent on pH, soil type, and hydrophilicity. At high temperatures, such as those that occur in the desert (38–49°C), it is a considerable inhalation hazard. There is a great deal of literature regarding the toxicology, physiology and biochemistry of HD.

Sulfur Mustard—bis-(2-chloroethyl) Sulfide (HD)

Sulfur mustard, or mustard gas, is a colorless oil with a MW of 159. Impurities can cause HD to give off a garlic-like odor. It is 5.4 times as dense as air, which enables it to settle in trenches (and hence making it well suited for war). Although it is a low volatility agent, the HD vapor was responsible for about 80% of the chemical exposure deaths during World War I. HD has also been known as "Yellow Cross," "Lost," "S-Lost," "H," or "Yperite." Because HD is denser than water and does not readily hydrolyze, it can remain a threat for a while in various aqueous environments and has caused skin blisters when handled many years after submergence (Aasted et al., 1985; Wulf et al., 1985). The formation of fluid-filled blisters by HD can cause immediate tissue damage yet latent pain that may take several hours. Clinical effects may occur hours later.

Exposure Physiology

Although skin is considered to be an important route of exposure for HD, many of the fatalities ascribed to HD exposure during World War I and the Iran–Iraq war were the result of inhalation. Inhaled HD is largely absorbed in the upper airway and rarely penetrates to the lung parenchyma unless the concentration or duration of exposure are sufficiently high. In humans, following inhalation exposure to HD, reports have identified bronchopneumonia, chest tightness, and, in long-term survivors, chronic bronchitis, lung fibrosis, productive cough, and chronic obstructive pulmonary disease (Ghanei and Harandi, 2007). Injury can develop slowly, becoming much more intense over time. One important issue with HD-induced lung damage is the proper maintenance of blood oxygenation. Hypoxia is usually secondary to inflammation and bronchitis. Other consequences following exposure include tracheobronchial stenosis and life-threatening pseudomembrane (casts) formation. Leukopenia can also occur several days after exposure and suggests compromise of the immune pathway that can progress to suppressed bacterial clearance and sepsis. HD exposure has also been shown to affect the CNS. Most of the casualties observed following an inhalation exposure to HD were from pulmonary damage generally due to complications of bronchopneumonia, sepsis, and immunosuppression. Experiments done in animals decades ago employed various routes of administration, including inhalation, which produced convulsions, hyperactivity, and abnormal movements (Vedder, 1925). Anderson et al. (1996) demonstrated the formation of mucus casts within 24 h of exposure in a HD vapor rat inhalation model. Casts can cause ventilation perfusion mismatch due to clogged airspaces and lead to respiratory failure. Heully and Gruninger (1956) reported that three children accidently exposed to HD had abnormal muscular activity with one child alternating between coma and agitation. Two of these children died.

In large animal studies, such as with swine, 6 h after a 10-min exposure to HD vapor from 67 to 157 µg/kg body weight resulted in respiratory acidosis, increased shunt fraction, and hypoxemia at the higher concentrations. Elevated bronchoalveolar lavage (BAL) levels of IL-8 and IL-1β were measured in the high-dose exposed animals suggesting a pro-inflammatory stimulation associated with airway injury (Fairhall et al., 2010). The LCt_{50} of HD has been estimated to be 1,500 mg × min/m^3 (Seto, 2011).

Exposure Biochemistry

The mechanism of biotransformation of HD has been elucidated. Once HD enters the target organ and blood, it forms an intermediate sulfonium ion which is transformed into a carbonium ion considered to be a strong electrophilic species capable of reacting with highly nucleophilic sites (Figure 36.5). These are robust alkylating agents that react with cellular constituents, such as SH^- and NH^- in DNA, RNA, lipids, and proteins. Byrne and Stites (1995) have shown that HD forms crosslinks with cysteine residues in proteins. HD reacts with RNA and DNA molecules at such sites as N7 guanine, N3 adenine, and O^6-guanine. The O^6 position is particularly critical for the action of O^6-alkyl-guanine-DNA-alkyltransferase in DNA repair (Ludlum et al., 1986) (Figure 36.5). HD also forms DNA crosslinks. Kehe and Szinic (2005) have discussed the likely role of HD in alkylating membrane-bound proteins and enzymes. Zhang et al. (1995) have assessed the effects of HD on basement membrane components. Their results indicated that HD can alkylate and form crosslinks with membrane adhesion molecules such as laminin. This may have important consequences in the case of a high-dose inhalation exposure to HD, whereby it can reach and directly affect the alveolar epithelial cell layer. Bone marrow, a site of cell proliferation, is also a target of HD toxicity (Dacre and Goldman, 1996). In 2008, Kan et al. provided some evidence that there may be causal link between the inhalation of HD and cancer in rats exposed to a single high dose of HD (3 mg total dose over 10 min) (Kan et al., 2008). The conclusions of this limited study have yet to be supported by continued research. However, the results obtained may provide the incentive for future studies.

In rodent studies using intravascularly administered radiolabeled HD, distribution occurred in highly perfused organs such as the kidney, heart, liver, intestine, and lung within 1 h after injection (Maisonneuve et al., 1994). These organs are sites of biotransformation. Capacio et al. (2008) showed that HD-plasma protein adducts can be measured in the blood following a single 10-min exposure to graded increases of HD in a rat aerosol inhalation model.

The role of GSH in detoxification of HD has been somewhat controversial. Sciuto et al. (2007) have shown that there may be a biphasic response to HD intoxication. Testing for pulmonary toxicity using an intravascular HD injection model in rats, it was shown that at 1 h post-exposure, BAL revealed a dose-dependent inflammatory stage that decreased over time from 3 to 24 h. Macrophage inflammatory protein (MIP-2) was the predominant chemokine in the BAL followed by IL1β, IL10, and TNFα. A second phase involved changes in the antioxidant response pathway, which was mostly affected at 6 h post-challenge. HD exposure increased BALF protein, GSH, and the activities of GSH peroxidase (GPX), catalase, GSH reductase, and SOD (Sciuto et al., 2007). Laskin et al. (2010) summarized that in some animal models of acute lung injury with HD and HD-like compounds, antioxidant markers such as GPX and GSH

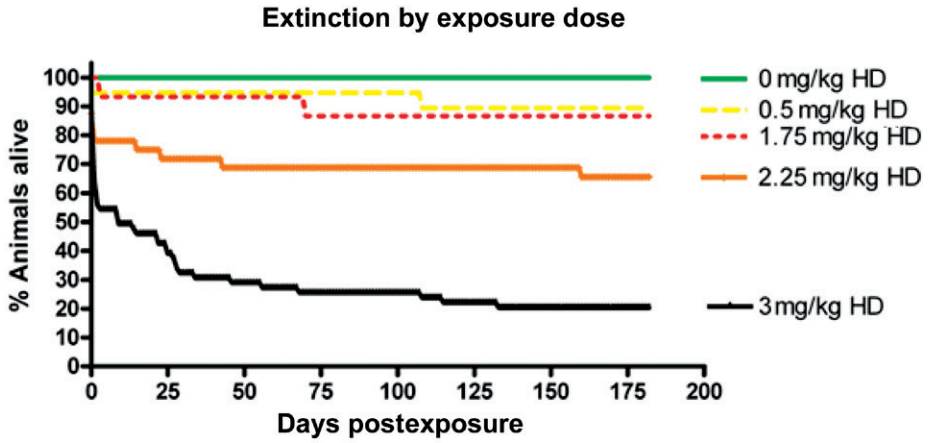

FIGURE 36.6 Shown here are 26-week survival curves of male rats exposed to a single 10 min inhaled HD. Concentrations represent the total dose delivered during exposure. Data indicate a delay in lethality based on dose. Exposures were done via intratracheal administration of aerosol in ventilated and anesthetized animals to avoid scrubbing in the nasal passages and providing a direct challenge to the lung. To control the rate of aerosol delivery, ventilation parameters (such as the tidal volume and the respiratory rate) were held constant for all exposed animals. *Source: (Olivera and Sciuto, 2014, unpublished results).*

increased, suggesting enhanced endogenous compensatory antioxidant activity. Brimfield et al., (2012) investigated mustard-induced, oxygen free-radical formation in an *in vitro* system using the spin-trapping technique. They concluded that the presence of peroxyl and hydroxyl free radicals could arise only when oxygen is reduced by carbon-based mustard radicals. The electron paramagnetic resonance (EPR) ROS signals disappeared by adding catalase and SOD to the reaction system.

Increased autophagy has also been reported in rats exposed to HD. Increases in LC3B-II and LC3B I were noted in rat lungs as early as 6 h and as late as 48 h post-exposure (Malaviya et al., 2010). Since this process might involve mitochondria, it is possible that HD might induce alterations in cell energy and metabolism (Uchiyama et al., 2008, from Malaviya et al., 2010). Dillman et al. (2005) showed that apoptotic pathways are also activated within 3 h of intravascular injection of HD in rats. This damage subsequently resulted in enhanced expression of proteins that arrest cell cycle progression and enhance programmed cell death. Presumably, apoptotic activation in the face of extensive DNA damage may be intended to avert multiple mutations that could lead to cancer formation. It is also apparent that tissue and cell damage is dose-related and does not appear to decrease over time, suggesting a long-term effect in the lung from a single HD challenge.

It is apparent from battle casualties (most recently from the Iran–Iraq war) that both soldiers and civilians continue to suffer debilitating compromised lung function 30+ years after initial exposure (Ghanei and Harandi, 2007). However, the long-term consequences of HD inhalation exposure have not been well examined in animals. Mortality at 3–8 and 15–19 weeks following a single HD intravenous exposure (3 mg over 10 min) occurred in rats (Figure 36.6). This dose approximately translates to LCt_{70} and LCt_{80}, respectively, over these time intervals. The data indicated that rats surviving a first phase with respect to lethality are not completely free of problems later. These data are supported by depressed respiratory function, which also suggests a link with temporal morbidity outcomes. Results from this long-term study in HD-exposed rats also revealed compromised respiratory function and symptoms of chronic obstructive pulmonary disease in rats that are similar to those described in soldiers and civilians exposed to HD during the Iran-Iraq war.

Biomarkers of HD exposure have focused on blood and urine evaluations. Historically, the metabolite thiodiglycol (TDG) was used as an indicator of exposure. However, the significance of linking TDG to HD exposure became problematic since TDG levels in the urine can be naturally elevated as a result of normal metabolism. However, as analytical techniques improved, more refined analyses revealed other metabolites that were indicative of actual HD exposure. In a large swine HD inhalation study, the monosulfoxide β-lyase metabolite of HD [1-methylsulfinyl-2-[2(methylthio) ethylsulfonyl) ethane] (MSMTESE)] was discovered in the urine (Fairhall et al., 2010). MSMTESE was present for up to 6 h post-exposure following a single 10-min inhalation challenge to 158 µg/kg HD. The detection of MSMTESE in the urine served as a valid biomarker for an HD inhalation exposure in this model.

Exposure Histopathology

In 15-year survivors of the Iran–Iraq war, histopathological examination of lung tissues revealed evidence of

increased asthma, chronic bronchitis, emphysema, airway stenosis, bronchiectasis, and lung cancer, and possibly lung fibrosis as well. The contributions of smoking and the presence of preexisting pulmonary disease as potential confounders against these conclusions were not taken into account.

Lewisite—b-Chlorovinyldichloroarsine (Agent L)

Lewisite (also called *Agent L;* MW = 207.3) is a colorless, oily liquid. Impure Agent L may have a faint odor of geraniums and could be blue-black in color. It is classified as a blistering, but not vesicating, agent due to its effects on the skin and eyes. Compared to HD, Agent L forms fluid-filled blisters accompanied by immediate pain. Exposure occurs through inhalation, ocular, or dermal routes. After acute dermal exposure, the liver, gallbladder, urinary bladder, lung, and kidneys are affected as well (Snider et al., 1990). The appearance of blisters can begin at any time, ranging from seconds to minutes based on exposure $[C] \times t$. Lesions resulting from various exposure routes are similar to HD. Hydrolysis products are more persistent than HD, and it is about 10 times as volatile. It is soluble in organic solvents and is readily absorbed by paint, rubber, and porous surfaces. As an organoarsenical, the enhanced reactivity of Agent L is linked to labile chlorine atoms, trivalent arsenic, and its capacity to form multiple chemical bonds with proteins. Agent L contains about 0.8–1.3 mg/mL of arsenic.

Exposure Physiology

Exposure to Agent L can occur through oral, dermal, ocular, ingestion, and inhalation pathways. Lewisite shock is observed following exposures to high levels. This mostly results from protein and plasma leakage from the capillaries, hypotension, and hemoconcentration. Agent L can readily penetrate the skin in both vapor and liquid form, causing systemic exposure; as little as 0.5 mL can cause serious problems, and at 2 mL, lethality can occur in humans. Vapor inhalation causes rhinorrhea, violent sneezing, and irritation to the nasal passages. These may be followed by expectoration of blood and coughing. According to Sidell (1997), Agent L does not cause bone marrow damage or immunosuppression. Clinically, large doses of arsenical compounds may lead to leukopenia. Since trivalent arsenic, As (III), is a major metabolite of Agent L, acute exposures might cause neurological damage. These may include loss of memory, problems in concentrating, anxiety, and confusion (Rodriguez et al., 2003). The inhaled LCt_{50} is estimated to be 1,500 mg × min/m^3 in mammalian species (Seto, 2011). These are close to earlier estimates of inhalation studies in mice, where the LCt_{50} for a 10-min exposure was 1,900–2,000 mg × min/m^3 (Silver and McGrath, 1943).

Currently, there is insufficient data on the carcinogenic effects of Agent L. Combustion by-products of Agent L, such as arsenic trichloride, vinyl chloride, and arsenic trioxide, have the potential to induce cancer. Arsenic trioxide and vinyl chloride are labeled Class A carcinogens by the U.S. Environmental Protection Agency (EPA 1984). However, it is not known if Agent L has any direct effect on cancer development. See Goldman and Dacre (1989) for a more detailed review on the chemistry of lewisite toxicity.

Exposure Biochemistry

Agent L will react with water to form chlorovinylarsenous acid (CVAA), which is slowly converted to arsinoxide. Metabolites can be found in the urine after exposure (Waters and Williams, 1950). It is highly distributed systemically, even after inhalation, due to its high lipophilicity. The reaction by-products include unstable chlorine atoms, As (III), and carbon. It is most likely that the metabolite As (III) is responsible for the observed systemic toxicity. As (III) can react as a nucleophile on thiol groups in proteins and lipids, particularly on lipoic acid, eventually forming alkylarsine sulfides. The binding of Agent L to sulfhydryl-containing proteins and enzymes inhibit pyruvate dehydrogenase activity, which is critical to glucose and fatty acid metabolism (Black, 2008). Agent L metabolites produce antioxidant imbalance, calcium metabolism imbalance, lipid peroxidation associated with oxidative stress, membrane impairment, and ultimately cell death (Sidell et al., 1997). Fidder et al. (2000) incubated labeled Agent L with human erythrocytes and found that 25–50% of the bound isotope formed protein adducts at cysteine residues of 93 and 112 of the β-globin molecule (Noort et al., 2002). The major excretion by-products of Agent L, including CVAA, are quantifiable markers in the blood that can be useful in detecting exposure.

Exposure Histopathology

There have been very limited studies on the toxicity of inhaled Agent L, specifically in the lungs. Decades ago, Vedder (1925) showed that in dogs exposed to Agent L, considerable nasal secretions, lacrimation, vomiting, and labored breathing were present until death. At postmortem, lungs were found to be edematous, with pseudomembranes extending from the nasal area to the bronchi. Airway mucosa was congested and edematous. Bronchopneumonia was also present. No other studies have systematically examined pulmonary pathological changes in animals exposed to Agent L.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The potential for human exposure due to intentional use or accidental release of CWAs and toxic industrial

chemicals will likely persist for many years. History has shown that exposure to these chemicals, regardless of the source, can be problematic for both civilians and military personnel. As such, continued study of the toxicity of these agents is of the utmost importance. All agents have the potential to cause significant morbidity and mortality by way of severely compromised pulmonary physiological homeostatic processes. The key target organ is the lung, and in many cases, regardless of the exposure route, respiratory failure is the cause of death. Subsequent exposure-related effects can involve altered respiratory function, compromised vital cellular metabolic/detoxification pathways, mitochondrial toxicity, hematotoxicity, and CNS toxicity. Other effects include immune response and associated release of cytokines and chemokines, altered antioxidant/oxidant pathways, increased free-radical formation, destruction of lung solute transport channels, and disruption of adaptive repair processes. All of the processes discussed here appear to be affected in a concentration-dependent manner; often with a latency period. For example, vesicant inhalation significantly alters the architecture of the lung to the extent that attempts to counteract the effects of damage through the innate repair process are compromised, leading to an obstructive pulmonary disorder.

The works cited herein show that although progress has been made in elucidating the toxicological, physiological, biochemical, and histopathological processes responsible for respiratory toxicity, much more effort is required to understand chemical-specific mechanisms and develop effective therapeutic measures. Three major issues will need to be addressed by future studies: (i) the development of a reliable, and appropriate animal inhalation exposure systems and the availability of human relevant animal models; (ii) examination of molecular mechanisms to identify potential therapeutic targets; and (iii) assessment of the long-term effects of inhaled CWAs. It is hoped that future efforts in this area will lead to the successful determination of therapeutic windows, treatment modalities, and effective medical countermeasures. A single therapeutic medical intervention likely will not be sufficient, but combinational therapies may be needed to counter the respiratory and systemic toxicities of CWAs.

Acknowledgments

We thank Dr. Gary Hatch and Dr. Michael Madden (EPA) for their critical review of this manuscript.

The U.S. army experimental studies cited herein were approved by the Animal Care and Use Committee at the U.S. Army Medical Research Institute of Chemical Defense, and all procedures were conducted in accordance with the principles stated in the *Guide for the Care and Use of Laboratory Animals* and the Animal Welfare Act of 1966 (P.L. 89-544), as amended. CHAPTER

37

Cardiovascular System as a Target of Chemical Warfare Agents

Csaba K. Zoltani

INTRODUCTION

On contact with toxicants, the heart reacts immediately with changes in its electrical homeostasis. Ancillary indicators, such as changes in the metabolites in body fluids, are time-delayed and initially less useful for diagnosis and for selection of countermeasures. This chapter describes how the heart is affected by and reacts to various chemical warfare agents (Balazs, 1981; Baskin, 1991; Acosta, 2001). The first section gives an overview of the anatomy and functioning of the heart (Opie, 1998), with emphasis on the constituents most vulnerable to toxic presence. The importance of cardiac neuronal changes as possible indicators of exogenous effects is underscored. The normal electrical state and signature of cardiac toxicity are described, followed in detail by the palette of military warfare agents and their modes of action at the cellular level, including description of their expression in the changed morphology of the tissue and modified electrical state (Ellison, 2008; Romano et al., 2008). The effect of the different poisons on the heart is strongly dose-related. The references provide a good summary of the expected effects of each of the anticipated conditions. Electrocardiograms (ECGs) (Wexler et al., 1947; Karki et al., 2004; Delk et al., 2007) illustrating the effect of the toxicants are provided when available. New biomarkers such as miRNAs, which are short noncoding RNA sequences that regulate gene expression and control cellular processes, are revolutionizing the detection and treatment of cardiotoxicity. Approaches to therapy and recommended antidotes for some of the discussed toxicants are given.

BACKGROUND

Cardiac Anatomy

The timed delivery of oxygenated blood to all parts of the body is the function of the four-chambered pump, the heart. It is enclosed in a double-layered sac, the pericardium, with the inner layer, the visceral pericardium, anchoring the heart and the outer layer attached to the sternum. A cardiac skeleton anchors the four heart valves and the atria and ventricles. The thick wall separating the two ventricles, the interventricular septum, houses the Purkinje fibers, which play an important part in the electrical activity of the heart.

Deoxygenated blood from the body enters the heart by the vena cava and empties into the right atrium. Through the tricuspid valve, blood then transits into the right ventricle and via the pulmonic valve enters the lungs, where it is oxygenated. It returns to the heart through the pulmonary veins and the atrium to the left ventricle. This muscular pump redistributes the oxygenated blood to all parts of the body.

The heart is mediated by an electrical system that is easily disturbed by toxicants changing the timing, flow, and magnitude of the electrical pulses, and thus interfering with the required pumping action. The activity of the heart is myogenic (the activity is initiated by the heart itself). Various components of the heart, such as the sinoatrial (SA) node, atrioventricular (AV) node, and the Purkinje fibers, are capable of pacemaker activity. Healthy atrial and ventricular tissue does not engage in pacemaker activity. The primary pacemaker is the SA node, but in diseased or affected states the secondary pacemakers take over.

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00037-3

The SA node lies in the right atrium in an epicardial location and functions as the primary source of the electrical impulse formation. It consists of specialized muscle cells smaller than ventricular cells containing few contractile elements. Because of its location, the action potential generated traverses the atria first, causing the primary contraction. The action potential is relayed to the AV node, the conduit for the electrification of the ventricles. The signal must pass through the AV node; otherwise, the atria and the ventricles are electrically insulated from each other. A time delay in transmission is needed for the atria to be emptied of blood.

The AV node is a subendocardial right atrial construct that is located within a fibrous stroma in the triangle of Koch. It is connected to both sympathetic and parasympathetic nerves. The bundle of His arises from the distal section of the AV node and goes to the summit of the ventricular septum. It is the only nonpathologic electrical conduction between the ventricles. The bundle of His divides into the left and right bundle branches that then become the Purkinje fibers that interweave the contractile cells of the ventricle and speed the excitation throughout the ventricles.

Action potential of the cardiac myocytes is initiated by inward sodium current in atria and ventricles, with inward calcium currents contributing to the upstroke in the SA and AV nodes. Slow inward currents result in lower resting and activation potentials. In the latter, membrane potentials range from −40 to −70 mV and activation threshold lies in the range of −30 to −40 mV and shows phase 4 depolarization. These cells are modulated by acetylcholine (ACh) and catecholamine. The duration of the action potential depends on the outgoing potassium current durations with the inward calcium currents of lesser importance. It is longest in the Purkinje fibers. Resting potentials of atrial and ventricular cells range from −80 to −90 mV, with activation thresholds in the range of −60 to −70 mV. Impulse conduction ranges up to 300 V/s in atrial and ventricular cells and up to 900 V/s in the Purkinje tissue.

B Innervation of the Heart

The autonomic nervous system guides the electrical and mechanical functions of the heart. The heart is innervated by both the sympathetic and parasympathetic systems, which have opposite effects and are activated reciprocally. They play important roles in arrhythmia susceptibility. Sympathetic stimulation originates from the intermediolateral column of the thoracic spinal cord. Its neurotransmitter, norepinephrine, is released from neurons of postganglionic fibers of stellate ganglia and epinephrine is released from the adrenal medulla. Both of these act on cardiac β-adrenergic receptors. Sympathetic nerves are predominantly on the epicardial surface. Receptors for norepinephrine on cardiac muscle are of the β-adrenergic kind. Postganglionic sympathetic neurons innervate the SA and AV nodes, the conduction system, and the myocardial fibers in the ventricles. Epinephrine, an amine, is the primary endogenous catecholamine produced in the adrenal medulla and regulates organic metabolism. It stimulates β_1 receptors, enhances ventricular contractility, and enhances SA nodal cell phase 4 depolarization, that is, impulse generation.

The cholinergic (i.e., parasympathetic system) acts through the vagal nerves by release of ACh that opposes the sympathetic stimulation. Parasympathetic preganglionic neurons originate in the medulla. Parasympathetic fibers terminate mainly on cells of the atria. Parasympathetic innervation is denser in the SA and AV nodes than the left ventricle. The right vagus nerve innervates the SA node. The neurotransmitter ACh and adenosine promote susceptibility to atrial fibrillation and shorten atrial refractoriness. Excessive stimulation causes bradyarrhythmia. The left vagus nerve innervates the AV node, where excessive stimulation results in AV block. Receptors for ACh are of the M2 muscarinic type and ACh binding to muscarinic receptors inhibits cAMP production. ACh has a negative chronotropic effect (slows heart), slows conduction (negative dromotropic effect), and also has a negative inotropic effect (decreases strength of contraction). The latter is through the activation of the current $I_{K,ACh}$, resulting also in shortening the action potential. ACh has three actions on cardiac muscle: it activates ACh-sensitive K-current, $I_{K,ACh}$; it inhibits the voltage time-dependent inward calcium current I_{Ca}; and it inhibits the hyperpolarization-activated inward current I_f, important for pacemaking. Ventricular muscle is not affected by vagal stimulation.

There are anatomical physiological differences between the sympathetic and parasympathetic systems. The parasympathetic ganglia lie within or close to the organ that postganglionic nerves innervate, whereas sympathetic ganglia lie closer to the spinal cord. There is limited parasympathetic innervation of the ventricles compared with the atria. The vagal nerve fibers are mostly intramural. The heightened adrenergic activation in the ventricles is potentially arrhythmogenic.

All catecholamine receptors are metabotropic. They act by initiating metabolic processes affecting cellular functions. β-adrenergic receptors, receptors for epinephrine, and norepinephrine act by stimulatory G proteins to increase cAMP in the postsynaptic cell. cAMP binds to and activates protein-kinase enzyme.

Disturbed balance between the parasympathetic and the sympathetic systems can result in disturbances in cardiac function. As discussed later, chemical warfare agents play an important role in disturbing this balance.

Neuropeptides

Vasoactive intestinal peptide (VIP), a neurotransmitter, is found in extrinsic and intrinsic nerves of the heart. VIP is released by the vagal nerve, and its effect is to increase I_f and pacemaker rates (Chang et al., 1994; Accili et al., 1996). VIP release takes place under high-frequency stimulation. As an internal brake, it limits the ability of ACh to excessively suppress the sinus node and other pacemakers. It also has an effect on the calcium-activated potassium channel.

VIP acts as a parasympathetic neurotransmitter in its involvement in the postsynaptic control of the heart. VIP is exactly opposite in its action to that of ACh. Vagal activity, causing release of ACh, slows the heart but co-release of VIP leads to tachycardia due to VIP-preferring receptors, leading to an increase in adenylate cyclase and accumulation of cAMP.

Neuropeptide Y (NPY) suppresses the pacemaker current I_f. Colocalized with norepinephrine in sympathetic nerve terminals on the heart, it is released with catecholamines during sympathetic neural activation. NPYs on cardiomyocytes have surface membrane binding sites and suppress contractility in concentrations of 10^{-9} or more. In ventricular myocytes, the L-type Ca^{2+} current as well as the delayed rectifier potassium currents are suppressed.

Energetics of the Heart

The heart requires a continuous supply of energy to be able to sustain its pumping action. Most of the energy is derived from fatty acids. Under ischemic or anaerobic conditions, glycolysis comes into play, consuming large amounts of glucose with the adverse effect of the formation of lactic acid (Jafri et al., 2001).

More than 95% of the metabolic energy is used in the form of adenosine triphosphate (ATP). Its concentration in a myocyte is approximately 10 mM. ATP is synthesized by oxidative phosphorylation in the mitochondria. There, acetyl CoA is broken down to CO_2 and hydrogen atoms. Electrons are pumped out to form a proton gradient across the mitochondrial membrane. The protons re-enter the mitochondria and combine with oxygen, eventually forming water.

The glycolytic pathway under hypoxic conditions produces only a limited amount of ATP. Pyruvate formed in glycolysis is transported into the mitochondria, where CO_2 is formed through cellular respiration. From each glucose molecule, 28 ATP molecules are formed in anaerobic glucose metabolism. The heart also has an energy reserve in the form of phosphocreatine (PCr), which is an immediate precursor of ATP. In the reverse Lohman reaction, creatine kinase (CK) favors the maintenance of the ATP concentration at required levels. The energy released during hydrolysis of the phosphoanhydride bond in ATP powers energetically unfavorable processes, such as the transport of molecules against a concentration gradient.

During conditions of hypoxia, ATP is first degraded to adenosine diphosphate, then to adenosine monophosphate, and then to adenosine. The latter diffuses into the circulating blood, where adenosine concentration rapidly increases under conditions of cellular damage. The action of adenosine is anti-inflammatory as well as inhibitory.

Electrophysiology

The sinoatrial node (SA), consisting of spindle-shaped cells, initiates the electrical activity of the heart. From its location in the right atrium in proximity to the superior vena cava, the electrical activity spreads to the atria, whose cells are larger than those of the SA. The pulse from the atria spreads to the atrioventricular node (AV), the gateway to the ventricles. The atria and the ventricles are electrically isolated. The AV node also slows the electrical activity, giving the atria time to fill. The bundle of His is the upper end of the electrical path, which through the Purkinje fibers allows the electrical signal to activate the ventricles and thus to pump the blood.

Each cell's activity goes through four phases of the action potential (Grant, 2009). The morphology of each type of cell is different. Also, the kinds of electrolytes moved and their quantity and speed are dictated by environmental conditions (Carmeliet and Vereecke, 2002). Xenobiotic interference with the transmission of the ions changes the electrical homeostasis and commences breakdown in the state of the tissue. The membrane currents, pump, and exchanger of importance in this regard are given in Table 37.1. Anionic chloride

TABLE 37.1 Membrane Currents, Pump and Exchanger of Importance

Current	Function/Origin	Effect
I_{Na}	Voltage-gated Na^+ current	Depolarization
I_{K}^+	Voltage-gated K^+ channel	
I_{Ca}^{2+}	L-type Ca^{2+} current	
I_{Cl^-swell}	Activated by cell swelling	Cell swelling
$I_{K,ATP}$	Activated by fall in intracellular ATP	Fall in ATP
I_f	Hyperpolarization-activated current carried by Na^+ and K^+ in sinoatrial and AV node cells and His-Purkinje cells and contributing to phase 4 depolarization	
$I_{K,ACh}$	Parasympathetic control of the heart	ACh
Na^+/K^+-ATPase	Moves Na^+ out, K^+ into cell against concentration gradient using ATP for energy	Stimulated by α, β recap. via PKA, PKC
Na/Ca	Exchanges intracellular Ca^{2+} for extracellular Na^+	Responsible for DAD

currents, especially swelling-activated, play an important role in the case of cyanide intoxication (Baumgarten and Clemo, 2003).

SIGNATURES OF CARDIAC TOXICITY

The ECG as a Diagnostic Tool for Poisoning

Recorded Morphological Changes on the ECG

At present, morphological changes of an ECG are insufficient to make a definite diagnosis regarding the nature of a poisoning; however, they are useful in giving guidance regarding which of the ion currents are affected and thus to the possible nature of the toxicity (Yates and Manini, 2012). Without access to and comparison with an ECG before an incident and the multitude of factors that need to be considered, the diagnosis may be erroneous. However, poisons cause definite changes in timing and morphology of the ECG of affected individuals (Dalvi et al., 1986; Gussak et al., 2004; Delk et al., 2007; Zoltani and Baskin, 2007), and thus an ECG constitutes an important tool in the initial evaluation.

Disequilibrium in the electrolyte balance can provide diagnostic clues. For example, hyperkalemia causes tall T-waves in leads II, III, and V_2 to V_4 when the potassium balance exceeds 5.5 mmol/L. In conjunction, the amplitude of the P-wave is reduced and QRS is widened. Hyperkalemia is usually present when the amplitude of the T-wave is higher than that of the R-wave. With increasing potassium concentration, P-waves widen and eventually disappear. Accentuated hyperkalemia results in asystole.

Hypokalemia results in decreased T-wave amplitude and ST-segment depression; however, accurate QT interval measurement is difficult. Malignant ventricular arrhythmias result when potassium concentrations become very low. Hypercalcemia shortens the QT interval, whereas hypocalcemia produces ST-segment prolongation.

Left bundle branch block is characteristic of poisoning and is defined by Zimetbaum et al. (2004) as QRS more than 0.12 s with delayed intrinsicoid deflection in the V_1, V_5, and V_6 leads more than 0.05 s. The risk of arrhythmia is greatest when QRS is 0.11 s or more. Right bundle branch block more than 0.12 s is a fairly good predictor of arrhythmic death.

Blockade of potassium, sodium, calcium channels, β-adrenergic receptor sites, and the Na^+/K^+-ATPase pump change the ECG and may give an indication of the type of poisoning present in the tissue (Delk et al., 2007).

Reductions in the outward potassium ion flow prolong QT, a harbinger of Torsade de Pointes (TdP), and ventricular fibrillation (VF). Sodium channel blockers delay the entry of sodium ions, widening the QRS complex. In extreme cases, asystole ensues. A subsidiary event may be ventricular tachycardia degenerating into VF.

For control of tachyarrhythmia, calcium channel blockers are used. Blockade of these channels decreases contractility and SA and AV node depolarization. Blocking β_1 receptor sites within the myocardium reduces the intracellular calcium concentration and the contractility. The potassium concentration is increased, which is an undesirable effect when the β_2 receptors are blocked.

Inhibition of the Na^+/K^+-ATPase pump results in $[K^+]_o$ and intercellular $[Na^+]_i$ increases, thus increasing the intracellular calcium concentrations.

Long QT

Important predictors of arrhythmia are changes in the duration of the QT trace, the time for ventricular repolarization, displacement of the ST-segment, and changes in the pattern of T-waves that may sometimes be seen as a T-wave and U-wave (Roden, 2008). It can be linked to ventricular tachycardia, including TdP. Lengthened QT increases the time available for intracellular calcium accumulation, enabling early after-depolarization (EAD) in the Purkinje fibers, and activates calmodulin (CaM) and calmodulin kinase (CaMK). CaMK is believed to enhance after-depolarization, triggering TdP. CaMK increases L-type calcium channel activity. Anderson (2006) reported that inhibition of CaMKII can prevent cellular arrhythmia when QT-prolongation is present (Zoltani and Baskin, 2007).

During the plateau phase of the action potential, there is a delicate balance between the L-type Ca^{2+} channels and the slowly and rapidly activating cardiac delayed rectifier currents, I_{Ks} and I_{Kr}. Due to the slow onset of I_{Ks} activation during the rectification of I_{Kr}, a limited amount of repolarizing current flows. The L-type Ca^{2+} channels are time-dependently inactivated while an outflowing potassium current occurs. With a net outflow of ions, repolarization takes place. It is critical that the I_{Kr} deactivates slowly. Thus, small changes in the inward or outward conductance, for example, the amount of current leaving or entering, have a deciding influence on the length of the repolarization. The effect of poisons on these processes plays an important role in determining the QT-segment length.

Biochemical Markers of Tissue Injury

Conventional Biomarkers

Protein markers released into the bloodstream have been used as indicators of cardiac injury. The gold-standard marker currently is troponin. Three types of troponin, as well as elevated creatine kinase–MB (CK–MB) levels and peripherally myoglobin, are used as indicators of cardiac tissue damage (Apak et al., 2005;

O'Brien, 2008). Biomarkers of heart failure (Mittmann et al., 1998), including natriuretic peptides that increase in response to wall stress and ST2, reflective of ventricular remodeling and cardiac fibrosis may also be a consequence of toxicity and are detailed by Maisel (2012).

Cardiac troponin complex consists of three parts. Troponin T facilitates contraction, troponin I (cTnI) inhibits actin–myosin interactions, and troponin C binds to calcium ions. Troponin I and T are specific to the heart, but cTnT is also expressed by injured skeletal muscle. In the course of cell damage, cardiac troponin is released from myocytes, facilitated by increased membrane permeability that allows smaller troponin fragments to traverse the membrane. Complicating the use of troponin levels is the fact that in cases where there is cardiac injury without cardiac cell membrane disruption, serum troponin level can increase. Also, altered ion homeostasis may not be reflected in troponin levels.

In cancer patients undergoing high-dose chemotherapy, elevated troponin I and CK–MB are predictors of ventricular systolic dysfunction, and thus are indicators of cardiac damage. Immunological ultraviolet-array is used for the determination of the level of CK–MB, where an elevation greater than twice normal is taken as an indicator of myocardial infarction (MI). Cardiac troponin is measured by electrochemiluminescent immunoassay. Cardiac impairment is indicated by the presence of troponin. The release of the enzymes has been linked to a mismatch between oxygen demand and expenditure in the tissue, lessening the time available for diastolic coronary perfusion, catecholamine release, and intense sympathetic stimulation. Warfare agent–associated cardiac toxicity is characterized by these conditions.

Is the increased level of troponin due to damage to the heart muscle? In-depth studies note that stroke victims without acute MI have elevated troponin levels. Severe renal dysfunction may also be a cause. Thus, until convincing proof is presented for noncardiac causes, increase in the presence of marker enzymes can be taken as an indicator of damage due to toxins in the cardiac tissue.

CK is an enzyme necessary for ATP generation. One of its forms, CK–MB, is found mainly in the myocardium and, on tissue damage, such as MI, becomes elevated. It takes up to 24 h for the elevated level to reach its peak. A difficulty resides in the fact that unlike troponin, an assay does not distinguish between cardiac and skeletal muscle damage. Also, in approximately one-third of MI cases, although CK–MB levels stay neutral, troponin elevation is noted. The normal level of troponin in the blood for troponin I is less than 10 μg/L and that for troponin T is 0–0.1 μg/L, whereas for CK–MB it is less than 3.0 ng/mL. For humans, the CK is in the range of 55–170 IU/L (international units per liter) and is less specific than CK–MB for cardiac tissue damage.

miRNA

Traditional biomarkers lack tissue specificity and their appearance in body fluids is time-delayed. For example, troponin levels are elevated between 3 and 12 h after myocardial injury. Recently, microRNAs have gained acceptance as alternate biomarkers (Yamakuchi, 2012; Gidlof et al., 2013; Sahu, 2013; Vickers, et al., 2014). Their tissue specificity, sensitivity, stability, and timeliness underlie their usefulness and have opened new therapeutic approaches. These noncoding RNAs play an important role as gene expression regulators, and miRNAs regulate fundamental cellular functions and toxicological outcomes. The number of identified miRNAs is large, and they regulate the majority of mRNAs.

miRNAs are short, 22-nucleotides-long, and modulate protein expression by binding to mRNA, thereby inhibiting translation or targeting them for degradation. As regulators of physiological processes, they play an important part in the developing pathology (Kim, 2013; Vacchi-Suzzi et al., 2013).

Biogenesis of miRNAs starts in the nucleus of the cell where miRNA genes are transcribed by RNA polymerase into primary miRNAs. The Drosha enzyme then creates the precursor miRNA. After export to the cytoplasm, cleavage by the Dicer enzyme produces the miRNA. The mature miRNA is incorporated into RISC (the RNA-induced silencing complex). The miRNA of the RISC complex binds to the target messenger RNAs preventing translation. After myocardial infarction, for example, miRNA levels increase signaling-reduced systolic function when the left ventricle ejection fraction is less than 50%.

Microvesicles shed from the cell, such as exomes, export the miRNAs and transport them to other locations, in effect constituting the intercellular communication and thereby regulating genetic function and protein generation.

In drug toxicity (Yokoi and Nakajima, 2013) as well as oncology, miRNAs are becoming useful tools in making diagnoses. As shown in Section VII, miRNAs offer new therapeutic approaches for warfare agent–caused cardiac toxicity.

INDICES OF THE TOXICITY OF WARFARE AGENTS

Classes of Warfare Agents

Three broad classes of warfare agents are considered: organophosphate (OP) nerve agents (Munro et al., 1994; Newmark, 2007); the cyanides (Baskin et al., 2009); and a third general category that is less weaponized but whose effects are important as potential terror agents, the arsenics and ricin.

Respiratory tract irritants such as phosgene and vesicants, including sulfur mustard, have subsidiary cardiac impact but the mode of disability is acute lung injury.

The classes of nerve agents of primary interest are the "G" agents, first synthesized in Germany. Denser than air, these agents hug the ground and represent a vapor hazard due to their volatility. Tabun (GA), sarin (GB), and primarily soman (GD) are the ones most widely used. "V" (venomous) agents were developed in the United Kingdom. VX is more toxic than the G agents. Novichok, developed in the Soviet Union, is the most potent nerve agent, but there is little public information available. Cyanides are less weaponized but are of concern. Arsenic and ricin are considered terror threats rather than battlefield weapons.

Background

Chemically induced cardiac failure has been the subject of a number of works. Baskin (1991) and Acosta (2001) provided an overview of the subject. Hypoxia is one of the effects of the decreased availability of ATP that decreases contraction in the muscle. The energy that is supplied by the phosphate bonds is possible only as long as aerobic glycolysis and oxidative phosphorylation are maintained. Under anoxic conditions this is no longer possible, and the adrenergic stimulus continuing calcium accumulation in the mitochondria leads to impairment of function, eventually causing dose-related lesions (Suzuki, 1968).

Signatures of Toxicity

Warfare agents disturb cardiac homeostasis. The main changes of concern include the following:

- Morphological tissue changes
- Enhanced neural stimulation
- Release of neuropeptides
- Activation of usually dormant cardiac currents
- Alteration in the storing and movement of ions
- Disturbances in energy use and storage

Ferrans et al. (1969) noted ultrastructural changes in myofibrils, including mitochondrial swelling and disorganization. Catecholamines also produce changes in the activity of oxidative enzymes. The decline in the activity progresses to the point at which necrosis is evident. Ancillary effects include loss of myocardial potassium and an increase in interstitial fluid. Intracellular calcium overload also develops as noted by Fleckenstein et al. (1974). It has been hypothesized that necrosis due to catecholamine overload may be caused by a defect in energy supply needed for the maintenance of cellular processes.

At low concentrations, the catecholamines, (epinephrine and norepinephrine) exert positive inotropic effects on the myocardium. High concentrations, however, can cause cardiac lesions (Inoue et al., 1998). Even physiologic concentrations, when extended over time, lead to cardiac damage, as shown by Szakacs and Mellman (1960). The LD_{50} of norepinephrine in rats is 680 mg/kg, but focal necrotic lesions are produced at doses as low as 0.02 mg/kg.

The oxidation product of catecholamine is adrenochrome, whose accumulation has also been linked to myocardial necrosis and morphological and subcellular alteration (Yates and Dhalla, 1975). Administration of adrenochrome to rats also induced heart arrhythmias. Free radicals may also contribute to these processes. It has been suggested that catecholamines may activate β-adrenergic receptors, stimulating adenylate cyclase, and thus elevating cAMP. This, in turn, activates protein kinase, increasing the phosphorylation of slow calcium channels and possibly resulting in overflow of calcium, leading to necrosis preceded by swollen sarcoplasmic reticulum (SR), altered enzymatic activities, and lower ATP.

Cyanide primarily blocks oxidative phosphorylation and ATP production. Every heart beat uses up to 2% of the energy available to the cell. Arsenic primarily causes long QT (LQT) interval on the ECG by blocking the fast potassium current, an action that is a precursor to VF.

The activation of dormant currents by the presence of xenobiotics, including cell swelling, radically changes the electrical homeostasis of the tissue (Zoltani and Baskin, 2007). Toxicities of major weaponized agents are given in Table 37.2.

Nerve Agents

There is a difference in distribution of nerve agents for different organs of the body as well as different locations within the heart. Roth et al. (1993) detail effects on the heart. Also, soman is deposited in "depots" where time-release effects cause unsuspected difficulties in treatment.

TABLE 37.2 Toxicities of Weaponized Agents

Agent	LCt_{50} (mg min/m^3)	ICt_{50} (mg min/m^3)	LD_{50} (mg/kg)
GA	400	300	14.28
GB	100	75	24.28
GD	70		5.0
VX	50	35	0.1428
Cyanide	2,500–5,000		1.1

Mechanism of Action

Nerve agents are OP compounds that irreversibly inhibit AChE, leading to ACh accumulation, and cause overstimulation of muscarinic and nicotinic ACh receptors. The effect at the SA node, the primary site of heart control, is inhibitory and bradycardia results. VX primarily affects neurotransmitter receptors, those of norepinephrine, and also affects the central nervous system not related to AChE inhibition.

Toxicants change the homeostatic distribution and timing of the presence of electrolytes, enzymes, and other constituents of myocytes and their environment. These changes affect and determine the current flow, in turn affecting the electrical state and possibly signaling the onset of electrical instability. Table 37.2 shows toxicities of weaponized nerve agents.

Electrocardiographic Signature of OPs

Disturbances in the electrical activity of the heart caused by xenobiotics are readily discernible in a surface ECG (Dalvi et al., 1986; Chuang et al., 1996; Yurumez et al., 2009).

OPs cause QT prolongation on the ECG that subsequently can degenerate into TdP. In one reported OP case, 79.7% had QT prolongations with ST-segment and T-wave abnormalities (Rubinshtein et al., 2002; Karki et al., 2004). Changes are ultimately expressed in arrhythmia, VF, and TdP, and severe disturbance of the energy homeostasis of the heart. Second-degree atrioventricular heart block as well as ST–T-wave alterations (Balali-Mood and Saber, 2012) have also been observed.

An initial indicator of an impending arrhythmia is prolongation of the QT interval. The lengthening can be caused by reduction in the outward currents or increased inward currents, for example, imbalance of inward and outward currents during the second and third phases of the cardiac cycle, such as the I_{Kr}, I_{Ks}, the $I_{Ca(L)}$, and I_{Na} currents. These currents can generate EAD and trigger activity at the end of repolarization. Primary sites are the Purkinje fibers and the mid-myocardial M cells. In the Purkinje fibers, at higher positive resting potentials than the ventricles, blockade is voltage-dependent, with increased block in the depolarized tissue. The failure of complete repolarization leads to dispersion of refractoriness and enhanced arrhythmogenicity. Acquired LQT interval involves pause-dependent or short–long–short RR interval sequences on the ECG and enhancement of sympathetic nervous system tone. LQT is favored in cases of severe bradycardia, hypokalemia, and conditions that lead to EAD. LQT may not be a sufficient condition for TdP. Stimulation of adrenergic receptors plays a significant role, but it can enhance or inhibit after-depolarization.

The electrical activity of the heart is modulated by hormones and neurotransmitters. Xenobiotics disturb their balance. The parasympathetic system releases ACh and the sympathetic system releases norepinephrine and epinephrine. These bind to α and β types of receptors. The α_1-receptors are present on the postsynaptic member of the organ and mediate vasoconstriction and stimulation of Na^+/K^+-ATPase, the Na^+/Ca^{2+} exchanger, and the Na^+/H^+ exchanger. This affects the I_{KATP} and inhibits the $I_{Na}{}^+$ and I_{to}. The α-receptor stimulation thus effectuates depolarization, and the α_2-receptor inhibits norepinephrine release.

Cardiac β_1-receptors and atrial and ventricular β2-receptors take part in positive inotropic response. Inhibition of catecholamines at β-adrenergic receptor sites interrupts the production of cAMP and inhibits calcium influx, producing a negative inotropic effect that yields a reduction in the heart rate.

The main effect of adrenergic stimulation is to enhance the intracellular adenylyl cyclase activity. This, in turn, increases cyclic adenosine monophosphate levels. Protein kinase A is activated, thus modulating phosphorylates, calcium, and potassium channels. Phosphorylation of the calcium channel increases the inward current leading to EAD.

β_1-Adrenergic stimulation increases the activity of the Na^+/K^+ pump and inhibits EAD. Hyperpolarization of resting membrane potential counteracts automaticity, leading to a decrease in heart rate. α_1-Adrenergic stimulation hyperpolarizes membranes and enables EAD and TdP by blocking potassium channels. Release of norepinephrine enhances α_1-adrenergic stimulation, facilitating EAD (Schomig et al., 1995). In LQT, increased sympathetic discharge may induce both bradycardia and TdP. Increased adenosine increases ventricular refractoriness and sympathetic tone setting the conditions for re-entrant arrhythmias. Hypokalemia prolongs cardiac action potential and may be the precursor of EAD. The net outward potassium currents are reduced and the inward calcium current is increased.

Toxic Effects of OPs on the Heart

The anticholinesterase effects of nerve agents depend on the sites where they act. The muscarinic effects in the heart act through the parasympathetic system, whereas the nicotinic effects act through the sympathetic system. Agents like tabun, sarin, and soman, analogous to ACh, are capable of changing the receptor sites, which increases the conductance of electrophysiological signals related to the enhancement of neuromuscular function. VX, however, counteracts the effect of ACh, interrupting neuromuscular function.

ACh is a neurotransmitter that is present in the parasympathetic nervous system and is stored in vesicles. Its function, under normal circumstances, is terminated

by AChE that is present in both the presynaptic and postsynaptic membranes. OPs inhibit AChE by electrophilic (a reactant that accepts an electron pair from a molecule with which it forms a covalent bond) attack of the enzyme. The neurotoxicity of OPs was exploited in the development of nerve gases. The key to the understanding of OP inhibition of AChE is the enzyme's serine hydroxyl group behavior. Normally, it attacks ACh at the carboxyl carbon, yielding a covalent bond between the enzyme and the ACh substrate. The transiently acetylated enzyme is next hydrolyzed and the active enzyme site is regenerated. The active serine hydroxyl group is attacked by the electrophilic phosphorus of the OP instead of the ACh. A covalent nonhydrolyzable bond is formed between the enzyme and the OP, leaving the enzyme in an inactivated form. Release of an alkyl chain further strengthens the phosphorus–enzyme bond. With AChE inactivated, the amount of ACh present increases, resulting in overstimulation of the tissue. The pathophysiological effects that result can be explained by the overabundance of the ACh. Overstimulation of muscarinic receptors in the heart leads to bradycardia.

SPECIFIC WARFARE AGENTS OF CONCERN REGARDING THE HEART

Nerve Agents

The heart may be affected by both muscarinic and nicotinic effects. Stimulation of the parasympathetic nerve endings (in the former) and excess ACh on the nicotinic receptors (in the latter) are of importance. The cardiovascular effects are tachycardia caused by the overstimulation of the sympathetic system, bradyarrhythmias, atrioventricular block, hypotension and QT prolongation, VF, and TdP (Grmec et al., 2004).

OP intoxication manifests itself in three phases. First, nicotinic phase hypertension and sinus tachycardia occur. Second, sinus bradycardia and parasympathetic overstimulation and ST-segment changes on the ECG and rhythm disturbances occur. During the last phase, TdP and sudden cardiac death occur. According to Ludomirsky et al. (1982), a QTc (QT corrected for heart rate) of 580 ms signals high probability of sudden cardiac death. Roth et al. (1993) provided further insight from actual cases.

A breakdown of actual cardiac symptoms for OP poisoning in hospital admissions is given by Karki et al. (2004). Sixty-seven percent of the acute OP cases had QT prolongation, 24% experienced ST-segment elevation, and 17% had inverted T-waves. Nine percent had atrial tachycardia, 9% had ventricular tachycardia, and 4% had VF. Sinus tachycardia was observed in 35% of admissions, whereas sinus bradycardia was noted in 28%. Noting that acidosis and electrolyte derangement play a major role in the development of cardiac events, they recommend "atropine in adequate doses very early in the course of the illness" as the strategy to be implemented. Table 37.3 summarizes the effect of OP on the electrophysiology of cardiac tissue.

OPs are known to induce time-delayed neurotoxicity. This is due to the inhibition of an esterase in nerve tissue, neuropathy target esterase (NTE), that is also found in muscle and blood cells. The NTE level in the blood is an indicator of the inhibition of the enzyme. Inhibition of NTE, aging, and the process of following the OP binding to an active esterase site that prevents the reactivation of the site are important for selection of an antidote against certain OP nerve agents. It is of primary concern for the Novichok agent. There is little information available regarding its neurotoxicity and cardiac toxicity caused by OP.

VX

The most toxic nerve agent available in the West is VX. It is an inhibitor of AChE, which acts by increasing the ACh at the nerve synapses. Toxicity sets in when more than 50% of the AChE enzyme is inhibited. The $AChE_{50}$ value for VX is taken as 0.023 mg/kg in an oral dose (Sidell, 1974). Activities of RBC-AChE and plasma butyrylcholinesterase (BChE) are other markers of toxicity of OPs. In tests on human volunteers, 1 μg of VX/kg by intravenous infusion showed a decrease in AChE activity of more than 50%, but for these tests no cardiac symptoms were recorded. VX produces intense stimulation of nicotinic ACh receptor ion channels and muscarinic ACh receptors. Although not recorded in human volunteer tests, cardiac effects are known to take place based on animal studies. VX exposure produces positive inotropic effects. Arrhythmia was noted in rats and dogs (Robineau and Guittin, 1987). In guinea pigs treated with VX, delayed after-depolarization was found (Corbier and Robineau, 1989). The effect of VX is ascribed to inhibition of the rat cardiac Na^+/K^+-ATPase α_1 isoform. At a concentration of 1 μM, the inhibition is 35% (Robineau et al., 1991). Physostigmine, hyoscine, and HI-6 are undergoing investigation as antidotes (Munro et al., 1994; Wetherell et al., 2007).

Tabun (GA)

GA, a unitary chemical munition, inhibits AChE, the enzyme responsible for the breakdown of the neurotransmitter ACh. When inhaled, its toxicity is half that of sarin. It decreases plasma and RBC-AChE activities significantly in the blood. At 20–25% of RBC-AChE baseline, the effect of the nerve agent becomes noticeable. There is no evidence of systemic toxicity other than the cholinesterase activity (Parker et al., 1990; Munro

TABLE 37.3 Effect of OP on the Electrophysiology of Cardiac Tissue

	Lesions				
AChE	**Anoxia**	**Acidosis**	**Modulated Ion Concentration**	**Release of Catecholamines**	**Second Messenger (VIP, Others)**

et al., 1994). GA has not been shown to produce organophosphorus-induced delayed neurotoxicity except at extremely high doses. The cardiac effect of GA conforms to OP-caused arrhythmias and AV block.

Sarin (GB)

Sarin was involved in terrorist attacks in Japan. The increase in sympathetic and parasympathetic tone results in tachycardia, ST-segment modulation (Abraham et al., 2001), and arrhythmia. Inhibition of cholinesterase within the neuroeffector junction also affects nerve impulse transmission by direct action. Direct action on muscarinic or nicotinic ACh receptors (Somani et al., 1992) is observed when the blood level of sarin exceeds the micromolar level. Sarin inhibits RBC-AChE 80–100% and plasma-BChE between 30% and 50% (Grob and Harvey, 1958). It also binds to aliesterase, an enzyme that contributes to ester-link hydrolysis.

Sarin exhibits OP-delayed cardiotoxicity. Allon et al. (2005) suggest epinephrine-induced arrhythmias as a possible cause in cases of sarin intoxication. The hypothesis is supported by Khositseth et al. (2005), who showed that epinephrine changes T-waves in the ECG where AT prolongation already exists.

Soman (GD)

The most widely used nerve agent, soman (GD), exerts a defining effect on cardiovascular function. Myocardial degeneration and necrosis were noted by Britt et al. (2000) in soman-exposed rhesus macaques. Generally, on contact, bradycardia and modulated cardiac output are followed by hypotension and changes in the ECG. Notably, AV conduction modulation, QT extension, T-wave, and ST-segment changes characteristic of myocardial infarction and ACh-induced coronary vasospasm are noted. For the cardiac effects of OP, important references include Sidell (1974), Kiss and Fazekas (1983), and Anastassiades and Ioannides (1984). McKenzie et al. (1996) also showed that in swine a dose of $2 \times LD_{50}$ soman intravenously increased coronary sinus plasma ACh by 314% and decreased coronary blood flow to 55% of control. The evidence indicates OP-caused deaths are due to ACh-caused coronary vasospasms that culminate in MI. This is seen as VF on the ECGs. Recently, the

Food and Drug Administration approved pyridostigmine bromide as a pretreatment for soman poisoning (Newmark, 2007).

Novichok

In literature, little is known about these agents developed in the Soviet Union. They are assessed to be 5-times to 10-times more toxic than VX (Smithson et al., 1995; Ellison, 2008). The toxicity of these binary agents does not rely primarily on the inhibition of AChE, but it is thought that they cause permanent neuropathy. Consequently, conventional nerve agent antidotes may not work. Reactive oximes such as potassium 2,3-butanedione monoximate may be useful in detoxification. No published information is available for cardiac pathologies caused by Novichok agents.

Antidotes for OP Nerve Agents

Enzymatic hydrolysis is a primary route for elimination of nerve agents. Specifically, treatment for OP intoxication includes atropine, a muscarinic receptor antagonist, an anticonvulsant such as diazepam, and a cholinesterase reactivator, an oxime. It has been found that drug-induced inhibition of ACh release and accumulation in the synaptic cleft, such as adenosine receptor antagonist early in the OP intoxication, improve the chances of survival. Some AChE reactivators, such as bispyridinum oximes, HI 6, and HLö 7 with atropine, are quite effective. A large number of other oximes are also undergoing investigation (Balali-Mood and Saber, 2012).

Cyanide

Classified as a blood agent, cyanide is usually deployed as hydrogen cyanide and cyanogen chloride. Considerable literature exists on the effects of cyanide (Suzuki, 1968; Baskin et al., 2009). Cyanide binds irreversibly to its target sites. In the human host, it preferentially accumulates in the hypothalamus and neural tissue. Its concentration in red blood cells is much greater than in plasma. Lethal dose is approximately 1 mg/kg or inhalation of 50 mL of hydrogen cyanide gas.

Toxicity

Cyanide binds to Fe^{3+} in heme-containing proteins. This inhibits the terminal cytochrome complex IV of the electron transport chain. The blocklock of complex IV by cyanide depletes ATP culminating in cell death. Oxygen is unable to reoxidize the reduced cytochrome a3. Thus, cellular respiration is inhibited, as well as ATP production, in essence depriving the cells, tissue, and, ultimately, the whole body of oxygen. Hypoxia evolves into metabolic acidosis and decreased oxygen saturation. The extent of lactic acidosis indicates the severity of the cyanide poisoning. In a collapsed individual, plasma lactate is an indicator of cyanide poisoning. In severe cyanide poisonings, up to 98% of the cyanide in the bloodstream is tightly bound to red blood cells. The ancillary response is myocardial depression and decline in cardiac output. Bradycardia, hypotension, and cardiac arrhythmia then develop into VF and cardiovascular collapse.

In severe cyanide poisoning, autonomic shock due to the release of biogenic amines plays a role. The coronary arterial vasoconstriction, resulting in an increase in central venous pressure, leads to the observed shock-like state that is not attributable to inhibition of cytochrome oxidase. In the liver, CN is metabolized by rhodanese to thiocyanate, which is excreted in the urine.

Hypoxia is one of the signatures of cyanide poisoning. In CN poisoning, as in ischemia, oxidative metabolism is blocked and acidosis is enhanced. Acidosis decreases contractility and metabolism while sparing ATP supplies.

A dose of 0.54 mg of hydrogen cyanide per kg of body weight is fatal (average of 1.4 mg). Data indicate that the heart absorbs the second most amount of cyanide per organ weight. However, in sublethal exposure, cyanide-fed rabbits (Okolie and Osagie, 2000) do not show hemorrhaging in the cardiac tissue that was noted by Suzuki (1968). Cyanide also causes decline in $[K^+]_i$ (i.e., significant hypokalemia) and an increase in $[Na^+]_i$. These changes were not reflected in the skeletal muscle. Cyanide caused decline in ATP, the energy source of the cell, to less than 10% of the normal value, which activates the otherwise dormant potassium channel and the outward current I_{KATP}. These changes result in shortening of the AP and decrease in the contraction.

Cyanide also causes endogenous catecholamine release (Schomig et al., 1995; Inoue et al., 1998). Inoue et al. (1998) also point out that cyanide-produced depolarization increases intracellular calcium due to the suppression of the potassium channels and activation of the voltage-dependent calcium channel. Anoxia induces suppression of the sodium pump and activates cation channels due to the decrease in ATP. A further consequence of the presence of cyanide in the tissue is inhibition of the Na^+/Ca^{2+} exchanger (NCX) (Ju and Allen, 2005). NCX is important for the pacemaker currents. Metabolic inhibition of NCX reduces the firing rate of pacemaker cells.

Cyanide poisoning is marked by metabolic acidosis and a large anion gap. The latter is a consequence of the blocked oxidative phosphorylation and the increased rate of glycolysis. Maduh et al. (1990) showed that cyanide also affects H^+ and, thus, the pH of the tissues. In turn, the Ca^{2+} transport process is disrupted, leading to an increase in cystolic $[Ca^{2+}]$. Acidification depolarizes the cell membrane and changes the potassium conductance.

Cyanide also exerts a strong influence on the vagus nerve, and thus on the VIP that under normal conditions exerts a strong inotropic and chronotropic effect.

TABLE 37.4 Effect of CN on the Electrophysiology of Cardiac Tissue

P	QRS	ST	T	Remarks	Reference
Disappearance (auricular arrest)	Change in amplitude, right axis deviation	Shortening, disappear	Incr. amplitude, origin of T-waves on QRS	0.11–0.20 mg/kg NaCN, inhalation, AV dissociation, HR↓, BBB, initial bradycardia, AV block, asystole	Wexler et al. (1947) (man)
	Lengthened	Absent or depressed, elevated after 20 s	Increased, decreased over time, T starts on top of R, diphasic, negative	0.4–0.8 mg/kg NaCNHR↓, bradycardia, Wenckebach, heart block, V-flutter, VF	Leimdorfer (1950) (cats)
		Short, shifted toward T-wave	Tall T, surpassing R, sometimes inverted	0.1 mg/kg NaCN, bradycardia, incomplete AV blockade, VF	Paulet (1955) (dog)
	Abnormal	Elevated, shortened	T-wave beginning high on QRS	0.3–0.6 sodium nitrite as antidote with sodium thiosulfate, atrial fibrillation	De Busk and Seidl (1969) (man)
	Narrow QRS	Nonspecific ST-T changes in anterior chest leads, shortened ST-segment	Fusion of T-wave into QRS, sharp rise of T-wave	Sinus tachycardia, acidosis with high anion gap	Chin and Calderon (2000) (man)
	Q-wave present in lead III, persisted after treatment of acidosis	Deviation of 4 mm in leads II, III, aVF, 2 mm in V_6, ST depression of 2–4 mm in V_1–V_4, *I*, aVL leads, normalization of ST-segment in precordial leads	T-wave inversion in II, III, aVF, V_5 and V_6 leads	Acidosis, CN level of 3 μg/mL, anion gap present	Sanchez et al. (2001) (man)

↑, increase; ↓, decrease.

VIP stimulates adenylyl cyclase activity. In ventricular myocytes, VIP potentiates voltage-gated Ca^{2+} channel currents and also acts on pacemaker currents.

As shown by Goldhaber et al. (1991), contractile failure (i.e., twitch shortening) is caused by cyanide. It is said to be due to failure of activation of the Ca^{2+} current. Electrocardiographic manifestations of CN poisoning have been shown by Wexler et al. (1947) and Katzman and Penney (1993), described by Zoltani et al. (2004), and are summarized in Table 37.4.

The ECG of an individual (Wexler et al., 1947) executed by inhalation of cyanic acid revealed that initially, between the first and third minutes, slowing of the heart rate was discernible with the disappearance of the P-wave. Later, the heart rate increased slightly. T-waves showed an increase in amplitude and a marked shortening of the ST-segment. One subject, unlike some others in this cohort, showed normal AV conduction until ventricular tachycardia and VF developed.

Antidotes for CN Poisoning

Bhattacharya et al. (1995) and Cummings (2004) described the following approaches:

1. Use of a nitrite (oxidizing agent such as sodium nitrite) to change the ferrous ion of hemoglobin to a ferric ion. The created methemoglobin binds cyanide, forming cyanmethemoglobin. One drawback, however, is that impairment of oxygen transport occurs (i.e., the amount of hemoglobin available is reduced). Amyl nitrite to generate methemoglobin is no longer preferred because it does not bind enough cyanide.
2. Sulfur donors for conversion of cyanide to thiocyanate by rhodanese or other sulfur transferases that are a source of sulfur. For moderate poisoning, sodium thiosulfate is the usual choice.
3. Use of cobalt chemistry that chelates the cyanide directly, such as hydroxycobalamin.
4. Hydroxocobalamins, precursors to vitamin B_{12}, are preferred in France and elsewhere in Europe. Hydroxocobalamin binds cyanide to form cyanocobalamin. It does not interfere with tissue oxygenation, but large doses are required to be effective.
5. In the United Kingdom, dicobalt edentate, which chelates the cyanide directly, is preferred, but assurance that cyanide poisoning is present is needed because this antidote contains cobalt, which can be toxic.

OTHER TERROR AGENTS

Arsenic

Arsine blood agents were first developed for battlefield use during World War I. Due to difficulties with dispersion, they were never used. Arsenic, however, has potential use as a terror agent (Sidell et al., 1997; Ellison, 2008).

Arsine is the simplest compound of arsenic. It is colorless and 2.5-times denser than air, with an odor resembling garlic. Arsine binds to hemoglobin of the red blood cells, destroying them. Poisoning kills by allosteric inhibition of metabolic enzymes. Arsenic disrupts ATP production. Arsenic inhibits pyruvate dehydrogenese, uncoupling oxidation phosphorylation. Arsenic poisoning also occurs through arsenic–oxygen compounds, especially arsenic trioxide, As_2O_3 (ATO), which is 500-times more toxic than pure arsenic.

ATO has been effectively used as a remedy for relapsed acute promyeloctic leukemia, but with the side effect that it causes QT interval prolongation, possibly heralding ventricular arrhythmia (Chiang et al., 2002). Abnormalities in $I_{Ca(L)}$ in myocytes were also noted (Sun et al., 2006). The direct effect of ATO on cardiac repolarization with its effect on I_{Kr} was noted by Haverkamp et al. (2000). ATO also causes cellular Ca^{2+} overload and augments action potential duration (Yamazaki et al., 2006). Chronic arsenic exposure leads to QT prolongation blockage of I_{Kr}, TdP, and T-U alternans, and to changes in the T-wave result (Little et al., 1990; Ficker et al., 2004).

It has been suggested that potassium ion channel alteration induced by arsenic may be related to hERG trafficking defects. ECG changes in arsenic poisonings have been reported by Fennel (1981). The T-waves are domed. ECG changes, especially when arsenic involvement is not severe, are reversible. Hemodialysis and BAL (dimercaprol) therapy (to remove excess lead) has been found to be effective. Sun et al. (2006) in a recent publication suggested that choline can normalize QT interval abnormality by inhibiting $[Ca^{2+}]_i$ and $I_{Ca(L)}$ in ventricular myocytes when ATO is present. Arsenic intoxication results in widened QRS by 0.06 s and prolonged QT (Ahmad et al., 2006). Ventricular tachycardia and VF have been reported by St Petery et al. (1970).

Ricin

Ricin, a toxic glycoprotein derived from the castor bean, causes hypotension and myocardial hemorrhage. The Center for Disease Control and Prevention (CDC) lists it as a category B agent because of its easy availability as a terrorist weapon. Only a limited amount of information is available in the open literature on the effect of ricin on the heart. The medical files of Georgi Markov, the Bulgarian journalist assassinated in London with what was assumed to be ricin, are not publicly available (Crompton, 1980).

Ricin is a glycoprotein comprising two chains linked by a disulfide bond. Its toxicity results from one of the chains inhibiting protein synthesis by irreversibly inactivating eukaryotic ribosomes. The lethal dose of ricin has been set at 1–20 mg/kg of body weight (Bradberry et al., 2003). Christiansen et al. (1994) performed extensive experiments on rabbits. Their main findings include the following:

1. Ricin caused vasodilatation and increased endothelial-dependent vascular relaxation, resulting in hypotension.
2. Ricin disturbed calcium homeostasis, leading to cell necrosis.
3. Ricin reduced both systolic and diastolic left ventricular function.
4. Ricin caused myocardial hemorrhage.

Balint (1974) and, later, Zhang et al. (1994) found that at the lethal dose in rabbits, ricin caused hemorrhage and necrosis. Christiansen et al. (1994) found that the release of norepinephrine from sympathetic nerves in the vasculature is not impaired by ricin. The CDC cite cardiovascular collapse (hypovolemic shock) with signs and symptoms of ricin poisoning that may be encountered.

ECG abnormalities in children who ingested castor beans have been noted by Kaszas and Papp (1960). These include QT interval lengthening, repolarization changes, and intraventricular conduction disturbances. Crompton (1980) later reported on experiments in pigs that experienced hemorrhagic lesions and an abnormal ECG due to ricin. Genes of ricin toxicity have been identified, suggesting therapeutic targets (Moreau et al., 2011). At the present time, no antidotes or effective therapy are available to counteract the effects of ricin.

THERAPEUTICS UNDERGOING DEVELOPMENT

Chemical warfare agents almost instantaneously affect the cardiac system. miRNA signatures give rapid and conclusive evidence of the affected site and degree of involvement. Predominantly, although not exclusively, the injury turns off genes expressed through miRNAs. Thus modulating genetic response to overcome dysregulation of miRNAs therapy aims to normalize miRNA expression, silence those that are overexpressed, and replace those that are downregulated.

The heart expresses a large number of miRNAs (Wang, 2011) that have been correlated with the genes that affect the heart's varied functions, including the

TABLE 37.5 Warfare Agent Induced Cardiac Pathologies

Cardiac Syndrome	Physical Symptom	Dysregulated miRNA	Cellular Expression	Reference
Heart failure	Inability of heart to pump sufficient blood	miR-423-5p miR-18b-3p miR-129-5p miR-1254 miR-675 miR-622	Siderophages generated	Sahu (2013); Mittmann et al. (1998)
Ischemia	Restricted blood flow to tissues	miR-1 miR-133a miR-208a miR-499	ATP level drop, surge in reactive oxygen, level necrosis, intracellular Na^+ up, pH decline	Gidlof et al. (2013); Vickers et al. (2014)
Modulated ion flow	ECG changes, arrhythmia	miR-1 miR-133	Membrane excitability, conduction changes, modulated repolarization	Grant (2009)
Vascular	Inflammation, vasodilation, hemorrhage	mir-126 miR-17 miR-146a	Endothelial cells promote vascular homeostasis, release factors including NO	Yamakuchi (2012)

electrophysiology. Many miRNAs have a large number of target genes. The change in the value of the particular miRNA from normal reflects not only the injured organ but also the degree of injury. Thus, for example, changes in the ECG can be related to particular miRNAs.

A common sign of cardiac injury is upregulation of miRNAs. An effective counter-measure is inhibition of the affected miRNAs. AMOs (anti-miRNA oligonucleotides), single-stranded 2′-*O* methyl–modified oligonucleotides fragments that are antisense to its target miRNA, have been used. The methyl group improves the binding to RNA. AMO acts by base-pairing producing loss-of-function of the miRNAs. Multi-target AMO (MT-AMO) enables a single AMO fragment to have the capability of targeting multiple miRNAs. miRNA sponges are similar but contain multiple binding sites for an miRNA seed family.

miRNA inhibitors bind to complementary mRNA sequences that result in post-transcriptional gene silencing. Engineered oligonucleotides, antogomirs, and miR erasers and sponges are currently preferred. Anti-miRNAs contain the reverse sequence of a mature miRNA that is able to reduce the endogenous levels of the miRNA. In addition, it must be cell-permeable, stable, and have high probability to be able to bind to the selected miRNA.

miRNAs play a role in cancer pathogenesis. miRNAs that function as tumor suppressors may be downregulated by disease whereas oncogenes are upregulated. mRNA targets of these miRNAs have been identified. This suggests that genes involved with atrial and VF can also be modulated. In fact, miR-1 changes in the myocardium of normal hearts have induced arrhythmias. In view of quantifiable association of miRNA and gene expression, cardiac injury caused by warfare agents may be amenable to therapies based on miRNAs.

Heart failure, ischemia, and vascular inflammation have specific associated miRNAs (Table 37.5). A pathological condition caused by an injury may reflect several conditions; thus, the miRNA expression profile may not be unique.

Ischemia upregulates several miRNAs, including the miR-15 family. As shown by Hullinger et al. (2012), oligonucleotides can effectively suppress expression of miR-15 and reduce infarct size and remodeling after ischemic injury.

Tissue-specific regulation of miRNAs has been achieved by adeno-associated viruses enabling continuous replacement. It has also been successfully used in gene therapy to overcome tumor genesis. Considerable details regarding miRNA therapy are provided by van Rooij (2011) and Thum (2011).

In replacement therapy, to restore loss of function caused by a warfare agent, miRNA mimics can be used to reintroduce miRNAs into affected cells that also reactivate pathways and target silenced genes. Lipoproteins would be the preferred means to introduce the encapsulated miRNA to achieve these ends.

For resolution of cardiotoxicity caused by warfare agents, miRNA approaches with specificity and timeliness offer myriad opportunities.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Per organ weight, the heart is the second most preferred depository for several of the warfare agents used.

Disturbance of the electrical homeostasis, the cellular energy production, and breakdown of the electrical control network within the tissue are mostly affected.

Areas that need further insight include the following:

- Chemical warfare agents cause miRNA concentration changes in body fluids. Tissue specificity and time of appearance of the changes after exposure need to be correlated with conventional biomarkers and electrophysiological markers, such as ECG changes.
- Means of reactivation, such as overcoming "aging" caused by OP-based agents.
- Nanoparticles that carry medicines show promising results. Their use as counteracting agents for xenobiotic poisoning needs to be examined.
- Does neuropathy target esterase (NTE) contribute to cardiac toxicity?

Human data for various cardiotoxic scenarios are unavailable. The means of prompt identification of the particular xenobiotic causing poisoning remains an urgent task. Progress in metabolomics and the identification biomarkers that result from metabolic changes caused by the presence of xenobiotics will enable the development of chip-based rapid-responding assaying devices.

Currently, PubMed does not give any hits for miRNA associated with warfare agents, including soman, tabun, or VX. Hopefully, this chapter will be an incentive to follow-up the approach outlined here, which has tremendous potential for the understanding and treatment of cardiac toxicity.

CHAPTER

38

Ocular Toxicity of Chemical Warfare Agents

Patrick M. McNutt and Tracey L. Hamilton

INTRODUCTION

The eye is highly sensitive to injury by a wide array of chemical warfare agents (CWAs). The most significant ocular injuries are caused by the vesicants, which can produce injuries ranging from conjunctival irritation and lacrimation at very low doses to corneal ulceration and loss of vision at high doses, with a permanent progressive corneal degeneration occurring in a small percentage of victims. Even CWAs that manifest with short-term and reversible ocular symptoms can result in incapacitation. In some cases, ocular symptoms may be a prodromic marker of exposure and indicative of future pathophysiologies. Thus, understanding the toxicological mechanisms underlying the ocular responses to a CWA is critical to evaluating their impact on the visual apparatus as well as to developing therapeutic strategies.

Traditionally, CWAs are divided into seven general categories based on their toxicological properties: vesicants, biological toxins, blood agents, tear agents, nerve agents, incapacitating agents, and choking agents (Table 38.1; Romano et al., 2008). In reviewing the toxicopathogenic processes by which these agents elicit ocular symptoms, it became apparent that they can alternatively be grouped into three categories based instead on the specific mechanisms of ocular toxicity: (i) those that cause acute ocular irritation via non-specific, cytotoxic mechanisms; (ii) those that cause ocular irritation via non-specific noncytotoxic mechanisms; and (iii) those that specifically target and disrupt neuro-ophthalmic behaviors (Table 38.2). It is proposed that this novel grouping may prove useful in considering the toxidromic progression (and treatments thereof) associated with each group of agents. For example, ocular exposure to the group 1 cytotoxic agents involves a common set of symptoms, including a pro-inflammatory response, chemosis, corneal lesions, corneal edema, limbal dysfunction, and the possibility of corneal ulceration at very high doses. Independent of the mechanism of toxicity, the clinical management of these injuries is essentially the same. In contrast, the group 3 neuro-ophthalmic modulators manifest by modulating either the activities of innervating ocular neurons or the ability of effector tissues to respond to neuronal signals. This modulation

TABLE 38.1 Representative CWAs of Each Major Category, Including Biotoxins and Incapacitating Agents

Vesicants		**Blood Agents**	
Mustard gas	HD	Hydrogen cyanide	AC
Nitrogen mustard	HN	Cyanogen chloride	CK
Lewisite	L	**Tear Agents**	
Phosgene oxime	CX	Mace	CN
Nerve Agents		CS gas	CS
Tabun	GA	CR gas	CR
Sarin	GB	OC gas	OC
Soman	GD	**Psychomimetic Incapacitating Agents**	
Cyclosarin	GF	3-Quinuclidinyl BZ	BZ
VX	VX	**Biological Toxins**	
VR	VR	Botulinum Toxin A	X
Choking Agents		Ricin toxin	W
Phosgene	CG	Staphyloccocal Enterotoxin B	UC
Diphosgene	DP	Saxitoxin	TZ
Chlorpicrin	PS	Tetrodotoxin	PP

TABLE 38.2 Agents Grouped by Nature of Ocular Manifestations. Italicized Items Represent Entire Agent Categories.

Ocular irritants, cytotoxic
Vesicants
Blood agents, aerosol delivery
Choking agents
Ricin
staphylococcal enterotoxin B
Ocular irritants, noncytotoxic
Tear agents
Ocular neuromodulation
Nerve agents
Tetrodotoxin
Saxitoxin
Botulinum
Blood agents, systemic
BZ

can be specific to particular neuronal subtypes, such as with cholinergic agonists or antagonists, or can be nonspecific, such as with blood agents. Nearly all of the CWAs discussed in this chapter can be distributed into one of these three groups based on their principal mode of toxicity. The blood agents are an interesting exception. Not only can the blood agents elicit neuro-ophthalmic responses to systemic exposure, but they can also be absorbed into the eye to produce a nonspecific ocular cytotoxicity. Thus, when the blood agent injury is caused by systemic distribution, they are primarily considered to be neuro-ophthalmic modulators, but when the exposure is due to ocular absorption, they are considered to be primarily cytotoxic ocular irritants.

Each of the agents listed in Table 38.1 manifests with some degree of ocular injury. Overall, however, the vesicants pose the most significant threat to the integrity and function of the eye. Vesicants are a class of highly reactive alkylating compounds that catastrophically disrupt cellular functions by forming covalent adducts with proteins, ribonucleic acid (RNA), and deoxyribonucleic acid (DNA). In contrast, the organophosphorus-like nerve agents (OPNAs) block acetylcholinesterase (AChE) activity, causing the synaptic accumulation of acetylcholine (ACh) and the overstimulation of cholinoreceptive neurons. The resulting cholinergic toxidrome potentiates sympathetic signaling, resulting in distinctive but reversible changes in the pupillary apparatus, the lens, and possibly the retina. Incapacitating agents such as 3-quinuclidinyl benzilate (BZ) elicits an anticholinergic toxidrome, producing effects that are the inverse of the OPNAs, including mydriasis and paresis of accommodation. Blood agents interfere with oxygen delivery and oxygen utilization, causing acute cytotoxicity due to progressive tissue hypoxia and necrosis. The tear agents are nonlethal, lacrimating agents that rapidly irritate mucosal membranes, peripheral ocular nerves, or both, causing significant acute discomfort that is typically transient and reversible. The conjunctiva is particularly susceptible to blood agents and tear agents because of its exposed location and extensive innervation. Finally ocular toxicities caused by exposure to three representative categories of exceedingly potent biotoxins will also be discussed: botulinum neurotoxins (BoNTs), a family of potent exotoxins produced by the *Clostridium* family of bacteria; ricin, a poison extracted from the castor bean; and *Streptococcus* enterotoxin B (SEB), a bacterial superantigen.

The list of CWAs, CWA derivatives, and potential CWAs with ocular toxicity is lengthy. In order to refine this discussion, representative CWAs were chosen from (i) traditional chemical and biotoxin threat agents identified by the US Department of Defense (DOD) and the Centers for Disease Control and Prevention (CDC); (ii) Schedule 1A–3A substances, as described in the 1993 United Nations Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and on their Destruction, also known as the 1993 Chemical Weapons Convention (CWC); and (iii) representative chemicals of toxidromic families. This chapter will not address agents that are no longer considered operationally relevant, such as chlorine or agents that are currently considered classified by the US government.

BACKGROUND

The Structure of the Eye

Understanding the effects of CWAs on vision requires a basic awareness of ocular structure, including tissue-specific aspects of injury response and regenerative capacities. Rather than providing a comprehensive description of the eye, this chapter will briefly address ocular structures that are specifically involved in the clinical manifestation of CWA toxicity. The eye can be considered to be constructed of three layers (or tunics), which provide the biochemical and structural foundations for the refraction and detection of light. Each layer plays a key role in enabling the entry and processing of light that enables appropriate visual perception. These layers are separated by fluid-filled chambers, which provide nourishment as well as structural support (Figure 38.1).

The outer layer of the eye includes the sclera, conjunctiva, cornea, and corneal limbus. As a result of their exposed locations, these tissues are primary targets for CWAs. The white, opaque sclera is a tough fibrous connective tissue layer containing interlacing type I collagen bundles and elastic fibers that gives the eye its shape. The anterior surface of the sclera is covered by the conjunctiva,

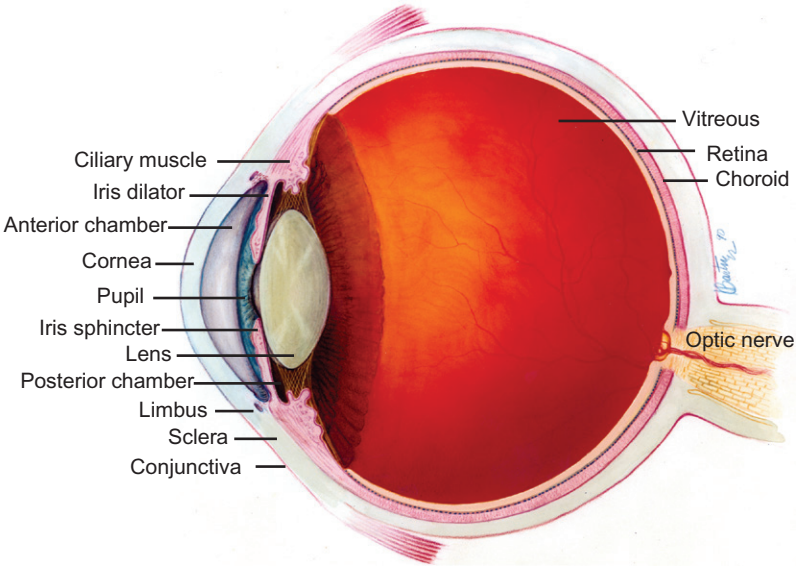

FIGURE 38.1 Anatomy of the eye. Diagram of the human eye, labeled with the structures involved in ocular toxicity following exposure to CWAs. *Source: Image modified with permission from National Eye Institute, National Institutes of Health, reference number NEA04.*

a layer of stratified columnar epithelial cells that produce mucus to help lubricate the eye. The conjunctiva is richly supplied with blood vessels and is highly susceptible to inflammation. At the front of the eye is a transparent, avascular, highly innervated tissue called the *cornea.* The cornea is responsible for protecting the eye against insults such as injury and infection. It also provides roughly two-thirds of the total refractive power of the eye and is therefore the major refracting lens (Meek et al., 2003). The corneal limbus is located at the junction between the conjunctiva and cornea and plays an essential role in sustaining and repairing the corneal epithelium. Limbal cytotoxicity, therefore, has severe consequences to corneal function, as discussed in the next section.

Between the cornea and the uveal tissues is the anterior chamber, which contains a watery fluid called the aqueous humor (AH). The anterior chamber exerts positive pressure against the corneal endothelium to help shape the cornea (a.k.a., intraocular pressure), and together the cornea and the AH form an outer lens that plays the most significant role in refracting light towards the center of the eye. The AH also provides nourishment for the tissues lining the anterior chamber, and consequently it is rich in metabolites (Goel et al., 2010). The AH is continuously secreted by the ciliary epithelium, flowing from the posterior chamber, through the iris into the anterior chamber and exiting the eye primarily via the trabecular meshwork, where it is absorbed into the bloodstream. Humans produce AH at approximately 3 μL/min, with the entire volume being replaced every 90 min (Goel et al., 2010). Consequently, CWAs that penetrate through the cornea to the anterior chamber may result in intracameral biomarkers that can subsequently be detected within the plasma or even result in systemic toxicity (Romano et al., 2008; McNutt et al., 2012a,b). AH production and drainage are critical to normal ocular function, and functional disruption results in long-term consequences to corneal integrity and vision.

The middle layer of tissues includes the choroid, iris, lens pupillary apparatus and ciliary body. General inflammation of these tissues is called *uveitis* or *iritis.* The choroid is the inner vascular layer of the eye, underlying the sclera and providing oxygen and nutrients to the retina. Like the conjunctiva, the choroid is prone to inflammation. However, due to its deep intraocular location, it is isolated from exposure to most CWAs. The iris is a contractile diaphragm that controls the size of the pupillary aperture, and therefore the amount of light that enters the eye. Pupil size is controlled by two iris muscles: the pupillary sphincter, which is responsible for constriction of the pupil, and the pupillary dilator, which is responsible for dilation of the pupil. These muscles are innervated by sympathetic and parasympathetic nerves that control constriction and dilation, respectively. Behind the iris is the posterior chamber, a narrow space delineated by the iris, lens, and ciliary structures through which AH flows. The lens is a crystalline structure that focuses light on the retina. The ciliary muscle controls focus (accommodation) by changing the shape of the lens under the control of the autonomic nervous system. Since changes in pupil size and accommodation are principal ocular symptoms associated with exposure to many CWAs, the function of the neuro-ophthalmic tissues will be described in greater detail in the section below.

The majority of the volume of the eye consists of the vitreous chamber, which is filled with the vitreous humor, a transparent, gelatinous mass of extracellular matrix material similar to the corneal stroma which is expressed during development. The vitreous humor holds the neural layer of the eye—the retina—in position. The retina is comprised of 10 layers of nervous tissue made up of millions of hierarchically organized light receptors that are connected to the brain by the optic nerve. The neural layer is not believed to exhibit specific responses to most agents, except in the cases where systemic distribution of neurotoxic CWAs may have a pathophysiological effect on retinal function and information processing.

Finally, there is the ocular adnexa (not shown), which are tissues that provide a supportive environment to the globe, such as the lacrimal glands, which are located underneath the outer portion of the upper eyelid, the eyelids, and the extraocular muscles. The lacrimal glands produce tears that help lubricate and moisten the eye, as well as flush away any foreign matter that may enter the eye. The extraocular muscles control convergence, allowing the eyes to synchronize and provide binocular vision.

Neuromodulation of Ocular Tissues

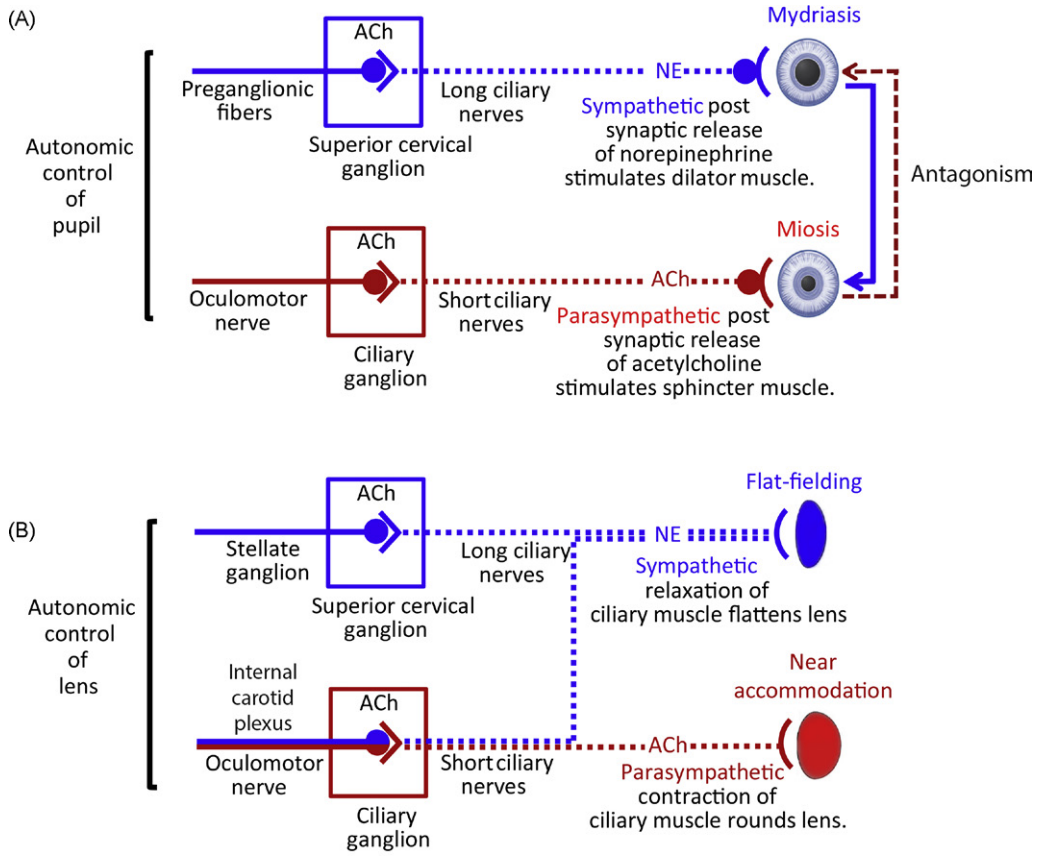
A number of CWAs exert their effects by modulating neuronal control over ocular function (Table 38.2). Autonomic neurons provide input to the intrinsic ocular muscles (the sphincter pupillae, the dilator pupillae, and the ciliary muscle) and the lacrimal glands. Neuronal afferents in the eye include sensory neurons from the conjunctiva and cornea, reflexive contributions to the iris, ciliary muscle, and eyelids, and the densely innervated retina. Finally, the extraocular muscles and eyelids are controlled by cholinergic motor neuron inputs.

Under normal conditions, pupil size and focal accommodation result from a balance between sympathetic (adrenergic) and parasympathetic (cholinergic) nerve inputs (Figure 38.2) (Levin and Kaufman, 2011). Autonomic control over pupil dilation is mediated by sympathetic postganglionic neurons originating from the superior cervical ganglion and synapsing with the iris dilator muscle. Stimulation of the sympathetic pathway results in the release of norepinephrine onto α-adrenergic receptors on the sphincter dilator, dilating the pupil and increasing the activation of light receptors in the retina. The short ciliary parasympathetic nerves project from the ciliary ganglion to form cholinergic synapses with the iris sphincter. Stimulation of the parasympathetic pathway results in pupillary constriction (miosis), reducing light input and causing tunnel vision. The dilator and sphincter muscles are also antagonistic, such that inhibiting one pathway is sufficient to allow the other pathway to become dominant. The system is further complicated by the differential expression of stimulatory and inhibitory receptors in the uveal muscle tissues, presumably coordinating the complex interplay of sympathetic and parasympathetic signaling (Whikehart, 2003).

Control over lens accommodation by the ciliary muscle is coordinated with pupil size and binocular convergence to optimize focus. The ciliary muscle receives both parasympathetic and sympathetic inputs from the ciliary ganglion via the short ciliary nerves. Postganglionic sympathetic signals result in the release of norepinephrine onto the ciliary muscle, activating β-adrenergic receptors and relaxing the muscle, which in turn optimizes refractive power for far vision. In contrast, parasympathetic activation activates muscarinic receptors, causing ciliary muscle contraction and rendering the lens more spherical for near-focus.

Structure and Regenerative Capacity of the Corneal Tissues

The degree of CWA absorption, penetration, and reactivity with conjunctival or corneal tissues is a major component of ocular toxicity. Irreversible ocular injuries are caused by those agents that disrupt the integrity of the cornea, causing deep keratitis, stromal scarring, endothelial toxicity and possible corneal perforation. Corneal function is critically dependent on the ability of the corneal epithelium and corneal endothelium to maintain stromal deturgescence by controlling fluid ingress at the anterior and posterior margins of the cornea, respectively. Disruption of either barrier results in



(C) Representative effects of neuro-ophthalmic agents on autonomic nervous system balance

- Organophosphorus nerve agents potential cholinergic signaling, shifting the balance towards Parasympathetic dominance.
- BZ block cholinergic signaling, shifting the balance towards Sympathetic dominance.
- Low-doses of systemic botulinum block cholinergic release, shifting the balance towards Sympathetic dominance.
- High-doses of systemic botulinum block cholinergic and adrenergic release, producing tonic and poorly responsive pupils that are not dominated by either autonomic pathway.

FIGURE 38.3 **Autonomic nervous system inputs to the pupil and the lens.** Diagram depicting the balance between sympathetic and parasympathetic signaling to the pupil (A) and lens (B), and summarizing how agents causing neuro-ophthalmic toxicity can alter this balance (C).

corneal edema, increased production of pro-inflammatory mediators, and entry of matrix-active enzymes into the stroma. Persistent corneal edema may then progress to corneal degeneration, with severe effects on vision that can require corneal transplants (Eagle et al., 1989; Alomar et al., 2011). Given the susceptibility of the cornea to chemical and mechanical injury, the preservation of vision depends on the regenerative capacity of the cornea.

The cornea is composed of five histologically distinct layers with different regenerative capacity: corneal epithelium, Bowman's or Bowman's-like layer, stroma, Descemet's membrane (DM), and corneal endothelium (Figure 38.3). The corneal epithelium is a stratified epithelium with 5–7 cell layers that provides a dynamic physical barrier between the external environment and intraocular space. Tight junctions among the different layers of corneal epithelial cells form a highly impermeable barrier to tear film and microorganisms (Klyce, 1972). The basal epithelial cells have several important functions, including the secretion of matrix factors, establishment of hemidesmosomal attachments to focal adhesion complexes in the anterior stroma, and proliferation to generate new epithelial cells. Anterior to the basal epithelial cells are the wing-like suprabasal cells. Over time, the suprabasal cells move superficially and terminally differentiate into the outer layers of squamous epithelial cells. These cells are shed from the ocular surface during normal wear and tear and are replaced by the steady superficial migration from underlying epithelium. Thus,

homeostasis of the corneal epithelium is critically dependent on mitotic renewal.

Regeneration of the corneal epithelium primarily relies on a small population of limbal epithelial stem cells (LESCs) located in the basal region of the limbus. Although LESCs slowly cycle during homeostasis, they can become highly proliferative in response to corneal injury, undergoing asymmetric division to produce daughter transit amplifying cells (TACs) that migrate into the basal layer of the corneal epithelium and undergo limited proliferation to replace corneal epithelial cells lost during normal exfoliation or due to injury (Ordonez and Di Girolamo, 2012). The limbal niche is highly vascularized, and factors that regulate niche function are delivered via multiple sources, including systemic circulation, tear film, AH, support cells in the LESC niche, keratocytes in the stroma, and corneal epithelial cells. Adverse conditions, such as chemical injury or persistent inflammation, can disrupt niche function, leading to a constellation of symptoms known as *limbal stem cell deficiency (LSCD*; Ahmad, 2012; Osei-Bempong et al., 2013). Dysregulation of the LESC niche has severe consequences for the corneal epithelium, which in turn evokes symptoms of corneal failure, such as invasion of goblet cells from the conjunctiva into the cornea, neovascularization, chronic inflammation, recurrent corneal erosions, keratitis, corneal ulceration, and stromal scarring.

Beneath the corneal epithelium is the corneal stroma, which encompasses about 90% of the corneal volume. The stroma is a highly ordered tissue composed of tightly packed collagen fibrils that are structured by keratin sulfate proteoglycans into lamella (Hassell and Birk, 2010). The uniform packing is critical in rendering the stroma transparent to light and is highly dependent on maintenance of the stroma in a deturgescent state by the barrier functions of the corneal endothelium and corneal epithelium. Persistent corneal edema caused by failure of these barriers ultimately results in corneal degeneration, with possible loss of vision (Eagle et al., 1989). Under normal conditions, the stroma is sparsely populated by keratocytes, a quiescent population of mesenchymal cells that secretes transparent corneal material. Keratocytes exhibit variable responses to corneal injury, depending on their proximity to the injury (West-Mays and Dwivedi, 2006; Wilson, 2012). After a penetrating injury to the cornea, nearby keratocytes undergo apoptosis, prompted by the stromal influx of signaling molecules from the tear film or AH. More distant keratocytes undergo a fibroblastic transformation, become active, begin to proliferate, and start synthesizing matrix metalloproteinases that assist in tissue remodeling and scar formation. If the entry of pro-inflammatory mediators into the stroma is reduced by re-establishment of barrier activity, the myofibroblasts disappear and the activated keratocytes continue to slowly repair the stroma.

The corneal endothelium is a monolayer of cells on the DM that regulate corneal nutrition and hydration by balancing a semipermeable barrier activity with active ion transport mechanisms. Since adult human corneal endothelial cells (CECs) do not appear to proliferate *in vivo*, the corneal endothelium has a limited ability to recover from cytotoxic injury (Joyce et al., 1996; Senoo and Joyce, 2000). Under normal conditions, gaps in the CEC monolayer are rapidly filled by the spreading of proximal cells, driven by morphologic changes that compensate for endothelial cell loss. Once the focal CEC density falls below the threshold level required for endothelial function (estimated to be 1,000–2,000 cell/cm^2) (Joyce et al., 1996) the corneal endothelium can no longer keep the stroma in a dehydrated condition, resulting in a persistent corneal edema that, in turn, causes secondary keratopathies such as anterior segment inflammation, epithelial bullae, and LSCD (Eagle et al., 1989; Petroll et al., 1995). Thus, while endothelial function can be restored after a mild injury by CEC spreading, more severe injuries may exceed the repair capacity of the human endothelium.

VESICANTS

Sulfur mustard, nitrogen mustard, and lewisite are considered Schedule 1A substances according to the CWC. These substances are defined as having few legitimate applications, if any. The largest section of this chapter will focus on the vesicant class of CWAs for three reasons. First, the vesicants pose the most significant threat to the eyes, with the development of irreversible, vision-threatening injuries following severe exposures. Second, the clinical, biological, and functional consequences of ocular exposure to vesicants have been extensively researched. Third, the vesicants have a high potency against ocular tissues and ocular injury can occur at doses that produce minimal systemic or cutaneous effects. Given the importance of eyesight in the sensory armature, ocular injury can not only incapacitate victims for days to weeks, but also incurs a significant degree of associated psychological distress.

The Mustard Gases

Sulfur mustard (HD; $C_4H_8Cl_2S$) and nitrogen mustard (HN-1; $C_6H_{13}Cl_2N$) are highly reactive adducting compounds that exert their cytotoxic effects through a combination of genotoxicity, production of reactive oxygen species (ROS), direct interference with protein function, and disruption of metabolism. Although the mustards are well known for their cutaneous blistering effects, the ocular injury is clinically distinct from the cutaneous injury, influenced by a variety of factors unique to

FIGURE 38.4 *Gassed*, by John Singer Sargent. *Source: Reprinted with permission from the John Singer Sargent Gallery.*

the eye, including structure, biochemical composition, and regenerative mechanisms. The tactical implications of HD use on troop morale and combat capability is beautifully captured in the John Singer Sargent painting *Gassed*, based on the artist's firsthand observations of a German mustard gas attack on British troops on August 21, 1918, in which he depicted lines of vesicant-blinded troops moving slowly toward casualty stations (Figure 38.4). Harry L. Gilchrist, the medical director of the Gas Service, US Army Expeditionary Force, described a similar phenomenon following a mustard attack on US soldiers (Gilchrist and Matz, 1933):

> At first the troops didn't notice the gas and were not uncomfortable, but in the course of an hour or so, there was marked inflammation of their eyes. … by the time the gassed cases reached the casualty clearing station, the men were virtually blind and had to be led about, each man holding on to the man in front with an orderly in the lead.

A combination of the physical properties of HD and the clinical consequences of HD exposure made it the most effective CWA during World War I, earning HD the moniker of "king of battlefield gases" (Fitzgerald, 2008; Ganesan et al., 2010). HD was responsible for 77% of all gas injuries in World War I (Hughes, 1942) and large-scale deployment in both World War I and during the Iran–Iraq war (1980–1988) resulted in well over 600,000 casualties, with estimates of 75–90% developing ocular injuries (Papirmeister et al., 1991). HD has also been used in a large number of smaller conflicts between 1917 and 1997, including by Egypt against North Yemen during 1963–1967, Italy against Ethiopia from 1935 to 1940, and the Soviet Union against China in 1934 and again in 1936–1937 (Tuorinsky, 2008).

Toxicokinetics of the Acute Ocular Mustard Injury in Human Victims

Due to the large aqueous–mucous interface between the corneal surface and the tear film and the high metabolic rate of corneal epithelial cells, eyes are roughly tenfold more sensitive to HD injury than skin or pulmonary tissue (Pickard, 1919; Solberg et al., 1997; Safarinejad et al., 2001). Therefore, it is not surprising that approximately 75–90% of HD casualties develop ocular symptoms, with 10% presenting with severe ocular damage (Pickard, 1919; Pechura and Rall, 1993). For example, of 998 victims exposed during the production of sulfur mustard at Edgewood Arsenal from September 1941 to March 1943, 78% developed acute ocular injuries (Uhde, 1946). A similar ratio held true for battlefield casualties during World War I and the Iran–Iraq war (Tuorinsky, 2008).

The spectrum of ocular injury among sulfur mustard victims is primarily determined by exposure time and concentration, with symptoms ranging from mild conjunctivitis to chronic advanced corneal disease (Pechura and Rall, 1993). A remarkable series of experiments involving live human military volunteers has provided rigorous concentration:time (Ct) data for the acute component of ocular mustard injury (Reed et al., 1918; Walker et al., 1928; Guild et al., 1941; Anderson, 1942; Smith and Dunn, 1991). Based on these experiments, exposure to 5–30 $mg\,min/m^3$ is the lowest detectable dose, producing a mild conjunctival injection without corneal involvement that resolves within days. Doses of 60–75 $mg\,min/m^3$ cause conjunctivitis, conjunctival and corneal irritation, and photophobia (Mandel and Gibson, 1917; Mann and Pullinger, 1944; Gates and Moore, 1946; Balali-Mood and Hefazi, 2005). In some cases, ocular injuries are sufficiently severe at 60 $mg\,min/m^3$ to render soldiers combat-ineffective and require medical treatment for 1–2 weeks. Severe intraocular injuries developed at exposures that exceeded 100 $mg\,min/m^3$, characterized by corneal edema, keratitis, ocular pain, blepharospasm, uveitis, neovascularization, and corneal perforation. The resulting corneal epithelial vesication and corneal edema require weeks to months to heal. Doses of 200 $mg\,min/m^3$ cause corneal edema and clouding, eyelid edema, and severe blepharospasm and

TABLE 38.3 Summary of Ocular Manifestations and Healing Times Following Exposure to SM Vapor

Injury Class	Estimated Dose (mg min/m^3)	Characteristic Ocular Manifestations	Symptomatic Recovery
Class I	12–70	Conjunctival injection and ocular irritation, without lacrimation, blepharospasm, or photophobia	1–2 weeks
Class II	100–200	Above symptoms plus mild corneal involvement, such as corneal edema and epithelial vesication. Symptoms appear 6–12 h after exposure, including edema and epithelial erosions.	6–12 weeks
Class III	>200	Corneal swelling, edema and epithelial lesions, with destruction of limbal blood vessels at higher doses. MGK may develop. At very high doses, penetrating corneal ulcers occur.	Months to never

Source: Adapted from Solberg et al. (1997).

require months to heal. At doses exceeding 400 mg min/m^3, severe corneal damage develops that requires months of hospitalization. At these doses, blindness can rapidly develop due to corneal scarring and corneal ulceration. Based on these experiments, the minimum incapacitating vapor dose was estimated to be 60 mg min/m^3 and the median incapacitating dose (ICt_{50}) was estimated to be 100–200 mg min/m^3 (Project Coordination Staff, 1946; Reutter and Wade, 1994). At this dose, 50% of soldiers exposed under battlefield conditions will be incapacitated by the resulting ocular injury. Estimates of battlefield air concentrations of mustard gas during World War I were 19–33 mg/m^3: thus, within 2 min, victims would exceed the minimum incapacitating dose, and a 5 to 10 min exposure would incapacitate 50% of soldiers (Solberg et al., 1997). Note that ocular exposure to liquid HD dramatically increases the risk of corneal ulceration and vision loss and therefore is far more dangerous than vapor-induced injury (Papirmeister et al., 1991).

Approximately 90% of soldiers and workers exposed to sulfur mustard in World War I initially presented with symptoms of conjunctivitis, photophobia, and blepharospasm. The subsequent injury progression was observed to follow one of three clinical trajectories (Classes I–III), which differed based on the nature of the symptoms and the recovery time (Table 38.3) (Hughes, 1945b). Class I injuries occurred in 75% of those with ocular presentation, involving mild symptoms without corneal involvement or significant chemosis that resolved within 1–2 weeks. Based on the Ct data presented here, Class I injuries are caused by doses ranging from 5–60 mg min/m^3. Class II injuries occurred in 15% of the victims, and correspond to a dose of 100–200 mg min/m^3. Class II injuries involve eyelid, conjunctival, and corneal lesions and result in incapacitation lasting 4–6 weeks. Signs of the Class II injury include chemosis, corneal edema, epithelial erosions, severe ocular pain, blepharospasm, and photophobia. Class III injuries occurred in 10% of victims and are caused by exposure to more than 200 mg min/m^3. Class III injuries are characterized by severely affected eyes, with significant corneal involvement. Symptoms include severe ocular pain, reduced vision, blepharospasm, uveitis, edematous eyelids, limbal necrosis, chemosis, corneal erosions, and corneal edema. Class III was further subdivided into Class IIIa and Class IIIb. Class IIIa victims presented with moderate corneal symptoms, with a prognosis of 6 weeks to 3 months before soldiers could return to duty. In contrast, Class IIIb victims exhibited severe corneal changes resulting in disability of more than 3 months, and possibly causing complete loss of vision. Of the 939 ocular casualties caused by accidental exposures in mustard gas production factories in England, 10.4% presented with Class III symptoms, but only 1% developed Class IIIb corneal lesions (Hughes, 1945a).

Evidence for a Delayed Ocular Mustard Injury in Human Victims

Starting in the late 1920s, reports appeared of a late-onset complication in survivors of severe HD ocular injuries, in which ostensibly healed eyes developed a "delayed keratitis" from 8 to 25 years after exposure (Pechura and Rall, 1993). It was initially noted that following recovery from the acute lesion, which took 4–6 months, patients remained largely asymptomatic for a decade or longer. However, approximately 1% of survivors subsequently developed a progressive ulcerative corneal disease that did not heal, characterized by photophobia, lacrimation, recurrent corneal erosions, idiotypic keratitis, decreased corneal sensitivity, and progressive corneal degeneration. As of 1939, approximately 300 victims of the severe form of mustard gas keratopathy (MGK) had been described in the literature (Phillips, 1940). In 1944, it was reported that this keratitis developed intermittently in Class III–injured veterans over a period of 8–17 years after initial exposure, with a sudden increase in incidence from 17 to 25 years (Mann, 1944). Strikingly, of the 84 patients with delayed-onset HD injuries that were involved in that study, 76 believed that they had fully recovered from the acute injury prior to clinical reappearance.

Additional evidence for the late-onset injury accumulated among survivors of the Iran–Iraq war, which represented the first instance of the prolonged deployment of

HD munitions during the modern era, producing 50,000–100,000 military and civilian casualties (Willems, 1989; Khateri et al., 2003). Medical follow-up of this population using modern clinical methods has been illuminating with regard to the scope and progression of the acute and late injuries. In the largest available study, 34,000 survivors of HD injury were screened 13–20 years after exposure (Khateri et al., 2003). While 60.7% of survivors had no ocular symptoms, 35% were classified as having mild symptoms, involving persistent conjunctival irritation; 3.6% as having moderate symptoms, involving corneal opacities, mild corneal edema, and band keratopathy; and 0.7% as having severe symptoms, which included corneal melting and neovascularization. In a separate, nonoverlapping study involving 134 patients examined 17–22 years after exposure, 83% of survivors presented with ocular complications, which included burning (69%), photophobia (64%), blepharitis (28%), tearing (12%), corneal ulceration (12%), and retinal and conjunctival complications (4.5%) (Namazi et al., 2009). In another study specifically evaluating ocular injury in 40 veterans from 16–20 years after a single, high-dose exposure, 39 reported persistent ocular sequelae, including chronic conjunctivitis (17.5%), corneal thinning (15%), limbal ischemia (12.5%), corneal opacity (10%), corneal vascularization (7.5%), and corneal epithelial defects (5%) (Balali-Mood et al., 2005). A total of 6 patients exhibited severe corneal involvement and were diagnosed with the severe form of MGK.

This delayed ocular HD injury is predominantly associated with the Class III survivors with latencies ranging from 1 to 40 years after exposure (Solberg et al., 1997; Balali-Mood and Hefazi, 2005). Onset is typically abrupt, characterized by the appearance of photophobia, tearing, and corneal and limbal lesions. However, the etiology of the late HD injury is still unknown. Corneal tissues removed from MGK victims during surgical interventions or postmortem exhibit signs of chronic inflammation, corneal thinning and ulceration, neovascularization, and corneal degeneration, suggesting a persistent injury that is beyond the healing capacity of the cornea (Richter et al., 2006; Javadi et al., 2007; Kanavi et al., 2010). Without a clear understanding of the etiopathogenesis of chronic HD injury, treatments have been mostly palliative in nature. Surgical interventions such as corneal keratoplasty and limbal stem cell transplants have had mixed outcomes, with successes largely restricted to mild cases of MGK (Richter et al., 2006; Javadi et al., 2007, 2011; Baradaran-Rafii et al., 2013).

Toxicokinetics of the Acute and Late-Onset Ocular Mustard Injuries

The acute symptomatic progression of the ocular HD injury has been well described (Mann and Pullinger, 1944; Tuorinsky, 2008). The duration of the latent period between exposure and the appearance of clinical symptoms is inversely correlated to the severity of exposure (Tuorinsky, 2008). At vapor doses that cause Class I injury, the latent period is 4–12 h. At moderate or high vapor doses that cause Class II or III injuries, the latent period may be as short as 1–3 h. Symptoms typically appear within an hour after exposure to liquid sulfur mustard. Following the latent period, the earliest symptoms of injury are sensations of grit in the eyes, ocular soreness, lacrimation, conjunctival injection, chemosis and corneal injection. In Class II or III injuries, the corneal epithelium sloughs from the basement membrane within 6–12 h, leading to severe pain, photophobia, corneal edema and impaired vision. By 24 h, corneal edema has increased the thickness of the cornea up to 300%, disrupting vision and causing corneal pain. After a week, corneas begin to show clinical improvement with subsiding edema. Class II injuries subsequently develop superficial corneal vascularization, secondary corneal edema, and recurrent corneal symptoms that persist for several weeks before ultimately resolving.

The progression of healing in more severely injured eyes is less straightforward. A review of dose response data and case studies has enabled clinicians to identify three clinical trajectories among Class III–injured eyes: (i) injury resolution similar to Class II, but over a period of months and without the subsequent reoccurrence of corneal symptoms; (ii) a chronic injury that develops immediately after the acute injury and fails to heal; and (iii) delayed-onset lesions that appear 1–40 years after exposure (Duke-Elder, 1972; Papirmeister et al., 1991; Javadi et al., 2005, 2007). The latter two trajectories are collectively referred to as MGK. Although the relationship between the chronic and delayed-onset forms of MGK is unclear, the severe form of each involves an idiotypic, noninfectious keratitis with secondary keratopathies such as persistent epithelial lesions, corneal neovascularization, and progressive corneal degeneration (Khateri et al., 2003; Mousavi et al., 2009). Since both the chronic and delayed-onset forms of MGK result from a severe corneal exposure and share similar symptoms, it may be that a common etiology is involved, despite temporal differences in clinical onset.

The pathogenic mechanisms responsible for MGK are unknown, but the most common clinical sequelae include recurring corneal epithelial lesions, corneal neovascularization, a progressive corneal degeneration and frequent impairment or loss of vision (Solberg et al., 1997; Javadi et al., 2005; Balali-Mood and Hefazi, 2006). In a study restricted to 48 veterans suffering chronic ocular symptoms, 31 (64.6%) developed MGK directly from acute injury (i.e., the chronic form), whereas the delayed-onset form developed in 17 (35.4%), with latencies ranging from 1 to 15 years (Javadi et al., 2005). Limbal

lesions were present in 81% of the MGK eyes, suggesting that development of limbal stem cell disorder is a common sequelae of MGK. Corneal signs included scarring (87.5%), neovascularization (70.8%), thinning (58.3%; resulting in corneal perforation in 4.2% of patients), and recurring epithelial defects (31.3%). In a separate study involving 149 seriously eye-wounded veterans, 90% of casualties with chronic ocular symptoms who were followed for 10–15 years showed no improvement, and in many cases, the injury became progressively worse (Ghasemi et al., 2009). According to these studies and many others, the delayed HD injury is usually progressive and difficult to clinically manage (Safarinejad et al., 2001). Not surprisingly, chemical warfare survivors with ophthalmologic complications suffer from a significantly lower quality of life as a consequence of their chronic injuries (Mousavi et al., 2009).

Mechanistic Studies of HD Toxicity

Animal models have been used to study the pathogenesis of acute and chronic HD ocular injuries for over 70 years (Mann and Pollinger, 1944; Pechura and Rall, 1993; Ruff et al., 2013). One of the most productive models has been an *in vivo* vapor exposure model in rabbits. The rabbit cornea is structurally similar to that of the human, and at functionally equivalent doses, rabbit and human eyes exhibit nearly identical lesions (Mann and Pullinger, 1944; Gates and Moore, 1946). Recently, a rabbit vapor HD exposure model has been shown to produce dose-dependent, multiphasic corneal injuries with sequelae similar to those observed in human victims (Kadar et al., 2001; Milhorn et al., 2010; McNutt et al., 2012a,b).

Using the rabbit vapor exposure model, the progression of structural, biochemical, and molecular changes during acute injury and the transition to MGK have been elucidated. Briefly, exposed corneas develop an acute lesion within 1 day, characterized by vesication of the corneal epithelium, stromal keratocytosis, corneal edema, and CEC loss. The corneal epithelium then undergoes a robust healing response, regenerating an intact, stratified epithelium with rudimentary hemidesmosomal attachments to adhesion plaques in the anterior stroma by 7 days after the exposure. Grossly, corneas appear to be healing from 1 to 2 weeks (the quiescent phase), with few clinical symptoms other than lingering edema. Resolving corneas subsequently undergo a rapid decrease in corneal thickness, reaching baseline levels by 6 weeks; a time frame that is similar to Class II or IIIa injuries in humans (Figure 38.5) (Kadar et al., 2001; McNutt et al., 2012a,b). In contrast, the failure of corneal edema to resolve at 3 weeks and beyond is the earliest clinical marker of MGK onset. Histopathological markers of MGK include recurring basal epithelial cell cytotoxicity, basement membrane zone degeneration, loss of LESCs, inflammatory cell infiltration, elevation of cytokines, persistent endothelial failure, delayed inmigration of keratocytes, stromal degeneration, and redundant deposition of basement membrane components caused by cyclical attempts to regenerate the epithelium (Kadar et al., 2001; McNutt et al., 2012a,b). Secondary pathologies, such as epithelial bullae formation, recurring corneal erosions, neovascularization, and LSCD, subsequently develop, further interfering with stable repair of the ocular surface. Postexposure, steroid-based anti-inflammatory protocols reduce and postpone the appearance of late injury. However, they do not prevent late injury, suggesting that anti-inflammatories fail to treat the central pathology response for MGK onset (Amir et al., 2000; Kadar et al., 2009; Gordon et al., 2010). The distinct pathophysiology of MGK revealed in these studies suggests the involvement of pathophysiologies that operate on different time scales and in different corneal compartments than during the acute injury. However, all studies agree that persistent edema is a primary causative factor underlying MGK onset.

Etiogenesis of the Delayed Ocular HD Injury: Current Theories

Damages to the corneal limbus and the corneal endothelium have emerged as pathophysiologies that may be critically involved in MGK onset, progression, or both. Both pathologies are consistent with clinical observations in human MGK corneas and are spatiotemporally expressed in such a way to contribute to the long-term corneal HD injury (Baradaran-Rafii et al., 2010; Jafarinasab et al., 2010).

In a clinical study of 35 Iranian patients diagnosed with MGK, all MGK eyes were demonstrated to exhibit LSCD (Baradaran-Rafii et al., 2010). Similar symptoms were observed in rabbit eyes expressing MGK symptoms, including goblet cell invasion (an indicator of limbal destruction) and a significant reduction of LESCs (Kadar et al., 2011, 2012). Interestingly, LESC loss did not appear to occur during the acute phase following HD exposure; rather, it developed concurrent with the appearance of MGK symptoms. These data have been interpreted to suggest that dysfunction of the LESC niche is a delayed phenomenon that occurs after the acute injury. A proinflammatory response and nerve damage has been found in the corneal limbus of both rabbits and humans during MGK onset, implicating their involvement in the initiation of the late ocular injury (Javadi et al., 2005; Kanavi et al., 2010; Kadar et al., 2011). Regardless of the causal relationship between LSCD and MGK, LSCD is a clinically important aspect of MGK and the delayed loss of LESCs raises the possibility of a postexposure therapeutic window during which limbotrophic treatments could preserve LESCs.

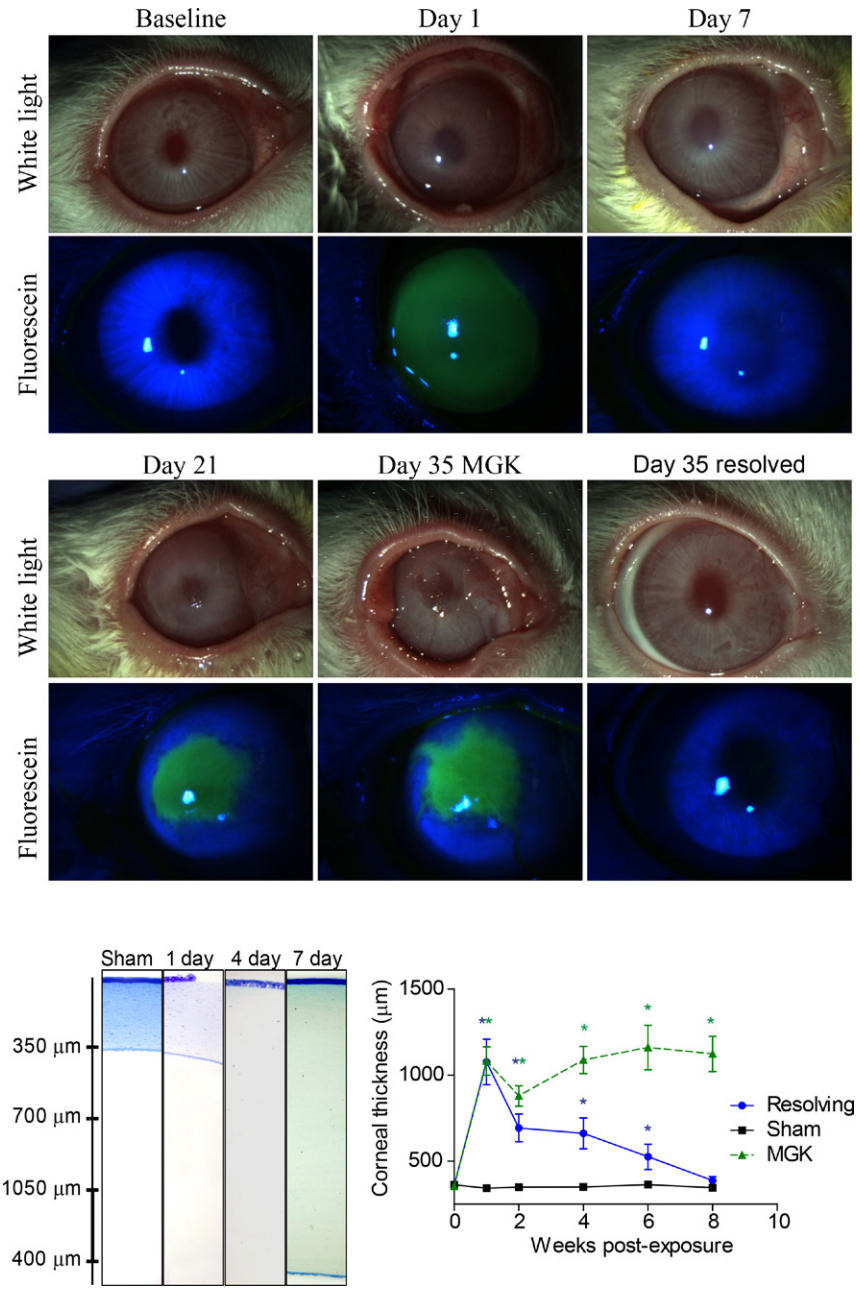


FIGURE 38.5 Development of acute and MGK injuries in HD-vapor exposed rabbit eyes. (Top panels) Rabbit eyes were exposed to HD vapor for 2.5 min and evaluated by slit-lamp examination using fluorescein uptake as a measure of epithelial vesication. All panels are from the same animal. Note the transient recovery of an impermeable epithelial cap by 7 days, only to be followed by a recurring epithelial lesion by 21 days in an MGK cornea. Middle right represents a resolved eye, which appeared to have fully healed. (Bottom left) Histology demonstrating massive increase in corneal edema during the first week, a result of cytotoxicity in the corneal epithelium and endothelium. Note: lesion margin in the epithelium of the 1 d cornea. (Bottom right) Longitudinal changes in corneal edema in resolving versus MGK eyes. Note the biphasic transition at 2 weeks in MGK corneas.

A second important pathology that was recently described is failure of the corneal endothelial barrier due to CEC loss. Early reports of HD toxicity included endothelial cell toxicity and uveitis in Class III injuries, suggesting that HD can penetrate through the cornea to the anterior chamber (Mann and Pullinger, 1944; Hughes, 1945b). Evidence of endothelial toxicity has also been identified in human MGK corneas, including reduced CEC density with increased variability in size and morphology (Jafarinasab et al., 2010). More recently techniques such as transmission electron microscopy, *in vivo* confocal microscopy, functional assessment of barrier,

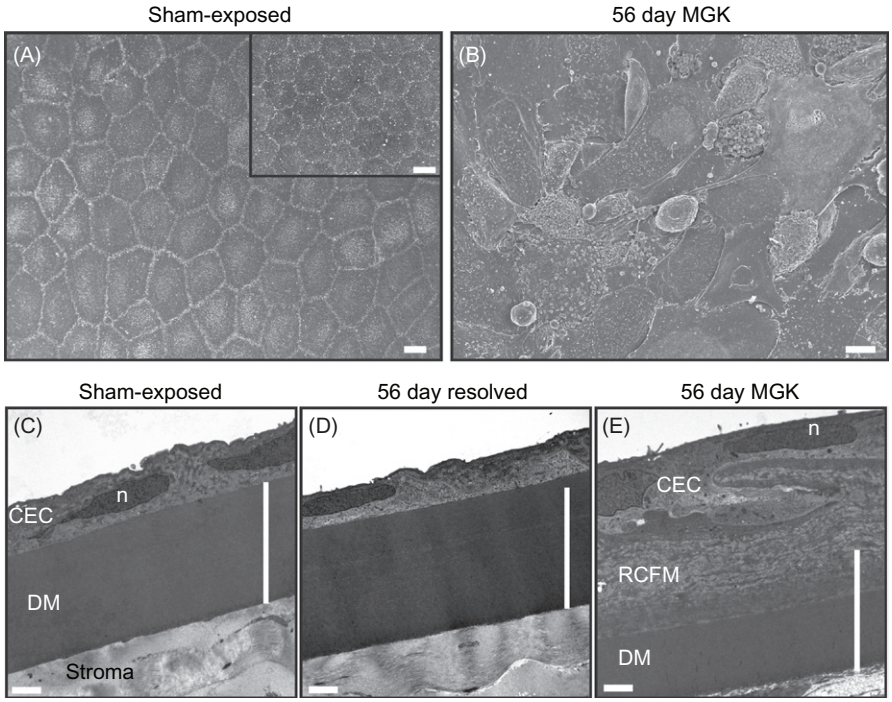

FIGURE 38.6 **Ultrastructural evidence of endothelial cytotoxicity.** (A–B): Scanning micrographs showing CEC morphologies in resolved (A) and MGK corneas (B–D) 8 weeks after SM exposure. Inset in A is a sham-exposed cornea at same magnification, highlighting the increased size of CECs in resolved corneas. Note evidence of ongoing cytotoxicity and a delayed healing response in B. Scale bars = 10 µm. Transmission micrographs of posterior cornea comparing ultrastructure of sham-exposed (C), resolved (D), and MGK (E) corneas 8 weeks after SM exposure. Note the extensive thickening of the posterior DM and formation of a retrocorneal fibrous membrane in the MGK cornea. For comparison, the vertical white lines represent the full thickness of the DM in sham-exposed controls. Labels: corneal endothelial cell (CEC); nucleus (n); Descemet's membrane (DM); retrocorneal fibrous membrane (RCFM). Scale bars = 2 µm.

and immunocytochemistry have been used to demonstrate in vapor-exposed rabbit eyes that corneal endothelial toxicity is associated with acute injury and MGK corneas, but not resolved corneas (McNutt et al., 2013). MGK corneas exhibited an idiotypic endothelial injury characterized by focal CEC loss, abnormal CEC morphologies, and a diffusively thickened DM (Figure 38.6). In contrast, resolved corneas exhibited a normal appearing corneal endothelium. Notably, other clinical endotheliopathies involving the rapid loss of large quantities of CECs, such as aphakic bullous keratopathy, produce secondary keratopathies that are strikingly similar to MGK, including epithelial bullae, delayed LSCD, and corneal inflammation (Taylor et al., 1983; Eagle et al., 1989; Alomar et al., 2011).

The potential involvement of endothelial toxicity in the late HD injury is intriguing for several reasons. First, it provides a mechanism to explicate the dose dependence of MGK onset, based on the permeation of sufficient doses of HD through the cornea to cause injury to the corneal endothelium. Second, it proposes that the clinically biphasic injury progression observed during the acute phase is an epiphenomenon arising from the differential healing capacities of the corneal epithelium and corneal endothelium. Furthermore, the limited ability to heal large endothelial lesions may contribute to the prolonged recovery time following Class III ocular injuries. Third, it provides a single pathology to explain both the chronic and delayed-onset forms of MGK. For example, in this model, the chronic form of MGK would be caused by the inability to restore an intact endothelial barrier, resulting in untreatable corneal edema. Alternatively, in the delayed-onset form of MGK, the delayed loss of CECs (i.e., as a consequence of aging, or due to delayed cytotoxic mechanisms such as genotoxicity) from an endothelium that is already diminished due to HD injury eventually results in endothelial failure and corneal decompensation. Additional implications of this hypothesis include the possibilities that therapies to restore the endothelium may mitigate the likelihood of MGK and that quantitation of endothelial loss may provide a diagnostic to identify corneas likely to develop MGK. Although there are still a large number of questions regarding the extent to which endothelial cytotoxicity and LSCD contribute to the acute injury and to MGK pathologies, it is encouraging that mechanistic studies have moved beyond the corneal epithelium to study other ocular tissues.

Lewisite

Lewisite was first synthesized in 1904 and stockpiled by the United States, Germany, and Japan during World War II. Although Lewisite is considerably more potent than HD, it produces immediate symptoms of physical discomfort, which rendered it relatively ineffective as a stand-alone chemical warfare agent. However Lewisite was found to increase the environmental persistence of HD by depressing its freezing point at doses that had no apparent physiological effect, and therefore Lewisite stockpiles were retained for several decades.

The toxicological effects of ocular exposure to lewisite (L; $C_2H_2AsCl_3$) are mediated by the interaction of inorganic arsenite (AsO_3^{3-}) with thiol groups of biologically active proteins, including dihydrolipoic acid (DHA). DHA is a co-factor in several critical enzyme systems critically involved in energy production, and disruption of DHA inactivates these enzyme complexes. For example, As^{3+} interaction with the E3 component of the pyruvate dehydrogenase complex prevents the conversion of pyruvate to acetyl-CoA, impairing ATP production and resulting in energy depletion, metabolic failure, and cytotoxicity (Young, 1999). Though lewisite injury progression can be mitigated by treatment with sulfhydryl-containing competitive antagonists of lewisite, such as 2,3-dimercaptopropanal (aka, British anti-lewisite; BAL), an ocular formulation of BAL is not currently available (Vilensky and Redman, 2003). Ocular neutralization of lewisite is very time-critical; unless BAL is topically administered with 2–5 min, lewisite eye injuries are irreversible.

Toxicokinetics of Ocular Lewisite Injuries

The distinctive toxicokinetic effects of lewisite exposure on ocular tissues produces an injury progression that is very different from the mustards (Ottinger et al., 1973; Romano et al., 2008; Tuorinsky, 2008). Unlike the latency associated with mustard exposure, lewisite causes rapid ocular irritation, lacrimation, blepharospasm, and chemosis. Eye pain occurs immediately, reaching its peak in 4–8 h. Corneal vesication, perforation, and blindness are observed following instillation of as little as 1 µL of neat lewisite to the corneal surface (Pechura and Rall, 1993). Vapor administration of 0.15 mg min/m^3 causes significant conjunctival injection and swelling of the eyelids, whereas corneal injuries occur at concentrations as low as 2.5 mg min/m^3. Permanent eye damage occurs at concentrations as low as 15.2 mg min/m^3. Since lewisite can be detected by smell at about 14–23 mg/m^3, permanent ocular injury is likely within 1 min of lewisite being detected that way (Gates et al., 1946). At high vapor doses or following liquid droplet exposure, delayed effects develop within 6–24 h, including vesication of the corneal endothelium, full-thickness keratocytosis, corneal edema, inflammatory cell infiltration, neovascularization, corneal perforation, and blindness.

Despite the twentyfold to thirtyfold increase in the toxicity of lewisite compared to the mustards, the ocular injuries caused by vapor exposure to lewisite are predicted to be less significant than HD under field conditions (Gates et al., 1946). Ocular irritation is almost immediate even at low concentrations, such that exposed personnel would be alerted to the presence of an irritant and able to rapidly take protective action. Second, the rapid onset of blepharospasm, ocular pain, and edema at low concentrations causes the eyes to close involuntarily, reducing the total ocular exposure.

Lewisite is very lipophilic, and ocular absorption has been reported to elicit toxicological responses in the ciliary body and iris (Young, 1999). At similar doses, lewisite is significantly more efficient than HD at evoking corneal edema (Pechura and Rall, 1993). At high doses, lewisite-exposed eyes rapidly develop miosis and severe uveitis, suggesting the trans-corneal permeation of lewisite to the inner chambers of the eye (Pechura and Rall, 1993). Since lewisite efficiently permeates the cornea to produce acute toxicity in posterior ocular tissues, it is also likely to cause CEC toxicity. This is consistent with a 1947 report that first described the symptomatic similarities between the mustards and lewisite, despite their distinctive modes of actions (Adler et al., 1947). Notably, this study also reported the focal loss of CECs following liquid instillation of Lewisite directly to the corneas of rabbits. It is currently unknown if lewisite exposure produces the equivalent of a late HD injury. While delayed-onset ocular effects analogous to severe HD-exposed eyes were not reported in lewisite-exposed rabbits, the rabbits were only followed for 30 days after exposure (Mann et al., 1946).

Phosgene Oxime

Although technically considered a vesicant, phosgene oxime (CX; Cl_2CNOH) does not produce blisters, and thus it is more appropriately considered an urticant, or nettle agent. Phosgene exposure causes significant pain on exposed skin and eyes through an unknown mechanism. Eyes rapidly develop conjunctivitis, lacrimation, lid edema, and blepharospasm after mild exposures, while more severe exposures can result in keratitis, iritis, corneal perforation, and blindness (Romano et al., 2008). In general, eye lesions are fairly similar to those caused by lewisite. Phosgene oxime injury has not been well studied, and long-term consequences of exposures are unknown.

Inhalational injury studies conducted in humans are limited to a controlled study with informed volunteers (Malatesta et al., 1983). This study reported that a vapor concentration of 1 mg/m^3 was the limit of physiological

detection. Exposure to 3 mg min/m^3 was defined as the minimum effective concentration causing an unpleasant or irritating sensation on the conjunctiva, nose, or skin. In the same study, mice, guinea pigs, and rabbits exposed to 3,000–15,000 mg min/m^3 phosgene oxime displayed agitation, respiratory difficulty, and intense lacrimation within 30 min. These symptoms appeared to resolve within 72 h, although no supportive histology or histopathology data were published.

NERVE AGENTS

The OPNAs include the G-series agents and the V-series agents, which are designated Schedule 1A substances (Table 38.1). The OPNAs inactivate AChE by alkyl phosphorylation of a serine hydroxyl group at the esteratic site of the enzyme (Romano et al., 2008). Once conjugated to AChE, the nerve agent eventually loses an alkyl side chain by hydrolysis in a process known as *aging*, further enhancing the stability of the enzyme–nerve agent complex. Inactivation of AChE by ageing is currently irreversible *in vivo*, and recovery of cholinergic function mainly depends on synthesis of new enzyme. Functionally, OPNA inhibition of AchE prolongs the residency of ACh neurotransmitter in the synapse, thereby resulting in the excessive stimulation of postsynaptic receptors. In the peripheral nervous system (PNS), the toxidromic progression is mediated by cholinergic overstimulation of several types of receptors, including nicotinic receptors at neuromuscular junctions; nicotinic receptors at autonomic ganglia; muscarinic receptors at parasympathetic efferents onto smooth muscles; and finally, muscarinic receptors on adrenal glands and sweat glands. Unlike the severe pathologies resulting from ocular exposure to the cytotoxic ocular irritants, the neuro-ophthalmic effects of exposure to OPNAs is comparatively mild and fully reversible.

Ocular symptoms are among the earliest and most sensitive indications of the cholinergic toxidrome caused by exposure to nerve agent vapor, particularly tearing, pupillary constriction (miosis) and loss of accommodation. Ocular symptoms of a cholinergic toxidrome can also be expressed at doses that do not cause other apparent evidence of toxicity, and therefore can serve as an early physiological marker of exposure to nerve agents (Baker and Sedgwick, 1996). For example, the most reliable indicator of exposure after the Tokyo sarin attack was miosis, which was observed in 90% of victims (Wiener and Hoffman, 2004). Ocular toxicity by OPNAs is specifically mediated by overstimulation of muscarinic receptors and excessive excitation of parasympathetic signaling within the eye, causing contraction of the pupillary sphincter and ciliary muscle and overstimulation of the lacrimal glands, which produces the toxidromic symptoms of miosis, blurred vision and tearing (Romano et al., 2008).

TABLE 38.4 Comparison of OPNA Lethal Ct_{50} and Miosis Ct_{50} Values

Agent	Lethal Ct_{50} (mg min/m^3)	Miotic Ct_{50} (mg min/m^3)
GA	400	2–3
GB	100	3
GD	70	<1
GF	Unknown	<1
VX	50	0.04

Source: Modified from Hurst et al. (2007) and Romano et al. (2008).

Miosis develops within seconds to minutes after the onset of ocular exposure to the agent or liquid vapor. This effect is a consequence of increased neurotransmission in the parasympathetic nervous system and is a result of the parasympathetic use of ACh as a neurotransmitter. The first intraocular target of nerve agents is the persistent overstimulation of parasympathetic muscarinic receptors on the pupillary sphincter muscle, causing the iris to contract and reduce light input into the eye (see Figure 38.2). This is corroborated by multiple findings. First, it was shown that nerve agent–induced miosis is inversely proportional to AChE activity in the iris (Soli et al., 1980). Second, pretreatment with the muscarinic receptor antagonist atropine prevents the miotic response (Dabisch et al., 2005). The second intraocular target of nerve agents is the ciliary muscles that control lens accommodation. In the presence of a nerve agent, overstimulation of the ciliary muscle alters the lens shape, increasing accommodation and thereby producing the blurred vision that is also characteristic of nerve agent exposure. While the dim and blurred vision reported following ocular exposure to OPNAs has been attributed to the reduced entry of light into the eye due to miosis, the presence of several subpopulations of cholinergic neurons within the retina raises the possibility that overstimulation of cholinergic terminals in the retina may contribute to the cholinergic toxidrome (Voigt, 1986). The final ocular target of the OPNAs is the parasympathetic inputs to the lacrimal glands, which causes increased tearing.

Notably, the miotic effect of OPNAs is mainly due to ocular absorption rather than systemic distribution, since liquid agent on the skin will not cause miosis until near-lethal doses (Table 38.4; Romano et al., 2008). In contrast, a droplet of liquid in or near the eye will cause miosis at very low concentrations (Hurst et al., 2007). Together, these suggest that the relatively privileged environment of the inner eye is more susceptible to direct absorption of nerve agent and drugs than to systemically circulated compounds. Furthermore, they indicate that the onset

of tearing with miosis, in the absence of pain, is a prodromic indicator of exposure to OPNAs.

PSYCHOMIMETIC INCAPACITATING AGENTS

Incapacitating agents are defined by the Department of Defense as "an agent that produces temporary physiological or mental effects, or both, which will render individuals incapable of concerted effort in the performance of their assigned duties" and are not intended to be lethal (Romano et al., 2008).

The development and use of psychomimetics as incapacitating agents have produced a variety of apocryphal stories, driven in part by the testing of LSD, PCP and BZ on military volunteers at Aberdeen Proving Ground (McFarling, 1980, National Research Council, 1984). Collectively, the incapacitating agents are an unusual category of agents, with varied physicochemical characteristics and psychopathological effects. The incapacitating agents include compounds with a wide spectrum of psychotropic effects resulting from psychomimetic activities, including agents that act as stimulants, depressants, psychedelics and deliriants. Psychomimetic agents that have been described in a military context include muscarinic antagonists, cannabinoids, indoles and anxiogenics.

The only psychomimetic chemical explicitly listed in the CWC is BZ, a Schedule 2A agent. BZ is an anticholinergic glycolate related to atropine that acts as a competitive antagonist of the postjunctional muscarinic receptors at ganglia and parasympathetic innervations onto smooth muscle and exocrine glands. By blocking the ability of muscarinic receptors to respond to the synaptic release of acetylcholine, BZ inhibits parasympathetic signaling and drives the ocular nerves toward sympathetic dominance. This shifts the pupillary balance toward mydriasis, failure of accommodation, and lacrimal paralysis. Thus, BZ effects on the eye are the opposite of the OPNAs, resulting in mydriasis, the loss of near-focus, and dry eye. Like nerve agents, once normal cholinergic signaling is restored, the ocular effects of BZ are fully reversed.

Unlike the prodromic effects of many agents on the ocular system, ocular symptoms of BZ inhalation occur secondary to more general signs of intoxication, such as incoordination, confusion, and slurred speech (Sidell et al., 1997). Although minimal human dose–response data are available for ocular symptoms of BZ exposure, relevant studies have been conducted in other species. The effective species-specific concentration:time values for mydriasis following inhalational exposure of BZ were less than 130 mg min/m^3 in dogs, 70 mg min/m^3 in monkeys, and 40 mg min/m^3 in rabbits (Ketchum, 1963; McNamara, 1963). At incapacitating doses (estimated to be 8 µg/kg), central effects persist in humans for 3–4 days; however, the persistence of ocular effects after such treatments were not described.

BLOOD AGENTS

The principal blood agents are hydrogen cyanide (AC; HCN) and cyanogen chloride (CK; NCCl). These agents are Schedule 3 toxic chemicals according to the CWC. Schedule 3A substances have legitimate, large-scale industrial uses; therefore, large stockpiles are likely to be available for repurposing as CWAs.

Cyanide is one of the least toxic of the lethal CWAs. The inhalational LCt_{50} values for AC and CK have been estimated to be 2,500–5,000 and 11,000 mg min/m^3, respectively (Simeonova, 2004). The cyanide ion (CN^-) is the toxic moiety, mediated primarily by its great affinity for the heme a_3 moiety of cytochrome c-oxidase in mitochondria, a key component in oxidative respiration. This interaction blocks the last stage in the electron transfer chain, resulting in cellular hypoxia and a shift of aerobic to anaerobic cellular respiration, leading to cellular ATP depletion and lactic acidosis. Therefore, tissues with high metabolic demands, such as neurons and cardiac cells, are key targets for toxicity. At lethal doses, death occurs within 6–8 min (Sidell et al., 1997).

Exposure to the blood agents can have two distinct effects on the eye, depending on the route of exposure. The retina and optic nerve are principal symptomatic targets of acute systemic cyanide exposure, with mydriasis commonly occurring at sublethal cyanide exposure and vision failure developing at higher doses. This is due to the metabolic inhibition of highly active neurons secondary to vascular distribution of the CN^- ion. The appearance of fixed and dilated pupils is common late in the toxidromic progression, but this is likely to result from the general loss of autonomic neuronal function rather than ocular-specific toxicity (Grant and Schuman, 1993).

Alternatively, topical administration of blood agents to the ocular surface results in local absorption and toxicity, primarily concentrated in anterior ocular tissues such as the conjunctiva and lacrimal glands. Thus, topical exposure to the blood agents elicits mild ocular symptoms, primarily characterized by lacrimation and conjunctival irritation. In animal studies, the administration of sodium cyanide (1.7–5.3 mg/kg/day) to the inferior conjunctival sacs of rabbits resulted in immediate conjunctival irritation and lacrimation (Ballantyne, 1983b). In a separate study, rabbits that were administered 0.9 mg/kg of hydrogen cyanide to the conjunctival sacs were reported to develop general keratitis (Ballantyne, 1983a). These two experiments involved the administration of

lethal doses of cyanide in liquid form directly to the conjunctiva, which is likely to lead to the very rapid cytotoxicity of local nerves, blood vessels, and epithelial cells. Exposure to sublethal concentrations of cyanogen chloride vapor similarly caused intense conjunctival irritation, severe blepharospasm, and lacrimation.

CHOKING AGENTS

The choking agents are chloropicrin (PS; CCl_3NO_2), phosgene (CG; $COCl_2$), and diphosgene (DP; $ClCO_2CCl_3$). These agents injure the nose, throat, and lungs, causing pulmonary edema and respiratory distress (Dembek, 2007). Although diphosgene has very similar physiochemical properties to phosgene, it readily condenses to a liquid and is therefore easier to handle and store. The ocular irritation caused by all three agents occurs at doses that are equivalent to the limit of olfactory detection. The acute symptoms of ocular exposure to phosgene and diphosgene (and possibly chloropicrin) are due to their hydrolysis to hydrogen chloride (HCl), creating what is essentially a chemical burn (Dembek, 2007). The longer-term respiratory symptoms are primarily due to hydrolysis as well as acylation, resulting from reaction of phosgene with nucleophilic moieties on macromolecules, such amino, hydroxyl, and thiol groups. Acylation denatures lipid and protein and disrupts enzymatic function and appears to play a more significant role than hydrolysis in longer-term pathophysiologies. In contrast, the mechanism of action for chloropicrin is not well understood, but may involve an oxidative reaction with biological thiols, such as glutathione and hemoglobin.

Although there is a paucity of acute human data containing ocular pathogenesis and toxicokinetics caused by phosgene or diphosgene, ocular irritation involving burning, conjunctivitis and lacrimation has been reported to develop within 20 min of exposure to 12 mg/m^3 phosgene (Bast and Bress, 2002). At concentrations of 30-40 mg/m^3, severe ocular irritation develops. Although phosgene's poor water solubility means that minimal hydrogen chloride is produced by hydrolysis, even small quantities are sufficient to elicit an initial irritation to the eyes, nasopharynx, and respiratory tract. Contact with liquid phosgene may result in corneal opacities and delayed perforation, consistent with a chemical burn injury and presumably resulting from the effects of HCl on the cornea.

Human exposure concentrations and times are better described for chloropicrin, which is roughly one-third as lethal as phosgene with an estimated median lethal dose of approximately 20,000 mg min/m^3. At low concentrations chloropicrin causes profuse lacrimation and conjunctivitis. At high concentrations it is severely irritating to the lungs, eyes, and skin. Thus the primary effects observed with short and long-term exposure to chloropicrin are sensory and respiratory irritation. The most likely route of ocular exposure is conjunctival and corneal absorption. Ocular irritation occurs prior to other symptoms of exposure, including respiratory irritation, and at doses that are below the limit of olfactory detection. Studies in human volunteers indicate that lacrimation and blepharospasm is apparent at 5.0 mg min/m^3, conjunctival irritation is apparent at 10–100 mg min/m^3, and intolerable ocular irritation developed at 500 mg min/m^3 (Fries and West, 1921, Prentiss and Fisher, 1937). These studies are consistent with more recent findings following an industrial accident in California that produced a plume of chloropicrin with estimated air concentrations between 0.17–1.0 mg/m^3 (Barry et al., 2010). Of the 324 residents who reported symptoms consistent with chloropicrin exposure, 302 (93.2%) presented with ocular symptoms such as lacrimation, ocular pain and burning.

RIOT CONTROL AGENTS

Riot control agents (RCAs), also called *irritants*, *lacrimators*, and *tear gas*, produce transient discomfort and eye closure that render the recipient temporarily incapable of fighting or resisting. The RCAs in use today are CS (2-chlorobenzalmalononitrile; $C_{10}H_5ClN_2$), CN (mace; C_8H_7ClO), CR (dibenzoxazepine; C_8H_7ClO), OC (oleoresin capsicum; $C_{18}H_{27}NO_3$), and various combinations of these agents. The RCAs share several characteristics that make them very effective as nonlethal agents, including rapid onset, with symptoms developing within seconds of exposure; a short duration of effect, with recovery occurring within 30 min after the end of exposure; and a high median lethal concentration with a low effective concentration meaning that they cause acute incapacitation without long-term effects or disabilities (Table 38.5) (Olajos, 2004). The eye is the most sensitive organ to RCAs, and although each RCA has slightly different effects, they all produce sensations of conjunctival and corneal burning, tearing, blepharospasm, and conjunctival injection. Barring direct application of solid RCAs to the eye or mechanical injury from the deployment of RCAs, the ocular symptoms are transient and fully reversible. Although RCAs are not considered to be CWAs according to the 1925 Geneva Convention, President Gerald Ford signed Executive Order 11850, banning the use of RCAs in war, except in defensive actions, without the advance approval of the president. Thus, although RCAs are incapacitating agents, they are not considered *military* incapacitating agents. However since RCAs are increasingly being deployed in other contexts and can theoretically be deployed in a military capacity, we will discuss them here.

TABLE 38.5 Toxicological Parameters of RCAs

Compound	Ocular Irritancy	Rate of Action	Irritancy Threshold (mg/m^3)	Intolerable Concentration (mg/m^3)	Lethal Concentration ($mg\,min/m^3$)
CS	Profound	Instantaneous	0.004	5	25,000
CN	Profound	Instantaneous	0.3	35	14,000
CR	Profound	Instantaneous	0.002	1	100,000
OC	Profound	Instantaneous	–	–	–
Chloropicrin	High	Rapid	2–9	50	20,000

Source: Modified from Olajos (2004).

RCAs can be categorized based on two general mechanisms of action. The C agents (CS, CN, and CR) are SN_2-alkylating agents that react readily with sulfhydryl-containing enzymes, such as lactate dehydrogenase. For example, CS reacts rapidly with the disulfhydryl form of lipoic acid, a coenzyme in the pyruvate decarboxylase system. These agents act as peripheral sensory irritants, which act primarily upon the eyes, respiratory tract, and skin. Despite small differences in potency, the C agents are similar in that exposure results in the near-instant ocular irritation, burning, and swelling of the conjunctiva, with uncontrolled lacrimation, blepharospasm, and increased intraocular pressure. The use of CS has largely replaced CN due to being significantly more effective as a sensory irritant, but much less toxic. Ocular irritancy studies for the C agents have been conducted in various animal species and in human volunteers (Punte et al., 1963; Ballantyne and Swanston, 1978). Generally, these studies were consistent in showing that exposure to low concentrations of CS was immediately irritating and rapidly became incapacitating at higher doses, but significant corneal toxicity did not occur until very high concentrations were achieved. For example, instillation of 5–10% CS to the corneal surface caused acute conjunctivitis, chemosis, keratitis, neovascularization, epithelial lesions, and corneal inflammation. The mechanism of injury at high concentrations is unknown, although it has been speculated that the alkylating properties of the C agents could disrupt protein structure. The poor water solubility of C agents limits their principal mode of action to the corneal epithelium. The potential for ocular irritation from CS is less than with CN; however, prolonged exposures to both will result in conjunctivitis and photophobia (Ballantyne et al., 1974).

The second class of RCAs is the capsaicins, represented by OC and its derivatives. The capsaicins are naturally occurring compounds of the capsicum plants, which include chili peppers and jalapenos. Capsaicin binds TRPV1, a vallinoid type I receptor that is activated by elevated temperature (43°C) or abrasion. TRPV1 is expressed by nociceptor neurons in the eye, and TRPV1 activation elicits symptoms of pain. Clinical signs of exposure to OC include lacrimation, transient conjunctivitis, redness, burning, pain, swelling, and blepharospasm. If applied directly to the eye, OC can cause neurogenic inflammation, insensitivity to chemical and mechanical stimuli, and loss of the blink reflex (Olajos and Salem, 2001). Generally, not much is known about the general toxicity of OC, but because it is a widely used food product, it is believed to be relatively nontoxic.

BIOLOGICAL TOXINS

Although there is ongoing disagreement over whether biotoxins should be classified as biological warfare agents (BWAs) or CWAs, they are clearly more similar to CWAs in their deployment, clinical manifestation, and medical management. Three categories of biotoxins will be discussed next, each of which exhibits a distinctive mechanism of action: neurotoxins, metabolic toxins, and bacterial superantigens.

Biological Neurotoxins

The BoNTs are highly lethal bacterial toxins produced by the *Clostridium* species, a family of bacteria that lives in the soil and in low-oxygen conditions. Clinical manifestations of botulism can occur following the ingestion, inhalation or injection of preformed toxin or by productive infection by toxin-expressing strains. There are currently eight known BoNT serotypes (/A–/H), of which /A, /B, /E, /F have been directly associated with human disease (Simpson, 2004; Dover et al., 2013). The toxin is expressed as a single 150 kDa peptide, which is post-translationally nicked to produce a dichain composed of a 100 kDa heavy chain (HC) and a 50 kDa light chain (LC) linked by a disulfide bond (reviewed in Simpson, 2004). The HC mediates binding to presynaptic receptors and entry of toxin into the neuron via synaptic endocytosis. Acidification of the endosome triggers the HC to form a pore in the endosome membrane allowing the translocation of the LC from the lumen to the neuronal cytosol.

The LC then targets and cleaves one or more of three soluble NSF attachment protein receptor (SNARE) proteins with exquisite specificity: synaptosomal-associated protein 25 (SNAP-25; BoNT/A, /C, /E); vesicle associated membrane protein 1-3 (VAMP1-3; BoNT-/B, /D, /F, /G); or syntaxin (BoNT/C). The SNARE proteins are essential components of the synaptic exocytosis mechanism, and their cleavage prevents functional assembly of the ternary complex, thereby blocking neurotransmitter release. The combination of efficient neuronal targeting and presynaptic activation renders BoNTs the most potent substances known, with estimated human lethal doses as low as 0.1–1 ng/kg.

BoNTs interfere with the synaptic release of ACh from several types of cholinergic neurons, including motor neurons, preganglionic neurons, parasympathetic neurons, and some sympathetic neurons, such as those that innervate sweat glands. Furthermore, although there is a partial selectivity for cholinergic synapses, BoNT can also impair neurotransmission at other types of synapses, including adrenergic and noradrenergic sympathetic synapses (MacKenzie et al., 1982). Chemical denervation of autonomic signaling can occur at ganglia, which are cholinergic; at the synaptic fasciculation, where the neuron releases neurotransmitter onto the smooth muscle cells; or in both locations. Thus, the effects of intoxication on ocular behavior can vary based on dose and time after intoxication. Regardless, prominent neurologic findings in all forms of botulism include diplopia, blurred vision, and dilated pupils with weak pupillary responses. Tear production may be reduced because of peripheral parasympathetic cholinergic blockade, and ptosis is common.

The speed that nerve terminals are intoxicated is closely related to neuronal activity, since higher rates of neurotransmitter release correspond to increased toxin uptake. Consequently, ophthalmic manifestations are among the earliest signs of clinical presentation (Konig et al., 1975; Levy et al., 1991). Common findings include accommodative paresis (59%), blurred vision (89%), mydriasis (52%), and photophobia due to paralysis of the cholinergic terminals of the parasympathetic nerves. Impairment of tear production results from paralysis of the autonomic nerves innervating the lacrimal glands, leading to dry eye. Paralysis of the extraocular muscles is also an early symptom, producing double vision (diplopia, 59%), fixed gaze (36%), nystagmus (56%), and drooping eyelids (blepharoptosis, 80%). Manifestations at very high doses include tonic pupils that are poorly responsive to light, suggesting significant paralysis of both autonomic pathways. Supersensitivity of the iris sphincter muscle to muscarinic agonists is a characteristic in severely intoxicated eyes, suggesting that antagonistic signaling via the sympathetic pathway is also impaired (Caya, 2001).

Given the ocular BoNT toxidrome, it is obvious why the botulinum toxins are included in the neuro-ophthalmic modulators. Unlike nerve agent, which stimulates the parasympathetic pathway, or BZ, which blocks the parasympathetic pathway, botulinum activity can chemically denervate both signaling pathways at high doses, leading to poorly responsive or tonic pupils. In contrast, at lower systemic doses BoNT preferentially blocks cholinergic neurotransmitter release, resulting in the dominance of the sympathetic signaling pathway.

The shellfish poison saxitoxin (STX) and the pufferfish poison tetrodotoxin (TTX) are also biological neurotoxins. Both toxins antagonize the voltage-gated sodium channels responsible for the rising phase of an action potential in neurons, thereby preventing action potential propagation and reducing or eliminating neurotransmitter release. Both toxins are exceedingly potent, with intravenous LD_{50} values of 10 µg/kg and 8 µg/kg, respectively. The inhalational LD_{50} value for STX is estimated to be 5 mg min/m^3 (the equivalent value for TTX is not available). Although there is minimal data on toxic effects following topical exposure in healthy eyes, in principle the conjunctiva and corneal epithelium should provide an effective barrier to ocular absorption. Interestingly, topical administration of STX or TTX to deepithelialized corneas or by subconjunctival injection produces a long-lasting anesthetic effect, without causing ocular irritation or corneal edema (Duncan et al., 2001). In contrast, systemic administration can paralyze the ocular neurons, blocking pupillary light responses, spontaneous or reflexive eye openings and gaze (Lan et al., 1999). At intermediate doses, patients may experience blurred vision, darkened vision, and loss of accommodation, with temporary blindness occurring at higher doses. There do not appear to be any chronic complications from ocular paralysis resulting from exposure to TTX or STX, and upon recovery, oculomotor coordination, pupillary responses, and visual acuity were reported to be physiologically normal. These data suggest that the corneal epithelium and endothelium act as effective barriers to prevent the transcorneal absorption of TTX or STX, and therefore, ocular responses to aerosol exposures are more likely to result from inhalation and systemic distribution than from direct corneal absorption.

Ricin

Ricin is a heterodimer glycoprotein that is isolated from the castor bean. After nonspecific internalization into a wide variety of cells, ricin cleaves a glycosidic bond on the 60S subunit of eukaryotic ribosomes, preventing protein synthesis and causing cytotoxicity within 8 h. The median LD_{50} of ricin is around 22 µg/kg in humans from injection or inhalation. There is little information available on the ophthalmic manifestations

of ocular exposure to ricin; however, topical administration to the eye is severely irritating, causing chemosis and conjunctivitis (Hunt, 1918; Grant and Schuman, 1993). Ocular instillation of 100 µg to rabbits, guinea pigs, or mice causes extensive ocular inflammation that may lead to permanent corneal damage and blindness. It is unlikely that ricin can penetrate into the globe, and therefore the direct action of ricin must occur principally at the ocular surface (Strocchi et al., 2005).

Staphylococcus Enterotoxin B

SEB is a 23- to 29-kDa polypeptide in the bacterial superantigen family that cross-links the major histocompatibility class II receptor and T-cell receptors. This short-circuits the antigen processing and presenting mechanism, stimulating the release of pathologic levels of proinflammatory cytokines while failing to activate regulatory feedback signaling (Ahanotu et al., 2006). Prior to the 1975 Biological Warfare Convention (the biological equivalent of the CWC), SEB was studied by the United States as a biological agent that could be used to incapacitate soldiers in the battlefield. SEB was an attractive potential BWA because it can easily be aerosolized, is stable, and at low doses can cause widespread systemic damage when inhaled. In most circumstances, aerosol exposure results in a profoundly incapacitating illness lasting as long as 2 weeks, but it does not cause death (Sidell et al., 1997). SEB-induced ocular injuries have been described only three times in literature, following exposures where workers placed contaminated materials close to their eyes in the laboratory. Symptoms appear within 1–6 h, and included significant eyelid edema, periocular swelling, and acute conjunctivitis with discharge. Symptoms resolved within a week, although at least one patient appeared to exhibit continued hypersensitivity. These suggest that casualties resulting from an inhalational exposure may present with ocular toxicities that can be acutely incapacitating although, as with ricin, primarily localized to the ocular surface (Rusnak et al., 2004).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

A wide array of CWAs and biological toxins exhibit acute ocular toxicities. The mode of action of these agents can be broken into three general categories: those that exhibit acute cytotoxic activity; those that stimulate symptomatic distress without directly causing cytotoxicity; and those that modulate neuro-ophthalmic signaling, thereby causing incapacitation, without directly injuring corneal tissues. The exquisite sensitivity of the eye to many of these agents enables the rapid appearance of ocular manifestations to serve as prodromic indicators of exposures. In the case of the CWAs that are most injurious to the eye—namely, vesicants—considerable research is still needed to identify therapeutic modalities that protect against long-term, progressive sequelae that can result in loss of vision. For most other agents, the ocular toxicity is mild or reversible at reasonable exposure estimates. However, one cannot discount the acute psychological distress of ocular pain or impaired vision, particularly if the causative agent is unknown and the prognosis is unclear. Until comprehensive treatments are identified for the cytotoxic CWAs, vision will always be a primary target of CWA deployment.

Acknowledgments

We would like to acknowledge Drs. Phillip Beske, Kyle Hubbard, Aaron Bradford, Scott Willens and Jeffrey Havens as well as Ms. Cindy Kronman and Ms. Riannon Hazell (USAMRICD) for editorial and administrative assistance. CHAPTER

39

Dermal Toxicity of Sulfur Mustard

Joshua P. Gray[1], *Michael P. Shakarjian*, *Donald R. Gerecke and Robert P. Casillas*

INTRODUCTION

Skin integrity is in part determined by the interaction of a number of proteins that form a continuum of molecules linking together to ensure the epidermis and dermis are tightly attached to one another. These macromolecules include the keratins that form the intermediate filaments in the cytoplasm of keratinocytes, integrins that are made of two subunits and found in the hemidesmosomes of the basal keratinocyte membrane, and a variety of laminins, collagens, and their receptors, situated both in the basement membrane that separates the epidermis from the dermis and in the dermis itself. Any chemical agent that disrupts this continuum of linking proteins will result in a breach in skin integrity and ensuing histopathology (Uitto et al., 2007). One such compound is the alkylating agent sulfur mustard [bis(2-chloroethyl) sulfide; HD; SM], which causes detachment of the epidermis from the dermis (this chapter uses the abbreviation SM for sulfur mustard because, in civilian dermatological research, HD is the abbreviation for the hemidesmosome, an important morphological structure found in the cell membrane of keratinocytes). Skin exposure to SM starts a complex series of events with a host of normal skin responses to wounding that interact with, influence, and regulate each other to result in cutaneous toxicity. Various mediators of injury that regulate inflammation, immune responses, cell death, and a number of signaling pathways have been implicated in the process. This chapter describes our current knowledge of the cutaneous actions of SM by discussing the basic mechanism of action and mediators involved to provide for the reader a comprehensive understanding of the histopathology of SM-exposed skin. The injury process is described and SM-induced injury is compared with other types of wound injury. Additionally, various vesicant injury models are described and potential therapeutic countermeasures are discussed.

BACKGROUND

Military Use

SM, a vesicant or blistering agent, has been used intermittently as a chemical warfare agent since 1917, when Germany first introduced it as a weapon against British soldiers in Ypres, Belgium. Subsequently, in the 1930s, it was reported to be used by Italy against Abyssinia (Ethiopia), by Poland against Germany, and by Japan against the Chinese. During the 1960s, SM was allegedly used by Egypt against Yemen. The last well-documented use in the 1980s was by Iraq against Iran and the Kurds (Papirmeister et al., 1991a,b,c). As recent as 2013, Syria, working with the Organization for the Prohibition of Chemical Weapons (OPCW) and the United Nations, has begun destroying its chemical weapon stockpile that included both nerve agents and SM. Also overseen by the OPCW, Libya completed destruction of its SM stockpile in 2013.

Wound Repair

Even repair of the simplest skin wound requires the coordination of a number of physiological processes and events. The tissue injury causes blood vessel disruption

and an activation of the inflammatory pathway that releases a battery of mediators. Re-epithelialization requires activation of additional pathways and the initiation of specific events at specific times, such as extracellular matrix remodeling and the proliferation and migration of keratinocytes. If these events are not precisely coordinated, then the end result can be delayed healing and/or scar formation. Because the repair process is complicated, a review of the wound healing events in dermal injury might be helpful. There are at least three phases to wound healing after dermal injury (Gurtner et al., 2008). Inflammation (first 24–48 h) is the first. This phase occurs early and involves activation of the coagulation cascade, inflammatory pathways, and immune system. These biological processes involve an attempt to maintain homeostasis by preventing blood and fluid loss, removing dead tissue, and preventing infection. The second is the wound repair phase (2–10 days after injury). This phase involves the proliferation and migration of several cell types. Keratinocytes migrate over the injured dermis, endothelial cells proliferate to form new blood vessels, and fibroblasts differentiate into myofibroblasts to initiate wound contraction. Third is the remodeling phase (2–3 weeks after injury). This phase results in the final wound repair. All the activated cellular processes turn off. Many cell types undergo apoptosis or leave the wound site. The extracellular matrix is remodeled and resumes normal functions.

These same basic phases are applicable to the injury caused by SM, but the pathology frequently is more severe than other types of dermal wounds and the basic timing of the various phases may be extended in SM injury (Papirmeister et al., 1991a,b,c; Dacre and Goldman, 1996; Balali-Mood and Hefazi, 2006). Normal clothing provides little protection to the skin from a liquid or vapor exposure to SM. Once in contact with the skin, the lipophilic properties of SM allow it to rapidly penetrate the epidermal barrier, while its high reactivity and bifunctional nature lead to alkylation of a wide range of molecules (Figure 39.1). The ultimate injury caused by SM is highly dependent on the dose and length of exposure to the agent, resulting in a wide range of histopathology. Erythema, resembling sunburn, may be the mildest and earliest form of skin injury, occurring 2–48 h after SM exposure (USAMRICD, 2007). The erythema may be accompanied by pruritus or burning pain and small vesicles may eventually develop, which coalesce to form bullae (Figure 39.2). Fluid-filled blisters increase in size, their color ranging from yellow to tan. The fluid itself does not contain active alkylating agent, nor does it have vesicating properties. When SM is applied as a liquid, the exposure concentration is even higher than that of a vapor application and severe lesions are more likely. The resultant wounds are prone to secondary infections and may cause chronic ulcers that are resistant to wound repair. There may be permanent pigmentation changes in the skin after exposure to SM. Clearly, the effects of SM on skin are complex and involve many systems and pathways. The following sections attempt to address the mechanism of action of SM and the systems and pathways involved in an organized way.

PATHOGENESIS

The bulk of what is known about human skin injury from SM has been gathered from victims of the military use of the compound (Requena et al., 1988; Balali-Mood and Hefazi, 2006; Hefazi et al., 2006). Nevertheless, there

are several reports in which the cutaneous vesicating effects of SM were studied experimentally in human subjects (Papirmeister et al., 1991a,b,c; Dacre and Goldman, 1996). In one comparative study (Daily et al., 1944), 12 volunteers had forearm vapor cup applications of SM, trifunctional nitrogen mustard (HN3), and lewisite. The conclusions were that SM exposure caused the largest vesicles formed, the earliest peak vesication, the longest healing time, and the most severe final scar. Lewisite was the second most potent agent and HN3 was the least potent, although the HN3 lesions had the most edema of the three vesicants examined. The results confirmed the previously published studies that followed the development of skin pathogenesis after topical exposure to SM.

Clinical injury by SM has been extensively reviewed. SM injury to human skin begins almost immediately after exposure, when the highly reactive bifunctional SM directly alkylates resident proteins. However, recognizable skin pathology does not usually occur for several hours to a day after exposure. The very first physical sign of SM exposure is usually erythema, which may or may not be associated with itching (Papirmeister et al., 1991a,b,c). This is often followed later by distinct fluid-filled blisters (Figure 39.2) that break open and become covered with a scab. Many researchers have noted that the blisters resemble those formed by epidermolysis bullosa (EB), a genetic or acquired skin pathology that results in a separation of the epidermis from the dermis (Figure 39.3). In both SM exposure and EB, there may be multiple rounds of blistering and healing in an individual (Balali-Mood and Hefazi, 2005; Pillay, 2008). In fact, some of the therapeutic agents for EB are being tested as potential medical countermeasures against SM injury. These are addressed later.

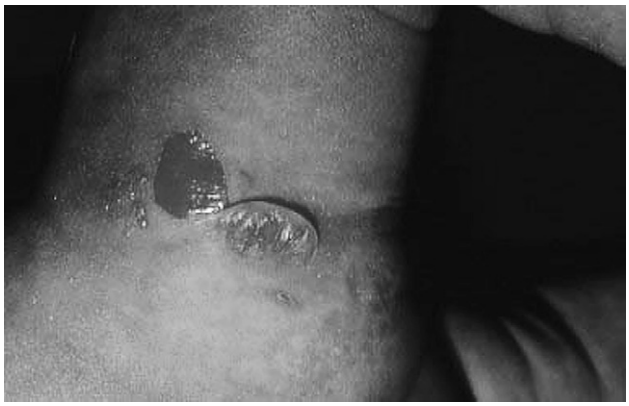

FIGURE 39.3 Fluid-filled bullous of patient with EB caused by truncated gamma-2 polypeptide chain of laminin-332 (formerly laminin 5, a heterotrimeric glycoprotein).

Cytotoxicity of SM

Although stable in lipophilic solvents, SM has a half-life of only 24 min at room temperature in aqueous physiological solutions because it rapidly reacts with water to form thiodiglycol and HCl. This rapid activation of SM in an aqueous environment also allows it to react with small molecules of biological interest, as well as proteins, carbohydrates, lipids, RNA, and DNA (Bartlett and Swain, 1949; Papirmeister et al., 1991a,b,c; Debouzy et al., 2002; Noort and van der Schans, 2002). The initial reaction involves the formation of a cyclic ethylene sulfonium ion that readily targets reactive groups on skin components, including sulfhydryls, phosphates, ring nitrogens, and carboxyl groups. As a bifunctional alkylating agent, SM forms monofunctional adducts and intramolecular and intermolecular cross-links. Because it is so reactive and indiscriminate in its molecular targets, SM affects many pathways and is cytotoxic on many levels. There are at least three independent mechanisms of cytotoxicity that have been proposed and each is addressed in separate sections.

Alkylation of DNA/Poly(ADP-Ribose) Polymerase Activation

One of the major targets of SM alkylation is DNA that can form both monofunctional adducts and bifunctional cross-links (Papirmeister et al., 1991a,b,c; Debiak et al., 2009), which can persist for at least 21 days (Batal et al., 2013). Complementary DNA strand and intrastrand cross-links occur after SM exposure (Walker, 1971). The cross-linking of cellular DNA underscores the importance of DNA repair pathways in preventing cytotoxicity of SM-exposed cells. These repair pathways include both the nucleotide and base excision pathways (Matijasevic and Volkert, 2007; Jowsey et al., 2009). However, recent evidence suggests that the homologous recombination is perhaps the most important mechanism for SM exposure, with nucleotide and excision pathways playing a supportive role (Jowsey et al., 2012).

DNA alkylation can also lead to single-strand and double-strand DNA breaks. These breaks trigger activation of a family of nuclear repair enzymes called poly(ADP-ribose) polymerases (PARP) (Papirmeister et al., 1985; Shall and de Murcia, 2000). Although low levels of PARP activation may signal repair, excessive activity can deplete cells of PARP's major substrate, NAD^+. Depletion of NAD^+, in turn, inhibits ATP production, which is essential for metabolism (Martens and Smith, 2008). Apoptosis or necrosis may result, depending on level of ATP depletion, cell type, and other factors (Rosenthal et al., 2001). Preventing the depletion of NAD^+ by interfering with PARP activation has been the rationale for testing PARP inhibitors as therapeutic countermeasures (Debiak et al., 2009). To date, the literature suggests this strategy has been unsuccessful *in vivo* (Casillas et al., 2000a,b).

Reactions with Glutathione/Oxidative Stress

It is also hypothesized that oxidative stress plays a key role in the cutaneous vesicating actions of SM. Under homeostatic conditions, a net reducing environment is maintained in tissues by the presence of glutathione (GSH), which serves as a buffer against cytotoxic electrophiles and reactive oxygen species (ROS). GSH peroxidase catalyzes the reaction of reduced GSH with hydrogen peroxide. Depletion of intracellular GSH allows the accumulation of oxidants such as H_2O_2, which become abundant and actively contribute to lipid peroxidation and other types of cellular damage. Dermatotoxic agents such as ultraviolet radiation (UVA) and psoralens have been shown to deplete intracellular GSH, resulting in cellular toxicity (Wheeler et al., 1986). The propensity of SM to react with sulfhydryls is thought to lead to a concentration-dependent depletion of reducing equivalents within cells. Recent findings also suggest that SM and related vesicants can interact with key intracellular reductases to generate mustard-free radicals (Brimfield et al., 2009). In other tissues, SM exposure has been shown to reduce GSH peroxidase and GSH reductase activity, potentially contributing to the depletion of reduced GSH (Husain et al., 1996; Jafari, 2007). In addition, inflammatory cells, which infiltrate into the skin in response to SM-induced injury, generate additional ROS that contribute to oxidative stress (Droge, 2002). This raises the possibility that the vesicating actions of mustard alkylating agents involve oxidative stress.

Recent evidence indicates that GSH depletion and oxidative stress are important mechanisms of cutaneous toxicity induced by SM and its vesicating analogues. Cutaneous GSH peroxidase gene expression is increased after SM treatment in the mouse ear vesicant model (MEVM), suggesting that this enzyme is important in reducing oxidative stress due to SM exposure (Buxton et al., 2001).Treatment with the monovalent mustard analogue, chloroethyl ethyl sulfide (CEES), has been shown to significantly deplete GSH in mouse and human keratinocyte cell lines (Tewari-Singh et al., 2011). Furthermore, depletion of intracellular-reduced GSH by buthionine sulfoxamine sensitizes keratinocytes treated *in vitro* with SM (Simpson and Lindsay, 2005) or CEES (Tewari-Singh et al., 2011).

There is more direct evidence from both *in vivo* and *in vitro* studies that CEES produces oxidative stress. CEES application to the dorsal skin of SKH-1 hairless mice led to time-dependent and dose-dependent increases in oxidative damage to tissue proteins as evidenced by modification by lipid peroxides, radical adduction, and the formation of protein carbonyls (Pal et al., 2009). Increased DNA oxidation, detected as the formation of 8-hydroxy-2-deoxyguanosine (8-OHdG), was also a consequence of CEES exposure. Subsequent studies with the JB6 mouse keratinocyte cell line and primary fibroblast in culture confirmed the ability of CEES to increase 8-OHdG and also increase both mitochondrial and cytosolic superoxide generation (Inturi et al., 2011). A report using mouse PAM212 keratinocytes in three-dimensional air–liquid interface cultures demonstrated concentration-dependent increases in hydrogen peroxide and protein carbonyl formation after topical application of CEES (Black et al., 2010a,b). These changes were accompanied by increases in the relative mRNA of Cu,Zn-SOD, catalase, thioredoxin reductase, and several glutathione-*S*-transferases (GSTs), suggesting a compensatory cellular response to oxidative stress. Although the role of GSTs in modulating mustard vesicant–induced cutaneous toxicity is unclear, their levels have been documented to increase overall in response to SM (Gross et al., 2006). In summary, there is now compelling evidence that the loss of cellular reducing equivalents and the increase in oxidative stress are key contributors to cutaneous toxicity by SM and its vesicating analogues.

Reactions with GSH/Calcium Homeostasis

Depletion of GSH also affects calcium homeostasis; treatment of primary human epidermal keratinocytes with buthionine sulfoxamine decreased the level of reduced GSH but increased intracellular Ca^{2+} (Ray et al., 1993). Neuroblastoma cells treated *in vitro* with 0.3 mM SM maintained high cell viability for nearly 9 h, which then decreased with time. The decrease in cell viability was prefaced by an increase in free intracellular calcium that occurred between 2 and 6 h after exposure (Ray et al., 1995). Intracellular-free calcium is a well-recognized marker of cell stress (Ruff and Dillman, 2007). Induction of intracellular calcium is thought to contribute to apoptosis induced by SM exposure in keratinocytes *in vitro* (Rosenthal et al., 2003). Despite these findings, Sawyer's group has shown that the sensitivity of primary human keratinocytes to SM was unaffected when calcium was reduced using chelators or increased using the membrane ionophore ionomycin (Sawyer and Hamilton, 2000). These findings suggest that although calcium levels are significantly altered by SM treatment, modulation of calcium alone is neither necessary nor sufficient for SM-induced apoptosis.

Inflammation

Inflammation is likely one of the major driving forces of the skin pathology caused by SM exposure. The contribution of cytokines to the inflammatory events is well established and their signaling pathways are important targets of medical intervention for potential countermeasures of vesicant injury. The literature linking inflammation and wounding is so extensive as to fill a book by itself. This section therefore only presents an overview

of the inflammatory response to dermal skin injury. In short, cytokine signaling involves several Janus kinase (Jak)-signal transducer and activator of transcription (Stat) pathways (O'Shea and Murray, 2008). These pathways are the major regulators of all the cell types involved in inflammation and they can be either positive or negative mediators to the inflammatory process. Both pro-inflammatory and anti-inflammatory events are under the influence of the Jak–Stat pathways and hundreds of cytokine receptors are regulated via these pathways including more than 40 type I and type II cytokine receptors and receptors for interleukins, interferons, growth-stimulating factors, leptin, erythropoietin, and many more.

As for vesicant-injured skin, the inflammatory response appears to be biphasic. This is based on our years of experience in addition to that of others who reported that inflammation played a minor role in the initial events of SM-induced cutaneous injury but had much greater importance at later stages (Papirmeister et al., 1991a,b,c). In another examination, the authors argued that inflammation may be more significantly involved in the vesication event than previously believed, with inflammatory cells and mediators contributing directly to the formation of the primary lesion (Cowan and Broomfield, 1993). In a recent study, Joseph et al. (2011), documented a correlation between markers of inflammation and DNA damage with structural changes in skin after SM exposure (Joseph et al., 2011).

Numerous accounts, from both *in vivo* and *in vitro* studies, have now documented an increase in a number of inflammatory cytokines in response to SM. Applications of SM in the MEVM have resulted in induction of IL-1β, IL-6, TNFα, and GM-CSF within 6 h (Sabourin et al., 2000; Wormser et al., 2005). Although IL-1α was not detected in these studies, its inducibility by SM vapor was confirmed in experiments in which the backs of hairless mice were exposed (Ricketts et al., 2000). Further, relative mRNA levels of IL-1β, IL-6, IL-8, and TNFα have been demonstrated to significantly increase within 24 h of SM vapor treatment in full-thickness skin biopsy samples from weanling pigs (WP) (Sabourin et al., 2002). Studies with cultured human keratinocytes have shown that these cells respond directly to SM with the production of cytokines. IL-1β, IL-6, IL-8, and TNFα were detectable in culture media from these cells 24 h after treatment with 100–300 μM SM (Arroyo et al., 2000). Cultured skin fibroblasts have also been shown to express TNFα in response to SM. The chemotactic activity of keratinocyte-derived IL-8 could initiate the transmigration of circulating granulocytes into SM-exposed tissues where they could contribute to the primary lesion. Other cytokines may be involved in priming and activation of the recruited immune cells. Although cytokine induction may occur via several means, there is now ample evidence that the inflammatory transcription factor NF-κB is one such pathway activated by SM (Atkins et al., 2000; Minsavage and Dillman, 2007; Rebholz et al., 2008). In fact, enhanced synthesis of the aforementioned cytokines in resident skin cells may occur as a result of this NF-κB activation (Ghosh et al., 1998).

Additional inflammatory mediators have been detected in cutaneous tissues as a consequence of SM treatment. These include free arachidonic acid (Lefkowitz and Smith, 2002) and its cyclooxygenase (Rikimaru et al., 1991; Dachir et al., 2004a,b) and lipoxygenase products (Tanaka et al., 1997). Furthermore, the increased capillary permeability observed would allow a variety of circulating inflammatory participants, such as complement components and kininogens, to enter the dermal interstitium (Rikimaru et al., 1991). Clearly, vesicant injury involves a host of inflammatory mediators similar to those seen in other types of wounds, where individual cytokines have been singled out as potential therapeutic targets.

Protease Activation

Although there may be protease involvement in the initial SM injury, most studies have viewed the involvement of serine and matrix metalloproteases (MMPs) in SM injury as a downstream event because MMPs in particular regulate various inflammatory and repair processes (Parks et al., 2004). The regulatory role confounds the potential use of MMP inhibitors as therapeutic agents because they play a beneficial role in wound repair and skin degradation. Increased protease activity after SM exposure has been reported *in vitro* in human peripheral blood lymphocytes (PBL) (Cowan and Broomfield, 1993) and human epidermal keratinocytes (Smith et al., 1991), *ex vivo* in rabbit skin organ cultures (Higuchi et al., 1988; Woessner et al., 1990) and human skin explants (Rikimaru et al., 1991; Lindsay and Rice, 1996), *in vivo* in hairless guinea pig (HGP) skin (Cowan et al., 1993, 1994; Kam et al., 1997), and *in vivo* in the mouse ear (Powers et al., 2000) and hairless mouse (Casillas et al., 2000a,b). The continued assessment of proteolytic activity in animal models is useful for characterizing specific proteases important to SM injury and for identifying effective protease inhibitors with therapeutic use in reducing or eliminating tissue injury caused by SM cutaneous exposure. The relationship between SM-increased protease activity and the subsequent vesication (blistering) that occurs in SM lesions remains unclear, but emerging literature implicating protease involvement is consistent with the known ability of proteases to degrade basement membrane components *in vitro* and *in vivo*. Inhibition of these proteases should reduce the extent of the injury, promote a more rapid recovery, and provide a useful adjunct to other therapeutic strategies aimed at

preventing SM-induced degenerative pathophysiological events (Cowan et al., 1993).

Apoptosis

Mechanisms underlying SM-induced apoptosis have been carefully explored using primary cultures of human keratinocytes. Treatment of keratinocytes with 100–300 μM SM resulted in activation of caspase 8, which initiates the Fas-dependent death receptor pathway, and caspase 9, which initiates the mitochondrial apoptotic pathway (Rosenthal et al., 2003). Fas and Fas ligand were upregulated in a concentration-dependent manner by SM leading to activation of caspase 3, the central executioner protease. Transfection of immortalized keratinocytes with a dominant-negative Fas-activated death domain resulted in a blunted caspase response to SM. Microvesication and tissue injury produced *in vivo* by SM exposure of transfected cells after grafting onto athymic nude mice was also reduced by this treatment.

Changes in intracellular calcium levels are known to activate the mitochondrial pathway of apoptosis. A key regulator of Ca^{2+}-dependent proteins is calmodulin. SM has been shown to cause a time-dependent induction of calmodulin in keratinocytes (Simbulan-Rosenthal et al., 2006). Moreover, depletion of calmodulin using antisense probes attenuated SM-induced activation of caspases involved in the mitochondrial pathway of apoptosis. Both antisense and pharmacological inhibition of calmodulin prevented SM-induced nuclear fragmentation in the keratinocytes. Bad, a proapoptotic Bcl-2 family member present in an inactive phosphorylated form in viable cells, was also activated by SM. Furthermore, cyclosporine A, a selective inhibitor of calcineurin, a Bad phosphatase, inhibited SM-induced keratinocyte apoptosis. These results suggest that calcium-dependent activation of Bad may be a mechanism by which SM induces apoptosis in keratinocytes.

One form of cellular demise common to epithelial cells is detachment-initiated apoptosis, also referred to as anoikis (Frisch and Francis, 1994). Epidermal keratinocytes rely on signals derived from the surrounding extracellular matrix for survival. It is possible that loss of these signals plays a role in SM-induced epidermal cell injury, and that cell detachment from the basal lamina precedes cytotoxicity. Several lines of evidence support this possibility. First, SM can alter the dynamics of cytosolic proteins that exert control over the attachment of cells to the basement membrane. For example, SM can modify intracellular actin microfilaments and keratin intermediate filaments known to be important in maintaining epithelial cell connections with the basal lamina. Thus, Hinshaw et al. (1999) reported that SM causes changes in the actin microfilament architecture and morphology of human keratinocytes within 3 h of exposure (Hinshaw et al., 1999). This was associated with a significant decrease in keratinocyte adherence without evidence of cytotoxicity. In addition, Werrlein and Madren-Whalley (2000) found that SM caused rapid, significant decreases in immunodetection of keratins 5 and 14, an intermediate filament pair found in undifferentiated keratinocytes (Werrlein and Madren-Whalley, 2000). In both *in vivo* (Gunhan et al., 2004) and *in vitro* studies with human keratinocytes (Dillman et al., 2003), and with purified proteins (Hess and FitzGerald, 2007), keratins 5 and 14 have been found to be alkylated by SM as well as nitrogen mustard (mechlorethamine, HN2) and 2-CEES, the monofunctional analog of SM. Sites of alkylation may be similar to dominantly acting mutations in keratins 5 and 14 that are known to be responsible for the human blistering disorder, EB simplex, in which, like SM-induced blistering, basal epidermal cells are targeted (Fuchs, 1997). The keratin cytoskeleton of basal keratinocytes links to the hemidesmosome and makes connections, through plectin, with the β4 cytoplasmic tail of integrin α6β4, thereby strengthening adhesion to the basement membrane via laminin-332 (Giancotti and Tarone, 2003). Alkylation of keratins 5 and 14 could cause aggregation and loss of function of the intermediate filament network and serve as a prelude to basal cell separation from the basement membrane.

In addition to its actions on epidermal cells, SM can directly alkylate extracellular matrix proteins in the skin, a process that can also alter the ability of basal keratinocytes to maintain vital connections with the basement membrane. In support of this idea, Gentilhomme et al. (1998) showed that SM treatment of human dermal equivalents reduced the ability of naïve keratinocytes to deposit laminin at the dermal–epidermal interface (Gentilhomme et al., 1998). In addition, Zhang et al. (1995a,b) found that treatment of fibronectin and laminin with SM interfered with the ability of human epidermal keratinocytes to adhere to these matrix proteins (Zhang et al., 1995a,b). This inhibitory action was determined to be alkylation-dependent, because it could be prevented by co-treatment with SM scavengers. SM and nitrogen mustard also reduce cell and tissue immunoreactivity for laminin-332, as well as integrin α6β4 and collagen XVII (also known as bullous pemphigoid antigen), two hemidesmosomal components that are critical for keratinocyte adherence (Smith et al., 1997a,b,c, 1998; Zhang and Monteiro-Riviere, 1997; Werrlein and Madren-Whalley, 2000; Kan et al., 2003). Interestingly, each of these proteins, like keratins, has been implicated in human blistering disorders involving separation of the epidermis at the dermal–epidermal junction (Pulkkinen and Uitto, 1998; Yancey, 2005). These findings suggest that SM can alter the interaction of basal cells with matrix proteins critical for basement membrane detachment. The alteration may occur by reducing protein functionality, decreasing

protein expression, or increasing protein degradation. By whichever mechanism, a negative alteration in these critical anchoring components could lead to basal cell detachment and initiate anoikis.

Signal Transduction Pathways

SM exposure induces the activation of many molecular signaling pathways (reviewed in Ruff and Dillman, 2007). These pathways mediate many responses including inflammation, cell proliferation, cell differentiation, and apoptosis. Some that involve inflammation include the transcription factor NF-κB and the p38 MAP kinase. NF-κB is a transcription factor that is induced within 2–4 h after SM exposure (Minsavage and Dillman, 2007). Dillman has suggested that this delayed induction is due to a nontraditional pathway of stimulation, whereby p90RSK phosphorylates IκB or the p65 subunit of NF-κB (Ruff and Dillman, 2007). The MAP kinase p38 is activated in response to damaging stimuli, including heat, UVA, and pro-inflammatory stimuli. Dillman's group and others have noted an increase in activation of p38 by phosphorylation and demonstrated that inhibition of p38 phosphorylation resulted in a decrease in SM-induced pro-inflammatory cytokine production *in vitro* (Kehe et al., 2009). However, the importance of NF-κB or p38 activation in mediating SM cutaneous injury has not been demonstrated *in vivo*. Also, although important for understanding SM-mediated toxicity, these pathways are difficult to target pharmacologically.

MODELS OF DERMAL SM EXPOSURE

Introduction

Although there has been considerable investigation of SM therapies since the publication of Bruno Papirmeister's landmark compilation of *Medical Defense Against Mustard Gas* nearly 25 years ago, no suitable treatment for SM exposure to the skin has been developed (Papirmeister et al., 1991c). Since that time, there has been an increased focus on civilian research as the perceived risk of a terrorist-driven exposure to civilian populations has been recognized. The field has dramatically changed direction from strategies and therapies based on protection from SM exposure to therapies designed to subvert the blistering process and increase the rate of wound healing. New pharmaceutical strategies will be increasingly focused on combination therapies that target multiple processes in blister formation and the wound healing process, together with increased recognition of the importance of pharmaceutics.

Although many advances have been made in the production of skin barrier protection or postexposure skin decontaminants (such as skin exposure reduction paste against chemical warfare agents and reactive skin decontamination lotion (RSDL), respectively), drug countermeasures against vesicants remain a subject of intense investigation. The primary treatment strategy after exposure to vesicants such as mustard gas is decontamination. However, given the high reactivity of SM, there is a very short timeframe (3–5 min) in which decontamination can be effectively accomplished (reviewed in Vogt et al., 1984; Wormser, 1991); and some studies suggest that an extractable reservoir persists for much longer. Furthermore, because SM exposure does not cause immediate pain or noticeable effects, exposure is often not recognized until the effective window for decontamination has passed. Therefore, much research has focused on the identification of treatments that can be performed after exposure has occurred. These treatments can be directed at any stage during the progression of injury resulting from vesicant exposure, including before or after blister formation. This chapter focuses on the progress that has occurred since Papirmeister's publications (Papirmeister et al., 1991a,b).

Model Systems for Screening SM

The lack of definitive *in vitro* and *in vivo* models for SM skin injury provides an ongoing challenge. No animal model has produced a macroblister like that known to occur in humans and the major clinical target for SM treatments (extensively reviewed in Papirmeister et al., 1991c). Furthermore, experimental animal models have different skin characteristics, including a reduced barrier for chemical penetration as compared with human skin (Bartek et al., 1972). The reduced barrier results in greater systemic toxicity in animals, complicating other measures of cutaneous injury. Despite these difficulties, animal models have displayed great utility, and surrogate endpoints such as microblister (epidermal–dermal separation) formation or edema are acceptable biomarkers for measuring efficacy of candidate compounds.

A systematic characterization of animal models including the euthymic HGP, WP, the MEVM, and the hairless mouse showed that SM-induced subepidermal blister formation and epidermal cell death in all models tested (Smith et al., 1997a,b,c). Hairless mice are useful models of human skin; the absence of hair on the skin and increased skin thickness reduce the rapid penetration of toxicants (Walter and DeQuoy, 1980). Thus, the hairless mouse has emerged as an effective model for characterizing vesicant injury mechanisms and for early screening of candidate therapeutics (Blank et al., 2000; Casillas et al., 2000a,b; Ricketts et al., 2000; Sabourin et al., 2003; Pal et al., 2009; Tewari-Singh et al., 2009, 2010, 2011, 2012, 2013, 2014; Anumolu et al., 2011; Dorandeu et al., 2011; Jain et al., 2011; Vallet et al., 2012).

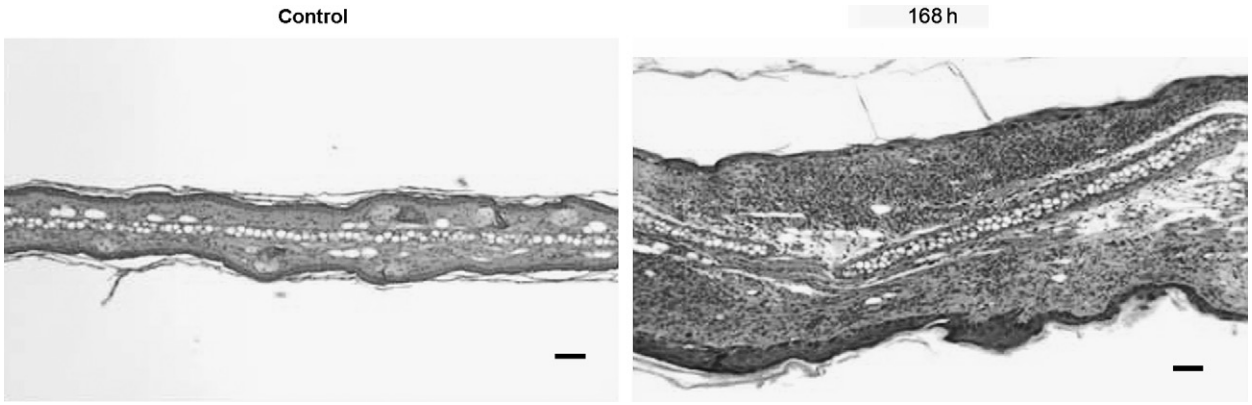

FIGURE 39.4 Biphasic inflammatory response in the MEVM: hematoxylin and eosin–stained paraffin sections of mouse ears with (right, 168 h after exposure) and without (left, carrier solvent, alone). Note the edema in the treated ear. The sample at 168 h after SM had a very large inflammatory cell infiltration.

First characterized in 1967, the HGP has been the most widely used model for vesicant exposure (Marlow et al., 1990a,b; Mershon et al., 1990; Yourick et al., 1991, 1992, 1993, 1995; Cowan et al., 1993, 1994; Graham et al., 1994; Smith et al., 1995; Kim et al., 1996; Kam et al., 1997; Millard et al., 1997; Dachir et al., 2010; Benson et al., 2011). Like human skin, SM-treated HGP experience defects in epithelial cell regeneration, basement membrane modifications, and increased necrosis and apoptosis, making them a good model for therapeutic testing (Kan et al., 2003; Dachir et al., 2006). There is one report utilizing the rabbit ear as a model of SM injury; however, we know of no reports further developing this model to screen candidate antivesicants (Zlotogorski et al., 1997).

The MEVM is performed by application of vesicant to the inner (medial) side of the ear (Casillas et al., 1997). Edema can be quantified by measuring 8-mm-diameter ear punch biopsy weights. Microscopic investigation shows clear histopathologic changes that include edema, epidermal–dermal separation, and necrosis. These effects occur in a dose-dependent manner (Figure 39.4). This model has been used to screen many compounds and remains the most cost-effective live animal screen available (Casillas et al., 2000a,b; Dachir et al., 2002, 2004a,b; Babin et al., 2003; Casbohm et al., 2004; Sabourin et al., 2004; Wormser et al., 2004a,b, 2005; Kiser et al., 2005; Amitai et al., 2006; Dillman et al., 2006). Furthermore, the benefits of a fully sequenced mouse genome and wide range of antibodies available make this model superior. Systemic effects do occur, as physiological and toxicological effects are detected in the contralateral (untreated) ear of animals (Babin et al., 2000).

WP and minipigs have also been used extensively for SM-induced skin injury (Lindsay and Rice, 1995; Brown and Rice, 1997; Graham et al., 1999; Chilcott et al., 2000; Graham et al., 2000a,b; Logan et al., 2000) (Figure 39.5) due to established similarities between human and pig skin (Graham et al., 2005). Erythema was found to peak at 24 h after a 15 min vapor exposure, with maximal edema occurring at 48 h after exposure (Smith et al., 1996, 1997a,b,c; Graham et al., 1999). The dermal–epidermal junction was also damaged at 48 h, with laminin 5 (renamed laminin 332) showing a progressive decrease in protein expression after SM injury (Smith et al., 1997a,b,c). Furthermore, inflammatory markers including IL-8, IL-6, IL-1β, and MMP-9 are induced within 72 h of treatment with SM (Sabourin et al., 2002). The WP is also used as a model of wound debridement to enhance repair (Graham et al., 2002a,b, 2006; Reid et al., 2007; Dalton et al., 2008), as discussed in greater detail later in this chapter.

The isolated perfused porcine skin flap (IPPSF) model is an effective *in vitro* model for SM exposure, characterized extensively by Monteiro-Riviere's laboratory (King and Monteiro-Riviere, 1990). Skin flaps consist of isolated, perfused skin with intact dermis and epidermis maintained by microcirculation in a system that mimics normal blood flow. Unlike other animal models, gross blisters are obtained, with blister-induced epidermal–dermal separation occurring at the upper lamina lucida (Monteiro-Riviere and Inman, 1995, 1997; Riviere et al., 1995). This model has allowed for several interesting experiments that could not have otherwise been performed. For example, the flow rate and composition of perfusing media can be altered: higher flow rate is associated with increased blister formation, whereas increased glucose in the perfusion medium has been shown to block the formation of microvesicles and blisters (Riviere et al., 1997). Whether increased glucose can protect against blister development in live animals has not been tested. No reports using this model have been published since 2004.

In addition to cell lines, artificial human skin has been used to test the effects of SM (Petrali et al., 1993). Human

FIGURE 39.5 Gottingen minipig SM cutaneous injury 24 h after 30–120 min vapor cap exposures.

skin equivalent, commercially available as EpiDerm, is a fully differentiated artificial human skin with both a dermis and an epidermis (Monteiro-Riviere et al., 1997). Full-thickness models (EpiDerm-FT) have been evaluated for their potential use in SM models as well, in particular focusing on the dermal–epidermal junction and basement membrane components (Hayden et al., 2009). Studies by our laboratories demonstrated CEES-mediated gene induction in EpiDerm-FT and demonstrated the usefulness of this model in histological evaluation after vesicant exposure (Black et al., 2010a,b, 2011). EpiDerm-FT might also be used as an *in vitro* assay for screening of potential medical countermeasures against vesicants, such as was performed with liposome-encapsulated GSH (Paromov et al., 2011).

Decontamination

If accomplished early, skin decontamination can be an effective means of reducing injury from SM exposure (Sidell et al., 1997). Most SM decontamination strategies focus on its removal with solvents or adsorption of SM to inert substances. Even simple techniques such as washing with soap and water are surprisingly effective (Aasted et al., 1987). Washing with many other substances has been suggested, including kerosene, oil, gasoline, surgical spirits, and neutral sodium hypochlorite (Sollmann, 1919a,b; Chiesman, 1944; Jelenko, 1974; Gold et al., 1994; Wormser et al., 2002). Exposure to mustard liquid can also be treated with the use of binding agents, of which Fuller's earth is the best example. Fuller's earth is clay-rich soil commonly used to purify hydrophobic materials, including oils and greases (Chilcott et al., 2001). In SM injury, it is thought to function by binding in a near-irreversible manner to SM, preventing its absorption, association, and reaction with skin components. Fuller's earth is the standard to which other decontamination agents are tested; modifications of this compound and other related clay-like materials may be more efficacious (Lyle et al., 1984, 1986, 1987; Joiner et al., 1987). However, it is difficult to contain and uncomfortable to apply. Other items, including flour and talcum powder, were shown to be effective in reducing the progression of injury (Van Hooidonk et al., 1983). However, decontamination is ineffective in cases of vapor exposures to SM, which occur over a longer time period (McNamara, 1960). These results suggest that nearly anything that could adsorb a hydrophobic product would be effective in reducing SM injury.

Another strategy for decontamination is active chemical neutralization, whereby the SM undergoes a chemical reaction to prevent its reaction with outside components. There have already been successes with this type of approach, with the best example being RSDL, a product approved for military use by the United States and a number of other nations (FDA, 2003). RSDL has been demonstrated to be as effective as Fuller's earth in its decontamination properties (Taysse et al., 2007). The first generation of this product was composed of a solution of potassium 2,3-butanedione monooximate and its free oxime, diacetyl monooxime, in a mixture of monomethyl esters of polyethylene glycol. The solvent portion of the lotion is designed to solubilize chemical weapons away from the skin, while the oxime component readily reacts with mustards and with nerve agents, producing less toxic products (Sawyer et al., 1991a,b). In domestic pigs, treatment with RSDL 5 min after exposure to SM resulted in significantly less injury observed 3 days after exposure (Taysse et al., 2007).

Other approaches to chemical neutralization include the use of sodium thiosulfate as a reducing agent to function by reacting with activated SM (Hatiboglu, 1960; Owens and Hatiboglu, 1961; Bonadonna and Karnofsky, 1965; reviewed in McKinley et al., 1982). Original studies (WWI–1970) focused on its use as an injectable drug to prevent the bone marrow suppression seen with exposure to SM and related mustard agents. Systemic administration of this and other antioxidant molecules such as *N*-acetyl cysteine is discussed later in this chapter.

Another thiol, 2,3-dimercapto-propane sulfonic acid, showed protection against injury in mice exposed to SM vapor (Pant et al., 2000).

Decontamination can also be accomplished by the application of creams containing fluorinated cross-linker monomers (Liu et al., 1999). Deactivation occurs when substances within the cream actively react with and decontaminate the agents. Care should be taken with administration of these creams because they can trap chemical agents on the skin and prevent natural off-gassing. This may result in enhanced injury if inadvertently applied after exposure to a chemical agent. In some cases, perfluorinated creams have caused an 18-fold reduction in the rate of skin absorption (Chilcott et al., 2002).

After exposure to SM, a significant fraction of the agent remains unreacted in the skin, in what is often described as a skin reservoir. This reservoir is thought to contribute to ongoing injury by continually releasing SM, allowing further damage to occur. Recent studies demonstrated that application of ^{14}C-labeled SM was extractable from an *in vitro* pig skin model for up to 6 h (Dalton et al., 2004; Hattersley et al., 2008). Future work might focus on targeting this reservoir to prevent ongoing damage; no therapies are currently available for this purpose. Although still present in unreacted form, it seems that SM in this reservoir cannot be removed from the skin through the methods discussed.

Treatment of Blisters

The prolonged pathology observed in SM injury suggests two pathological mechanisms: an ongoing toxicity that contributes to a stepwise progression culminating in blister formation and a healing process that has been subverted. This is quite unlike the wound healing of thermal injuries. Aspiration (removal of the fluid within the blister) and deroofing (removal of the epidermal layer that constitutes the roof of the blister) are the main courses of action taken for larger, coalesced blisters to promote the healing process reviewed in Jenner and Graham (2013).

More recently, work has focused on the use of physical debridement of tissues, the surgical removal of tissue beyond the epidermal (roof) layer, to enhance the rate of wound healing (Graham et al., 2005) (Table 39.1). The slow rate of healing suggests that SM-modified proteins or other cellular components are preventing the normal healing process (Eldad et al., 1998). SM-mediated cross-linking of structural proteins such as laminins may not be easily repaired and may contribute to a delayed wound healing response (Zhang et al., 1995b). This could occur by promoting prolonged inflammation or by preventing the normal wound closure event that occurs as dermal cells migrate across and repair the blister area. Early studies demonstrated that SM-induced lesions in the skin of WP or Yucatan miniature pigs underwent faster wound healing when treating lesions by debridement after exposure to SM, whether the debridement was performed by CO2 laser or surgically (Graham et al., 1997, 2002a; Rice et al., 2000). Furthermore, when combined with skin grafting, debridement promotes wound repair (Graham et al., 2002b; Rice, 2003). Further investigations into different types of debridement in conjunction with other therapies are underway (Evison et al., 2006; Dalton et al., 2008).

THERAPEUTICS

Antioxidants

Chemical scavengers may be used to inactivate free radical forms of SM or the oxygen or nitrogen radicals thought to be formed as a consequence of SM activation. If given early enough after SM exposure, such scavengers might directly deactivate SM and perhaps reduce the reservoir of SM present in the skin. However, scavengers seem to have efficacy beyond the lifetime of SM itself in the skin, suggesting that other physiological mechanisms such as inflammation and oxidative stress might be reduced by these agents (reviewed in Papirmeister et al., 1991c). Scavengers have mostly been tested for their ability to reduce leukopenia and death due to the systemic effects of mustard exposure, rather than the reduction of skin injury (reviewed in Papirmeister et al., 1991c). Although most work has focused on scavengers as therapeutics in pulmonary exposures in which ongoing oxidative stress contributes to toxic outcomes such as pulmonary fibrosis or chronic obstructive pulmonary disease, there has been limited research of their efficacy in treating cutaneous injury.

Sodium thiosulfate, a potent antioxidant and scavenger, has been shown to be effective in reducing leukopenia and platelet decrease when given systemically in treatment for nitrogen mustard, particularly when given before exposure (Owens and Hatiboglu, 1961; Bonadonna and Karnofsky, 1965; McKinley et al., 1982). In the IPPSF model, perfusion with sodium thiosulfate modestly reduced microvesicle formation and attenuated the vascular response (Zhang et al., 1995a,b). However, it has limited efficacy against skin injury (Vojvodic et al., 1985; Zhang et al., 1995a,b).

GSH depletion has been shown to occur in several tissues and cell lines in response to mustard treatment (Omaye et al., 1991; Ray et al., 1995; Kulkarni et al., 2006). Depletion of GSH by buthionine sulfoximine treatment of isolated human leukocytes increased their sensitivity to SM toxicity (Gross et al., 1993). Given the critical role of GSH in maintaining the intracellular reducing state of the cell, restoration or pretreatment with GSH may

TABLE 39.1 Comparison of Dermabrasion (Debridement) Strategies for Enhancing the Rate of SM-Induced Skin Injury Repair

Therapy	Time of administration	Agent route	Species/System	Efficacy	Reference
Reactive skin decontamination lotion (RSDL)	Pretreatment	Topical	*In vitro*, human skin	18-fold reduction in skin absorption rate, may partially extract SM from the skin reservoir	Chilcott et al. (2002)

Debridement, surgical tangential excision	48 h posttreatment	Topical, liquid, 2 h	WP	Mild improvement in healing	Graham et al. (2000a,b)
Debridement, surgical tangential excision and skin grafting	48 h posttreatment	Topical, liquid, 2 h	WP	Improved histological skin structure	Graham et al. (2000a,b)
Debridement, Versajet	48, 72, and 96 h posttreatment	Not specified	WP	No improvement at day 14	Dalton et al. (2008)
Debridement, Compound W	48, 72, and 96 h posttreatment	Not specified	WP	No improvement at day 14	Dalton et al. (2008)
Debridement, Collagenase Santyl	48, 72, and 96 h posttreatment	Not specified	WP	No improvement at day 14	Dalton et al. (2008)

WP, weanling pig.

protect against SM toxicity. Pretreatment of the basal epidermal keratinocyte cell line SVK-14, the upper respiratory tract cell line BEAS-2B, or the lower airway type II epithelial cell line A549 with GSH was shown to provide resistance to SM toxicity (Smith et al., 1997a,b,c; Andrew and Lindsay, 1998; Lindsay and Hambrook, 1998). Similar results were seen with other human cell lines, including G361, SVK-14, HaCaT, and NCTC human skin cells (Simpson and Lindsay, 2005). Also, stimulation of GSH concentration by pretreatment with GSH itself or the cysteine precursor 10 mM L-oxothiazolidine-4-carboxylate was shown to be protective against SM *in vitro* (Gross et al., 1993; Amir et al., 1998). However, these early successes did not translate effectively to animal model systems. Reduced GSH (400 mg/kg) given once before and twice after SM did not protect mice from SM toxicity (Kumar et al., 2001). Because GSH would be difficult to administer cutaneously, it is an unlikely therapeutic agent for the skin.

Cysteine is an amino acid with a reduced sulfur group that acts as an antioxidant. Cysteine residues are selectively alkylated in proteins by SM and the bifunctional nature of SM allows chemical cross-linking (Byrne et al., 1996). Early studies with nitrogen mustard in mice demonstrated that pretreatment with cysteine protected against toxicity (Contractor, 1963). However, microvesicle formation and dark basal cell formation were not protected in the IPPSF model (Zhang et al., 1995a). *N*-acetyl-L-cysteine (NAC) acts both as a scavenger and as an inducer of GSH synthesis, restoring the normal reducing status of the cell. Because SM lowers intracellular-reduced GSH, its restoration may contribute to increased tissue survival and repair. In addition, pretreatment with NAC may elevate GSH levels above normal and offer protection against low concentrations of SM (Atkins et al., 2000). *In vitro*, pretreatment with NAC protected PBL from 10 μM SM (Gross et al., 1993). Endothelial cells pretreated with NAC were resistant to loss of cell adherence and rounding after exposure to 250 μM SM (Dabrowska et al., 1996). Liposomes-containing NAC increased the viability of HaCaT keratinocytes in an *in vitro* study if given simultaneously

with CEES (Paromov et al., 2008). Although antioxidants have proven to be efficacious if given before SM exposure, their ability to ameliorate skin damage or enhance wound repair has not been shown.

Silibinin is the main active flavonone of silybin, an extract of the milk thistle plant (*Silybum marianum*). Silibinin or silybin has been tested in clinical trials as a chemotherapeutic agent (Singh and Agarwal, 2005; Deep and Agarwal, 2010) for hepatitis, for diabetic nephropathy, and other indications. The compound has diverse effects, including anti-inflammatory, antioxidant, and anti-metastatic effects (Gu et al., 2007; Singh and Agarwal, 2009; Deep and Agarwal, 2010). Topical silibinin (1 mg) attenuated CEES-mediated pathology in the skin of SKH-1 mice when applied 30 min after CEES exposure, including epidermal thickness, apoptosis, induction of pro-inflammatory genes, lipid peroxidation, and DNA oxidation (Tewari-Singh et al., 2012). Future studies must analyze longer time points than 24 h to determine the effects on wound healing.

Ebselen (2-phenyl-1,2-benzisoselenazol-3(2H)-one) is an organo-selenium compound that functions as an anti-oxidant; it can directly scavenge hydrogen peroxide and peroxynitrite, mimics GSH peroxidase, and acts as an anti-inflammatory agent (Schewe, 1995). Ebselen itself reduced HN2-mediated inflammation at 24 h in the MEVM when applied in three treatments after exposure, with the first starting at 15 min. Although several ebselen derivatives are in development and have shown efficacy in *in vitro* studies in skin and lung cell lines, these have not yet been tested in animal models (Pino et al., 2013, 2014). Both ebselen and silibinin were noted to have diverse effects beyond those of antioxidants alone; future work should determine the relative importance of these functions versus their anti-oxidant properties.

Proteolytic Inhibitors

Proteases play a critical role in wound repair and remodeling, and therefore are likely important targets for the enhancement of wound repair (Mohan et al., 2002). In particular, damage to the basement membrane by MMPs is thought to be one mechanism responsible for dermal–epidermal separation seen in SM-induced blister formation. This could occur by upregulation of MMP expression, reduced competition for MMPs by adhesion molecules, or both (Mol, 1999; Danne et al., 2001; Shakarjian et al., 2006). MMP-9 expression is upregulated in WP skin (Sabourin et al., 2002) and the MEVM after SM exposure (Chang et al., 2006). Inhibition of proteases might therefore ameliorate damage caused by SM to structural components of the skin (Table 39.2). Explant cultures of SM-treated human skin co-treated with Ilomastat showed no epidermal–dermal separation (Schultz et al., 2004). SM-induced MMP-9 mRNA in the MEVM was partially inhibited by pretreatment with the MMP-9 inhibitor GM 1489 (Gerecke et al., 2005). The antibiotic doxycycline is also an MMP inhibitor that was shown to attenuate

TABLE 39.2 Summary of the Effects of Protease Inhibitors on SM Toxicity

Therapy	Time of administration	Therapy route	Therapy concentration	Agent route	Species/ system	Efficacy	Reference
Doxycycline	Co-treatment, then posttreatment	In media	500 μM	In media	HaCaT cells, *in vitro*	Reduced cellular detachment, but did not prevent apoptosis	Lindsay et al. (2007)
Doxycycline	1 h posttreatment	In media	100 μM	In media, 200 μM	HEK keratinocytes, *in vitro*	Reduction of SM-induced IL-8 production	Nicholson et al. (2004)
Doxycycline	Co-treatment	Topical	90 μM	Topical	*In vitro* human skin explants	No effect on SM-induced dermal–epidermal separation	Schultz et al. (2004)
GM 1489[a]	Pretreatment 15 min	Topical	20 μL of 25 mM	Liquid	Mouse	Reduced expression of MMP-9 mRNA	Gerecke et al. (2005)
Ilomastat	Pretreatment 15 min	Topical	20 μL of 25 mM	Liquid	Mouse	No effect	Gerecke and Sabourin (2005)

SM-induced pulmonary and ocular injury (Guignabert et al., 2005; Horwitz et al., 2014). However, doxycycline does not protect HaCaT viability; cells lose adherence and undergo apoptosis (Lindsay et al., 2007).

Microvesication of human skin *in vitro* was inhibited by treatment with MMP inhibitors such as Ilomastat, but HGP skin had no decrease in microvesication or necrosis after repeated treatments with Ilomastat (Mol and van den Berg, 2006). Mol and van den Berg suggest that this may be due to lack of delivery of the MMP inhibitor to the site of action. Although MMP inhibitors may reduce the ongoing injury caused by upregulation of MMP-9, most inhibitors have difficulty penetrating the skin. Another study demonstrated that treatment of an ex vivo human skin model with the metalloprotease inhibitor GM6001 blocked microvesication even when given 8 h after HD exposure (Mol et al., 2009). The application of pharmaceutical concepts may aid in the development of better delivery systems that would enhance the efficacy of this class of drugs.

More recent studies have suggested that MMP-9 is released by fibroblasts in response to keratinocyte stimulation by SM (Ries et al., 2008). Mustard-stimulated release of MMP-9 only occurred in coculture of human dermal fibroblasts with HaCaT keratinocytes or with culture of human dermal fibroblasts with conditioned media from HD-treated HaCaT cells, suggesting that paracrine signaling is responsible (Ries et al., 2008). Our work showed a dramatic increase in cytokine expression and activation of mediators of inflammation within 24 h after HD exposure, which may contribute to MMP-9 induction (Figure 39.6) (Gerecke et al., 2009). Together these data suggest that inhibition of fibroblast activation after vesicant exposure may also reduce MMP-9 activation and release.

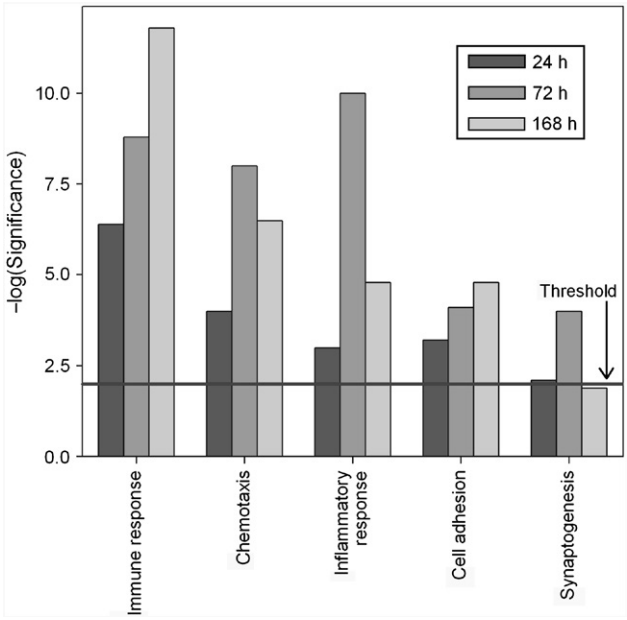

FIGURE 39.6 Results of biological processes sorting for microarray data from three different time points after SM exposure using the MEVM. The time points were 24, 72, and 168 h after exposure. The bars represent positive fold change increases over the carrier solvent alone samples. The immune response genes were within the top three biological processes activated for all the time points studied.

Steroids, Corticosteroids, and Glucocorticoids

Steroids have shown some efficacy in reducing inflammation and blister formation in response to SM or genetic blistering diseases such as bullous pemphigoid (Di Zenzo et al., 2007). Early studies showed that several types of corticosteroids were effective in reducing edema induced by SM (Dannenberg and Vogt, 1982). Glucocorticoids were shown to be effective in reducing edema in the initial phase of injury but did not affect the overall rate of healing (Vogt et al., 1984). Hydrocortisone given systemically or topically 2 h before HD administration resulted in a reduction in ear inflammation in the MEVM (Babin et al., 2000; Casillas et al., 2000a,b). Steroids given after SM exposure also enhance wound healing in a Yorkshire pig model of SM injury (Reid et al., 2008). Dexamethasone in combination with the nonsteroidal anti-inflammatory diclofenac produced more than a 60% reduction in edema in mouse ears treated with SM (Dachir, et al., 2004a,b). However, reduction of edema, although important, did not necessarily correlate with a reduction in the progression of injury, as seen later in this work. Studies using newer steroids such as clobetasol showed improved healing, lower severity of basal cell necrosis, and less inflammation (Reid, et al., 2008). Co-treatment of steroids with nonsteroidal anti-inflammatory drugs (NSAIDs) shows greater promise: co-treatment with diclofenac and tacrolimus in the HGP exposed to SM vapor showed less erythema, reduced lesion area, and fewer lesions (Dachir et al., 2008). A similar combination of steroid (Adexone) and NSAID (Voltaren) applied to mouse ears treated with SM led to reduced inflammation, less edema, reduced area of clinical damage, and reduced damage to epithelial cells (Dachir et al., 2004a,b).

Nonsteroidal Anti-Inflammatory Drugs

Several studies have demonstrated that NSAIDs administered systemically or topically offer protection against continued SM-mediated toxicity. This suggests that inflammation is a key component of SM-induced injury, as it is with other cutaneous injuries, such as those induced by UVA (Yourick et al., 1995). These results suggest that inflammation is involved in the ongoing pathology of SM-induced injury, and that anti-inflammatory drugs should be considered as part of a

drug cocktail for treatment of SM injury. Early studies with indomethacin in the HGP model showed that oral pretreatment could attenuate erythema and cutaneous injury (Yourick et al., 1995). Partial protection by indomethacin against microvesicle formation was found in the IPPSF model (Zhang et al., 1995b). Significant reductions in SM-induced early edema were found when indomethacin was administered from 24 h before exposure to 24 h after exposure (Babin et al., 2000) or when given 20 min after SM challenge (Kiser et al., 2001). Topical indomethacin given 2 h before SM exposure in the MEVM protected against early (24 h) but not late (72 h) edema (Casillas et al., 2000a,b).

Early studies using the MEVM showed that posttreatment with NSAIDs, particularly in combination with steroids, could diminish SM-induced inflammation at early time points, although later effects were not measured (Dachir et al., 2002). As mentioned, Voltaren, an NSAID, administered in combination with the steroid Adexone, reduced skin injury (Dachir et al., 2004a,b). More recently, bifunctional compounds containing NSAIDs (ibuprofen or diclofenac) tethered to pyridostigmine, an acetylcholinesterase inhibitor, were somewhat effective against SM dermal toxicity (Amitai et al., 2005). This combination was effective in the MEVM in reducing subepidermal blistering (Amitai et al., 2006). In fact, subepidermal blistering in the MEVM was reduced by these tethered pharmaceuticals (Amitai et al., 2006).

TRPV1 Ligands

An emerging hypothesis suggests a neurological component to SM toxicity in the skin. Nonmyelinated sensory C-fibers arising from the dorsal route ganglion transmit sensory information from the skin to the central nervous system in response to noxious stimuli, such as pain and heat. These fibers function as dual sensory efferents and release nociceptive and inflammatory neuropeptides such as substance P, peripherally (Szallasi and Blumberg, 1999; Szolcsanyi, 2004). Agents such as capsaicin, the active ingredient in hot peppers, produce analgesia by binding as an agonist to the transient receptor potential V1 channel (TRPV1) (Szolcsanyi, 2004). Capsaicin rapidly produces desensitization and interferes with the release of neuropeptides from sensory fibers (Campbell et al., 1993). Moreover, TRPV1 are expressed on cells in a number of nonneuronal cutaneous tissues, including keratinocytes and mast cells (Li, et al., 2007). Capsaicin and its structural analogs, known collectively as vanilloids, have been shown to have anti-inflammatory activity, as demonstrated by inhibition of edema, mast cell degranulation, and leukocyte migration (Brand et al., 1990; Bunker et al., 1991). Pretreatment of skin with vanilloids before SM exposure was shown to significantly reduce edema formation (Babin et al., 2000, 2003; Casillas et al., 2000a,b; Sabourin et al., 2003). One such vanilloid, olvanil, is a highly lipophilic analog of capsaicin and has been shown to reduce SM-induced histological damage and edema as well as cytokine and chemokine mRNA induction (Casillas et al., 2000a,b; Sabourin et al., 2003). Analogs octyl homovanillamide and heptyl isovanillamide were shown to display similar protective activities against SM (Casbohm et al., 2004). There appears to be much promise in following these leads and more closely examining the role of neurogenic inflammation and neuropeptides in the cutaneous damage induced by SM.

Cooling

Because of its high vapor pressure, exposure to SM in hot environments can exacerbate exposure. The toxicity of SM also relies on its ability to chemically react with biological molecules within the skin in a temperature-dependent manner. *In vitro* tests showed that human skin keratinocytes treated with SM and cultured at 25°C had less injury after 24 h than keratinocytes grown at 37°C (Sawyer and Risk, 1999). Similarly, HGP with skin exposed to SM had less injury after 72 h if treated for 4.5 h after exposure with cold (Sawyer and Risk, 1999). Other studies showed that anesthetized swine skin exposed to mild cooling (15°C) for 2–4 h after SM exposure had significantly less injury progression after 7 days (Sawyer et al., 2002). However, later studies demonstrated that this effect was temporary, slowing the rate of injury progression rather than reducing overall injury. Tissue and animal studies showed that temperature-mediated inhibition of injury was reversible on return of the tissue to normal body temperature (37°C). Sawyer et al. (2002) have suggested that cooling might be used as a temporary measure that "increases the therapeutic window in which other medical countermeasures are useful (Sawyer and Nelson, 2008)." Later tests with VX poisoning showed similar results, lengthening the time for entry of VX into the bloodstream (Sawyer et al., 2011). Although this work has been largely ignored by literature, cooling would be inexpensive, effective, and easily applied by first responders.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Countermeasure research to date has focused primarily on the development of therapeutics, but little attention has been given to the use of advances in drug delivery or pharmaceutics. Weak efficacy can sometimes be enhanced by the use of better delivery mechanisms. Drug delivery by encapsulation of active moieties in nanoparticles has been increasingly used for chemotherapeutic agents such as doxorubicin (Haley and Frenkel,

2008). However, with the exception of barrier creams, nanoparticle-mediated cutaneous SM detoxification has largely been limited to decontamination (Hobson, et al., 2002a,b,c; Braue and Hobson, 2005; Stengl et al., 2005; Prasad et al., 2007a,b,c; Singh et al., 2009). Most studies with creams focus on the use of nanoparticles that increase the rate of deactivation of the chemical agent (Koper et al., 1999). Liposomes used as delivery devices for hydrophilic or hydrophobic antioxidants have shown enhanced drug delivery efficacy using *in vitro* models (Paromov et al., 2011). NAC-containing liposomes have been used to treat CEES-induced lung injury, suggesting that encapsulated scavengers may be effective at restoring intracellular reducing agents after SM exposure (Hoesel et al., 2008). Formulations that allow effective dermal delivery may enable the development of scavengers, antioxidants, or protease inhibitors for SM treatment. NAC-containing liposomes tested on an *in vitro* model of the skin (Epiderm) maintained cell viability if given concomitantly with SM; whether posttreatment was efficacious is unknown (Paromov et al., 2011). These studies demonstrate that advances in pharmaceutics may dramatically improve the efficacy of previously discarded therapies.

Effective management of SM-exposed patients is likely to include combination therapies that act at the same stage or at different stages of the SM injury and recovery process to enhance overall efficacy. Dermabrasion has been shown to be effective in conjunction with split-thickness wound grafting (Graham et al., 2002b). Other studies have shown increased efficacy when NSAIDs are administered in conjunction with steroids (Dachir et al., 2002, 2004a,b, 2008). It is therefore likely that several therapies with limited efficacy could have an additive or synergistic effect for enhancement of SM-mediated injury healing.

Perhaps the largest problem inhibiting the development of effective preventive and therapy-based countermeasures is our continued lack of understanding of which of the many actions of SM are critical events leading to SM injury. The major difficulty of SM is that, although a large number of biochemical pathways are altered, the identification of pathways with pharmacological significance has yet to be clearly established. Previous studies suggested that the PARP pathway, calcium mobilization, and intracellular pH are affected in SM-mediated injury, but therapies designed against these pathways have not demonstrated effectiveness beyond *in vitro* approaches or have not shown feasibility for development as drugs. It is likely that these pathways, although important, are not the initiating events of toxicity, and therefore targeting these pathways might have limited effectiveness. Only anti-inflammatory drugs seem to be moderately effective in the treatment of SM injury. If SM is to be effectively treated, then more research into the basic mechanisms of SM injury needs to be performed. As Brimfield suggests, "the search for the primary biochemical lesion is still underway (Brimfield, 2004)." Given the complex progression of SM injury, multiple interventions used in combination against various components of the progression of injury are likely to be required to deliver the best result.

Skeletal Muscle

Ramesh C. Gupta, Snjezana Zaja-Milatovic, Wolf-D. Dettbarn and Jitendra K. Malik

INTRODUCTION

The skeletal muscles account for about half of a mammal's body weight, and as a result, they receive proportionately large amounts of administered doses of chemicals. Skeletal muscle is a target organ for a variety of chemicals and adverse or toxic effects can range from minor muscle weakness or slight pain to complete paralysis. Skeletal muscles present major targets for the toxicity of organophosphate (OP) nerve agents, exceeded only by the brain. Morbidity and mortality associated with OP intoxication occurs due to the effects of these compounds on skeletal muscles in general and the muscles of respiration in particular. Deaths from overdose of OPs are due in part to respiratory paralysis following depolarization of the neuromuscular blockade. Understanding the skeletal muscle system in the context of OP poisoning is essential, but it is also very complex because different fiber types of muscles often respond differently, even to the same OP compound. The distinct features of slow and fast muscles are the most fascinating research aspects of skeletal muscles.

Skeletal muscles are enriched with both cholinergic and noncholinergic elements that are directly or indirectly modulated by OP nerve agents. Motor innervation plays an important role in the regulation of many properties of skeletal muscles, including neuromuscular activity. Changes in the activities of acetylcholinesterase (AChE) and choline acetyltransferase (ChAT) appear to greatly modulate neuromuscular activity and can modify neuromuscular transmission. At the cholinergic synapse, AChE plays an important role in the removal of acetylcholine (ACh) from the synaptic cleft. Inhibition of this enzyme by compounds such as OP nerve agents profoundly modifies neuromuscular transmission, as seen in twitch potentiation, fasciculation, muscular weakness, and muscle cell death by necrosis or apoptosis. Because of their high metabolism, skeletal muscles are very vulnerable to OP-induced oxidative/nitrosative stress due to excess free radical generation. In the past two decades, interest in skeletal muscles has been rising because of their involvement in intermediate syndrome (IMS) and tolerance development related to the toxicity of OP pesticides. OP-induced effects on skeletal muscles can occur at one or multiple sites (the nerve fiber, the nerve terminal, the junctional cleft, the motor endplate, and the myofibrils). This chapter describes structural and functional aspects of skeletal muscles in the context of OP nerve agents' toxicity.

BEHAVIORAL EFFECTS

In general, exposure to sublethal sign-producing doses of an OP nerve agent exerts prominent motor, behavioral, and autonomic symptoms. The motor symptoms are fasciculations, fibrillations, and body tremors. Fasciculations and fibrillations occur due to antidromic neural discharge from excess junctional ACh, while tremors are of a central origin (Gupta et al., 1986; Misulis et al., 1987). OP-induced behavioral studies indicate that different nerve agents [e.g., soman, sarin, tabun, and *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX)] require different concentrations to produce equitoxic effects, degree of AChE inhibition, and myonecrosis. Acute symptoms of equal severity in male Sprague-Dawley rats by soman, sarin, tabun, and VX can be achieved at doses of 100, 110, 200, and 12 μg/kg, administered subcutaneously (s.c.), respectively (Gupta et al., 1987a,b, 1991). Based on the equitoxic doses, VX is the most toxic and tabun is the least toxic OP nerve agent.

Rats receiving an acute dose of soman (100 μg/kg, s.c.) exhibit symptoms of toxicity, such as salivation, muscle fasciculations, and severe tremors, within 5–15 min. Within 20–30 min, signs of toxicity are maximal and can

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00040-3

persist for 4–6 h. Thereafter, the intensity is reduced to a mild form, but the signs of toxicity can still be observed after 24 h. Rats usually become free of overt signs after 72 h. With VX, onset of symptoms and appearance of maximal severity are delayed by approximately 20 min compared to other nerve agents (Gupta et al., 1987a,b, 1991). During peak toxicity of soman, signs such as complex posturing movements and tremors are indicative of pronounced CNS effects compared to moderate peripheral muscle fasciculations. Muscle fasciculations superimposed upon this activity are less prominent than the signs of gross motor unit activity. This is in contrast to the OP compound diisopropylphosphorofluoridate (DFP), which exerts greater peripheral activity with fasciculations and fewer central toxicity signs (Gupta et al., 1985, 1986, 1987a,b). This suggests that AChE inhibitors differ in their propensity to produce central or peripheral effects and that peripheral effects are required for muscle necrosis (Gupta et al., 1985, 1986, 1987a,b; Misulis et al., 1987).

CHOLINERGIC SYSTEM

Key elements of the cholinergic system include a neurotransmitter, ACh; an enzyme, AChE, which hydrolyzes ACh; and an enzyme, ChAT, which synthesizes ACh. All skeletal muscles contain these cholinergic components, but their quantities can significantly vary from muscle to muscle; i.e., fast fiber-containing muscle has greater values than slow fiber-or mixed fiber-containing muscle.

Normal Activity of AChE and its Molecular Forms

Muscle AChE (E.C. 3.1.1.7) is partly concentrated in the endplate region; i.e., 20–40% of the total amount found in the whole muscle (Hall, 1973; Younkin et al., 1982). Using a histochemical technique, Müntener and Zenker (1986) demonstrated the presence of AChE in the sarcoplasm of limited areas in sections of normal rat muscles. Normal activity of AChE varies from muscle to muscle; i.e., higher AChE activity is found in fast fibers (type II fibers in general, and type IIB fibers in particular) than in slow fibers (type I fiber) containing muscle. Enzyme activity in mixed fiber muscle is found in between the values of slow and fast muscles (Table 40.1). AChE plays an essential role in the removal of ACh at the neuromuscular junction (NMJ). Inhibition of AChE activity, which results in accumulation of ACh, profoundly modifies neuromuscular transmission by producing fasciculations and twitch potentiation. At high rates of stimulation, the muscle is unable to maintain a normal contraction, and muscle hyperactivity often ensues in muscle fiber necrosis.

TABLE 40.1 Normal Values of AChE and BuChE Activity in Rat Skeletal Muscles

Muscle	AChE Activity (μmol Substrate/g/h)	BuChE Activity (μmol Substrate/g/h)
EDL (fast fiber muscle)	105.8 ± 1.0	9.7 ± 0.8
Soleus (slow fiber muscle)	60.1 ± 1.2	10.3 ± 0.3
Diaphragm (mixed fiber muscle)	78.3 ± 1.6	10.2 ± 0.2

The substrates used were acetylthiocholine iodide and butyrylthiocholine iodide for AChE and BuChE activity, respectively. Each value represents mean ± SEM (n=5–6).

It is well established that AChE exists in nerves and muscles in a range of globular and asymmetric molecular forms. A wide variety of sedimentation profiles have been established for AChE molecular forms in different mammalian muscles (Massoulie and Bon, 1982). The variations seen in the ratios of these molecular forms between different muscles are wide and complex. Qualitative and quantitative variations exist among different species, as well as the young versus adults (Barnard et al., 1984). In the rat extensor digitorum longus (EDL, a fast-twitch muscle), the G_1 (4S), G_4 (10S), and A_{12} (16S) molecular forms are predominant, while in the soleus (SOL, a slow-twitch muscle) and diaphragm (a mixed muscle), a fourth major molecular form is also present, called the A_8 (12S). In rat SOL, the majority of the total AChE activity is contributed by the 12S and 16S forms, whereas in the diaphragm, it is 4S and 10S, and in the EDL, it is 4S (Grosswald and Dettbarn, 1983a,b; Patterson et al., 1987) (Table 40.2).

In the rat, the 16S form is found in high concentrations at the endplates, and it is thought to be involved in neuromuscular transmission. The different molecular forms of AChE in SOL and EDL have apparent K_m values similar to that found in the diaphragm muscle (Grosswald and Dettbarn, 1983a,b). There appears to be no difference between catalytic sites of the molecular forms of AChE in fast-EDL and slow-SOL muscles, despite the different molecular form patterns and activity in these muscles.

Inhibition of AChE and its Molecular Forms by Nerve Agents

In general, following an acute exposure to OP nerve agents, signs of cholinergic toxicity appear within a few minutes and are caused by irreversible inhibition of AChE activity in neuronal tissues. Inhibition of AChE causes excess accumulation of ACh at central and peripheral synaptic sites, leading to failure of neuromuscular,

TABLE 40.2 Total AChE Activity and Percent Contribution of Molecular Forms to Total AChE Activity in Rat Skeletal Muscles

			Molecular Forms			
		Total Activity	A_{12} (16S)	A_8 (12S)	G_4 (10S)	G_1 (4S)
EDL	w/ PI	93.8 ± 7.5	18.7 ± 1.8	–	26.4 ± 3.5	54.9 ± 4.1
	w/o PI	102.9 ± 4.7	18.7 ± 1.6	–	30.2 ± 2.8	51.1 ± 3.1
Soleus	w/ PI	53.6 ± 4.7	26.8 ± 1.9	33.7 ± 2.3	15.2 ± 1.0	24.3 ± 0.9
	w/o PI	61.4 ± 5.3	25.9 ± 2.2	33.0 ± 2.2	16.3 ± 1.3	24.8 ± 1.4
Diaphragm	w/ PI	81.4 ± 6.1	26.9 ± 1.4	14.2 ± 0.9	28.8 ± 0.3	30.1 ± 1.7
	w/o PI	89.5 ± 4.9	24.6 ± 1.8	14.8 ± 0.9	29.7 ± 1.7	30.9 ± 1.5

Activity values are expressed as μmol ACh hydrolyzed/g/h tissue for total activity and as a percentage of the total distribution for molecular forms. Values are the mean ± SD (n=6–8 muscles); w/ PI, protease inhibitors present; w/o PI, protease inhibitors absent. No statistical significance was found comparing the presence versus absence of protease inhibitors for values of the individual molecular forms or total activities.

respiratory, and cardiovascular functions. For some OP compounds, a close relationship exists between the severity of toxic signs and the inhibition of AChE during the acute phase of intoxication. The observable toxic effects usually do not persist for more than 4–6 h, while recovery of AChE activity occurs at a much slower rate, such as 7–14 days or even 3–4 weeks, depending on the tissue and the inhibitor.

Gupta et al. (1987a) demonstrated that selective inhibition of AChE activity in skeletal muscles was apparent within 1 h of soman administration (100 μg/kg, s.c.) in rats when SOL showed the maximum inhibition (87%), whereas EDL showed the least inhibition (47%). AChE activity in skeletal muscles was maximally depressed during the following 3–6 h, the time when animals showed severe signs of toxicity. Recovery was clearly apparent during the next 3–7 days in all three skeletal muscles (SOL, EDL, and diaphragm); 7 days after soman treatment, enzyme recovery was greater than 90% in EDL and diaphragm compared to 75% in SOL. Within 1 h, all molecular forms of AChE were reduced to less than 10% of control in SOL and diaphragm (Figure 40.1). In EDL, the 16S form, mainly localized at the NMJ, was not affected at this time, while the 10S form was completely inhibited and the 4S form was reduced to 50%. Further inhibition was seen after 24 h but even then the 16S form was the least inhibited in EDL. After 3 days of soman treatment, the AChE molecular forms in all three muscles showed signs of recovery. This was particularly evident in the 16S form in EDL and diaphragm where it appeared to be approximately 75% of controls. In the SOL, the 16S form had recovered to only about one-third of the control when measured after 3 days; 7 days after soman, the 16 and 4S forms in the EDL and diaphragm had fully recovered. The activities of the 10S EDL form and the 10 and 12S diaphragm forms were still reduced, while in the SOL the activity of all forms remained below the control.

In similar experiments, tabun (200 μg/kg, s.c.) produced differential AChE inhibition in various skeletal muscles (SOL = diaphragm > EDL), which was similar to that seen with soman (Gupta et al., 1987a,b). The varying degrees of AChE inhibition in the skeletal muscles treated with tabun, however, correlated well with the observed difference in the number of myonecrotic lesions; i.e., the greater the AChE inhibition (during the initial 24 h period), the higher the number of lesions found in the diaphragm and SOL. EDL, with a low level of AChE inactivation, had the smallest number of lesions. This observation was in agreement with a similar pattern of histochemical observations following soman and sarin administration (Meshul et al., 1985; Gupta et al., 1987a, 1991). The reason for this difference in susceptibility to a particular nerve agent may be due to (i) variations in location of AChE in different muscles (Grosswald and Dettbarn, 1983a), (ii) changes in ACh release due to a different firing pattern (Misulis et al., 1987), and (iii) pharmacokinetic variables, which influence the delivery of a particular OP compound. With tabun toxicity, inhibition and recovery of AChE molecular forms, especially the 16S form associated with the NMJ (endplate region), corresponded well with the appearance and disappearance of necrotic lesions. The delay in the molecular form's return to normal is due to the fact that the heavier molecular forms (16, 12, and 10S) are based on an assembly of the monomeric 4S form. Synthesis of the 4S form increases when the assembly of the heavier forms lags behind.

Following an acute exposure to sarin (110 μg/kg, s.c.), AChE activity in skeletal muscles was reduced to 23% in SOL and 48% in diaphragm within 1 h, while EDL AChE was significantly unaffected. By 24 h, however, a still-greater inhibition was seen for these muscles, and in EDL, AChE activity was reduced to 43%. In an early phase, recovery of AChE was rapid, but still not complete

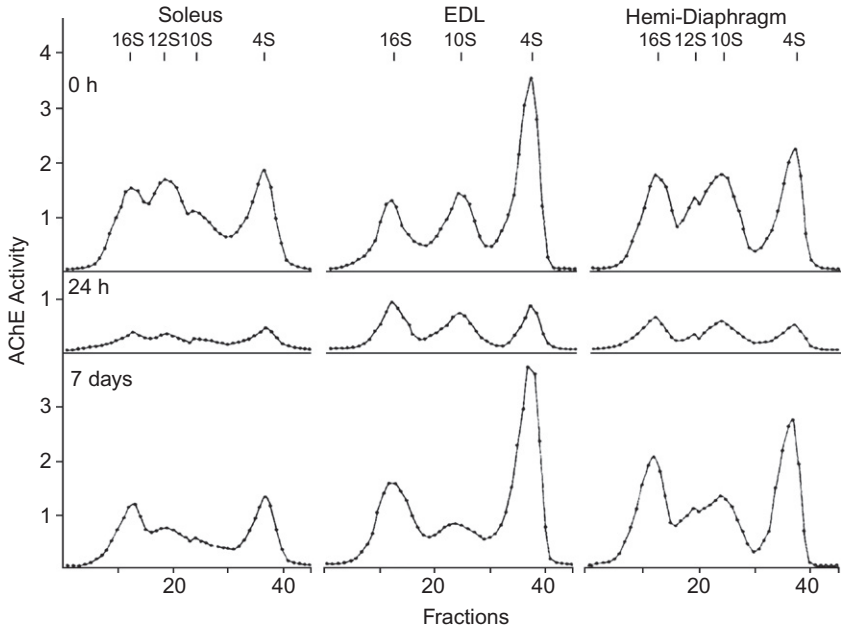

FIGURE 40.1 Representative profiles of the activity of the AChE molecular forms in the SOL, EDL, and hemidiaphragm muscles. Profiles at the top of each column are from untreated muscles, followed by profiles of activity of AChE molecular forms of muscles 24 h and 7 days after receiving an acute dose of soman (100 μg/kg, s.c.). The AChE activity scale is in arbitrary units based on the μmole substrate hydrolyzed/min by the enzyme activity in each fraction. The sedimentation values of the AChE molecular forms are given in the profiles of untreated muscles above the associated peaks. Sedimentation values were determined by the location of the added sedimentation standards, β-galactosidase (16.0 S), catalase (11.1 S), and alkaline phosphatase (6.1 S), following velocity sedimentation of the gradients.

when measured after 7 days of treatment. Activities of the AChE molecular forms, after 1 h of sarin injection, were significantly depressed in the SOL and diaphragm, while those in the EDL showed significant inhibition only after 24 h (Figure 40.2). By day 7 in SOL, activities of the 4 and 10 S molecular forms of AChE had recovered to higher than control levels, while in the diaphragm, a significant shift toward the 4 S molecular form had taken place so that the AChE profile resembled that of a control EDL. In EDL, the activity of 4 and 16 S molecular forms recovered at a faster rate than the 10 S molecular form.

Following VX administration (12 μg/kg, s.c.), within 1 h, AChE activity of all three skeletal muscles was reduced to between 8% and 17% of control with incomplete recovery by the end of 7 days. At the same time, VX caused significant inhibition in the activity of all molecular forms in all three muscles (Figure 40.3). In EDL, the activity of 4 and 10 S showed significant recovery 24 h later, while those of SOL and diaphragm remained inhibited. By day 7, the activity of all forms had recovered and an excess of activity was seen in the 4 S form of EDL and diaphragm, shifting the latter profile toward that of the EDL and contributing a higher protection to the total AChE activity.

Butyrylcholinesterase

Butyrylcholinesterase (BuChE, E.C. 3.1.1.8) activity in skeletal muscles is significantly lower than AChE activity (Table 40.1). Also, unlike variable AChE activity, all three muscles (SOL, EDL, and diaphragm) contain equal levels of BuChE activity. Following soman administration (100 μg/kg, s.c.) in rats, maximal inhibition of BuChE activity in skeletal muscles was observed after 24 h. At this time, SOL was greatly affected (98%), followed by the diaphragm (87%) and EDL (60%). A rapid recovery of BuChE was noticed during 48–72 h after soman treatment and enzyme activity returned to baseline values when measured after day 7 (Gupta et al., 1987a).

Tabun (200 μg/kg, s.c.) caused significant inhibition of BuChE activity within 1 h in skeletal muscles (in the SOL, EDL, and diaphragm, 14%, 50%, and 35% remaining activity, respectively), but maximal inhibition appeared after 3 h in SOL (6% remaining activity), and after 24 h in diaphragm and EDL (7% and 11% remaining activity, respectively) (Gupta et al., 1987b). Unlike AChE, the recovery rate of BuChE appeared to be rapid, as the enzyme activity in the diaphragm and EDL recovered to baseline values by day 7. At this time, SOL BuChE activity still remained significantly inhibited. After 1 h of sarin administration (110 μg/kg, s.c.), BuChE activity was significantly inhibited in the SOL and EDL (78% and 79% remaining activity, respectively), but not in diaphragm. With sarin, maximal BuChE inhibition was noted after 24 h in SOL, EDL, and diaphragm (39%, 71%, and 43% remaining activity, respectively). In similar studies, within 1 h VX (12 μg/kg, s.c.) caused significant

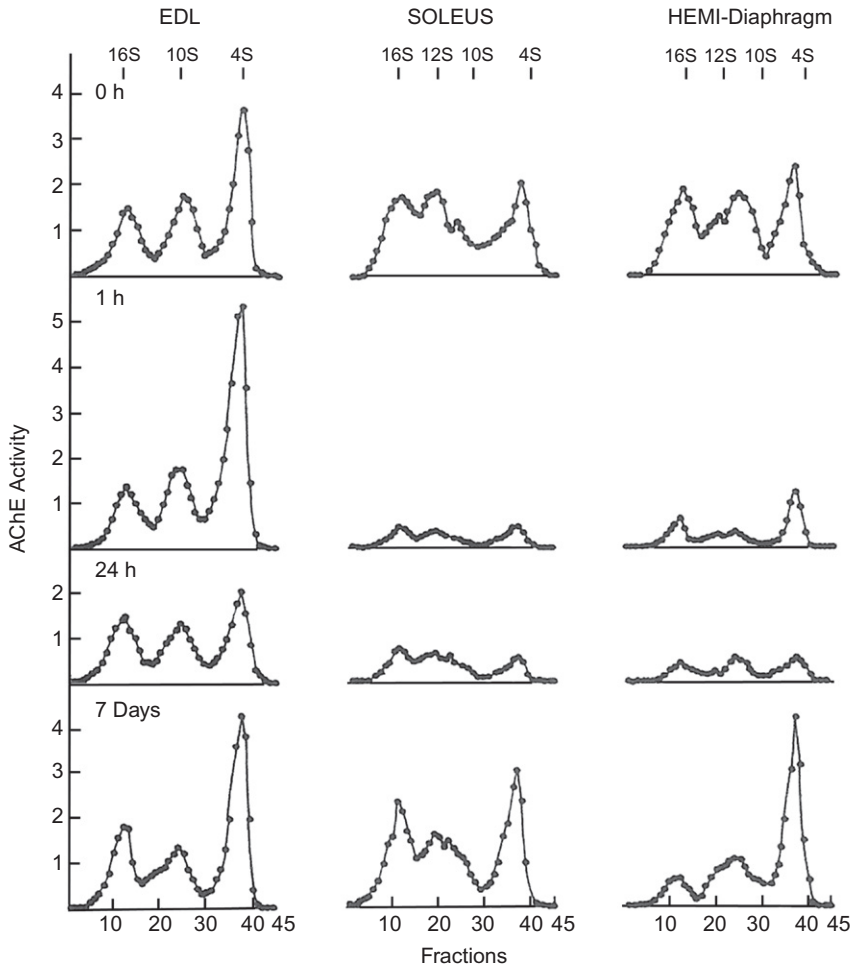

FIGURE 40.2 Representative profiles of the AChE molecular forms in the EDL, SOL, and hemidiaphragm muscles from rats following an acute sublethal injection of sarin (110 µg/kg, s.c.). Profiles at the top of each column are from untreated muscles, and subsequent profiles show the activity of the AChE molecular forms 1 h, 24 h, and 7 days, respectively, after sarin treatment. For further details, see Figure 40.1.

and maximal inhibition of BuChE in all three muscles (29%, 60%, and 60% remaining activity, respectively). When measured after 24 h, EDL and diaphragm showed marked recovery, while SOL still had 41% inhibition. All three muscles showed complete recovery of BuChE when measured after 7 days.

Choline Acetyltransferase

Existence of ChAT (acetyl-CoA-choline *O*-acetyltransferase, EC 2.3.1.6) in skeletal muscles is probably of neural origin, and its activity varies among skeletal muscles. ChAT activity can be altered by increased or decreased neuromuscular activity. It appears that neuromuscular activity exerts a regulatory influence on neuronal production of ChAT. Alterations in ChAT activity in response to variations in muscular activity represent changes in enzyme synthesis, although effects on catabolism of the enzyme or on exoplasmic transport of enzyme to the nerve terminal cannot be ruled out. Acute exposure to an OP compound DFP (1.5 mg/kg, s.c.) caused insignificant increase, while repeated administration at a low dosage (0.5 mg/kg/day for 5 days) resulted in significant increase in ChAT activity (diaphragm 140%, EDL 150%, and SOL 156%). Significant increase in ChAT activity was noted even after 2 weeks of repeated administration.

Acetylcholine Receptors

Acetylcholine receptors (AChRs) are of two types: muscarinic (mAChR) and nicotinic (nAChR) based on the agonist activities of the natural alkaloids, muscarine and nicotine, respectively. These receptors are functionally different. The muscarinic type being G protein-coupled receptors mediate a slow metabolic response via second messenger cascades, while the nicotinic type are ligand-gated ion channels, which mediate a fast

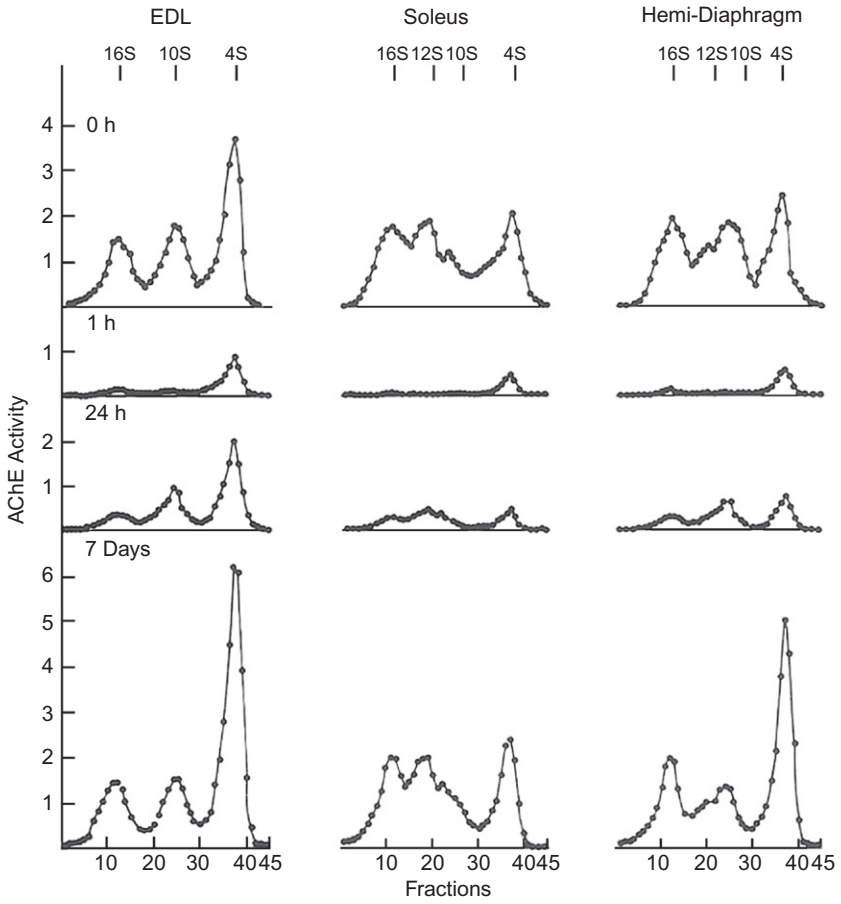

FIGURE 40.3 Representative profiles of the activity of the AChE molecular forms in the EDL, SOL, and hemidiaphragm muscles from rats following an acute, sublethal injection of VX (12 μg/kg, s.c.). For further details, see Figure 40.1.

synaptic transmission of the neurotransmitter. Skeletal muscles are enriched with nAChRs and are devoid of mAChRs.

The nAChRs, with a molecular mass of 290 kDa, are composed of five receptor subunits (α, β, δ, ε, and γ) arranged symmetrically around the central pore. Adult muscle is composed of α2βαδγ, whereas fetal muscle has α2βδε (Mishina et al., 1986). Experimental studies in the late 1970s revealed that in relatively immature muscle cells, the AChRs are distributed uniformly over the entire sarcolemma (Bevan and Steinbach, 1977). At about the time of the initial innervation, aggregations/clusters of AChRs appear, in addition to the relatively low-density receptors (Braithwaite and Harris, 1979). During the course of embryonic development, the low-density receptors disappear, and almost all AChRs in the adult muscle fibers are localized to the region of the NMJ (Fambrough, 1979). Sohal and Boydston (1982) suggested that neither the total receptor content nor the ability of the receptors to cluster seems an essential element for the formation and maintenance of the morphological aspects of the NMJs or for the growth and maturation of the muscle. It is yet to be established what exactly, if any, role nAChRs have in the formation of the NMJ.

At the mammalian NMJ, where nAChRs are localized, stimulation of the presynaptic nerve causes release of the neurotransmitter ACh from the nerve terminals. Released ACh diffuses across the gap, separating nerve and muscle cells and interacts with specific receptors associated with the postsynaptic muscle membrane to produce increased membrane permeability to some cations. When two molecules of ACh bind to an nAChR, a conformational change occurs in the receptor, resulting in the formation of an ion pore. The nAChRs are a family of cationic channels whose opening is controlled by ACh and nAChR agonists and they are the key molecules in cholinergic nicotinic transmission at the NMJ. At this site, the opening of a pore produces a rapid increase in the cellular permeability of Na^+ and K^+ ions, resulting in the depolarization and excitation of the muscle cell, thereby producing a muscular contraction. Adult vertebrate muscle fibers are highly sensitive to ACh only in the region of the NMJ. Muscle fibers of fetal and neonatal rats are also sensitive to ACh in regions outside the NMJ.

Excessive ACh or long-acting cholinomimetic agents can produce muscle paralysis due to prolonged depolarization of the endplate, a phenomenon referred to as depolarization block. Prolonged transmitter (ACh) receptor (nAChR) interactions, as a result of the high concentrations of accumulated ACh, produce a depolarization block, similar to that seen with agents such as decamethonium. Furthermore, there is a possibility of the same postjunctional area being activated repeatedly, resulting in desensitization of receptors (desensitization block). These forms of neuromuscular block usually produce muscle weakness and paralysis.

The binding site for cholinergic effectors is believed to reside primarily in the α-subunits. Evidence for this fact is based on affinity-labeling experiments in which analogs of ACh (bromoacetylcholine and 4-(-*N*-maleimidophenyl) trimethylammonium) have been shown to label only the α-subunits. Receptors also demonstrate high-affinity binding of the polypeptide α-neurotoxins, such as α-bungarotoxin (αBT), which interacts specifically and in an essentially irreversible manner with nAChRs. At the nAChRs, αBT competes for binding with both cholinergic agonists (e.g., carbamylcholine chloride and decamethonium bromide) and antagonists (e.g., curare) (Karlin, 1980). Berg et al. (1972) reported binding of αBT to AChRs in rat diaphragm muscle and found that 90% of the binding that occurred was "endplate-specific."

Some of the toxic effects of OP nerve agents and pesticides are unrelated to inhibition of AChE. However, the exact mechanism by which OP nerve agents and other anti-AChE compounds affect nAChRs is yet to be elucidated. Some of the biochemical and morphological alterations have been attributed to an excess amount of ACh in the synaptic cleft resulting from AChE inactivation. Many anti-AChE agents have been shown to produce postsynaptic morphological, biochemical, and electrophysiological alterations in adult mammalian skeletal muscle after acute and long- term treatment (Fenichel et al., 1972; Laskowski et al., 1977; Hudson et al., 1978). Normally, at the motor endplate, the small electrical nerve impulse releases the chemical transmitter ACh which diffuses across the synaptic membrane and attaches to the postsynaptic receptors on the muscle membrane. However, during AChE inhibition by OPs, unhydrolyzed ACh does not diffuse from the cleft, but repeatedly combines with postsynaptic receptors. The prolonged presence of ACh in the synaptic area appears to cause some of the myopathic changes. This was supported by observations of paraoxon, causing antidromic firing and increasing spontaneous miniature endplate potential (MEPP) frequency to 38 times the control rates (Laskowski and Dettbarn, 1971).

In an early study, Gupta et al. (1986) demonstrated that an acute exposure to DFP (1.5 mg/kg, s.c.) changed neither nAChR density (B_{max}) nor the affinity constant (K_D) in the diaphragm muscle. Subchronic DFP treatment (0.5 mg/kg/day, s.c., for 5 days) caused a marked decrease in B_{max} (56%), without significant change in K_D. Chronic treatment with anti-AChEs reduced the total number of nAChRs by 42–45% in the endplate region (Chang et al., 1973). Later studies revealed that in sublethal doses, OPs induce symptoms that cannot be solely attributed to AChE inhibition, indicating a direct interaction with postsynaptic nAChRs (Menking et al., 1990). Tattersall (1990) investigated the effects of DFP, sarin, soman, VX, and ecothiophate on the nAChR ion channel at the adult mouse muscle endplate by using single-channel recording techniques. DFP, sarin, and soman had no effect on open times at concentrations up to 100 μM, but ecothiophate and VX were found to have voltage- and concentration-dependent, open-channel blocking at concentrations of 1–50 μM. In similar experiments, Bakry et al. (1988) demonstrated that OP nerve agents and echothiophate bind to AChRs, inhibit or modulate binding of radioactive ligands to these receptors, and modify events regulated by them. The OPs also bound to allosteric sites on the nAChR (identified by inhibition of ^{3}H-phencyclidine bonding), but some bound also to the receptor's recognition site (identified by inhibition of ^{125}I-αBT binding). Soman and echothiophate in micromolar concentrations acted as partial agonists of the nAChR and induced receptor desensitization. On the other hand, VX acted as an open-channel blocker of the activated receptor and also enhanced receptor desensitization. Membrane fragments from Torpedo electric organs were used to determine these interactions using ^{3}H-phencyclidine as a probe. The results were consistent with the hypothesis that OPs bind to, and irreversibly phosphorylate, an allosteric site on the ion channel associated with the nAChR.

In the context of OP toxicities, it needs to be emphasized that for a normal muscle contraction, the ratio of AChE to nAChRs is crucial in determining the minimum AChR density. Since the AChE recovers at almost the same rate as do the AChRs, a balance of AChE to AChR is maintained over the postsynaptic surface during recovery. A relatively constant ratio of AChE to AChR is very important for maintaining normal neuromuscular function.

NONCHOLINERGIC SYSTEM

Muscle Excitotoxicity

Involvement of the cholinergic neurotransmitter ACh in muscle excitotoxicity has been known for a long time. There is also mounting evidence showing the presence of glutamatergic machinery (receptors, transporters,

and glutamate itself) at the NMJ (Pinard and Robitaille, 2008). It has been suggested that glutamate and ACh are co-released at the NMJ. Glutamate might be a mediator or modulator of neuromuscular transmission. Glutamate receptors present at the NMJ are predominantly an *N*-methyl-D-aspartate (NMDA) subtype. Furthermore, it was demonstrated in *in vivo* studies that a noncompetitive NMDA receptor (NMDAR) antagonist, known as memantine, blocks muscle fasciculations induced by AChE inhibitors (DFP, soman, sarin, tabun, and VX), suggesting an involvement of NMDARs (Gupta and Dettbarn, 1992; McLean et al., 1992). Of course, memantine exerts several additional pharmacological actions, including nAChR blockage. Unlike the well-understood role of cholinergic excitotoxicity, the role of glutamate excitotoxicity is yet to be established in AChE inhibitor-induced muscle toxicity.

Oxidative/Nitrosative Stress

Although the exact mechanism underlying skeletal muscle damage by OP nerve agent-induced hyperactivity still remains unclear, mounting evidence indicates that free radicals play an important role. During normal conditions, free radicals are generated at a low rate and subsequently taken care of by the well-developed scavenger and antioxidant systems. However, during exhaustive hyperactivity of the skeletal muscles caused by anti-ChE, excessive amounts of reactive oxygen species (ROS) and reactive nitrogen species (RNS) (hereafter referred to collectively as *ROS*) are generated and exceed the capacity of the muscle defense system, thus producing oxidative stress. Excessively generated ROS can cause muscle injury by reacting with cellular components, such as membrane phospholipids, mitochondrial enzymes/proteins and nucleic acids. Consequently, this leads to skeletal muscle cell apoptosis/necrosis, inflammation, and loss of cell viability.

A causal relationship appears to exist between excitotoxicity, ROS, lipid peroxidation, and muscle cell injury/death. One of the well-recognized targets of ROS-induced injury is peroxidation of lipids and the formation of prostaglandin F_2-like compounds, such as F_2-isoprostanes (F_2-IsoPs). Studies have shown that the assay of these compounds provides an accurate measure of lipid peroxidation (Roberts and Morrow, 2000; Dettbarn et al., 2001). Quantification of F_2-IsoPs and nitric oxide (NO) in skeletal muscles (SOL, EDL, and diaphragm) has provided strong evidence that AChE inhibitor-induced toxicity initiates lipid peroxidation and muscle cell injury (Dettbarn et al., 2001; Gupta et al., 2001a,b; Milatovic et al., 2001). Yang and Dettbarn (1998) found a significant increase of F_2-IsoPs in diaphragm muscle (156%) 1 h after DFP injection (1.7 mg/kg, s.c.), when muscle hyperactivity was maximal.

The primary reason for the increased generation of ROS appears to be a decreased rate of ATP synthesis in the mitochondria, which is related to a loss of cytochrome oxidase (COX) activity. COX is the terminal complex in the mitochondrial respiratory chain, which generates ATP by oxidative phosphorylation. During intense muscle hyperactivity, the activity of COX is reduced, leading to an increase in the electron pressure within the electron transport chain and to increased ROS production (Yang and Dettbarn, 1998). More than 90% of O_2 consumption in the cells is catalyzed by COX. The chance of intermediary products, such as superoxide anion, hydrogen peroxide, and the hydroxyl radical, escaping is small under conditions where COX remains active. A reduced capacity of this enzyme, however, increases the risk for an incomplete reduction of O_2 and further O_2 radical formation.

Xanthine oxidase (XO) is another enzyme that contributes to increased ROS generation. During normal conditions, 80–90% of native XO exists as xanthine dehydrogenase (XD), but during metabolic stress and increased Ca^{2+}, XD is converted to a reversible oxidase form. XO uses molecular O_2 instead of NAD^+ as an electron acceptor. Molecular O_2 is thereby reduced and the superoxide radical (O_2^-) is formed. During hyperactivity of the muscle by AChE inhibitors, regeneration of ATP is insufficient, not due to the lack of O_2, but due to greater utilization and impaired synthesis of ATP (Gupta et al., 1994, 2000a,b, 2001a, 2002). Unlike ischemia, O_2 is present during oxidative stress caused by prolonged contractile activity. This suggests that subsequent to the conversion of XD to XO, O_2 is continuously univalently reduced to superoxide anions. This occurs during oxidative stress when ATP utilization exceeds the rate of ATP synthesis during increased muscle activity. Yang and Dettbarn (1998) provided direct evidence for the role of COX and XO in muscle injury by its hyperactivity, showing that during DFP-induced muscle hyperactivity, a decrease in COX activity and an increase in XO activity occurred. The NAD(P)H oxidases can also be the major O_2^- generating sources in contracting skeletal muscle (Sakellariou et al., 2014). Blockage of muscle fasciculations provided prevention of these enzyme changes.

Another ROS contributing to oxidative stress is peroxynitrite ($ONOO^-$), which is formed by the reaction of NO with superoxide (O_2^-). $ONOO^-$ has the potential to modify biomolecules through several different mechanisms and is a good candidate for mediation of the NO-dependent pathophysiological process. Under normal conditions, NO is widely regarded as a multifunctional messenger/signaling molecule and is thought to have two physiological functions in skeletal muscle. The first is to promote relaxation through the cGMP pathway, and the second is to modulate muscle contractility that depends on reactive oxygen intermediates. At the NMJ,

NO appears to be a mediator of (i) early synaptic protein clustering, (ii) synaptic receptor activity and transmitter release, and (iii) downstream signaling for transcriptional control (Blottner and Luck, 2001). NO has also been demonstrated to modulate excitation–contraction coupling in the diaphragm muscle (Reid et al., 1998). Within skeletal muscle cells, all three known nitric oxide synthase (NOS) isoforms (neuronal, nNOS; endothelial, e-NOS; and inducible, iNOS) are present, but nNOS, which is Ca^{2+} dependent, seems to predominate, and is concentrated at the sarcolemma and postsynaptic surface of the NMJ (Stamler and Meissner, 2001). In a recent study, NOS has been demonstrated to play the role of mechanosensor in skeletal muscle fibers (Smith et al., 2002). Neuronal NOS in skeletal muscles is involved in the regulation of metabolism and muscle contractility. Kobzik et al. (1994) reported for the first time that the NOS activity of individual muscles could be correlated primarily with type II fibers (being highest in the EDL), while Frandsen et al. (1996) found the distribution of nNOS homogeneous.

Data presented in Table 40.3 show the levels of citrulline (determinant of NO/NOS) in skeletal muscles of control rats and those treated with an acute dose of DFP (1.5 mg/kg, s.c.). In control muscles, markedly higher citrulline levels were found in the SOL, followed by the EDL and diaphragm. The observed higher level of NO in the SOL could be due to a greater activity of NOS. Within 1 h of DFP exposure, when rats exhibited signs of peak severity and maximal reduction of AChE activity (90–96%), the levels of citrulline were maximally increased (272–288%), and remained significantly elevated in all three muscles (> twofold) when measured after 2 h. The finding of elevated NO by DFP-induced muscle hyperactivity (Gupta et al., 2002) was supported by previous studies showing that increased muscle contractility generates significantly greater quantities of ROS/RNS (Yang and Dettbarn, 1996; Clanton et al., 1999). A significant increase in NO is known to cause the inhibition of mitochondrial function and thereby appears to be the cause of the impaired synthesis of ATP.

TABLE 40.3 Citrulline Levels (nmol/g) in Skeletal Muscles of Rats after 1 h of DFP (1.5 mg/kg, s.c.) Injection

High-Energy Phosphates Depletion and Myonecrosis

Recently, interest in the role of energy metabolites (especially ATP) in chemical-induced mitochondrial/cytotoxicity has been reinvigorated, since ATP appears to be a switch to decide whether cells die from apoptosis or necrosis. Muscle necrosis is probably caused by increased contractile activity in individual muscle fibers. Calcium is believed to regulate mitochondrial oxidative phosphorylation, thereby contributing to the maintenance of cellular energy homeostasis (Glancy et al., 2013). In normal cells, the mitochondrial Ca^{2+} content is relatively low compared to that in the cytoplasm. However, abnormally high cytosolic Ca^{2+} levels (due to NMDAR activation and impaired Ca^{2+} extrusion, which is an energy-dependent process) perturb many cellular processes. The major changes include (i) reduced cytochrome-c oxidase activity, (ii) increased XO activity, (iii) mitochondrial damage due to excessive mitochondrial Ca^{2+} accumulation, (iv) reduced ATP synthesis, and (v) increased production of O_2^- and NO^-, resulting in increased $OONO^-$ formation. The extreme vesiculation and disruption of the sarcoplasmic reticulum (SR) under the endplate, as well as the swollen mitochondria may reflect Ca^{2+} overloading of the muscle Ca^{2+}-binding capacity, which could result in high sarcoplasmic Ca^{2+} levels, which in turn leads to necrosis (Salpeter et al.,1982). The control of intracellular Ca^{2+} concentration is of great importance to muscle fibers, and a transient rise leads to contraction. An increased net influence of Ca^{2+} forces the mitochondria and SR to maintain Ca^{2+} homeostasis by sequestering the excessive amounts of this ion. This is an energy-consuming process and occurs in preference to ATP formation. The ensuing lack of energy ultimately causes the free sarcoplasmic Ca^{2+} to rise and an excessive ROS formation, leading to necrosis. The energy required for muscle contraction is derived from the breakdown of ATP. As soon as ATP is broken down, it is promptly restored in the so-called Lohman reaction at the expense of phosphocreatine (PCr).

Table 40.4 presents the data of high-energy phosphates (i.e., ATP and PCr) and their metabolites in the skeletal muscle of control rats and those treated with an acute dose of DFP (1.5 mg/kg, s.c.). Analyses of control muscles revealed the levels of ATP and PCr to be higher in the EDL, followed by the diaphragm and the SOL. The values of energy charge potential (ECP = ATP + 0.5ADP/TAN) in SOL, EDL, and diaphragm were 0.86± < 0.01, 0.91± < 0.01, and 0.86± < 0.01, respectively. At the time of maximal severity (i.e., 1 h after DFP exposure), the levels of ATP, total adenine nucleotides (TAN = ATP + ADP + AMP), PCr, and total creatine compounds (TCC = PCr + Cr) were maximally reduced in all three

muscles, and they remained reduced to the same degree after 2 h. Similar results were found with soman toxicity.

AChE inhibitors cause depletion of energy-rich phosphates (ATP and PCr) due to a combination of impaired synthesis and greater utilization of ATP during muscle hyperactivity. In fact, the time course of necrosis correlates with the reduced levels of PCr, the reduction of which may have been the result of an increased demand for energy and a low rate of ADP phosphorylation, caused by an increased level of sarcoplasmic Ca^{2+}. AChE inhibitor-induced increases in NO (Table 40.3) can exert cellular toxicity primarily by depleting energy stores through multiple mechanisms: (i) by prolonging poly-(ADP-ribose) polymerase activation; (ii) by inhibiting mitochondrial enzymes, such as COX, aconitase, and creatine kinase (CK); and (iii) by inhibiting the glycolytic enzyme phosphofructokinase. NO, at nanomolar concentrations, can directly and specifically inhibit mitochondrial respiration by competing with molecular O_2 for binding to COX, thereby causing an inhibition of ATP synthesis (Brown and Cooper, 1994). Other factors that contribute to the decline of energy metabolites may include damage to mitochondria, a higher rate of ATP utilization needed to generate NAD^+ in the ADP-ribosylation of nuclear proteins, enhanced influx of sarcoplasmic Ca^{2+}, an increased number of contractile protein cross-bridges, and the release of ATP in concert with ACh from the nerve terminals. The net effect of AChE inhibitor-induced muscle hyperactivity is a reduced cellular energy level.

MUSCLE ACTIVITY—EMG

AChE inhibitors (DFP, 1.5 mg/kg, s.c.; or soman, 100 μg/kg, s.c.) at a toxic sign-producing sublethal dose elicit prominent motor, behavioral, and autonomic symptoms. As mentioned earlier, the motor symptoms are fasciculations, fibrillations, and body tremors. Fasciculations and fibrillations are due to antidromic neural discharge from excess junctional ACh, while tremors are of a central origin. Misulis et al. (1987) demonstrated a difference in the pattern of motor symptoms in rats treated with soman or DFP. Soman produces complex posturing movements and tremors affecting virtually the entire body, while DFP produces movements that are similar to fasciculations or myokymia. Muscle fiber necrosis is also more frequent at symptom-producing doses of DFP than equivalent doses of soman. This suggests that the AChE inhibitors differ in their propensity to produce central or peripheral effects and that peripheral effects are required for muscle necrosis.

Electromyographic (EMG) findings indicate that soman and DFP produce different responses (Figure 40.4). The majority of the motor symptoms induced by soman are due to impulses descending from the CNS, and a proportion of these symptoms are epileptiform activity. This activity is not generated at spinal levels. In contrast, DFP produces motor symptoms mainly by peripheral action that depends on a functioning nerve terminal (Misulis et al., 1987). Anderson (1987) also demonstrated that DFP and soman have opposite effects on skeletal muscle

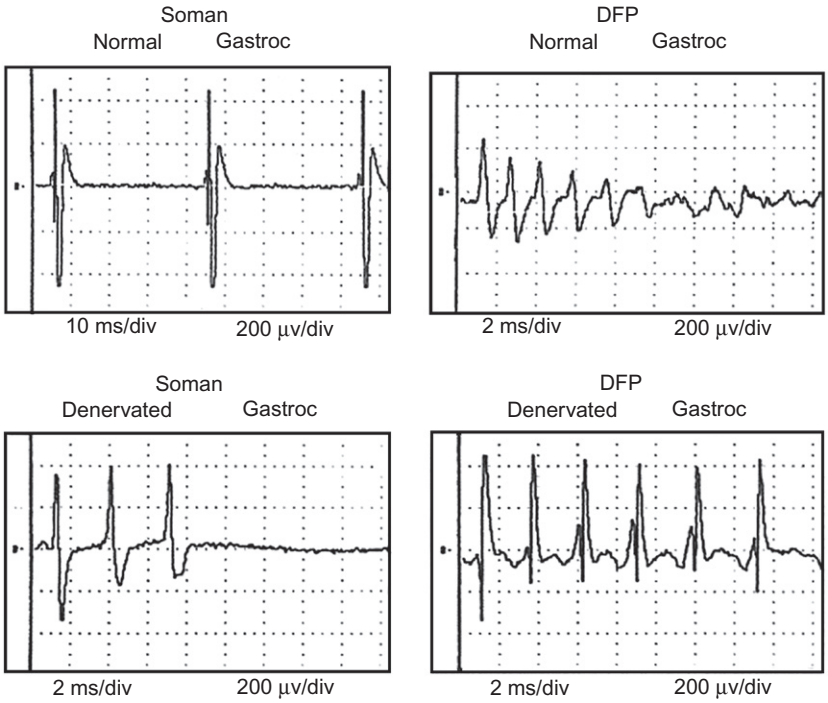

FIGURE 40.4 EMG recordings from normal and acutely denervated lateral gastrocnemius in response to soman (100 μg/kg, s.c.) or DFP (1.5 mg/kg, s.c.). Left, soman; right, DFP; top, nondenervated muscle; bottom, denervated muscle. Note the difference in time base and voltage scale. The differing morphology of the normal DFP waveform occurs due to electrode orientation and distance from the muscle fiber and does not represent a systematic difference between the effects of individual agents.

contracture during tetanic stimulation. DFP significantly decreased the ability of rat skeletal muscle to maintain a contracture. Soman, on the other hand, increased muscle force in a frequency-dependent manner. The opposite actions of DFP and soman on muscle contractility might be the consequence of a difference in effects of these two agents on postsynaptic muscle ACh receptors. The finding of Anderson (1987), which saw an increase in contracture following soman, was somewhat surprising in view of the work of Dettbarn (1984) and Gupta et al. (1987a,b), who reported that soman is as effective as other AChE inhibitors in producing muscle necrosis (Table 40.6). However, Meshul et al. (1985) reported that soman appears to spare motor endplates from structural damage and thereby may account for maintaining muscle function (Anderson, 1987). Thus, different AChEIs can produce opposite effects on muscle contracture.

MUSCLE FIBER HISTOPATHOLOGY

By using actomyosin ATPase reaction, analysis of untreated rat SOL revealed predominantly type 1 fibers with a few type 2A and 2B fibers. In contrast, EDL is composed predominantly of type 2 fibers with few type 1 fibers. The total fiber numbers are approximately 1800 in SOL and 2500 in EDL (Gupta et al., 1989).

OP pesticides and nerve agents and some carbamates in a single sublethal dose are known to cause fasciculations and induce myopathy (histopathological changes) in the diaphragm, SOL, EDL, sternomastoid, gastrocnemius, triceps, and tibialis of experimental animals. Pathological changes in skeletal muscles by AChE inhibitors are observed in the region adjacent to the motor endplate. Patterson et al. (1987) determined the necrotic lesions by assessing endplates in skeletal muscles of rats acutely intoxicated with DFP (1.5 mg/kg, s.c.). In SOL, these are found only in the midsection of the muscle, while in EDL, the endplates are found throughout the muscle length. In EDL, the fibers are innervated at different levels throughout the length of the muscle, while in SOL, the nerve makes functional contact just in the midsection. No endplates or lesions are found outside this area. Gupta et al. (1985, 1986) found the highest number of lesions in all three muscles (diaphragm, SOL, and EDL) of rats within 24–48 h after a single injection of DFP (1.5 mg/kg, s.c.), when the inhibitory effect on AChE activity was also maximal (Table 40.5). The diaphragm muscle had the highest number of lesions, followed by the EDL and SOL.

Data on soman (100 μg/kg)-, sarin (110 μg/kg)-, tabun (200 μg/kg)-, and VX (12 μg/kg)-induced pathological changes in skeletal muscles of rats are presented in Table 40.6. Following soman treatment, the number of

TABLE 40.5 Number of Necrotic Fibers Following a Single Sublethal Injection of DFP (1.5 mg/kg, s.c.)

Time After DFP Administration	Soleus		EDL		Diaphragm	
	AChE	Lesions	AChE	Lesions	AChE	Lesions
Control	100%	0	100%	0	100%	0
1 day	24%	27 ± 6[a]	17%	64 ± 11[a]	13%	308 ± 58[a]
2 day	24%	39 ± 9[a]	14%	71 ± 12[a]	13%	333 ± 63[a]

Value are means ± SEM of necrotic lesions (n=5).

necrotic fibers in the SOL and the diaphragm was found to increase for up to 24 h, and no new lesions appeared thereafter. By day 7, these two muscles appeared to have fully recovered from the soman effect. In EDL, no morphological changes were seen at any time. While the acute toxic effects of tabun are more or less similar to soman, there are also some significant differences between these two agents. Unlike soman, tabun caused prolonged AChE inhibition and progressive development of muscle necrosis over a period of 3 days. While the primary toxic effect of tabun occurs due to inhibition of AChE activity, some of the differences seen in regard to other nerve agents may be due to additional actions of the cyanide group that is released during AChE inhibition. The inhibitory effect of CN on oxidative metabolism could result in reduced *de novo* synthesis, delaying synthesis of AChE and prolonged inhibition of Ca^{2+} sequestration into the SR of skeletal muscles. Therefore, in the context of OP nerve agent-induced myopathy, soman, sarin, tabun, or VX caused the greatest number of lesions in the diaphragm,

followed by the SOL, and then in the EDL during the first 24–48 h (Gupta et al., 1987a,b, 1991). With all four OP nerve agents, the greatest number of lesions occurred in animals exhibiting severe muscle fasciculations (Gupta et al., 1986, 1987a,b, 1991; Inns et al., 1990; Bright et al., 1991). By day 7, muscles recovered from soman-induced myopathy, but not from any other nerve agents since the necrotic lesions were still evident.

The earliest lesions are focal areas of abnormality in the subjunctional section of the muscle fiber adjacent to the motor endplate, including eosinophilia and sarcoplasmic swelling (Laskowski et al., 1977; Gupta et al., 1985, 1986; Patterson et al., 1987). Mitochondria are disrupted as evidenced by clumping of highly reactive material of lactate dehydrogenase (LDH) and reduced nicotinamide adenine dinucleotide (NADH) reactions. These focal changes progress to a breakdown of subjunctional fiber architecture, loss of striations, and then phagocytosis. Longitudinal sections reveal that necrosis affects only a small segment of fiber lengths. During the latter stages, progressively greater lengths of muscle fibers are affected (Gupta et al., 1986; Patterson et al., 1987). Serial cross sections of 10 μm thickness indicate that the number of lesions correlates with the greatest density of endplates (Patterson et al., 1987). The longer the lag between injection and sacrifice, the greater the extent of the lesions. A significant increase in blood CK activity coincides with the appearance of myonecrosis, indicating destruction of the muscle membrane (Sket et al., 1989; Gupta et al., 1991, 1994).

Subjunctional changes in the muscle fibers, such as supercontraction of subjunctional sarcomeres, as well as disruption of cytoarchitectural organization, are always present (Gupta et al., 1986, 1987a,b, 1991; Inns et al., 1990; Bright et al., 1991). The initial changes are in the mitochondria which first swell and then show lysis of the central cristae. Myelin figures beneath the endplate are frequently observed, while the region more distal to the endplate is less affected. The nucleoli of the muscle cell nuclei are enlarged and move to the periphery of the nucleus. This myopathy can be induced with OP prototype DFP (Gupta et al., 1986; Misulis et al., 1987; Patterson et al., 1987, 1988; Sket et al., 1991a,b), or the OP nerve agents soman, sarin, tabun, and VX (Gupta et al., 1987a,b, 1991; Inns et al., 1990; Gupta and Dettbarn, 1992).

Laskowski et al. (1975) reported ultrastructural changes in the subsynaptic folds that were quite varied, even between muscle fibers from the same diaphragms of rats acutely treated with paraoxon. The fact that some endplates were totally degenerated after 2 days of paraoxon treatment, while others appeared almost normal even after 5 days, indicates that some endplates are more resistant than others. The most consistent change at the endplates was the presence of vesicular structures in the synaptic clefts. Some regions of the subsynaptic folds contained varying sizes of vacuoles and vesicles. There appears to be a wide variation in the severity of the lesions in the subsynaptic folds even in the same muscle. After 2 days of paraoxon treatment, the muscle surrounding the motor endplate often showed less cytoarchitectural organization than control muscles. Myelin figures beneath the endplate were frequently observed, while the region of muscle distal to the endplate was less severely affected.

Regardless of the diversity in OP structures, it is evident that induced myopathy is dose-dependent and rests on both a critical duration and degree of AChE inhibition. The higher number of necrotic lesions found with faster rates of AChE inactivation indicate the involvement of ACh in the generation of myopathy (Wecker et al., 1978a,b; Gupta et al., 1986, 1987a,b, 1991). Regardless of the OP involved, AChE inhibition of more than 80% for about 2 h is necessary to initiate severe muscle fiber necrosis. AChE inhibition resulting in an excess of ACh and its prolonged functional interactions with the nAChRs is responsible for producing lesions. However, some anticholinesterase (anti-ChEs) agents have been shown to interact directly with the nicotinic receptors (Tattersall, 1990, 1992). The OP compounds acting directly on postsynaptic membranes or on components of the muscle cell were also considered in the etiology of myopathy (Laskowski and Dettbarn, 1971). However, the prior injection of either tubocurarine or α-bungarotoxin can prevent development of the myopathy and indicates that neither the OP *per se* nor ACh by itself causes the damage; rather, the damage is due to changes from transmitter–receptor interaction. Tubocurarine and α-bungarotoxin, by occupying the postjunctional receptors, prevent the ACh from interacting with the receptor. The primary defect is at both presynaptic and postsynaptic sites. This not only supports the concept of an abnormal neurotrophism as a mechanism of myopathy, but it also allows the possibility that the primary defect is in the cholinergic system of nerve and muscle.

Evidence for the involvement of locally elevated levels of ACh was confirmed since denervation prevented myopathy or nicotinic ACh receptor blockade with α-bungarotoxin (Wecker and Dettbarn, 1976; Dettbarn, 1984). It was clearly demonstrated that transection of the phrenic nerve to the rat hemidiaphragm prevented myopathic development, while in the contralateral innervated hemidiaphragm, the number of lesions increased. Thus, the common denominator is muscle hyperactivity, such as fasciculations (Gupta et al., 1986, 1987a,b, 1991; Adler et al., 1992). The longer the muscle hyperactivity lasts, the greater the number of necrotic muscle fibers found.

There is ample evidence that ACh accumulation is involved in causing Ca^{2+} influx into skeletal muscle fibers during anti-ChE poisoning. Experiments with sarin

(25–150 µg/kg, s.c.) in mice revealed a similar role of Ca^{2+} in muscle fiber damage (Inns et al., 1990). Ca^{2+} increase was found in the diaphragm of those mice to which sarin had been administered at doses of 50 µg/kg or above. Calcium accumulation, which was confined to the region of the motor endplates, occurred earliest and remained the longest in the diaphragm from those animals receiving the highest doses of sarin. Generally, Ca^{2+} accumulation can be detected on day 1 after injection and none after day 7. This observation coincides with the duration of appearance and disappearance of muscle lesions. It was suggested that Ca^{2+} is among a series of events that ultimately lead to myonecrosis. Mitochondrial damage by excessive Ca^{2+} is expected to cause a partial or complete depletion of ATP synthesis and consequently excessive generation of oxygen- and nitrogen-free radicals and eventually myotoxicity (Gupta and Dettbarn, 1987, 1992; Gupta et al., 2001a,b, 2002). Together, following an acute exposure to an OP compound at a higher dose, a causal relationship exists between a critical level of AChE inhibition, Ca^{2+} accumulation, depletion of ATP, and appearance of muscle fiber necrosis.

Chronic exposure (30–60 days) of rats to paraoxon, at doses (0.05–0.1 mg/kg, s.c./day) that do not produce parasympathomimetic effects, led to necrosis of muscle fibers in diaphragm muscle, which was qualitatively similar to that following the administration of a single high dose of paraoxon (0.23 mg/kg, s.c.). The lesion was characterized by the presence of central nuclei, fiber splitting, and breakdown of fiber architecture followed by phagocytosis and necrosis. With either dose, AChE inhibition occurred in the endplate regions, not in the nonendplate regions (Wecker and Stouse, 1985).

MUSCLE CYTOTOXICITY BIOMARKERS

CK and CK isoenzymes

CK catalyzes the synthesis of ATP and PCr in a reversible Lohmann reaction. Table 40.7 shows the normal distribution of CK and its isoenzymes in the skeletal muscle of untreated control male Sprague-Dawley rats. The findings revealed that the fast-muscle EDL had the maximal CK activity, followed by diaphragm, with the lowest in the SOL. Electrophoretic separation of CK isoenzymes in all three muscles revealed the existence of only CK-MM isoenzyme. Further separation of CK-MM isoenzyme for subforms showed only CK-MM3 in all three muscles. Compared to muscles, serum had very little CK activity; however, the CK consisted of three distinct isoenzymes: CK-BB (15.3%), CK-MB (3.9%), and CK-MM (80.8%). Further electrophoresis of the serum CK-MM isoenzyme revealed the presence of three subforms: CK-MM1 (6.3%), CK-MM2 (24%), and CK-MM3 (69.7%) (Gupta et al., 1994). Literature abounds showing that the CK-MM3 subform secretes from muscles into the plasma, where it converts into the MM2 and MM1 subforms by carboxypeptidase-N2.

Within 1 h of exposure to carbofuran (1.5 mg/kg, s.c.), CK activity was significantly reduced in the SOL, while it increased in the diaphragm. At the same time, activities of CK and all three CK isoenzymes were significantly elevated in serum. An important finding was that carbofuran or methyl parathion caused a shift in the serum CK-MM subform; i.e., higher sequential conversions of CK-MM3 subform to CK-MM2 and CK-MM2 to CK-MM1, possibly due to enhanced carboxypeptidase-N2 activity (Gupta et al., 1994).

LDH and LDH Isoenzymes

LDH catalyzes the synthesis of lactate and pyruvate in a reversible reaction and is commonly used as a biomarker of cell damage or death. Normal distribution of LDH and its isoenzymes in skeletal muscles of rats revealed that in controls, LDH activity was found to be highest in the EDL, followed by the diaphragm, and lowest in the SOL (Table 40.8). Compared to muscles, the enzyme activity was meager in serum. Interestingly, all three muscles and serum contained all five electrophoretically

TABLE 40.7 Normal Distribution of CK and CK Isoenzymes in Skeletal Muscles and Serum of Rats

		CK Isoenzymes		
	Total CK	**CK-BB (CK-1)**	**CK-MB (CK-2)**	**CK-MM (CK-3)**
Soleus	2,062,800 ± 71,065 (100)	ND	ND	2,062,800 ± 71,065 (100)

[b]*Significant difference between EDL and diaphragm ($p<0.01$).*

distinct LDH isoenzymes, although with varying quantities. Each muscle presented a characteristic LDH isoenzyme pattern. For example, EDL contained a large proportion of LDH-5 (62.6% of total activity) and very little LDH-1 (3.5%). SOL, on the other hand, had a very small amount of LDH-5 (11.3%) and about 20% each of the other four isoenzymes (LDH-1–LDH-4). In general, values of LDH isoenzymes in diaphragm were intermediate to the EDL and soleus. Diaphragm had predominantly LDH-5 and LDH-4 (40% and 27.7%, respectively). In control serum, isoenzyme LDH-5 was 87% of the total LDH activity (100%).

Total LDH activity was significantly enhanced in EDL, diaphragm, and serum by carbofuran (1.5 mg/kg, s.c.) or methyl parathion [5 mg/kg, administered intraperitoneally (i.p.)] within 1 h of injection. Each AChE inhibitor caused marked elevation of all five isoenzymes in serum, with maximum increases in LDH-1 and LDH-4 (threefold). Unlike serum, muscle LDH isoenzymes depicted variable patterns by carbofuran or methyl parathion intoxication. A significant decline in ATP appears to be the mechanism involved in leakage of cytoplasmic/mitochondrial enzymes into circulation (Gupta et al., 1994). For further details on muscle toxicity biomarkers, see Gupta et al. (2014).

SKELETAL MUSCLE AND TOLERANCE DEVELOPMENT

Repeated application of OP nerve agents or pesticides for a prolonged period in concentrations that initially do not produce obvious symptoms of toxicity can lead to a limited degree of adaptation, as seen in a reduction of the duration and intensity of muscle fasciculations, muscle fiber necrosis, and behavioral tolerance (Wecker and Dettbarn, 1976; Gupta et al., 1985, 1986). Various cholinergic mechanisms in skeletal muscles underlying this phenomenon have been well-documented, including (i) reduced cholinergic-binding sites of muscarinic and nicotinic receptors, (ii) reduced uptake of choline, and (iii) stimulation of AChE synthesis (Gupta et al., 1985, 1986). In an *in vivo* subchronic study (DFP, 0.5 mg/kg, s.c./day for 14 days) in male rats, Gupta and Dettbarn (1986) demonstrated complete recovery of protein synthesis in skeletal muscles (the SOL, EDL, and diaphragm) during the tolerance phase (day 14) from inhibition of protein synthesis observed during the toxicity phase (day 5). Further, during the toxicity phase (day 5), inhibition of *in vivo* protein synthesis was comparable to that seen from an acute dose of DFP (1.5 mg/kg, s.c.). Additional mechanisms that may contribute to general tolerance are the availability of other serine active site enzymes, such as carboxylesterase (CarbE) and BuChE. Although the functional role of these enzymes is unknown, binding to and inhibition of these enzymes reduce the free concentration of inhibitors that otherwise would have been available to interact with AChE (Gupta et al., 1985). This is supported by studies showing that the toxicity of OPs can be potentiated by inhibition of CarbE, and tolerance to soman develops when plasma CarbEs recover during chronic exposure (Sterri et al., 1981).

A major mechanism causing adaptation to the necrotic action of DFP at the NMJ is the reduction of nAChRs (B_{max}, 56%) without significant change in affinity constant (K_D). This loss of receptors can also explain the disappearance of fasciculations that was observed between days 3 and 5 of treatment (Gupta et al., 1986). Whether presynaptic receptors regulating fasciculations are involved in this process remains to be determined. Changes in the postsynaptic receptor density could occur as an adaptation mechanism of the cell to the excessive cholinergic stimulation caused by AChE inhibition. The loss of ACh receptors may be caused by a reduction of junctional folds (Laskowski et al., 1975) on which most of the nicotinic ACh receptors are located. Changes in the ionic milieu, especially increases in Ca^{2+} caused by the increased neuromuscular activity during DFP-induced fasciculations, may be involved in the loss of secondary junctional folds. In essence, at the NMJ, the two major mechanisms leading to adaptation are (i) an increased recovery of AChE activity as a result of *de*

novo synthesis (Gupta et al., 1986) and (ii) a reduction in nAChR binding sites (Gupta et al., 1985, 1986, 1987a,b). Finally, mechanisms such as modification of ACh release from presynaptic sites may be an additional contributing factor (Carlson and Dettbarn, 1988).

SKELETAL MUSCLE INVOLVEMENT IN IMS

OP insecticide-induced IMS was reported for the first time in human patients in Sri Lanka in 1987 (Senanayakeand Karalliedde, 1987; Karalliedde and Henry, 1993). Thereafter, this syndrome has been reported in South Africa (1989), Turkey (1990), Belgium (1992), India (2003), and many other countries. IMS is clearly a separate entity from acute cholinergic crisis and delayed neuropathy. IMS is a life-threatening complication of OP poisoning, which most commonly occurs 48–72 h after exposure. Thus far, IMS has not been documented with OP nerve agents. Clinically, IMS is characterized by acute respiratory paralysis and weakness in the territories of several cranial motor nerves, neck flexors, and facial, extraocular, palatal, nuchal, and proximal limb muscles. Despite severe AChE inhibition, muscle fasciculations and muscarinic receptor-associated hypersecretory activities are absent. Based on EMG findings from OP-poisoned patients and experimental studies on laboratory animals, it has been found that the defect in IMS is at the neuromuscular endplate and postsynaptic levels, but the effects of neural and central components in muscular weakness have not been ruled out. EMG in the early stages reveals marked decrements at low rates of repetitive nerve stimulation and increments at a high rate, suggesting diverse types of impaired neuromuscular transmission. IMS seems to be due to persistent AChE inhibition at the endplate, presumably leading to combined presynaptic and postsynaptic impairment of neuromuscular transmission. Currently, very little is known about the type of damage at the motor endplate or about risk factors associated with IMS. For details on the involvement of muscles in IMS, see De Bleecker (2006).

PREVENTION/TREATMENT OF MYOPATHY

Various pharmacologic and therapeutic drugs have been tested to prevent or treat myopathy. Drugs effective in the treatment of neuromuscular signs of anti-ChE toxicity include (i) oximes that reactivate the phosphorylated AChE (Thiermann et al., 2005; Marrs and Vale, 2006), (ii) subparalyzing and paralyzing doses of *d*-tubocurarine (Clinton and Dettbarn, 1987; Patterson et al., 1987), (iii) atropine sulfate/atropine methyl nitrate (Patterson et al., 1987; Clinton et al., 1988), (iv) diazepam, and (v) creatine phosphate (Clinton et al., 1988). In several studies, reversible AChE-inhibiting carbamates, atropine, or anticonvulsants were given with oxime to achieve an optimal effect. Some of the drugs, including AChE reactivators, muscarinic and nicotinic ACh receptor blockers, NMDAR antagonists, anticonvulsants, and antioxidants, are described here briefly in terms of their prophylactic/therapeutic efficacy. It should be noted that some of these agents, however, produce toxicity when given for an extended period of time, thereby limiting their utility.

ACHE REACTIVATORS AND ACH RECEPTOR BLOCKERS

The standard treatment of nerve agent-induced muscle toxicity calls for the reactivation of the phosphorylated AChE with an oxime. Oximes such as obidoxime (bis(4-formylpyridiniomethyl) ether dioxime, also known as Toxogonin), pralidoxime (2-pyridine aldoxime methochloride/2-PAM) and a few others have been found very effective when given in combination with other drugs such as atropine, *d*-tubocurarine, and diazepam. Effectiveness of pretreatment with oximes varies with the chemical structures of the nerve agents and depends on the time after exposure. For example, it has been established that asoxime chloride (HI-6) effectively reactivates AChE inhibited by soman, while TMB-4 is known as one of the most efficient reactivators of tabun-inhibited enzyme. In *in vivo* studies, Jovanovic (1983) evaluated the effects of two bis-pyridinium oximes (BDB-27 and HGG-12) on neuromuscular blockades induced by nerve agents (sarin, soman, tabun, and VX) in rats, and effectiveness was compared with the two most potent oximes (HI-6 and TMB-4). It was found that BDB-27 was equal or superior to HI-6 in sarin, soman, and VX, and to TMB-4 in tabun-poisoned animals. The potency of HGG-12 was equal to HI-6 only in soman poisoning, but it was much less pronounced against neuromuscular blockades induced by the other nerve agents. In general, oxime therapy becomes progressively ineffective with time due to changes in the enzyme-inhibitor complex, which loses an alkyl radical. This so-called aged phosphorylated enzyme complex is resistant to oxime reactivation (Radic and Taylor, 2006). Thus, prevention of formation of the enzyme-inhibitor complex seems to be one of the preferred strategies in the treatment of myopathy.

The best pretreatment should include agents that prevent access of the nerve agent to AChE without affecting its activity, or a combination of drugs that would decrease the release of ACh from nerve terminals and

partially block access to the nicotinic and the presynaptic and postsynaptic muscarinic receptors. So far, timely administration of atropine sulfate or atropine methyl nitrate, in combination with an oxime (such as 2-PAM) or diazepam, is currently the treatment of choice for OP poisoning. Atropine modifies ACh receptor interaction at the NMJ postsynaptically by shortening the opening time of the ion channel, and possibly by lowering Na^+ conductance. Atropine sulfate has been observed to reduce motor activity and muscle necrosis caused by AChE inhibitors (Clinton and Dettbarn, 1987). Atropine methyl nitrate is four times more potent than atropine sulfate in its peripheral effects and has been confirmed to ameliorate peripheral motor activity caused by AChE inhibitors (Clinton et al., 1988). Atropine methyl nitrate (16 mg/kg, s.c.) failed to ameliorate the central effects of both soman and DFP due to its quaternary structure that hinders its passage across the blood–brain barrier (BBB; Clinton et al., 1988).

Earlier studies with *d*-tubocurarine and atropine indicated that nicotinic and muscarinic ACh receptor blockers can modulate the release of ACh induced by an inhibitor of AChE (Carlson and Dettbarn, 1988). The effects of these drugs, whether inhibiting or stimulating ACh release, are concentration dependent and determined by the frequency of nerve activity (Bowman, 1980; Wessler et al., 1987a,b). Therefore, drugs that reduce axonal hyperexcitability by decreasing the amount of ACh released from the nerve terminals without interfering with normal transmission, provide another pretreatment possibility. Protection against DFP-induced myopathy was achieved by using small concentrations of atropine sulfate (16 mg/kg, s.c.) or atropine methyl nitrate (16 mg/kg, s.c.) and *d*-tubocurarine (75 µg/kg, s.c.) that prevented fasciculations and muscle necrosis without interfering with normal neuromuscular function (Patterson et al., 1987). In this study, pretreatment agents acted presynaptically by preventing DFP-induced backfiring and muscle fasciculations, possibly by reducing the release of ACh. The protective drugs in the concentrations used had no significant effect on the normal characteristics of conduction and transmission. Carlson and Dettbarn (1988) showed that *d*-tubocurarine or atropine sulfate in subparalytic concentrations prevented the increases in MEPP frequency when given prior to an AChE inhibitor, or attenuated the increased frequency to normal when given after the increase of frequency. At a subparalytic dose *d*-tubocurarine (50 µg/kg, given intravenously) is known to suppress fasciculations by preventing repetitive firing of nerve terminals. Furthermore, *d*-tubocurarine and atropine sulfate reduced Ca^{2+} influx and ACh release (through presynaptic receptors), which is associated with repetitive activity, as seen during AChE inhibitor-induced antidromic firing.

NMDAR Antagonist

In a series of *in vivo* experiments, rats receiving a sublethal dose of soman (100 µg/kg, s.c.), sarin (110 µg/kg, s.c.), tabun (200 µg/kg, s.c.), VX (12 µg/kg, s.c.), or DFP (1.5 mg/kg, s.c.) developed seizures and severe muscle fasciculations within 15–20 min that lasted for about 4–6 h. Marked inhibition of AChE activity and necrotic lesions in skeletal muscles (the SOL, EDL, and diaphragm) became evident between 1 and 24 h postinjection and persisted for several days. Pretreatment of rats with the NMDAR antagonist memantine (18 mg/kg, s.c.), given with atropine sulfate (16 mg/kg, s.c.) 60 and 15 min prior to DFP or nerve agents, respectively, significantly attenuated AChE inhibition and prevented myonecrosis and muscle fasciculations, as well as other signs of behavioral toxicity. No muscle fasciculations were seen at any time (Gupta and Dettbarn, 1992).

Protection of AChE inhibition was greater when memantine was given prophylactically than therapeutically. It is noteworthy that memantine itself does not influence normal activity of AChE in non-OP-treated animals. Although the precise mechanism involved in reduction of AChE inhibition by memantine against nerve agents is yet to be elucidated, spontaneous reactivation as the cause of the remaining high-enzyme activity was ruled out since the enzyme activity was determined within a short period of time; i.e., 1 h after acute intoxication with soman, sarin, tabun, VX, or DFP (Gupta et al., 1986, 1987a,b, 1991; Gupta and Dettbarn, 1992), and AChE activity remained low when only atropine sulfate (16 mg/kg, s.c.) was used. Studies by McLean et al. (1992) revealed that memantine did not prevent inhibition of AChE by edrophonium, an anionic site inhibitor, or by decamethonium, a peripheral site inhibitor. Thus, memantine appears to bind to a different modulatory site to protect this enzyme's activity. The other mechanisms by which memantine might have attenuated AChEI's toxicity may include the following:

- Reduced reflex excitability of both flexors and extensors (Wand et al., 1977)
- Reduced high frequency of repetitive activation of peripheral nerves by reducing the permeability of Na^+ and Ca^{2+} in axonal membranes (Wesemann and Ekenna, 1982; Wesemann et al., 1983)
- Blockage of nicotinic ACh receptor-ion channel complex (Masuo et al., 1986)
- Prevention of neural hyperexcitability (McLean et al., 1992)
- Central muscle relaxation (Grossmann and Jurna, 1977)
- Reduced seizures by uncompetitive NMDAR blockage (Danysz et al., 1994; Carter, 1995; Parsons et al., 1999)
- Prevention of cellular energy depletion (Gupta and Goad, 2000).

Although not all of these mechanisms have been investigated in the protection of OP nerve agent-induced myopathy by memantine, it appears that memantine provides protection by multiple mechanisms. It needs to be mentioned that no significant change occurred in AChE activity in skeletal muscles of OP-untreated rats receiving memantine and atropine sulfate. Prophylactic administration of memantine and atropine sulfate also blocked the AChEI-induced increase in levels of citrulline and F_2-isoprostanes, markers of NO synthesis and lipid peroxidation, respectively (Milatovic et al., 2005). Memantine has the advantage of providing prophylactic benefits without producing sedation or any other side effects. Thus, memantine may prove to be a superior drug to many other agents.

Anticonvulsants and Anesthetics

The prevention and treatment of OP-induced myopathy are both complex since individual AChEIs differ in their major sites of action. As mentioned earlier, soman-produced muscle hyperactivity was generated mainly in the CNS, while DFP-induced hyperactivity arose approximately equally from the CNS and the peripheral nervous system (PNS) and NMJ. Clinton et al. (1988) reported that in the case of both soman (90 µg/kg, s.c.) and DFP (1.5 mg/kg, s.c.) poisoning, ketamine (25 mg/kg, s.c.) reduced centrally generated motor activity, while atropine methyl nitrate (16 mg/kg, s.c.) and sodium phenytoin (15 mg/kg, intravenously) had no significant effect. It was suggested that the effectiveness of ketamine may alter patterns of neuronal firing by reducing high-frequency neuronal discharges that are characteristic of seizures (MacDonald and McLean, 1986). Ketamine is known to act on sodium channels by producing a dose-dependent reduction of inward sodium current in a manner similar to that of local anesthetics, with a resultant suppression of high-frequency neuronal bursts, which are manifested as excess muscle activity seen with OP poisoning. Since ketamine and drugs in its class also have specific anticholinergic effects at both nicotinic and muscarinic (more potent at nicotinic than at muscarinic) receptors (Kloog et al., 1977), it may be a direct antagonist in the CNS against the cholinergic activation caused by AChEIs (Gupta et al., 1987a,b). Additionally, ketamine can inhibit excitation–contraction coupling within the muscle by altering Na^+ conductance at the muscle membrane (Marwaha, 1980a,b).

The anticonvulsant phenytoin did not reduce central motor activity induced by either soman or DFP (Clinton et al., 1988). Phenytoin suppresses sustained high-frequency neuronal firing through a membrane potential-dependent blockade of Na^+ channels with resulting inhibition of nonsynaptic events involved in epileptogenesis (MacDonald and McLean, 1986; Yaari et al., 1986). The failure of phenytoin to control the seizures induced by AChEIs suggests that they may not result from the same mechanisms of epileptogenesis as seizures produced by maximal electrical shock, against which phenytoin is most effective. Conventional anticonvulsant compounds have been reported to provide limited protection against nerve agent-induced seizures and muscle necrosis when given therapeutically (Lipp, 1972; Clinton et al., 1988). Sedation, tolerance, and abuse potential limit prophylactic use of benzodiazepine compounds, however.

In animal models, clonidine (alpha2 adrenergic agonist) has also been reported to prevent nerve agent-induced seizures (Buccafusco et al., 1988). Prophylactic use of clonidine may be limited by the marked ataxia and sedation produced by this drug in effective concentrations.

Antioxidants, Spin-trapping Agents, and Creatine

Scavenging or prevention of the ROS generation originated through various excitotoxicity mechanisms are of particular interest. An antioxidant such as the lipid-soluble vitamin E (α-tocopherol) is an excellent blocker of ROS production, as it extracts hydrogen and interrupts lipid peroxidation. Vitamin E mainly acts as a chain-breaking antioxidant and radical scavenger, protecting cell membranes against oxidative damage. There are reports demonstrating that vitamin E concentrates in the mitochondria, the major site for the generation of ROS, as well as energy metabolites. Therefore, vitamin E regulates ROS production, maintains oxidative phosphorylation in mitochondria, and accelerates the restitution of high-energy metabolites.

A synthetic spin-trapping agent such as phenyl-*N*-*tert*-butylnitrone (PBN) is capable of scavenging many types of free radicals. This compound is widely used to trap ROS in a variety of physical, chemical, and biological studies using electron magnetic resonance spectrometry. PBN is known to be concentrated in the mitochondria, where it reacts with ROS and forms stable adducts, thereby maintaining normal levels of energy metabolites. In addition, PBN has other pharmacological actions, such as (i) reversible Ca^{2+} channel blockade (Anderson et al., 1993), (ii) direct reversible interaction with AChE against phosphorylation by DFP (Zivin et al., 1999; Milatovic et al., 2000a,b), and (iii) protection of COX activity (Milatovic et al., 2001).

Pretreatment with PBN (75, 150, or 300 mg/kg, i.p.) 30 min prior to DFP injection (1.7 mg/kg, s.c.) in a dose-dependent manner protected AChE activity from inhibition, and prevented muscles from undergoing necrosis and rats from fasciculations (Milatovic et al., 2000a,b) (Table 40.9). The protective mechanism of PBN is proved

TABLE 40.9 Protective Effect of PBN Against DFP-Induced Fasciculations, AChE Inhibition, and Necrosis in Rat EDL

	Control	DFP[a]	PBN + DFP[b]	DFP + PBN[c]
Fasciculations	–	+	–	+
Necrotic fibers/cross-section of muscle	2 ± 2	82.55 ± 2.98*	0**	67.0 ± 4.59
AChE activity	12.17 ± 0.73 (100%)	3.70 ± 0.35* (30%)	10.85 ± 0.59** (89%)	2.97 ± 0.17 (24%)

Activity of AChE is expressed in terms of nmol/mg protein/min and number of necrotic fibers/1,000 muscle fibers. Ranking of fasciculations: – , absent; + , high frequency affecting all muscles. Values are means ± SEM of 5 muscles.
* Significant difference between control and DFP-treated rats ($p<0.01$).
** Significant difference between DFP-treated rats and PBN + DFP-treated rats ($p<0.01$).
[a]*DFP (1.7 mg/kg, s.c.) was given 1 h before sacrificing the rats.*
[b]*PBN (300 mg/kg, i.p.) was given 30 min before DFP (1.7 mg/kg, s.c.).*
[c]*PBN (300 mg/kg, i.p.) was given 20 min after DFP (1.7 mg/kg, s.c.) administration.*

to take place due to its ROS/RNS scavenging property (Gupta et al., 2000a, 2001b). Treatment with PBN 20 min after DFP exposure neither prevented fasciculations nor protected AChE activity. While the role of PBN as an antioxidant is well established, its prophylactic effect against excitotoxicity induced by an AChEI is due to its protection of AChE from critical inhibition (Milatovic et al., 2000a,b). Unlike PBN, vitamin E neither prevented DFP-induced muscle fasciculations nor protected AChE. Both vitamin E and PBN concentrate in the mitochondria, so they can regulate ROS production, maintain oxidative phosphorylation, and accelerate restitution of high-energy metabolites (Gupta et al., 2001a,b).

Since the major energy sources are ATP and PCr, an increase of both compounds in muscles through administration of creatine appears to sustain ATP levels under stress conditions. This is supported by the findings that rats pretreated intravenously with PCr showed reduced muscle necrosis that otherwise would have been seen following DFP treatment. PCr did not attenuate the DFP-induced muscle fasciculations that generated the necrosis (Clinton and Dettbarn, 1987).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Skeletal muscles are the target of a variety of chemicals, especially OP nerve agents. These agents modulate structural and functional properties of the muscles, and the toxic effects can range from minor chest pain, muscle cramps in the legs, complete paralysis, and even death. Both *in vivo* and *in vitro* data strongly implicate that OP nerve agents initially exert acute toxicity by excitotoxicity involving not only the cholinergic system, but also processes associated with noncholinergic mechanisms. These processes include the glutamatergic system, excess generation of free radicals (ROS/RNS), and alterations in antioxidants and the scavenging system, causing oxidative stress, lipid peroxidation, high-energy phosphate depletion, and muscle necrosis. Wide variations exist between slow and fast fiber-containing muscles, and they further appear to respond differently to each OP nerve agent. Available sensitive biomarkers are indicative of cytotoxicity and mitochondrial toxicity (Gupta et al., 2014). Myopathy induced by AChE inhibiting OP nerve agents is a serious concern, since it is untreatable in most circumstances. Instead, prevention seems a better option. More potent AChE reactivators need to be developed for better therapeutic efficacy against OP nerve agent-induced myopathy.

Acknowledgments

The authors would like to thank Robin B. Doss and Michelle A. Lasher for their technical assistance in the preparation of this chapter.

CHAPTER

41

Reproductive Toxicity and Endocrine Disruption of Potential Chemical Warfare Agents

Timothy J. Evans

INTRODUCTION

Reproduction is a critical biological process in all living systems and is required for species survival. The immediate, short-term, toxicological concerns regarding chemical warfare and acts of agricultural and industrial terrorism are concerned primarily with human and animal incapacitation and mortality. Logically, most of the currently available literature on these aspects of warfare and terrorism focuses on these immediate adverse health effects and their sequelae. However, the entire scope of the effects of these toxic insults can involve severe emotional and financial distress and diminished prognosis for long-term survival of exposed human and animal populations as a result of toxicant-induced spontaneous abortions, congenital defects, and infertility. It is therefore important for individuals working in human and veterinary medicine, the military, public health, government regulatory agencies, industry, and agriculture, as well as public policy-makers, to be familiar with some of the potential adverse reproductive effects of these types of toxicants on exposed humans and animals. This chapter reviews what is currently understood about the potential effects of chemical warfare agents (CWAs), nuclear fallout, and hazardous industrial and agricultural wastes on human and animal reproductive function.

For the purposes of this chapter, the term "reproduction" is used primarily in reference to vertebrate species of animals (especially mammals) and is inclusive of "development" (Figure 41.1), which is sometimes treated as a separate topic in toxicology texts. This particular chapter emphasizes what is currently known about the adverse effects of known CWAs and selected environmental contaminants on male and female reproductive function, as well as xenobiotic-induced effects on the growth, maturation, and sexual differentiation of the embryo and fetus. Endocrine disruption is an extremely common mechanism of action for xenobiotics associated with impaired reproductive function and is discussed along with reproductive toxicity in this chapter. Efforts have been made to clarify the currently used terminology related to these topics and to provide the reader with a brief description of proposed mechanisms of action and observed reproductive outcomes associated with selected toxicants that might be relevant to chemical warfare and/or acts of terrorism.

Unfortunately, although there is relative lack of information documenting long-term reproductive effects of the types of toxicants covered in this book, space constraints still limit the amount of information that can be presented in this chapter. There are a number of recently published textbooks and book chapters that cover some of these and related subjects in greater detail and provide information that is complementary to what is presented in this chapter (Senger, 2003; Naz, 2005; Golub, 2006a,b; Gupta, 2006, 2007c; Evans, 2007; Capen, 2008; Foster and Gray, 2008; Rogers and Kavlock, 2008; Romano et al., 2008). This is especially true with respect to normal reproductive anatomy and function (Senger, 2003; Evans, 2007), and the reader is directed to these publications and the other references cited in this chapter to gain additional insight into specific areas of reproductive function and toxicology.

It is important to understand that the areas of toxicology involving the long-term effects of CWAs and environmental

contaminants, reproductive toxicity, in general, and endocrine disruption, in particular, are in continual flux. New data and exceptions to "classical" mechanisms of action are being reported on a regular basis, and there continues to be ongoing debate about the effects of chronic low-level exposures to toxicants available for or arising from military and terrorist activities and various aspects of normal as well as xenobiotic-induced abnormal reproductive functions. Every effort has been made to accurately represent what is currently understood about the topics of discussion in this chapter. Controversial topics or those currently still subject to debate within the scientific community have been noted whenever possible.

IMPORTANT DEFINITIONS AND CONCEPTS

Chemical Warfare Agents

For the purposes of this chapter, "chemical warfare agent" (CWA) is used as a fairly comprehensive term to refer to a diverse group of toxicants commonly discussed within the context of chemical incapacitation for crowd control during riots or death or incapacitation associated with military use or terrorism. The lachrymatory and irritant riot control agents include α-chlorbenzylidene malonitrile (CS), dibenz (*b,f*)-1:4 oxazepine (CR), ω-chloroacetophenone (CN), and oleoresin of capsicum (OC pepper spray) (Salem et al., 2008a). The CWAs currently of greatest interest and for which the greatest amount of data have been gathered are arsenicals, chlorine gas, phosgene and phosgene oxime, sulfur mustard, ricin, hydrogen cyanide and cyanide-related compounds, and organophosphate nerve agents (Wismer, 2007; Kikilo et al., 2008).

Environmental Contaminants Associated with Industrial or Agricultural Terrorism

For the sake of completeness, this chapter also discusses the adverse reproductive effects of potential toxicants, such as ionizing radiation, pesticides, and other organic environmental contaminants, as well as heavy metals, which are known to adversely affect reproductive function. Although all of these potential toxicants have been or are currently being released into the environment in generally low concentrations as a consequence of normal industrial and agricultural activities, the results of accidents, such as those that occurred in Chernobyl in the former Soviet Union (ionizing radiation), Bhopal, India (methyl isocyanate or MIC), Seveso, Italy, and Times Beach, Missouri (dioxins), and Minamata, Japan, and Basra, Iraq (methyl mercury), underscore the potential impact that large-scale industrial or agricultural terrorism-related releases of these contaminants could have on populations of humans and animals. In fact, these environmental contaminants have the potential to become "low-tech" CWAs in the hands of terrorists and less sophisticated military organizations.

Reproduction

As represented in Figure 41.1, reproduction in humans and domestic, wild, and laboratory vertebrate animals encompasses a wide range of physiological processes and associated behaviors and anatomical structures involved in the production of the next generation and the survival of a given species of animal (Senger, 2003; Evans, 2007). The physiological processes involved in reproduction generally include the following: gametogenesis (production of sperm or ova) and the prepubertal and peri-pubertal changes leading to its onset; release of gametes (i.e., sperm transport and maturation, penile erection and ejaculation of sperm (mammals), copulation between a male and a female of the same species (several vertebrate classes) and ovulation of oocytes); formation of the zygote (i.e., sperm storage, capacitation, and other processes leading to fertilization, or union, of a single sperm with an egg); embryonic and fetal development during the incubation process in egg-bearing vertebrates or, especially in the case of mammals, during pregnancy (gestation) (i.e., activities related to the initiation and progression of zygote cleavage, blastocyst formation, separation of the germ layers, placentation

(mammalian species), neurulation, and organogenesis (including sexual differentiation)); "birth" of a single or multiple offspring (hatching in oviparous vertebrates); and, finally, in mammalian species, the initiation and maintenance of milk production (lactation) for the postpartum nutrition of offspring (Evans, 2007).

Reproductive Toxicity

For the purposes of this chapter, "reproductive toxicity" refers to any manifestations of xenobiotic exposure, including "endocrine disruption," reflecting adverse effects on any of the physiological processes and associated behaviors and/or anatomical structures involved in animal reproduction or development (Figure 41.1). This is a fairly broad definition that encompasses developmental toxicity, as well as any toxic effects of postpubertal exposures to xenobiotics on either male or female reproduction. "Developmental toxicity" refers to any adverse effect on the developing organism associated with either preconception parental exposures to toxicants or postconception xenobiotic exposures to the embryo, fetus, or prepubertal offspring, and adverse effects associated with developmental toxicity of xenobiotics might not necessarily be observed until after the affected individuals have reached sexual maturity (Hodgson et al., 2000; Eaton and Klaassen, 2001; Evans, 2007).

Teratogenesis

The term "teratogenesis" is derived from the Greek word for monster (*teras*) and is a form of developmental toxicity (Rogers and Kavlock, 2008). "Teratogenesis" refers specifically to developmental defects induced by toxicant exposures occurring between conception and birth (Hodgson et al., 2000; Eaton and Klaassen, 2001; Evans, 2007; Rogers and Kavlock, 2008). The types of abnormalities that are typically associated with teratogenesis include embryonic or fetal death, morphological, functional, and/or neurobehavioral abnormalities, and decreased growth rate and/or birth weight (Evans, 2007; Rogers and Kavlock, 2008).

With respect to teratogenesis, there are six basic tenets of teratology, first defined by J. G. Wilson in 1959, that need to be kept in mind whenever gestational exposure to a teratogenic xenobiotic is suspected or when a chemical is being evaluated for its teratogenic potential (Wilson, 1977; Evans, 2007):

1. Susceptibility to teratogenesis depends on the genotype of the conceptus and the manner in which it interacts with environmental factors.
2. Susceptibility to teratogenic agents varies with the developmental stage at the time of exposure.
3. Teratogenic agents act in specific ways (mechanisms) on developing cells and tissues to initiate abnormal embryogenesis.
4. The final manifestations of abnormal development are death, malformation, growth restriction, functional disorder.
5. The access of adverse environmental influences to developing tissues depends on the nature of the influences (agent).
6. Manifestations of deviant development increase in degree as dosage increases from no effect to the totally lethal level.

Mechanisms of Reproductive Toxicity and Teratogenesis

In general, normal reproduction and development require rapidly replicating and differentiating cells undergoing mitosis and, within the gonads, meiosis. There is a wide range of specific mechanisms of action by which xenobiotics can adversely affect reproductive function, including embryonic and fetal development. Many of these mechanisms are the same as those for toxicants affecting other organ systems and essentially involve some sort of toxicant-induced interference with the cell cycle, cellular dysregulation, and alterations in cellular maintenance, which, when possible, the body attempts to repair, either successfully or unsuccessfully (Gregus, 2008). Oxidative damage and interference with normal enzymatic reactions are two common mechanisms by which xenobiotics and, especially, some CWAs (Smith et al., 2008) can cause the dysregulation and altered maintenance of cells within various organs and tissues.

Teratogenesis can be associated with each of the following mechanisms of action: excessive cell death; interference with apoptosis; reduced cellular proliferation rate; failed interactions between cells; impaired morphogenetic movements; reduced synthesis of components essential for growth and development; mechanical disruption; and alterations in pH (Hood et al., 2002; Hood, 2006; Evans, 2007). Some teratogens are capable of more than one mechanism of action, and it is important to keep in mind that the observed developmental abnormalities associated with exposure to any given teratogen will, in large part, be dependent on the timing of the exposure to that xenobiotic during gestation. Familiarity with the timing of important developmental events in species of interest is critical in the diagnosis and prevention of teratogenesis, as is the design of experiments investigating the teratogenic potential of different chemicals in animal models (Evans, 2007).

Normal reproduction and development require signaling within and between a variety of diverse organs and, in sexual reproduction and mammalian pregnancy, critical communication even takes place between distinctly different organisms (i.e., male and female and mother and offspring, respectively) (Evans, 2007). It should be remembered that premature parturition or

spontaneous abortion can be induced by any circumstances that cause fetal or, potentially, maternal stress and initiate the cascade of endocrine and neural signaling events that would normally lead to parturition. Any sublethal intoxication or emotionally traumatic event in a pregnant woman or animal has the potential to threaten fetal survival.

The dependency of reproductive function on signaling pathways inclusive of gene transcription makes this physiological process especially prone to adverse effects associated with xenobiotic-induced disruption of or interference with cell-to-cell, organ-to-organ, and/or even animal-to-animal communication. Many of the mechanisms that interfere in some way with physiological signaling activity can be classified as forms of "endocrine disruption," but there is a great deal of overlap between the various different mechanisms for reproductive toxicity. The level of exposure to a particular toxicant is an important determinant of what toxic effects are observed, and xenobiotics that "disrupt" endocrine pathways can do so without interactions with endogenous receptors using mechanisms of action that can cause other forms of toxic insult at various dosages.

Reproductive Toxicants

Any xenobiotic associated with adverse effects on development of male or female reproductive function can be classified as a "reproductive toxicant" (Evans, 2007; Rogers and Kavlock, 2008). Even chemicals adversely affecting animal well-being have a potential negative impact on development and reproductive function. This chapter attempts to focus on toxicants that are available for or could arise from military and terrorist activities and specific mechanisms of actions that have a direct effect on the male and/or female reproductive tract or that target normal embryonic and/or fetal growth and maturation (Evans, 2007).

Teratogens

The subclass of reproductive toxicants capable of inducing teratogenesis is referred to as "teratogens." Some teratogenic chemicals induce their adverse effects indirectly on the fetus by altering maternal synthesis of essential nutrients or by other mechanisms that do not require their transport across the placenta. However, many teratogens directly affect fetal development by crossing the "placental barrier" and entering the fetal circulation. The passage of nutrients, hormones, and other endogenous, as well as exogenous, substances across the placenta has been traditionally thought of by some references as primarily a function of the intimacy (i.e., number of tissue layers) between the maternal and fetal circulations, especially with respect to maternal immunoglobulins that cross some types of placentation but not others (Evans, 2007). Although it is true that placental characteristics, such as thickness, surface area, carrier systems, and lipid protein characteristics can influence the passage of xenobiotics across the placenta and that the placenta is generally impermeable to chemicals with molecular weights greater than 1,000 Da, most xenobiotics have molecular weights less than 500 Da and cross the placenta by simple diffusion (Foster and Gray, 2008). It is currently thought that a potential teratogen's molecular size, degree of ionization, protein binding, and lipid solubility are the most important determinants of that chemical's ability to move from the maternal circulation across the placenta into the fetal circulation (Rozman and Klaassen, 2001; Senger, 2003; Evans, 2007; Foster and Gray, 2008). Some toxic xenobiotics can be actively transported by mechanisms intended for structurally similar endogenous molecules (Rozman and Klaassen, 2001), and there is some experimental evidence to suggest that transplacental transport of lead can mimic that of calcium (Evans et al., 2003; Evans, 2007).

Endocrine Disruption

"Endocrine disruption" is a developing multidisciplinary area of research involving aspects of both toxicology and endocrinology (McLachlan, 2001) and is a potential mechanism of action for many toxicants, especially those affecting reproduction. This term has been defined in a variety of different ways, depending on the circumstances and the intended audience. Endocrine disruption can also be defined fairly narrowly with respect to toxicant origin (synthetic versus naturally occurring), source or site of toxicant exposure (exposure from warfare-related or terrorism-related activities versus exposure from environmental contamination), xenobiotic mechanism of action (receptor agonism and/or antagonism versus other mechanisms independent of direct interactions between xenobiotics and receptors), and/or the timing of exposure (prenatal versus postnatal exposures) (Krimsky, 2000, 2001; Evans, 2007). However, the definition of endocrine disruption used in this and another book chapter previously written by the author (Evans, 2007) is fairly broad and encompasses the effects of any synthetic or naturally occurring xenobiotic that can affect the endocrine system of exposed individuals (i.e., the balance of normal hormonal functions) and, as a result of exposure, cause physiological alterations (Keith, 1997; Hodgson et al., 2000; Evans, 2007). Within the broad scope of this definition, reproduction, including prenatal and prepubertal development, certainly would be expected to be one of the physiological functions most profoundly affected by chemicals associated with chemical warfare or environmental contamination capable of endocrine disruption; however, adverse effects on other nonreproductive endocrine systems can also be associated with exposures to xenobiotics (Guillette, 2006; Evans, 2007). Thyroid function, glucocorticoid

metabolism, and other endocrine as well as enzymatic factors associated with adipogenesis have recently been shown to be susceptible to interference by several different classes of chemical compounds (Cooke and Naz, 2005; Newbold et al., 2005, 2006; Grün and Blumberg, 2006; Guillette, 2006; Evans, 2007; Capen, 2008).

Mechanisms of Endocrine Disruption

Although the imitation and/or inhibition of the actions of androgens and, especially, estrogens by xenobiotics is what was first referred to as endocrine disruption, both the multidisciplinary area of study and mechanism of action generally referred to as endocrine disruption have evolved over the years to encompass a wide range of specific mechanisms of action that can ultimately result in adverse effects on invertebrate and/or vertebrate animals (McLachlan, 2001; Evans, 2007). Endocrine disruption involves many mechanisms of action that can ultimately result in adverse effects on animal species. The mechanisms of action involved in endocrine disruption can include effects that are mediated directly by interactions between the xenobiotic and an endogenous hormone receptor (i.e., the xenobiotic functions as a ligand for an endogenous receptor and a receptor–ligand complex is formed), as well as those adverse effects that alter hormonal functions without direct interactions between the toxicant and an endogenous receptor (Keith, 1997; Evans, 2007; Capen, 2008). It should also be noted that a given xenobiotic can potentially disrupt the normal balance of hormonal function by more than one mechanism that is independent of direct interactions between the toxicant and an endogenous hormone receptor (Evans, 2007).

"Classic" endocrine disruption can involve imitation or mimicry of the interactions between cellular receptors and endogenous hormones (i.e., receptor agonism) and/or a blockade or inhibition of the formation of receptor–hormone complexes (i.e., receptor antagonism) (McLachlan, 2001; Evans, 2007), and both genomic and nongenomic physiological responses can be affected by this mimicry or blockade of endogenous hormone receptor–mediated activity (Thomas and Khan, 2005; Evans, 2007). Endocrine disruption can also be mediated by the complex interactions between the endogenous aryl hydrocarbon receptor (AhR) and its major agonists, which are xenobiotics belonging to the class of environmental contaminants referred to collectively as "halogenated aromatic hydrocarbons" or "polyhalogenated aromatic hydrocarbons" (PAHs) (Safe, 2005; Evans, 2007).

Endocrine disruption that is independent of interactions between xenobiotics and endogenous hormone receptors can occur in a variety of different ways, including alterations in the number of hormone receptor sites (upregulation or downregulation) or direct or indirect hormone modifications that alter hormonal function (Keith, 1997; Evans, 2007). Xenobiotics can change the rate of synthesis or destruction of endogenous hormones and can alter how hormones are stored, how they are released into and/or transported within the circulation, or even how they are eventually cleared from the body (Keith, 1997; Sikka et al., 2005; Evans, 2007; Capen, 2008). Any xenobiotic toxic to hormone-producing organs or tissues (e.g., testis and ovary) also has the potential to decrease hormone synthesis and thereby to indirectly cause endocrine disruption (Devine and Hoyer, 2005; Evans, 2007).

In addition to the aforementioned mechanisms of endocrine disruption, there has recently been increasing interest in the association between prenatal exposures to some hormonally active toxicants and the postnatal development of neoplasia (cancer) involving the reproductive tract, as well as the occurrence of transgenerational or vertically transmitted adverse reproductive effects (Crews and McLachlan, 2006). Either genetic mutations (i.e., alterations in the genotype or deoxyribonucleic acid (DNA) sequence) or epigenetic changes, such as DNA methylation of CpG nucleotides in the promoter regions of genes, which are heritable but nongenetic modifications in the properties of a cell (inherited phenotypic alteration without genotypic change), are possible explanations for these phenomena (McLachlan, 2001; Crews and McLachlan, 2006; Evans, 2007). Patterns of DNA methylation are generally established during development at the gastrulation stage (i.e., lineage-specific pattern in somatic cells) and after sex determination (i.e., germ line–specific lineage pattern in the gonad), and DNA methylation can facilitate genomic imprinting, which results in the expression of the allele from only one parent (i.e., monoallelic expression) (McLachlan, 2001; Anway and Skinner, 2006).

Endocrine-Disrupting Chemicals, Endocrine Disruptors, and Hormonally Active Agents

Any reproductive toxicant capable of endocrine disruption can also be considered an endocrine-disrupting chemical (EDC) or an endocrine disruptor. Another term frequently used with respect to endocrine disruption, especially regarding xenobiotics that interact with endogenous hormone receptors, is hormonally active agent (HAA). In most instances, "EDC," "endocrine disruptor," or "HAA" can be used interchangeably to discuss the actions of a given xenobiotic (Evans, 2007).

THE REPRODUCTIVE TOXICITY OF SELECTED TOXICANTS

It should be remembered that the use of CWAs will invariably be associated with wars, acts of terrorism,

revolutions, and civil unrest, all of which do not occur in a vacuum and will be concurrent with emotional stress, famine, and other conditions leading to reproductive failure. As a result, information is relatively lacking with respect to specific adverse reproductive effects, as well as endocrine disruption, related to acute and, particularly, low-level, chronic exposures to many potential CWAs. In addition, much of the information that does exist regarding the long-term reproductive and teratogenic effects of these types of weapons is, unfortunately, somewhat contradictory. Although it is possible that exposures to some CWAs might not generally be associated with serious adverse reproductive effects, the discrepancies between the results of different studies are probably, in part, due to variability in individual responses to specific toxicants and the complexity of analyses of human epidemiological data. In addition, differences in dosing regimens, routes of exposure, and the animal models utilized for *in vivo* studies can confound comparisons of experimental results. The relative insensitivity of many reproductive endpoints might also contribute to the impression that some chemical weapons do not adversely affect reproductive function.

The embryo and fetus, without a developed blood–brain barrier and with only rudimentary DNA repair mechanisms and hepatic detoxifying and metabolizing capabilities, are especially susceptible, as compared with adults, to the adverse effects of low-level exposures to xenobiotics (Newbold et al., 2006; Evans, 2007). There has recently been increasing concern within the regulatory, public health, and scientific communities about the effects of prenatal exposures to potential reproductive toxicants, especially those capable of endocrine disruption, on humans and animals. To increase our understanding of the long-term adverse reproductive effects associated with warfare and acts of terrorism, public knowledge of the use of CWAs or awareness of massive releases of reproductive toxicants associated with confirmed acts of terrorism should result in increased surveillance for phenotypic abnormalities in the most susceptible populations of humans and animals exposed during embryonic, fetal, and early postnatal development. Based on these epidemiological observations, carefully designed experiments mimicking "real life" exposures can be performed in multiple laboratory animal species, using sensitive biomarkers of toxic insult to reproductive development and function, to further elucidate the adverse reproductive effects of xenobiotic exposures likely to be associated with military and/or terrorist activities.

Our relative lack of understanding of the effects of CWAs and other xenobiotics on reproductive function can also be attributed to the complexity of the entire reproductive process and the mechanisms by which it is regulated. It should be evident from Figure 41.1 that maximum reproductive efficiency, including normal embryonic and fetal development, is dependent on the structural and functional integrity of multiple organs and tissues, as well as various physiological processes and signaling pathways within and (with respect to sexual reproduction and pregnancy) between individuals. Putative reproductive toxicants can affect one or several different steps in the reproductive process, depending on the physiological timing, duration, and level of exposure (Evans, 2007; Foster and Gray, 2008).

In "real life," humans and animals can be exposed to some toxicants both prenatally and postnatally. Many organic xenobiotics have the potential to bioaccumulate within exposed individuals, possibly affecting future generations by way of genetic and epigenetic effects. However, reproductive endpoints, such as conception rates and sperm counts, are relatively insensitive, and subtle toxicant-induced changes in reproductive efficiency can be overlooked or missed (Evans, 2007).

Much of the evidence for the adverse reproductive effects of selected toxicants will be based on cases involving wildlife exposures to environmental contaminants or on the experimental results of research exposing laboratory animals to large pharmacological doses of potential toxicants. When available, data are presented from accidental or intentional human and domestic animal exposures to toxicants associated with riot control and chemical warfare or with environmental catastrophes during which incidences of infertility, spontaneous abortion, and teratogenesis have been traced over the course of a number of years.

From an epidemiological perspective, it can be extremely challenging to determine the exact cause of reproductive abnormalities in humans and animals. Questions will often remain regarding whether the observed poor reproductive outcomes associated with acute exposures to toxicants are due to direct effects of these chemicals on reproductive function or are secondary to toxicant-induced systemic disease and its accompanying stress (e.g., spontaneous abortions and preterm births in intoxicated pregnant women or animals). There are multiple factors, including exposures to mixtures of toxicants and other concurrently occurring causes of reproductive failure, that need to be taken into consideration in heterogeneous populations in which exposures to toxic agents are not uniform between individuals. This is especially true in instances when there is a significant time interval between exposure to potential toxicants and the observed reproductive outcomes.

The Reproductive Toxicity of Riot Control Agents

The major lachrymatory and irritant riot control agents include α-chlorbenzylidene malonitrile (CS),

dibenz (*b,f*)-1:4 oxazepine (CR), ω-chloroacetophenone (CN), and oleoresin of capsicum (OC pepper spray) (Salem et al., 2008a). Exposure of pregnant women or animals to these compounds could be expected to be associated with maternal and/or fetal stress, which could potentially lead to the induction of premature parturition (Evans, 2007). Although the riot control agents CS and CN are both alkylating agents with at least the potential to adversely affect embryonic and fetal development, neither of these chemicals has yet been found to be embryotoxic or teratogenic (Sanford, 1976; Salem et al., 2008a). Limited studies performed with laboratory animals suggest that CR is neither embryotoxic nor teratogenic and that OC, with the possible exception of a slightly reduced crown–rump length, is not associated with any adverse effects on reproductive function (Salem et al., 2008a).

The Reproductive Toxicity of CWAs

Given current global politics and the "War on Terrorism," pertinent information regarding many newer potential CWAs is very likely to be unavailable for public review. To be as complete as possible, some of the more historical and currently available CWAs are discussed in the context of their primary, immediate, adverse effects on humans and animals. By organizing this discussion in that manner, the potential adverse reproductive effects of "new" CWAs can be anticipated based on the similarities of those toxicants to existing chemical weapons. For simplicity, CWAs are broadly classified as vesicants (i.e., blistering agents), inhibitors of protein synthesis (e.g., ricin), inhibitors of cellular respiration or "blood agents" (e.g., hydrogen cyanide and cyanide-related compounds), and nerve agents (i.e., organophosphate compounds).

Vesicants

Arsenicals

Although arsenicals are discussed in this chapter with respect to their use in chemical warfare, the metalloid element arsenic, which is classified as a carcinogen, is also a potential environmental contaminant. Arsenicals continue to have important industrial and agricultural uses, and arsenic-containing feed additives, pesticides, and wood preservatives are all still readily available. In general, arsenic binds to sulfhydryl groups, with the activities of thiol-containing enzymes, including those involved in cellular energy production, frequently being adversely affected (Wismer, 2007). Increased capillary permeability is also associated with many acute intoxications involving arsenic.

It is important when discussing the toxicity of arsenicals to distinguish between the effects of organic and inorganic forms of arsenic. Several organic arsenicals, including lewisite (dichloro (2-chlorovinyl) arsine or Agent L), diphenylcyanoarsine, and diphenylchloroarsine, have been used as vesicants and systemic toxicants (Ishii et al., 2004; Wismer, 2007). Like other arsenicals, Lewisite has been associated with fetal death in laboratory animals; however, lewisite is reported not to be teratogenic (Wismer, 2007). In contrast, a degradation product of diphenylcyanoarsine and diphenylchloroarsine, diphenylarsinic acid, has recently been associated with abnormal brain development in humans (Ishii et al., 2004). Inorganic forms of arsenic, particularly arsenite and arsenate, have been associated with neoplasia, estrogenic activity, and testicular and ovarian toxicity, as well as congenital neural tube, skeletal, and gonadal abnormalities, in laboratory rodents (Golub, 2006b). Epidemiological evidence in human populations has suggested that acute arsenic exposures with sublethal, maternal toxicity, and subchronic exposures to elevated arsenic concentrations in drinking water have been associated with increased incidences of spontaneous abortions, stillbirths, and preterm deliveries (Golub, 2006b).

Chlorine Gas

Chlorine (Cl_2) is one of the more commonly produced chemicals in the United States, and chlorine gas is a potent oxidant that is very irritating and, potentially, corrosive (Wismer, 2007; Kikilo et al., 2008; Smith et al., 2008). Chlorine gas is used as a pulmonary and choking agent, and exposure is frequently associated with moderate to severe painful irritation of the eyes and respiratory tract (Wismer, 2007). Such stressful sublethal exposures in late-gestational women or animals might be expected to be associated with the induction of premature parturition and, possibly, spontaneous abortion. Oxidative stress can definitely have adverse effects on reproductive function, but the chronic disease usually associated with chlorine gas exposure is primarily related to the ocular and respiratory systems (Smith et al., 2008). The limited information available regarding the reproductive effects of chlorine gas indicates that it is teratogenic (Wismer, 2007).

Phosgene and Phosgene Oxime

The most important industrial use of phosgene (Agent CG or carbonyl chloride) is in the production of isocyanates (Kikilo et al., 2008), and MIC exposure is discussed with respect to its accidental release in Bhopal, India. Phosgene is classified as a choking agent, and it acylates sulfhydryl, amine, and hydroxyl groups. Phosgene oxime (Agent CX), a halogenated oxime, is a nonpersistent chemical blistering agent, which, like phosgene, interacts with sulfhydryl and amine groups (Wismer, 2007). Other than possible adverse reproductive outcomes related to maternal and/or fetal stress or

increased dermal absorption of concurrently used CWAs, phosgene oxime is unlikely to have direct adverse effects on reproductive function.

Sulfur Mustard

Sulfur mustard (*bis*-(2-chloroethyl) sulfide; mustard gas, Agents HD, H, or HS) and analogs, such as 2-chloroethyl ethyl sulfide, are vesicants that can damage cells by alkylation of macromolecules (i.e., DNA, ribonucleic acid (RNA), and proteins), oxidative stress, glutathione depletion, and inflammation (Watson and Griffin, 1992; Dacre and Goldman, 1996; Wismer, 2007; Smith et al., 2008). Similar to ionizing radiation and a variety of other radiomimetic alkylating agents, such as busulfan, cyclophosphamide, and nitrogen mustard, sulfur mustard and its analogs can target rapidly dividing cells in multiple organs, including the testes and ovaries, as well as the developing embryo and fetus (Wismer, 2007; Foster and Gray, 2008; Hurst and Smith, 2008; Rogers and Kavlock, 2008). Consistent with DNA alkylation, as well as possibly other mechanisms of action, men exposed to sulfur mustard gas have been reported to have lower sperm counts and testosterone concentrations for several weeks after respiratory exposure, and Iraqi use of mustard gas has been associated with alterations in the newborn sex ratio and an increase in some birth defects (Pour-Jafari, 1994; Azizi et al., 1995; Wismer, 2007).

However, despite the epidemiological and laboratory animal evidence indicating that sulfur mustard is a teratogen and reproductive toxicant in humans and animals (Pour-Jafari, 1994; Azizi et al., 1995; Wismer, 2007), contradictory research data involving several different routes of exposure have suggested no adverse sulfur mustard–related reproductive effects, especially at levels of exposure not associated with maternal intoxication (Watson and Griffin, 1992; Dacre and Goldman, 1996; Wismer, 2007). Although based on its mechanisms of action it appears that exposures to sulfur mustard should be associated with several potential adverse reproductive outcomes, including maternal and/or fetal stress-induced premature parturition, additional mustard gas inhalation experiments should be performed in rodent and nonrodent animal models to confirm this suspicion.

Inhibitors of Protein Synthesis

Ricin

The seeds of the ubiquitous castor bean plant (*Ricinus communis*) contain high concentrations of a highly toxic, relatively stable, heterodimeric, glycoprotein toxin called ricin, which is a type 2 ribosome-inactivating protein (RIP) (Burrows and Tyrl, 2001; Millard and LeClaire, 2008; Salem et al., 2008b). The inhibition of protein synthesis by ricin and related type 2 RIPs has been associated with endothelial toxicity and, depending on the route of exposure, severe gastrointestinal or respiratory disease and death (Millard and LeClaire, 2008). Although it would be anticipated that acute sublethal ricin intoxication would be associated with spontaneous abortion or preterm delivery secondary to maternal and/or fetal stress, ricin has also been shown to have direct adverse effects on reproductive function in female rabbits, causing spontaneous abortion and inhibiting ovulation and implantation in this species (Salhab et al., 1999). Because of the availability of the raw ingredients and the relative ease of its extraction, ricin has the potential to be a "low-tech" alternative for terrorist attacks targeting public water supplies (Salem et al., 2008b). Additional research is needed to gain a better idea of the adverse reproductive effects that would be anticipated with sublethal and/or chronic exposures to ricin and related toxins (Millard and LeClaire, 2008).

Inhibitors of Cellular Respiration ("Blood Agents")

Hydrogen Cyanide and Cyanide-Related Compounds

With respect to their use in chemical warfare and, most likely, acts of terrorism, hydrogen cyanide (Agent AC, hydrocyanic acid (liquid form), or prussic acid), cyanogen halides, and other cyanide-related compounds are frequently described as "blood agents" (Wismer, 2007; Kikilo et al., 2008). The major mechanism of action associated with acute cyanide intoxication is the formation of a stable complex with the ferric iron (Fe^{3+}) in cytochrome oxidases, resulting in cytotoxic hypoxia from the inhibition of cellular respiration, oxygen utilization, and energy production (Wismer, 2007; Ballantyne and Salem, 2008). As a result of the rapid lethality of this class of compounds, very few studies have been conducted to investigate the adverse reproductive effects of hydrogen cyanide and cyanide-related compounds (e.g., cyanogen halides, cyanides, and nitriles). However, there is evidence to suggest that cyanide exposure in laboratory animals and livestock exposures to plants containing cyanogenic glycosides can be associated with embryonic and fetal death, as well as teratogenesis (Burrows and Tyrl, 2001; Wismer, 2007; Ballantyne and Salem, 2008). In addition, it would be anticipated that sublethal cyanide-induced hypoxia could cause enough maternal and/or fetal stress to result in spontaneous abortion or preterm deliveries.

Nerve Agents

Organophosphate Nerve Agents

The development of easily disseminated nerve agents as chemical weapons has been of interest to both military strategists and terrorist organizations because of the ability of these chemicals to rapidly incapacitate and kill opposing forces as well as civilian populations. The major chemical nerve agents, tabun (Agent GA), sarin (Agent GB), soman (Agent GD), cyclosarin (Agent GF),

and Agent VX, are extremely toxic and even very brief exposures to these nerve agents can be lethal (Watson et al., 2006; Wismer, 2007; Kikilo et al., 2008). These chemicals are classified as organophosphorus, organophosphate, or "OP" compounds, and their mechanism of action involves the competitive and irreversible inhibition of acetylcholinesterase (AChE) (Watson et al., 2006; Gupta, 2007a; Wismer, 2007). Commonly used OP and carbamate pesticides also inhibit AChE, and these chemicals, although generally less potent than those designed for use as CWAs, usually have longer lasting effects and the potential to be used as low-tech chemical weapons.

There have been some discrepancies between the results of various studies evaluating the reproductive toxicity of different OP compounds. Although decreased libido has been observed in men after acute exposures to both OP nerve agents and insecticides, this "reproductive" effect is most likely related to the neurobehavioral effects, such as posttraumatic stress disorder, associated with acute exposures to these chemicals (McDonough and Romano, 2008). Some nerve agents have been associated with postimplantation morbidity and mortality in laboratory animals (Wismer, 2007), but rats and rabbits exposed to soman did not apparently experience fetal toxicity or prenatal mortality, even with maternal illness (Wismer, 2007). Similarly, low-level exposures to other nerve agents, as well as some insecticides, have not consistently resulted in impaired fertility and developmental abnormalities (McDonough and Romano, 2008). However, adverse reproductive effects have recently been reported by several authors in association with OP insecticide exposures (Sikka and Gurbuz, 2006; Joshi et al., 2007; Peiris-John and Wiskremasinghe, 2008). Chlorpyrifos exposure has resulted in decreased sperm counts and testosterone concentrations as well as testicular degeneration in laboratory animals (Joshi et al., 2007). Similar abnormalities have also been observed in humans after low-level exposures to OP insecticides (Sikka and Gurbuz, 2006; Peiris-John and Wiskremasinghe, 2008). It has been reported that OP insecticides can cause disturbances in the feedback loops within the hypothalamic–pituitary–adrenal axis, thereby affecting the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Sikka and Gurbuz, 2006), and some members of this class of pesticides have even been reported to have anti-androgenic activity (Kitamura et al., 2006). In addition, exposures to OP insecticides can cause oxidative stress, leading to increased apoptosis within the testes (Sikka and Gurbuz, 2006).

As mentioned previously, maternal and/or fetal stress associated with sublethal exposures to OP insecticides could lead to an increased incidence of spontaneous abortions or preterm births in intoxicated pregnant women and animals. Because of lower levels of detoxifying enzymes (i.e., paraoxonase), the fetus appears to be more susceptible to OP intoxication than adults, and developmental neurotoxicity and growth restriction have been associated with low-level prenatal exposures of humans to OP insecticides (Desaiah, 1998; Eskenazi et al., 2008; Peiris-John and Wickremasinghe, 2008). In addition to the maternal and fetal effects, OP insecticides can also have direct toxic effects on the placenta, possibly involving (depending on the species) AChE inhibition within the placental cholinergic system (Pelkonen et al., 2006).

Because the effects of OP insecticides are generally longer lasting and more diverse than those of OP nerve agents, extrapolations between OP insecticides and nerve agents need to take into consideration the toxicokinetic and toxicodynamic differences between these two classes of OP compounds (McDonough and Romano, 2008). Given their frequent occupational use and the duration of the toxic effects of OP insecticides, it is probably more likely that adverse reproductive outcomes will be investigated and observed with exposures to these compounds than with exposures to nerve agents specifically designed for immediate incapacitation without environmental persistence. Depending on the circumstances, acute or low-level exposures to OP nerve agents might not be associated with overt effects on reproductive function, especially when direct toxicant-induced effects on reproductive performance are of secondary importance to neurological and/or psychological concerns and the reproductive endpoints being assessed are relatively insensitive. Duration, route, and amount (i.e., dose) of nerve agent exposure, the developmental period during which exposure occurs, and the reproductive endpoints and animal species being evaluated are factors that will need to be taken into consideration in the design of future studies investigating the direct effects of nerve agents on fertility and embryonic and fetal development.

The Reproductive Toxicity of Environmental Contaminants Resulting from Acts of Terrorism

Not all acts of chemical warfare will necessarily involve weapons specifically designed for that purpose. Especially in instances of terrorism or military attacks involving nongovernmental militias or governments with limited weapons resources, chemical warfare can be low-tech and make use of toxic chemicals in commercially available products or those hazardous materials present at manufacturing, processing, or storage facilities. Ionizing radiation can be released into the environment through strategic military use of nuclear weapons or from nuclear accidents involving municipal power plants, nuclear-powered aircraft carriers, and submarines, or the explosion of misplaced, misused, or stolen nuclear "weapons of mass destruction." In addition, many potential reproductive toxicants, including

pesticides, are routinely used in various manufacturing and agricultural processes. Acts of terrorism or military strikes on industrial or agricultural complexes have the potential to greatly increase the exposure of humans and animals to a large number of different toxicants in the air, water, soil, and food chain.

Depending on the circumstances, both short-term and long-term (i.e., immediate and delayed) morbidity and mortality can be observed in environmental disasters. In these types of catastrophic events, illness and death can be due to the direct effects of toxicants, or they can arise secondarily from other factors associated with the environmental release of xenobiotics. Related conditions, such as famine, can accompany disasters and negatively impact reproductive function in humans and animals. The very real or, in some cases, imagined or exaggerated threats to human and animal welfare from environmental contaminations can be associated with instances of mass fear, panic, and emotional incapacitation. These psychological stresses can affect reproductive function and, especially, gestational length and fetal survival in humans and animals. Emotional responses are naturally heightened with toxic exposures involving pregnant women and children.

Ionizing Radiation

Ionizing radiation can target rapidly dividing cells in multiple organs, including the testes and ovaries, as well as the developing embryo and fetus (Cockerham et al., 2008; Foster and Gray, 2008; Rogers and Kavlock, 2008). Exposure of males to ionizing radiation can result in diminished spermatogenesis and testosterone production by the testes, with increased secretion of LH and FSH by the anterior pituitary (Cockerham et al., 2008). Consistent with these effects, Ukrainian workers involved in the clean-up of radioactive materials after the Chernobyl nuclear accident had increased ultramorphological sperm abnormalities (Fischbein et al., 1997; Cockerham et al., 2008). Similar to the radiation-induced endocrine effects observed in the testes, ovarian steroid production is reduced by exposure to ionizing radiation (Cockerham et al., 2008). Depending on the timing and dose of the radiation exposure, ionizing radiation can cause pubertal failure, ovarian failure, or premature menopause in women. Clusters of Down syndrome cases in Belarus 9 months after the explosion at the Chernobyl nuclear power plant suggest a radiosensitive phase of oogenesis in mammals at the time of ovulation and conception (Zatsepin et al., 2007). High radiation exposure in late-gestational women or pregnant animals has the potential to cause spontaneous abortion or preterm births associated with maternal and/or fetal radiation sickness and stress. Depending on the stage of development and the dose of radiation, exposure of the conceptus, embryo, or fetus to ionizing radiation can result in lethality or morphologic abnormalities (Cockerham et al., 2008), and observations in humans and animals after the Chernobyl incident are consistent with these developmental effects (Østerås et al., 2007; Peterka et al., 2007). In addition, anxiety associated with exposures of pregnant women to ionizing radiation from the Chernobyl nuclear accident reportedly led to increased incidences of spontaneous abortions in several European countries, even in instances when the exposure was minimal (Cordero, 1993).

Pesticides and Other Organic Contaminants

Pesticides and other organic contaminants are ubiquitous in both industrial and agricultural settings. Acts of terrorism have the potential to increase the exposure of humans and animals to these types of xenobiotics in the environment by targeting industrial and agricultural complexes. The massive release of pesticides, in particular, has the potential to be a readily available means of inciting fear and inducing morbidity and mortality in humans and animals. In fact, as mentioned previously, carbamate and OP insecticides have the same basic mechanism of action as the previously discussed AChE-inhibiting nerve agents, and MIC, an intermediate in the production of carbamate insecticides, contains a cyanide moiety.

There have been many well-documented instances of reproductive abnormalities in species of wildlife living in environments contaminated by a wide range of industrial and/or agricultural chemicals (McLaclan, 2001; Hess and Iguchi, 2002; Guillette, 2006; Jobling and Tyler, 2006; McLaclan et al., 2006; Evans, 2007). Wildlife populations are very likely sentinels for exposure to reproductive toxicants because of the contamination of the aquatic habitats in which many of them live and the bioaccumulation of some organic chemicals in predators (Hess and Iguchi, 2002). There is also recent evidence to suggest that domestic animals can act as potential sentinels for human exposure to endocrine disruptors and that hyperthyroidism in cats might be associated with exposure to polybrominated diphenyl ethers (PBDEs) (Dye et al., 2007).

Based on the observations of reproductive toxicity (including endocrine disruption) in wildlife and domestic animals, as well as ongoing concerns about reproductive dysgenesis in human populations and the observed effects of industrial accidents involving MIC and dioxins, there has been increasing interest in the effects of prenatal exposures of humans to suspected endocrine disruptors and other reproductive toxicants. However, when impaired reproductive function is discovered in adults, it is difficult to comment with complete certainty on the relative contributions of prenatal versus postnatal exposures to reproductive toxicants. There is a wide array of pesticides and other organic environmental

contaminants that have the potential to adversely impact reproductive function. Specific epidemiological or laboratory studies suggesting adverse reproductive effects of exposures to these xenobiotics are discussed with respect to observed abnormalities in male and female reproductive function, as well as embryonic and fetal development.

Adverse Effects of Pesticides and Other Organic Contaminants on Male Reproductive Function

"Androgenization" or a state of indeterminate sexual development encompasses both feminization and demasculinization in males and, similar to the testicular dysgenesis syndrome described in humans, has been observed in populations of various vertebrates, including fish, amphibians, reptiles, birds, and mammals (Edwards et al., 2006; Evans, 2007). Adult and immature amphibians exposed to the herbicide atrazine and hatchling, juvenile, and adult male alligators originating from a lake previously contaminated with dichlorodiphenyltrichloroethane (DDT) and other persistent bioaccumulated pesticides have been reported to exhibit varying patterns of androgenization (Hayes et al., 2006; Milnes et al., 2006; Evans, 2007). Although still somewhat controversial, there is evidence to support the observation that sperm counts in men within some industrialized regions of the world have been decreasing over the past several decades (Swan et al., 2000; Jørgensen et al., 2006; Skakkebæk et al., 2006). The findings of epidemiological studies have suggested a relationship between decreased anogenital distance and prenatal exposures of male infants and phthalates used as plasticizers, as well as a correlation between reduced semen quality in men within certain regions of the United States and the metabolites of several economically important herbicides (Swan et al., 2003a,b, 2005). In addition, a recently completed epidemiological study in Italy has demonstrated a significant relationship between postnatal exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and abnormal semen and endocrine parameters in men (Mocarelli et al., 2008).

The dicarboximide fungicides, vinclozolin and procymidone, and/or their metabolites inhibit the binding of androgens to nuclear androgen receptors and can demasculinize and feminize the prenatally exposed male fetus or induce important alterations in prepubertally or peripubertally exposed offspring (Monosson et al., 1999; Gray et al., 2006; Evans, 2007). While still subject to debate among scientists, vinclozolin has also been reported to be capable of inducing epigenetic modifications that facilitate the occurrence of transgenerational or vertically transmitted reproductive abnormalities (Anway et al., 2005; Anway and Skinner, 2006). Linuron, *p,p′*-DDE, prochloraz, PBDEs, and selected OPs can function as androgen receptor antagonists (Gray et al., 2006; Kitamura et al., 2006), and AhR-mediated effects of TCDD can interfere with the biosynthesis of testosterone and disrupt testosterone signal transduction pathways (Jana et al., 1999; Sikka et al., 2005; Mocarelli et al., 2008).

The testes have xenobiotic biotransformation capabilities within both Leydig and Sertoli cells (Thomas and Thomas, 2001). Although many toxicants and/or their metabolites are capable of producing relatively nonspecific effects, such as oxidative stress, there are a number of pesticides and other organic compounds that target specific cell populations within the testes. Several toxicants targeting Sertoli cells, including diethylhexyl phthalate and 2,5-hexanedione (a metabolite of *n*-hexane), have age-specific and species-specific effects (Thomas and Thomas, 2001; Creasy and Foster, 2002; Foster and Gray, 2008). Tri-*o*-cresyl phosphate, an industrial chemical used in lacquers and varnishes that is associated with some organophosphate insecticides, inhibits LH-induced steroidogenesis in the Leydig cells but, after Leydig cell–mediated conversion to its active metabolite, causes morphological abnormalities in Sertoli cells (Thomas and Thomas, 2001; Creasy and Foster, 2002; Evans, 2007).

As mentioned previously with regard to sulfur mustard, a variety of radiomimetic alkylating agents, including busulfan, cyclophosphamide, and nitrogen mustard, can target rapidly dividing mitotic or meiotic germ cells in the testes. In some instances, xenobiotics can target a specific population of germ cell precursors, such as spermatogonia spermatocytes or round or elongate spermatids (Creasy and Foster, 2002; Evans, 2007; Foster and Gray, 2008). TCDD appears to adversely affect several populations of spermatozoal precursors and alters the sex ratio in favor of female offspring (i.e., decreased viability of Y chromosome–bearing sperm) (Thomas and Thomas, 2001; Ishihara et al., 2007; Foster and Gray, 2008; Mocarelli et al., 2008).

Adverse Effects of Pesticides and Other Organic Contaminants on Female Reproductive Function

A wide range of agricultural and industrial chemicals has estrogenic and/or anti-estrogenic activities (Evans, 2007), and some of the synthetic xenobiotics most commonly discussed with respect to these activities include DDT, polychlorinated biphenyls, and TCDD (McLachlan, 2001). Effluents from industrial and agricultural activities have been shown to have androgenic activities and are associated with masculinization of female fish (Orlando et al., 2004; Gray et al., 2006; Evans, 2007).

The effects of toxicants on specific cell types within the ovaries are not as well-understood as they are in the testes (Thomas and Thomas, 2001). Many female reproductive toxicants do not actually target particular cell lines but, rather, disrupt the endocrine milieu of the tubular genitalia or cause changes in ovarian structures

secondary to alterations in the hypothalamic–pituitary–gonadal axis (Yuan and Foley, 2002). Like the testes, the ovaries also have some xenobiotic biotransformation capabilities, and oxidative damage can adversely affect ovarian structure and function (Thomas and Thomas, 2001; Yuan and Foley, 2002). Phthalates and TCDD can delay or decrease ovulations and, like sulfur mustard and ionizing radiation, some of the alkylating agents reported to adversely affect rapidly dividing germ cells within the testes can also adversely affect primordial follicles within the ovary (Thomas and Thomas, 2001; Devine and Hoyer, 2005). Several PAHs (i.e., BaP, 3-methylcholanthrene (3-MC) and DMBA) and 1,3-butadiene appear to target oocytes in preantral follicles, and DMBA can adversely affect antral follicular development (Devine and Hoyer, 2005; Evans, 2007).

Adverse Effects of Pesticides and Other Organic Contaminants on Embryonic/Fetal Development

As has been emphasized previously, the developing fetus undergoing phenotypic sexual differentiation is particularly susceptible to the adverse effects of various agonists and antagonists of estrogen and androgen receptors (Hess and Iguchi, 2002; Evans, 2007). A large number of xenobiotics, including many pesticides (e.g., carbamates, OPs, organochlorines, and pyrethroids) and other potential organic environmental contaminants, have been recognized as potential teratogens in humans and animals (Desaiah, 1998; Evans, 2007; Rogers and Kavlock, 2008). Alkylating agents with radiomimetic activity, such as busulfan, cyclophosphamide, and nitrogen mustard, cause teratogenesis by targeting rapidly replicating cells (Rogers and Kavlock, 2008). TCDD has been found to be teratogenic both in laboratory animals exposed experimentally (Kransler et al., 2007; Aragon et al., 2008) and in humans exposed after an accidental release in Seveso, Italy, in 1976 (Alaluusua et al., 2004). Accidental exposure to MIC in Bhopal, India, in 1984 resulted in a significant increase in spontaneous abortions and neonatal mortality in humans (Varma, 1987; Varma and Mulay, 2006), and these epidemiological data were corroborated by the results of a subsequent rodent experiment (Varma, 1987). In addition, some xenobiotics can cause fetal death and spontaneous abortion by having direct toxic effects on the placenta, rather than on the fetus itself (Pelkonen et al., 2006; Gupta, 2007c).

Heavy Metals

Heavy metals are routinely used in various manufacturing processes and are contained within many products commonly used by humans. Acts of terrorism have the potential to increase the environmental exposure of humans and animals to heavy metals by targeting industrial complexes and sewage treatment facilities. Because a number of heavy metals have the potential to affect different stages of reproductive function by different mechanisms of action, the adverse effects of metals on male and female reproduction and embryonic and fetal development are discussed separately.

Adverse Effects of Heavy Metals on Male Reproductive Function

Excessive cobalt can potentially interfere with normal spermatogenesis and even generalized hypoxia related to increased blood viscosity that affects the testes (Thomas, 1995; Evans, 2007). Chromium and vanadium have also been associated with adverse reproductive effects, and cis-platinum exposure has been associated with the death of spermatocytes and spermatids, as well as disruption of Sertoli cell tight junctions (Thomas, 1995; Thomas and Thomas, 2001; Evans, 2007). Exposure of male laboratory animals to organotin compounds has been associated with reduced testicular size, alterations in testicular morphology, and impaired spermatogenesis (Ema and Hirose, 2006; Evans, 2007).

Lead and cadmium are ubiquitous heavy metals and have been associated with testicular toxicity and impaired fertility in a number of species. Divalent lead is known to interact with physiological processes involving calcium and generally has an affinity for sulfhydryl groups (Evans, 2007). Lead is reported to be toxic to germ cells as well as Leydig cells and can suppress anterior pituitary secretion of LH and FSH (Thomas and Thomas, 2001; Evans, 2007). Lead also appears to be able to adversely affect the ability of spermatozoa to fertilize ova; however, this effect, like others associated with lead exposure, appears to be dependent on age and individual variations in susceptibility, adaptation, and reversibility (Sokol, 2006; Evans, 2007). Like lead, cadmium is thought to adversely affect male reproduction by inhibition of spermiation as well as by interactions with the hypothalamic–pituitary–gonadal axis and adverse effects on the endothelium of the testicular and epididymal vasculature (Thomas, 1995; Creasy and Foster, 2002; Akinloye et al., 2006; Evans, 2007). Cadmium can also alter the junctional complexes between adjacent Sertoli cells and disrupt the integrity of the blood–testis barrier (Thomas and Thomas, 2001; Akinloye et al., 2006; Evans, 2007).

Adverse Effects of Heavy Metals on Female Reproductive Function

The ovaries do not appear to be as sensitive to the toxic effects of heavy metals as do the testes (Thomas, 1995; Evans, 2007). The neuroendocrine function of the hypothalamic–pituitary–gonadal axis appears to be targeted by lead in females as well as in males (Evans, 2007). Anterior pituitary release of FSH and LH and

ovarian steroidogenesis can be inhibited by cadmium (Thomas, 1995; Hoyer, 2006; Evans, 2007). Exposure of female laboratory animals to organotin compounds has been associated with reductions in follicular development and size as well as the formation of corpora lutea, and it has recently been suggested that tributyltin and cadmium might also have estrogenic activities (Ema and Hirose, 2006; Golub, 2006b; Evans, 2007).

Adverse Effects of Heavy Metals on Embryonic/Fetal Development

Several heavy metals have been identified as teratogens and possible abortifacients in humans and animals, and the adverse effects of prenatal lead exposure on the developing nervous systems of both human and laboratory animal species have been well-documented (Rice, 1998; Evans et al., 2003; Rogers and Kavlock, 2008). Prenatal exposure to organotins has been associated with pregnancy loss and impaired ossification in rodents (Ema and Hirose, 2006). The outcomes of an industrial accident in Japan and misuse of contaminated grain in Basra, Iraq, clearly demonstrated the developmental neurotoxicity of organic mercury (i.e., methyl mercury and related compounds) in humans and animals (Cordero, 1993; Chang and Guo, 1998; Golub, 2006b). Other heavy metals, including cadmium, have been associated with placental toxicity as well as developmental neurotoxicity (Hastings and Miller, 1998; Gupta, 2007b), and it has been recently reported that cadmium and other metals or metalloids might also have estrogenic effects (Golub, 2006b).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Reproduction is a critical biological process required for financially viable livestock production as well as long-term survival of human and animal populations. Toxicant-induced spontaneous abortions, congenital defects, and infertility can have devastating effects on humans, domestic animals, and wildlife species. There is growing global concern about all of the potential adverse effects, including those on reproduction, of exposures to CWAs, and other xenobiotics resulting from military or terrorist activities. The information presented in this chapter is intended to familiarize the reader with terminology and concepts pertinent to reproductive toxicity, including endocrine disruption, and to provide an overview of what is understood about the adverse reproductive effects of selected toxicants. It is hoped that the information and references provided in this chapter will assist readers in making informed decisions in their interpretation of experimental or epidemiological data and their preparation for future experiments or clinical investigations.

Liver Toxicity of Chemical Warfare Agents

Shashi K. Ramaiah and Atrayee Banerjee

INTRODUCTION

Xenobiotic-induced liver injury has become the most frequent cause of acute liver failure in humans in the United States and around the world, exceeding all other causes combined (Watkins and Seef, 2006). Owing to its detoxification mechanisms, the liver protects the individual against xenobiotic-induced injury. Certainly, the liver toxicity caused by chemical warfare agents (CWAs) is a potential area of concern.

Chemical-induced liver injury is encountered in a variety of circumstances. Some natural toxins, such as the peptides of *Amanita phalloides*, the pyrrolizidine alkaloids, the toxin of the cycad nut, and other plant toxins, are hazards posed by the environment. Some mycotoxins are ingested unknowingly because of feed contamination due to climatic conditions that favored fungal growth. Other circumstances of exposure to hepatotoxins include the contamination of water supply with cyanobacterial toxins, which led to the tragic death of 60 patients in a hemodialysis clinic in Brazil in 1996 (Jochimsen et al., 1998).

Research in the last decade has focused on elucidating different mechanisms for chemical-induced liver injury. Investigators have attempted to understand the basis for such hepatic injury. The goal of this chapter is to provide a basic understanding of liver pathophysiology and to introduce the general concepts of liver injury. The chapter also describes a few examples of CWAs that can inflict liver damage.

STRUCTURAL ORGANIZATION OF THE LIVER

The hepatic lobule and hepatic acinus are relatively well accepted models to describe the structure and functional aspects of the liver. Histologically, the *hepatic lobule* is a hexagonal region of the liver parenchyma around the central vein. Typically, six portal triads, consisting of branches from the portal vein and hepatic artery as well as bile ductules, border the edge of the lobule. Cords of hepatocytes are arranged radially around the central vein, and blood sinusoids form between them. The hepatic parenchyma is divided into three zones based on proximity to the central vein. The area closest to the central vein is termed *centrilobular*, the area near the portal triads is *periportal*, and the area between the centrilobular and periportal parenchyma is termed *midzonal*.

Alternatively, *hepatic acinus* is defined as the structural and functional unit in the liver based on the hepatic microcirculation. In simple terms, the hepatic acinus is defined as a parenchymal mass organized around the portal triad. Within the acinus, blood drains from the portal area via the sinusoids into the central hepatic vein. The acinus is arbitrarily divided into zone 1, which corresponds to the periportal zone of the hepatic lobule; zone 2, which corresponds to the midzonal parenchyma; and zone 3, which corresponds to the centrilobular zone. The majority of blood supply to the liver is from the portal vein. Approximately 60–80% of the blood originates from branches of the portal vein and supplies nutrients and toxins from the gastrointestinal tract while 20–40% of the blood originates from the hepatic artery, supplying oxygen (Treinen-Moslen, 2001). The blood from the portal vein and hepatic artery is mixed in the penetrating vessels, which then enter the sinusoids. Blood flows sequentially through zone 1, zone 2, and zone 3 before draining via the central vein. Because of this preferential blood circulation, hepatocytes in zone 1 receive blood that is 9–13% oxygenated, whereas zone 3 is relatively hypoxic—the blood is 4–5% oxygenated and nutrient-depleted (Treinen-Moslen, 2001).

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00042-7

In addition to hepatic parenchymal cells, which are hepatocytes, hepatocyte stem cells, termed *oval cells*, are reported to be located in the canals of Hering, where bile canaliculi from the hepatic cords converge on bile ductules of the portal triad. It is postulated that new hepatocytes travel down hepatic cords to replace the aging and damaged hepatocytes from zone 3.

Sinusoids lined by specialized endothelium are blood channels located between hepatocyte cords. The endothelial lining of the sinusoids is discontinuous and has fenestrae to facilitate the movement of fluid and molecules less than 259 kDa in size (Watkins, 1999; Treinen-Moslen, 2001; Plumlee, 2004). This material enters the space of Disse, which is located between the endothelium and the hepatocytes. Within the space of Disse, hepatocytes contact free and protein-bound molecules, which may be absorbed by diffusion or active transport.

Hepatic Functional Capacity

The liver contributes to a plethora of functions. Liver filters the blood drained from the gastrointestinal tract via the portal vein for xenobiotics, endotoxins, ammonia, and other bacteria-derived products (Treinen-Moslen, 2001; Plumlee, 2004). The liver is directly involved in glucose homeostasis (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004); cholesterol synthesis and uptake (Treinen-Moslen, 2001); synthesis of proteins such as clotting factors, albumin, and very-low-density lipoprotein (Treinen-Moslen, 2001; Plumlee, 2004); storage of glycogen, lipids, minerals, and vitamins (Plumlee, 2004); metabolism and excretion of hemoglobin breakdown products (Plumlee, 2004); steroid hormones (Brown, 2001); and drug metabolites.

The hepatic zones have remarkable regiospecificity and metabolic diversity to accommodate the numerous functions of the hepatocytes. In addition to differences in oxygen gradients (zone 3 hepatocytes are oxygen-depleted compared to zone 1 hepatocytes), hepatocytes of zone 3 in particular are rich in drug-metabolizing enzymes. Zone 3 hepatocytes are involved in glycolysis and lipogenesis (Plumlee, 2004), and zone 1 hepatocytes are mitochondria-rich (Treinen-Moslen, 2001; Plumlee, 2004). Functions of zone 1 hepatocytes include bile salt extraction, fatty acid oxidation, gluconeogenesis, and protein synthesis (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004; Plumlee, 2004). Zone 1 hepatocytes have the highest levels of glutathione (GSH; Treinen-Moslen, 2001).

Bile secretion is a major function of the liver. Bile is composed of bile salts, bilirubin, GSH, phospholipids, cholesterol, proteins, organic anions, metals, and conjugated xenobiotics (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004). Bile salts and bilirubin enter bile canaliculi via active transport through hepatocyte membranes. Canaliculi are dynamic structures located between hepatocytes and formed by hepatocyte membranes (Treinen-Moslen, 2001; Plumlee, 2004). Energy-dependent transport exists for certain hormones, drugs, and other xenobiotics. These include a group of multiple drug resistance p-glycoproteins that transport lipophilic cationic drugs, estrogens, phospholipids, and canalicular multiple organic anion transporters involved in the movement of molecules conjugated to GSH, glucuronide, and sulfate. Metal and mineral transport is important for mineral homeostasis and occurs through facilitated diffusion and receptor-mediated endocytosis across the sinusoidal membrane. Lysosomes are involved in storage and export of metals and minerals into canaliculi.

Canaliculi enter canals of Hering in the portal triad and lead to intrahepatic bile ducts, which coalesce to form the hepatic bile duct. The bile duct empties the bile into the gallbladder, which then is released into the duodenum. Bile that is excreted into the small intestine enhances nutrient uptake, protects enterocytes from oxidation, and facilitates the excretion of xenobiotics and endogenous waste in the feces (Treinen-Moslen, 2001).

Hepatic Cellular Components

In addition to the hepatocytes and the hepatocytic stem cells (oval cells), which are parenchymal in origin, there are four types of nonparenchymal cells present within the liver. The nonparenchymal cells include the endothelial cells lining the sinusoids; bile duct epithelium; Kupffer cells, which are resident macrophages; the *Stellate* cells, also called *Ito cells* or *fat-storing cells*; and the pit cells or large granular lymphocytes. In the rat, hepatocytes represent about 60% of the total cell number and 80% of hepatic tissue volume. Nonparenchymal cells in the rat are estimated to constitute about 30% of total cellular population, but comprise only 6–7% of tissue volume due to their small size relative to hepatocytes (Dahm and Jones, 1996).

Kupffer cells represent 80% of the fixed macrophages in the body. These cells are mostly located within the sinusoidal lumina in close association with endothelial cells. Kupffer cells function as phagocytes, ingesting foreign material which may arrive through the portal circulation (Treinen-Moslen, 2001; Plumlee, 2004), as well as apoptotic or necrotic hepatocytes. Kupffer cells have other immune functions in that they act as antigen-presenting cells and secrete various cytokines. Kupffer cells may store minerals and are also involved in the pathogenesis of a variety of liver diseases induced by toxins such as ethanol (Laskin, 1990; Thurman et al., 1998).

Stellate cells are located within the sinusoids and store fat and vitamin A (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004; Plumlee, 2004). In the event

of liver injury, stellate cells may become activated to a myofibroblast-like phenotype (Plumlee, 2004; Maddrey, 2005). Activated stellate cells produce collagen and play a role in the pathogenesis of hepatic fibrosis.

Pit cells are natural killer cells that have anti-neoplastic actions (Treinen-Moslen, 2001; Plumlee, 2004). They are also involved in granuloma formation (Plumlee, 2004).

FACTORS INFLUENCING HEPATIC TOXICITY

Preferential Hepatic Uptake

As mentioned previously, the liver has a dual blood supply. The hepatic artery delivers material from the systemic circulation and the portal blood flow delivers directly from the gastrointestinal system. The portal system is involved in the *first pass effect*, where the nutrients and xenobiotics that are absorbed from the stomach and intestines are filtered through the liver before reaching the systemic circulation (Treinen-Moslen, 2001). The space of Disse allows close contact between circulating plasma, plasma proteins, and hepatocytes, allowing rapid diffusion of lipophilic compounds across the hepatocyte membrane. Some compounds are specifically taken up by sinusoidal transporters, including phalloidin from several species of mushrooms in the genus *Amanita*, microcystin produced by the cyanobacteria *Microcystis aeruginosa*, and bile acids.

Liver cells have the potential to accumulate high levels of metals and vitamins, which can lead to toxic injury. Excessive vitamin A storage in stellate cells acutely leads to the activation and proliferation of these cells (Treinen-Moslen, 2001), while chronic high levels can lead to hepatic fibrosis and portal hypertension, precipitating increased fibrosis (Zimmerman, 1999; Piñeiro-Carrero and Piñeiro, 2004; Maddrey, 2005). The liver is also responsible for iron homeostasis. There is a receptor mediated uptake of iron from the sinusoids and sequestration in storage proteins such as ferritin. High levels of iron cause lipid peroxidation of zone 1 hepatocytes (Treinen-Moslen, 2001). A common example of hepatic accumulation of metals is copper-mediated liver toxicity noted in certain breeds of dogs (e.g., Bedlington terriers, Dobermans, and Dalmatians) where copper is stored within lysosomes of hepatocytes, resulting in progressive accumulation of copper resulting in liver necrosis (Rolfe and Twedt, 1995).

Xenobiotic Metabolic Bioactivation

Most xenobiotic agents absorbed by the small intestine are highly lipophilic. Renal excretion is the primary mechanism of xenobiotic removal, but kidney excretion of lipophilic compounds, which are frequently protein-bound in the circulation, is poor (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Watkins, 1999). Such lipophilic compounds must be metabolized to increase their water solubility for excretion (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Zimmerman, 1999). Microsomal enzymes within the liver add functional groups or conjugate xenobiotics to water-soluble molecules to facilitate excretion. While these reactions often function in the detoxification of compounds, there is significant potential for toxification (Zimmerman, 1999). Examples of phase I reactions include oxidation, reduction, and hydrolysis. Phase I enzymes, which are predominantly located in zone 3 of the hepatic lobule, may produce reactive metabolites.

Many hepatic enzymes are present in the smooth endoplasmic reticulum of the hepatocyte. When liver tissue is homogenized, the endoplasmic reticulum breaks down into small vesicles known as *microsomes*; thus, these enzymes are termed *microsomal enzymes*. As a rule, microsomal enzymes require oxygen and reduced nicotinamide adenine dinucleotide (NADPH) to function (Dahm and Jones, 1996; Brown, 2001). Most phase I enzymes contain heme, giving them a red coloration, and they absorb light at a wavelength of 450 nm. Most cytochrome P450s act as mixed function oxidases. Genes for cytochrome P450s are highly conserved in mammals. There are three gene families, CYP1, CYP2, and CYP3, and more than 36 cytochrome P450 isoenzymes have been identified in animals (Dahm and Jones, 1996; Watkins, 1999).

Oxidation is the major phase I reaction produced by the group of cytochrome P450s. Important substrates for CYP450s include steroid hormones and lipid-soluble drugs (Brown, 2001). Oxidative reactions frequently lead to the formation of highly reactive epoxides. These toxic metabolites are usually detoxified rapidly by phase II conjugation or other mechanisms, such as microsomal epoxide hydrolases (Watkins, 1999; Piñeiro-Carrero and Piñeiro, 2004).

Non-cytochrome P450 enzymes may also be involved in oxidative reactions. One such enzyme is alcohol dehydrogenase, whose substrates include vitamin A, ethanol, and ethylene glycol. Aldehyde dehydrogenase is another enzyme. Most reduction reactions also involve microsomal enzymes, with the exception of ketone reduction. Nitro compounds are reduced to amines, and volatile anesthetics undergo dehalogenation by microsomal enzymes. Hydrolysis reactions are involved in the metabolism of compounds with amide bonds or ester linkages, as in the conversion of aspirin to salicylate (Brown, 2001).

Phase II/Conjugation Reactions

Phase II enzymes may be cytosolic or microsomal (Dahm and Jones, 1996; Brown, 2001). Phase II enzymes

are predominantly involved in conjugating phase I metabolites or xenobiotics with functional groups. Phase II metabolites are rarely reactive, but there are a few exceptions, such as the glucuronide of the nonsteroidal anti-inflammatory drug diclofenac and the GSH conjugate of α-naphthothiourea (ANTU). Phase II enzymes conjugate a polar group to the substrate at a hydroxyl group, carboxyl group, amino group, or sulfhydryl group produced through the actions of phase I microsomal enzymes. Polar molecules that are added to the substrate include glucuronic acid, sulfate derived from sulfuric acid ester, acetate, GSH, methyl groups derived from methionine, and amino acids such as glycine and cysteine. These polar groups significantly increase water solubility of the substrate facilitating rapid renal or biliary excretion.

Glucuronidation is the most common phase II reaction in humans, though it is deficient in the neonate (Sturgill and Lambert, 1997; Brown, 2001; Piñeiro-Carrero and Piñeiro, 2004). Substrates for glucuronidation usually include steroid hormones, thyroxin, and bilirubin, as well as many drugs, including salicylates and acetaminophen. Glucuronyl transferases are microsomal enzymes that catalyze the transfer of glucuronide from uridine 5′-diphosphate (UDP; Watkins, 1999). UDP may be depleted in patients overdosed with acetaminophen or other drugs that undergo this detoxification pathway. Products of glucuronidation may be excreted in the bile or urine. Those excreted in the bile may undergo hydrolysis in the intestine, which leads to reabsorption of the parent compound in a phenomenon called *enterohepatic cycling* (Brown, 2001). Similar to CYP 450 enzymes, some agents can also induce glucuronyl transferases, such as phenobarbital (Sturgill and Lambert, 1997).

Sulfation is the primary conjugation reaction for substrates with phenol groups or aliphatic alcohols (Sturgill and Lambert, 1997; Brown, 2001). These reactions are catalyzed by sulfotransferases in the cytoplasm. Agents that undergo sulfation include acetaminophen, morphine, ascorbic acid, and endogenous compounds like chondroitin, heparin, and some steroids. The pool of available sulfates may become saturated in drug overdoses.

Drugs with amine and hydrazine groups may be conjugated to acetate (Sturgill and Lambert, 1997). Sulfonamides often undergo acetylation (Brown, 2001). *N*-acetyltransferase is an enzyme in the cytoplasm involved in acetylation reactions.

GSH and cysteine both have sulfhydryl groups that readily bind many phase I metabolites (Brown, 2001). GSH is a free-radical scavenger that prevents membrane damage from reactive metabolites. These reactions may be spontaneous or catalyzed by GSH peroxidases, which are selenium-dependent enzymes. Because these enzymes are cytosolic, damaged membrane phospholipids must be released by phospholipase A2 for detoxification. GSH is also involved in the reduction and recycling of other antioxidants, such as vitamins E and C (Dahm and Jones, 1996). When oxidized, GSH forms a dimer, which must be reduced by GSH reductases, which are NADPH-dependent enzymes. GSH may be depleted in the acetaminophen-overdosed or fasting person (Dahm and Jones,1996; Sturgill and Lambert, 1997; Piñeiro-Carrero and Piñeiro, 2004). *N*-acetylcysteine is frequently used to replenish GSH.

Phase III Reactions

In addition to phase I and II biotransformation enzymes, studies suggest the involvement of hepatic transporter systems involved in drug efflux from hepatocytes as a means for the liver to rid itself of foreign chemicals. These are termed *phase III transporter systems*. Several transporter families that mediate uptake of chemicals into liver and excretion of chemicals from liver into blood, bile, or both have been cloned and identified. In general, the organic anion transporting polypeptide family (Oatps), along with organic cation transporter 1 (Oct1) and organic anion transporter 2, mediate the uptake of a large number of xenobiotics from the blood to the liver. Conversely, multidrug resistance proteins (Mdrps), multidrug resistance-associated proteins (Mrps), and breast cancer resistance protein (Bcrps) mediate the efflux of xenobiotics from the liver into bile or blood (Klaassen and Slitt, 2005).

Pathologic Manifestations of Hepatic Injury

Hepatic Steatosis/Fatty Liver

Hepatic steatosis is the accumulation of fat droplets within the hepatocytes. Steatosis is usually a common response noted with a variety of liver toxicants and represents a potentially reversible injury to hepatocytes (Treinen-Moslen, 2001). Grossly, the affected liver will be swollen, with rounded edges, friable, and light brown to yellow in color. Compounds that produce prominent steatosis include the antiepileptic drug valproic acid and the antiviral agent fialuridine. Other toxins that may cause hepatic steatosis include aflatoxin and white or yellow phosphorus. Although steatosis has been considered benign and reversible, there are recent reports that suggest the progression of the steatosis stage to steatohepatitis, fibrosis, and cirrhosis (Ramaiah et al., 2004). Recently, there is a syndrome noted in obese individuals, who are often type 2 diabetics, called nonalcoholic fatty liver disease (NAFLD), where hepatocytes are markedly steatotic and there is a marked inflammatory component (Diehl, 2005). Other disorders that result in fatty livers include hepatotoxic chemicals such as thioacetamide,

ethanol, and carbon tetrachloride. It should be noted, however, that several endocrine abnormalities result in steatosis, thus assigning the cause to a specific etiology should be done with caution.

Steatosis is termed *microvesicular* if the fat droplets are small and do not completely displace the nucleus. Microvesicular steatosis likely indicates a slow lipid accumulation (Bastianello et al., 1987; Plumlee, 2004) and may indicate a deficiency in mitochondrial β-oxidation of fatty acids. It is a relatively severe form of steatosis and has been associated with certain toxins, including aflatoxin in primates and dogs (Bastianello et al., 1987; Zimmerman, 1999) and valproic acid in humans (Sturgill and Lambert, 1997; Zimmerman, 1999). In contrast, macrovesicular steatosis describes hepatocytes containing large, usually single fat droplets that displace the hepatocyte nucleus to the periphery of the cytoplasm. Macrovesicular steatosis indicates an imbalance between fatty acid uptake and secretion of very-low-density lipoproteins. This may be due to increased triglyceride mobilization, decreased fatty acid oxidation, decreased synthesis of very-low-density lipoproteins, or other metabolic anomalies (Sturgill and Lambert, 1997; Zimmerman, 1999; Treinen-Moslen, 2001; Plumlee, 2004).

Steatohepatitis

Steatohepatitis is the accumulation of lipids and the presence of inflammatory cells within hepatic parenchyma. Steatohepatitis is usually the next stage of steatosis if untreated (Lieber, 1994; Bautista, 2002; French, 2003). The inflammatory cells are usually neutrophils and macrophages. Conditions usually associated with steatohepatitis are alcoholic liver disease, NAFLD, and endotoxemia secondary to intestinal disease. Any toxic compounds that cause steatosis can also result in steatohepatitis if the condition is left untreated. Steatohepatitis may progress to fibrosis/cirrhosis and hepatocellular carcinoma if the inciting cause is not removed or treated (Diehl, 2002).

Apoptosis Versus Necrosis

Two forms of cell death are described within hepatocytes: apoptosis and necrosis. As with other organs, apoptosis is often called *programmed cell death* and is a normal physiologic process. Individual cells are affected (Dahm and Jones, 1996), cell death is not associated with inflammation, and normal architecture of the hepatic parenchyma is maintained, allowing regeneration (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004). Apoptotic cells undergo cell shrinkage and nuclear condensation and pyknosis, but mitochondrial function (Piñeiro-Carrero and Piñeiro, 2004) is maintained and the cell membrane remains intact (Zimmerman, 1999). Apoptotic cells are occasionally seen in the centrilobular area but are rapidly phagocytosed by macrophages and other hepatocytes (Plumlee, 2004). Apoptosis may be induced by xenobiotics due to oxidative stress (Piñeiro-Carrero and Piñeiro, 2004), decrease in apoptotic suppressors, or enhanced expression of apoptosis genes (Dahm and Jones, 1996).

Necrosis is the predominant form of cell death in most hepatotoxic insults. The term *necrotic* is used to describe dead and dying cells, which are often identified by homogeneous eosinophilic cytoplasm on hematoxic and eosin stained liver sections with variable loss of nuclear and cellular detail. Degenerative changes to the hepatocyte may precede necrosis. During necrosis, cells lose osmotic homeostasis and there is swelling of hepatocytes and organelles on an ultrastructural basis (Dahm and Jones, 1996; Treinen-Moslen, 2001), both of which can be observed microscopically. Energy production fails due to loss of calcium homeostasis (Dahm and Jones, 1996; Zimmerman, 1999). Eventually, the cell membrane ruptures, and leakage of cell contents occurs.

Necrosis is often initiated by damage to membranes, either the plasma membrane of the cell or the membranes of organelles, particularly mitochondria (Zimmerman, 1999). Cell membrane damage is often caused by membrane phospholipid peroxidation. Plasma membrane damage interferes with ion regulation, calcium homeostasis, energy production, and decrease in the ability of that organelle to sequester calcium. Inhibition of protein synthesis is an alternative mechanism that may cause cell necrosis. Toxins that act in this way include phalloidin and related mushroom toxins, which inhibit the action of ribonucleic acid (RNA) polymerase, and therefore mRNA synthesis (Piñeiro-Carrero and Piñeiro, 2004).

Hepatic Pigment Accumulation

Various substances may accumulate within hepatocytes or Kupffer cells. These substances may be visible by microscopy as pigment. Occasionally, these pigments lend a grossly visible tint to the liver. Bile pigment may accumulate in canaliculi and bile ducts, particularly in zone 3, leading to a yellow to green color (Plumlee, 2004; Zimmerman, 1999). Iron, in the form of hemosiderin, is stored in the liver as a yellow-brown pigment that may be visualized using Pearl's Prussian blue. Copper may be yellow-brown and is visualized using rhodenase. Lipofuscin may be present within hepatocytes as a senile change. This yellow-brown pigment represents lipid accumulation within lysosomes.

Hepatic Cholestasis

Cholestasis may be transient or chronic (Treinen-Moslen, 2001) and may be subdivided into canalicular cholestasis and cholangiodestructive cholestasis. Canalicular cholestasis can be produced by drugs or other chemicals that damage the bile canalicular structure

and function. A key component of bile secretion involves several adenosine triphosphate (ATP)–dependent export pumps, such as the canalicular bile salt transporter, that moves bile salts and other transporters that export bile constituents from the hepatocyte cytoplasm to the lumen of the canaliculus. Some of the drugs bind these transporter molecules, resulting in the arrest of bile formation or movement within the lumen of the canalicular system (Klaassen and Slitt, 2005). Secondary bile injury can result if there is cholestasis due to the detergent action of bile salts on the biliary epithelium or hepatocytes in areas of cholestasis. Cholestasis can occur simply as a result of physical obstruction of canaliculi within the liver parenchyma (intrahepatic) or outside the liver (extrahepatic). Causes of cholestasis may include hepatobiliary tumors, endotoxemia, hepatocyte swelling, and intraductal crystals such as calcium salts of plant saponins. Disruption of actin filaments within the hepatocyte may cause cholestasis by preventing the normal pulsatile contractions that move bile through the canalicular system to the bile ducts. Drugs that bind to actin filaments such as phalloidin, those that affect cytoskeletal assembly such as microcystin, and those that affect calcium homeostasis and cellular energy production can generate this type of energy.

Cholangiodestructive cholestasis is caused by bile duct obstruction, which may be intrahepatic or extrahepatic. Bile duct injury may lead to the sloughing of epithelial cells into the lumen, cell edema, and inflammation, which may contribute to obstruction (Treinen-Moslen, 2001; Plumlee, 2004). Chronic lesions associated with cholangiodestructive cholestasis typically include bile duct proliferation and periductular fibrosis. Vanishing bile duct syndrome, characterized by a loss of bile ducts, has been seen in chronic cholestatic disease in humans (Zimmerman, 1999; Treinen-Moslen, 2001) and has been produced experimentally in dogs (Uchida et al., 1989).

Hepatic Fibrosis/Cirrhosis

Fibrosis usually results from chronic inflammation, which can be the result of continuous exposure to a variety of hepatotoxic chemicals, such as organic arsenicals, vinyl chloride, or high doses of vitamin A (Zimmerman, 1999), chronic ethanol ingestion, and NAFLD. Fibrosis usually occurs around the portal area, in the space of Disse, and around the central veins. This results in loss of liver architecture and function. The hepatocytes are replaced with fibrous material, and thus there is hepatocyte loss. Periportal fibrosis may lead to portal hypertension.

Cirrhosis

Hepatic cirrhosis is typically the end stage of liver disease. Cirrhosis describes an irreversible change (Treinen-Moslen, 2001) characterized by accumulation of excessive collagen deposition in the form of bridging fibrosis, which disrupts the hepatic architecture. Cirrhosis may be micronodular or macronodular, depending on the amount of fibrosis and tissue regeneration. Liver transplantation is the only solution to restore adequate liver function in human medicine.

Pathomechanisms of Hepatic Injury

Mechanisms of liver injury have been divided into two categories: intrinsic and idiosyncratic. Intrinsic injury may lead to steatosis, necrosis, cholestasis, or a mixed form of damage, often with minimal inflammation (Sturgill and Lambert, 1997). Intrinsic liver injury is a predictable, reproducible, dose-dependent reaction to a toxicant (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Zimmerman, 1999; Piñeiro-Carrero and Piñeiro, 2004). A threshold dose exists for xenobiotics causing intrinsic liver injury. There is commonly a predictable latent period between the time of exposure and clinical evidence of liver injury. This type of liver injury accounts for the vast majority of toxic liver injury and is often caused by reactive products of xenobiotic metabolism, most commonly electrophiles and free radicals. A few drugs cause intrinsic liver injury without bioactivation. An abbreviated summary of mechanisms of intrinsic liver injury is illustrated in Figure 42.1.

Idiosyncratic responses are, by contrast, unpredictable responses to a drug or other toxicant. They are rare, non-dose-dependent, and often associated with extrahepatic changes (Sturgill and Lambert, 1997; Zimmerman, 1999; Piñeiro-Carrero and Piñeiro, 2004; Shenton et al., 2004). Idiosyncratic drug reactions often occur after sensitization, followed by reexposure to a drug. There is a usually a delay of 1–5 weeks (and occasionally several months) between the time of the first dosing and the time that clinical signs become evident, but onset is expedited with rechallenge (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Watkins, 1999). Hepatic changes associated with idiosyncratic drug reactions include necrosis, cholestasis, or both; and there is often an inflammatory response involving macrophages and eosinophils. Extrahepatic clinical signs may include pyrexia, rash, and peripheral eosinophilia. Some idiosyncratic drug reactions resemble serum sickness. Some of the mechanisms of liver injury are described in more detail next.

Oxidative Stress and Free Radicals with Classic Examples

Free radicals are generated within hepatocytes in several ways, such as ionizing radiation, oxidative metabolism by cytochrome P450, reduction and oxidation (redox) reactions that occur during normal metabolism, transition metals such as iron and copper, and from

FIGURE 42.1 Multiple metabolic pathways involved in the mediation of hepatic injury for any compound. The liver is central to the metabolism of xenobiotic (and some endogenous) compounds, which produces water-soluble products amenable to urinary or biliary excretion. Some compounds undergo metabolic activation to produce free radicals, electrophiles, or other toxic products that may induce hepatic injury.

FIGURE 42.2 Metabolism and mechanism of acetaminophen toxicity. Bioactivation of acetaminophen by P450 enzymes results in the formation of the reactive intermediate (NAPQI), which forms covalent protein adducts with GSH, which then is converted to mercapturic acid. When the amount of the reactive metabolite formed exceeds the GSH available for binding, the excess metabolite binds to tissue molecules, resulting in centrilobular hepatic necrosis.

nitric oxide generated by a variety of inflammatory cells. The reactive species that are generated result in lipid peroxidation of membranes, oxidative modification of proteins, and lesions within DNA (Crawford, 1999).

Free radicals have unpaired electrons, making them highly reactive. They may be formed by one electron oxidation or reduction reactions, leading to cationic or anionic radicals, respectively (Dahm and Jones, 1996). Alternatively, hemolytic bond scission leads to neutral radical formation. Oxygen free radicals result from metabolic processes, leukocytic respiratory burst, or the effects of ionizing radiation. Hydroxyl radicals, superoxide radicals, and hydrogen peroxide are major reactive oxygen species. The free radical nitric oxide (NO), an important cell-signaling agent released by leukocytes, may react with superoxides to form peroxynitrite.

Free radicals cause peroxidation of phospholipids within the plasma membrane of the cell, as well as the membranes of the mitochondria and endoplasmic reticulum. The radicals act by removing a proton (H^+) from a methylene carbon within a polyunsaturated fatty acid, forming a lipid free radical. This lipid free radical then may abstract a proton from a neighboring polyunsaturated fatty acid, generating more lipid free radicals. It is estimated that this can occur 4–10 times per initiation. Effects of lipid peroxy radicals on the cell membrane include increased permeability, decreased fluidity, and inactivation of membrane proteins (Dahm and Jones, 1996). Additionally, mitochondrial membranes lose polarity (Watkins, 1999).

Lipid peroxy radicals can react with metal ions stored within the hepatocyte, generating more lipid radicals. It is estimated that propagation by this mechanism can occur in 4–10 steps per initiation (Dahm and Jones, 1996). The most frequent mechanism of free radical production leading to hepatocellular injury involves phase I metabolism of xenobiotics and the cytochrome P450 system. Phase I metabolism may lead to bioactivation of the substrate to a high-energy reactive intermediate molecule in preparation for phase II conjugation reactions. However, in circumstances such as overdosage, phase I products may accumulate. Lesions produced by these compounds are mostly centrilobular because the cytochrome P450s responsible for metabolism are mostly situated in the centrilobular areas of the liver.

The classic examples of this process are cell death resulting from carbon tetrachloride and acetaminophen toxicosis (Figure 42.2). Acetaminophen has a hydroxyl group that can undergo immediate phase II conjugation reactions. Indeed, at therapeutic doses, 90% of this substrate undergoes glucuronide or sulfate conjugation in humans (Court and Greenblatt, 1997; Sturgill and Lambert, 1997). These are major metabolic pathways in most species, but the glucuronyl transferase

deficiency in cats in part explains the sensitivity of felines to this drug.

Acetaminophen in itself is not considered toxic. Cellular injury is caused by the unstable metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI; Figure 42.2). Under normal conditions in humans, 5% of a dose of acetaminophen is oxidized to NAPQI, which is rapidly neutralized by conjugation with GSH (Sturgill and Lambert, 1997; Maddrey, 2005; Figure 42.2). Toxic levels of NAPQI may accumulate under certain conditions, as when large amounts of substrate are available for metabolism due to either large ingestions or inadequate glucuronidation. Metabolism of acetaminophen to NAPQI is increased in individuals who regularly consume alcohol or take medications that induce microsomal enzymes (e.g., antiepileptic therapy). The hepatic pool of GSH becomes overwhelmed and depleted, permitting the accumulation of NAPQI. Possible additional risk factors that lower the threshold for hepatotoxicity have been identified; they include fasting and malnutrition, which deplete GSH reserves (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004).

The reaction that produces NAPQI generates superoxide anions as a by-product. Interactions of NAPQI with other cellular molecules also generate reactive oxygen species, leading to oxidative stress on hepatocytes (Dahm and Jones, 1996; Zimmerman, 1999). The role of calcium and Kupffer cell activation have been implicated as contributing factors for acetaminophen-induced liver injury by producing reactive nitrogen species (Treinen-Moslen, 2001).

NAPQI also acts as an electrophile, targeting the mitochondria in particular. This reactive metabolite forms covalent adducts with cellular molecules, particularly proteins with thiol groups. Other targets in addition to mitochondrial proteins include plasma membrane proteins involved in calcium homeostasis and adenine nucleotides (Dahm and Jones, 1996; Sturgill and Lambert, 1997).

Disruption of Calcium Homeostasis

Calcium ions (Ca^{2+}) are important for the mediation of hepatic injury. Cytosolic-free calcium is maintained at relatively low concentrations compared to the extracellular levels. The majority of intracellular calcium is sequestered within the mitochondria and endoplasmic reticulum. Membrane associated calcium and magnesium ATPases are responsible for maintaining the calcium gradient (Farrell et al., 1990). Significant and persistent increases in the intracellular calcium result from nonspecific increases in permeability of the plasma membrane, mitochondrial membranes, and membranes of the smooth endoplasmic reticulum. Calcium pumps in the mitochondrial membrane require NADPH; thus, depletion of available NADPH can cause the release of calcium from mitochondria (Cullen, 2005).

Elevated cytoplasmic calcium activates a variety of enzymes, with membrane-damaging effects. The major enzymes that are involved in activation by calcium include ATPases, phospholipases, proteases, and endonucleases. Thus, increased calcium causes increased mitochondrial permeability and induction of apoptosis and necrosis. Calcium is required for maintenance and function of the cytoskeleton as well (Dahm and Jones, 1996; Delgado-Coello et al., 2006).

Although cell injury results in increased calcium, which causes a variety of damaging effects, the cause-and-effect relationship of calcium to cell damage is not known. The chemicals that cause liver damage by this mechanism include quinines, peroxides, acetaminophen, iron, and cadmium.

Inhibition of Mitochondrial Function

Mitochondria function in the process of producing energy, in the form of ATP, for the cell by oxidative phosphorylation. Hepatocytes are highly metabolically active and require a continuous supply of ATP. Hepatocytes active in detoxification or replacement of damaged tissue have even greater ATP requirements (Dahm and Jones, 1996). Compounds that may disrupt mitochondrial oxidative phosphorylation include bile acids and amiodarone. Mitochondria are also critical to modulation of cell redox status, osmotic regulation, pH control, and cytosolic calcium homeostasis and cell signaling. Mitochondria are important targets for virtually all types of injurious stimuli, including hypoxia and toxins. Mitochondria are targeted by oxidants, electrophiles, lipophilic cations, and weak acids. Damage is often precipitated by increases in cytosolic calcium.

Hepatic injury is frequently accompanied by morphological changes in mitochondria. Mitochondrial changes evident as structural abnormalities include greatly increased size and the development of crystalline inclusions. These changes are usually regarded as pathologic, reflecting as either a protective or degenerative response to injury. Mitochondrial damage may result in the formation of high-conductance channels (the so-called mitochondrial permeability transition) in the inner mitochondrial membrane. This is an irreversible change, and because membrane potential is critical for mitochondrial oxidative phosphorylation, it constitutes a death blow to the cell.

Oxidative phosphorylation produces reactive oxygen species (Watkins, 1999). These are deactivated by antioxidants present within the mitochondrion. GSH is present within mitochondria as a scavenger for peroxides and electrophiles. Synthesis of GSH requires ATP

and takes place outside the mitochondrion. A greater than 90% depletion in GSH reserves decreases the ability of the mitochondrion to detoxify reactive oxygen species produced by oxidative phosphorylation. GSH *S*-transferase, the enzyme required for recycling of GSH, may become overwhelmed by toxicants and reactive metabolites (Dahm and Jones, 1996).

Xenobiotics may cause cell death by their effects on mitochondrial DNA. Some antiviral dideoxynucleoside analogs can disrupt mitochondrial DNA synthesis through the inhibition of DNA polymerase gammas, leading to depletion of mitochondria and consequent hepatocyte death.

Chemicals that damage mitochondrial structure, enzymes, or DNA synthesis can disrupt beta oxidation of lipids and oxidative energy production within hepatocytes. Prolonged interruption of beta oxidation leads to microvesicular steatosis, which can progress to macrovesicular steatosis. This sequence of events has been noted with both alcoholic and nonalcoholic steatohepatitis. The role of mitochondria has been extensively studied with NAFLD, a major issue in human medicine. Alcoholic steatosis and other forms of hepatic steatosis have been linked to impairment of ATP homeostasis, and mitochondrial abnormalities have been reported in a growing body of literature.

There are several drugs that inhibit beta oxidation of fatty acids in mitochondria leading to lipid accumulation, such as aspirin, valproic acid, and tetracyclines.

Disruption of Cytoskeleton

Changes in intracellular calcium homeostasis produced by active metabolites of xenobiotics may cause disruption of the dynamic cytoskeleton. There are a few toxins that cause disruption of the cytoskeleton through mechanisms independent of biotransformation. Microcystin is one of these toxins. Microcystin is produced by the cyanobacterium *M. aeruginosa*. Similar toxins are produced by other species of cyanobacteria. The hepatocyte is the specific target of microcystin, which enters the cell through a bile-acid transporter. Microcystin covalently binds to serine/threonine protein phosphatase, leading to the hyperphosphorylation of cytoskeletal proteins and deformation of the cytoskeleton (Treinen-Moslen, 2001).

Phalloidin and related toxins found in some mushrooms, including *A. phalloides*, act by binding tightly to actin filaments and preventing cytoskeletal disassembly (Treinen-Moslen, 2001).

Cholestatic Mechanisms

Sinusoidal transporters and canalicular transporters are involved in the movement of bile salts from the sinusoids into the canaliculi. Within the hepatocyte, transcytosis is mediated by cytoskeletal transport mechanisms. Bile is moved within the canaliculi through actions of the hepatocyte cytoskeleton, causing contraction of the canalicular lumina (Treinen-Moslen, 2001). Xenobiotics acting on any of the above systems may influence bile transport and secretion.

Most chemicals that cause cholestasis are excreted in the bile, including the mycotoxin sporodesmin, which concentrates 100-fold in the bile (Treinen-Moslen, 2001). α-naphthylisothiocyanate (ANIT) is a hepatotoxicant that damages bile duct epithelium and hepatocytes. The drug is used experimentally in rodents as a model of intrahepatic cholestasis. A single dose of ANIT induces acute cholangitis; prolonged exposure causes bile duct hyperplasia and biliary fibrosis. Although the biochemical and histological features of ANIT toxicity are well documented, the mechanism by which ANIT causes liver injury remains uncertain. ANIT does not cause liver damage *in vivo* until it appears in bile (Jean and Roth, 1995).

This drug is initially detoxified in hepatocytes by conjugation with GSH. ANIT–GSH complexes are secreted into bile, but they are unstable and rapidly dissociate, which exposes biliary cells to high concentrations of the parent compound, which presumably causes direct cytotoxicity. The reappearance of ANIT in bile also leads to enterohepatic cycling, reuptake of the drugs in the intestine, and repetitive rounds of GSH conjugation and secretion. This not only delays elimination of the drug, but also depletes GSH progressively from hepatocytes and leads to hepatocellular damage. In addition, ANIT is known to cause hepatotoxicity by neutrophil- and platelet-dependent mechanisms (Jean and Roth, 1995).

Idiosyncratic Reactions

Many idiosyncratic drug reactions are believed to be immune-mediated. Neoantigens may result from adducts formed from the interaction of reactive drug metabolites with cellular proteins. These neoantigens may be processed by Kupffer cells or other antigen-presenting cells, transported to the cell surface, and presented as antigens. Cell- and antibody-mediated immune response may cause severe liver damage. Various drugs are believed to cause immune-mediated idiosyncratic reactions in humans, including halothane, diclofenac, phenytoin, and sulfonamides (Sturgill and Lambert, 1997; Watkins, 1999; Zimmerman, 1999; Treinen-Moslen, 2001).

Liver injury can be a result of both direct cytotoxicity and antibody-dependent cellular toxicity. Alcoholic liver disease is another example of possible immune-mediated damage. Acetaldehyde, produced by the metabolism of ethanol, forms adducts with hepatic proteins similar to halothane, resulting in higher antibody titers, to which some of the liver damage following ethanol ingestion may be attributed (Ramaiah et al., 2004). However,

the role of immune-mediated liver damage following ethanol ingestion is minimal compared to other known mechanisms of alcohol liver damage.

WARFARE AGENTS AFFECTING LIVER

Fungal and Plant Toxins

Microcystins

The microcystins are hepatotoxic products of freshwater blooms of cyanobacteria of *Microcystis*, *Anabena*, and *Oscillatoria* species (Chen et al., 1993; Luu et al., 1993), with *M. aeruginosa* being the most common. Nearly 60 microcystin cyclic hepatopeptides have been identified, of which microcystin-LR, also known as the *fast death factor*, is the most common, and the toxin of choice to be weaponized (Craig et al., 1993; Rinehart et al., 1994). This toxin has been reported to be responsible for the deaths of wild animals and agricultural livestock (Carmichael, 1988). A potential threat to the health of humans has been recognized in countries where water supplies are contaminated with cyanobacteria (Yu, 1989; Gkelis and Zaoutsos, 2014). In 1996, microcystin-LR was also implicated in the death of 50 Brazilian dialysis patients (Jochimsen et al., 1998).

This potent mammalian liver toxin (Carmichael, 1988) acts by altering the hepatocyte cytoskeleton actin filaments, leading to disruption of the structural integrity of the sinusoids. This causes massive necrosis in the liver leading to cell death. The toxic effects of microcystin-LR have been reported due to the presence of 3-amino-9-methoxy-10-phenyl-2,6,8 trimethyl deca,4,6 dienoic acid (ADDA), which is believed to be essential for its functioning. In addition, microcystins are known to be potent and specific inhibitors of catalytic subunits of protein phosphatases 1 and 2A (Cohen and Cohen, 1989; Honkanen et al., 1990; Yoshizawa et al., 1991), and activate the enzyme phosphorylase b. Microcystin administered intraperitoneally in mice caused disruption of bile flow in less than 10 min, and death within a few hours due to hypovolemic shock induced by interstitial hemorrhage following liver necrosis (Carmichael, 1988). Death was also reported within hours of administration of aerosol (LD_{50}, 67 μg/kg body weight) in mice. In humans, microcystin ingestion leads to diarrhea, vomiting, weakness, and pallor, with death occurring in a few hours if a lethal dose is taken. For further details, see chapter 31.

Aflatoxins

Aflatoxins were first isolated more than 40 years ago after the outbreak of disease and deaths in turkeys. These toxins are produced as secondary metabolites by the fungi *Aspergillus flavus* and *Aspergillus parasiticus* at temperatures between 24°C and 35°C and humidity exceeding 7% (Williams et al., 2004). These fungi are known to infect a variety of crops, such as peanuts, walnuts, pecans, pistachios, and corn.

Aflatoxins are bisfuran polycyclic compounds, and depending on the characteristic blue or green fluorescence produced under ultraviolet light, these compounds are known as aflatoxin B_1, B_2, G_1, and G_2, respectively. Although these compounds have been recognized as potent mutagens and carcinogens, they are still not as toxic as botulinum or ricin. Before the first Gulf War, aflatoxins were not recognized as biological warfare agents; however, they were weaponized by Iraq for missile delivery, and at present, they can be considered as agents of biological warfare (Marshall, 1997; Zilinskas, 1997).

Of the several aflatoxins, aflatoxin B_1 (AFB_1) is the most prevalent and the most potent. AFB_1 is converted to an unstable metabolite (the 8,9-epoxide), is highly electrophilic, and forms covalent adducts with RNA, DNA, and proteins (Roebuck and Maxuitenko, 1994). In addition, aflatoxin M_1, a metabolite of AFB_1, has been found in the milk of cows fed AFB_1.

AFB_1 is acutely toxic in all species tested thus far, with an LD_{50} ranging from 0.5 mg/kg for the duckling to 60 mg/kg for the mouse (Wogan, 1973). Acute exposure to AFB_1 has been reported to cause hepatic lesions with edema, biliary proliferation, and parenchymal cell necrosis. In addition, aflatoxin B_1 poisoning has been reported to cause jaundice, rapidly developing ascites, and portal hypertension, with high mortality resulting from massive gastrointestinal bleeding. In children, aflatoxin produces a condition called *Reye syndrome*, resulting in disturbed consciousness, fever, convulsions, and vomiting (Palmgren and Ciegler, 1983).

Ricin

Ricin, a potent plant toxin, was discovered by Peter Hermann Stillmark in 1889 (Flexner, 1897) as the first plant lectin. It was extracted from the seeds of castor plants (*Ricinus communis*) and has been considered a CWA since World War I. Although ricin is less toxic than botulinum or anthrax, easy availability and lack of a specific antidote make it a weapon of choice, and it has been included in Schedule 1 of the Chemical Weapons Convention (CWC). To date, more than 750 cases of intoxication in humans have been reported (Rauber and Heard, 1985). Being a ribosome-inactivating protein, a single molecule of ricin reaching the cytosol can kill that cell as a consequence of protein synthesis inhibition (Eiklid et al., 1980). Ricin is also very stable and extremely toxic by several routes of exposure, including ingestion and inhalation; however, compared to oral exposure, inhalation of ricin has been reported to be more harmful. In humans the lethal dose has been reported to be 5–10 μg/kg body weight.

In addition to pulmonary toxicity, ricin has been reported to be a major hepatotoxicant (Kumar et al., 2003). Studies by Muldoon et al. (1992) reported that humans exposed to ricin experience increased hepatic transaminase and lactate dehydrogenase activities. Furthermore, mice treated with ricin experienced significant oxidative stress, resulting in hepatic GSH depletion and lipid peroxidation (Muldoon and Stohs, 1991). Elevation of lipid peroxidation is reported to originate mainly from the damaged Kupffer cells, which are believed to be the target of this toxin in the liver (Skilleter et al., 1981). The high sensitivity of Kupffer cells has been ascribed to the ability of ricin to bind to the mannose receptors present on these cells (Skilleter et al., 1981; Magnusson and Berg, 1993). For further details on ricin toxicity, see chapter 27.

Abrin

Abrin, a potent toxin, is extracted from the seeds of the rosary pea (*Abrus precatorius*). Due to its easy availability and preparation, this toxin is an attractive option for weaponizing in poor countries, and thus has also been included in the Schedule 1 of the CWC. The mechanism of action of abrin is very similar to that of ricin; however, in mice, abrin is 75 times more toxic than that of ricin (0.04 µg/kg for abrin is equivalent to 3 µg/kg of ricin). Similar to ricin, inhalation of abrin is found to be more toxic than ingestion. However, abrin ingestion has reported to be toxic to the liver, unlike ricin. At the cellular level, abrin is a potent toxalbumin known to cause cell death by inhibiting protein synthesis (namely, type 2 ribosomal inhibitory protein). Further, abrin is also known to induce endothelial cell damage leading to an increase in cell permeability, fluid and protein leakage, and tissue edema.

Bacterial (Anthrax)

Anthrax is a disease caused by the spores of the bacterium *Bacillus anthracis*. It is a recognized biological warfare agent. In the United States, anthrax was deliberately spread through the postal system in 2001 via letters sent to several legislators and other public figures with powder containing anthrax. This resulted in 22 cases of anthrax infection. Inhalation and cutaneous exposure are the main routes of infection. Recent studies have revealed that laboratory animals infected with anthrax have developed significant liver injury. Studies by Moayeri et al. (2003) reported that mice infected with *B. anthracis* developed extensive liver necrosis and pleural edema. Liver lesions in these animals ranged from small hemorrhagic infarcts to large areas of centrilobular coagulative necrosis. A significant increase in alanine aminotransferase and aspartate aminotransferase was also observed in these animals. Liver dysfunction was also indicated by decreased serum albumin levels in these animals in response to toxin exposure over time. For further details on anthrax toxicity, see chapter 29.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

In spite of significant advances in human knowledge about the mechanisms of liver damage, scientists seem to have a long way to go before all the mechanisms of toxicity in liver for a given chemical are completely established. In the meantime, new platforms (such as multiplex, multicolored flow cytometry and mesoscale discovery) and new "omics approaches" have provided additional tools for researchers to obtain breakthroughs in the area of liver toxicity. Clearly, current reports on the number of CWAs targeting the liver are limited, and with further research and case studies, these numbers will continue to grow. With the changing political global climate and the potential for CWAs, target organ toxicities, especially the liver, will likely gain attention.

CHAPTER

43

Renal System

Sharon M. Gwaltney-Brant

INTRODUCTION

The kidney and urinary system are responsible for the maintenance of homeostasis by regulating the body's fluid and electrolyte balance, eliminating waste products, maintaining acid–base balance, secreting regulatory peptides and hormones, and metabolizing and excreting endogenous compounds and xenobiotics. The kidney receives 20–25% of cardiac output, putting it at risk for exposure to high levels of blood-borne toxicants. Besides exposure to directly toxic compounds, the kidney can be exposed to toxicants through metabolic activation of xenobiotics by renal tubular epithelial enzyme systems (e.g., cytochrome P450 enzymes). In its excretory capacity, the kidney and urinary tract are exposed to progressively higher levels of toxicants because they are concentrated within the renal/urinary tubules. Loss of renal function because of toxic kidney injury can result in severe systemic derangement and death of the individual; therefore, in theory, toxicants that target the kidney might be considered to be potential agents of chemical or biological warfare. However, if the goal of a chemical warfare agent is to rapidly incapacitate or kill civilians or opposing personnel, then a primary nephrotoxicant would make a poor choice of weapon because of the long delay in clinical effects from the time of exposure. Once renal damage has occurred, it may take many hours or up to a few days before signs of renal insufficiency develop to the point at which the victim is effectively incapacitated. Renal injury occurring subsequent to a chemical or biological attack is generally a matter of collateral damage rather than targeted injury, and many of the chemical agents used in warfare and terrorism have minimal effects on the kidney or urinary system. The renal effects that do develop will be seen in the individuals who survive the acute chemical attack and live long enough for evidence of renal insufficiency to develop.

ANATOMY AND PHYSIOLOGY

Functional Anatomy

In mammals, the kidneys are paired organs that reside ventrolateral to the lumbar vertebrae and musculature. Mammalian kidneys are bean-shaped to horseshoe-shaped with uniform to multilobulated external surfaces, depending on species, and a medial indented hilar region from which renal artery, renal vein, lymphatics, nerves, and ureter emerge. On sagittal section, the kidney displays two distinct regions, the outer cortex and the inner medulla. The renal cortex corresponds to approximately 80% of total renal mass, and the normal cortex:medulla ratio is 1:2 to 1:3 in most species (Maxie and Newman, 2007). The medulla is divided into ray-shaped sections known as renal pyramids that have their bases at the corticomedullary junction and their apices (papillae) that empty into a renal calyx or pelvis at the hilar area. The number of renal pyramids in the kidney varies with species. Uni-pyramidal or uni-papillate kidneys have a single renal papilla into which renal lobes empty, whereas multi-pyramidal or multi-papillate kidneys have two or more papillae. From the hilar region, urine is channeled to the distal urinary bladder via the ureter, and from the bladder, urine is voided from the body via the ureter.

Renal blood flow originates from the renal arteries, which are direct branches off of the aorta. Renal arteries progressively branch to form interlobar arteries, arcuate arteries, interlobular arteries, and afferent arterioles, the latter of which provide blood to the glomerulus. The kidney receives up to 20–25% of cardiac output, with the cortex receiving the majority (90%) of the blood flow, and the medulla (6–10%) and papilla (1–2%) receiving considerably less direct blood flow (Schnellmann, 2008). Thus, blood-borne toxicants are delivered in higher amounts to the cortex, whereas the medulla and papilla

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00043-9

are exposed to higher luminal levels of toxicants that concentrate in the urine. Because of the relative sluggishness of medullary and papillary filtrate transport, these areas are also exposed to intraluminal toxicants for prolonged periods of time.

The functional unit of the kidney is the nephron, which comprises the renal corpuscle (Bowman's capsule and the glomerulus), proximal tubule, loop of Henle, and distal tubule (Figure 43.1). The number of nephrons per kidney varies with species size, ranging from approximately 10,000 in mice compared with approximately 1,000,000 in humans and 7,000,000 in elephants (Braun, 2008). High hydrostatic pressure from afferent arterioles results in ultrafiltration of plasma within the branching and anastomosing capillaries that form the glomerulus. Six to nine nanometer fenestrae within the glomerular basement membrane (GBM) form the "sieve" through which the plasma filtrate passes. Filtrate moves through Bowman's capsule and flows into the proximal renal tubule, which has three anatomically and functionally different segments. The S_1 segment is the most proximal segment that consists of the convoluted portion of the proximal tubule, and it contains epithelial cells with tall brush borders, well-developed lysosome systems, and numerous basally located mitochondria. The S_2 segment extends from the end of the convoluted tubule to the beginning of the straight segment; its epithelial cells have shorter brush borders, fewer mitochondria, and fewer lysosomes than S_1 cells. The S_3 segment consists of the remaining distal straight segment of the proximal tubule and extends into the outer reaches of the medulla. The S_1 and S_2 segments have higher oxygen consumption, sodium/potassium ATPase activity, and gluconeogenic capacity, whereas the S_3 segment has higher transport capabilities for secretion of certain compounds (e.g., organic acids) and is the primary site for metabolic activation of some toxicants (Castro et al., 2008).

The proximal tubule functions in the passive reabsorption of water and active reabsorption of sodium and potassium (via sodium/potassium ATPase pumps), as well as other solutes, including calcium, phosphorus, bicarbonate, glucose, amino acids, proteins, and various xenobiotics (Rouse and Suki, 1985). Each segment of the proximal tubule has a different range of capacity for reabsorption of various solutes; for instance, the S_1 segment reabsorbs a higher percentage of bicarbonate, glucose, amino acids and low-molecular-weight proteins, whereas the S_2 segment reabsorbs more calcium and phosphorus. Ultimately, the proximal tubule reabsorbs

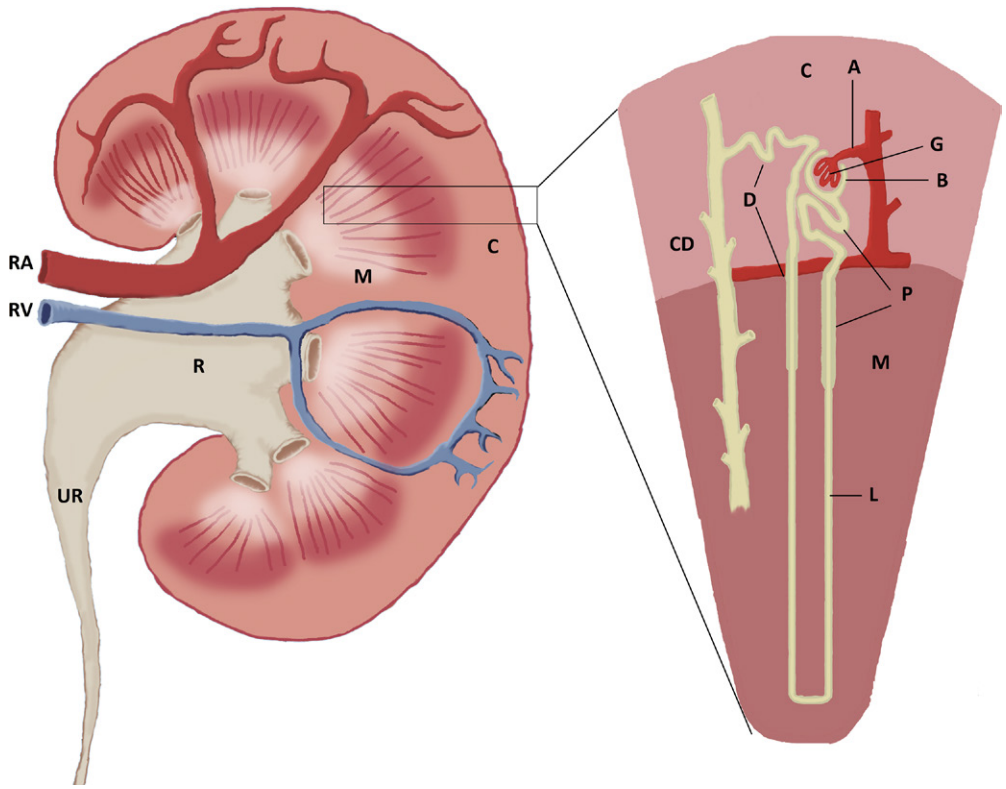

FIGURE 43.1 Diagrammatic view of the kidney showing the relationship of the cortex (C), medulla (M), renal pelvis (R), renal artery (RA), renal vein (RV), and ureter (UR). Enhanced view of microanatomy of the classical nephron (A, afferent arteriole; G, glomerulus; B, Bowman's capsule; P, proximal tubule; L, loop of Henle; D, distal tubule; CD, collecting duct).

60–90% of solute and water that was filtered through the glomerulus. Excretory functions of the proximal tubule include the active secretion of weak organic anions and cations. The absorptive and secretory capacities of the various proximal tubule segments can be induced or inhibited because of pathological or physiological alterations in filtrate composition.

Leaving the proximal tubule, filtrate enters the loop of Henle, which is composed of a thin-walled descending limb and a thick-walled ascending limb that extends to the level of the outer medullary region. Countercurrent exchange mechanisms within the loop result in reabsorption of approximately 20% of filtered water and 25% of filtered sodium and potassium (Schnellmann, 2008). The loop resides largely within the poorly oxygenated renal medulla and contains ATPases with high oxygen demand, making the loop of Henle especially susceptible to hypoxic injury (Brezis et al., 1984). The macula densa sits at the junction of the ascending loop of Henle and the proximal aspect of the distal tubule, in close proximity to the nephron's selfsame afferent arteriole, permitting feedback between macula densa and arteriole. The macula densa "reads" the intratubular solute concentrations and provides feedback to the afferent arteriole, resulting in vasoconstriction or vasodilation that decreases or increases, respectively, the glomerular filtration rate (GFR), thus regulating fluid loss and urine production. The final segment of the distal tubule along with the collecting duct function to reabsorb most of the remaining intraluminal electrolytes and water as needed to regulate the volume and composition of the urine. Collecting ducts progressively intersect and anastomose toward the renal papilla and ultimately empty into the renal calyx, renal pelvis, or ureter, depending on species. Peristaltic action of the ureter propels urine toward the urinary bladder for temporary storage and elimination via the urethra.

In addition to its role in regulation of waste excretion and water/electrolyte balance, the kidney secretes a variety of hormones and regulatory peptides vital for normal systemic homeostasis. Secretion of erythropoietin by renal peritubular interstitial cells promotes red blood cell formation; significant chronic renal disease is often associated with anemia because of decreases in erythropoietin secretion. Renin secreted from the juxtaglomerular cells increases systemic and renal blood pressure and aldosterone release. Prostaglandins and prostacyclin are produced by a variety of renal cells and aid in regulation of renal vascular tone, mesangial contractility, and processing of water and electrolytes by the renal tubules.

Biotransformation

In addition to its other functions, the kidney also plays an important role in xenobiotic metabolism. Renal tubular epithelium contains a variety of biotransformation enzymes including cytochrome P450 monooxygenases, flavin-containing monooxygenases, reductases, hydrolases, UDP-glucuronosyltransferases, sulfotransferases, glutathione-*S*-transferases, cysteine conjugate β-lyase, methylases, and acetylases (Rankin and Valentovic, 2005). Although the majority of biotransformation reactions result in inactive metabolites that are then eliminated via the urine, some biotransformation reactions result in the formation of reactive intermediates or metabolites that can cause nephrotoxicity. For example, the blue-green algal toxin cylindrospermopsin requires bioactivation by cytochrome P450 enzymes for it to become genotoxic (Zegura et al., 2011). Biotransforming enzymes are not evenly distributed throughout the kidney, but rather tend to be concentrated in specific sites of the renal tubular epithelium, thereby resulting in a particular pattern of injury depending on which enzyme system was involved in the formation of toxic intermediates.

The cytochrome P450 superfamily is composed of a large number of member enzymes and is divided into four gene families (CYP1, CYP2, CYP3, and CYP4). Individual enzymes (e.g., CYP1E2) are named by family (e.g., CYP1), subfamily (e.g., E) and individual (e.g., 2) designations. This superfamily of enzymes is of major importance in biotransformation of xenobiotics throughout the body and is most prominently expressed in the liver. Cytochrome P405 expression in the kidney is approximately 10% of that of the liver (Cummings et al., 1999). The highest concentrations of P450 in the kidney are in the renal cortex, with smaller amounts in the medulla (Rankin and Valentovic, 2005). There is considerable variability in the amount and activity of individual P450 enzymes within the kidney depending on species, age, and gender. Along the nephron, cytochrome P450 expression is highest within the epithelium of the S_2 and S_3 segments of the proximal tubules, so xenobiotics that are bioactivated by P450 to toxic metabolites will preferentially cause damage to those nephron segments first. Flavin-containing monooxygenases catalyze the oxidation of nitrogen-containing, sulfur-containing, phosphorus-containing, selenium-containing, and other nucleophilic heteroatoms-containing compounds in xenobiotics (Cashman and Zhang, 2002). Six isoforms of flavin monooxygenases (FMO1, FMO2, FMO3, FMO4, FMO5, and FMO6) have been identified and the expression of these monooxygenases within tissues varies depending on species, gender, age, and tissue. Glutathione-*S*-transferases catalyze the conjugation of electrophilic sites in xenobiotics with the tripeptide L-γ-glutamyl-L-cysteinylglycine, thus protecting macromolecules from injury from electrophiles (Rankin and Valentovic, 2005). Glutathione-*S*-transferase activity is highest in the proximal tubular cells, although distal tubules do express some activity as well.

TOXIC RESPONSES OF THE URINARY SYSTEM

Acute Renal Failure

Acute renal failure is the sudden decrease in renal function resulting in retention of nitrogenous wastes, and it is a common manifestation of acute nephrotoxic injury (Schnellmann, 2008; Langston, 2010). "Acute kidney injury" (AKI) is the term that has been suggested as most appropriate for use when discussing renal injury, because it encompasses all phases of kidney insult, ranging from minor elevations of serum chemistry renal values to anuric renal failure (Karajala and Kellum, 2010).

The primary manifestation of AKI is decreased GFR resulting in excess accumulation of nitrogenous wastes in the blood (azotemia). Decreased GFR can result from prerenal, renal, or postrenal etiologies. Decreased cardiac output, hypovolemia, and renal vasoconstriction are common prerenal events that can decrease GFR. Postrenal causes of reduced GFR include obstruction of renal tubules or of the lower urinary tract by casts or crystals. Renal tubular injury, glomerular injury, interstitial renal disease (e.g., inflammation, neoplasia), and renal vascular compromise are all primary renal factors that can lead to decreased GFR. In humans, 20–80% of AKI is attributable to prerenal factors, 10–45% is attributable to primary renal factors, and postrenal factors cause 5–15% of AKI (Langston, 2010). Of primary renal factors, ischemia/reperfusion and nephrotoxicosis are thought to be responsible for more than 90% of AKI cases in humans (Schnellmann, 2008).

Damage to kidneys by nephrotoxicants occurs through a variety of different mechanisms, including: direct injury to renal tubular epithelium leading to epithelial cell necrosis with sloughing and obstruction of tubules by cellular debris (tubular casts); detachment of lethally injured cells from the basement membrane resulting in back-leakage of filtrate across the exposed basement membrane and adherence of detached cells to sub-lethally injured cells still attached to the basement membrane causing lumen obstruction; renal vasoconstriction resulting in hypoxia and ischemic necrosis of renal structures; damage to the glomerular filtration barrier; and impairment of renal healing and repair (Counts et al., 1995). Most nephrotoxic agents cause injury at the level of the renal tubules, and many toxicants will target specific tubule segments.

Clinical effects of AKI generally do not become apparent until GFR is approximately 40% of normal and nitrogenous wastes have accumulated (Khan et al., 2013). Depending on the individual and the dose of toxicant received, this may take several hours to a few days after an acute toxic insult, making nephrotoxicants a poor choice of chemical weapon if the goal is to rapidly disable an opponent. The clinical signs of acute renal injury and/or failure can include polydipsia, nausea or vomiting, lethargy, anorexia, weakness, dehydration, and polyuria/oliguria/anuria. More severe cases may have halitosis, oral ulceration, abdominal (renal) pain, palpably enlarged kidneys, and cardiac arrhythmias. Clinical laboratory abnormalities indicative of AKI include elevations in blood urea nitrogen (BUN) and serum creatinine (azotemia), hyperphosphatemia, hyperkalemia or hypokalemia, and metabolic acidosis. *Uremia* is the term used when azotemia is accompanied by typical clinical signs of AKI. Advanced cases of uremia may present with gastrointestinal ulceration, anemia, peripheral neuropathy, encephalopathy, metastatic mineralization, and cardiac dysfunction.

The ability of the kidney to heal after an acute toxic insult is dependent on several factors, including the dose and type of toxicant, the amount of functional kidney remaining, the presence and severity of secondary uremic conditions (e.g., soft tissue mineralization), and the degree of medical intervention and supportive care provided during the acute crisis. Mild to moderate renal tubular injury with retention of tubular basement membrane has a reasonable prognosis for tubular regeneration provided that supportive care is administered until tubules have had a chance to recover. In uncomplicated acute tubular injuries, regeneration of epithelial cells generally begins approximately 7–10 days after the renal insult; in mild cases, full recovery of architecture may occur within 2–3 weeks, with longer recovery periods being required for more severe renal injury (Maxie and Newman, 2007). In situations in which nephrons have been fully obstructed by cellular debris or crystals, or if basement membrane integrity is lost, regeneration may be incomplete, resulting in long-term renal insufficiency and/or progression to chronic renal failure (CRF).

Chronic Renal Failure

The kidneys have a large compensatory capacity to adapt to injury resulting in loss of functional renal mass, with potential increases in GFR by 40–60% in nephrons not directly affected by the insult (Schnellmann, 2008). Biochemical evidence of renal injury generally is not detectable using current renal parameters (i.e., BUN, serum creatinine) until 50–70% decreases in GFR occur. For these reasons, significant renal injury may occur before any clinically detectable evidence of renal insufficiency develops. CRF is a common result of long-term exposure to toxicants, and many of the alterations found when CRF is finally diagnosed are related to secondary compensatory changes triggered by the initial injury. Toxicant-induced nephron loss causes a decrease in overall GFR, which triggers an increase in blood flow and pressure to surviving nephrons in an attempt to

re-establish normal whole-kidney GFR. Increased glomerular pressure can contribute to degenerative changes such as glomerular sclerosis, tubular atrophy, and interstitial fibrosis, which, in turn, further the progression of renal injury (Brenner et al., 1982). Intraglomerular hypertension results in glomerular hypertrophy, hyaline deposition within glomerular capillary walls, mesangial dysfunction, microaneurysm formation, and thrombosis attributable to endothelial injury (Polzin, 2010). As the glomerulus expands, focal denudation of the glomerular basement membrane occurs, allowing leakage of larger proteins into the glomerular filtrate (proteinuria). Other factors such as cytokines expressed by inflammatory cells, elaboration of reactive oxygen species (ROS), lipid accumulation, increased extracellular matrix deposition, and tubulointerstitial injury contribute to the progression toward CRF (Schnellmann, 2008).

Clinical effects associated with CRF include uremia, gastrointestinal disorders (uremic gastritis, uremic enterocolitis), polyuria, polydipsia, nocturia, dehydration, atrial hypertension, peripheral neuropathy, uremic encephalopathy, myopathy, platelet dysfunction, cachexia, and hypokalemia (Polzin, 2010). Edema caused by retention of sodium and water, renal secondary hyperparathyroidism, and anemia caused by decreased erythropoietin synthesis are common manifestations of CRF. Immunosuppression is a potential complication of CRF in humans, and studies of dogs with CRF have shown impaired immunological function as well (Kravola et al., 2010). Patients with CRF may show few outward signs of illness until late in the course of their disease; in some instances, acute decompensation may occur during periods of physical or emotional stress (Hosseininejad and Hosseini, 2008). Lesions of CRF include kidneys that are small and irregular in shape with uneven capsular surfaces. On cut section, pale streaks (fibrosis) may be seen within the interstitium and the parenchyma may be gritty on cutting because of mineralization and/or crystal deposition.

Patterns of Toxic Injury

Identification of the target site of action of nephrotoxicants can assist in determining the functional impact and potential mechanism of toxicity. Compounds that are directly toxic to cells may cause injury to the glomerulus or the S_1 segment of the proximal tubule as they first enter the nephron. Conversely, direct-acting toxicants may be dilute in the initial ultrafiltrate and may not cause injury until they reach the more distant nephron, where they may reach toxic concentrations as water is gradually reabsorbed and/or the pH changes. Some toxicants require bioactivation to exert their toxic effects and may cause site-specific injury to the segments of the nephron where those bioactivation processes are most active. Figure 43.2 illustrates the distribution of lesions within the nephron and lower urinary tract that can be induced by chemical warfare agents.

Glomerular Injury

The glomerular capillaries are the first component of the nephron to be exposed to blood-borne toxicants. The glomerular cells, matrix, and mesangium are susceptible to toxic injury by several different mechanisms, including direct injury to cellular components, formation of oxygen-derived free radicals, disruption of extracellular substrates (e.g., basement membranes), immune-mediated injury, and disruption of renal hemodynamics (Khan et al., 2013). Direct injury or injury secondary to reactive oxygen intermediates can result in endothelial loss, glomerular podocyte injury, and necrosis of mesangial cells and substrate (mesangiolysis). Further damage could occur secondary to cytokines released by inflammatory cells responding to the site of injury. Alterations in the GBM secondary to cellular injury can result in disruption of the glomerular filtration barrier, leading to proteinuria. Deposition of an immune-mediated reaction to various toxicants (e.g., mercurial, gold salts) can result in thickening of the GBM, disrupting the glomerular filtration barrier and leading to membranous glomerulonephropathy.

Proximal Tubular Injury

Tubular injury is the most common pattern of renal injury induced by toxicants and the proximal tubule is most frequently affected by nephrotoxicants (Schnellmann, 2008). Damage to the proximal tubule may occur because of direct damage from toxicants, metabolic activation of toxicants, ischemia-reperfusion, or physical or chemical disruption of endothelium and/or basement membrane. The S_1 segment is the most vulnerable to injury from toxicants that exert direct injury because the epithelium in this area is exposed to the toxicant first. The proximal convoluted tubule epithelium is actively involved in endocytosis of various compounds that bind to the brush border, sequestering the compounds in phagolysosomes. When this process is overwhelmed by the presence of certain toxicants (e.g., uranyl ion), loss of phagolysosome membrane integrity occurs, resulting in lysosomal leakage and cell injury or necrosis (Khan et al., 2013). This type of injury is most commonly associated with the S_1 and S_2 segments of the proximal tubule. In contrast, the straight segment (S_3) is most susceptible to injury by metabolic activation, transporter-associated accumulation, and ischemia-reperfusion.

Various metabolic derangements, such as severe acid–base imbalances, induced by toxicants can result

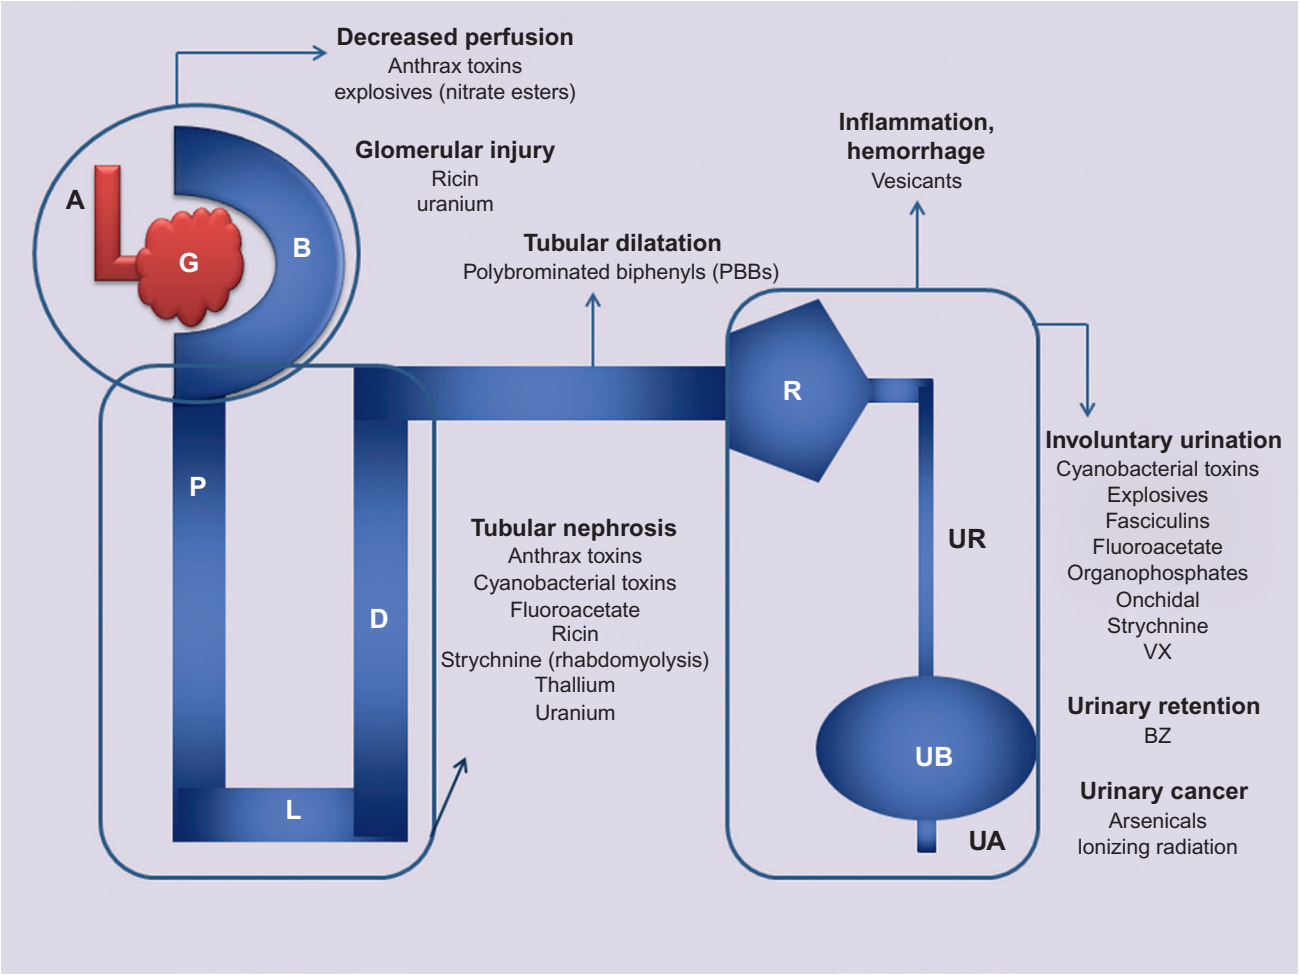

FIGURE 43.2 Cartoon of the nephron and lower urinary tract showing sites of injury caused by various chemical and biological warfare agents (A, afferent arteriole; G, glomerulus; B, Bowman's capsule; P, proximal tubule; L, loop of Henle; D, distal tubule; C, collecting ducts; R, renal pelvis; UR, ureter; UB, urinary bladder; UA, urethra).

in injury to renal tubules. Prolonged muscle activity from tremors or convulsions (e.g., from nerve agents) may result in rhabdomyolysis with myoglobinemia causing renal tubular damage (Hamilton et al., 1989). Similarly, intravascular hemolysis that occurs during a chemical warfare toxidrome can result in hemoglobinuric nephropathy with resulting renal tubular injury. Decreased cardiac output, hypovolemia, and anemia can result in ischemia of renal tissue and precipitate tubular injury; renal ischemia can also occur secondarily to toxicosis from agents that alter oxygen delivery to tissues (e.g., cyanide).

In humans and dogs, the renal tubules and interstitium are related in such a way that significant injury to one results in a reaction in the other; for this reason, the terms "tubulointerstitial disease" and "chronic interstitial nephritis" are often applied to lesions found in the kidneys of these species (Khan et al., 2013). The latter term acknowledges the fact that, in advanced tubulointerstitial disease, it is difficult to determine which injury came first, that to tubules or to interstitium.

Distal Nephron/Renal Papillary Injury

Toxic injury to the distal nephron is relatively uncommon, and injury to this area generally manifests as decreased urine concentrating ability or as defects in acid secretion resulting in metabolic acidosis (Khan et al., 2013). Injury to the renal papilla is most commonly seen with toxicants that impede blood flow to this normally poorly perfused area. Direct injury to renal papillae from renally excreted irritants (e.g., vesicants such as cantharidin) may also occur.

Lower Urinary Tract

Toxicants that cause injury to the ureters, urinary bladder, and urethra tend to be those that directly interact

with the urothelium (Cohen, 2013). Direct cytotoxicity to urothelium by vesicants such as cantharidin can result in necrosis, ulceration, and hemorrhage. Ionizing radiation and genotoxic chemicals can damage DNA within the regenerative layer of the urothelium, inducing mutations and increasing the potential for development of urinary tumors. Not all toxic effects on the lower urinary tract are related to cellular injury. Psychotropic or neurotoxic agents can affect neuromuscular control of the bladder, resulting in the involuntary retention or voiding of urine.

TOXIC EFFECTS OF CHEMICAL WARFARE AGENTS

Very few compounds selected as agents of chemical warfare have significant and direct effects on the urinary system, and any injury to the kidney can be considered an unintended consequence of most chemical weapons. Indirect renal injury can occur because of a variety of effects of chemical weapons, including hemodynamic abnormalities causing decreased renal perfusion (e.g., shock, hypotension), acid–base derangements, or induction of pigmenturia attributable to rhabdomyolysis or hemolysis.

Vesicants

Vesicants are agents that produce chemical burns on body surfaces. Phosgene oxime, an urticariant, is not a true vesicant because it does not produce blisters, but is included in this section. Through their action on the skin, respiratory tract, and eyes, these agents tend to incapacitate rather than kill, although systemic involvement and death can occur with severe exposures or because of secondary complications such as bacterial infections, shock, or multi-organ failure.

The biochemical mechanisms of injury from vesicant agents are poorly understood. Mustards (bis-(2-chloroethyl) sulfide) are thought to act as alkylating agents that form highly reactive electrophiles that combine with nucleophilic sites on cellular macromolecules to form stable adducts that interfere with normal function of cells and disrupt the epidermal–dermal junction (Hurst et al., 2008). Once tissue injury has been established, activation of massive local inflammatory response leads to vesicle development. Depletion of glutathione may also contribute to the vesicant injury through loss of protection against oxygen-derived free radicals and lipid peroxidation, resulting in a "snowballing" effect of cellular damage. The biochemical mechanism of action of the arsenical lewisite (b-chlorovinyldichloroarsine) may involve interactions with enzymatic sulfhydryl groups, resulting in inhibition of the pyruvate dehydrogenase complex, leading to inactivation of carbohydrate metabolism. As with mustards, depletion of glutathione resulting in increased lipid peroxidation and ROS generation may also play a role in lewisite-mediated cellular injury. Phosgene oxime may act by direct necrotizing effects of chlorine, by enzymatic inactivation of target cells, and/or by activation of macrophages, recruitment of neutrophils, and production of ROS, although the exact mechanism remains obscure (Hurst et al., 2008).

Renal lesions with vesicant exposures are not commonly encountered and, in many cases, may be nonspecific secondary effects attributable to multiorgan failure associated with fatal exposures. Mustards have been reported to cause hemorrhagic nephritis, oliguria, anuria, albuminuria, and casts in mortally injured victims (Papirmeister et al., 1991). Microscopic lesions associated with sulfur mustard victims included calcified and hemoglobin-containing intratubular casts (Alexander, 1947). Although lewisite is an arsenical vesicant, renal lesions typical for inorganic arsenic toxicosis have not been reported in laboratory species or human patients exposed to lewisite (Hurst et al., 2008). No specific renal lesions have been reported with exposure to phosgene oxime. For further details on vesicants toxicity, readers are referred to Chapter 8.

Nerve Agents

Nerve agents classically include the organophosphorus (OP) compounds (e.g., soman, sarin, cyclosarin, tabun, and VX) originally developed as insecticides, but repurposed and refined for use as warfare agents as their extreme toxicity was recognized (Sidell et al., 2008). Although developed and stockpiled for use in Germany during World War II, nerve agents were not used on the battlefield until 50 years later during the Iran–Iraq War. Since then, nerve agents have been used both in battle and in terrorist attacks, such as the 1995 release of sarin on commuter trains in Japan that killed 12 people. Onchidal, an anticholinesterase mollusc toxin, has similar clinical effects as the OP nerve agents and is considered here and under the term "nerve agent" (Abramson et al., 1989).

Nerve agents act by binding and inhibiting acetylcholinesterase (AChE), an enzyme that hydrolyzes the neurotransmitter acetylcholine (ACh). The cholinergic system is the only known system to terminate the action of a neurotransmitter via enzymatic cleavage. When anticholinesterase agents such as OPs and onchidal disable AChE, ACh accumulates within the synapse, resulting in continued stimulation of cholinergic pathways and development of the classic nicotinic and muscarinic signs (Anadon et al., 2009; Watson et al., 2009). Urinary system signs associated with anticholinesterase poisoning include involuntary urination because of cholinergic stimulation of bladder musculature. Acute renal injury has occasionally

been reported after anticholinesterase poisonings and may be attributed to hemodynamic dysfunction leading to shock and hypovolemia during the cholinergic crisis, which, in turn, results in decreased renal perfusion (Bloch-Shilderman and Levy, 2007). Because the mechanism of anticholinesterase poisoning is biochemical, few characteristic gross lesions would be expected beyond nonspecific organ congestion and presence of increased bronchial secretions (Meerdink, 2004). Histopathologic evidence of skeletal muscle necrosis, myocardial hemorrhage and necrosis, and neuronal necrosis within the hippocampus, cerebral cortex, amygdala, and thalamus have been reported after severe OP intoxication (Gupta et al., 1987a,b, 1991; Gupta and Crissman, 2013).

Depleted Uranium

Depleted uranium (DU) is previously enriched uranium that has had its radioactivity largely spent and, as such, is a very weak alpha and gamma emitter (Gwaltney-Brant, 2013). Lesions produced by depleted uranium are thereby related to the metal itself rather than any emitted radiation. Uranium is poorly absorbed orally, and absorption via inhalation requires uranium to be soluble and of small size (<10 μm). Once absorbed, uranium is converted to uranyl ion that complexes with citrate, bicarbonate, or plasma proteins and is distributed via the blood, ultimately accumulating in bone and in the proximal tubules of the kidney. In the proximal tubular epithelium, uranyl ion is cleaved from its complex and causes damage to renal tubules and glomeruli, resulting in proteinuria, glucosuria, aminoaciduria, and, with larger exposure levels, acute renal failure. Glomerular lesions include endothelial swelling and necrosis, glomerular sclerosis, and disruption of glomerular fenestrae. Tubular epithelium becomes vacuolated and necrotic, and over time a mosaic of degenerating and regenerating tubules and glomeruli can be seen along with interstitial inflammation and fibrosis. On removal of uranium exposure, tubules and glomeruli may fully regenerate, provided that fibrosis has not developed. For more details on DU toxicity, see Chapter 33.

Thallium

Thallium is a heavy metal that has historically been used as a pesticide and as a therapeutic agent, and has been used illegally as an agent for suicide attempts and intentional poisonings of small groups of people (Thompson, 2009). Thallium is rapidly absorbed via most routes and is widely distributed throughout the body, although the highest levels occur in the skin. Thallium substitutes for potassium in many cellular enzymatic and transport systems, causing widespread disruption of cellular function. Clinically, the classic syndrome of thallium poisoning involves gastroenteritis, polyneuropathy, and alopecia. Renal injury may occur secondarily and is characterized by elevations in BUN and urine protein levels. Histopathological lesions in the kidney include necrosis of epithelium of loop of Henle, degeneration and necrosis of proximal convoluted tubules, and stromal edema. On electron microscopy, degenerative changes were seen in mitochondria, microvilli, and endoplasmic reticulum (Danilewicz et al., 1979). For further details on thallium toxicity, see Chapter 14.

Ricin

Ricin is a lectin isolated from the seeds of the castor bean plant (*Ricinus communis*) that acts as a ribosome-inactivating protein, enzymatically depurinating adenine residues of 28S ribosomal RNA and irreversibly arresting protein synthesis (Lapadula et al., 2013). The toxicity of ricin has been known for centuries, and more than 750 human cases of intoxication have been reported (Poli et al., 2007). Its potency, worldwide availability, and ease of production have made ricin a biological warfare agent of interest in many countries, but its widespread use as such has not been reported. Ricin has been used as an agent of political assassination, with the most famous incident being the murder of Georgi Markov, a Bulgarian dissident who died a few days after a ricin-impregnated bead was injected into his thigh via a specially modified umbrella (Papaloucas et al., 2008). The fact that the ricin had to be injected into Markov underscores one of the drawbacks in its use as an agent of warfare or terrorism: the toxicity of ricin is largely route-dependent (Poli et al., 2007). Dermal absorption of ricin does not occur to any significant degree; ingestion results primarily in gastrointestinal injury, which is largely survivable if patients receive appropriate therapy. Parenteral administration via injection is not feasible for large-scale use, and efficient inhalational administration requires refinement in manufacturing and delivery methods that make it less desirable as an efficient warfare or terrorism weapon (Schep et al., 2009).

Clinical signs and pathologic lesions in ricin toxicosis are largely route-specific, with ingestion causing primarily gastrointestinal signs (vomiting, diarrhea, abdominal pain) and with inhalation resulting in respiratory signs such as wheezing, pneumonia, and pulmonary edema (Poli et al., 2007). At larger oral or inhaled dosages or with parenteral administration (i.e., injection), more serious systemic effects can develop, including hemorrhagic diarrhea, fever, vascular collapse, hypotension, dehydration, cyanosis, hypovolemic shock, and death after 3 or more days. Liver failure and kidney failure have been reported in human cases with survival beyond several days. Systemic lesions after ricin ingestion by humans include gastrointestinal

ulceration and hemorrhage, diffuse nephritis, and necrosis of liver, spleen, and lymph nodes. Renal lesions associated with ricin toxicosis resemble lesions of hemolytic-uremic syndrome, which is most commonly associated with verocytotoxin-producing *Escherichia coli* (Taylor et al., 1999; Korcheva et al., 2005). In rodents exposed intratracheally to lethal levels of ricin, initial renal injury occurs in the glomerulus, which shows leukocytosis, accumulation of proinflammatory RNA transcripts, substantial damage to 28S rRNA, and accumulation of fibrin and fibrinogen, resulting in glomerular thrombotic microangiopathy (Wong et al., 2007). Renal tubular degeneration and necrosis develop subsequent to the glomerular injury. Mice exposed to sublethal levels of ricin did not have development of histopathological lesions and 28S rRNA damage within the kidney. In dogs with naturally occurring fatal ricin toxicosis, membranous glomerulonephritis devoid of fibrin deposits and renal tubular degeneration and necrosis have been reported (Roels et al., 2010). For details on ricin toxicity, see Chapter 27.

Anthrax Toxins

Anthrax is a zoonotic disease caused by *Bacillus anthracis* that has a long association in human history. Inhalational anthrax, also known as woolsorter's disease because of its association with English woolsorters, is of concern because of its ability to be spread via aerosol route and its high mortality in humans lacking rapid access to appropriate treatment. A 2001 bioterrorist attack in the United States resulted in the deaths of 5 out of 11 individuals who had development of inhalational anthrax. In addition to inhalational anthrax, other forms of anthrax include gastrointestinal anthrax, cutaneous anthrax, and meningitis, with the latter occurring as a complication attributable to bacteremia from any of the other forms of the disease (Purcell et al., 2007).

B. anthracis produces two major toxins, lethal toxin (LT) and edema toxin (ET), which play essential roles in its virulence (Sweeney et al., 2010). As with many bacterial toxins, anthrax toxins are binary in structure, possessing a cell-binding, pore-forming subunit that gains entry into cells and an enzymatic component that produces the toxic effect. LT is a zinc endopeptidase that cleaves mitogen-activated protein kinases, whereas ET is a potent calmodulin-dependent adenyl cyclase. Although ET is less potent than LT on a molar basis, it produces death more rapidly and is primarily responsible for the renal effects of anthrax (Fioved et al., 2005). ET causes decreased renal perfusion as well as possible direct cytotoxic effects on renal tubular epithelium, leading to increases in BUN and serum creatinine. Histopathologic renal lesions of anthrax include degeneration and necrosis of cortical tubular epithelial cells. For further details on anthrax toxicity, see Chapter 29.

Cyanobacterial Toxins

Blue-green algae produce a variety of toxins, including anatoxins, microcystins, nodularins, and cylindrospermopsin (Patocka et al., 2011; Puschner and Roegner, 2012). Anatoxin-a and anatoxin-a(s) are not directly nephrotoxic, but their effects on the nervous system (nicotinic and anticholinesterase, respectively) can result in loss of voluntary bladder control and involuntary urination. Microcystins and nodularins are primarily hepatotoxins that cause apoptosis and necrosis of hepatocytes through interference with cytoskeletal structures after acute exposure. Death from acute microcystin toxicosis is attributable to liver failure, with any renal injury generally attributed to terminal multi-organ failure. Chronic administration of microcystins to rats resulted in nephrotoxicity caused by disruption of cytoskeletal structures of the renal tubular cells (Milutinovic et al., 2003). Nodularins have been reported to produce renal lesions after acute exposure (Simola et al., 2012). The lesions were described as radiating streaks of acute tubular necrosis primarily affecting proximal tubular epithelium, with multifocal extensions of necrosis into more distal tubules and collecting ducts. In both microcystin and nodularin toxicosis, decreased renal perfusion may also play a role in the renal lesions that develop. Cylindrospermopsin binds to DNA, causing DNA damage, inhibiting protein synthesis, and inducing oxidative damage to cells (Solter and Beasley, 2013). As with microcystins and nodularins, the liver is the primary target of cylindrospermopsin, with renal injury thought to be a combination of direct toxic injury as well as ischemic injury attributable to cardiovascular compromise in terminal stages of toxicosis. Renal lesions include acute degeneration and necrosis of proximal and distal convoluted tubules. In addition to cytotoxicity, cylindrospermopsin can be bioactivated to a genotoxic compound by cytochrome P450 enzymes (Zegura et al., 2011). The genotoxic nature of cylindrospermopsin also makes it a concern as a potential human and animal carcinogen. For further details, readers are referred to Chapter 31 on cyanobacterial (blue-green algae) toxins.

Other Agents

Many potential agents of chemical warfare have little to no direct injurious effect on the kidney or urinary system, but instead may cause indirect renal injury and/or urinary dysfunction. Nitrate esters used as explosives can cause profound hypotension with the potential to result in renal ischemia secondary to decreased renal perfusion (Gahagan and Wismer, 2012). Metabolic acidosis, proteinuria, glucosuria, and myoglobinuria were reported in a survey of five human cases of cyclonite

(C-4) plastic explosive ingestion, and chronic renal insufficiency developed in a dog that recovered from seizures caused by ingestion of cyclonite (Kuccukardali et al., 2003; Fishkin et al., 2008). Chronic or repeated exposure to the riot control agent chloropicrin (PS, nitrochloroform) has been reported to cause kidney injury, but the mechanism or nature of renal injury has not been fully described (Salem et al., 2008). Cattle fed 25 g of polybrominated biphenyls per day for 33–60 days had development of degeneration and necrosis of cells of the collecting ducts and convoluted tubules, whereas those fed 250 mg per day had no development of signs or lesions of toxicosis (Moorhead et al., 1978). Toxic inhalants such as phosgene, chlorine, and hydrogen cyanide do not appear to cause direct injury to the kidney, nor do they appear to cause chronic or long-term renal effects (Tuorinsky and Sciuto, 2008).

Agents that cause neuromuscular dysfunction resulting in fasciculations, tremors, or seizures include compounds such as nerve agents, strychnine, fasciculins, and fluoroacetate. Although none of these has a direct toxic effect on the kidney, all have the potential to induce involuntary urination during the period of intoxication, and myoglobinuria or hemoglobinuria secondary to severe muscle injury from prolonged tremor or convulsion can cause acute renal tubular degeneration and necrosis. Incapacitants and psychotropic agents such as LSD also can result in loss of voluntary bladder control without causing overt lesions within the urinary system (Ketchum and Salem, 2008). Similarly, agents that produce neuromuscular blockade, paralysis, or unconsciousness such as tetrodotoxin or botulinum toxin can cause loss of voluntary bladder control, but cause no direct action on the kidney (Williams et al., 2007; Dembek et al., 2007). Conversely, the antimuscarinic nerve agent 3-quinuclidinyl benzilate (BZ) can cause urinary retention necessitating urethral catheterization to empty the bladder (Barreuto and Nelson, 2006).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Despite the fact that some nephrotoxic agents (e.g., ethylene glycol) have been used in cases of malicious poisoning of individuals or in cases of suicide, in general, the urinary system makes a poor target for chemical warfare agents whose goal is to rapidly and consistently disable, incapacitate, or kill people on a large scale. Although renal dysfunction can lead to debilitating illness and death of the individual, barriers to the use of nephrotoxins as chemical weapons include delay between exposure and development of clinical signs, difficulty in ensuring delivery of appropriate doses to the targets, and individual variation in response to nephrotoxic agents. Given these barriers, it is not surprising that agents that have been developed to be used for chemical warfare tend to target other organ systems that can accomplish the goal of rapid incapacitation of the opponent more efficiently than primary nephrotoxicants.

CHAPTER

44

The Immune System as a Target for Chemical Warfare Agents

Kavita Gulati and Arunabha Ray

INTRODUCTION

A chemical warfare agent (CWA) is a substance that is intended for use in military operations to kill, seriously injure, or incapacitate people because of the severe pathophysiological changes induced by them in various body systems. A United Nations (UN) report from 1969 defines CWAs as "chemical substances, whether gaseous, liquid, or solid, which might be employed because of their direct toxic effects on man, animals, and plants." However, the Chemical Weapons Convention (CWC) defines chemical weapons as including not only toxic chemicals, but also ammunition and equipment. Toxic chemicals are stated to be "any chemical which, through its chemical effect on living processes, may cause death, temporary loss of performance, or permanent injury to people and animals." Normally, they are either liquids or solids.

CWAs have been used in war since time immemorial. In 600 BC, Hellebore roots were used successfully by the Athenians to contaminate water supplies during the siege of Kirrha. Spartans ignited pitch and sulfur to create toxic fumes during the Peloponnesian War in 429 BC. The uses of CWAs on the battlefield reached a peak during World War I, and the French were the first to use ethylbromoacetate. It was followed by *o*-dianisidine chlorosulphonate, chloroacetate, chlorine, phosgene, hydrogen cyanide, diphenylchloroarsine, ethyldichloroarsine and methyldichloroarsine, and sulfur mustard, resulting in nearly 90,000 deaths and over 1.3 million casualties (Eckert, 1991). CWAs were most brutally used by the Germans in gas chambers as one way of carrying out the mass genocide of Jews during World War II, and they have been used intermittently both in war, as in the Iraq–Iran war, and in terrorist attacks, such as the one carried out in the Tokyo subway stations in 1995. It is estimated that nearly 100,000 U.S. troops may have been exposed to CWAs during Operation Desert Storm in the first Gulf War (Chauhan et al., 2008). In 2013, Syrian armed forces used organophosphate (OP) nerve agents and other CWAs against its own people.

CWAs have been widely condemned since they were first used on a massive scale during World War I. However, as already indicated, they are still stockpiled and used in many countries, as they are cheap and relatively easy to produce and can cause mass casualties. Although the blood agent creatine kinase (CK) is extremely volatile and undergoes rapid hydrolysis, the degradation of three types of vesicant CWAs, sulfur mustard, nitrogen mustard, and lewisite results in persistent products. For example, sulfonium ion aggregates formed during hydrolysis may be persistent and may retain vesicant properties. The nerve agents include the V agent *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX), as well as three G agents (tabun, sarin, and soman). VX gives rise to two hydrolysis products of possible concern: EA 4196, which is persistent; and EA 2192, which is highly toxic and possibly persistent under certain limited conditions (Small, 1984). Thus, their long-term persistence in the body may lead to alterations in the immune system of the exposed population. This chapter describes the immunotoxicity of CWAs and gives an insight into the probable mechanisms of such effects.

Immunotoxicity deals with immune dysfunction resulting from exposing an organism to a xenobiotic and explores the mechanisms underlying these effects in a biological system. The immune dysfunction may take the form of immunosuppression or, alternatively, exaggerated immune reaction such as allergy, autoimmunity, or

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00044-0

any number of inflammatory-based diseases or pathologies. Immunotoxicity adversely affects the functioning of both local and systemic immune systems, which are activated on exposure to toxic substances, including CWAs. Observations in humans and animal studies have clearly demonstrated that a number of environmental and industrial chemicals can adversely affect the immune system. Immunosuppression may lead to the increased incidence or severity of infectious diseases or cancer, since the immune system's ability to respond adequately to invading agents is suppressed. Toxic agent-induced immunostimulation can cause autoimmune diseases, in which healthy tissue is attacked by an immune system that fails to differentiate self-antigens from foreign antigens. For example, the pesticide dieldrin induces an autoimmune response against red blood cells, resulting in hemolytic anemia.

Although immunotoxicology is a relatively new field, a considerable amount of data has accumulated during the past few years on the immunotoxicity of certain xenobiotics. The majority of the research thus far has focused on environmental contaminants. Thus, from the defense point of view, considerable work is still required to investigate the immunotoxicity of several chemicals, and some bacterial and fungal toxins that may be potential CWAs. Furthermore, there are several chemicals used in the defense industry to which industrial workers may be constantly exposed. These chemicals, following low-level exposure to humans and animals, may cause immunological alterations. Thus, studies on such chemicals are being conducted to understand the potential risks of such exposure on the host's defense, as well as the cellular and molecular mechanisms of such immunomodulatory action.

THE IMMUNE SYSTEM

The immune system is composed of several organs, cells, and noncellular components, which act in an interrelated manner to protect the host against foreign organisms and chemical substances. The immune system participates in the mechanisms responsible for the maintenance of homeostasis, and an altered immune system reflects the adverse changes in both internal and external microenvironments. The immune system protects organisms against pathogens or other innocuous substances like pollens, chemicals, indoor molds, potential food allergens, and environmental agents, and it acts as layered defenses of increasing specificity. Most simply, physical barriers (e.g., skin) prevent pathogens and xenobiotics from entering the organism. If they breach these barriers, the innate immune system provides an immediate but nonspecific response. However, if pathogens successfully evade the innate response, there is a third layer of protection (i.e., the adaptive immune system), which is activated by the innate response. Here, the immune system adapts during an infection to improve its recognition of the pathogen, and its response is then retained after the pathogen or xenobiotic has been eliminated. This immunological memory allows the adaptive immune system to respond faster, and with a stronger attack, each time the same insult is encountered (Kindt et al., 2007).

The immune system protects organisms from infection with layered defenses of increasing specificity. The layered defense includes mechanical, chemical, and biological barriers, which protect organisms from toxic substances. Skin, a mechanical barrier, acts as the first line of defense against infection. In the lungs, coughing and sneezing mechanically eject pathogens and other irritants from the respiratory tract, while mucus secreted by the respiratory and gastrointestinal tract traps and entangles microorganisms and other toxins (Boyton and Openshaw, 2002). Chemical barriers also protect against infection. The skin and respiratory tract secrete antimicrobial peptides such as β-defensins. Enzymes such as lysozyme and phospholipase A2 in saliva, tears, and breast milk are also antibacterials (Hankiewicz and Swierczek, 1974; Moreau et al., 2001). In the stomach, gastric acid and proteases serve as powerful chemical defenses against ingested pathogens.

Innate Immune System

The innate immune system defends the host from infection and toxicants in a nonspecific manner. This means that the cells of the innate system recognize a threat and respond in a generic way but do not confer long-lasting or protective immunity to the host. The innate immune response was initially dismissed by immunologists, as it was thought to provide a temporary holding of the situation until a more effective and specific adaptive immune response develops. It is now clear that the innate immune system plays an important role as a dominant system of host defense in most organisms (Litman et al., 2005). The major function of the innate immune system is to recruit immune cells to sites of infection and inflammation. Inflammation is one of the first responses of the immune system to infection or irritation through the production of cytokines. These cytokines released by injured cells serve to establish a physical barrier against the spread of infection. Several chemical factors are produced during inflammation (e.g., histamine, bradykinin, serotonin, leukotrienes, and prostaglandins), which sensitize pain receptors, cause vasodilation of the blood vessels, and attract phagocytes. The inflammatory response is characterized by redness, heat, swelling, pain, and possible dysfunction of the organs or tissues involved. The fluid exudate contains mediators

for four proteolytic enzyme cascades: the complement system, the coagulation system, the fibrinolytic system, and the kinin system. The exudate is carried by lymphatics to lymphoid tissue, where the toxin of a foreign organism can initiate an immune response.

The activation of the complement cascade helps to identify the invading substance, activate cells, and promote clearance of dead cells by specialized white blood cells (WBCs). The cascade is composed of nine major components, designated C1 to C9, which are plasma proteins synthesized in the liver, primarily by hepatocytes. These proteins work together to trigger the recruitment of inflammatory cells. One of the main events is the splitting of C3, which gives rise to various peptides. One of them, C3a (anaphylatoxin), can stimulate mast cells to secrete chemical mediators; and another, C3b (opsonin), can attach to the surface of a foreign body and facilitate its ingestion by WBCs. C5 is a powerful chemotactic of white cells and causes release of mediators from mast cells. Later components from C5 to C9 assemble in a sequence at the surface of bacteria/xenobiotics and lead to their lysis, ridding the body of neutralized antigen–antibody complexes. The main events of this system can also be directly initiated by the principal enzymes of the coagulation and fibrinolytic cascade, thrombin and plasmin, and by enzymes released from WBCs. Further, an innate immune system leads to the activation of an adaptive immune system.

Adaptive Immune System

The adaptive immune system is composed of highly specialized systemic cells and processes that eliminate pathogenic challenges and provide the ability to recognize and mount stronger attacks each time the same pathogen is encountered. Antigen specificity requires the recognition of specific "nonself" antigens during a process called *antigen presentation.* The ability to mount these immune responses is maintained in the body by "memory cells." The cells of the adaptive immune system are special types of leukocytes, B cells and T cells, which constitute about 20–40% of WBCs. The peripheral blood contains 20–50% of circulating lymphocytes and the rest move within the lymphatic system (Kindt et al., 2007). B cells and T cells are derived from the same pluripotential hematopoietic stem cells in the bone marrow, and are indistinguishable from one another until after they are activated. B cells play a large role in the *humoral immune response*, whereas T cells are intimately involved in *cell-mediated immune (CMI) responses*. B cells derive their name from the bursa of Fabricius, an organ unique to birds, where the cells were first discovered. However, in nearly all other vertebrates, B cells and T cells are produced by stem cells in the bone marrow (Kindt et al., 2007). T cells are named after the thymus, where they develop and through which they pass. In humans, approximately 1–2% of the lymphocyte pool recirculates each hour to optimize the opportunities for antigen-specific lymphocytes to find their specific antigen within the secondary lymphoid tissues. Both B cells and T cells carry receptor molecules that recognize specific targets.

T cells express a unique antigen-binding molecule, the T-cell receptor (TCR), on their membrane. There are two well-defined subpopulations of T cells: T helper (T_H) and T cytotoxic (T_C) cells. They can be distinguished from one another by the presence of either CD4 or CD8 membrane glycoproteins on their surfaces. T cells displaying CD4 generally function as T_H cells whereas those displaying CD8 function as T_C cells. T cells recognize a nonself target, such as a pathogen, only after antigens have been processed and presented in combination with a self-receptor called a major histocompatibility complex (MHC) molecule. T_C cells only recognize antigens coupled to class I MHC molecules, while T_H cells only recognize antigens coupled to class II MHC molecules.

B cells are the major cells involved in the creation of antibodies that circulate in blood plasma and lymph, known as *humoral immunity.* Like the TCR, B cells express a unique B-cell receptor (BCR), which in this case is an immobilized antibody molecule. The BCR recognizes and binds to only one particular antigen. A critical difference between B cells and T cells is how each cell "sees" an antigen. T cells recognize their cognate antigen in a processed form (as a peptide in the context of an MHC molecule), while B cells recognize antigens in their native form. Once a B cell encounters its cognate (or specific) antigen [and receives additional signals from a helper T cell (predominantly of the Th2 type)], it further differentiates into an effector cell, known as a *plasma cell.*

Plasma cells are short-lived cells (2–3 days) that secrete antibodies that circulate in blood plasma and lymph, and these cells are responsible for humoral immunity. Antibodies (or immunoglobulin, Ig) are large, Y-shaped proteins used by the immune system to identify and neutralize foreign objects. In mammals, there are five types of antibody: IgA, IgD, IgE, IgG, and IgM. Differing in biological properties, each has evolved to handle different kinds of antigens. These antibodies bind to antigens, making them easier targets for phagocytes, and trigger the complement cascade. About 10% of plasma cells will survive to become long-lived, antigen-specific memory B cells (Lu and Kacew, 2002). Already primed to produce specific antibodies, these cells can be called upon to respond quickly if the same foreign body reinfects the host. This is called *adaptive immunity* because it occurs during the lifetime of an individual as an adaptation to infection with that pathogen and prepares the immune system for future challenges.

A number of animal models have been developed and validated to detect chemical-induced direct immunotoxicity. Several compounds, including certain drugs, have been shown in this way to cause immunosuppression or skin allergic responses. This chapter discusses the various mechanisms of immunotoxicity by which a compound affects different cell types and interferes with immune responses, ultimately leading to immunotoxicity as well as sensitizing capacity.

TARGETS OF IMMUNOTOXICITY

Effects on Precursor Stem Cells

The bone marrow is an organ with precursor stem cells that are responsible for synthesizing peripheral leukocytes. All leukocyte lineages originate from these stem cells, but once distinct subsets of leukocytes are established, their dependence on replenishment from the bone marrow differs widely. The turnover of neutrophils is very rapid (i.e., more than 10^8 neutrophils enter and leave the circulation in a normal adult daily), so there is dependence on new formation in the bone marrow. In contrast, macrophages are long-lived and have little dependence on new formation of precursor cells. The adaptive immune system, comprising antigen-specific T and B lymphocytes, is almost completely established at around puberty and therefore essentially consists of independent bone marrow in the adult.

As a consequence of their high proliferation rate, stem cells in the bone marrow are likely to be extremely vulnerable to cytostatic drugs and chemicals like CWAs. Lineages like neutrophils with rapid turnover will be most vulnerable and will be affected first by such treatments and exposures. After prolonged exposure, macrophages and T or B cells of the adaptive immune system are also suppressed.

Effects on Maturation of Lymphocytes

T lymphocytes mature in the thymus by a very complex selection process that takes place under the influence of the thymic microenvironment and ultimately generates an antigen-specific, host-tolerant population of mature T cells. This process involves cellular proliferation, gene rearrangement, apoptotic cell death, receptor up- and down-regulation, and antigen-presentation processes, and is very vulnerable to a number of chemicals. Drugs may target different stages of T-cell differentiation like naive T cells, proliferating and differentiating thymocytes, antigen-presenting thymic epithelial cells and dendritic cells, and cell death processes (Vos et al., 1999). In general, immunosuppressive drugs may cause a depletion of peripheral T cells, particularly after prolonged treatment and during early stages of life, when thymus activity is high and important in establishing a mature T-cell population. In addition, suppression of T cells may result in suppression of the adaptive immune system by affecting the maturation of B cells, and thus antibody level.

Effects on the Initiation of Immune Responses

The innate and adaptive immune systems act together to eliminate invading pathogens. Ideally, T cells tailor the responses to neutralize invaders with minimal damage to the host. The recognition of autoantigens is maintained by two distinct signals that govern lymphocyte activation. One is the specific recognition of antigens via clonally distributed antigen receptors, and the other is antigen-nonspecific co-stimulation or help, which involves interactions of various adhesive and signaling molecules expressed in response to tissue damage, linking initiation of immune responses to situations of acute danger for the host (Vos et al., 1999). This helps to aim immune responses at potentially dangerous microorganisms (nonself), while minimizing deleterious reactions to the host (self). Xenobiotics, however, can interfere with the initiation of immune responses if they act as antigens, by forming haptens or by releasing previously hidden self-antigens. They may also trigger an inflammatory response or disturb the cooperation between T and B cells.

CWAs with large molecular weights can function as antigens and become targets of specific immune responses themselves. This is particularly relevant for foreign protein pharmaceuticals, as these can activate both T and B lymphocytes. The resulting immune responses may lead to formation of antibodies, and induce specific memory, which can lead to allergic responses to the drug. Immunotoxic effects may occur after repeated treatment with the same CWA. However, low-molecular-weight CWAs cannot function as antigens because they are too small to be detected by T cells. Reactive chemicals that bind to proteins, however, can function as haptens and become immunogenic if epitopes are derived from prime T cells, which in turn provide co-stimulation for hapten-specific B cells. This effect is responsible for allergic responses to many new epitopes formed by chemical haptens.

Modification of autoantigens can also lead to autoimmune responses to unmodified self-epitopes. Haptenated autoantigens can be recognized and internalized by antigen-presenting cells. These cells subsequently present a mixture of neo- and self-epitopes complexed to distinct class II major histocompatibility (MHC-II) molecules on their surface and neospecific T cells. T helper (Th) cells provide signals for B cells. This leads to production of either anti-hapten or

anti-self antibodies, depending on the exact specificity of the B cell. Moreover, once these B cells are activated, they can stimulate autoreactive Th cells recognizing unmodified self-epitopes. This process is called *epitope (determinant) spreading* and causes the diversification of adaptive immune responses. For example, injection of mercury salts initially induces a response directed only to unidentified chemically created neoepitopes, but after 3–4 weeks, it includes reactivity to unmodified self-epitopes. Thus, the allergic response may gradually culminate as autoimmune responses reflecting the relative antigenicity of the neo- and self-epitopes involved (Lu and Kacew, 2002).

Induction of Inflammation and Noncognate T–B Cooperation

Cytotoxic chemicals or their reactive metabolites can induce tissue damage, which causes the release of proinflammatory cytokines like tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), and IL-6, and attracts inflammatory cells like granulocytes and macrophages. Cytokines produced during this inflammatory response activate antigen-presenting cells and accumulation of tissue debris. The epitopes of antigens on debris provide co-stimulation for Th cells, which lead to the initiation of an adaptive immune response. Reactive xenobiotics may also stimulate adaptive immune responses by disturbing the normal cooperation of Th and B cells. Normally, B cells receive stimulation from Th cells that recognize epitopes of the same antigen. However, when Th cells respond to nonself-epitopes on B cells, such B cells may be noncognately stimulated by the Th cells. This occurs during graft-versus-host responses following bone marrow transplantation, when Th cells of the host recognize nonself-epitopes on B cells of the graft and vice versa. This leads to T- and B-cell activation and results in production of autoantibodies to distinct autoantigens like deoxyribonucleic acid (DNA), nucleoli, nuclear proteins, erythrocytes, and basal membranes. Drug/chemical-related lupus is characterized by a similar spectrum of autoantibodies, and noncognate—graft-versus-host-like—T–B cooperation, therefore, is suggested to be one of the underlying mechanisms.

EXPOSITION OF AUTOANTIGENS AND INTERFERENCE WITH CO-STIMULATORY SIGNALS

Self-tolerance involves specific recognition of autoantigen leading to selective inactivation of autoreactive lymphocytes at birth, but tolerance is not established for epitopes of autoantigens that are normally not available for immune recognition. Pharmaceuticals can expose such sequestered epitopes by disrupting barriers between the antigen and the immune system [i.e., blood–brain barrier (BBB), blood–testis barrier, and cell membranes]. Tissue damage, cell death, and protein denaturation induced by chemicals can largely increase the chances of such autoantigens for immune recognition. Antigen recognition followed by co-stimulation of signaling molecules leads to the activation of lymphocytes and initiation of immune responses. Many xenobiotics have the inherent capacity to induce or inhibit this co-stimulation due to their intrinsic adjuvant activity.

REGULATION OF THE IMMUNE RESPONSE

The type of immune response elicited in response to a foreign pathogen or allergen is the result of a complex interplay of cytokines produced by macrophages, dendritic cells, mast cells, granulocytes, and lymphocytes. Immunotoxic chemicals that somehow influence the immune system can lead to either immunosuppression or immune exaggeration; i.e., hypersensitivity and autoimmunity. Hypersensitivity is an immune response that damages the body's own tissues. Hypersensitivity reactions require a presensitized (immune) state of the host. They are divided into four classes (Type I–IV) based on the mechanisms involved and the time course of the hypersensitive reaction. Type I hypersensitivity is an immediate or anaphylactic reaction, often associated with allergy. Symptoms can range from mild discomfort to death. Type I hypersensitivity is mediated by IgE released from mast cells and basophils. Type II hypersensitivity occurs when antibodies bind to antigens on the patient's own cells, marking them for destruction. This is also called *antibody-dependent (or cytotoxic) hypersensitivity*, and is mediated by IgG and IgM antibodies. Immune complexes (aggregations of antigens, complement proteins, and IgG and IgM antibodies) deposited in various tissues trigger Type III hypersensitivity reactions. Type IV hypersensitivity (also known as *cell-mediated* or *delayed type hypersensitivity*) usually takes between 2 and 3 days to develop. Type IV reactions are involved in many autoimmune and infectious diseases, but they may also involve contact dermatitis (poison ivy). These reactions are mediated by T cells, monocytes, and macrophages. The actual development of clinical symptoms is influenced by the route and duration of exposure, the dosage of the pharmaceutical, and by immunogenetic (MHC haplotype, Th1-type versus Th2-type responders, etc.) and pharmacogenetic (acetylator phenotype, sulfoxidizer, Ah receptor, etc.) predisposition of the exposed individual. Moreover, atopic individuals that tend to mount Th2 immune responses are more susceptible to anaphylaxis triggered by an IgE response to

chemical haptens than typical Th1 responders. Genetic variation in metabolism of pharmaceuticals is important as it determines the formation and clearance of immunotoxic metabolites. The slow-acetylating phenotype, for instance, predisposes for drug-related lupus because reactive intermediates of phase I metabolism have an increased opportunity to bind proteins as they are only slowly conjugated.

Immune dysregulation can also be in the form of immune suppression and both innate and adaptive arms of the immune systems play crucial roles. A wide variety of physiological, pharmacological, and environmental factors can exert a negative influence on the immune system and sometimes result in immunotoxicity. Recent experimental data have shown that emotional and environmental stressors influence the functioning of the immune system, and this is reflected in the various markers of specific immunity (Ray et al., 1991; Koner et al., 1998). Such experimental stressors consistently suppressed both humoral and CMI responses in experimental animals. Both antibody-forming cell counts and antibody titer were lowered, and a neuroendocrine–immune axis concept was proposed. Similar attenuations in CMI responses were also seen after such stressors and delayed type hypersensitivity (DTH) responses, leukocyte/macrophage migration indices and also cytokine profiles (both Th1- and Th2-dependent). Further analysis of the mechanisms involved indicated that central nervous system (CNS)–mediated changes could have contributed to this immunotoxicity. Depletion or antagonism of brain dopamine aggravated emotional stress-induced immune suppression, whereas psychoactive drugs like benzodiazepines and opioids prevented this response (Ray et al., 1992; Puri et al., 1994). In another set of experiments, rats exposed to several environmental pollutants like dichlorodiphenyltrichloroethane (DDT) showed graded degrees of immune suppression and immunotoxicity when the exposure lasted for a reasonably long period of time. Gradual accumulation in the various body tissues resulted in a variety of untoward effects in the immune system, which was particularly susceptible to such xenobiotic-induced damage (Banerjee et al., 1996; Koner et al., 1998). Both humoral and CMI response were affected, depending on the quantum and duration of exposure to these xenobiotics. Further, a combination of emotional stress and xenobiotic exposure had additive effects on the immunotoxicity parameters studied (Banerjee et al., 1997). Recent studies revealed that such emotional stress and xenobiotic-induced immunotoxicity was accompanied by derangements in oxidative stress parameters, such as enhancements in 3,4-methylenedioxyamphetamine (MDA) levels and lowering of glutathione (GSH) and superoxide dismutase (SOD) levels in the blood (Koner et al., 1997; Gulati et al., 2007; Ray and Gulati, 2007).

IMMUNOTOXICITY OF CWAS

Very few studies have been conducted to explore the immunomodulation and immunotoxic potential of CWAs, and there is little evidence that these drugs are associated with such undesirable, immunologically significant effects. The reason may be due to confounding factors such as stress, nutritional status, lifestyle, co-medication, and genetics (Vos et al., 1999). Few conventional compounds have been shown to induce unexpected enhancement of immune competence. Xenobiotic-induced hypersensitivity reactions and autoimmune disorders are a major concern, whereas some of these chemicals result in immunosuppression. In particular, impaired activity of the first line of defense of the natural immune system can have disastrous consequences. These are generally not influenced by the genetic predisposition of the exposed individual, but on actual outbreak of infections and the general immune status prior to exposition. This explains why immunosuppressive xenobiotics are most likely to have clinical consequences in immunocompromised individuals such as young children or the elderly, and can be aggravated further by stressful situations.

The exposure to CWA, depending on the type of agent and duration of exposure, can result in immunodepressed conditions or allergic and autoimmune diseases. CWAs can be classified in many different ways. They may take the form of solids, liquids, or gases. Volatile substances mainly contaminate the air, and persistent substances, which are nonvolatile, mainly cover surfaces. Some agents (e.g., sulfur mustard) may appear as solids in northern European winter conditions (freezing point 14.4°C), as a liquid at a wide range of temperatures (boiling point 219°C) or as a vapor evaporating from the liquid phase. CW agents may also be encountered as mixtures or solutions of one agent in another, or of an agent in a solvent. The mixing of lewisite with sulfur mustard has been undertaken to lower the vapor pressure and freezing point of the mustard, and hence to increase its persistence, without reducing the effective CW payload of weapon systems.

CWAs mainly used against people may also be divided into lethal and incapacitating categories. A substance is classified as an incapacitating agent if less than 1/100 of the lethal dose causes incapacitation (e.g., through nausea or visual problems). The limit between lethal and incapacitating substances is not absolute but refers to a statistical average. CWAs are generally classified according to their principal target organs, as follows:

1. **Nerve agents**. These agents are extremely toxic compounds that work by interfering with the nervous system. They include soman, sarin, cyclosarin, tabun, and VX.

2. **Blister agents/vesicants**. These compounds severely blister the eyes, respiratory tract, and skin on exposure. They include nitrogen mustard, sulfur mustard, and lewisite.
3. **Choking agents**. These agents cause severe irritation primarily affecting the respiratory tract. They include phosgene, ammonia, methyl bromide, and methyl isocyanate.
4. **Blood agents**. These agents are absorbed into the blood and interfere with the oxygen-carrying capacity (e.g., arsine, cyanides, and carbon monoxide).

Nerve Agents

Nerve agents are highly toxic organophosphorus compounds (OPs) that represent potential threats to both military and civilian populations, as evidenced in recent terrorist attacks in Japan (Ohtomi et al., 1996). Commonly known as *nerve agents* or *nerve gases*, these are the deadliest of CWAs. These agents have both chemical names and two-letter NATO codes. These are categorized as G agents: GA (tabun), GB (sarin), GD (soman), GF (cyclosarin), and V agents: VE, VG, VM, and VX. (The letter *G* represents Germany, the country of origin; and the letter *V* denotes "venomous"). Their initial effects occur within 1–10 min of exposure followed by death within 15–30 min for sarin, soman, and VX, and within 30–60 min for tabun. The ease and low cost of production make sarin gas a weapon of mass destruction in the hands of terrorist groups and dictators. While people in the immediate vicinity of a sarin attack may receive neurotoxic doses, people remote from the vicinity are likely to receive subclinical exposures.

Short- and long-term health effects from exposure to OP nerve agents and insecticide nerve agents are compiled on the basis of scientific literature published on health effects in humans and animal studies. Four distinct health effects are identified: acute cholinergic toxicity, OP-induced delayed neuropathy (OPIDN), subtle long-term neuropsychological and neurophysiological effects, and a reversible muscular weakness called *intermediate syndrome.* Each effect has data suggesting threshold exposure levels below which it is unlikely to be clinically detectable. High-level exposure results in definitive cholinergic poisoning; intermediate-level cholinergic effects include miosis, rhinorrhea, or clinically measurable depression of cholinesterase; and low-level exposure results in no immediate clinical signs or symptoms. Threshold exposure levels for the known long-term effects from OP nerve agents are at or above intermediate-level exposures (Brown and Brix, 1998). However, subclinical doses of sarin cause subtle changes in the brain, and subclinical exposure to sarin has been proposed as an etiology of Gulf War syndrome. For further details of Gulf War Syndrome, see chapter 6.

The wide use of cholinesterase inhibitors in various spheres of human activities and the risk of acute and chronic intoxications associated with this process prompted investigation of the role of acetylcholinesterase (AChE) and nonspecific esterases in the immunotropic effects of these chemicals. They irreversibly bind to AChE that normally catalyzes the hydrolysis of acetylcholine (ACh) at the cholinergic synapses and neuromuscular junctions (NMJs). The inhibition of degradation results in accumulation of ACh in the cholinergic synapses, causes the overstimulation of peripheral and central cholinergic nervous systems, and is clinically manifested as acute cholinergic crisis (featuring convulsions, respiratory failure, and sometimes death) (Marrs, 1993; Taylor, 2006).

Immunotoxicity of Nerve Agents

Kalra et al. (2002) suggested that low doses of sarin are highly immunosuppressive, and suppress glucocorticoid production. The effects of sarin exposure on the immune system are attenuated by ganglionic blockers and decreased glucocorticoid level may be a biomarker for cholinergic toxicity. In addition, nerve agents cause the activation of multiple noncholinergic neurotransmitter systems in the CNS, resulting in mutagenic, stressogenic, immunotoxic, hepatotoxic, membrane, and hematotoxic effects (Bajgar, 1992). The CNS and the immune system communicate bidirectionally, and cholinergic agents modulate the immune system. The ability of OP compounds to induce an alteration of the immune system was primarily demonstrated in animals or humans exposed to OP insecticides (OPIs). The results provide evidence that a number of functions are altered in animals or humans exposed to OP compounds, especially neutrophil function, natural killer (NK) cells, cytotoxic T-cell and humoral immune functions, and spontaneous as well as mitogen-induced lymphocyte proliferations (Casale et al., 1984; Hermanowitz and Kossman, 1984; Li et al., 2002; Newcombe and Esa, 1992; Sharma, 2006). In addition, a decreased number of cells in the spleen and thymus (Ladics et al., 1994), an inhibition of chemotaxis in neutrophils (Ward, 1968), inhibition of monocyte accessory functions, and inhibition of interleukin-2 production (Pruett and Chambers, 1988; Casale et al., 1993) were reported following the exposure to OPs, at relatively high toxic doses.

Lee et al. (1979) were the first to draw attention to the possible effects of OPs on human leukocyte function. They demonstrated that lymphocyte proliferation to phytohemaglutinin *in vitro* was decreased in the presence of OPs. Although most of the studies described the results of OPI exposure, there are studies about the immunotoxic effects of highly toxic nerve agents and their by-products. Marked impairment in neutrophil chemotaxis and neutrophil adhesion, and a reduction in the NK cell and cytotoxic

T-cell function were observed in workers exposed to OPIs and by-products of sarin (Hermanowitz and Kossman, 1984; Newcombe and Esa, 1992; Li et al., 2002). Kant et al. (1991) documented a decrease in the weight of the thymus, an important immune organ in severely affected soman survivors, but other tests of immune function did not show differences between control and soman-exposed rats. Samnaliev et al. (1996) described a decrease in the number of plaque-forming cells (PFCs) in soman-exposed rats after the administration of sheep red blood cells (SRBCs) as an antigen. However, Johnson et al. (2002) demonstrated that OP-induced modulation of immune functions can involve not only their suppression, but also their activation. Similar activation of some immune functions involving "acute phase response," such as increase in the synthesis of acute phase proteins, increase in release of histamine from basophile leukocytes, and activation of macrophages, was observed following exposure to soman (Newball et al., 1986; Sevaljevic et al., 1992). Although most of the studies dealt with exposure to high doses, Kassa et al. (2004) confirmed that not only symptomatic, but also asymptomatic, doses of sarin were able to modify various immune functions. The proportion of T lymphocytes was found to be decreased, while the B-cell levels were raised. However, sarin significantly suppressed nonspecific, *in vitro*, stimulated proliferation of both T and B cells, which suggests that it can also block normal immune response to infection. While the lymphocyte-mediated immunity is suppressed, the peritoneal and alveolar macrophages and NK cells were activated after exposure to both levels of sarin, which was determined to be the result of compensatory reactions of immune functions rather than the result of direct effects of inhalation.

Immunosuppression may result from direct action of acetylcholine upon the immune system, or it may be secondary to the toxic chemical stress associated with cholinergic poisoning (Pruett et al., 1992). Further, immunomodulation at low levels seems to be very complex, and it is suggested that other protein targets probably are very sensitive to some anticholinesterases (anti-AChEs), including nerve agents. However, the function of these protein targets is not yet known (Ray, 1998). Some immune functions are probably stimulated due to the development of "acute phase response" generally characterized by the inflammatory reaction of OP-exposed organisms (Sevaljevic et al., 1989, 1992). Other immune functions are suppressed due to immunotoxicity of OP compounds. Although these findings are difficult to extrapolate directly to low-level exposures to nerve agents, they indicate that subtle alteration of the immune system could also occur in humans at exposure levels that do not cause any clinical manifestation. Post-intoxication immunodeficiency can promote infectious complications and diseases.

It has been shown that T lymphocytes have AChE located on the plasma membrane, while B cells are esterase-negative (Szelenyi et al., 1982). Thus, AChE inhibition by toxic agents in sublethal doses may play an important role in immunodeficiency following exposure to nerve gases. Zabrodskii et al. (2003) showed inhibition of AChE in T cells and a decrease in the number of esterase-positive T lymphocytes (and, to a certain extent, monocytes and macrophages) directly correlated with suppression of T-cell-dependent antibody production and with the degree of DTH reduction, upon exposure to dimethyl dichlorovinyl phosphate, sarin, VX, lewisite, tetraethyl lead, and dichloroethane. This presumably involves the loss of some functions by T lymphocytes (e.g., by Th1 cells), which leads to the attenuation of T-dependent immune reactions. This can be explained by excessive ACh stimulation of the muscarinic and nicotinic receptors present on T lymphocytes. As a result, the optimal ratio of cyclic adenosine monophosphate (cAMP) to cyclic guanosine monophosphate (cGMP) in immunocytes, which is essential for their proliferation and differentiation, is distorted (Richman and Arnason, 1979). Thus, the anti-AChE effect of lewisite, TEL, and DCE may be one of the important mechanisms in the formation of T-cell-mediated immunodeficiency.

A study showed that malathion (an OPI) in acute noncholinergic doses enhanced the humoral immune response to SRBCs and macrophage function, and also caused mast cell degranulation. When effects of acute administration of malathion were observed in mast cell-deficient mice, the humoral activation was not observed, suggesting that the mast cells contribute to the increases in macrophage function and humoral immunity observed in normal mice (Rodgers et al., 1996).

The effects of subchronic doses of malathion exposure on humoral and CMI responses were studied in male albino mice, rats, and rabbits using SRBCs, tetanus toxoid, and ovalbumin as antigens. The humoral immune response was assessed by estimating serum immunoglobulin (IgM and IgG) concentrations, antibody titer against antigens, and splenic-PFCs. The CMI response was studied by using the leukocyte migration inhibition (LMI) and macrophage migration inhibition (MMI) tests. In general, there were the following responses: (i) attenuation in the antigen-induced antibody response, (ii) suppression of PFCs, and (iii) marked inhibition of LMI and MMI factors. Subchronic malathion exposure-induced differential degrees of humoral and CMI suppression in these experimental animals. However, both cellular and humoral immune responses were decreased in a dose-time-dependent pattern and a consistent trend was observed. The threshold level of the malathion for inducing immune suppression varies on the basis of species of animals, type of antigen used, and method of immunological assay (Banerjee et al., 1998).

In another recent study, rats were administered with malathion alone and in combination with bradykinin potentiating factor (BPF), and the effects were compared to the vehicle group on immune parameters. The results showed that the concentration of total globulin, total immunoglobulins, IgG, IgM, circulatory immune complexes, total number of RBCs and platelets, and hemoglobin concentrations decreased significantly in malathion-exposed animals. The number of total leukocytes and lymphocytes increased. Histopathological changes of bone marrow and spleen after malathion exposure were consistent with these findings. Administration of double and triple injections of BPF resulted in the recovery of bone marrow and splenic changes, normalization of peripheral blood elements, reduction of elevated proinflammatory markers (IL-2, IL-4, and TNF-α), total plasma peroxide, and oxidative stress index (OSI), while the total antioxidant capacity (TAC) increased. Our results suggest that exposure to malathion has negative effects on immune function that is mediated through alteration of cytokines, antioxidants, and direct damage of bone marrow (BM). Also, BPF can ameliorate both physiological and morphological changes (Ahmed, 2012).

In another study involving malathion-poisoned human subjects, significant levels of malathion residue of 503–702 mg/L were seen, and this was associated with significant enhancements of IL-2, IL-4, and TNF-α levels in blood, whereas no significant changes in immunoglobulin levels were seen. This study thus showed altered levels of cytokines in the blood of malathione-exposed subjects (Seth et al., 2008). Kassa et al. (2001) showed that rats exposed once or repeatedly to three various low concentrations (0.8, 1.25 and 2.5 µg/L) of sarin for 60 min in an inhalation chamber induced immunotoxicity. Nonconvulsive concentrations of sarin caused subtle suppression of spontaneous, as well as lipopolysaccharides-stimulated proliferation of spleen lymphocytes and bactericidal activity of peritoneal macrophages.

Blister or Vesicant Agents

Blister agents act on skin and other epithelial tissues and severely damage the eyes, respiratory tract, and internal organs and destroy different substances within cells of living tissue. The symptoms vary depending upon the compound and the sensitivity of the individual. Acute mortality is low; however, they can incapacitate the enemy and overload the already burdened health care services during wartime. Some of these agents are sulfur mustard (HD), nitrogen mustard (HN), lewisite (L), and phosgene oximine (CX).

HD was the most widely used CWA in the Iran–Iraq war (1980–1988), resulting in over 100,000 chemical casualties. It acts as an alkylating agent with long-term toxic effects on several body organs, mainly the skin, eyes, and respiratory system (Willems, 1989). The extent of tissue injury depends on the duration and intensity of exposure. When absorbed in large amounts, SM can damage rapidly proliferating cells of bone marrow and may cause severe suppression of the immune system (Willems, 1989).

Immunotoxicity

Evidence that HD causes immunosuppression in humans has emerged from several areas of investigation. The earliest evidence came from clinical observations of humans directly exposed to HD during World War I, who showed significant changes (quantitative and qualitative) in the circulating elements of the immune system. Stewart (1918) studied 10 fatal cases of HD poisoning and observed striking depression of the bone marrow production of WBCs. Among the HD casualties during the Iran–Iraq conflict, leukopenia was the most common finding, accompanied by total bone marrow aplasia and extensive losses of myeloid stem cells (Balali-Mood, 1984; Eisenmenger et al., 1991). These findings provide further evidence of an association between suppression of immunologic functions and an increased incidence of infectious disease.

HD was widely used during the Iran–Iraq conflict, and there are many reports of influence of HD on the respiratory, gastrointestinal, and endocrine systems, as well as the immune system (Balali-Mood, 1984; Budiansky, 1984; Balali- Mood and Farhoodi, 1990; Sasser et al., 1996; Emad and Razaian, 1997). The influence of HD on the immune system has been the subject of many researchers since 1919 (Krumbhaar and Krumbhaar, 1919; Hektoen and Corper, 1921). Early investigations on HD casualties during the Iran–Iraq war showed decreased immunoresponsiveness, expressed as leukopenia, lymphopenia, and neutropenia, as well as hypoplasia and atrophy of bone marrow (Willems, 1989; Tabarestani et al., 1990; Balali-Mood et al., 1991). Chronic exposure to HD has been associated with the impairment of NK cells among workers in poison gas factories in Japan (Yokogama, 1993). Similarly, CMI was found to be suppressed following mustard gas exposure (Zandieh et al., 1990).

Leukopenia has been the first manifestation to appear within the first days of postexposure. Thrombocytopenia and anemia followed later if the patients survived (WBCs of some patients dropped to less than 1,000 per cm^3). Although most of these patients suffered skin burns, clinicians reported cases that had minor skin lesions and yet developed leukopenia. Bone marrow biopsies revealed hypocellular marrow and cellular atrophy involving all elements (Willems, 1989). Studies on the status of immunocompetent cells in the blood of patients exposed to HD showed that T cell

and monocyte counts dropped in 54% and 65% of the patients, respectively, from day 1 and up to the 7th week postexposure (Hassan and Ebtekar, 2002). Eosinophil counts dropped in 35% and neutrophil numbers in 60% of the patients. B lymphocyte counts were normal up to the 7th week (Manesh, 1986). The majority of the patients showed increased levels of IgG and IgM during the 1st week, but the percentage decreased over the next 6 months. The percentage of patients with increased levels of C3, C4, and CH50 was somewhat higher than that of healthy controls during the 1st week and up to the 6th month (Tabarestani et al., 1990), and it remained higher 3 years postexposure, especially in the severely affected group. And 8 years after exposure, there was a significant increase in the number of atypical leukocytes, such as myelocytes. The severely affected group presented with significantly lower CD56 NKs, as well as CD4 and CD8 counts compared with healthy controls (Yokogama, 1993). Hassan and Ebtekar (2002) reported that there was no major difference between the severely affected patients and healthy controls concerning CD19 B cells, CD14 monocytes, and CD15 granulocytes. The moderately and mildly affected patients did not significantly differ in their leukocyte subset counts from the control group 8 years after exposure (Mahmoudi et al., 2005). Follow-up studies on the clinical conditions of exposed Iranian victims still show that they suffer from three major problems: recurrent infection, septicemia and death, respiratory difficulties, and lung fibrosis, as well as a high incidence of malignancies, septicemia, and death.

Hassan and Ebtekar (2002) suggested that patients with moderate clinical manifestations may be experiencing a shift from Th1 to Th2 cytokine patterns since leukocyte cultures from this patient group showed a decrease in IFN-γ levels. When absorbed in large amounts, HD can damage rapidly proliferating cells of bone marrow and may cause severe suppression of the immune system (Sasser et al., 1996). Moreover, this alkylating agent has been reported to produce short- and long-term suppression of antibody production in both animals and humans. It also affects complemented system factors C3 and C4. Incidences of acute myelocytic and lymphocytic leukemia are reported to be 18 and 12 times higher in patients exposed to HD, in comparison with the normal group (Zakeripanah, 1991). Willems (1989) reported that exposure to HD could result in the impairment of human immune function, especially in the number of B and T lymphocytes. Hence, SM is still a potential threat to the world and effective therapeutic measures must be taken for the relief of the victims of this incapacitating agent. Ghotbi and Hassan (2002) showed that the percentage of NK cells, which play an important role in cellular immunity, was significantly lower in severely affected patients than in the control group.

Studies on animal models have shown that alkylating agents such as HD mainly affect B cells, which is why hypogammaglobulinemia is one of the main features in animal models, whereas studies of human cases, following a treatment with cytotoxic drugs, suggest that low-dose exposure to alkylating agents impairs cellular immunity, and high-dose exposure to such agents impairs both cellular and humoral responses (Marzban, 1989; Malaekeh et al., 1991). There are reports suggesting that HD can produce toxicity through the formation of reactive electrophobic intermediates, which in turn covalently modify nucleophilic groups in biomolecules such as DNA, ribonucleic acid (RNA), and proteins (Malaekeh et al., 1991), resulting in disruption of cell function, especially cell division (Crathorn and Robert, 1966). As a result, these agents are particularly toxic to rapidly proliferating cells, including neoplastic, lymphoid, and bone marrow cells. Mahmoudi et al. (2005) reported higher IgM levels after 16–20 years of exposure to HD compared to the control group. A significant decrease in the number of NK cells in severely affected patients is probably due to the destructive effect of this alkylating agent on NK cell precursors in bone marrow. However, the activity of NK cells was found to be noticeably above normal, which possibly compensates for the reduction in the number of these cells.

Korkmaz et al. (2006) explained the toxicodynamics of HD in three steps: (i) binding to cell surface receptors; (ii) activation of reactive oxygen species (ROS) and reactive nitrogen species (RNS), leading to peroxynitrite ($OONO^-$) production, and (iii) $OONO^-$-induced damage to lipids, proteins, and DNA, leading to poly ADP ribose polymerase (PARP) activation. This could provide a lead for devising strategies for protection against and treatment of mustard toxicity.

A study was conducted to evaluate the incidence of immunocompetence among survivors of the chemical bombardment of Halabja in the Kurdistan region of Iraq. In the research, 40 exposed and 40 unexposed controls were studied to determine their immune system status 12 years after bombardment. Skin reactivity to tuberculin, DPT (diphtheria, pertussis, tetanus) vaccine, TD (tetanus, diphtheria) toxoid and measles vaccine was negative in 62.5% of the exposed cases, compared to unexposed persons, none of whom showed any negative reactions. The total leukocyte count was normal among 70% of the exposed cases, whereas the total lymphocyte count was within subnormal ranges in 80% of the exposed cases. All the subjects displaying negative skin reactions had subnormal lymphocyte counts, which reflected impaired CMI. The immunoglobulin assay for exposed cases revealed subnormal values for IgG and IgA, while IgM levels were above the normal range in 22.5% of cases when compared to that of controls, which showed no abnormal values. This result revealed that

there was a deficiency in antibody-mediated immunity. There were significant differences between the exposed and the control samples with respect to total leukocytes, neutrophil count, lymphocyte count, IgG, and IgA. The immunological reactions were more closely related to the effects of mustard gas, which appeared to be long lasting. They concluded that long-term effects were produced by CWAs on victims who have survived in Halabja and, in particular, on their immune system at both antibody and cell-mediated levels. This study confirmed the immunosuppressive properties of mustard compounds and indicated increased vulnerability of the exposed individuals to secondary opportunistic or pyogenic bacterial infections due to injuries that occurred frequently among chemical survivors in Halabja (Hama et al., 2008).

In conclusion, the results suggest that exposure to HD causes a higher risk of opportunistic infections, septicemia, and death following severe suppression of the immune system, especially in the case of lesions and blisters produced by these agents. As alkylating agents, they form covalent linkages with biologically important molecules, resulting in disruption of cell function, especially cell division. As a result, these agents are particularly toxic to rapidly proliferating cells including neoplastic, lymphoid, and bone marrow cells. However, there is still a paucity of information regarding the long-term immunosuppressive properties of HD in the setting of battlefield exposure to this agent.

Choking Agents

Choking agents act on the pulmonary system causing severe irritation and swelling of the nose, throat, and lungs; e.g., phosgene (CG), diphosgene (DP), chlorine, and chloropicrin (PS). These inhalational agents damage the respiratory tract and cause severe pulmonary edema in about 4 h, leading to death. The effects are variable, rapid, or delayed, depending on the specific agent (Gift et al., 2008).

Phosgene was first used as a chemical weapon in World War I by Germany, and later by French, American, and British forces. In this conflict, phosgene was often combined with chlorine in liquid-filled shells, so it was difficult to state the number of casualties and deaths attributable solely to phosgene. In military publications, it has been referred to as a "choking agent," "pulmonary agent," or "irritant gas." Since World War I, phosgene has rarely been used by traditional militaries, but the extremist cult Aum Shinrikyo used this agent in an attack against the Japanese journalist Shouko Egawa in 1994. Nowadays, phosgene is primarily used in the polyurethane industry for the production of polymeric isocyanates (USEPA, 1986). Phosgene is also used in the polycarbonate industry and in the manufacture of carbamates and related pesticides, dyes, pharmaceuticals, and isocyanates.

As mentioned earlier, the primary exposure route for phosgene is by inhalation. Suspected sources of atmospheric phosgene are fugitive emissions, thermal decomposition of chlorinated hydrocarbons, and photooxidation of chloroethylenes. Individuals are most likely to be exposed to phosgene in the workplace during its manufacture, handling, and use (USEPA, 1986). Phosgene is extremely toxic by acute inhalation exposure. Severe respiratory effects, including pulmonary edema, pulmonary emphysema, and death have been reported in humans. Severe ocular irritation and dermal burns may result following eye or skin exposure. Chronic inhalation exposure to phosgene has been shown to result in some tolerance to the acute effects noted in humans, but it may also cause irreversible pulmonary changes of emphysema and fibrosis (U.S. Department of Health and Human Services, 1993).

Primarily because of phosgene's early use as a war weapon, many exposure studies have been performed over the past 100 years to examine the effects and mode of action of phosgene following a single, acute (less than 24 h) exposure. Many studies have examined the effects of acute phosgene exposure in animals, but the human data are limited to case studies following accidental exposures.

Most studies were performed in rodents and dogs, with exposure concentrations ranging between 0.5 and 40 ppm (2–160 mg/m^3) and duration intervals ranging from 5 min to 8 h. Acute exposure studies in animals suggest that rodent species may be more susceptible to the edematous effects of phosgene acute exposure than larger species with lower respiratory volumes per body weight such as dogs and humans (Pauluhn, 2006; Pauluhn et al., 2007).

Pauluhn et al. (2007) reported that acute phosgene exposure results in increased lung lavage protein, phospholipid content, enzyme levels, number of inflammatory cells, and lethality (LC_{50}). Rats seem to be able to survive approximately threefold higher levels of lung edema than humans (hundredfold versus thirtyfold), thus rat responses in short- and long-term assays may still be relevant to humans even if it is ultimately shown that rats produce higher levels of edema following acute phosgene exposure.

Immunotoxicity

Acute exposure to phosgene has been shown to result in immunosuppression in animals, as evidenced by an increased susceptibility to *in vivo* bacterial and tumor cell infections (Selgrade et al., 1989) and viral infection (Ehrlich and Burleson, 1991), as well as a decreased *in vitro* virus-killing and T-cell response (Burleson and Keyes, 1989). Selgrade et al. (1989) reported that a single 4-h exposure to phosgene concentrations as low as 0.025 ppm significantly enhanced mortality due to

streptococcal infection in mice. Furthermore, when the exposure time was increased from 4 to 8 h, a significant increase in susceptibility to *streptococcus* was seen at an exposure concentration of 0.01 ppm.

Selgrade et al. (1995) administered *Streptococcus zooepidemicus* bacteria via an aerosol spray to the lungs of male Fischer-344 rats immediately after phosgene exposure and measured the subsequent clearance of bacteria. They also evaluated the immune response, as measured by an increase in the percentage of polymorphonuclear (PMN) leukocytes in lung lavage fluid of uninfected rats similarly exposed to phosgene. This experiment showed that all phosgene concentrations from 0.1 to 0.5 ppm impaired resistance to bacterial infection and that the immune response is stimulated by phosgene exposure. After 4 weeks following exposure, bacterial resistance and immune response returned to normal.

Yang et al. (1995) also reported a decrease in bacterial clearance in the lungs at 24 h after infection following a single 6-h exposure to phosgene concentrations of 0.1 and 0.2 ppm. In comparison with single exposures, the multiple daily exposures extending to 4 and 12 weeks in the Selgrade et al. (1995) report showed a slight enhancement of effect in the 0.1 ppm group at 24 h postinfection, but no adaptation, or lessening of the effect. Yang et al. (1995) found that if the bacteria are administered 18 h after single phosgene exposures rather than immediately, the clearance is normal, which indicates that recovery from the toxic effect of phosgene is rapid.

When inhaled, phosgene is either rapidly hydrolyzed to hydrogen chloride (HCl) and carbon dioxide (CO_2) and exhaled (Diller, 1985; Schneider and Diller, 1989) or penetrates deep into the lungs and is eliminated by rapid reactions with nucleophilic constituents of the alveolar region (Pauluhn et al., 2007). As phosgene is electrophilic, it reacts with a wide variety of nucleophiles, including primary and secondary amines, hydroxy groups, and thiols. In addition, it also reacts with macromolecules, such as enzymes, proteins, or other polar phospholipids, resulting in a marked depletion of GSH (Sciuto et al., 1996) and forms covalent adducts that can interfere with molecular functions. Phosgene interacts with biological molecules through two primary reactions: hydrolysis to hydrochloric acid and acylation reactions. Although the hydrolysis reaction does not contribute much to its clinical effects, the acylation reaction is mainly responsible for the irritant effects on mucous membranes. The acylation reactions occur between highly electrophilic carbon molecules in phosgene and amino, hydroxyl, and sulfhydryl groups on biological molecules. These reactions can result in membrane structural changes, protein denaturation, and depletion of lung GSH. Acylation reactions with phosphatidylcholine are particularly important, as it is a major constituent of pulmonary surfactant and lung tissue membranes. Exposure to phosgene has been shown to increases the alveolar leukotrienes, which are thought to be important mediators of phosgene toxicity to the alveolar–capillary interface. Phosgene exposure also increases lipid peroxidation and free radical formation. These processes may lead to increased arachidonic acid release and leukotriene production. Proinflammatory cytokines, such as interleukin-6, are also found to be substantially higher 4–8 h after phosgene exposure. In addition, studies have shown that postexposure phosphodiesterase activity increases, leading to decreased levels of cAMP. Normal cAMP levels are believed to be important for maintenance of tight junctions between pulmonary endothelial cells, and thus for prevention of vascular leakage into the interstitium. Oxygenation and ventilation both suffer, and breathing is dramatically increased.

Diller (1985) and Schneider and Diller (1989) reported that inhalation of phosgene at high concentrations results in a sequence of events, including an initial bioprotective phase, a symptom-free latent period, and a terminal phase characterized by pulmonary edema. The first is an immediate irritant reaction likely caused by the hydrolysis of phosgene to hydrochloric acid on mucous membranes, which results in conjunctivitis, lacrimation, and oropharyngeal burning sensations. This symptom complex occurs only in the presence of high-concentration (>3–4 ppm) exposures but does not have any prognostic value for the timing and severity of later respiratory symptoms. The most important finding to identify during this stage is a laryngeal irritant reaction causing laryngospasm, which may lead to sudden death. The irritant symptoms last only a few minutes and then resolve so long as further exposure to phosgene ceases.

The second phase, when clinical signs and symptoms are generally lacking, may last for several hours after phosgene exposure. The duration of the latent phase is an extremely important prognostic factor for the severity of the ensuing pulmonary edema. Patients with a latent phase of less than 4 h have a poor prognosis. Increased physical activity may shorten the duration of the latent phase and worsen the overall clinical course. Unfortunately, there are no reliable physical examination findings during the latent phase to predict its duration. However, histologic examination reveals the beginnings of an edematous swelling, with exudation of blood plasma into the pulmonary interstitium and alveoli. This may result in damage to the alveolar type I cells and a rise in hematocrit. The length of this phase varies inversely with the inhaled dose. The third clinical phase peaks approximately 24 h after an acute exposure and, if lethality does not occur, recedes over the next 3–5 days. In the third clinical phase of phosgene toxicity, the accumulating fluid in the lungs results in edema. Oxygenation and ventilation both suffer, and breathing is dramatically increased. Often, positive end expiratory

pressure (PEEP) is required to stent open alveoli that would otherwise collapse and result in significant ventilation/perfusion mismatch. This hyperventilation causes the protein-rich fluid to take on a frothy consistency. A severe edema may result in an increased concentration of hemoglobin in the blood and congestion of the alveolar capillaries.

Increased levels of protein in bronchoalveolar lavage have been shown to be among the most sensitive endpoints characterizing the early, acute effects of phosgene exposure, and they are rapidly reduced after the cessation of exposure (Sciuto, 1998; Sciuto et al., 2003). With continuous, chronic, low-level phosgene exposure, there may be transition of edema to persistent cellular inflammation, leading to the synthesis of abnormal Type I collagen and pulmonary fibrosis. An increased synthesis of Type I relative to Type III collagen can lead to chronic fibrosis (Pauluhn et al., 2007). Surfactant lipids are important for maintaining alveolar stability and for preventing pulmonary edema. Pauluhn et al. (2007) reported that the induction of surfactant abnormalities following phosgene exposures is a key pathophysiological event leading to pulmonary edema and chronic cellular inflammation, which caused the stimulation of fibroblasts and the synthesis of abnormal collagen in pulmonary fibrosis. As discussed earlier, a breach in the chemical layer of defense followed by pulmonary edema may lead to a cascade of other immunological responses and reactions. There are limited studies, in both humans and experimental animals, to evaluate the immunotoxicity of chronic low-level environmental exposures to phosgene. The lack of studies examining the effects in humans or laboratory animals from chronic exposure to phosgene is a concern and the sequelae of effects leading to phosgene-induced pulmonary fibrosis is not well understood.

Animal infectivity models have been important in the demonstration of enhanced susceptibility to viral and bacterial infection as a result of low-level toxicant exposure. Ehrlich and Burleson (1991) demonstrated an enhanced and prolonged viral infection using an influenza virus infectivity model in the rat following inhalation of the toxicant gas phosgene. Fischer-344 rats were exposed to either air or a sublethal concentration of phosgene, and they demonstrated peak pulmonary influenza virus titers 1 day after infection. Virus titers in rats exposed to air declined rapidly, falling below detectable levels by the 4th day of infection. However, a significantly enhanced and prolonged pulmonary influenza virus infection was observed on days 3 and 4 after infection in the rats exposed to phosgene. Virus was cleared below detectable limits on day 5 after infection in the animals exposed to phosgene. Thus, inhalation of sublethal concentrations of phosgene resulted in an increased severity of pulmonary influenza virus infection. This study provides a demonstration of the prolongation of rat viral infectivity by exposure to phosgene.

Phosgene, also known as carbonyl chloride, carbon oxychloride, and chloroformyl chloride, is a toxic air pollutant and a potential occupational health hazard. Studies were initiated to evaluate the measurement of pulmonary NK activity as a method to assess pulmonary immunocompetence, and to determine whether exposure to phosgene resulted in local pulmonary or systemic immune dysfunction. Fischer-344 male rats were exposed either to filtered air or to 1.0 ppm of phosgene gas for 4 h. The effect of phosgene on lung NK activity was quantified at different times after acute phosgene exposure. Pulmonary NK activity was measured by mincing lung tissue into small pieces prior to incubation with collagenase. Whole-lung homogenate was assayed for NK activity. Acute phosgene exposure resulted in suppressed pulmonary NK activity on days 1, 2, and 4 after exposure; however, normal levels of biological activity were observed 7 days after exposure. The suppressed NK activity was not restored after adherent cells were removed from the lung homogenate, thus indicating that the effect of phosgene on NK activity was not due to immunosuppression via mobilization of suppressor alveolar macrophages. Pulmonary immunotoxicity was also observed after exposure at 0.5 ppm, while no adverse effects were observed at 0.1 ppm of phosgene. Systemic immunotoxic effects were observed for NK activity in the spleen, but not in the peripheral blood, making it important to evaluate systemic immune functions since secondary effects—distant to the original interaction—may occur, with potentially serious consequences (Burleson and Keyes, 1989).

Blood Agents

Agents like SA (arsine), cyanide, and carbon monoxide are absorbed into the blood and affect its oxygen-carrying capacity and are thus termed *blood agents.* They are highly volatile and rapid-acting, and they produce seizures, respiratory failure, and cardiac arrest. Hydrogen cyanide has been known as a potent toxicant for over 200 years. It was used as a CWA during World War I by France. Although it is highly volatile (and was later considered militarily useless because of its volatility), no deaths from its military use during World War I were ever reported. After World War II, the importance of hydrogen cyanide as a CWA diminished rapidly, primarily as a result of the rise of nerve agents. Although reduced in importance, there are some reports of hydrogen cyanide being used as a war gas by Vietnamese forces in Thailand territories and during the Iran–Iraq war in the 1980s (Sidell, 1992).

Hydrogen cyanide can be detoxified rapidly by humans. It is very volatile, and massive amounts of the gas are needed for it to be effective as a CWA. Cyanide is primarily an environmental contaminant of industrial processes. It is used in the metal-processing industry for electroplating, heat treating, and metal polishing, and it can be found in wastewater from many mining operations that use cyanide compounds in the extraction of metal, such as gold and silver, from ore.

The acute toxicity of cyanide has been well documented in humans and experimental animals. Symptoms of toxicity in humans include headache, breathlessness, weakness, palpitations, nausea, giddiness, and tremors (Gupta et al., 1979). Depending on the degree of intoxication, symptoms may include metallic taste, anxiety, confusion, headache, vertigo, and hyperpnea, followed by dyspnea, convulsions, cyanosis, respiratory arrest, bradycardia, and cardiac arrest. Death results from respiratory arrest (Berlin, 1977), and onset is usually rapid. Effects on inhalation of lethal amounts may be observed within 15 s, with death occurring in less than 10 min. Hydrogen cyanide should be suspected in terrorist incidents involving prompt fatalities, especially when the characteristic symptoms of nerve agent intoxication are absent. Chronic exposure to low-level cyanide can result in neuropathies, goiter, and diabetes. Cyanide and derivatives prevent the cells of the body from using oxygen. Cyanide acts by binding to mitochondrial cytochrome oxidase, blocking electron transport and thus inhibiting enzymes in the cytochrome oxidase chain, and in turn blocking oxygen use in metabolizing cells and preventing the use of oxygen in cellular metabolism. These chemicals are highly toxic to cells and, in high doses, may result in death. Cyanide is more harmful to the heart and brain, as these organs require a large amount of oxygen.

Immunotoxicity

There are very few reports about the immunotoxicity of the hydrogen cyanide; however, acrylonitrile [also known as vinyl cyanide (VCN)], an environmental pollutant that is metabolized to cyanide, has been shown to be an animal and human carcinogen, particularly in the gastrointestinal tract (Mostafa et al., 1999; National Toxicology Program Technical Report Series, 2001). Hamada et al. (1998) evaluated the systemic and local immunotoxic potential of VCN and demonstrated that VCN induces immunosuppression, as evident by a decrease in the PFC response to SRBCs, a marked depletion of spleen lymphocyte subsets, and bacterial translocation of the normal flora, leading to brachial lymph node abscess. These results suggested that VCN has a profound immunosuppressive effect, which could be a contributing factor in its gastrointestinal tract carcinogenicity.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The immune system of humans and animals is extremely vulnerable to the action of xenobiotics for several reasons. The immune response is associated with rapidly multiplying cells and synthesis of regulatory/effector molecules, and the immune system works as an amplifier for this integrated information network. Immunologic tissue damage can result from the activation of the cellular and biochemical systems of the host. The interactions of an antigen with a specific antibody or with effector lymphocytes trigger a sequence of humoral and cellular events that produce the pathophysiologic effects that lead to tissue injury or disease. Stem cells often appear to be sensitive targets for therapeutic and environmental toxicants, most likely because of their rapid proliferation. Xenobiotics or various drugs that are toxic to the myelocytes of the bone marrow can cause profound immunosuppression due to loss of stem cells.

Humans are now under a sustained and increasing pressure of xenobiotic exposure. Xenobiotics can stimulate the immune system as antigens by provoking a substantial immune response. Even mild disturbances of this network could result in detrimental health effects. The influence of the xenobiotics on the immune system is either suppressive or enhancing. The former leads into immunosuppression, with consequent increased susceptibility to infection and cancer. The latter is associated with the development of autoimmune reactivity, such as delayed hypersensitivity, atopy, systemic or organ-specific immunopathology, and granuloma formation. It is likely that overall immunosuppressive effects of xenobiotics are caused by interference with cellular proliferation and differentiation, down-regulation of cytokine signaling, and enhanced apoptosis of immune cells. In contrast, autoimmune reactions are induced by abnormal activation of immune cells followed by dysregulated production of cytokines, resulting in harmful inflammatory response.

The field of immunotoxicology is developing rapidly. Attempts must be made to conduct basic research into the cellular and molecular mechanisms of the immunomodulatory actions of various xenobiotics. Newly emerging technologies, such as genomics, proteomics, and bioinformatics, certainly will be helpful to investigate the interactions between the immune system and xenobiotics in their full complexities. Toxic compounds may be antigenic or act as haptens and can evoke an antibody response. If these antibodies bind to the determinant on the parent molecule, which is responsible for causing toxicity, that development can lead to the biological inactivation of the parent molecule, thereby preventing toxicity. This may constitute an immunological antidote

that could neutralize the toxicity of certain compounds. Thus, passive administration of these antibodies may be used to prevent the toxic effects of the specific compound, and this approach may be useful in biological or chemical warfare to protect against the toxicity of known chemicals or toxins. The antibodies can also be used to protect industrial workers against the toxic effects of known chemicals or gases during accidental exposure. Although this assumption seems logical, it will involve elaborate and time-consuming research to identify the site of the parent molecule responsible for causing toxicity, to chemically link the molecule with a large protein molecule that should be immunogenic but not toxic, and to screen various antibodies raised for their capacity to prevent the toxicity of the compound.

CWAs have been widely condemned since their first use on a massive scale during World War I. In 1993, the United States signed the Chemical Weapons Treaty, which required the destruction of all chemical weapon agents, dispersal systems, and production facilities by April 2012. The United States destroyed 45% of its stockpile of chemical weapons by 2007. As of 2012, stockpiles have been eliminated at 7 of the 9 chemical weapons depots, and 89.75% of the 1997 stockpile has been destroyed by the treaty deadline of April 2012. The rest are scheduled to be destroyed by 2017. The most recent arms control agreement in international law, the Convention of the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and Their Destruction, known for short as the CWC, outlaws the production, collection, and use of chemical weapons. It is administered by the Organization for the Prohibition of Chemical Weapons (OPCW), an intergovernmental organization based in The Hague. However, in early 2007, multiple terrorist bombings had been reported in Iraq using chlorine gas. These attacks wounded or sickened more than 350 people. Thus, in view of the current global scenario, it appears that the use of CWAs may continue in different types of warfare, as these agents are not only inexpensive, but easy to disseminate with the help of unsophisticated devices. Hence, the medical profession should assemble on a common platform through globally recognized organizations like the World Health Organization (WHO) and make efforts to monitor, research, and study the scientific and medical aspects of CWAs in the interest of humanity. The guidelines on the prevention and management of CWA-induced insults should be updated to reduce morbidity and mortality. Nations worldwide should ensure that adequate supplies of antidotes, protective equipment, and decontamination devices are available in adequate quantities and at all times.

The impact of the immune system is enormous in the health of human beings. CWA-exposed individuals are prone to immune system-mediated diseases. Immunological diseases are growing at epidemic proportions that require aggressive and innovative approaches to develop new treatments. Developing vaccines by recognizing the molecular patterns of some of the xenobiotics can be another approach to tackle the issue and is the most critical challenge for the research community. Furthermore, one of the great therapeutic opportunities for the survivors of war is organ transplantation. However, immune system-mediated graft rejection remains the single greatest barrier to widespread use of this technology. Thus, the most pressing requirement is a multisectorial approach involving health, defense, agriculture, and environmental specialists, with clearly defined roles for each, to establish and maintain effective, robust, and sustainable strategies to countermeasure this threatening situation.

CHAPTER

45

Alternative Animal Toxicity Testing of Chemical Warfare Agents

Gopala Krishna and Saryu Goel

INTRODUCTION

Chemical warfare agents have been in existence for centuries. They are substances with toxic properties that are used to kill, injure, or incapacitate humans. Broadly, these are categorized into two groups: chemical or biological.

1. Chemical warfare agents use poisons that kill, injure, or incapacitate. These can be gases or liquids and are more commonly dispersed as aerosols.
2. Biological warfare agents use living organisms such as bacteria (e.g., *Bacillus anthracis*, the causative agent of anthrax) or viruses (e.g., Variolae, the virus that causes smallpox).

Further, these warfare agents have been subdivided into multiple classes in the public domain. These include choking gases and lung irritants, blister agents (vesicants), blood agents, nerve agents, incapacitants and psychoactive chemicals, harassing or riot-control agents, vomiting agents, herbicides, Napalm, and obscurant smoke and masking agents. The main routes of entry of these include inhalation, ingestion, injection, and absorption.

The US Food and Drug Administration (FDA), in collaboration with the US Department of Defense (DOD), continues to support the US military and the nation's counterterrorism efforts. The FDA has helped make critical medical products available for combat readiness so that armed forces are better-equipped for combat. It has helped US Special Forces obtain medical products for airborne hospitals used in evacuating battlefield casualties. The FDA has provided consultation and review to help make investigational and licensed medical products such as vaccines and drugs available to combat forces. In developing such warfare agents for counterterrorism, extensive testing of their efficacy and safety is required, especially in animals and humans. A schematic diagram showing the effects of warfare agents and use of 3Rs concept is shown in Figure 45.1. The agreement on Mutual Acceptance of Data (MAD; www.oecd.org/chemicalsafety/testing/mutualacceptanceofdatamad.htm) eliminated the need for duplication of tests in each country before approval of or ban on a substance within Organization for Economic Cooperation and Development (OECD) countries, thus reducing animal use.

It is noted that animal testing is highly controversial and has become an emotional issue in recent years (Krishna, 2010; SOT, 2013a,b). Keeping the focus of this chapter in mind, testing of chemical warfare agents in humans is not practical, especially at toxic doses, and is considered unethical. To address this issue, it is important to understand and recognize the growing impact of alternatives to animal and/or human testing. These methods include *in vitro* toxicity, metabolism, and efficacy/potency testing in a variety of scenarios.

Anadon et al. (2013) highlighted the value of *in vitro* testing in science. They stated that there is a correlation of toxicological data from *in vivo* animal studies to *in vitro* assays. They propose an integrated *in vitro* testing strategy by taking into consideration the following: exposure modeling of chemical agents for *in vitro* testing; data gathering, sharing, and read-across for testing a class of chemical; a battery of tests to assemble a broad spectrum of data on different mechanisms of action to predict toxic effects; applicability of the test and the integrated *in vitro* testing strategies; and flexibility to adjust the integrated *in vitro* testing strategies to test substances (Goldberg and Frazier, 1989; Hartung,

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00045-2

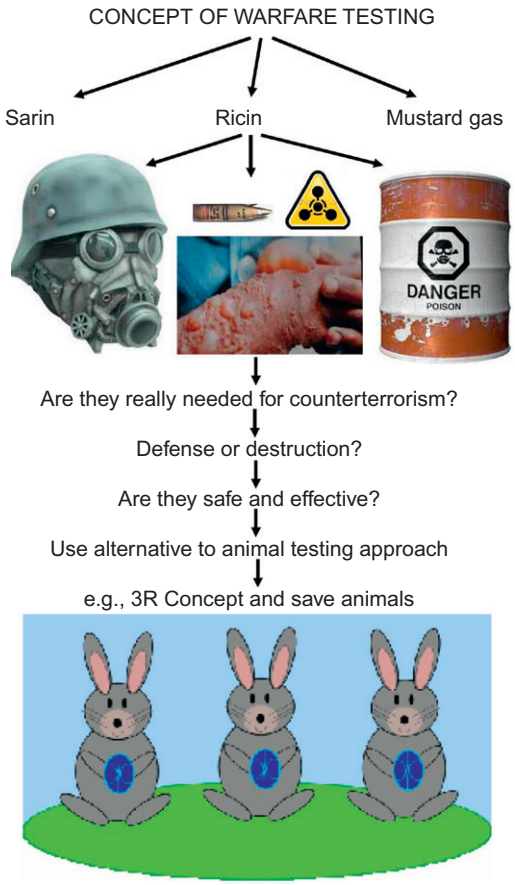

FIGURE 45.1 Alternative concept of warfare testing.

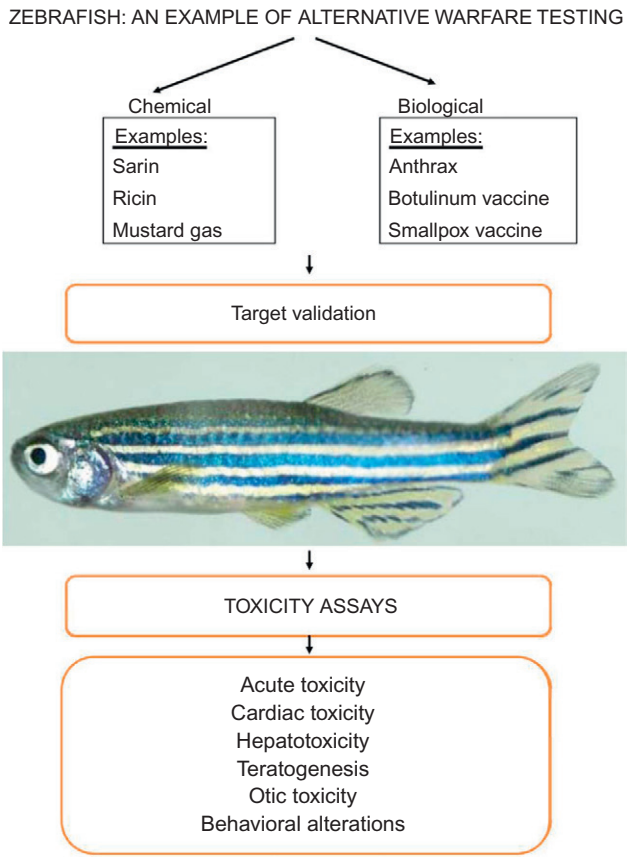

FIGURE 45.2 Zebrafish as an alternative animal model in warfare testing.

2011; Hartung et al., 2013). However, they emphasize validating *in vitro* systems to ensure reliability and suitability for humans; thus, the data can be invaluable and effective. Schechtman (2002) reviewed the implementation of the 3Rs (refinement, reduction, and replacement) validation and regulatory acceptance considerations for alternative toxicological test methods and suggested pros and cons of *in vitro* testing.

Animal testing is an essential part of basic research, especially in inventing and developing effective chemical warfare. Animal testing is defined as the use of nonhumans, such as vertebrate and nonvertebrate animals or organisms, in scientific experimentation in search of answers for the good of humankind and the pursuit of basic knowledge (Krishna et al., 2014). Vertebrate animals ranging from zebrafish to nonhuman primates are commonly used worldwide. However, their use is heavily regulated. An example of zebrafish testing strategy is shown in Figure 45.2. More recently, the zebrafish has been identified as an important vertebrate model for studying the development of embryos and pathogenesis of human diseases (Lieschke and Currie, 2007). When compared with mammalian models, experimental results show that zebrafish embryos exhibit similar responses to test agents (Hill et al., 2005). This suggests that the zebrafish model can be used as a bridge between the *in vitro* and the *in vivo* model in the toxicity screening process.

Similarly, invertebrates such as fruit flies (*Drosophila*) and earthworms are also commonly used in research, when applicable, but their use is excluded from regulations. Around the globe, animal testing is conducted under the strict regulatory guidelines that set fundamental standards for the humane use of animals for training, experimentation, biological testing, or for other related purposes. These regulations and guidelines require minimizing harm to animals through 3Rs, reduction, refinement, and replacement, as initially described by Russell and Burch (1959) searching for alternatives including consideration for hierarchical use of species and *in vitro* methods.

In this chapter, a brief history of chemical warfare use in humans, their classification, use of alternative methods of animal testing, particularly *in vitro* toxicology tests, structure activity relationships, and the use of the 3Rs including "Animal Rule" (FDA, 2009, 2010) and "human-on-a-chip" to possibly test warfare agents are described.

BRIEF HISTORY OF CHEMICAL WARFARE USE

- Poisonous agents have been used as tools of war for thousands of years, even as early as 600 BC; some examples include poisoned arrows, boiling tar, arsenic smoke, and noxious fumes (www.opcw.org/about-chemical-weapons/history-of-cw-use/).
- In the 1900s, modern chemical warfare began on the battlefields of World War I. Chlorine and phosgene gases were released from canisters on the battlefield and dispersed by the wind. The first large-scale attack with chlorine gas occurred on April 22, 1915, at Ieper in Belgium.
- The use of several different types of chemical weapons, including mustard gas (yperite), resulted in 90,000 deaths and more than one million casualties during the war. Those injured in chemical warfare suffered from the effects for the rest of their lives; thus, the events at Ieper during World War I scarred a generation. By the end of World War I, 124,000 metric tons of chemical agents had been expended. The means of delivery for chemical agents evolved over the first half of the twentieth century, increasing these weapons' already frightening capacity to kill and maim through the development of chemical munitions in the form of artillery shells, mortar projectiles, aerial bombs, spray tanks, and landmines.
- After witnessing the effects of such weapons in World War I, it appeared that few countries wanted to be the first to introduce even deadlier chemical weapons on the World War II battlefields. However, preparations were made by many countries to retaliate in kind should chemical weapons be used in warfare. Chemical weapons were deployed on a large scale in almost all stages during World War I and World War II, leaving behind a legacy of old and abandoned chemical weapons that still presents a problem for many countries.
- During the Cold War, the United States and the Soviet Union both maintained enormous stockpiles of chemical weapons, amounting to tens of thousands of metric tons. The amount of chemical weapons held by these two countries was enough to destroy much of the human and animal life on Earth.
- Iraq used chemical weapons in Iran during the war in the 1980s, and Iraq also used mustard gas and nerve agents against Kurdish residents of Halabja, in Northern Iraq, in 1988.
- The two most recent examples of the use of chemical weapons are the sarin poisoning incident in Matsumoto, a Japanese residential community, in 1994, and the sarin attack on the Tokyo subway in 1995, both perpetrated by the Aum Shinrikyo doomsday cult. These two attacks re-focused international attention on the potential use of chemical weapons by terrorists and on the dangers posed by these chemical weapons.
- The devastating impact chemical weapons have had in the past and the potential for the use of modern—even more deadly—chemical agents not only by States at war, but also by non-State actors in other violent conflicts, provide the imperative for an international effort to uphold the ban on such weapons and to work toward the complete global elimination of chemical weapons.

TOP FIVE CHEMICAL WARFARE AGENTS

It has been reported that sarin, ricin, mustard gas, agent 15, and chlorine gas are the top chemical warfare agents (www.livescience.com/39332-5-chemical-warfare-agents.html).

1. *Sarin* is a deadly toxic organophosphate compound with no color, taste, or odor. Although it is produced as a liquid, its low evaporation point allows it to turn into a gas quickly when exposed to the environment. Sarin, also known as GB by military personnel, was originally developed as a pesticide in Germany in 1938; since then, it has been classified by many national governments as a chemical nerve agent. Nerve agents are the most toxic and fast-acting chemical warfare agents in the world. People exposed to large amounts of sarin quickly lose control over their bodily functions and, if not treated immediately, can fall into a coma or succumb to respiratory failure.
2. *Ricin* is derived from a common plant, the castor bean (*Ricinus communis*), and is native to the Mediterranean and Middle East and cultivated elsewhere as an ornamental plant. It is also the source of castor oil, which has many uses in medicine, food, and industry. Ricin is also a highly potent toxin that can kill a person in amounts as small as a few grains of sand.
3. *Mustard gas*, or sulfur mustard $(Cl\text{-}CH_2CH_2)2S$, is a chemical agent that causes severe burning of the skin, eyes, and respiratory tract. It can be absorbed into the body through inhalation, ingestion, or by contact with the skin or eyes. First used during World War I, the gas is effective at incapacitating its victims en masse. Sulfur mustard is generally colorless in its gaseous state, although it may have a faint yellow or green tint. It is easily recognized by its trademark "mustardy" odor, although some compare its smell with that of garlic, horseradish, or sulfur.

4. *Agent 15* is also called compound 3-quinuclidinyl benzilate, BZ, or "Buzz." It is a powerful chemical warfare agent. As one of the most potent psychoactive chemical agents, only a small amount of BZ is needed to produce complete incapacitation. When used as an aerosol, BZ is absorbed through the respiratory system (it has no odor). It can also be absorbed through the skin or the digestive system. It takes approximately 1 h for BZ to take effect, and the symptoms of exposure include confusion, tremors, stupor, hallucinations, and coma that can last for more than 2 days. Use of BZ was suspected in the Bosnian conflict in 1995. Similarly, in January 2013, Syrian government troops may have used Agent 15 on rebels.
5. *Chlorine gas* is another chemical agent with a history of use going back almost 100 years. During World War I, chlorine gas, sometimes known as bertholite, was used by the German army during the Second Battle of Ypres in Belgium. Because chlorine can be pressurized and cooled into a liquid, it can be easily shipped and stored in tanks. When released as a gas, chlorine stays close to the ground and spreads quickly, making it an ideal agent for warfare or terrorism. Although it is used less often today (because more lethal agents exist), chlorine is easy to manufacture and disguise because it has many other civilian uses such as water sanitation. In 2007, chlorine gas bombs were used to kill dozens of people during the fighting in Iraq.

Toxicology of these warfare agents and many more have been elegantly described elsewhere in this book. Table 45.1 lists a variety of warfare agents. The focus of this chapter is alternatives of animal testing of such warfare agents. The tests mentioned and the strategies described might have to be optimized to suit such test-setting, depending on the type of warfare agent whether it is liquid, solid, aerosol, or even a biological agent.

TABLE 45.1 Listing of Multiple Categories of Chemical Warfare Agents

Name	CAS Number	Chemical Name
BLOOD AGENTS		
Arsine	7784-42-1	
Cyanogen chloride	506-77-4	
Hydrogen cyanide	74-90-8	
VOMITING AGENTS		
Adamsite	578-94-9	(10-Chloro-5,10-dihydrophenarsazine)
Diphenylchloroarsine	712-48-1	
Diphenylcyanoarsine	23525-22-6	
NERVE AGENTS		
Cyclohexyl sarin	329-99-7	Cyclohexylmethylphosphonofluoridate
GE	1189-87-3	Phosphonofluoridic acid, ethyl-, 1-methylethyl ester
Sarin	107-44-8	Phosphonofluoridic acid, methyl-, 1-methylethyl ester
Soman	96-64-0	Phosphonofluoridic acid, methyl-, 1,2,2-trimethylpropyl ester
Tabun	77-81-6	Phosphoramidocyanidic acid, dimethyl-, ethyl ester
VE	1189-87-3	Phosphonofluoridic acid, ethyl-, 1-methylethyl ester
Amiton	78-53-5	Phosphorothioic acid, *S*-[2-(diethylamino)ethyl] *O*,*O*-diethyl ester
GV (also GP)	141102-74-1	Phosphoramidofluoridic acid, dimethyl-, 2-(dimethylamino)ethyl ester
VM	21770-86-5	Phosphonothioic acid, methyl-, *S*-[2-(diethylamino)ethyl] *O*-ethyl ester
VX	50782-69-9	Phosphonothioic acid, methyl-, *S*-[2-[bis(1-methylethyl)amino]ethyl] *O*-ethyl ester

(*Continued*)

Name	CAS Number	Chemical Name
BLISTER AGENTS		
Mustard gas	505-60-2	Bis(2-chloroethyl) sulfide
Nitrogen mustard	0538-07-08	Bis(2-chloroethyl)ethylamine
Nitrogen mustard	51-75-2	Bis(2-chloroethyl)methylamine
Nitrogen mustard	555-77-1	Tris(2-chloroethyl)amine
Phosgene oxime	1794-86-1	
2-Chloroethyl ethyl sulfide	0693-07-02	
Sesqui mustard	3563-36-8	1,2-Bis(2-chloroethylthio)ethane
Ethyldichloroarsine	598-14-1	
Lewisite	541-25-3	2-Chlorovinyldichloroarsine
Lewisite-2	40334-69-8	Bis(2-chlorovinyl)chloroarsine
Lewisite-3	40334-70-1	Arsine, tris(2-chloroethenyl)-
Methyldichloroarsine	593-89-5	Arsonous dichloride, methyl-
Mustard/Lewisite		
Phenyldichloroarsine	696-28-6	Arsonous dichloride, phenyl-
RIOT CONTROL/TEAR AGENTS		
Bromobenzylcyanide	16532-79-9	4-Bromophenylacetonitrile
Chloroacetophenone	532-27-4	
Chloropicrin	1976-06-02	
CNB		10% CN, 45% benzene, 45% carbon tetrachloride
Fentanyl	437-38-7	Propanamide, *N*-phenyl-*N*-[1-(2-phenylethyl)-4-piperidinyl]-
CNC		30% CN in chloroform
CNS		23% CN, 38% chloropicrin, 38.4% chloroform
Dibenz-(*b,f*)-1,4-oxazepine	0257-07-08	
O-chlorobenzylidenemalononitrile	2698-41-1	CS1, CS2, CSX all have CS as agent
PULMONARY (CHOKING) AGENTS		
Ammonia	7664-41-7	
Chlorine	7782-50-5	
Hydrogen chloride	7647-01-0	
Phosgene	75-44-5	
Diphosgene	503-38-8	Trichloroacetyl chloride
Titanium tetrachloride	7550-45-0	
Nitric oxide	10102-43-9	
Perflurorisobutylene	382-21-8	1,1,3,3,3-Pentafluoro-2-(trifluoromethyl)-1-propene
Red phosphorous	7723-14-0	
Sulfur trioxide-chlorosulfonic acid		(Smoke mixture)
Sulfur trioxide	7446-11-9	
Chlorosulfonic acid	7790-94-5	
Zinc oxide	1314-13-2	
Agent 15 (similar to BZ)		
3-Quinuclidinyl benzilate	6581-06-2	3-Quinuclidinyl benzilate
Delta-9-THC	33086-25-8	Delta-9-Tetrahydrocannabinol
China White	79704-88-4	Alpha-methylfentanyl
Fentanyl	437-38-7	Propanamide, *N*-phenyl-*N*-[1-(2-phenylethyl)-4-piperidinyl]-
LSD	50-37-3	D-Lysergic acid *N,N*-diethylamide
Phenothiazine	92-84-2	Phenothiazine
Thorazine	50-53-3	Chlorpromazine

THE CONCEPT OF 3RS

The concept of 3Rs is further explained by the National Center for the Replacement, Reduction, and Refinement of animals in research (NC3Rs; http://eslav-eclam.org/other-associations/nc3rs). This is a widely accepted ethical framework for conducting scientific experiments using animals humanely. This includes:

- *Replacement*: Use methods that avoid or replace the use of animals defined as "protected" under the Animals (Scientific Procedures) Act 1986, amended 2012 (ASPA), in an area where they would otherwise have been used. "Protected" animals are all living vertebrates (other than humans), including some immature forms, and cephalopods (e.g., octopus, squid, cuttlefish). These can be:
  - Absolute replacements—those that do not involve animals at any point.
  - Relative replacements—those that avoid or replace the use of "protected" animals.
  - Examples include:
    - Computer modeling (such as Lhasa, 2014) (Figure 45.3).
    - Human volunteers (e.g., for noninvasive imaging studies).
    - Invertebrates, such as *Drosophila* (fruit fly) and nematode worms.
    - Immature forms of vertebrates—mammal, bird, and reptile embryos up to the last third of their gestation or incubation period, larval forms of amphibians and fish until the stage where they become capable of independent feeding, and cephalopods until the point at which they hatch.
    - *In vitro* methodologies, utilizing established human or animal cell lines, animal cells, tissues, and organs from animals killed by a humane method, and abattoir material from the meat industry (Figures 45.4 and 45.5).
- *Reduction*: Use methods that minimize animal use and enable researchers to obtain comparable levels of information from fewer animals or to obtain more information from the same number of animals, thereby further reducing future use of animals.
  - Examples include:
    - Sharing data and resources, such as MAD agreement.
    - Improved experimental design and statistical analysis.
    - Integrated genotoxicity testing using fewer animals and collecting maximum information. The concept of integrating toxicity assessment, which uses fewer animals but a variety of relevant toxicity data can be collected and

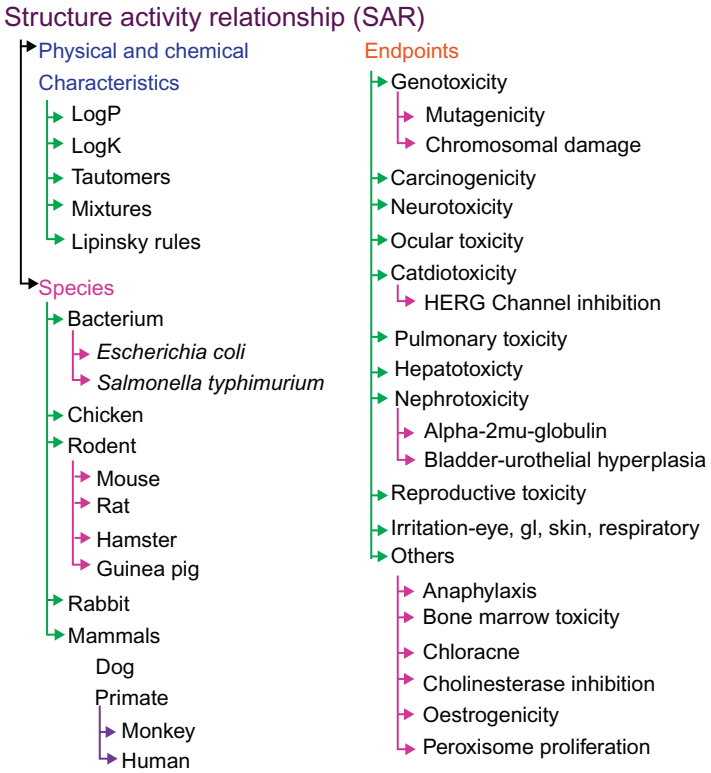

FIGURE 45.3 *In silico* endpoints commonly used to achieve 3Rs.

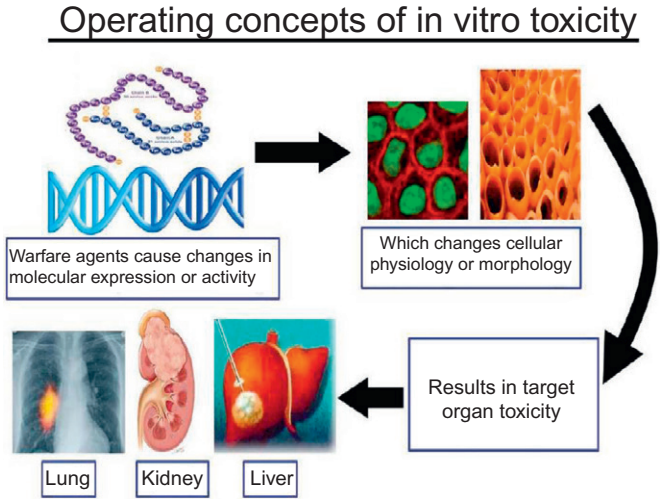

FIGURE 45.4 Warfare agents cause changes at the molecular level (DNA or protein) that are expressed at the cellular level, which in turn result in target organ toxicity (e.g., liver, kidney) and can be studied and extrapolated to whole animal or humans based on *in vitro* studies.

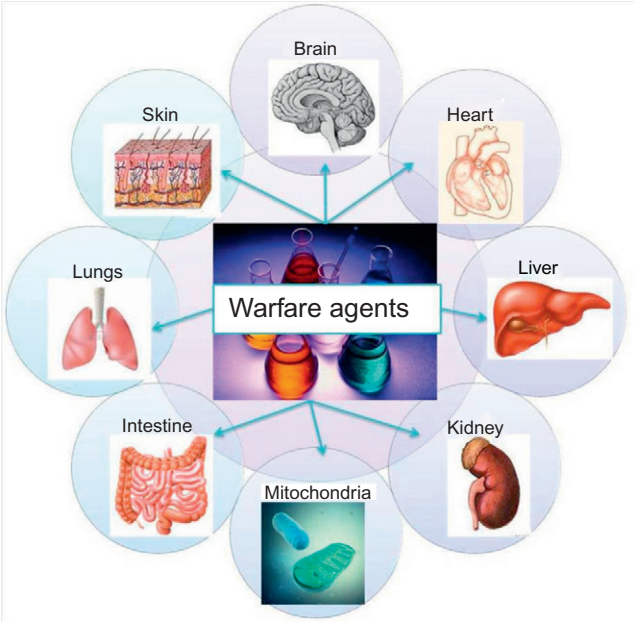

FIGURE 45.5 Warfare agents interact with various cells, organelles, and organ systems to produce their toxicological effects. These effects can now be studied using various *in silico* or *in vitro* tools minimizing the use of animal testing.

evaluated (Krishna et al., 1994, 1995a,b, 1998, 2000; Figure 45.6). As an example, an integrated *in vivo* genotoxicity testing philosophy and a practical approach, as applied to pharmaceuticals, is currently practiced and is recommended by the International Conference on Harmonization (ICH) guidance (ICH, 2006). In this case, a rodent (primarily rat) micronucleus assay is integrated with routine 2-week to 4-week repeat dose toxicity and toxicokinetic studies. This approach has several advantages. First, it utilizes the general principles of toxicology that govern the overall toxicity profile of a test substance. Second, factors such as the dose and/or route of test agent administration, metabolism, principles of toxicokinetics, and saturation of defense mechanisms are considered in evaluating genotoxicity. Third, it uses the concept of administering multiple tolerable doses aiding in achieving steady-state plasma test agent levels, which is more relevant for risk assessment compared with high acute doses. Fourth, it helps minimize the amount of test agent, number of animals used, and other resources. This integration approach can be extended to other toxicology studies and other relevant genotoxicity endpoints may be assessed. Based on experience reported in the literature, integrating micronucleus assessment in routine toxicology testing is promising and should be utilized when practical. A number of genotoxicity endpoints can be easily evaluated in peripheral blood lymphocytes of exposed subjects by genetic monitoring.

- Modern imaging techniques
  - Noninvasive, whole-body imaging of small animals using techniques such as X-ray, CT, SPECT, PET, and MRI is helping to reduce the number of animals used in basic research and testing of chemical warfare agents. Figure 45.7 illustrates such an example. The same animal can be imaged multiple times to monitor visually, often in real time, the progression or regression of infection or disease. This avoids the need to sequentially sacrifice animals at different time points, allowing significant reductions in the number of animals used per study.

- *Refinement*: Use improvements to scientific procedures and husbandry that minimize actual or potential pain, suffering, distress, or lasting harm and/or improve animal welfare in situations in which the use of animals is unavoidable. Refinement applies to the lifetime experience of the animal. There is evidence that refinement not only benefits animals, but also can improve the quality of research findings. Figure 45.8 shows a unique refinement of housing mice.
  - Examples include:
    - Noninvasive techniques.

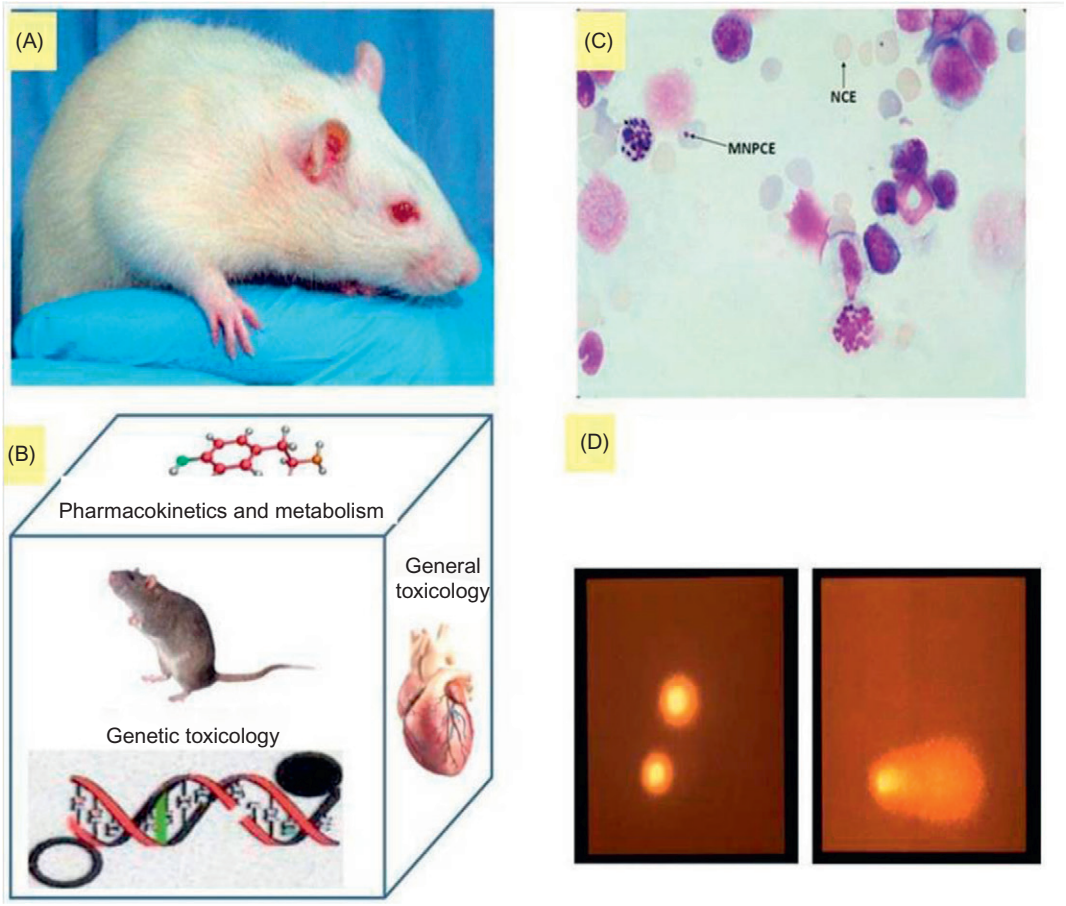

FIGURE 45.6 Integrated *in vivo* genotoxicity of warfare agents can be evaluated using samples obtained during the general toxicity study. (A) Samples are obtained from the animal (e.g., rat). (B) The test agent is exposed to *in vivo* biochemical processes, including metabolism and opportunity to interact with the DNA, thereby providing intact animal with homeostatic assessment of the genotoxic potential of test agent. (C) The blood sample/bone marrow is obtained and stained to detect presence of micronuclei in polychromatic erythrocytes; if positive, then the test agent is considered as clastogenic. (D) Cells, particularly from the liver, are processed and tested for DNA strand breaks in the COMET assay. The breaks in the DNA are observed as a comet-shaped migration of DNA from the nucleus of the cell after gel electrophoresis in treated compared with intact round nucleus, suggesting unaffected DNA (control).

- Appropriate anesthetic and analgesic regimes for pain relief.
- Training animals to voluntarily cooperate with procedures (e.g., blood sampling) so that they have greater control over the procedure and are less stressed.
- Accommodation and environmental enrichment that meet the animals' physical and behavioral needs (e.g., providing opportunities for nesting for rodents).

INTERNATIONAL COOPERATION ON ALTERNATIVE TEST METHODS

In 2009, the United States, Canada, Japan, and European Union signed a memorandum of cooperation that could reduce the number of animals required for consumer product safety testing worldwide (International Cooperation on Alternative Test Methods (ICATM); http://ntp.niehs.nih.gov/?objectid=62A650A4-DD4B-D0A8-C26C7AE0A57F82E8). A similar approach can be used for evaluating chemical warfare agents. The agreement is hoped to yield globally coordinated scientific recommendations for alternative toxicity testing methods that should speed their adoption in each of these countries, thus reducing the number of animals needed for safety testing. A flowchart of this is shown in Figure 45.9.

ICH: The ICH of Technical Requirements for Registration of Pharmaceuticals for Human Use.

OECD: The OECD has a Test Guideline program that deals with chemicals.

ICCR: The International Cooperation on Cosmetics Regulation (ICCR) is an international group of cosmetic regulatory authorities from the United States (FDA), Japan (Ministry of Health, Labor, and Welfare),

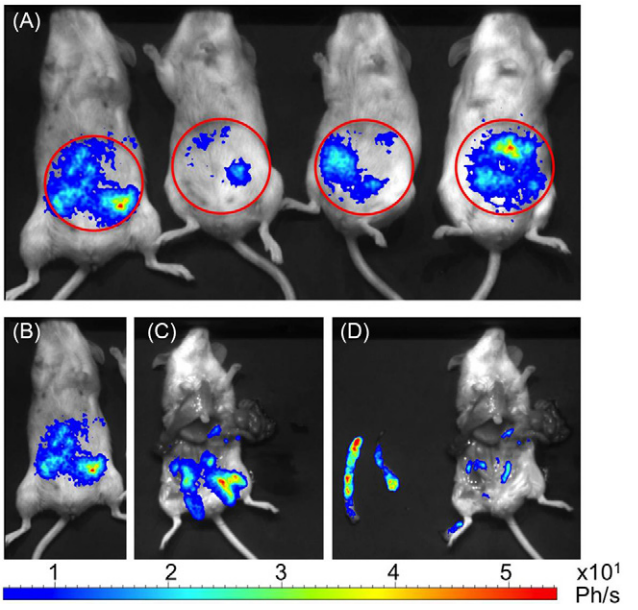

FIGURE 45.7 Localization of bioluminescent parasites in intra-abdominal mesenteric fat in infected mice. Infection was monitored by bioluminescence imaging (BI) technique. On day 40 after infection (A), mice showed intraperitoneal parasites localized by BI. One representative mouse (B) was dissected and the adipose tissue localization was verified *in situ* by BI (C) and confirmed after removing the adipose tissue and re-imaging (D).

FIGURE 45.8 The "mouse house" is a refinement using a transparent red plastic house that enables the mice to perform natural behaviors such as nesting, hiding, and climbing, which are important for their welfare. The house appears dark to the mice, yet the transparent walls allow the scientist to make observations without disturbance (www.scanbur.com).

the European Union (EC, DG Enterprise), and Canada (Health Canada). This multilateral framework maintains the highest level of global consumer protection while minimizing barriers to international trade.

The alternative toxicology methods listed and suggested may be used for chemical warfare agents, as applicable. Nonanimal methods for toxicity testing currently being used are listed in Table 45.2. This was initially compiled by an organization called AltTox (2013), but was modified to serve the purposes of this chapter.

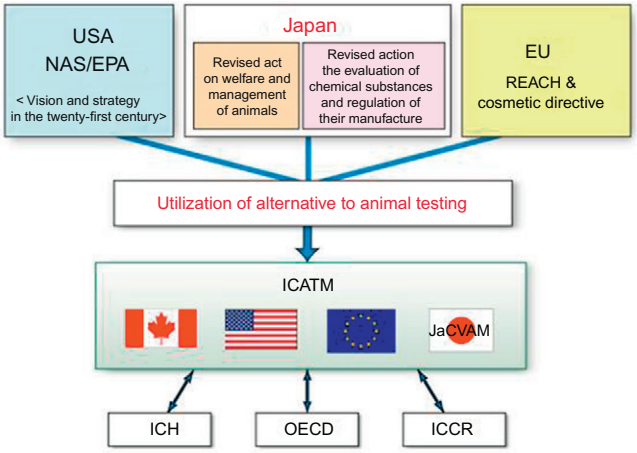

FIGURE 45.9 International Cooperation on Alternative Test Methods.

These methods are also used by organizations such as Registration, Evaluation, Authorization, and Restriction of Chemicals (REACH, 2013).

ALTERNATIVES TO ANIMAL TESTING OF CHEMICAL WARFARE AGENTS

Greenfield et al. (2014) report that the US Army Medical Research Institute of Chemical Defense (USAMRICD) has been commissioned with a mission to develop medical countermeasures against exposure to chemical warfare agents as well as against agents of biological origin. Over the years, this organization has reduced the number of animals used in their research protocols by 92%. Based on a report by the US House of Representatives Committee on the Armed Services regarding the use of animals in DOD military experiments, initiatives to promote alternatives to reduce, refine, and replace (3Rs) were undertaken in 1992. During this time, while adopting the 3Rs, the DOD also added a fourth R, responsibility. This organization developed a unique concept called the management by objective program based on science and technology objectives. One such major objective was to develop reduction, refinement, and replacement strategies for the use of animals in research. The goal was to develop technologies that would incrementally reduce reliance on animal and human subject research and improve the experimental conditions using animals. This further requires introducing a minimum of one improvement per year in experimental protocols using animals.

The scientists at the USAMRICD have taken advantage of emerging computer and biological technologies in the design of molecular modeling software and in the development and maintenance of cell culture models to

TABLE 45.2 Alternative Test Methods and Testing Strategies for Chemical Warfare Agents

Endpoint	Method Name	Test Type
Acute mammalian toxicity (oral)	Acute toxic class method	*In vivo*
	Fixed dose procedure	*In vivo*
	Up-and-down procedure	*In vivo*
	Normal human keratinocyte neutral red uptake (NHK NRU) assay	*In vitro*
	Balb/c 3T3 neutral red uptake assay	*In vitro*
Acute mammalian toxicity (hematotoxicity)	Colony Forming Unit-Granulocyte/Macrophage Assay for acute neutropenia in humans	*In vitro*
Acute mammalian toxicity (inhalation)	Acute toxic class method	*In vivo*
Acute toxicity testing of pesticides	Guidance for waiving or bridging of mammalian acute toxicity tests for pesticides (acute oral, dermal, inhalation; primary eye and dermal; dermal sensitization)	*In vivo*
Biologics and vaccines	Enzyme Linked Immuno-Sorbent Assay (ELISA) for swine erysipelas vaccines batch potency testing	*In vitro*
	ELISA for human tetanus vaccines batch potency testing	*In vitro*
	Toxin binding inhibition test for human tetanus vaccines batch potency testing	*In vitro*
	Batch potency testing of erythropoietin concentrated solution	*In vivo*
	Deletion of target-animal safety test for batch safety testing of veterinary vaccines after consistency in 10 consecutive batches	*NA*
	ELISA for *in vitro* batch potency testing of *Leptospira* veterinary vaccines	*In vitro*
	Use of humane endpoints in animal testing of veterinary biologics, including rabies vaccines	*In vivo*
	Veterinary vaccine potency assays: exemptions from Standard Requirements tests; master reference qualification and requalification	*NA*
	Cell-based assay for stability and potency of botulinum neurotoxin type A products	*In vitro*
	Alternative test procedure for tuberculin, Purified Protein Derivative (PPD) Bovis, intradermic	*In vivo*
Carcinogenicity	Three cell transformation assays (CTA): (Syrian Hamster Embryo (SHE) CTA performed at pH 6.7, SHE CTA performed at pH 7.0, and BALB/c 3T3 CTA)	*In vitro*
Chronic toxicity	*Ending* 1-year dog studies of pesticides	*In vivo*
Dermal absorption/ penetration	*In vitro* skin absorption methods	*In vitro*
Ecotoxicity	Acute aquatic toxicity: upper threshold concentration step-down approach	*In vivo*
	Acute avian toxicity (oral): Sequential testing procedure to minimize numbers of birds used	*In vivo*
	Fish embryo toxicity	*In vivo*
Endocrine active substances	Androgen receptor binding assay (rat prostate cytosol)	*Ex vivo*
	Aromatase inhibition assay (human recombinant)	*In vitro*
	Stably transfected trans-activation *in vitro* assays to detect estrogen receptor agonists	*In vitro*
	Estrogen receptor binding assay rat uterine cytosol (ER-RUC)	*Ex vivo*
	H295R steroidogenesis assay	*In vitro*
	US EPA Tier 1 Screening Battery	*In vitro/In vivo*
	BG1Luc ER TA test method for estrogen agonists and antagonists	*In vitro*
Eye corrosion	Bovine corneal opacity permeability (BCOP) test	*Ex vivo*
	Cytosensor Microphysiometer modified	*In vitro*
	Fluorescein Leakage	*In vitro*
	Hen's egg test-chorioallantoic membrane (HET-CAM)	*In vitro*
	Isolated chicken eye (ICE) test	*Ex vivo*
	Isolated rabbit eye test	*Ex vivo*
	Routine use of topical anesthetics, systemic analgesics, and humane endpoints	*In vivo*
	Sequential testing strategy for eye irritation and corrosion	*In vitro/Ex vivo/In vivo*

(*Continued*)

Endpoint	Method Name	Test Type
Eye irritation	Cytosensor Microphysiometer modified	*In vitro*
	Rabbit low-volume eye test (LVET)	*In vivo*
	Routine use of topical anesthetics, systemic analgesics, and humane endpoints	*In vivo*
	Sequential testing strategy for eye irritation and corrosion	*In vitro/Ex vivo/In vivo*
Genotoxicity	Bacterial reverse mutation (Ames) test	*In vitro*
	In vitro cell gene mutation test	*In vitro*
	In vitro chromosomal aberration test	*In vitro*
	In vitro mammalian cell micronucleus test	*In vitro*
	In vitro sister chromatid exchange test	*In vitro*
	In vitro unscheduled DNA synthesis test	*In vitro*
	Saccharomyces cerevisiae gene mutation assay	*In vitro*
	S. cerevisiae mitotic recombination assay	*In vitro*
Immunotoxicity/skin sensitization	Local lymph node assay (LLNA)	*In vivo*
	Reduced LLNA: rLLNA	*In vivo*
	Nonradiolabelled LLNA: DA	*In vivo*
	Nonradiolabelled LLNA: BrdU-ELISA	*In vivo*
	LLNA for Potency Categorization of Skin Sensitizers	*In vivo*
Phototoxicity	3T3 Neutral Red Uptake Phototoxicity Test	*In vitro*
	3T3 NRU Phototoxicity Test: Application to UV filter chemicals	*In vitro*
Preclinical and nonclinical safety studies for drug development	Guidance on nonclinical safety studies for the conduct of human clinical trials and marketing authorization for pharmaceuticals M3(R2) (harmonized guidance can reduce use of animals)	*In vivo*
	Preclinical safety evaluation of biotechnology-derived pharmaceuticals, ICH S6(R1)	*In vivo*
Pyrogenicity	Human whole blood IL-1	*In vitro*
	Human whole blood IL-6	*In vitro*
	Human cryopreserved whole blood IL-1	*In vitro*
	PBMC IL-6	*In vitro*
	MM6 IL-6	*In vitro*
	Limulus amebocyte lysate (LAL) test	*In vivo/In vitro*
Reproductive and developmental toxicity	Embryonic stem cell test for embryotoxicity	*In vitro*
	Micromass embryotoxicity assay	*Ex vivo*
	Whole rat embryotoxicity assay	*Ex vivo*
	Extended one-generation reproductive toxicity study	*In vivo*
Skin corrosion	EST-1000 human reconstructed epidermis	*In vitro*
	Membrane Barrier Corrosivity Test Method (Corrositex®)	*In vitro*
	EpiSkin® human skin model	*In vitro*
	EpiDerm™ human skin model	*In vitro*
	Rat skin transcutaneous electrical resistance (TER) assay	*Ex vivo*
	SkinEthic™ human skin model	*In vitro*
	Vitrolife-Skin™ human reconstructed epidermis	*In vitro*
Skin irritation	EpiSkin® skin irritation test (with MTT reduction)	*In vitro*
	EpiDerm™ skin irritation test (with MTT reduction)	*In vitro*
	EpiDerm™ SIT model (EPI-200)	*In vitro*
	SkinEthic™ RHE model	*In vitro*

meet the animal reduction goals. In addition, scientists, when possible, have adopted the use of less sentient animal species.

As an example, computer modeling of the molecular structure of nerve agents, physiological enzymes, and neurotransmitters are used to predict and eventually determine how these chemical compounds interact at the molecular level. A test compound that inhibits acetylcholinesterase (AChE) aging has also been studied via computer modeling to determine the specific molecular events that occur at the peripheral anionic site of AChE, which subsequently prevents a potent AChE inhibitor, such as the nerve agent sarin, from irreversibly binding to the AChE molecule (Khan et al., 2000). With this knowledge, the most likely candidates for chemical intervention in the prevention or treatment of nerve agent exposure can be determined. To this end, multiple cell lines or cell cultures are used in research and have led to a reduction of animal usage in research programs for blistering chemical warfare agents. In an effort to evaluate the effects of blister agents, or vesicants, particularly sulfur mustard, and to develop medical countermeasures against such agents, alternatives to animals have proven particularly useful. Several cell line or culture systems, such as peripheral blood lymphocytes, human epidermal keratinocytes, and the HeLa, a human epithelial tumor line, have been adapted and developed by scientists into valuable models for studying vesicant injury. In addition, studies have used a commercial human skin equivalent model and skin biopsy specimens from the Cooperative Human Tissue Network. The USAMRICD also has developed the technology to process and generate a human epidermal model, which possesses typical structural components of human epidermis *in vivo* to include hemidesmosomes, anchoring filaments, and elements of a true basement membrane. The use of these alternative models has especially led to a decrease in the number of rodents required for these studies.

The USAMRICD also promotes the use of less sentient or less regulated animal species, for example, the use the *Aplysia californica*, a large naked marine mollusk or gastropod with anterior sensory tentacles, commonly referred to as the sea hare or sea slug. These slugs possess large and discrete neural ganglia and unique neural anatomy that makes these invertebrate animals an excellent and widely used model for neural transmission and neurotoxin research. Murphy and Glanzman (1997) have described "classical conditioning" based on neurological studies in Aplysia. It appears to be mediated, in part, by long-term potentiation due to activation of *N*-methyl-D-aspartate-related receptors. In certain sulfur mustard experimental protocols, the USAMRICD has used SKH-1 hairless mice as an appropriate substitute for the hairless guinea pig. The main histological feature of skin lesions produced in a SKH-1 hairless mouse after exposure to sulfur mustard is the formation of microblisters at the dermal–epidermal junction. Similar microblisters also occur in sulfur mustard lesions of hairless guinea pigs. Although laboratory mice are not subject to the Animal Welfare Act, provisions for their care and use are contained in the *Guide for the Care and Use of Laboratory Animals*.

ANIMAL EFFICACY RULE

The animal efficacy pathway was formed soon after the terror attacks of 2001, which included a harrowing series of incidents in which spores of anthrax were sent through the US Postal Service, killing several people and sickening many more (www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/CFRSearch.cfm?CFRPart=314&showFR=1&subpartNode=21:5.0.1.1.4.9).

In response to the attacks, legislators and regulators determined that a regulatory process needed to be established to test the safety and effectiveness of so-called medical countermeasures while taking into account the extremely dangerous nature of the pathogens against which they would need to protect their subjects. The problem, at its most basic level, was testing a drug product in humans that could potentially kill them. However, testing for efficacy in humans is not performed. Instead, the FDA ultimately established the animal efficacy rule, which is an approval pathway through which manufacturers can apply for conditional approval of a medical countermeasure based on efficacy testing in human analogues such as pigs or chimpanzees or other appropriately relevant models. Safety testing is still conducted in humans.

Pyridostigmine bromide is the first drug approved under the "animal efficacy rule" that allows use of animal data for evidence of the drug's effectiveness for certain conditions when the drug cannot be ethically or feasibly tested in humans.

The "animal efficacy rule," which became effective on June 30, 2002, is an important component of the FDA's efforts to make medical countermeasures available to treat or prevent the effects of biological and chemical agents. The "animal efficacy rule" enabled the FDA to approve pyridostigmine bromide to increase survival after soman poisoning despite the impossibility of ethically conducting human studies on the effectiveness of the drug.

The nerve agent soman causes loss of muscle control and death from respiratory failure. Evidence of the effectiveness of pyridostigmine bromide as a pretreatment for exposure to soman was obtained primarily from studies in monkeys and guinea pigs. This evidence shows that administration of the drug before exposure to soman, together with atropine and pralidoxime administered after exposure, increases survival. The FDA believes

that, based on the animal evidence of effectiveness, pyridostigmine bromide is likely to benefit humans exposed to soman.

The agency's safety assessment is based on long-term use of pyridostigmine bromide, which was first approved by the FDA in 1955, to treat a neuromuscular disease called myasthenia gravis. The Department of the Army has submitted data from multiple controlled trials and uncontrolled clinical experience demonstrating pyridostigmine bromide is well-tolerated at the doses intended for military use. The dose used for myasthenia gravis is higher than the dose used for pretreatment to protect against soman.

To use this potentially life-saving drug correctly, military personnel must carefully follow instructions and use the drug only under specific circumstances. For example, if US troops faced the threat of exposure to soman, then they would be given instructions to take pyridostigmine bromide every 8 h before the anticipated exposure. Soldiers would be warned that the drug is not effective and should not be taken at the time of, or after, exposure to soman.

The troops are to use the drug in conjunction with other protective measures, including chemical protective masks and battle dress garments. Furthermore, effectiveness depends on the rapid use of the antidotes atropine and pralidoxime and discontinuation of pyridostigmine bromide at the first indication of nerve gas exposure. The Department of Defense plans to provide all military personnel with extensive training, before deployment, regarding the proper use of pyridostigmine bromide, as well as other methods used in the prevention and treatment of nerve agent poisoning.

A leaflet that explains the drug's use, benefits, and side effects will be provided to military personnel when the drug is distributed. The leaflet advises that pyridostigmine bromide should not be used by persons who have a history of bowel or bladder obstruction, or sensitivity to certain medicines used during surgery (like physostigmine). Side effects that may occur include stomach cramps, diarrhea, nausea, frequent urination, headaches, dizziness, shortness of breath, worsening of peptic ulcer, blurred vision, and watery eyes.

The approved dose of pyridostigmine bromide for soman pretreatment is one 30 mg tablet every 8 h. The leaflet states that pyridostigmine should be started at least several hours before exposure to soman and emphasizes that it must be discontinued on exposure to nerve gas, at which point the antidotes atropine and pralidoxime are administered.

During the Gulf War, the FDA had allowed distribution of pyridostigmine bromide under its Investigational New Drug provisions because pretreatment with this drug had the potential to help save lives if nerve agents were used.

Johnson & Johnson's Levaquin (levofloxacin), an antibiotic intended to treat pneumonic plague, became the first product to receive FDA (2012a) approval via the Animal Rule. The product received approval based on testing in African green monkeys infected with pneumonic plague. None of the placebo control group survived contact with the virus, whereas 94% of the Levaquin group survived.

The FDA's (2012b) approval of raxibacumab marks just the second approval under the Animal Rule, and it is also the first monoclonal antibody. The drug is also notable in that it is intended to treat inhalation anthrax—the pathogen perhaps most responsible for the formation of the animal efficacy rule.

Raxibacumab was tested in one study involving monkeys and three studies involving rabbits. As with Levaquin, none of the animals in the control groups survived being infected with inhalation anthrax, whereas 64% of monkeys and 44% of rabbits in one study treated with raxibacumab survived. The FDA also said GSK's animal studies showed the drug was an improvement over existing antibiotic therapies, according to the animal studies. It is said that the drug is specifically aimed at defending against another bioterrorism-type event. Although antibiotics are approved to prevent and treat anthrax infection, raxibacumab is the first approved agent that acts by neutralizing the toxins produced by *B. anthracis*.

- *Improvements to Animal Rule*
  Both approvals come as the FDA and other government entities are looking into ways to refine the Animal Rule process and the protections it affords to the human subjects it is intended to protect.

  Members of the Alliance for Biosecurity (Gronvall et al., 2007) have made three recommendations for effective implementation of Animal Rule.
- First, the Department of Health and Human Services, the FDA, and other US agencies provide strategic direction about how countermeasures may be used. This will aid development and testing.
- Second, the FDA, along with the National Institute of Allergy and Infectious Diseases, should actively develop scientific consensus on animal models for specific disease threats.
- Third, the FDA should develop a consistent interpretation of the Rule within the agency.
- Aebersold (2012) reviewed the FDA experience with medical countermeasures under the Animal Rule. The author concludes that even though only a few drugs or biologicals have been approved since the Animal Rule became effective, several investigational drugs have been placed in the National Strategic Stockpile for use as medical countermeasures, if needed.

TABLE 45.3 Agents Approved Using "Animal Rule"

Compound	Company	Purpose
Abthrax (Raxibacumab)	Glaxo Smith-Kline (GSK)	Anthrax vaccine
Cynokit	Orphan Medical, Inc/Merck Sante	Cyanide poisoning
Ciprofloxacin	Bayer	Anthrax
Levofloxacin	Janssen Pharmaceuticals	Plague (*Yersinia pestis*)
Pyridostigmine bromide (PB)	US Army	Soman

- The FDA has also clarified suggested issues, one of which is an animal model qualification program. The qualification process is limited to animal models used for product approval under the Animal Rule (www.fda.gov/Drugs/DevelopmentApprovalProcess/DrugDevelopmentToolsQualificationProgram/ucm284078.htm). A qualified model may be used for efficacy testing in development programs for multiple investigational drugs for the same targeted disease or condition. Such animal models are considered to be product-independent (i.e., not linked to a specific drug).

The Animal Rule states that the FDA can rely on the evidence from animal studies to provide substantial evidence of the effectiveness of a drug only when all of the following four criteria are met:

a. There is a reasonably well-understood pathophysiological mechanism of the toxicity of the substance and its prevention or substantial reduction by the product.
b. The effect is demonstrated in more than one animal species expected to react with a response predictive for humans, unless the effect is demonstrated in a single animal species that represents a sufficiently well-characterized animal model for predicting the response in humans.
c. The animal study endpoint is clearly related to the desired benefit in humans, generally the enhancement of survival or prevention of major morbidity.
d. The data or information regarding the kinetics and pharmacodynamics of the product or other relevant data or information, in animals and humans, allow selection of an effective dose in humans.

The FDA (2003) approved pyridostigmine bromide for combat use by US military personnel to protect them from the lethal effects of the nerve gas soman (www.fda.gov/Drugs/EmergencyPreparedness/BioterrorismandDrugPreparedness/ucm130342.htm).

Sullivan et al. (2009) have reviewed the usefulness of the Animal Rule in the development and regulatory approval process of the Ebola virus. Ebola virus infection is a highly lethal disease for which there are no effective therapeutic or preventive treatments. Several vaccines have provided immune protection in laboratory animals, but because outbreaks occur unpredictably and sporadically, vaccine efficacy cannot be proven in human trials, which are required for traditional regulatory approval. The FDA has introduced the Animal Rule to allow laboratory animal data to be used to show efficacy when human trials are not logistically feasible. In this review, the authors describe immune correlates of vaccine protection against Ebola virus in animals. This research provides a basis for bridging the gap from basic research to human vaccine responses in support of the licensing of vaccines through the Animal Rule. Table 45.3 lists a few agents approved using the Animal Rule.

HUMAN ON A CHIP

Hartung and Zurlo (2012) have discussed various alternative approaches for medical countermeasures to biological and chemical terrorism and warfare. One such approach focuses on the development of a human-on-a-chip shown in Figure 45.10. This involves the combination of different three-dimensional (stem) cell-based organ equivalents combined with microfluidics. The prospects of such approaches, their impact on the field of alternative approaches, and necessary complementary activities are discussed. They emphasize the need to adapt quality assurance measures and experiences from validation while executing such newer approaches.

Similarly, scientists at the Edgewood Chemical Biological Center (ECBC) and academic collaborators are performing research on organoids (small swatches of human tissue) on microchips (www.kurzweilai.net/human-on-a-chip). This research focuses on *in vitro* human organ constructs, such as for the heart, liver, lung, and the circulatory system, in communication with each other. The goal is to assess effectiveness and toxicity of drugs in a way that is relevant to humans and their ability to process these drugs. It is said that "the screening models will be used to assess the efficacy and safety

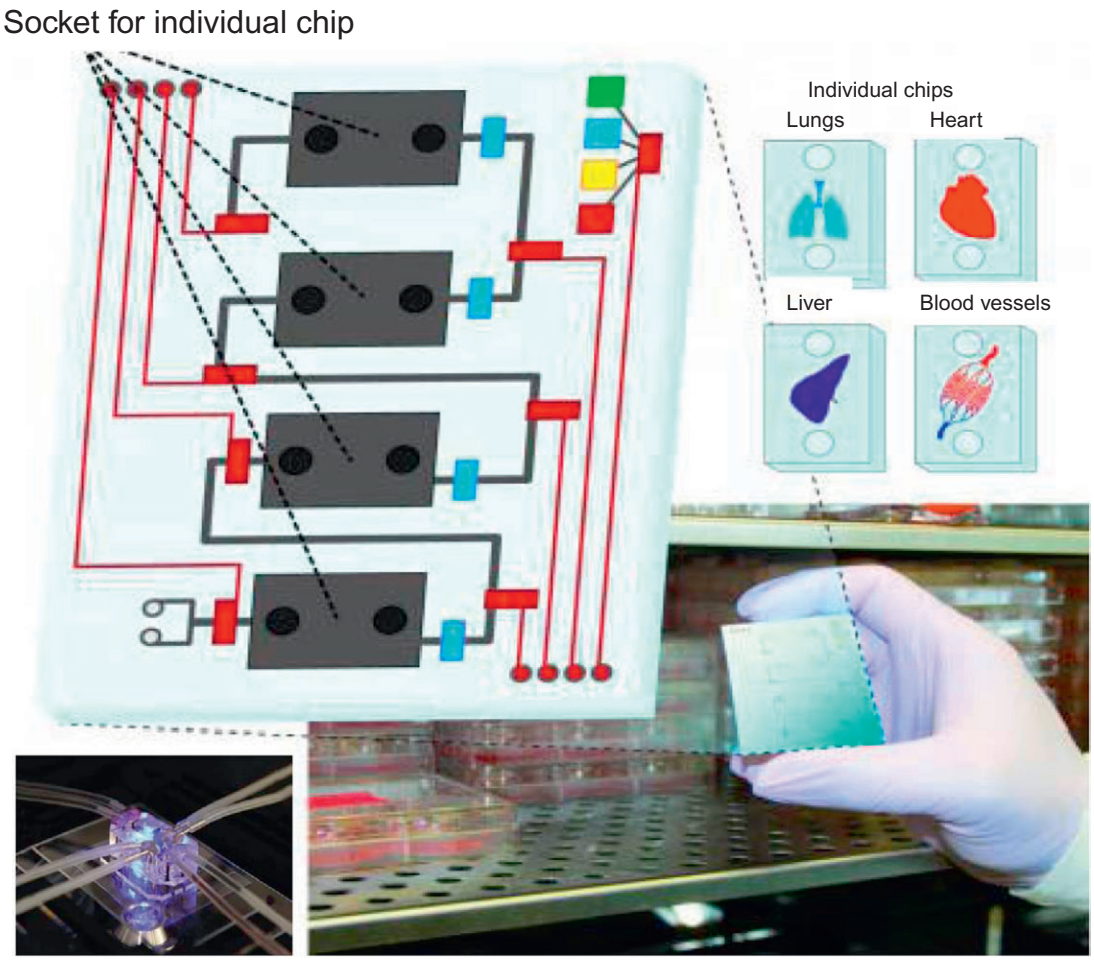

FIGURE 45.10 "Human on a chip" *in vitro* human organ constructs (for heart, liver, lung, and the circulatory system) in communication with each other used to assess effectiveness and toxicity of warfare agents that are relevant to humans (Human on a Chip, 2014).

of medical mitigation procedures and countermeasures for the soldier and the nation as a whole."

Each organ on a chip is approximately the size of a thumb drive and is an "organoid" (a structure that resembles an organ in appearance or function) designed to mimic the properties of an actual human organ. The organoids are created by induced pluripotent stem cells made from adult skin cells. They comprise multiple layers of cells growing on a membrane and connected to each other by microfluidics (tiny microchannels) that copy the function of blood vessels. Their primary purpose is to take the place of animal research. It is proposed that animal tests do not always give the results seen in people. Because of the species-specific differences by which compounds are metabolized, a drug tested on a laboratory rat does not always translate well to a human. In some cases, such as with asthma, no animal testing can mimic the human response. Because human on a chip is made from human cells, it is the next best thing. Human tissue reacts like human tissue.

New Predictive Models of Toxicity

The researchers anticipate that new predictive models of toxicity will result from the more accurate human on a chip testing, saving time and money. This technology is hoped to result in fewer test failures than animal studies. The ECBC center houses the only laboratories in the United States that the Chemical Weapons Convention permits to produce chemical warfare agents for testing purposes. It is said ECBC will test the human on a chip against chemical warfare agents to learn more about how the body will respond to agent exposure and explore various treatment options for exposures. For the military, human on a chip research is hoped to save lives.

Labant (2014) points out using *in vitro* ADME-Tox assays and getting more biological data from each experiment. The use of specialized instrumentation, such as single-stage accelerator mass spectrometer (SSAMS), is suggested so trace amounts of metabolites can be

FIGURE 45.11 SSAMS is a robust and ultrasensitive bioanalytical tool. AMS technology can provide a compound-independent and matrix-independent platform that enables innovative *in vitro* and *in vivo* study designs.

identified and quantitated (Figure 45.11). Similarly, use of flow cytometry in toxicological testing has truly enhanced the collection of a large amount of data from each experimental unit either *in vivo* or *in vitro* while reducing animal use (Krishna et al., 1993; Criswell et al., 1998a,b, 2003; Darzynkiewicz et al., 2011; Dertinger et al., 2011; Willjam et al., 1991).

Examples of alternative studies conducted using a variety of warfare agents are briefly listed here. Worek et al. (2007) described the use of highly toxic organophosphorus (OP) warfare nerve agents and underlined the necessity for effective medical treatment. Acute OP toxicity is primarily caused by inhibition of AChE. Reactivators (oximes) of inhibited AChE are a mainstay of treatment. *In vitro* studies with human tissue enabled the evaluation of oxime efficacy without animal experiments and with no need for interspecies extrapolation. Dorandeu et al. (2007) emphasized the use of swine, especially minipigs, based on similarities in a number of interesting biological and physiological characteristics (skin, cardiovascular), as an alternative to other commonly used species such as dogs, macaque, and marmoset. Szinicz et al. (2007) described development of antidotes against chemical warfare agents as "orphan drugs" given that these poisonings are rare. Computer models are being established to estimate the therapeutic effect of an antidote in various human poisoning scenarios. This approach compensates for the lack of human clinical pharmacodynamic studies given the obvious ethical issues preventing human volunteer studies with these agents. Krishnan et al. (2009) and Reddy et al. (2011a,b) tested a variety of warfare agents in multiple alternative methods, including short-term genotoxicity and physiologically based pharmacokinetic modeling of warfare agents, for example, cyclotrimethylenetrinitramine (RDX), ethylenediaminedinitrate, diethylenetriaminetrinitrate, and 3-nitro-1,2,4-triazol-5-one.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Alternatives in animal testing have come a long way in thought and action. Over the years, scientists have continuously improved such methods so that the goals of the 3Rs are achieved. For example, the roadmap for the development of alternative (nonanimal) methods for systemic toxicity testing by Basketter et al. (2012) and challenges in developmental neurotoxicity testing in the twenty-first century versus *in vitro* opportunities by Smirnova et al. (2014) are noteworthy. In recent years, the application of alternatives in testing warfare agents has been much appreciated in light of the threat and/or actual terrorist attacks. A variety of such methods either has been validated or are being validated. Continued global efforts in innovation with reliable assays, instrumentation, and strategies are hoped to produce much anticipated results so these methods can be routinely used in warfare testing and counterterrorism. Regulatory agencies around the globe are working in collaboration with academia and industry, so the stakeholders, thoughts, talk, and action are on the same page. Meaningful cooperation is sought, as needed, to achieve a common goal of reliable and quality data for our efforts. This kind of collective and collaborative effort and efficient use of resources with funding from multiple bodies, especially the government, will continue to provide impetus in fully achieving the ultimate goal of reducing, refining, and replacing animal use, as applicable, in toxicity and efficacy testing and finding viable alternatives, especially for warfare testing. Going forward, it is believed that with continued innovations in technologies, the instrumentation, ideas, and vision, such as "organ or organs-on-a-chip" and "human-on-a-chip" as proposed by Lee et al. (2013) and others, would become a reality. With these advancements, the concerns of excessive use of animals in testing would continue to decrease, but with quality data still generated while using these remarkable alternatives.

Genomics and Proteomics in Brain Complexity in Relation to Chemically Induced PTSD

Beena M. Kadakkuzha, Xin-an Liu and Valerio Rizzo

INTRODUCTION

Posttraumatic stress disorder (PTSD) is an anxiety disorder rooted in an extremely traumatic experience, usually one that threatens severe injury or death. PTSD is characterized by symptoms in three primary domains: (i) reminders of the exposure (flashbacks, intrusive thoughts, and nightmares); (ii) activation (hyperarousal, insomnia, agitation, irritability, impulsivity, and anger); and (iii) deactivation (numbing, avoidance, withdrawal, confusion, derealization, dissociation, and depression). Signs and symptoms can last beyond 1 month (even though such periods can occur long after the original traumatic exposure) and therefore reflect a persistent, abnormal adaptation of neurobiological systems to the stress of witnessed trauma. According to the World Health Organization, mental disorders account for 4 out of 10 of the leading causes of disability in developed countries, and epidemiological data suggests that 7.8% of people will experience PTSD in their lifetimes (Kessler et al., 1995; Roth et al., 2011). Clinical studies have shown a high prevalence of PTSD in war veterans, especially in those who suffered from chemical warfare. Based on symptom severity and persistence, PTSD is generally categorized into three types: acute, chronic, and delayed onset. In acute PTSD, symptoms normally last less than 3 months. In chronic PTSD, symptoms may last 3 months or more. In delayed onset of PTSD, symptoms first appear at least 6 months after the traumatic event. The estimated lifetime prevalence of PTSD is about 8% in the US population, with women (10.4%) more than twice as likely as men (5%) to experience PTSD. According to the same report, the prevalence ranges from 3% to 58% in high-risk groups, such as combat veterans and victims of violent crimes such as rape, sexual molestation, physical attack, and violence.

Current diagnostics for PTSD rely on subjective measures and patient recall, making it difficult to accurately diagnose the condition or differentiate its symptoms from those of depression or anxiety. The exact causes of PTSD and the long-term changes in the body, especially the brain, caused by it are still unknown. Identifying specific areas of the brain whose key functions are altered in response to a specific disorder is key to understanding the fundamental causes and sustaining factors of disease pathology. Recent advances in brain imaging technologies have allowed scientists to analyze the brains of patients afflicted with a variety of neurological disorders. Whole-brain imaging studies offered valuable information about the permanent changes and long-term effects of PTSD in the brain (Hull, 2002; Brown et al., 2014). However, some of these key brain areas are also involved in a number of closely associated brain disorders, such as anxiety and depression (Kroes et al., 2011); and distinguishing subtle morphological changes between these closely related neurological disorders through brain imaging is extremely challenging. Additionally, whole-brain imaging studies can provide only a snapshot of the current morphological status, requiring the development of advanced methodologies that can predict the predisposition of an individual, mainly the altercations in genetic makeup, which serve as molecular signatures of PTSD. High-throughput genomics and proteomics approaches have been widely applied for identifying

Handbook of Toxicology of Chemical Warfare Agents.

biomarkers for many diseases, as well as characterizing the molecular toxicology of chemical agents.

There are many questions that are relevant to address while trying to characterize the molecular fingerprint of a complex disease like PTSD. Determine whether there are changes in gene expression—that is, can the activity or output of particular genes associated with the onset of PTSD after exposure to traumatic events, or some environmental factors such as toxic chemical exposure, affect the way our genes behave and the RNA they make, ultimately resulting in the alteration of the body's production of various proteins and hormones? Do those changes contribute to the development of PTSD? Can we identify specific variants in the genetic architecture that are involved in alterations in gene expression and associated with PTSD? Answers to these questions will help researchers understand what happens with our genes and the proteins they make and related basic biology as we are exposed to trauma and toxic environment. This, in turn, could educate us concerning new intervention efforts, including medication that offsets biological factors leading to PTSD's development. In this chapter, we briefly discuss the outcomes of current research in the anatomical changes in the brain, genomic factors leading to PTSD development, and recent advances in genomics, transcriptomics, and proteomics to understand PTSD at the molecular level and develop early diagnostic tools and specific pharmacotherapy.

THE EFFECT OF PTSD ON DIFFERENT REGIONS OF THE BRAIN

Earlier brain imaging studies have identified a few key regions in which patients with PTSD appear to have altered stress response structure and function. The neurobiological systems regulating stress response pathways and the network of brain regions known to regulate fear and emotive behavior also seem to play a role in PTSD. Investigations to identify neurobiological markers for PTSD originally presumed that abnormalities were acquired as a consequence of traumatic experience. However, certain abnormalities in a patient with PTSD could simply represent preexisting conditions or functionally dormant pathology, which arise through trauma exposure and hence are detected upon investigation. Patients with PTSD showed drastic changes in the hippocampus and amygdala, as well as cortical regions including the anterior cingulate, insula, and orbitofrontal region (Shin et al., 2006; Bremner et al., 2008). All these areas form a neural circuit mediating, among other functions, adaptation to stress and fear conditioning, and changes in these circuits are considered directly related to the development of PTSD (Rauch et al., 2006).

THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

The "headquarters" of the mammalian neuroendocrine stress response system is the hypothalamic-pituitary-adrenal (HPA) axis; as such, it has been the main target for investigation in PTSD patients. Briefly, the HPA axis is made of endocrine hypothalamic components, including the anterior pituitary and the adrenal glands as effector organs. Upon exposure to stress, neurons in the hypothalamic paraventricular nucleus secrete corticotropin-releasing hormone from nerve terminals in the median eminence into the hypothalamohypophyseal portal circulation, which stimulates the production and release of adrenocorticotropic hormone (ACTH) from the anterior pituitary. ACTH in turn stimulates the release of glucocorticoids from the adrenal cortex. Prolonged glucocorticoid exposure has adversarial effects on hippocampal neurons, involving reduction in dendritic branching, loss of dendritic spines, and impairment of neurogenesis (Fuchs and Gould, 2000).

Cortisol, secreted in the adrenal cortex in response to stress, is an informative biomarker that can be used to differentiate PTSD from normal patients. Outcome from a simulation study supported the hypothesis proposed by Yehuda and colleagues that high stress intensity and strong negative feedback loops may cause a hypersensitive neuroendocrine axis that results in hypocortisolemia in PTSD (Yehuda et al., 1993; Sriram et al., 2012). Also, low-dose dexamethasone suppression testing suggests that hypocortisolemia in PTSD occurs due to increased negative feedback sensitivity of the HPA axis (Wingenfeld et al., 2007). In summary, these studies suggest that decreased availability of cortisol, due to irregular regulation of the HPA axis, may lead to abnormal stress reactivity and fear processing.

HIPPOCAMPUS

Reduced hippocampal volume is a well-known hallmark of PTSD. Initial magnetic resonance imaging studies determined smaller hippocampal volumes in Vietnam veterans with PTSD and patients with abuse-related PTSD compared with controls (Bremner et al., 1997). Therefore, severity of trauma and memory impairments were related to the decrease in hippocampal volumes. However, reduced hippocampal volume has not been observed in children with PTSD (De Bellis et al., 1999). Additionally, proton magnetic resonance spectroscopy investigations further demonstrated a reduction of the levels of *N*-acetyl aspartate (NAA), a marker of neuronal integrity, in the hippocampus of adult patients with PTSD (Villarreal et al., 2002). Hippocampal volume reduction in PTSD likely reflects a neurotoxic effect

of repeated exposure to stress-increased glucocorticoid levels or glucocorticoid sensitivity, although decreased hippocampal volumes might also be a preexisting vulnerability factor for developing PTSD (van der Werff et al., 2013).

Convincing evidence suggested a smaller hippocampal volume in trauma-exposed persons diagnosed with more severe, unremitting PTSD (Gilbertson et al., 2002). In fact, early life stressors can affect hippocampal volume and predispose for the disorder (Yehuda et al., 2010). However, at this stage, the way that trauma affects hippocampal volumetric (as well as other histopathological) measures is not well understood. Interestingly, functional neuroimaging studies have also shown deficits in hippocampal activation during verbal declarative memory tasks in PTSD patients (Bremner et al., 2003). Both hippocampal atrophy and functional deficits select serotonin reuptake inhibitors (SSRIs) most likely due to an increase of neurotrophic factors and neurogenesis (Nestler et al., 2002).

AMYGDALA

Investigators have suggested the idea that aberrant stress response and an enhanced amygdala-induced augmentation of emotional memories in PTSD subjects may be underpinned by abnormal amygdala functioning (Elzinga and Bremner, 2002), since its functional role is in mediating both stress responses and emotional learning. However, no clear evidences for structural alterations of the amygdala have been confirmed in PTSD patients. Functional imaging studies have revealed amygdala hyperresponsiveness in PTSD subjects when stressful scripts (Hendler et al., 2003; Shin et al., 2004), cues, and trauma reminders were presented (Shin et al., 2006). On the other hand, PTSD patients showed increased amygdala responses even to general emotional stimuli that were not trauma-associated (Shin et al., 2006) or subliminally threatening cues (Hendler et al., 2003; Bryant et al., 2008). Amygdala hyperactivity seems to be related to specific genetic traits (Hariri et al., 2002; Kilpatrick et al., 2007); hence, it may likely play a role in developing PTSD. Actually, several investigations have found a positive relationship between activation of the amygdala and PTSD symptom severity (Shin et al., 2004).

PTSD patients show a hyperactive amygdala as a consequence of trauma and throughout the course of the disorder; hence, reducing the activity of the amygdala could potentially prevent onset of the disorder, or it could be therapeutic for individuals who have already developed psychopathology. These findings led to the hypothesis that noradrenergic activity could promote amygdala-dependent fear memories. Indeed, researchers have speculated that adrenergic receptor antagonists could potentially reduce the severity of PTSD symptoms; adrenergic receptor modulators, such as prazosin (α1 receptor antagonist; (Raskind et al., 2007), clonidine (α2 receptor agonist; (Boehnlein and Kinzie, 2007; Strawn and Geracioti, 2008) and propranolol (β receptor antagonist; (Brunet et al., 2011; Pitman, 2011), have shown promising results as elements of therapy for PTSD.

CORTEX

The prefrontal cortex (PFC), and particularly the medial PFC, are highly involved in the extinction of fear memories (Sherin and Nemeroff, 2011) and, in general, in the inhibitory control of inappropriate cognitive and emotional responses that are mediated in part by the amygdala (Elzinga and Bremner, 2002). Given this large inhibitory role of the PFC over the amygdala, researchers have speculated that impaired PFC functioning may trigger amygdala hyperactivity and hence exacerbate emotional responsiveness. Actually, individuals with PTSD exhibit smaller volumes of PFC, its major subregions, and specifically the anterior cingulate cortex (ACC); (Yamasue et al., 2003; Woodward et al., 2006). Therefore, PTSD symptom severity could likely be related to these volumetric reductions (Zoladz and Diamond, 2013). Moreover, shape abnormalities (Corbo et al., 2005), as well as a decrease in NAA levels in the ACC (De Bellis et al., 2000) have also been reported.

However, recent evidence has suggested that volume loss in the PFC and ACC could also be a consequence of PTSD rather than a preexisting risk factor (Kasai et al., 2008). Functional imaging studies have demonstrated a reduced activity of the medial PFC in PTSD patients in response to stimuli, such as trauma scripts (Shin et al., 2004; Britton et al., 2005), combat pictures and sounds (Bremner et al., 1999), trauma-unrelated negative narratives (Lanius et al., 2003), fearful faces (Shin et al., 2005), and impaired performance on PFC-dependent tasks (Koenen et al., 2001). Finally, PTSD patients show impaired abilities to extinguish fear (Peri et al., 2000) and reduced activities of PFC regions during extinction trials (Bremner et al., 2005).

These individuals exhibited a reduced activity of PFC or a complete failure to activate PFC brain regions during the presentation of trauma-associated stimuli (Shin et al., 2004; Britton et al., 2005); hence, it is likely that a reduced activation of PFC, along with amygdala hyperactivity, could lead to the development of the intrusive emotional thoughts and memories often experienced by PTSD patients. Actually, reduced PFC activity could lead to greater governance of behavior by more primitive brain areas, such as the amygdala, impairing brain processes involved in adaptation, behavioral flexibility, and cognition. As for the volume decrease, it is still unclear

whether the reduced PFC inhibition of lower brain areas, such as the amygdala, is a result of the disorder or a preexisting condition for developing PTSD. Investigations of twin brothers who were discordant for PTSD (Gilbertson et al., 2006) supported the hypothesis that reduced PFC functioning is both a preexisting condition and a risk factor for the development of PTSD. Moreover, animal and clinical studies mainly suggest a complex interaction among early life stress (Karssen et al., 2007; Lyons et al., 2010), gene-environment influences (Garrido, 2011), and the well-described adverse effects of stress on PFC functioning in adulthood (Arnsten, 2009) which could interact to influence PTSD susceptibility and posttrauma expression. SSRI treatment has been shown to restore medial PFC activation patterns (Shin et al., 2006).

Although these findings using brain imaging studies advances our understanding of PTSD pathology, it falls short of identifying predispositions to the disease. The significant progress in genetics and genomics has generated approaches that screen the full genome and genetic network rather than individual genes. The recent move towards the "omics" fields, including genomics and proteomics, offer enormous opportunities to analyze genes, RNA transcripts, and protein expression patterns in diseased and normal tissues. Such approaches have equipped researchers with many advantages and given access to thousands of new molecular targets for disease screening and drug discovery. In the rest of this chapter, we discuss the genomic and proteomic methods that are currently used to understand the molecular level players in PTSD.

UNDERSTANDING PTSD: GENOMICS AND PROTEOMICS

The central dogma of biology coined by Francis Crick (1958) proposed that an organism's genetic information encoded in its DNA molecules is transcribed into RNA molecules (transcriptome), which are then translated to proteins (proteomes) that facilitate particular biological functions. In addition to the transfer of information from genome to proteome, proteome functions are regulated by epigenetic mechanisms such as posttranslational modifications and regulation via noncoding RNA (ncRNA). The development of advanced techniques over the past two decades have allowed the scientific community to take a closer look at the genome, transcriptome and proteome of any tissue or organ, and these tools have proved to be invaluable in studying complex tissues such as the brain. Monitoring the specific activity of a genome by measuring messenger RNA (mRNA) expression levels of large gene sets can identify molecular profiles correlated to disease states, which may then be developed as diagnostic tools.

The human brain is one of the most complex biological structures. It consists of approximately 100 billion neurons and a nearly equal number of nonneuronal cells (Azevedo et al., 2009). Neurons that perform a specific function are assembled into circuits, and the neurons within each circuit talk to each other through unique connections called *synapses.* Anomalies that affect communication within neural circuits lead to neurological disorders and affect regular brain functions (Geula, 1998). For over a century, researchers have tried to understand human brain functions using simple animal models such as worms, flies, snails, mice, and rats. Over the past two decades, molecular genetics studies have enabled a common conceptual framework for the development and basic function of the nervous system. However, because many debilitating human disorders are genetically complex and phenotypic screens are difficult to perform, large-scale genomic approaches to discover genes that are uniquely expressed in brain circuits and regions that control complex behaviors are becoming highly significant.

A comprehensive picture of the genomic factors underlying an individual's susceptibility to complex diseases is essential to understanding a disease like PTSD, where it is often difficult to make an absolute clinical diagnosis. One such study showed that a single-nucleotide polymorphism (SNP) of the gene Oprl1 is associated with PTSD symptoms in humans, and an altered expression of this gene in the amygdala of mouse models led to alterations in fear processing that may lead to PTSD development (Andero et al., 2013). Another study of adult civilians with PTSD has shown that individuals with a history of childhood abuse have very discrete and profound changes in gene activity patterns compared to adults with PTSD but no history of child abuse (Mehta et al., 2013). The outcome of both these studies provide evidence that susceptibility to developing PTSD may be coded in one's DNA; and the exposure to traumatic events may act as the trigger for PTSD onset. In addition, scores of recent studies on epigenetic mechanisms state that DNA is not the only element that carries all the information for a specific phenotypic outcome, and specific alterations in epigenetic signatures such as DNA methylation were more frequent in the PTSD group that suffered child abuse (Mehta et al., 2013). This study also found that the subjects with PTSD and a history of child abuse demonstrated more changes in genes linked with nervous system development and regulation of the immune system, while the PTSD patient group with no child abuse history showed more changes in genes linked with apoptosis (cell death) and regulation of growth rate. Although the symptoms in both the PTSD groups were the same, these findings showed that the specific affected biological pathways might lead to different mechanisms of PTSD symptom formation within

the brain. These studies provide ample evidence that PTSD is associated with distinct molecular fingerprints, and identifying the key genetic factors for PTSD etiology will not only improve understanding of the underlying pathophysiology, but may also lead to new avenues for preventing and treating this distressing disease in the early stages.

APPLICATIONS OF GENOMIC AND TRANSCRIPTOMICS METHODS

Transcriptomics and gene expression profiling methods analyze the expression of thousands of genes simultaneously in a single biological sample by quantifying the levels of individual mRNA transcripts. Some of the earlier methods used for the identification of genes in different parts of the brain include differential display, representational difference analysis, serial analysis of gene expression, and massively parallel signature sequencing. These techniques are relatively expensive and laborious, which led to the search for high-throughput screening techniques that can capture dynamic gene expression changes and perform large-scale gene expression profiling in complex neuronal systems (Kadakkuzha and Puthanveettil, 2013).

Microarrays hold the promise of becoming a revolutionary tool for large-scale analyses of genome sequence and gene expression (Young, 2000; Noordewier and Warren, 2001). The most commonly used formats are the oligonucleotide microarray (Fodor et al., 1993) and the complementary DNA (cDNA) microarray (Schena et al., 1995). Over the years, microarray technology has advanced to support maximum coverage of the transcriptome. The successful applications of microarray technology offer a robust and unbiased approach to acquire global gene expression patterns in the whole brain, specific tissue, or single neuron. cDNA arrays are often used in RNA expression analyses, while oligonucleotide arrays are used for sequence analyses. Oligonucleotide arrays offer a number of advantages over cDNA microarrays, such as increased specificity of hybridization, which is key to SNPs (LaForge et al., 2000), mutational analysis (Hacia, 1999), identification of splice forms, and, alternatively, polyadenylated transcripts (Hu et al., 2001). Microarrays have been extensively used to study expression profiles of complex neuropsychiatric disorders using both animal models (Lin et al., 2012) and RNA from postmortem human brain tissue (Lehrmann et al., 2003). Thus, microarrays can be effectively applied toward robust screening of a large number of genes, which are altered with PTSD onset.

Validation of microarray results is often performed by another sensitive technique such as qualitative real-time polymerase chain reaction (qRT-PCR), which detects the PCR product by combining a thermal cycler with a fluorescent spectrophotometer (Higuchi et al., 1993). The qRT-PCR reaction can be performed in two different formats. In the first, the double-stranded DNA generated is detected by the binding of a fluorescent dye such as SYBR green I that intercalates only to the double-stranded DNA (Ponchel et al., 2003). The second uses a fluorescent reporter molecule that is released due to the exonuclease activity of the DNA polymerase enzyme. qRT-PCR is widely used as a robust method for quantitative gene expression analysis (Gibson et al., 1996). Apart from qRT-PCR, another widely used approach to validate gene expression in transcriptomics is *in situ* hybridization. Fluorescence *in situ* hybridization (FISH) was developed in the 1980s, and it rapidly became a powerful technique (Langer-Safer et al., 1982). In the FISH method, a small RNA fragment of the mRNA transcript to be tested is fluorescently labeled and used for hybridization in fixed samples. The probe binds to the complementary sequences within the sense transcript, which can be visualized by fluorescence microscopy. FISH can identify whole chromosomes, centromeres, telomeres, specific regions or genes, or aberrations in interphase tumor nuclei, and it can be effectively used to identify novel mRNA transcripts, the levels of specific genes expressed, and their cellular localization. Using this technique, a genomewide, three-dimensional map of the entire human brain is constructed that details where each gene is "turned on or off."

Very often, however, the molecular characterization of clinical samples is complicated and limited by the available amount of samples. Strategies to overcome this problem include amplification of the starting material or of the signal to be detected, or miniaturization of the method. Novel means are also required to measure gene expression with allele-specific and splice-variant-specific profiles. Such technologies promise to be a further big step from bench to bedside. Although microarrays are still widely used, an increasing number of studies now use direct sequencing of transcripts by high-throughput sequencing technologies such as RNA Sequencing (RNA-Seq), also known as "next-generation" or "deep" sequencing (Wang et al., 2009). Unlike microarrays, RNA-Seq is not limited to detecting transcripts that correspond to existing genomic sequences and has significantly low, if any, background signaling. In addition, RNA-Seq does not have an upper limit for quantification, offering a large dynamic range of expression levels over which transcripts can be detected. The most commonly used techniques to analyze genetic and genomic various are shown in Figure 46.1.

SNP genotyping is an advanced genotyping method that measures SNPs between genomes. In an SNP, a single base pair is mutated at a specific locus, leading to the malfunction of the specific gene product and a disease

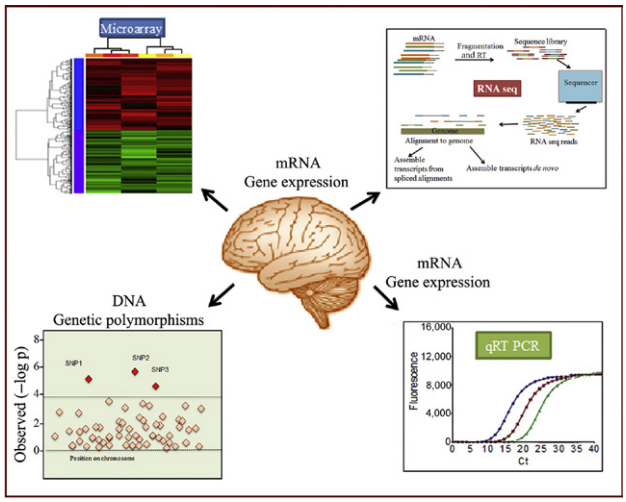

FIGURE 46.1 The most commonly used techniques to identify the genomic and transcriptomic changes associated with specific diseases. In microarray, RNA-Seq, and qRT-PCR, mRNA isolated from samples is characterized to observe any changes in gene expression. In SNP, DNA is used to identify a single base pair mutation at a specific locus on the chromosome.

phenotype. Over 1 million SNPs are currently reported to be present within the human genome (Sachidanandam et al., 2001). Even though very small numbers of SNPs cause changes in gene function or expression, it is critical to identify SNPs, as they are implicated in a number of diseases. There are multiple platforms to perform SNP genotyping, and multiple studies have shown that specific SNPs are associated with PTSD. A genomewide SNP association analysis in 1,578 European Americans, 300 of whom suffered from PTSD, and 2,766 African Americans, 444 of whom had PTSD, using an Illumina Omni1-Quad microarray, found novel common risk alleles for PTSD (Xie et al., 2013). This study yielded close to 90,000 SNPs and found a new susceptibility gene for PTSD called the *Tolloid-Like 1 gene (TLL1).* A similar genomewide association study (GWAS) from a cohort of veterans reported an SNP (rs8042149) located in the retinoid-related orphan receptor alpha (*RORA*) gene associated with PTSD susceptibility (Logue et al., 2013). RORA has been implicated in prior GWAS studies of psychiatric disorders and is known to have an important role in neuroprotection and other behaviorally relevant processes. This study represents an important step toward identifying the genetic underpinnings of PTSD.

Another well-studied example is the FK506 binding protein 5 (*FKBP5*), a glucocorticoid receptor co-chaperone regulator (Mehta et al., 2011) that has reduced expression levels in PTSD (Yehuda et al., 2009). In a cross-sectional study on childhood abuse, four specific SNPs of the *FKBP5* gene were found to be predictors of adult PTSD symptoms (Binder et al., 2008). These four SNPs were identified as rs3800373, rs9296158, rs1360780, and rs9470080 in a study done on European Americans and African Americans who were originally screened for lifetime PTSD (Xie et al., 2010). All four of these SNPs showed a similar linking pattern (Shinozaki et al., 2011), which supported a genetic as well as an environmental basis for childhood abuse and the subsequent onset of PTSD in adulthood.

In another study, the peripheral expression levels of *FKBP5* gene expression and volumes of specific brain structures such as the hippocampus, amygdala, and medial orbitofrontal cortex in 39 patients with PTSD were compared before and after cognitive behavioral therapy. Microarray and qRT-PCR analysis found that there was a significant increase in FKBP5 expression and hippocampal volume in patients with PTSD. Another similar study on pituitary adenylate cyclase-activating polypeptide (PACAP)–PAC1 receptor found that these were involved in abnormal stress responses underlying PTSD in a sex-specific manner in heavily traumatized individuals (Ressler et al., 2011). Analyzing the levels of PACAP in the blood and extensive SNP genotyping of *PACAP* and *PAC1* genes showed a single SNP within the *PAC1* gene (rs2267735) that predicts PTSD diagnosis and symptoms in females only. The study also found that methylation of the PAC gene in peripheral blood is associated with PTSD.

THE ROLE OF ncRNA AND EPIGENETICS IN PTSD

Earlier in this chapter, SNPs associated with a number of genes were described as genomic indicators of PTSD vulnerability. Recent studies provide evidence that epigenetic mechanisms and ncRNA are also involved in the development of PTSD, increasing the molecular complexity further. An initial animal model study examining DNA methylation of the brain-derived neurotrophic factor (*BDNF*) gene in rat models of PTSD found a significant increase in *BDNF* DNA methylation in the dorsal hippocampus, the highest increase in the dorsal CA1 subregion, and a significant methylation decrease in the ventral hippocampus (CA3) following the stress regimen (Roth et al., 2011). However, this study has found no change in *BDNF* DNA methylation in the medial PFC or basolateral amygdala. Interestingly, the mRNA levels of *BDNF* decreased in both the dorsal and ventral CA1, providing key evidence that traumatic stress can induce central nervous system (CNS) gene methylation and alter gene expression in key brain areas, leading to the pathophysiology of PTSD.

A recent study on African Americans involved in the Grady trauma project, which investigated the relative contribution of genetic and trauma-related risk factors for PTSD in a cross-sectional study of a highly

traumatized, low-socioeconomic-status, minority urban population, has found that DNA demethylation altered the transcription of *FKBP5*, leading to long-term dysregulation of the stress hormone system for stress regulation associated with PTSD (Klengel et al., 2013). It has been reported that PTSD patients who faced significant abuse in childhood displayed more changes in gene expression associated with CNS development and immune system regulation, whereas those without a history of childhood abuse displayed more changes in gene expression associated with cell death and growth rate regulation. Specific altercations in the DNA methylation profile were up to 12-fold higher in PTSD patients with a history of childhood abuse (Mehta et al., 2013). In a similar study, gene expression profiles in the dorsolateral prefrontal cortex Brodmann area (BA) of 46 postmortem patients with or without PTSD have been investigated using human mitochondria-focused cDNA microarrays (hMitChip3) (Su et al., 2008). A total of 119 differentially expressed genes were found between the control and PTSD patients, and the majority of the genes altered in the PTSD samples belong to the neuronal function-survival networks. Similarly, a recent study using bold sera from US military service members evaluated temporal changes in DNA methylation in select promoter regions of immune system–related genes between PTSD diagnosis, pre- and post-diagnosis, and in control patients. This study found reduced mC levels at the promoter regions of a long-ncRNA H19 and interleukin-18 (IL18) in those who did not develop PTSD after deployment, while those who did develop PTSD had increased levels of IL18 (Rusiecki et al., 2013).

MicroRNA (miRNA) has recently emerged as an epigenetic modulator of gene expression in psychiatric diseases like schizophrenia and depression (Miller and Wahlestedt, 2010). miRNAs are short, single-stranded RNA sequences that regulate gene expression by binding to the regulatory regions of mRNA and preventing translation, representing another mechanism of regulating gene expression besides up- or down-regulation of transcription (Fabian et al., 2010). In a recent study reporting the connection between miRNAs and PTSD, miRNA profiles of the PFCs from fluoxetine-treated and control wild-type C57BL/6N mice were dissected 74 days after they were subjected to either a single, traumatic electric shock to the foot or a mock treatment (Schmidt et al., 2013). Fluoxetine is an antidepressant effectively used both in PTSD patients and in mice suffering from a PTSD-like syndrome. Using miRBase 18.0 screening and qRT-PCR validation, the study found five miRNAs, including one (mmu-miR-1971) that showed significant reduction in fluoxetine-treated shocked mice.

The relevance of the noncoding genome to human disease has mainly been studied in the context of the miRNA expression and function. However, it is still a beginning of the recognition of the nature and extent of the involvement of other ncRNA in disease. A GWAS of PTSD was conducted using a group of primarily African-American women from the Detroit Neighborhood Health Study that included 94 PTSD cases and 319 controls exposed to at least one traumatic event, as well as an independent cohort of primarily European-American women from the Nurses' Health Study II, which was composed of 578 PTSD cases and 1,963 controls (Su et al., 2008). More than 700,000 markers were screened using Illumina HumanOmniExpress BeadChip. The results found a genomewide significant association of one marker mapping to a novel RNA gene, lincRNA AC068718.1. The study also performed pathway analysis to obtain a protein functional interaction network, and found pathways related to telomere maintenance and immune function. This study demonstrated the emerging evidence that noncoding RNAs may play a crucial role in shaping the landscape of gene regulation with putative pathological effects that lead to phenotypic differences.

TOXIC CHEMICAL EXPOSURE AND HUMAN DISEASES

Scores of studies point to the influence of an individual's genetic information and social conditions in the development of PTSD. However, it is also important to address the role of other external factors, such as brain cell damage and nervous system damage caused by chemical exposure. It has been reported that residents from regions of high-intensity warfare and chemical weapons during the Iran–Iraq war (1980–1988) had a significantly higher risk of meeting the criteria for lifetime and current PTSD compared with the residents of high-intensity warfare alone (Hashemian et al., 2006). Currently, PTSD development following trauma or exposure to chemical warfare agents (CWAs) is poorly understood. Although every individual with PTSD has been exposed to a traumatic event, studies show that the majority of people who experience trauma do not develop PTSD. It is intriguing why some people remain resilient, some experience short-term difficulties, and others develop a chronic problem such as PTSD.

According to the Research Advisory Committee report on "Scientific Progress in Understanding Gulf War Veterans' Illnesses: Report and Recommendations," almost 30% of the veterans from the Gulf War were disabled by chronic symptoms such as severe headaches, memory problems, confusion, dizziness, blurred vision, and tremors (http://www.va.gov/RAC-GWVI/Gulf_War_Illnesses_links.asp). Notably, Gulf War veterans have developed amytrophic lateral sclerosis at twice the rate of veterans who did not serve in the Gulf War. Based on the research data collected, the committee identified

the nerve gases sarin and pyridostigmine bromide, as well as multiple pesticides, as potential factors in the development of neurological disorders. More research is needed to better understand the veterans' vulnerability to PTSD after exposure to CWAs, especially to consider why only a small portion of the veterans who experienced childhood abuse developed the symptoms.

GENOMIC APPLICATIONS: UNDERSTANDING THE RELATIONSHIP BETWEEN PTSD AND CHEMICAL TOXICITY

The development of modern genomic analysis techniques offers an unparalleled opportunity to investigate neurological diseases such as PTSD due to exposure to CWAs and other toxic chemicals. CWAs like organophosphate (OP) insecticides and nerve gases are capable of changing neuronal activity, primarily via cholinergic pathways. These CWAs bind irreversibly to acetylcholinesterase (AChE), an important regulator of the neurotransmitter acetylcholine (ACh) that leads to lasting changes in neuronal activity. Studies in rodent brains have shown that the exposure could affect brain regions critical for attention, anxiety, and addiction. Nerve agents affect the CNS and the peripheral nervous system, as well as the cardiovascular, respiratory, gastrointestinal, and metabolic systems. Most importantly, they cause behavioral and psychological changes in humans that lead to memory loss and depression. One of the nerve agents used in previous wars, sarin, is suspected to be one of the key factors responsible for Gulf War syndrome.

Animal models have greatly aided our understanding of the effects of CWAs on the cellular functions, molecular pathways, organ functions, and gene expression changes that are observed in humans. Earlier studies on rats showed that sarin usually induced neurotoxicity by affecting the mRNA expression of alpha tubulin in the CNS. The study used northern blots to look at the differential expression of alpha tubulin mRNA in different regions of rat brain. Another similar study found a differential distribution of AChE mRNA expression following exposure to sarin (Damodaran, 2003). These studies clearly showed that exposure to sarin causes gene expression changes in the CNS that may lead to neurotoxicity, as well as behavioral and psychological changes. Another study looked at sarin-induced global gene expression pattern changes at different times after exposure by microarray (Damodaran et al., 2006). Analysis of gene expressions at an early point (15 min; 0.5 × LD_{50}) and a later point (3 months; 1 × LD_{50}) identified specific gene expression changes to each time and seven genes that were consistently altered in both time points (Ania-9, Arrb-1, CX-3C, Gabab-1d, Nos-2a, Nrxn-1b, and PDE2). Further genomewide study in the rat brain at another early point (2 h: 0.5 × LD_{50}) following sarin exposure showed that 46 genes were significantly altered compared to the control animals. Most of these 46 genes belong to ion channels, calcium channels, and binding proteins. The study also found that many genes are involved in the pathogenesis of sarin-induced pathology and OP-induced delayed neurotoxicity. These studies indicate that exposure to sarin can lead to neurodegeneration at a later time and result in neuropathological alterations. Pachiappan and colleagues applied single (3 and 24 h) or repeated (2 × 24 h) doses of sarin (5 μg/mL) on human neuronal cells (SH-SY5Y) to identify altered gene expressions (Pachiappan et al., 2009). Microarray analysis in this study identified over 200 genes that were significantly altered following sarin administration. The study also found that repeated doses over 48 h persistently down-regulated genes linked to neurodegenerative mechanisms, which indicates the adverse effects of sarin exposure for a prolonged time.

O-ethyl-*S*-2-diisopropylaminoethyl methylphosphonothiolate (VX), another member of the family of OP compounds used in chemical warfare, is a very potent nerve agent. A recent microarray study using cultured human neural cells (hN2) exposed to 0.1 or 10 μM of VX for 1 h has shown changes in gene expressions after 6, 24, and 72 h (Gao et al., 2013). The altered genes were subjected to functional pathway analysis, and many of them were found to be involved in pathways related to nervous system development and function. Advancement in genomics may also shed light on some other poorly understood toxic effects of nerve agents. It has been reported that civilians exposed to industrial OPs, such as pesticides, have a higher incidence of Parkinson's disease (Hatcher et al., 2008; Manthripragada et al., 2010), although it is not clear whether nerve agents lead to similar neurodegenerative effects. There are many relevant questions about neurological disorders and the use of CWAs. Some questions to be asked are as follows: Are long-term regional differences seen in the brain after nerve agent exposure also reflected in large-scale gene expression changes? Can changes in gene expression profiles be correlated with altered behavioral patterns? And does neuroinflammation, one of the acute effects of nerve agents (Svensson et al., 2001; Williams et al., 2003; Chapman et al., 2006), diminish across time? Genomics analysis of subjects exposed to CWAs may provide ample information to answer these questions and provide additional information in the efforts to understand the spectrum of chronic effects of nerve agent exposure.

Microarrays are still highly useful to characterize changes in gene expression due to a toxicant of interest, identify up- or down-regulated genes, map regulatory pathways modulated by the toxicant, and, in the case

of CWAs, identify potential therapeutic targets in these pathways (Thomas et al., 2001; Hamadeh et al., 2002). Nevertheless, RNA-Seq offers high technical reproducibility and large dynamic range compared to microarrays, and it can be used effectively to identify differential gene expression to understand complex disorders like PTSD. Recent efforts, such as the STRONG STAR Consortium to Alleviate PTSD (STRONG STAR-CAP), led by the University of Texas Health Science Center at San Antonio, is employing next-generation sequencing and mass spectrometry (MS) to research PTSD, including treatments. The enormous potential of RNA-Seq is offering an invaluable resource to investigate the transcriptomic profile of the brain in different layers. A similar recent study showed a transcriptomic analysis of distinct regions of a brain with Alzheimer's disease using Illumina RNA-Seq analysis to examine gene expression levels, splicing isoforms, and alternative transcript start sites from the total brain and the frontal and temporal lobes of healthy and Alzheimer's postmortem tissue. The findings reveal a significant representation of genes associated with neuronal cytological structure and synapse function.

PROTEOMICS

High-throughput genomic and transcriptomics approaches are indispensable to understanding the molecular map of complex diseases. However, their application is limited by the fact that they can assess only gene expression changes. Translation of mRNA into protein is a highly regulated and complex mechanism that is modulated at different levels. Effects due to changes in protein expression, modification, or function can lead to the development of diseases and only be inferred from the analysis of protein expression profiling. The proteome was initially defined as the complete complement of proteins that are expressed by a genome; subsequently, it was denoted as "the total set of expressed proteins by a cell, tissue, or organism at a given time under a determined condition" by Wilkins et al. (1996). To assess protein expression status, different proteomics techniques need to be utilized.

Proteomics is widely applied in biological sciences to study protein expression, posttranslational modification, protein-protein interactions, and protein–nucleic acid interactions. It gives a new platform for studying complex biological functions involving large numbers and networks of proteins (Husi and Grant, 2001; Martins-de-Souza et al., 2011). Since Patrick O'Farrell first presented two-dimensional gel electrophoresis (2DE) in 1975, proteomics has given rise to a new scientific approach for comparative global proteome analyses, especially when combined with MS for protein identification. As a result of the development of in-gel digestion protocols and related optimizations (Shevchenko et al., 1996), the resolution power of 2DE can lead to the separation of more than 2,000 protein spots on large-format gels. Thus far, 2DE followed by MS is the most used proteomic technique in studies of psychiatric disorders (Kromer et al., 2005; Ditzen et al., 2006). Typically, mass spectrometers have three main features: an ionization source (e.g., matrix-assisted laser desorption/ionization and electrospray ionization), a mass analyzer (e.g., time of flight and quadrupole), and a detector (Bayes and Grant, 2009), which measures the mass-to-charge (m/z) ratio of ionized particles. The 2DE-MS approach provides direct information on intact proteins and protein isoforms. Figure 46.2 depicts a major technique currently used in proteomics methodology for PTSD diagnosis.

Link et al. (1999) launched shotgun proteomics in 1999, which increased the capacity for proteome characterization. Shotgun-MS was originally designed as a nongel/MS-direct approach, which was regarded as a more sensitive and reproducible proteome representation compared to 2DE proteomics. Shotgun-MS includes shotgun-MS, liquid chromatography-MS (LC-MS/MS), and multidimensional protein identification technology.

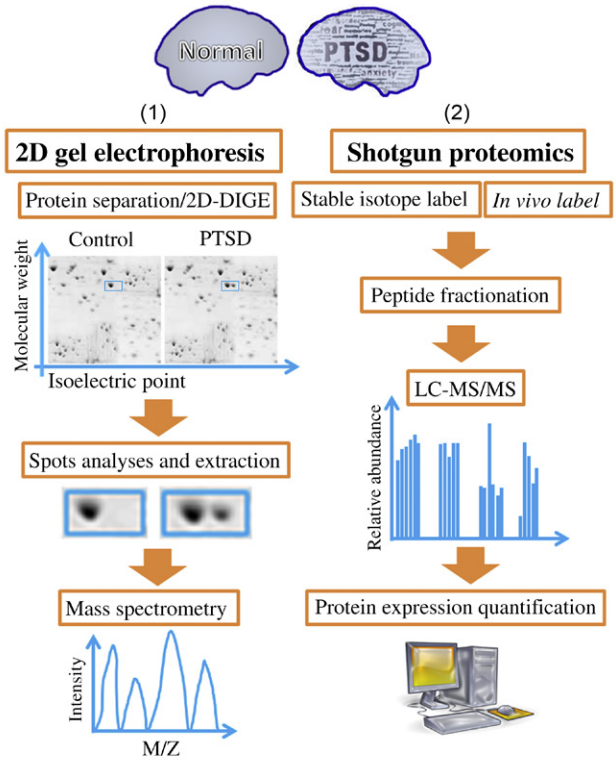

FIGURE 46.2 A major technique used in proteomics methodology for PTSD diagnosis. (1) Two-dimensional gel electrophoresis for proteomics; 2D-DIGE: proteomes mixed in gel; (2) shotgun proteomics methodology.

Basically, this approach involves digesting the whole proteome of interest using specific enzymes and subsequently identifying the resulting peptides by MS, while proteome quantification and sample comparison rely on a label-free MS methodology or stable isotope labeling. MS analysis is capable of identifying small modifications, like point mutations, phosphorylation, and glycosylation; it can also detect the primary structure of proteins and peptides (e.g., amino acid sequences (Davidsson et al., 2003)). Based on its applications, proteomics includes (i) expression proteomics, which studies protein expression profiles; (ii) comparative proteomics, which compares physiological and diseased states; (iii) structural proteomics for structure investigations; and (iv) functional proteomics, which studies the interaction between molecules. Due to its high levels of accuracy and ultrasensitivity, proteomics has become a preeminent tool in many ways, especially in neuroscience (Tyers and Mann, 2003).

NEUROPROTEOMICS: PROTEOMICS APPLICATIONS IN NEUROSCIENCE

Neuroproteomics is the study of the proteomes of the nervous system (Bayes and Grant, 2009), which is of great importance in functional studies. Bayés and Grant (2009) have reviewed four major categories of neuroproteomics, including (i) expression neuroproteomics, which refers to the qualitative and quantitative cataloguing or profiling of neuroproteomes; (ii) functional neuroproteomics, which addresses functional properties of individual proteins, as well as their organization into substructures, complexes, and networks; (iii) clinical neuroproteomics, which includes the identification of biomarkers and disease mechanisms for neurological, neurodegenerative, and psychiatric diseases which also benefit from drug discovery; and (iv) neuroproteomic informatics, which handles analyzing proteomic data sets using computational tools and databases. A typical example of a proteomic approach to study the effects of complex neurological diseases is the shotgun analysis of postmortem dorsolateral PFC brain tissue from major depression disorder (MDD) patients (Martins-de-Souza et al., 2012). Gel electrophoresis, followed by shotgun data-independent, label-free, LC-MS led to identification of distinct proteome fingerprints between MDD and control subjects. Another study tackled the proteomic profile of the anxiety disorder–applied quantitative proteomic approach, where metabolic labeling of the HAB/LAB mouse model with stable isotopes is used to identify a large number of proteins in a high-throughput manner (Zhang et al., 2011). Differentially expressed proteins were subjected to pathway discovery analyses that suggested several biological processes and pathways were affected in the genetic predisposition to extremes in trait anxiety. Although these studies drew no connection between the proteins and pathways connected with PTSD, it may encourage similar efforts in proteomic research.

PROTEOMICS APPROACHES TO UNDERSTANDING NATURAL AND CHEMICAL TOXICITY-INDUCED PTSD

Despite the enormous medical and economic consequences of traumatic injury to the CNS, relatively little study has been directed toward elucidating the proteomic profile of posttraumatic psychopathology, due to the complexity of the molecular mechanisms of the disease. Some of these proteins may serve as diagnostic and prognostic markers to assess the severity of tissue damage. Studies of proteomic biomarkers of PTSD risk have been in play for a long time; yet they have been limited by many technical issues, such as optimizing the sample collection time frame and the variation in the timing between the traumatic incident and the biological sample collection. In spite of these limitations, the initial research provided key insights into the biological mechanisms underlying PTSD vulnerability. A key observation from initial proteomics studies was the high concentrations of inflammatory proteins; together, these studies indicated increased concentrations of inflammatory cytokines related to the risk for PTSD onset (Gill et al., 2008, 2010). Proteomics makes it possible to identify molecular mechanisms and molecular targets for PTSD through a large-scale screen in patients and a validated animal model for protein expression profile analysis. In a recent study, a large-scale proteomic approach and MS with the use of human proteomic databases were employed to identify differential serum proteomic profile in combat-related PTSD and healthy controls (Kozarić-Kovăić et al., 2010). The study found more than 100 proteins expressed differently between individuals with PTSD and healthy controls. These results indicated the direction for a larger analysis of this type in people with PTSD. This pilot study offers a good basis for further proteomic research, which could help in better diagnosis and treatment of PTSD, as well as clarification of its etiology.

Sulfur mustard (SM, bis-(2-chloroethyl) sulfide), a potent alkylating agent and a chemical reagent used in chemical warfare, is indicated in PTSD development. A quantitative proteomic approach using stable isotope-labeling combined with immobilized metal affinity chromatography tested the effect of SM in a human keratinocyte cell culture model. The study found large-scale protein phosphorylation changes resulting from SM exposure and characterized more than 2,300 phosphorylation

sites, many of which showed altered levels in response to SM treatment. The study also found new proteins that are associated with SM toxicity (Everley and Dillman, 2010).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

It is clear that PTSD is not a monolithic disorder that can be characterized by unique and consistent mental and biological traits, as the development of this disorder results from complex interactions among numerous factors. Genetic background, as well as environmental factors, may contribute to whether one is sensitive to complex circumstances such as trauma exposure, leading to PTSD development. Recent research studies provided solid evidence that specific DNA functions can be modified by such exposure through epigenetic pathways, resulting in alterations in gene expression leading to a pathological phenotype. This chapter provided a comprehensive picture of the technological advances in genotyping, expression profiling, and proteomics, which offer exciting and promising approaches in understanding the basis of PTSD, as well as improved diagnosis and therapy. Additionally, short- and long-term exposure to toxic chemicals, such as OP nerve agents and insecticides, and other CWAs contribute toward PTSD onset. The combination of genomic and proteomic information will allow early and more accurate prediction of individuals' susceptibility to chemical exposure–related trauma, development of PTSD, and disease progression. Although significant discoveries have been made, there is obviously substantial promise and potential remaining to be fully realized through increasing use of and further development of these technologies.

CHAPTER

47

Clinical and Cellular Aspects of Traumatic Brain Injury

Jason Pitt and Yiuka Leung

INTRODUCTION

Generally, traumatic brain injury (TBI) is a sporadic mechanical impact to the head that leads to acute or chronic impairments in neurological function. It is the most common cause of death in North America in individuals between ages 1 and 45 years (Rutland-Brown et al., 2006; Rosenfeld et al., 2012), accounting for 30.5% of all injury-related deaths. There are approximately 1.7 million cases of TBI annually in the United States, leading to 1.4 million emergency department (ED) visits, 275,000 hospitalizations, and 52,000 deaths. Costs of TBI, including direct medical expenses and indirect costs related to loss of productivity, amount to an estimated $76.5 billion each year. TBI occurs most commonly to children aged 0–4 years, adolescents aged 15–19 years, and adults older than 65 years. The leading causes of TBI-related deaths were injuries by firearms (34.8%), motor vehicle accidents (31.4%), and falls (16.7%). TBI-related death rates are highest in adults older than 75 years, and males are more likely to die from TBI than females across all age groups (Faul et al., 2010).

Our understanding of the pathophysiology of TBI has been advanced primarily through the use of several rodent models (Figure 47.1). This chapter summarizes our understanding of the cellular and molecular mechanisms that account for neurological abnormalities observed after TBI. The points of this work can be summarized as follows: TBI includes both primary and secondary injuries; primary injuries lead to necrosis; secondary injuries lead to apoptosis or alterations in synaptic function; and several pathological changes suggest that TBI is a risk factor for other neurological diseases.

A VARIETY OF MOUSE MODELS ARE USED TO STUDY TBI

Our understanding of the cellular and molecular changes that occur after TBI have been advanced through the use of animal models of TBI. In general, animal models of TBI deliver mechanical forces to the skull in a controlled manner. Many of the outcomes in animal models mimic those observed in human TBI, such as concussion, contusion/hemorrhage, and diffuse axonal injury (DAI). As with any experimental model, however, there is a trade-off between reproducibility and physiological relevance. A brief description of commonly used animal models of TBI follows. Readers interested in further details about different animal models of TBI should read the work by Xiong et al. (2013).

Highly reproducible models include fluid percussion injury and controlled cortical impact. In fluid percussion injury, a pressure pulse is sent through a fluid reservoir placed on the exposed dura. This pressure pulse displaces the brain to generate focal and diffuse injuries. Controlled cortical impact drives a rigid object directly onto the exposed dura. Both of these models require removal of a portion of the skull (craniotomy). This decreases variability of the injury but reduces the physiological relevance of the TBI.

More biomechanically relevant models include blast injuries, penetration injuries, weight-drop, and repeated mild injuries. Blast injuries deliver a pressurized gas wave to the head. Because this model uses a pressure wave that is difficult to focus, the animal's body must be protected using a Kevlar jacket. Blast injuries are excellent models of TBIs suffered as a result of improvised

Handbook of Toxicology of Chemical Warfare Agents.

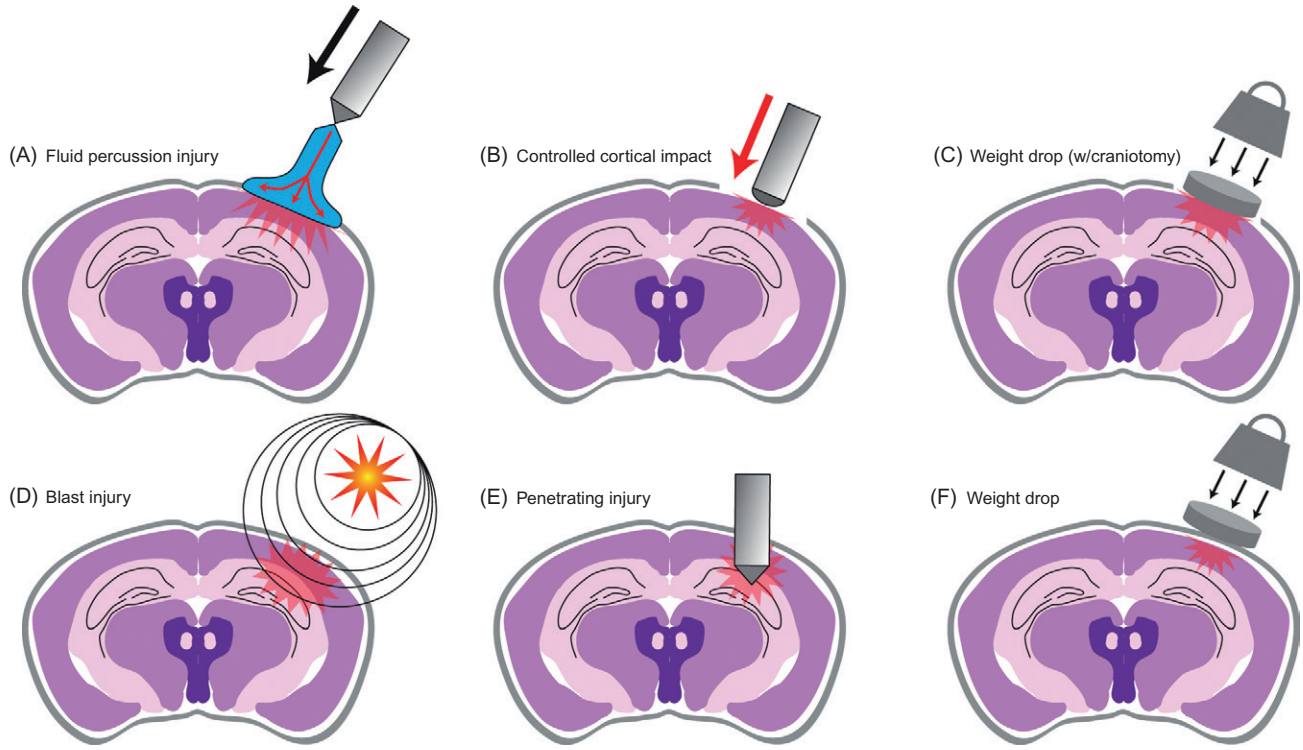

FIGURE 47.1 Mouse models of TBI.

explosive devices, which are the primary cause of head injuries in modern military conflicts. Penetrating injuries drive a projectile into the brain with high energy to mimic TBIs that occur from gunshot wounds. In weight-drop models, a free-falling weight is dropped on the exposed skull. In some weight-drop models, a craniotomy is performed to increase reproducibility.

Repeated mild injury models are of particular interest because they mimic injuries that occur in contact sports. Repeated injuries have been delivered using fluid percussion, blast, and weight-drop models. Although more characterization is needed, repeated mild injury models suggest that even mild TBIs can produce rapid, disastrous effects.

CLINICAL MANIFESTATION AND MANAGEMENT OF TBI

TBI Is Usually Classified Using the Glasgow Coma Scale

TBI is a heterogeneous entity. The severity of TBI can be classified according to various injury scoring systems, with each carrying different impacts on prognosis and treatment. The most commonly used scoring system is the Glasgow Coma Scale (GCS) at initial presentation (Vos et al., 2002; Moppett, 2007) (Table 47.1). A GCS score

TABLE 47.1 Using the GCS to Assess Head Injury Severity

Behavior	Response	Score
Eye opening	Open and blinking spontaneously	4
	Open to verbal stimuli	3
	Open to painful stimuli	2
	No response	1
Verbal	Aware of self, time and location	5
	Slight confusion	4
	Inappropriate replies	3
	Incomprehensible replies	2
	No reply	1
Motor	Follows commands	6
	Appropriate purposeful withdrawal from pain	5
	Normal flexion in response to pain	4
	Abnormal flexion in response to pain	3
	Extension in response to pain	2
	No response	1

Classification:
Coma—3
Severe head injury—4–8
Moderate head injury—9–12
Mild head injury—13–15.

of 13–15 is considered mild injury, 9–12 is moderate, and 8 or less represents severe TBI. The initial severity of TBI has prognostic value regarding the long-term outcome of the injury (Thornhill et al., 2000). Although the majority of TBI cases are mild (>75%) (Faul et al., 2010), the minority of patients presenting with moderate or severe TBI have a very poor prognosis, with mortality rate as high as 55%. Of all patients with a post-TBI GCS of 12 or less, 2% die within the first hour and 8% die within the first 6 h (Peek-Asa et al., 2001).

Although the GCS excels as a universal tool for TBI classification because of its simplicity, reproducibility, and prognostic power, its use may sometimes be limited by clinical confounders, such as anesthesia, sedation, paralysis, and coexisting intoxication. These confounding factors are especially prominent in patients with a low GCS score (Stocchetti et al., 2004). Hence, CT-based scoring systems are sometimes used by neurotrauma centers for a more objective classification on TBI. These include the Marshall scale, which has been shown to be accurate in predicting risks of increased intracranial pressure (ICP) but lacks reproducibility in cases of multiple brain injuries (Marshall et al., 1992), and the Rotterdam scale, which was developed more recently to overcome the limitations of the Marshall scale but still lacks validation in large populations (Maas et al., 2005). The details of these scales are beyond the scope of this chapter.

Primary Brain Injury and Secondary Insults Are Two Distinctive Phases of TBI

TBI is often divided into two distinct but related phases: primary brain injury and secondary insults (Werner and Engelhard, 2007; Greve and Zink, 2009). Clinically, primary brain injury often requires surgical attention, whereas secondary injury is managed in the intensive care setting, where the prevention and treatment of these secondary insults become the major focus of neurotrauma intensivists. Primary brain injury happens at the time of the initial mechanical impact to the skull.

The transfer of external mechanical forces to intracranial contents can lead to intra-axial damage and/or extra-axial injuries. Intra-axial damage involves the brain parenchyma. Focal cerebral contusions occur most commonly after TBI. Injuries involving abrupt acceleration/deceleration result in direct resonant impact of the brain with the base of the skull. Hence, the basal, frontal, and temporal areas are especially susceptible to contusion due to their anatomical distribution in relation to the bony areas of the cranial vault. In addition, shearing forces during mechanical impact can cause DAI. Patients with DAI often present with profound coma without elevated ICP, and often have a very poor prognosis. The cellular and molecular outcomes of intra-axial damages are described in greater details in other sections of this chapter.

Extra-axial damage involves nonbrain cranial structures. Penetrating trauma, blast waves, or direct impact can result in skull fracture and rupture of intracranial vessels. Depending on the location of the impacting force, different types of hematomas may result.

1. Epidural hematoma (EDH). Direct impact to the lateral surfaces of the head may cause rupture of the middle meningeal arteries embedded within the dura, forming an EDH. EDHs usually appear as a well-demarcated, biconvex lens-shaped density on CT scan. Bleeding in EDH is usually from a high-pressure arterial source but is initially tamponaded by the tightly tethered dura. However, as the hematoma expands and strips the dura from the skull, it gradually creates an intense headache. Classically, patients with EDH are described as having a lucid period right after injury, when bleeding is still contained and tamponaded by the dura. This lucid period is followed by sudden loss of consciousness, when expansion of hematoma becomes large enough to cause significant increase in ICP and compression or herniation of brain tissue.
2. Subdural hematoma (SDH). Impact to the frontal regions, as well as shearing forces from linear or rotational acceleration/deceleration, can tear the subdural bridging veins and result in SDH. On CT, SDHs appear as poorly demarcated crescent-shaped densities. Unlike EDH, SDH occurs between the dura and the arachnoid layers. Hence, SDH lacks the additional layer of "protection" offered by the rigid dura. Clinically, patients with SDH present with gradually increasing confusion and headaches. Acute SDH has a high mortality rate and often requires prompt surgical evacuation.
3. Subarachnoid hemorrhage (SAH). SAH refers to bleeding that occurs in the subarachnoid space, which is between the arachnoid and pia mater and is normally filled with cerebrospinal fluid (CSF). The majority (>85%) of SAHs occur in patients with a preexisting intracerebral vascular lesion, most commonly an aneurysm (van Gijn and Rinkel, 2001), which serves as a functional weak point that is susceptible to rupture when intravascular pressure is elevated. However, in the setting of trauma, sufficient external forces could lead to rupture of intracerebral vessels without preexisting vascular abnormalities. Radiologic clues for traumatic SAH include localized bleeding in the superficial sulci, adjacent skull fracture, cerebral contusion, as well as external evidence of traumatic injury (Rinkel et al., 1993). Clinical suspicion for SAH should be high for patients reporting sudden, severe headaches (often

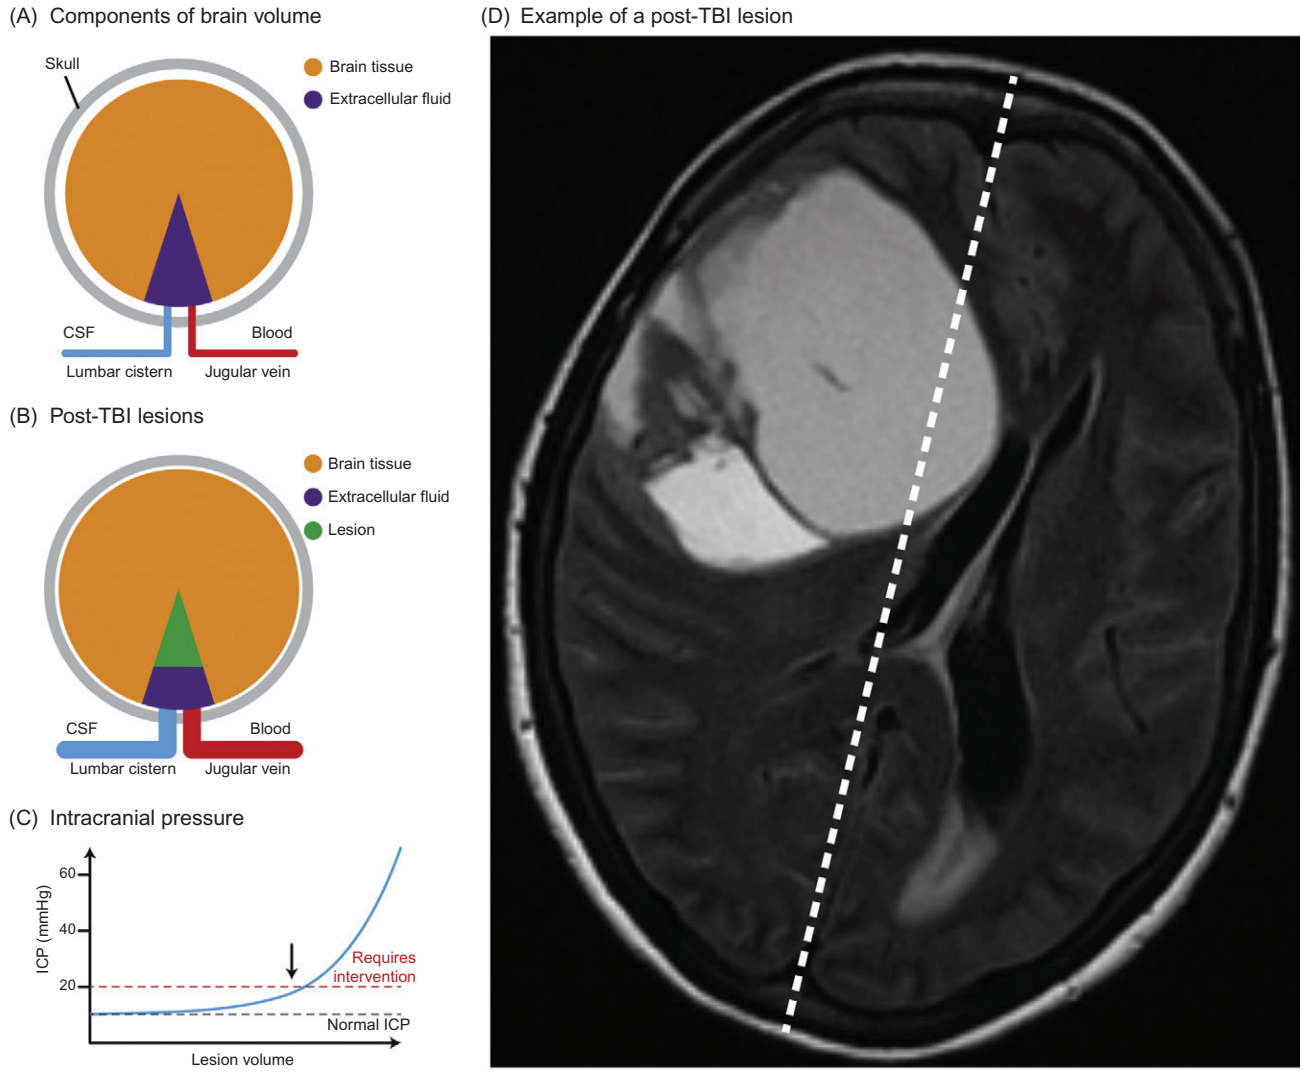

FIGURE 47.2 Regulation of brain volume is critical for maintaining safe ICP. (A) Brain tissue and the extracellular fluid (comprising blood and CSF) contribute to normal brain volume. (B) Brain lesions that occur after TBI increase intracranial volume. (C) An initial increase in intracranial volume only leads to minimal increase in ICP because of a compensatory outward flow of CSF and blood. Once this protective mechanism has been exhausted (arrow), ICP begins to increase with a steep slope. (D) Magnetic Resonance Imaging (MRI) showing midline shift of brain contents secondary to decompensated increase in intracranial volume (in this case by a growing tumor). Loss of sulci/gyri prominence and asymmetric compression of ventricles are seen. White line depicts the expected midline of the brain.

described as "thunderclap" headache or "the worst headache of my life"). In these cases, emergent CT of the head should be obtained. If CT fails to identify intracranial bleeding but clinical suspicion for SAH remains high, then a lumbar puncture must be performed to look for blood in the CSF.

Intracranial bleeding after TBI can be further exacerbated by coagulopathies, which develop in up to one-third of TBI patients (Zehtabchi et al., 2008; Allard et al., 2009; Wafaisade et al., 2010). Coagulopathies may result either from underlying anticoagulation medications (e.g., warfarin, clopidogrel) or from TBI-induced platelet dysfunction, release of systemic tissue factor, and activation of endogenous anticoagulation pathways (Maegele, 2013). All hematomas, intracranial bleeding from penetration injuries or skull fracture, entrainment of air, or foreign objects can all result in increases in ICP. In the acute setting, rapid increases in ICP can cause brain tissue to herniate within the skull, which can lead to compression of cranial nerves, leading to various neurological findings. The most dreaded complication is brain stem compression, which leads to suppression of many neurological functions important for survival, such as regulation of respiration and circulation (Figure 47.2).

Secondary insults of TBI result from cellular perturbations caused by primary injury. Secondary injury can happen at any later time point after the initial impact.

Although the primary injury of TBI is a major predictor of outcome, secondary insults can contribute to further worsening of prognosis (McHugh et al., 2007).

The mechanisms of secondary injury include neurotransmitter-mediated excitotoxicity, free-radical injury to cell membranes, electrolyte imbalances, mitochondrial dysfunction, inflammatory responses, apoptosis, secondary ischemia from vasospasm, focal microvascular occlusion, and vascular injury (Werner and Engelhard, 2007). These events can lead to cerebral edema and further increases in ICP. The detailed molecular mechanisms of these events are described later in this chapter.

A critical aspect in post-TBI intensive care management is the avoidance of these secondary brain insults, which would otherwise be well-tolerated but can exacerbate neuronal injury in cells made vulnerable by the initial TBI. Of particular importance is the prevention of hypotension and hypoxia (which decrease substrate delivery of oxygen and glucose to injured brain), fever and seizures (which may further increase metabolic demand), and hyperglycemia (which may exacerbate ongoing injury mechanisms), as discussed in the following sections.

TBI management focuses on stabilization of primary injury and prevention of secondary injury. We discuss management strategies during the early resuscitation period, as well as postresuscitation intensive care therapeutic goals. It is important to remember that at any period after TBI, the main goal is to avoid hypoxia and hypotension, the two most critical factors in predicting post-TBI outcome (Manley et al., 2001; Brain Trauma Foundation et al., 2007a; McHugh et al., 2007). Presence of prehospital hypoxia (PaO_2 <60 mmHg) and hypotension (systolic pressure <90 mmHg) is strongly associated with a poorer outcome (OR, 2.1 [95% CI, 1.7–2.6] and OR, 2.7 [95% CI, 2.1–3.4], respectively) (McHugh et al., 2007).

Immediate Care After TBI Shares the Same Principles as Advanced Life Support

For TBI patients and patients on advanced life support (ALS), the primary focus is on securing airway, breathing, and circulation (the ABCs of ALS). This may require intubation to maintain adequate oxygenation and fluid resuscitation or use of pressors to maintain perfusion pressure. The patient's heart rate, blood pressure, respiratory rate, and temperature should be continuously monitored. Neurological examination should be performed to assess the GCS score, and should be reassessed at regular intervals. A secondary survey should be performed to assess other extracranial injuries. All patients with TBI should be assumed to have an unstable cervical spine, and precautions should be applied to stabilize the spine (e.g., using a C-collar, "log-roll" precautions) to avoid cervical spinal cord or brain stem impingement during movements of the head. Blood should be sent to check for complete blood count, glucose, electrolytes, blood gases, and pH, as well as toxicology screen. As soon as the patient is stabilized, CT scan of the head should be obtained. CT can reveal skull fractures, intra-axial or extra-axial hemorrhages, significant brain contusions, and edema, which can guide downstream treatment strategies. If initial neurological examination or imaging shows findings suggestive of decompensated ICP elevation and impending herniation (Figure 47.2), then emergent treatment should be started immediately, including head elevation, maneuvers to improve venous drainage, and osmotic therapy.

Surgical Management is Often Necessary for Primary Injury

Timing and indications for surgical intervention after TBI are based on neurological status and radiological findings. Intracranial bleeding extrapleural hematoma (EPH), SDH, SAH causing significant midline shift should be evacuated surgically regardless of hematoma size. In the absence of midline shift, surgical evacuation of hematomas is recommended if the blood volume is large, or if the patient has a GCS less than 8. For penetrating injuries and skull fractures, surgery for superficial debridement and repair of dural tears and CSF leaks are often recommended. However, debridement of deeper tissues and aggressive extraction of intracranial foreign bodies and bone fragments have not been shown to improve outcome or prevent delayed infection, as long as prophylactic broad-spectrum antibiotics are administered in the setting of penetrating injuries. Occasionally, decompressive craniectomy (removal of a substantial portion of the skull) is performed in conjunction with hematoma evacuation to help decrease ICP. However, the efficacy of decompressive craniectomy in outcome improvement is still controversial, and ongoing clinical trials are underway to determine the benefits versus risks of this technique (Jiang et al., 2005; Cooper et al., 2011; Ho et al., 2011; Servadei, 2011).

Targeted Therapies Are Used to Prevent Secondary Injury in the Intensive Care Unit

After the initial resuscitation phase, TBI patients are monitored in the intensive care unit (ICU), where the major goal of care is to maintain cerebral and systemic perfusion, to correct electrolyte and coagulation abnormalities, and to minimize secondary insults.

Maintenance of Adequate Cerebral Perfusion Improves Outcome after TBI

Adequate cerebral perfusion pressure (CPP) is essential to prevent cerebral ischemia or toxic pooling

of inflammatory mediators. Optimal CPP after TBI is between 50 and 70 mmHg, with 60 mmHg being the target (Elf et al., 2005; Jaeger et al., 2010). CPP is equal to mean arterial pressure (MAP) minus ICP (CPP = MAP – ICP). Because CPP cannot be readily measured, MAP and ICP are used as surrogate measures. Goal CPP should be achieved first by reducing ICP, then optimizing MAP.

Patients with TBI should be positioned strategically to minimize ICP elevation. Head of the bed should be elevated to 30°. The neck should be in a neutral position without external compression to ensure adequate venous drainage from the brain to the heart. ICP monitoring is invasive, requiring surgical insertion of a ventricular catheter, but it is indicated in severe TBI (Brain Trauma Foundation et al., 2007b). Ventricular catheters are both diagnostic and therapeutic, allowing drainage of CSF if ICP is too high. In general, CSF drainage is recommended if ICP increases to more than 20 mmHg (Chesnut et al., 2012). If CSF drainage alone is inadequate, then osmotic therapy with hyperosmolar agents (mannitol or hypertonic saline) should be considered. These hyperosmolar agents create an osmotic gradient that draws water across the blood–brain barrier (BBB), thereby decreasing interstitial volume in the brain. Caution should be applied when using these agents, because they invariably trigger diuresis and may lead to an acute decrease in MAP.

MAP can be maintained with fluid infusion and the use of vasopressors. Normal saline is the fluid of choice to maintain euvolemia. Use of albumin is associated with a twofold increase in mortality and should be avoided (Chesnut et al., 2012). Infusion of excessive volume should also be avoided, because hypervolemia may cause further ICP elevations by raising central venous pressure and impeding venous return from the brain. In addition, hypertension may exacerbate intracranial hemorrhage.

Other Targeted Therapies

Many pharmacologic agents and therapeutic strategies have been tested in clinical trials for management of secondary insults after TBI. Unfortunately, no specific neuroprotective agent or strategy has been shown to improve outcome (Maas et al., 2008).

Hyperglycemia or hypoglycemia should be avoided. Hyperglycemia is associated with poor outcome after TBI and should be avoided. However, aggressive treatment of hyperglycemia with insulin infusions has the risk of iatrogenic hypoglycemia, which also leads to adverse outcomes. Glucose control remains a controversial issue in TBI and other critical care arenas. There is a lack of consensus on the exact range of target glucose levels. In general, it is recommended to avoid extremes of hyperglycemia or hypoglycemia.

Normothermia should be maintained. Prehospital hypothermia is strongly associated with poorer outcome after TBI (McHugh et al., 2007). However, hyperthermia has been postulated to exacerbate secondary inflammatory insults. There is no clear evidence, however, that hyperthermia leads to worsened neurological damage or outcome (Childs, 2008). Despite many clinical trials, neither therapeutic hypothermia nor antipyretic treatments have been shown to correlate with improved mortality or morbidity (Henderson et al., 2003; Sydenham et al., 2009). Hypothermia could potentially lead to coagulopathies, metabolic derangements, and increased infections, and is thus not recommended as routine practice.

Early use of antiepileptics may improve outcome. Posttraumatic seizures (PTS) may develop in up to 20% of patients with TBI (Temkin et al., 1990). Seizures increase cerebral blood flow and metabolic demand, which increases ICP and aggravates secondary brain injury (Vespa et al., 2007). Thus, early antiepileptic therapy is recommended, which can reduce the rate of early PTS, but does not prevent later development of PTS (Temkin, 2001).

Glucocorticoids may worsen outcome. Steroids were considered in the treatment of TBI due to postulated potential in reducing inflammation and edema. However, a large clinical trial showed that use of methylprednisolone in early TBI is associated with increased mortality without benefits (Roberts et al., 2004; Edwards et al., 2005). Thus, the use of glucocorticoids is not recommended.

TBIs INCREASE ICP

TBI is often associated with brain edema (or brain swelling), which increases ICP. It is important to note that there are two types of brain edema: cytotoxic brain edema and vasogenic brain edema. Cytotoxic brain edema is caused by disturbances in the osmotic balance of neural cells, such that increased water influx leads to necrosis, as observed in cases of excitotoxicity. Vasogenic brain edema involves disruption of BBB integrity. The BBB is a series of tight junctions between vascular epithelial cells. These tight junctions are dynamic structures that are maintained by the astrocytic endfoot processes that line the vascular epithelium. In pathological states (such as TBI), the tight junctions between epithelial cells are replaced by porous structures that allow the entry of large macromolecules (and their accompanying solvent) into the brain.

To understand the relationship between ICP and brain herniation, it is important to conceptualize the cranium as a rigid vault packed with three major components: brain tissue (~80%), blood (~8%), and CSF (~12%). The physical law of compliance governs the relationship

between ICP and the volume of these three components: an increase in pressure leads to a decrease in volume. Blood and CSF, both being fluids, are much more easily displaced than the solid brain parenchyma. Hence, when intracranial volume increases (e.g., due to acute intracranial bleeding), CSF and blood are the first components to be "pushed out" of the cranial vault. ICP drains from the cranium into the communicating subarachnoid space in the spinal column, whereas venous blood drains back to the heart. The flexibility of CSF and blood volume within the cranium creates a compensatory "cushion," such that increases in intracranial volume do not lead to elevated ICP initially. This "cushioning" effect lasts for as long as there is blood or CSF to be displaced. However, when intracranial volume expands beyond a certain level, this compensatory mechanism becomes exhausted. ICP will now begin to increase steeply with further volume expansion (Figure 47.2), and brain tissue now becomes the only other element left to be compressed by the increased ICP. Such compressive forces can lead to herniation of the brain across various weak points in the brain or across the tentorium. Brain herniation manifests with a wide variety of clinical signs and symptoms, depending on the area of the brain being compressed. Compression of the brain stem can lead to respiratory center depression and cardiac arrest. Other ominous signs suggestive of impending herniation include unilaterally or bilaterally fixed and dilated pupil(s), decorticate or decerebrate posturing, and the Cushing triad (bradycardia, hypertension, and respiratory depression).

Because a TBI that increases ICP is likely to have a poor outcome, it was thought that preventing edema would have therapeutic benefits. However, antiedematous therapy (e.g., steroids, superoxide dismutase, calcium antagonists, and inhibitors of bradykinin and glutamate receptors) has not proved effective in clinical trials conducted after TBI (Unterberg et al., 2004). This suggests that management of functional impairments associated with TBI will require targeting more upstream changes in cell signaling pathways. In line with this, intracranial lesions do not always lead to increased ICP, and increased ICP does not always equate increased risk of herniation. In certain conditions, such as pseudotumor cerebri, ICP can be chronically elevated but well-compensated with decreased ventricular size and intracranial CSF volume. Hence, patients with pseudotumor cerebri are not at significantly increased risk for brain herniation. Neuroimaging can be helpful in assessing the degree of intracranial distortion from elevated ICP. Concerning radiological findings suggestive of decompensated ICP elevation include loss of gray/white distinction, loss of sulci/gyri prominence, asymmetrical compression or enlargement of ventricular space, mass effect (distortion of size or position of normal brain structures), and midline shift (Figure 47.3). These findings should prompt immediate medical or surgical therapy.

COGNITIVE IMPAIRMENTS AFTER TBI RESULT FROM NEURONAL AND SYNAPTIC LOSS

Memories are stored in the connections between neurons (termed synapses). Our ability to form, recall, and lose memories requires the formation, maintenance, and loss of specific synapses. In general, we consider memories to be stored in two broad areas: the hippocampus (for short-term memories) and the cerebral cortex (for working and long-term memories). The cerebral cortex is also responsible for coordinating our conscious behavior based on multiple factors, including sensory information, emotional states, and previous events. Our seamless encoding of conscious experience is attributed to a vast network of synaptic connections within and between the cortex and hippocampus (Figure 47.3). As such, the loss of neurons and synapses is attributable to the cognitive decline observed in many pathological states, including TBI. In fact, impaired short-term memory and attention are characteristic of the majority of all TBIs (Faul et al., 2010). The superficial location of the cerebral cortex makes it particularly vulnerable to TBI.

Neuronal Loss Is an Irreversible Cause of Cognitive Impairment

Neurons are polarized cells with a number of extensive projections. In general, neurons receive information at their dendrites or cell body and transmit information along their axons (Figure 47.4). Although a vast oversimplification, it is generally true that more neurons can allow a greater diversity of information to be encoded. Thus, the loss of neurons disrupts information processing and accounts for the severe changes in behavior observed in several neurodegenerative disorders (e.g., Alzheimer disease, Parkinson disease, and Huntington disease).

Cell death can occur through a variety of mechanisms, such as necrosis, autophagy, apoptosis, and necroptosis. Of these, necrosis and apoptosis are highly relevant to TBI. Necrosis is uncontrolled cell death caused by acute disruption of the plasmalemma. In TBI, necrosis can occur through shearing forces that rip apart axons or osmotic imbalance due to hyperactive ionic conductances that occur during excitotoxicity. Conversely, apoptosis is a form of programmed cell death and is controlled by a variety of intracellular signaling cascades. Briefly, apoptosis occurs when contents in the intramembrane space of the mitochondria leak into the cytoplasm. Notable examples include cytochrome c, Smac/DIABLO, and

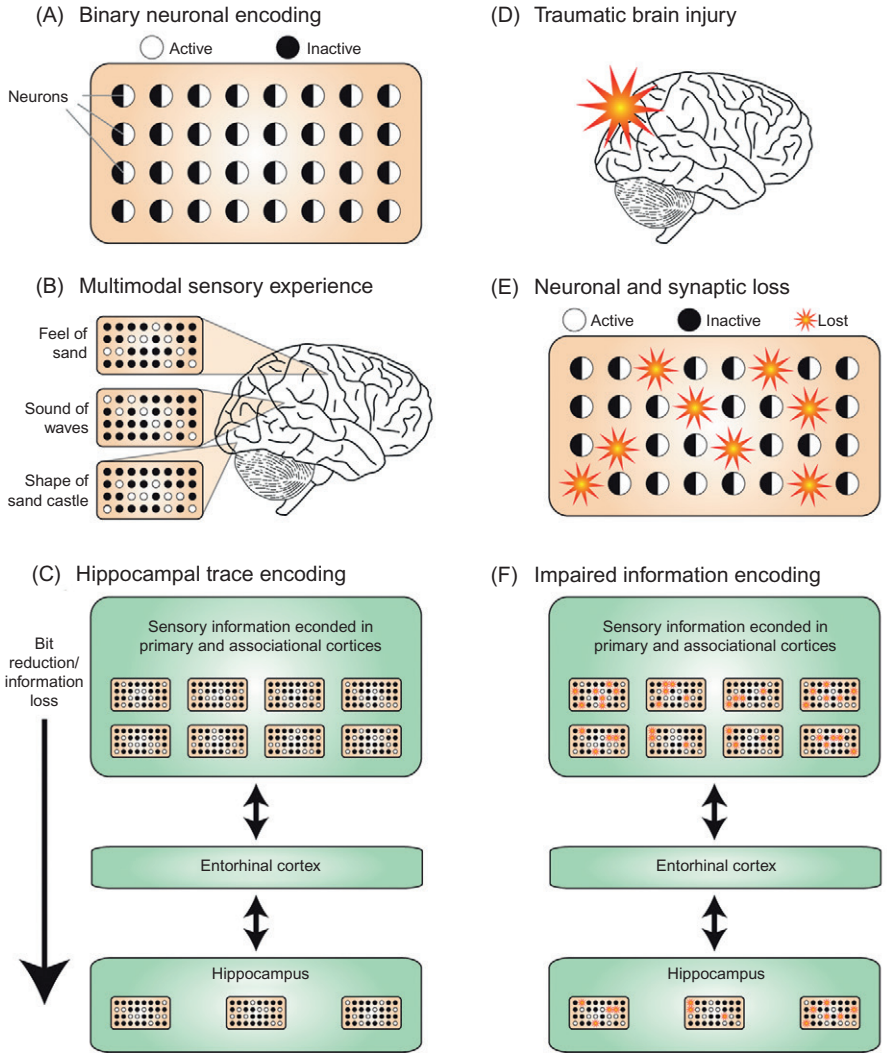

FIGURE 47.3 Cortical and hippocampal networks integrate sensory information. (A) The brain is often thought of as a computer. The binary code used by the brain is the activity (or inactivity) of specific neurons. Even a simple network of 30 neurons can encode more than 100 million (2^{30}) different information states. (B) Different patterns of neuronal activity in distinct brain regions encode a variety of sensory information. (C) Extensive interconnections between the cortex and hippocampus (via the entorhinal cortex) allow the encoding of memory traces and allow us to seamlessly integrate and store a variety of sensory information. Because there are fewer neurons and synapses in the hippocampus than in the cortex, information is lost during the encoding of memory traces, which may contribute to why memories are not as vivid as primary sensory experience. (D) and (E) The loss of neurons that occurs after a TBI reduces the amount of information we can encode. In fact, DAI may also sever connections between brain regions. (F) The result of neuronal loss is impaired information encoding and retrieval. The loss of neurons (and more specifically, synapses) explains the cognitive deficits that occur after a TBI.

Omi/Htra2, which lead to the activation of caspases—cysteine proteases that cleave a variety of intracellular contents. Through autoproteolytic activation, caspases create a feed-forward loop of proteolysis that inevitably leads to cell death. Accordingly, the cell contains the Bcl-2 family of proteins, which regulate mitochondrial permeability and caspase activity. A detailed description of apoptosis and its regulation by Bcl-2 proteins is beyond the scope of this chapter. Readers interested in additional details about the regulatory role of Bcl-2 proteins in apoptosis should read the work by Youle and Strasser (2008).

The loss of neurons through necrotic and apoptotic pathways may explain some of the cognitive impairment that occurs after TBI. Both necrotic cell death and apoptotic cell death are detectable in human cases and animal models of TBI. In controlled cortical contusion rat TBI models, cortical and hippocampal degeneration is evident within hours of injury, and the magnitude of degeneration is related to TBI severity (Sutton et al., 1993). Hippocampal neuron loss is relevant to memory impairments and a feature of the majority of severe TBI cases. A postmortem analysis by Kotapka et al. (1992) demonstrates how extensive this loss can be—most

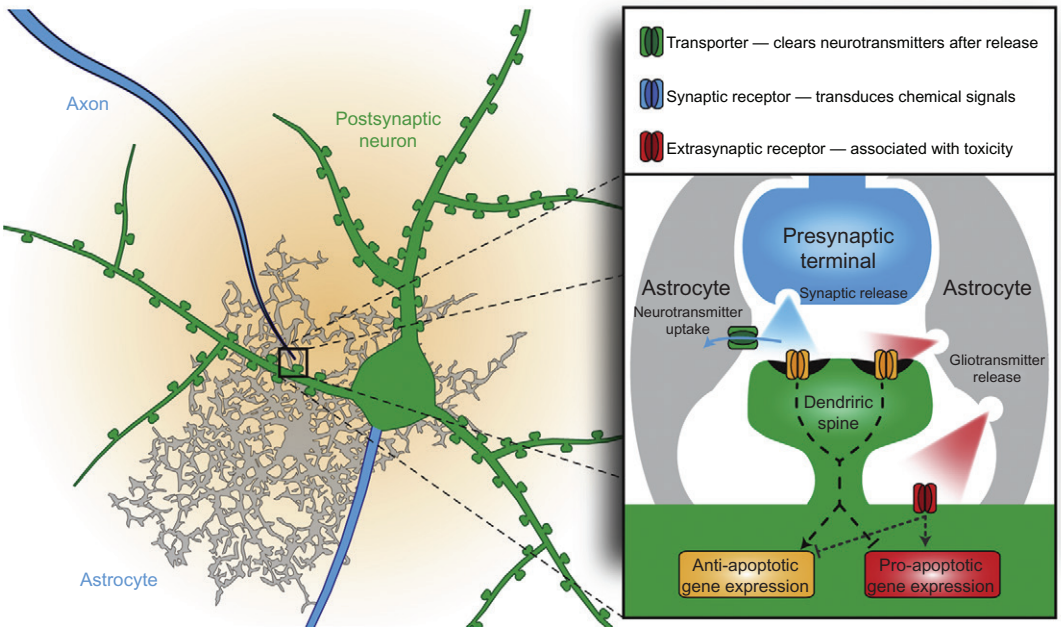

FIGURE 47.4 The synapse is a tripartite structure. Many synapses consist of three components: (i) a presynaptic site; (ii) a postsynaptic site; and (iii) a glial element. Presynaptic sites typically occur on axons and release neurotransmitters in an activity-dependent manner. Neurotransmitters bind to receptors on the postsynaptic site and elicit a cellular response. The activity of neurotransmitters is regulated by astrocytic processes, which express transporter proteins to uptake neurotransmitters such as glutamate. There is also emerging evidence that astrocytes may release neuroactive compounds (called "gliotransmitters") in an activity-dependent manner (called "gliotransmission"). Because of their peripheral location at the synapse, gliotransmitters from astrocytes tend to activate presynaptic and extrasynaptic receptors. Hyperactivation of extrasynaptic NMDA receptors (NMDARs) can lead to apoptotic cell death.

patients with severe, fatal TBI lose more than two-thirds of their neurons in region CA1 (Kotapka et al., 1992). The loss of neurons in the hippocampus after TBI correlates with cognitive impairments in human patients and rodent TBI models (Hicks et al., 1993; Bigler et al., 1997; Tate and Bigler, 2000).

Synaptic Loss is a Potentially Reversible Cause of Cognitive Impairment

In addition to neuronal loss, more subtle alterations in neuronal and synaptic function are observed after TBI. Because these changes do not involve stark cell loss, they are potentially reversible. Before discussing alterations, it is perhaps important to give an overview of synaptic structure and function. Synapses can be either electrical or chemical. We focus on chemical synapses (called synapses for the rest of the chapter) because they are, by far, the most common type of synapse. Synapses are incredibly small structures, with a diameter of 300 ± 150 nm and a gap of only 20 ± 2.8 nm (Ribrault et al., 2011). By and large, synapses comprise three parts: a presynaptic site, a postsynaptic site, and a glial element (Figure 47.4).

Presynaptic sites are typically found along axons and are the site of neurotransmitter release. The postsynaptic site is typically found on dendrites and cell bodies. The postsynaptic site contains a high density of neurotransmitter receptors that bind neurotransmitters and transduce the signal into a cellular response. Postsynaptic sites that occur at dendritic spines are very plastic to allow the storage of new information (i.e., memory formation). Finally, the glial element is an astrocytic projection that is involved in buffering the concentration of ions and neurotransmitters in the extracellular space. Astrocytic projections play an important role in preventing neurotransmitters from leaking outside the synapse or building up to toxic levels—preventing astrocytic uptake of the excitatory neurotransmitter glutamate leads to lethal, convulsive seizures.

All three of these synaptic elements are affected by TBI (Figure 47.5). Presynaptic sites are destroyed by DAI, in which rotational forces cause a shearing of axons. DAI can be measured in vivo using diffusion tensor imaging. Loss of white matter (i.e., axons) scales with TBI severity—moderate-to-severe TBI patients have obvious, global white matter damage, whereas mild TBI patients have more subtle alterations. Axonal damage measured by diffusion tensor imaging also correlates with cognitive impairments (Kraus et al., 2007). Postsynaptic alterations are also obvious after TBI. In controlled cortical impact mouse TBI models, dendritic spine density is reduced in the cortex and hippocampus within days of the injury

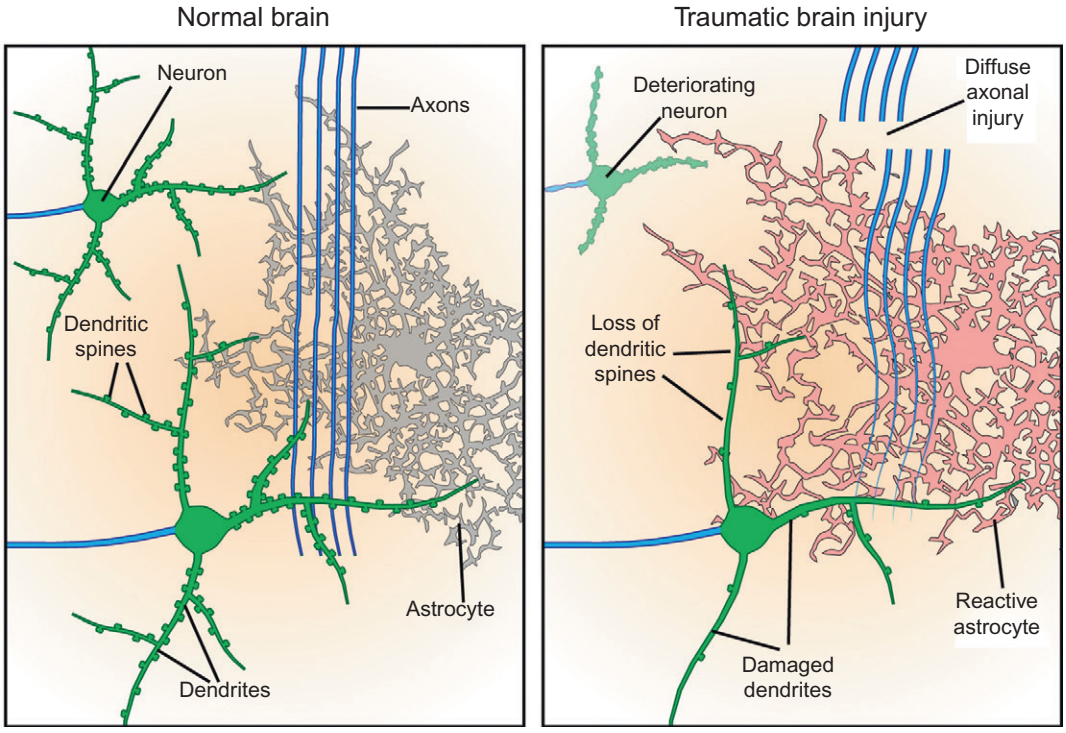

FIGURE 47.5 Traumatic brain injury causes cell death, synapse loss, axon damage, and astrocyte reactivity.

(Gao et al., 2011; Winston et al., 2013). The loss of dendritic spines reduces the number of postsynaptic sites, thus reducing neuronal excitability and restricting release from the presynaptic site. Thus, TBI can compromise synaptic function at presynaptic and postsynaptic sites in the absence of stark neuronal loss. Finally, glial elements are disrupted after TBI. One of the earliest and most reliable alterations is, in fact, reactive astrogliosis. It is not clear whether glial damage occurs before, after, or simultaneously with neuronal damage. However, it is likely that both cell types experience acute injury simultaneously, but neurons are more vulnerable to damage. Markers of neuronal injury are detected earlier than markers of glial injury in the CSF of children after TBI (Berger et al., 2002).

The brain is a dynamic organ, and dendritic spines are perhaps the most dynamic structures in the brain, showing the ability to rapidly retract and grow in an experience-dependent manner (Schubert and Dotti, 2007). In a unilateral fluid percussion injury rat TBI model, the excitatory synapse marker PSD95 is downregulated in the cortex and hippocampus (Campbell et al., 2012a). In harmony with this PDS95 reduction, the density of dendritic spines, particularly in the cortex, decreases acutely (<24 h) after fluid percussion injury (Campbell et al., 2012b). However, after 1 week, the density of dendritic spines recovers. Interestingly, hippocampal neurons have a higher density of dendritic spines 1 week after TBI compared with controls. The significance of this is not clear, although the authors speculate that elevated spine density in the hippocampus may explain the epileptogenic activity reported after TBI.

PRIMARY AND SECONDARY INJURIES INITIATE CELL DEATH THROUGH DISTINCT PATHWAYS

Neurological injuries that result from a TBI are classified as focal versus diffuse and primary versus secondary (Figure 47.6). Focal injuries occur in confined areas of the brain and are caused by contact forces to the head. Diffuse injuries occur over more widespread brain regions and are caused by inertial forces to the head. Primary and secondary injuries are distinguished based on their cause—primary injuries are caused directly by a TBI, whereas secondary injuries result from downstream effects of the original TBI. As a result, primary injuries occur immediately after the TBI and are associated with necrotic cell death. However, secondary injuries may take hours to weeks to manifest and are generally attributable to apoptotic cell death. The physical and cellular basis for these injuries is discussed.

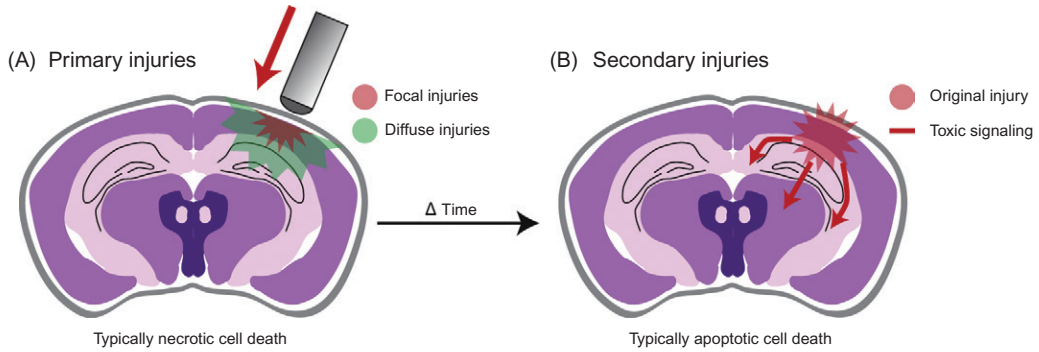

FIGURE 47.6 TBI comprises several types of injury. (A) Primary injuries result from the physical forces of the TBI. Focal damage is caused by contact forces that drive the brain into the skull, whereas diffuse damage is caused by inertial forces (linear and rotational accelerations of the head that shear axons). (B) Over time, secondary injuries emerge due to aberrant cellular signaling cascades that emanate from the initial site of damage.

Initial Primary Injuries Cause Necrosis

The mechanical force of a TBI causes immediate injury due to contact and inertial forces. Contact forces are the forces that prevent the head from moving after impact, which drives the brain into the skull. Even in the absence of skull fracture, movement along naturally occurring ridges and protuberances of the skull causes focal injuries to the cerebral cortex. Inertial forces are the linear and rotational accelerations of the head. Inertial forces cause axonal shearing, particularly at the junction of gray and white matter, which have different densities. This accounts for the diffuse nature of injuries that result from inertial forces. The primary injuries caused by contact and inertial forces are not likely to be treatable due to the limited regenerative capabilities of the central nervous system (CNS). Instead, these injuries must be prevented through the use of protective equipment.

The DAI that occurs during primary injury impairs the propagation of signals from the cell body of neurons to presynaptic terminals. White matter tracts are particularly susceptible to shearing forces incurred during a TBI. DAI is only confirmed by microscopic analysis, although there are many in vivo imaging and detection methods that are used to assess axonal integrity. Diffusion tensor imaging is an MRI variant that measures the diffusivity of water molecules. In white matter, water is unable to diffuse freely and is restricted in certain directions. This directional restriction of diffusion is termed anisotropy. By measuring the fractional anisotropy of different brain regions, white matter maps can be created to trace bundles of axons. Diffusion tensor imaging can readily detect DAI in moderate-to-severe TBI patients, whereas mild TBI patients show some subtle alterations (Inglese et al., 2005; Kraus et al., 2007). Using *in vivo* microdialysis in patients with mild TBI (Glasgow Coma Score = 9), Petzold et al. (2011) monitored axonal injury by detecting neurofilament heavy chain, an intermediate filament found in axons. Extracellular levels of neurofilament heavy chain show two phases of elevation: a pronounced, immediate elevation and a delayed, longer-lived elevation (Petzold et al., 2011). Presumably, these phases reflect primary and secondary neuronal loss: the marked, early elevation is likely due to axonal shearing, which spills out the intra-axonal contents, whereas the later elevation is due to neuronal loss through secondary injuries.

Axons in the CNS may be particularly vulnerable to rotational and translational forces due to the high compaction of myelin. Myelin is a lipid-rich substance that wraps around 0.3- to 2-mm-long segments of axons. The purpose of myelin is twofold: myelin insulates the axon to speed the conduction of action potentials and myelin reduces metabolic demand by decreasing the number of ions that move across the membrane during an action potential. Myelin in the peripheral nervous system (PNS) is moderately compact, providing some cushioning to allow peripheral nerves to withstand compression forces. PNS myelin is synthesized by Schwann cells, which produce an extracellular matrix (ECM) that contains proteins that support axonal regeneration, such as laminin-2 (Chen and Strickland, 2003)—this explains the minimal regenerative properties of the PNS. Myelin in the CNS, however, is highly compacted to allow a greater density of synapses. However, this comes at the cost of providing minimal cushioning in the event of compression forces. CNS myelin is synthesized by oligodendrocytes, which also secrete little to no ECM. As a result, when axons are severed, the myelin sheath does not have the appropriate growth signals to allow regeneration. In fact, CNS myelin contains factors that may actually prevent axonal regeneration (Huang et al., 2005). This lack of regenerative abilities in the CNS highlights the importance of preventing TBIs through the use of proper protective equipment.

Later Secondary Injuries Initiate Programmed Cell Death

Hours or days after the primary injury, secondary injuries develop. Secondary injury is caused by the release of substances that alter synaptic function, blood flow, ionic and neurotransmitter homeostasis, metabolic function, and inflammatory signaling pathways. This section focuses on mechanisms of neuronal loss by secondary injuries; mechanisms of synaptic alterations are discussed in the next section.

Apoptotic Markers Are Detectable Postmortem in TBI Patients and Experimental Models

As discussed, apoptosis is a highly regulated form of programmed cell death that culminates in the activation of caspases. Caspase 3 activation is detectable in the vicinity of cerebral contusions (Petzold et al., 2011), highlighting the importance of maintaining the integrity of BBB. Disruption of the BBB is associated with TBI and a variety of neurodegenerative disorders (Figure 47.2 and Chapter 49). A variety of other pro-apoptotic markers are detectable in the CSF of infants and children after severe TBI, including cytochrome c, caspase 1, and Fas. The increase in pro-apoptotic markers was greater in girls; however, the cause of this gender difference is not clear (Satchell et al., 2005).

The expression of pro-survival and pro-apoptotic genes in cortical neurons was measured using antisense mRNA (aRNA) amplification in individual cortical neurons with fragmented DNA (a sign of cellular damage). After 12 h, pro-survival genes (e.g., neurotrophins, TrkB, and superoxide dismutase) are downregulated in injured neurons. After 24 h, the levels of many pro-survival gene expression return to normal, although by this time the pro-apoptotic genes caspase-2 and bax are upregulated. The study by O'Dell et al. (2000) shows that genetic alterations occur rapidly after TBI and compromise cell health.

If apoptotic pathways are activated after TBI and play a role in the ensuing impairments, then apoptosis inhibitors should offer some therapeutic benefits. Continuous administration of the calpain inhibitor AK295 15 min after injury rescues motor deficits in a fluid percussion injury TBI rat model. However, only marginal improvements were observed in memory function (Saatman et al., 1996). Along these lines, inhibiting formation of the mitochondrial permeability transition pore with cyclosporine A has therapeutic benefits in a variety of TBI models, although utility in human TBI patients has yet to be demonstrated (Okonkwo et al., 1999; Sullivan et al., 2000; Mazzeo et al., 2009). Taken together, these data show a clear connection between TBI and activation of apoptotic pathways.

Glutamate Dysregulation Can Lead to Cell Death Through Necrotic Swelling, Excitotoxic Calcium Elevations, or Hyperactivation of Extrasynaptic NMDA Receptors

The principal excitatory neurotransmitter in the CNS is glutamate. There are two classes of ionotropic glutamate receptors—NMDA and non-NMDA receptors. Non-NMDA receptors desensitize rapidly and show no voltage gating. NMDA receptors (NMDARs), however, desensitize slowly and are only active when the cell is depolarized enough to remove a Mg^{2+} ion that blocks the ion channel. Glutamate levels are tightly regulated by glutamate transporters expressed in neurons and astrocytes.

Persistent glutamatergic activity leads to excitotoxicity through two routes: necrosis and apoptosis (Figure 47.7). In both routes, persistent glutamatergic input depolarizes the cell and allows hyperactivation of NMDA receptors, which desensitize much more slowly than non-NMDA receptors and thus allow more ions to enter the cell. Acutely, as sodium and calcium rush in through ionotropic glutamate receptors, they make the cell hyperosmotic. Acute swelling can lead to rapid necrotic cell loss. Alternatively, if the cell successfully reestablishes ionic imbalance across its membrane, it will deplete its ATP stores. To replenish ATP, mitochondrial activity increases, which elevates the production of free radicals (termed reactive oxygen species, ROS) that lead to oxidative stress. Both oxidative stress and sustained Ca^{2+} elevations can induce cell death by activating apoptotic proteases through formation of mitochondrial transition pores that allow the efflux of pro-apoptotic signaling molecules.

Nilsson et al. (1990) used microdialysis to measure changes in a variety of energy-related metabolites and neurotransmitters in a weight-drop rat TBI model. Two hours after TBI, extracellular glutamate levels increase in relation to TBI severity; mild TBI increases glutamate eightfold, whereas severe TBI increases glutamate 13-fold. Increases in glutamate coincide with higher levels of lactate, the end product of glycolysis (Nilsson et al., 1990). Because astrocytes display higher levels of anaerobic metabolism than neurons, these data suggest that after TBI, neuronal activity is upregulated, which leads to increased glutamate uptake and glycolytic activity in astrocytes in an attempt to buffer this excess glutamate. As discussed, increased levels of glutamate will eventually lead to intracellular calcium increases, which can lead to apoptosis or more subtle alterations in cellular/synaptic function. Readers interested in additional details about the role of glutamate excitotoxicity in TBI should read the work by Arundine and Tymianski (2004).

Because glutamate is a ubiquitous, excitatory neurotransmitter with potentially toxic consequences, the extracellular level of glutamate is tightly regulated. After presynaptic release, glutamate is rapidly taken up by

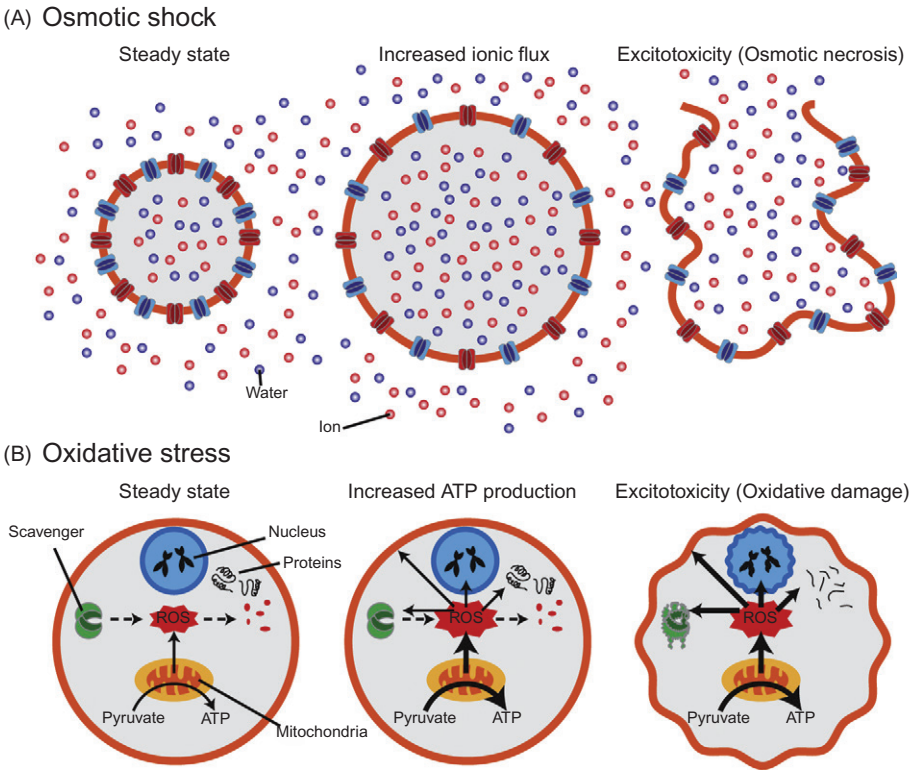

FIGURE 47.7 Excitotoxicity occurs through two routes. Excitotoxicity is caused by excessive glutamatergic signaling. (A) Continuous ionic flux increases the osmolarity of the cell. In extreme cases, this will drive enough water into the cell to cause osmotic necrosis. (B) If the cells survive the massive influx of ions, then ionic imbalance is reestablished in an ATP-dependent manner through a variety of ion pumps. As more ATP is generated through the TCA cycle and oxidative phosphorylation, ROS are produced. High rates of ATP production will produce toxic levels of ROS that cannot be scavenged by intracellular reducing agents (e.g., ROS, glutathione, and Nicotinamide adenine dinucleotide phosphate (NADPH)). ROS oxidize a variety of macromolecules to damage the DNA, proteins, and membranes of the cell. Ultimately, this oxidative damage results in apoptosis.

astrocytes. As discussed, astrocyte processes surround many synapses and play a role in buffering neurotransmitter levels. In the case of glutamatergic transmission, astrocytes regulate extracellular glutamate levels through high-affinity excitatory amino acid transporters (EAATs 1 and 2). For many years, astrocytes were viewed as morphologically simple cells due to their visualization using antibodies against the intermediate filament glial fibrillary acidic protein (GFAP). It is now clear that GFAP occupies a mere 10% of astrocytic volume and that astrocytes extend numerous tortuous processes to sample nearly all of their occupied volume, with essentially no overlap between adjacent astrocytes (Halassa et al., 2007). However, neighboring astrocytes are coupled to one another via gap junctions to create an extensive network with greater buffering capacity and potentially unappreciated signaling capabilities. Readers interested in additional details about astrocytic network functions should read the work by Giaume et al. (2010).

After injury, astrocytes undergo a series of morphological and functional alterations termed reactive astrocytosis, which is characterized by cellular hypertrophy and, in extreme cases, reentry into the cell cycle. Reactive astrocytosis is one of the most reliable markers of neurological damage and occurs within days of TBI. Although reactive astrocytosis is generally thought of as neuroprotective, cellular hypertrophy may lead to glutamate release through volume-sensitive anion channels (Takano et al., 2005). Additionally, the epileptiform activity that occurs after some TBIs will release high levels of glutamate and increase metabolic demands. Because glutamate uptake is driven by ionic gradients that are established in an ATP-dependent manner, depletion of energy stores and reduced metabolic support will necessarily reduce glutamate uptake. Because of their peripheral location at synapses, glutamate released from astrocytes may be particularly toxic due to the activation of extrasynaptic NMDA receptors.

NMDA receptors are found at and away from the synapse. In general, synaptic NMDA receptors are considered neuroprotective, whereas activation of extrasynaptic NMDARs leads to apoptosis (Figure 47.4). This may be a homeostatic adaptation that eliminates leaky synapses (i.e., those that allow glutamate to escape and

active extrasynaptic NMDARs). The details of synaptic versus extrasynaptic NMDA receptor signaling are still not clear, although it does appear that these two pathways have opposing functions on pro-survival, CREB-dependent gene expression and pro-death, FOXO-dependent gene expression. Readers interested in additional details about the cytotoxic effects of extrasynaptic NMDA receptors should read the work by Hardingham and Bading (2010).

ROS and Inflammatory Cytokines are Upregulated After TBI

A commonly reported event that occurs after TBI is an increase in ROS from mitochondria. ROS are highly reactive free radicals (e.g., superoxide and hydroxyl radicals) that damage a range of macromolecules, including lipids, proteins, and DNA. Thus, cells maintain reducing conditions through production of NADPH and glutathione, which work with superoxide dismutase to neutralize ROS. Elevated levels of ROS are indicative of cellular stress and will eventually lead to cell death if left unchecked.

Bayir et al. (2002) published a comprehensive analysis of antioxidant reserve and oxidative damage after TBI. Early on, 1 day after TBI, CSF samples from children and infants with severe TBI show higher levels of the oxidative stress marker F2-isoprostane. F2-isoprostane levels normalized after day 2. However, levels of the antioxidant ascorbate are reduced immediately after TBI (day 1) and continue to decline afterward (up to day 7). Glutathione, an important reducing agent, levels show a biphasic response to TBI: glutathione is elevated immediately after TBI and declines after 5 days (Bayir et al., 2002).

A variety of antioxidant compounds have been used to scavenge ROS in rodent TBI models and human TBI patients (Dohi et al., 2006; Hall et al., 2010). Some ROS scavengers produce positive impacts on survival and neurological outcomes in larger phase III clinical trials (Marklund et al., 2001; Hall et al., 2010). Despite this, ROS scavengers are not currently used as a therapeutic option to treat TBI.

In Neurons, Cell Death Is Also Caused by Attempted Reentry into the Cell Cycle

Neurons are *postmitotic* cells; thus, they no longer undergo cell division. This loss of reproductive capabilities is attributable to their complex cellular morphology. To undergo cell division, neurons must retract their intricate dendritic and axonal arbors—an impossible task. Neurons that reenter the cell cycle invariably fail to complete the task and die. Because of this, neurons actively suppress cell-cycle reentry. This suppression is removed in several neurodegenerative disorders, including TBI.

Cyclin-dependent kinase inhibitors, such as flavopiridol, prevent cell-cycle progression. In a lateral fluid percussion injury rat model of TBI, the expression of genes associated with DNA injury and cell-cycle progression are upregulated. These genetic alterations appear to play a causative role in neuronal cell death, because intracerebroventricular injection of the cell-cycle inhibitor flavopiridol reduces neuron loss. Flavopiridol also reduces the activation of astrocytes and microglia, although it is unclear whether cell-cycle reentry occurs in neurons, glia, or both or whether neuronal dysfunction and glial dysfunction synergize during TBI (Di Giovanni et al., 2005).

POTENTIAL MECHANISMS OF SUBTLE SYNAPTIC IMPAIRMENTS IN TBI

Synapses are maintained in part through neurotrophic signaling. Neurotrophins are a class of proteins that activate receptor tyrosine kinases (Trk receptors) to regulate the growth and maintenance of synapses. Cell growth is stimulated by neurotrophins through their activation of Rho GTPases, a diverse family of proteins that (in general) positively regulate the stability and growth of actin filaments and microtubules. Through their positive impact on cytoskeletal organization, neurotrophins induce the outgrowth of dendrites and axons in a variety of neurons. The importance of neurotrophic support on synaptic maintenance is illustrated in mice that lack brain-derived neurotrophic factor (BDNF), a neurotrophin implicated in learning and memory. BDNF knockout mice develop normal dendritic arbors but fail to maintain them (Gorski et al., 2003). Because dendrites are important postsynaptic sites, this reduction in dendritic arborization reduces the number of possible synaptic contacts.

As discussed, neurotrophic expression is downregulated in neurons with DNA fragmentation after TBI (O'Dell et al., 2000). However, whole brain analysis shows upregulation of neurotrophins within the same time frame in a controlled cortical impact TBI rat model (Oyesiku et al., 1999). Another study using in situ hybridization shows that some neurotrophins increase after mild TBI (e.g., BDNF), whereas others (e.g., NT-3) decrease (Hicks et al., 1999). These data suggest that nondamaged neurons and glia upregulate their expression of neurotrophins to offset the decreased expression in injured neurons. However, upregulation of neurotrophins may be deleterious as high levels of neurotrophins activate the low-affinity $p75^{NTR}$, which is linked to pro-apoptotic and synapse-degenerating signaling pathways.

The loss in postsynaptic sites is regulated by enzymes that control the polymerization state of actin. Work by Campbell et al. (2012a) provides mechanistic insights

into the postsynaptic alterations that occur in a fluid percussion injury rat TBI model. Within 18 h after injury, PSD95 levels in the cortex and hippocampus decline, indicating the loss or shrinkage of postsynaptic sites. Reduction of PSD95 is preceded by an increase in the activity of cofilin—an actin-severing enzyme. When cofilin is activated, it breaks apart actin filaments and causes the shrinkage of dendritic spines (i.e., excitatory postsynaptic sites). Normally, cofilin is held in an inactive state through phosphorylation of Ser3, which disallows interactions between cofilin and actin. However, TBI increases the activation of the protein phosphatase calcineurin, which dephosphorylates and activates cofilin. Because calcineurin activity is regulated by calcium–calmodulin, these results suggest that calcium dysregulation after TBI may cause the loss of excitatory synapses through cofilin-dependent actin depolymerization.

TBIS REPRODUCE PATHOLOGICAL HALLMARKS OF ALZHEIMER DISEASE

Alzheimer Disease Is a Dementia Associated with Aberrant Aβ and Tau Signaling

Alzheimer disease (AD) is a progressive dementia that is classically characterized by amyloid plaques, tau neurofibrillary tangles, and brain atrophy. Amyloid plaques are extracellular aggregates composed mostly of aggregated forms of Aβ. Although plaques are easily detected postmortem, cognitively normal elderly individuals can have high levels of plaques (Buckner et al., 2005). Additionally, a population of Japanese AD patients with a specific mutation in Aβ (E22Δ) exhibited dementia in the absence of plaques (Tomiyama et al., 2008). Therefore, many experts in the field have moved away from the amyloid cascade hypothesis proposed by Hardy and Higgins (1992) and instead believe the soluble oligomer hypothesis, in which diffusible Aβ oligomers (AβOs) attach at or near synapses and alter synaptic function (Hardy and Higgins, 1992; Wilcox et al., 2011). A similar movement has occurred with regard to the microtubule-associated protein tau: soluble tau oligomers are viewed as more toxic than insoluble tau neurofibrillary tangles. Finally, it is absolutely critical to remember that the best correlate with dementia severity is not brain atrophy, but rather synapse loss (Terry et al., 1991). Thus, although most view AD as being typified by plaques, tangles, and atrophy, these are antiquated views.

Aβ is derived by proteolytic processing of the amyloid precursor protein (APP) by a group of proteases called the secretases to produce a number of soluble peptides with diverse cellular functions. Aβ is produced when APP is cleaved outside the membrane by β-secretase (now identified as BACE-1) and within the membrane by γ-secretase. The strongest support for a causative role for Aβ in AD progression comes from human genetics. There are several mutations and duplications in APP and γ-secretase that can lead to heritable familial AD (FAD). FAD-association mutations can increase Aβ production (Swedish, Flemish), promote Aβ polymerization into toxic forms (Osaka and Arctic), or shift the metabolism of APP to produce more Aβ that is 42 amino acids long (Florida, London), two amino acids longer than normal and far more prone to polymerization. It is important to note that one mutation exists that actually decreases the risk of development of AD (Icelandic) by disrupting Aβ production (Jonsson et al., 2012).

Based on studies using tau knockout mice, it appears that Aβ induces synaptic loss and eventually cell death by structural and functional modifications to tau. Normally, tau is localized in axons, where it binds to and stabilizes microtubules. However, when tau is phosphorylated, it leaves the microtubule and activates a protein phosphatase 1 (PP1) through its phosphatase activating domain (PAD). PAD likely acts as an autoregulatory mechanism to limit the time that tau spends away from the microtubule and to prevent tau from becoming hyperphosphorylated—tau hyperphosphorylation is associated with AD progression. In fact, when tau is hyperphosphorylated in AD, it no longer interacts with axonal microtubules and translocates to the cell body and dendrites.

Tau is phosphorylated by a number of kinases, but glycogen synthase kinase 3β (GSK3β) appears to be highly relevant to AD. AβOs indirectly activate GSK3β, thus causing tau phosphorylation. Phosphorylated tau activates PP1 through its PAD. PP1 dephosphorylates both tau and GSK3β, which keep the kinase active and inevitably lead to tau hyperphosphorylation. The functional consequence of tau hyperphosphorylation is "synaptic starving," in which impaired axonal transport disrupts the delivery of critical proteins and energetic substrates to the synapse, eventually leading to synapse loss (Mandelkow et al., 2003). Alterations in intracellular trafficking are likely due to prolonged GSK3β activation (Kanaan et al., 2011). GSK3β phosphorylates the motor protein kinesin, which delivers vesicular cargo to presynaptic and postsynaptic sites. Phosphorylation by GSK3β causes kinesin to dump its cargo, which, in the case of chronic GSK3β activation, can lead to depletion of synaptic components. Thus, the tau–PP1–GSK3β positive feedback, which may be initiated by Aβ, inevitably leads to tau pathology and synaptic dysfunction.

TBI Patients Have Elevated Levels of Aβ

Amyloid pathology is observed in rodent TBI models and human TBI patients. In fact, diffuse amyloid plaques are present in the brains of professional boxers with TBI

at levels comparable with those observed in AD patients (Roberts et al., 1990). APP, BACE-1, presenilin (a component of γ-secretase), and Aβ accumulate in the terminal portion of severed axons after TBI (Chen et al., 2004). By concentrating APP and the secretases together, Aβ production is favored. Increased Aβ production leads to oligomer formation and eventually synaptic dysfunction and loss. Accordingly, Aβ accumulation increases with repetitive head injury and correlates with injury severity (Uryu et al., 2002; Tran et al., 2011). However, attenuating Aβ production with a γ-secretase inhibitor does not prevent the loss of dendritic spines after a controlled cortical impact TBI (Winston et al., 2013). This suggests that although TBI may promote the onset of AD pathology, acute synaptic damage occurs through alternative routes. It is likely that elevated Aβ levels may play a role in the chronic effects of TBI on synaptic structure and function, although this is purely speculative.

Tau Is Hyperphosphorylated After TBI

Because TBIs increase Aβ burden, and because Aβ acts upstream of tau, TBIs also induce tau pathology. Brains from TBI and AD patients show tau hyperphosphorylation at the same amino acid residues (Schmidt et al., 2001), and both occur in cortical pyramidal cells, albeit in different subpopulations (Hof et al., 1992). Neurofibrillary tangles are found in TBI patients years after a single TBI (Johnson et al., 2012). The development of tau pathology after a TBI takes some time, because a single mild TBI does not increase tau pathology after 3 weeks in hTau mice, which express human tau isoforms. Instead, multiple TBIs are required to observe tau pathology, although astrocyte reactivity is apparent 3 weeks after a single TBI (Ojo et al., 2013). Because of the axonal localization of tau, one likely cause of tau pathology in TBI is DAI, which occurs when delicate axons are torn apart during rapid head acceleration (Elson and Ward, 1994). However, based on the time required for tau pathology to become apparent, it is likely that increased Aβ production drives tau hyperphosphorylation through alterations in intracellular signaling.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

TBI is a multifactorial and sporadic neurodegenerative syndrome that is caused by contact and inertial forces that lead to primary injuries that are focal or diffuse, respectively. Early primary injuries cause necrotic cell loss. The surviving cells have compromised cellular function or support, leading to secondary injuries. Secondary injuries lead to aberrant cell signaling, impaired synaptic function, and apoptotic cell death. The mechanisms of apoptotic cell death have multiple factors and include glutamate excitotoxicity, oxidative damage, and reduced neurotrophic support. In the absence of marked cell loss, synaptic loss is also observed after TBI. Synaptic impairments are the result of impaired neurotransmitter homeostasis, which leads to aberrant calcium signaling. Pathological overlaps between TBI and AD also contribute to the loss of synapses and neurons.

CHAPTER

48

Excitotoxicity, Oxidative Stress, and Neuronal Injury

Snjezana Zaja-Milatovic and Ramesh C. Gupta

INTRODUCTION

Exposure to anticholinesterase (anti-AChE) agents, organophosphates (OPs) and carbamates (CMs) in the form of insecticides and chemical warfare agents (CWAs) affects or threatens much of the world's population. The widespread use and easy accessibility to more than 100 different OPs used as insecticides worldwide result in a huge number of intoxications and several hundred thousand fatalities annually (Gunnell and Eddleston, 2003). Other derivatives of phosphoric acid, nerve agents used in warfare, are considered the most toxic compounds of all chemical weapons. Devastating effects of these agents have been demonstrated during the Iraqi conflict with Iranian troops and Kurdish civilians, as well as a terrorist attack on the Tokyo subway train system that occurred in 1995, resulting in over 5,500 casualties (Nozaki et al., 1995; Nagao et al., 1997). Terrorist attacks involving warfare nerve agents, weapons of mass destruction, or other industrial chemicals present worldwide security threats and health concerns. Therefore, anti-AChE agents represent a significant potential threat not only to the military, but also to the general civilian population.

Pharmacologically, all these compounds are acetylcholinesterase (AChE) inhibitors. Their acute symptoms are attributed to accumulation of acetylcholine (ACh), thus exhibiting cholinergic toxicity. Phosphorylation of the esteratic site of the enzyme diminishes its capacity to catalyze its endogenous substrate ACh (Taylor, 1990). Most OP compounds combine with AChE only at the esteratic sites, and the stability of the bond depends upon the structure of the compound that is attached. OP compounds containing larger alkyl groups may hinder cleavage, leaving the phosphorylated AChE inactivated almost indefinitely. As a result, normal activity recurs only upon the synthesis of a new enzyme. This process is known as *aging*, and its time course varies depending on the nerve agent. Consequently, the hydrolysis of ACh is prevented, leading to accumulation of ACh in the synaptic cleft and overstimulation, followed by the desensitization of muscarinic and nicotinic ACh receptors.

The constantly activated nicotinic cholinergic receptors generate involuntary skeletal muscle contraction, followed by complete depolarization block, the clinical manifestation of which is flaccid paralysis. In a manner similar to the events in the peripheral nervous system (PNS), the accumulation of ACh in central nervous system (CNS) nerve endings causes anxiety, disorientation, and general convulsions, followed by loss of consciousness and respiratory arrest. Anti-AChE agent-induced ACh accumulation at the muscarinic sites also enhances the activity of various secretory glands, leading to excessive salivation, lacrimation, bronchorrhea, diarrhea, and sweating. The severity of poisoning by nerve agents varies from minor cases (mild dyspnea, blurred vision, and glandular hypersecretion) to more severe poisoning, which is characterized by severe dyspnea, skeletal muscle fasciculation, convulsions, and unconsciousness, which occurs soon after an intense exposure of only a few minutes (Goldfrank et al., 1982; Weinbroum, 2005). Thus, depending upon the degree of AChE inhibition, cholinergic stimulation may also lead to respiratory failure, coma, and death.

Convulsions are a major sign of OP nerve agent poisoning (Misulis et al., 1987). OP-induced seizures rapidly progress to status epilepticus (SE), which leads to profound structural brain damage (Lemercier et al., 1983; McLeod, 1985). Excitotoxic levels of glutamate following soman exposure are thought to be involved in the dendritic and synaptic damage as an early toxicological

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00048-8

response that leads to neuronal dysfunction and memory impairment (Carpentier et al., 1991). Anti-AChE exposure is also associated with oxidative stress, synaptic architecture dysfunction, and cellular deterioration in the brain, especially in the hippocampus (Johnson et al., 2008; Zaja-Milatovic et al., 2009, Milatovic et al., 2010).

EXCITOTOXICITY AND OXIDATIVE INJURY

The most consistent pathological findings in acute experiments with anti-AChE agents include degeneration and cell death in the pyriform cortex, amygdala, hippocampus (where the CA1 region is preferentially damaged), dorsal thalamus, and cerebral cortex. It has been shown that soman-induced seizures produce an increase in extracellular glutamate in the pyriform cortex (Wade et al., 1987) and the cornu ammonis (CA) region of hippocampus (Lallement et al., 1992), followed by activation of *N*-methyl-D-aspartate (NMDA) glutamate receptors in the CA1 region. Moreover, glutamate stimulates the continuous release of ACh (Anderson et al., 1994), contributing to further excitatory stimulation, prolongation of the seizures, and neurodegeneration in vulnerable brain regions (Wade et al., 1987; Lallement et al., 1991, 1992). This excitotoxic injury caused by increased levels of glutamate also causes cognitive dysfunction (Phillips et al., 1998; O'Dell et al., 2000; Faden et al., 2001). Increased synaptic glutamate concentrations following OP exposure also alter glutamate receptor expression (Piehl et al., 1995; Cebers et al., 2001) and perturb NMDA receptor subunit distribution, thus changing the overall physiology of the receptor and the functionality of the hippocampus (Cebers et al., 1999).

Although seizures can induce neuronal death, they may also have nonlethal pathophysiological effects on neuronal structure and function. Dendritic spines represent the structural sites of contact for the majority of excitatory, glutamatergic synaptic inputs into neurons, and they are strongly implicated in mechanisms of synaptic plasticity and learning. NMDA and other glutamate receptor subtypes are clustered in dendritic spines (Rao and Craig, 1997; O'Brien et al., 1998), which serve as integrative units in synaptic circuitry and participate in synaptic plasticity (Yuste and Denk, 1995). The accumulation of glutamate receptor clusters in spines is governed by excitatory synaptic activity and increases when activity is suppressed (Rao and Craig, 1997; O'Brien et al., 1998). Conversely, excitotoxicity produces a rapid and profound loss of dendritic spines in cultured neurons (Halpain et al., 1998), mimicking the loss in dendritic spine synapses in neurological conditions, including epilepsy, aging, and schizophrenia (Jeffrey et al., 1997; Jiang et al., 1998). This suggests that receptor localization at synapses might be critical to excitotoxicity and govern neuronal vulnerability to excitotoxicity.

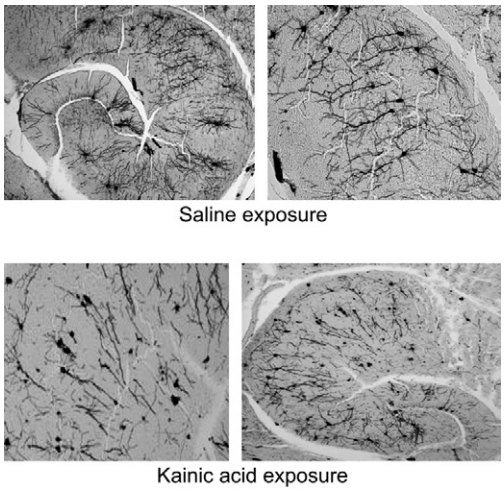

FIGURE 48.1 Photomicrographs of mouse hippocampi with pyramidal neurons from the CA1 hippocampal area of brains 1 h after saline (control) and kainic acid (KA, 1 nmol/5 μL, ICV) injections. Treatment with KA induced degeneration of the hippocampal dendritic system and decrease in the total length of the dendrite and spine density of hippocampal pyramidal neurons.

Earlier studies investigating the role of glutamate receptors in mediating seizure-induced brain damage showed that kainic acid (KA)-induced epilepsy damaged limbic structures in rats (Ben-Ari et al., 1980). Kainate is a rigid analog of glutamate, the principal excitatory neurotransmitter in the CNS, and it is a very potent stimulant of a subset of the ligand-gated ion channel, called KA receptors (Milatovic et al., 2005b). Activation of the KA subtype of ionotropic gluatamate receptors results in sustained epileptic activity in the hippocampus, followed by a selective pattern of neuropathology that is similar to human temporal lobe epilepsy (Schwob et al., 1980; Ben-Ari and Cossart, 2000). Kainate administration and intense seizure activity associated with SE is sufficient to induce oxidative stress, degeneration of hippocampal CA neurons, and hyperexcitability of surviving hippocampal CA neurons (Ben-Ari, 2001; Dong et al., 2003; Zaja-Milatovic et al., 2008) (Figure 48.1).

The hypothesis concerning OP-induced neuronal oxidative injury is that overstimulation of glutamatergic receptors results in sustained epileptic activity in the hippocampus and neuropathologic changes predominantly in the pyramidal neurons. Cell damage is thought to result from intense transient influx of calcium, leading to mitochondrial functional impairment characterized by activation of the permeability transition pores in the inner mitochondrial membrane, cytochrome c-release, depletion of adenosine triphosphate (ATP), and simultaneous formation of reactive oxygen species (ROS) (Cadenas and Davies, 2000; Patel, 2002; Nicholls et al.,

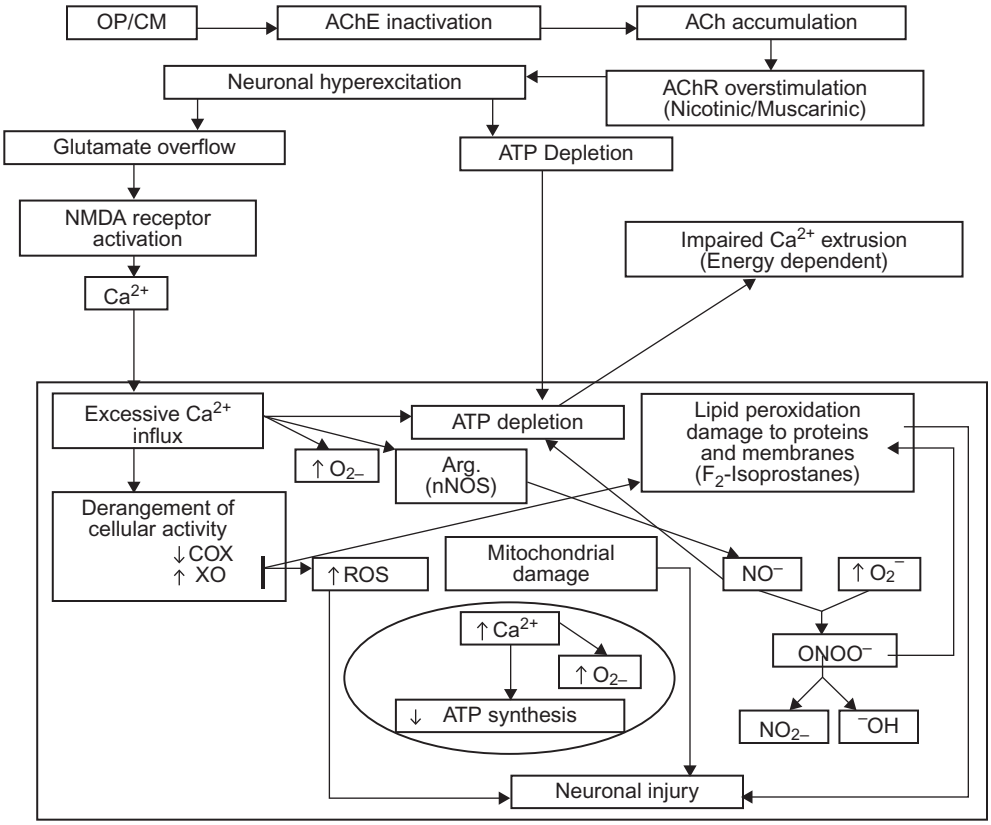

FIGURE 48.2 A schematic diagram showing possible mechanisms involved in an anti-AChE-induced neuronal injury or death by excessive production of ROS/RNS, leading to lipid peroxidation.

2003). In addition, an increase in cytoplasmic calcium ions triggers intracellular cascades through stimulation of enzymes, including proteases, phospholipase A_2, and nitric oxide synthase (NOS), which also leads to increased levels of free radical species and oxidative stress (Lafon-Cazal et al., 1993; Farooqui et al., 2001). Since free radicals are direct inhibitors of the mitochondrial respiratory chain, ROS generation perpetuates a reinforcing cycle, leading to extensive lipid peroxidation and oxidative cell damage (Cadenas and Davies, 2000; Cock et al., 2002). Previous studies have supported a role of oxidative stress and excessive generation of ROS and reactive nitrogen species (RNS) in anti-AChE-induced neurotoxicity (Dettbarn et al., 2001; Gupta et al., 2001a,b, 2007; Milatovic et al., 2005a; Zaja-Milatiovic et al., 2009).

Two radicals that play predominant roles as initiators of lipid peroxidation are the hydroxyl radical (OH^-) and the peroxynitrite radical ($OONO^-$). The superoxide anion radical (O_2^-), which is generated during the electron transport process in mitochondria, is involved in the generation of both OH^- and $OONO^-$. Superoxide dismutase (MnSOD and Cu/ZnSOD) converts O_2 to hydrogen peroxide (H_2O_2), which is then converted to OH^- via the Fenton reaction, catalyzed by Fe^{2+}, Cu^+, or Mn^{2+}. $OONO^-$ is generated from the interaction of NO with O_2^-. A major stimulus for NO production is the elevation of intracellular Ca^{2+}, which binds to calmodulin, resulting in the activation of NOS. Peroxynitrite is a powerful oxidant exhibiting a wide array of tissue damaging effects, including lipid peroxidation, inactivation of enzymes and ion channels via protein oxidation and nitration, and inhibition of mitochondrial respiration (Virag et al., 2003). Peroxynitrite, which dissipates during oxidation (Wang et al., 2003), has also been found to induce nitration as well as oxidation of adenine, guanine, and xantine nucleosides (Sodum and Fiala, 2001). Low concentrations of peroxynitrite trigger apoptotic death, whereas higher concentrations induce necrosis with cellular energetics [ATP and nicotinamide adenine dinucleotide (NAD)] serving as a switch between the models of cell death. Thus, increased ROS and RNS production has been directly linked to oxidation of proteins, deoxyribonucleic acid (DNA), and lipids, which may cause injury or induce a variety of cellular responses through the generation of secondary metabolic reactive species (Figure 48.2).

LIPID PEROXIDATION AND *IN VIVO* MARKERS OF OXIDATIVE DAMAGE

Due to a high concentration of substrate polyunsaturated fatty acids (PUFAs) in cells, lipid peroxidation is a major outcome of free radical-mediated injury (Montine et al., 2002a,b). A critical aspect of lipid peroxidation is that it will continue until the oxidizable substrate is consumed or termination occurs, making it fundamentally different from many other forms of free radical injury, in that the self-sustaining nature of the process may entail extensive tissue damage (Porter et al., 1995). Decreased membrane fluidity following lipid peroxidation makes it easier for phospholipids to exchange between the two halves of the bilayer, increase the leakiness of the membrane to substances that do not normally cross it other than through specific channels (e.g., K^+ and Ca^{2+}), and damage membrane proteins, inactivating receptors, enzymes, and ion channels (Halliwell and Gutteridge, 2006; Halliwell, 2007). Increases in Ca^{2+} induced by oxidative stress can activate phospholipase A_2, which releases arachidonic acid (AA) from membrane phospholipids. The free AA can then both undergo lipid peroxidation (Farooqui et al., 2001) and act as a substrate for eicosanoid synthesis (Milatovic et al., 2011a). Increased prostaglandin (PG) synthesis is immediately linked to lipid peroxidation because low levels of peroxides accelerate cyclooxygenase (COX) action on PUFAs (Smith, 2005). Phospholipase A_2 can also cleave oxidized AA residue from membranes.

The use of reactive products of lipid peroxidation as *in vivo* biomarkers is limited because of their chemical instability and rapid and extensive metabolism (Gutteridge and Halliwell, 1990; Moore and Roberts, 1998). For these reasons, other more stable lipid products of oxidative damage have generated intense interest in recent years as *in vivo* markers of oxidative damage. These compounds include the F_2-isoprostanes (F_2-IsoPs), F_4-neuroprostanes (F_4-NeuroPs), and isofurans (IsoFs) (Morrow et al., 1990; Fessel et al., 2002; Milatovic and Aschner, 2009; Janicka et al., 2010; Milatovic et al., 2011b).

F_2-IsoPs are PG-like compounds that are produced by a non-COX free radical-catalyzed mechanism involving the peroxidation of AA. Formation of these compounds initially involves the generation of four positional peroxyl radical isomers of arachidonate, which undergo endocyclization to PGE_2-like compounds. These intermediates are reduced to form four F_2-IsoP regioisomers, each of which can consist of eight racemic diastereomers (Morrow et al., 1990). In contrast to COX-derived PGs, nonenzymatic generation of F_2-IsoPs favors the formation of compounds in which the stereochemistry of the side chains is oriented *cis* in relation to the prostane ring. A second important difference between F_2-IsoPs and PGs is that F_2-IsoPs are formed primarily *in situ*, esterified to phospholipids, and subsequently released by phospholipases (Gao et al., 2006), whereas PGs are generated only from free AA (Morrow et al., 1990; Milatovic et al., 2011a).

The measurement of F_2-IsoPs is a method that has been extensively replicated as an efficient means of quantifying free radical damage in *in vivo* models associated with neurodegenerative diseases, including Alzheimer's disease (Montine et al., 1999), inflammation (Milatovic et al., 2003, 2004), metal toxicity (Milatovic et al., 2009, 2011c), and excitotoxicity (Milatovic et al., 2005b; Zaja-Milatovic et al., 2008, 2009). Since AAs present throughout the brain and in different cells in the brain at roughly equal concentrations, F_2-IsoPs reflects damage to brain tissue, but not necessarily to neurons.

Similar studies of lipid peroxidation products have been performed for other substrate lipids. Of particular interest are oxidation products of docosahexaenoic acid (DHA), which have been termed F_4-NeuroPs; (Roberts et al., 1998). In contrast to AA, which is evenly distributed in all cell types in all tissues, DHA is highly concentrated in neuronal membranes (Salem et al., 1986; Montine et al., 2004). Thus, determination of F_4-NeuroPs permits the specific quantification of oxidative damage to neuronal membranes *in vivo* (Montine et al., 2004; Milatovic and Aschner, 2009). In fact, to our knowledge, F_4-NeuroPs are the only quantitative *in vivo* marker of oxidative damage that is selective for neurons.

Another F_2-IsoPs analog may be formed by peroxidation of eicosapentaenoic acid (EPA, C20:5, ω-3) that leads to the production of F_3-IsoPs. Levels of F_3-IsoPs can significantly exceed those of F_2-IsoPs generated from AA, perhaps because EPA contains more double bonds and is therefore more easily oxidizable (Gao et al., 2006). It has also been shown that in the presence of increased oxygen tension in the microenvironment in which lipid peroxidation occurs, an additional oxygen insertion step may take place (Fessel et al., 2002; Milatovic and Aschner, 2009). This step diverts the IsoP pathway to form tetrahydrofuran ring-containing compounds termed IsoFs, which are functional markers of lipid peroxidation under conditions of increased oxygen tension. Thus, measurements of IsoFs represent a much more robust indicator of hyperoxia-induced lung injury than measurements of F_2-IsoPs. Like IsoPs, IsoFs are chemically and metabolically stable, so they are well suited to act as *in vivo* biomarkers of oxidative damage.

The enzymatic and free radical peroxidation of PUFAs which contains at least three double bonds, like AA and DHA, could lead to malondialdehyde (MDA). This product can be generated by thromboxane synthase, but a report from the Biomarkers of Oxidative Stress Study (BOSS) showed that peripheral levels of MDA derive primarily from nonenzymatic peroxidative degradation

of unsaturated lipids (Kadiiska et al., 2005). 4-hydroxy-2-nonenal (HNE) is also reactive aldehyde arising from peroxidation of ω6 fatty acid (Uchida, 2003; Gueraud et al., 2010). HNE is formed under various conditions like auto-oxidation and stimulated microsomal lipid peroxidation (Neely et al., 2005). MDA and HNE are able to covalently modify proteins and alter their functions (Butterfield et al., 2006). In addition to protein modification, these lipid peroxidation products can interfere with synthesis of DNA and ribonucleic acid (RNA), alter cell metabolism and signaling, and mediate brain-induced oxidative damage. Several studies suggest that MDA and HNE can promote the degeneration of cholinergic neurons, Aβ aggregation, and amyloidogenesis (Pedersen et al., 1999; Butterfield et al., 2006).

ROS and RON can react with the DNA molecule and induce purine or pyrimidine base or sugar lesions, nitration and deaminations of purines, and DNA–DNA or DNA–protein cross-links (Dizdaroglu et al., 2002). These processes lead to mutations and impaired transcriptional and posttranscriptional processes and compromise protein synthesis (Colurso et al., 2003). In addition, DNA damage, oxidative phosphorylation, and altered cell metabolism may lead to apoptosis and promote neuronal death (Fishel et al., 2007; Becker and Bonni, 2004). ROS and RNS can also attack amino acids, leading to the formation of carbonyl derivatives (Stadtman and Levine, 2003). Oxidation of protein also leads to protein fragmentation and protein cross-linking. In addition, peroxynitrite and a hydroxyl radical can react with tyrosine and form other indexes of protein oxidation, 3-nitrotyrosine, and ortho-tyrosine, respectively. These protein products are relatively stable, with sensitive assays available for their detections (Chakravarti and Chakravarti, 2007).

ANTI-ACHE-INDUCED SEIZURES, OXIDATIVE INJURY, AND NEURODEGENERATION

Lipid peroxidation, mitochondrial dysfunction, reduced neuronal energy levels, and reduced cytochrome c-oxidase (COx) activity support the contention that anti-AChEs, such as diisopropylfluorophosphate (DFP) and carbofuran (CF), cause neuronal injury by excessive formation of ROS (Yang and Dettbarn, 1998; Milatovic et al., 2000a,b, 2001, 2005a; Gupta et al., 2001a,b). Additionally, our studies showed that seizure-induced cerebral oxidative damage in adult animals is accompanied by alterations in integrity of the hippocampal CA1 dendritic system (Gupta et al., 2007; Zaja-Milatovic et al., 2008, 2009; Milatovic et al., 2010).

A single injection of DFP [1.5 mg/kg, subcutaneously (s.c.)] or another AChE inhibitor, CF (1.5 mg/kg, s.c.), produces toxic signs in rats, including salivation, tremors, "wet dog" shakes, fasciculations, and mild to moderate seizures with rearing and rolling over, with progression to severe seizures within 7–15 min (Milatovic et al., 2006; Gupta et al., 2007; Zaja-Milatovic et al., 2009). Signs of maximal intensity such as severe muscle fasciculations, seizures, and convulsions develop within 15–30 min and last for more than 2 h before tapering off. By 24 h, animals are free of toxic signs. The observed signs are typical of anti-AChE toxicity and reveal the involvement of both the CNS and the PNS (Gupta et al., 2001a,b; Milatovic et al., 2005a). Analysis of brains from saline-treated control rats revealed regional variability in brain AChE activity (cortex, 222.0 ± 10.7; amygdala, 529.2 ± 10.29; and hippocampus 301.2 ± 9.5 μmol/g wet weight). A single acute dose of DFP (1.5 mg/kg, s.c.) suppressed AChE activity to less than 20% in all brain regions, compared to the controls, at 60 min following the exposure. Similarly, 60 min after a single acute dose of CF (1.5 mg/kg, s.c.), AChE was markedly depressed (% remaining activity: cortex, 10.02 ± 1.04%; amygdala, 18.18 ± 1.48%; and hippocampus, 12.75 ± 0.74%) (Gupta et al., 2007). At the time of high AChE inhibition and resultant severe seizure activity, significant increase in biomarkers of global free radical damage (F_2-IsoPs) and the selective peroxidation biomarker of neuronal membranes (F_4-NeuroPs) were seen in the brains of DFP and CF-exposed animals.

While twofold elevations are seen in F_2-IsoPs levels, F_4-NeuroPs levels are more than fivefold higher than that of controls (Figure 48.3). The results confirm the presence of oxidative damage in the cerebrum as a novel aspect of anti-AChE toxicity. The selective increase in F_4-NeuroPs indicates that neurons are specifically targeted by this mechanism.

DFP exposure also caused marked elevation in brain citrulline levels, which indicates NO/NOS activity (Gupta et al., 2001b, 2007). Control levels of citrulline are similar in the hippocampus (247.90 ± 4.10 nmol/g)

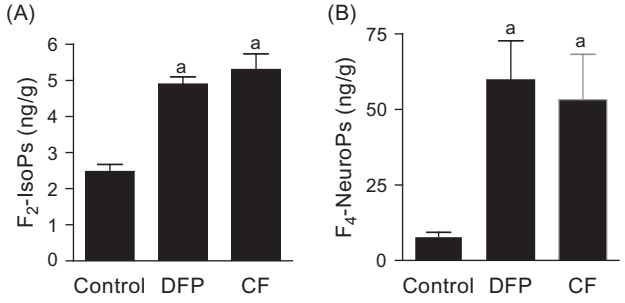

FIGURE 48.3 Effect of DFP (1.5 mg/kg, s.c.) and CF (1.5 mg/kg, s.c.) on F2-IsoPs (A) and F4-NeuroPs (B) levels in rat brain. Values are mean ± SEM (n = 4–6). (a) Significant difference between controls and DFP- or CF-treated rats ($p < 0.05$).

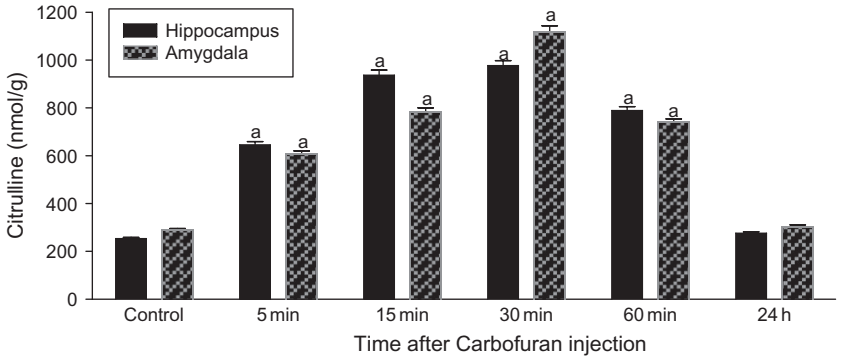

FIGURE 48.4 Citrulline levels in brain regions of rats intoxicated with an acute dose of CF (1.5 mg/kg, s.c.). Values of citrulline are presented as mean ± SEM (n = 4–6). (a) Significant difference between values from controls and CF-treated rats ($p < 0.05$).

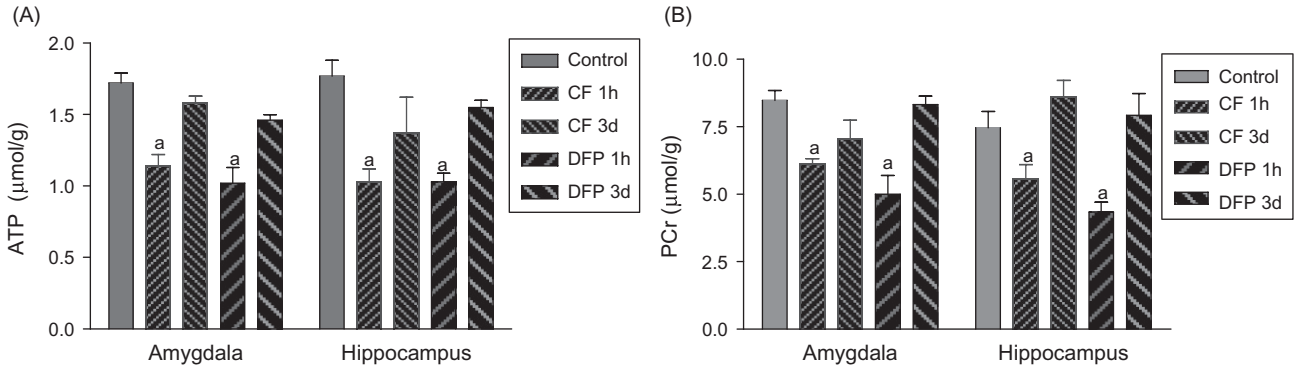

FIGURE 48.5 Levels of HEPs, ATP (A) and PCr (B), in the amygdala and hippocampus of rats intoxicated with an acute dose of CF (1.25 mg/kg, s.c.) or DFP (1.25 mg/kg, s.c.). Rats were sacrificed 1 h or 3 days after CF or DFP injection. Values of ATP and PCr are presented as mean ± SEM (n = 4–6). (a) Significant difference between values from controls and DFP- or CF-treated rats ($p < 0.05$).

and the amygdala (293.20 ± 6.90 nmol/g) (Gupta et al., 2007). Within 5 min of CF injection, the citrulline levels were elevated more than twofold in the investigated brain areas. Within 15 min of CF treatment, the levels of citrulline were significantly higher in both brain regions and were maximally elevated at 30 min post-injection (threefold to fourfold). They remained elevated up to 60 min but returned to control levels when measured 24 h later (Figure 48.4). A similar response was seen following DFP exposure.

Many reports provide evidence that NO impairs mitochondrial/cellular respiration and other functions by inhibiting the activities of several key enzymes, particularly COx, thereby causing ATP depletion (Yang and Dettbarn, 1998; Dettbarn et al., 2001; Gupta et al., 2001a,b; Milatovic et al., 2001). Results from our experiments also showed that 1 h after DFP (1.5 mg/kg, s.c.) or CF (1.5 mg/kg, s.c.) treatment, the levels of ATP and PCr were significantly reduced in the hippocampus and amygdala (Figure 48.5). With either DFP or CF treatment, the reduction in ATP and PCr levels was similar in the amygdala and hippocampus. During the course of these excitatory processes, a high rate of ATP consumption, coupled with the inhibition of oxidative phosphorylation, compromises the cell's ability to maintain its energy levels, and excessive amounts of ROS and RNS may be generated. Thus, the combination of impaired synthesis of ATP with its greater utilization during brain hyperactivity appears to result in a significant depletion of ATP. Three days after anti-AChE treatment, significant recovery of ATP and PCr is observed in discrete brain regions (Figure 48.5). The rapid decrease in energy metabolites at the onset of seizures indicates early onset of mitochondrial dysfunction, in turn further increasing ROS production and neuronal injury.

An important question that emerged from previous studies is whether brain hyperactivity, such as seizures, first generates increases in ROS and then causes a decrease in high-energy phosphates (HEPs). The findings revealed that within 5–15 min after CF injection (the time required for onset and development of clinical signs), NO levels increased more than fivefold to sixfold in the cortex and more than twofold to threefold in the amygdala and hippocampus. The maximum increase in NO occurred at 30 min post-injection in all three brain regions. The data also revealed that the maximum

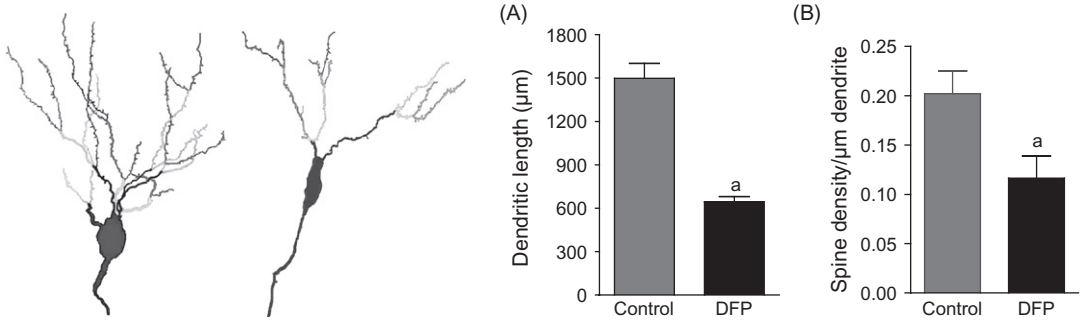

FIGURE 48.6 Morphology and quantitative determination of dendritic length (A) and spine density (B) of hippocampal pyramidal neurons from the CA1 sector of rats treated with saline (control) or DFP (1.5 mg/kg, s.c.) and sacrificed 1 h after the treatment. A total of 4–6 Golgi-impregnated dorsal hippocampal CA1 neurons were selected and spines counted by using the Neurolucida system. (a) Significant difference between controls and DFP-treated rats ($p < 0.05$). Treatment with DFP induced degeneration of the hippocampal dendritic system and decrease in the total length of the dendrite and spine density of hippocampal pyramidal neurons. Tracing and counting are done using the Neurolucida system at 100× magnification under oil immersion (MicroBrightField, VT).

decline in HEPs occurred 1 h after CF injection. This agrees with our previous data showing that a rapid and significant increase in NO precedes increases in lipid peroxidation, mitochondrial dysfunction, and loss of energy metabolites, as well as a reduction of COx activity and an increase in xanthine oxidase (Dettbarn et al., 2006). Therefore, the findings suggest that in the case of CF, the increase in ROS preceded the decrease in HEPs.

Seizures, convulsions, and CNS lesions are typical results of systemic application of sublethal doses of anti-AChE agents (Sparenborg et al., 1992). The most consistent pathological findings in acute experiments include degeneration and cell death in the pyriform cortex, amygdala, hippocampus (where the CA1 region is preferentially destroyed), dorsal thalamus, and cerebral cortex. The early morphological changes in AChEI-induced SE include dendritic swelling of pyramidal neurons in the CA1 region of the hippocampus (Carpentier et al., 1991). Therefore, we have investigated whether seizure-induced cerebral oxidative damage in adult rats is accompanied by alterations in the integrity of the hippocampal CA1 dendritic system. Our results showed that anti-AChE-induced early increases in biomarkers of global free radical damage (F_2-IsoPs) and the selective peroxidation biomarker of neuronal membranes (F_4-NeuroPs) was accompanied by dendritic degeneration of pyramidal neurons in the CA1 hippocampal area (Zaja-Milatovic et al., 2009). Anti-AChE-induced brain hyperactivity targeted the dendritic system with profound degeneration of spines and regression of dendrites, as evaluated by Golgi impregnation and Neurolucida-assisted morphometry (Figure 48.6).

Rats injected with DFP show a significant decrease in total dendritic length and spine density compared to pyramidal neurons from the hippocampal CA1 area of control rats (Figure 48.6). Taken together with the biochemical data presented previously, our results suggest that oxidative damage that selectively targets cerebral neurons is a hitherto-unrecognized aspect of anti-AChE toxicity. Results also revealed that anti-AChE exposure is associated with oxidative and nitrosative stress, alteration in energy metabolism, and consequent degeneration of pyramidal neurons from the CA1 hippocampal region of rat brain. Ultimately, the additive or synergistic mechanisms of cellular disruption caused by anti-AChE agents lead to cellular dysfunction and neurodegeneration.

OXIDATIVE DAMAGE AND DENDRITIC DEGENERATION FOLLOWING KA-INDUCED EXCITOTOXICITY

Since excessive presynaptic release of glutamate and activation of NMDA and non-NMDA receptors have a significant role in anti-AChE-induced neurotoxicity, we have investigated the role of glutamatergic excitation, oxidative injury, and neurodegeneration in the model of KA excitotoxicity. We have used intracerebroventricular (ICV) injection of KA, which is known as an experimental model for the investigation of cerebral vulnerability, particularly during acute brain disorders and SE (Schwob et al., 1980; Ben-Ari and Cossart, 2000). The study was designed to investigate whether F_2-IsoPs and F_4-NeuroPs formation correlated with the vulnerability of pyramidal neurons in the CA1 hippocampal area following KA-induced excitotoxicity. Our results showed that ICV KA-induced early increase in biomarkers of oxidative damage, F_2-IsoPs, and F_4-NeuroPs were accompanied by dendritic degeneration of pyramidal neurons in the CA1 hippocampal area.

Time-course changes in biomarkers of oxidative damage in the rat model of anti-AChE-induced seizures showed that the highest increase in F_2-IsoPs was

TABLE 48.1 Cerebral Concentrations of F_2-IsoPs and F_4-NeuroPs and Dendritic Degeneration of Hippocampal Pyramidal Neurons Following KA-Induced Seizures in Mice

	F_2-IsoPs (ng/g)	F_4-NeuroPs (ng/g)	Dendritic Length (μm)	Spine Density (Number/100 μm Dendrite)
Control	3.07 ± 0.05	13.89 ± 0.58	1032.10 ± 61.41	16.45 ± 0.55
KA 30 min	4.81 ± 0.19*	34.27 ± 2.71*	363.44 ± 20.78*	8.81 ± 0.55*
KA 60 min	3.40 ± 0.18	18.55 ± 1.26	425.71 ± 23.04*	7.44 ± 0.56*

Data from KA-exposed mice were collected 30 or 60 min post-injection.*One-way ANOVA showed $p < 0.0001$ for each end-point. Bonferroni's multiple comparison test showed significant difference ($p < 0.001$) compared to vehicle-injected control.

evaluated 1 h after the injection of anti-AChE agent or 40 min after the beginning of seizure symptoms (Gupta et al., 2007). In the model of KA-induced excitotoxicity the earliest time point evaluated was 30 min since seizures start immediately after the ICV KA injection. Elevated levels of these *in vivo* markers of oxidative damage are in agreement with our previous findings (Montine et al., 2002c; Milatovic et al., 2005b; Gupta et al., 2007), as well as those of others (Patel et al., 2001), and indicate that KA injection leads to profound cerebral and neuronal oxidative damage in mice.

Our results also showed that the transient rise in F_2-IsoPs and F_4-NeuroPs is accompanied by rapid evolution of dendritic abnormalities, which becomes apparent due to significant decrease in dendritic length and spine density of pyramidal neurons as early as 30 min post-KA injection. However, the recovery in both oxidative damage biomarkers at 60 min after the injection was not paralleled by the rescue of damaged neurons from the CA1 hippocampal area. Extended seizure activity (60 min) induced the same level of dendritic length and spine density decrease when compared to 30 min following KA injection (Table 48.1). Together, these data suggest that both oxidative stress and neurodegeneration occur as an early response to seizures, but they do not determine whether oxidative stress is a cause or an effect of seizure-induced CA1 cell damage. Neuronal damage processes triggered by sustained seizure activity may occur as a continuum, last longer than formation of oxidative lipids, and, although not evident by the markers, may already be in progress when the peak increases in F_2-IsoPs and F_4-NeuroPs occur. Thus, we investigated dynamic changes in lipid peroxidation and dendritic structures immediately after seizures occur, but future studies over the longer period should be able to determine the long-term course of these spine and dendritic changes. It is very likely that the spine loss seen in our study is the initial phase of more chronic spine loss and progressive neurodegeneration reported in other studies (Muller et al., 1993; Jiang et al., 1998; Zeng et al., 2007).

In vivo data have also established that KA induced a significant increase (more than twofold) in citrulline concentrations 30 min following the injection (Zaja-Milatovic et al., 2008). Although we did not determine whether increased citrulline originated from a combination of NOS isozymes or one in particular, our data agree with the results from the models of anti-AChE toxicity and activated innate immunity (Milatovic et al., 2003, 2004; Gupta et al., 2007) and indicate that a subset of NOS activity also contributes to cerebral oxidative damage in the model of KA-induced excitotoxicity.

NEUROINFLAMMATION AND OXIDATIVE INJURY

Neuronal injury caused by seizures is accompanied by an inflammatory reaction involving gliosis, and induction of inflammatory mediators, including PGs, cytokines, cell adhesion proteins, and matrix metalloproteinases (Jourquin et al., 2003; Zaja-Milatovic et al., 2009). Sustained release of inflammatory mediators and increased oxidative and nitrosative stress activate additional microglia, promoting their proliferation and resulting in further release in inflammatory factors. Owing to this sustained nature of inflammation, the blood–brain barrier (BBB) may be compromised, increasing infiltration of peripheral macrophages into the brain parenchyma, further perpetuating the inflammatory process (Rivest, 2009). Animals exposed to soman at doses producing convulsions exhibit a rapid increase in active astrocytes and the accumulation of glial fibrillatory acidic protein (GFAP; Zimmer et al., 1997).

Activation of innate immunity occurs simultaneously with several pathogenic processes and responses to stressors and injury, thereby greatly confounding any clear conclusion about cause-effect relationships. For these reasons, we have adapted a simple but highly specific model of isolated innate immune activation: ICV injection of low-dose lipopolysaccharide (LPS). LPS

TABLE 48.2 Cerebral Oxidative Damage and Dendritic Degeneration in Mice

	24 h	24 h	72 h	72 h
	ICV Saline	**ICV LPS**	**ICV Saline**	**ICV LPS**
F_2-IsoPs (ng/g tissue)	3.26 ± 0.19	4.77 ± 0.26*	3.13 ± 0.11	2.98 ± 0.17
F_4-NeuroPs (ng/g tissue)	13.91 ± 1.17	58.50 ± 5.98*	12.30 ± 1.18	16.80 ± 0.96
Dendritic length (μm)	1018 ± 113	324 ± 37*	848 ± 60	1030 ± 61
Spine density (spine no./100 μm dendrite)	16.89 ± 1.67	5.86 ± 0.57*	17.09 ± 1.13	16.77 ± 0.87

Effects of ICV saline (5 μL, control) and ICV LPS (5 μg/5 μL) treatment determined at 24 and 72 h following exposure.
Each value represents mean ± SEM (n = 4–6).

specifically activates innate immunity through a Toll-like receptor (TLR)-dependent signaling pathway (Imler and Hoffmann, 2001; Akira, 2003). Activation of proteins (CD14 and adaptor protein MyD88) signals transduction cascade, primarily via NF-κB activation but also through c-Fos/c-Jun-dependent pathways, culminate in the generation of effector molecules, including bacteriocidal molecules. Free radicals generated by NAD phosphate oxidase and myeloperoxidase (MPO), as well as cytokines and chemokines are known to attract an adaptive immune response (Milatovic et al., 2004).

We have employed an ICV model and identified the molecular and pharmacologic determinants of LPS-initiated cerebral neuronal damage *in vivo* (Montine et al., 2002a; Milatovic et al., 2003, 2004). Interestingly, the degree of oxidative damage in this model was equivalent to what we observed in diseased regions of brain from patients with degenerative diseases (Reich et al., 2001). Results from our studies with mice showed that a single ICV LPS injection induced delayed, transient elevation in both F_2-IsoPs and F_4-NeuroPs 24 h after exposure and then returned to baseline by 72 h post exposure (Table 48.2; Milatovic et al., 2003). While others have shown that altered gene transcription and increased cytokine secretion occur rapidly and peak within a few hours of LPS exposure, it is likely that the delay in neuronal oxidative damage observed in our experiments is related, at least in part, to the time required to deplete antioxidant defenses.

To address if oxidative damage is related to neurodegeneration, we directly examined the dendritic compartment of neurons, which is largely transparent to the standard histological techniques used so far to investigate ICV LPS-induced damage. Using Golgi impregnation and Neurolucida-assisted morphometry of hippocampal CA1 pyramidal neurons (Leuner et al., 2003; Milatovic et al., 2010), we first determined the time course of dendritic structural changes following ICV LPS in mice. Our results show a time course similar to neuronal oxidative damage, with maximal reduction in both dendrite length and dendritic spine density 24 h post LPS and, remarkably, a return to baseline levels by 72 h (Table 48.2). Thus, these data strongly imply that neuronal oxidative damage is closely associated with dendritic degeneration following ICV LPS. We and others have shown that primary neurons enriched in cell culture do not respond to LPS (Minghetti and Levi, 1995; Xie et al., 2002); therefore, our results also showed that LPS-activated microglial mediated paracrine oxidative damage to neurons.

It is becoming increasingly evident that neuroinflammation and associated oxidative damage plays a crucial role in the development and progression of brain diseases. Glia, and particularly microglia, are central to mediating the effects of neuroinflammation. Emerging evidence suggests that the number of activated microglia and the release of inflammatory mediators from these cells increase with age. This amplified or prolonged exposure to inflammatory molecules, including cytokines, chemokines, ROS, and PGs in the aged brain may impair neuronal plasticity and underlie a heightened neuroinflammatory response.

SUPPRESSION OF SEIZURE-INDUCED OXIDATIVE INJURY AND NEURODEGENERATION

Antioxidants

Antioxidants [e.g., vitamins, glutathione (GSH), selenium, zinc, creatine, and arginine] and antioxidant enzymes (e.g., superoxide dismutase, catalase, GSH reductase, and GSH peroxidase) exert synergistic actions in scavenging free radicals. A large body of literature (e.g., Fang et al., 2002) supports the notion that antioxidants play an important role in preventing many human

diseases (e.g., cancer, atherosclerosis, stroke, rheumatoid arthritis, and neurodegeneration). Vitamin E has been recognized as one of the most important antioxidants. Vitamin E inhibits ROS-inducing generation of lipid peroxyl radicals, thereby protecting cells from peroxidation of PUFAs in membrane phospholipids, from oxidative damage of cellular proteins and DNA, and from membrane degeneration (Topinka et al., 1989). Vitamin E mainly acts as a chain-breaking antioxidant and radical scavenger, protecting cell membranes against oxidative damage (Van Acker et al., 1993). In addition, vitamin E regulates ROS production (Chow et al., 1999), maintains oxidative phosphorylation in mitochondria, and accelerates restitution of high-energy metabolites (Punz et al., 1998). Decreased levels of vitamin E in response to hyperoxia or treatment with convulsants reported in studies (Onodera et al., 2003; Mori et al., 2004; Rauca et al., 2004) suggest that vitamin E in the brain is consumed to prevent oxidative damage. Vitamin E also prevented metasystox (OP insecticide)-induced changes in lipase activity and lipid peroxidation in the brain and spinal cord of rats (Tayyaba and Hasan, 1985).

A synthetic spin-trapping agent such as phenyl-*N*-*tert*-butylnitrone (PBN) is also capable of scavenging many types of free radicals. This compound is widely used to trap ROS in a variety of physical, chemical, and biological studies using electron paramagnetic resonance spectrometry. PBN is known to be concentrated in the mitochondria, where it reacts with ROS and forms stable adducts, and thereby maintains normal levels of energy metabolites. Numerous *in vitro* and *in vivo* experiments have shown the beneficial effects of PBN on the prevention of neuronal degeneration. Protective effects are described in experimental models of brain ischemia/reperfusion (Carney and Floyd, 1991; Fetcher et al., 1997; Gido et al., 1997), excitotoxicity (Lancelot et al., 1997; Milatovic et al., 2002), inhibition of NOS induction (Miyajima and Kotake, 1995), and in different models of seizures (He et al., 1997; Thomas et al., 1997). Additional findings also corroborate that PBN effectively prevents neurodegeneration in Parkinson's disease (Sack et al., 1996; Frederiksson et al., 1997), Alzheimer's disease and anti-AChE neurotoxicity (Sack et al., 1996; Gupta et al., 2001a,b). Thus, PBN has been proven to rescue neurons in multiple experimental injury models. Other pharmacological properties of spin-trapping agents have been described that could influence the outcome of oxidant injury. These have been described for PBN as reversible Ca^{2+} channel blockade in vascular muscle, causing vasodilatation (Anderson et al., 1993); direct effect on striatal function, including inhibition of excitation–contraction coupling (Andersen et al., 1996); and induction of hypothermia (Pazos et al., 1999).

Previous studies have shown that antioxidant pretreatment suppressed DFP- or CF-induced alterations in HEP, their metabolites, and citrulline levels, supporting the possibility that increased generation of ROS/RNS contributes to the depletion of energy phosphates (Gupta et al., 2001a,b). PBN or vitamin E treatment alone did not alter the levels of HEPs, their major metabolites, or citrulline in any of the brain regions. Vitamin E pretreatment suppressed the depletion of HEP and their metabolites and increased citrulline levels without preventing seizures (Gupta et al., 2001a). The protective efficacy provided by vitamin E against DFP- or CF-induced changes in energy metabolites was of varying degrees in different brain regions and could partly be due to pharmacokinetic variables involved in attaining different levels of vitamin E in different brain regions. However, PBN pretreatment 1 h before the anti-AChE agent protected mitochondria and maintained the cellular level of high-energy metabolites, but it also prevented DFP- or CF-induced convulsions and seizures (Gupta et al., 2001a,b). This could primarily be due to a protective interaction of PBN with AChE, sufficient to protect a critical fraction of AChE against phosphorylation by DFP or carbamylation by CF (Zivin et al., 1999; Milatovic et al., 2000a,b). We have also shown that AChE inhibitor-induced increases in NO (citrulline) were significantly prevented by PBN and by vitamin E (Gupta et al., 2001a). There is evidence that suggests that PBN inhibits the induction of inducible NOS (iNOS) by reducing the expression of iNOS protein (decrease in mRNA expression), thus preventing the overproduction of NO (Miyajima and Kotake, 1997).

The efficacy of the spin-trapping agent PBN and the antioxidant vitamin E was tested to suppress increase in NO and lipid peroxidation and prevent neurodegeneration of pyramidal neurons in the CA1 hippocampal area in the model of KA-induced excitotoxicity (Zaja-Milatovic et al., 2008). Vitamin E or PBN alone did not alter basal citrulline and F_4-NeuroPs levels or dendritic arborization. However, vitamin E and PBN suppressed KA-induced increases in citrulline and cerebral and neuronal markers of oxidative damage, F_2-IsoPs and F_4-NeuroPs, respectively (Figures 48.7 and 48.8).

Importantly, vitamin E and PBN completely suppressed both reduction in dendrite length and reduction in spine density of pyramidal neurons from the CA hippocampal area from KA-exposed mice (Figure 48.9).

A close concordance was found between these results, showing that protection of the cerebrum from neuronal oxidative damage also protected hippocampal CA1 pyramidal neurons from dendritic degeneration. These agents did not alter kainate-induced seizure severity, indicating that the protective effect of vitamin E and PBN is most likely mediated by scavenging ROS and preventing lipid peroxidation and consequent neuronal damage, not by a specific effect on seizures *per se*. Furthermore, since antioxidants minimize lipid peroxidation following an

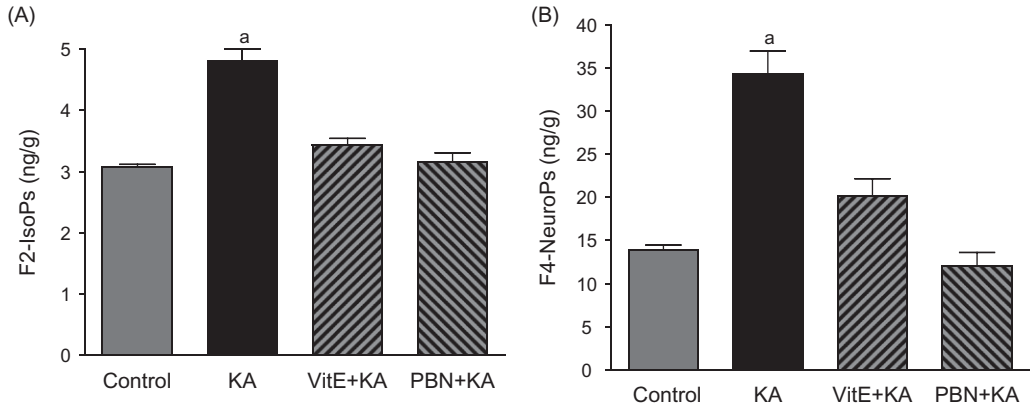

FIGURE 48.7 Ipsilateral cerebral F2-IsoPs (A) and F4-NeuroPs (B) concentrations following ICV KA with or without vitamin E (Vit E) or PBN pretreatment. increase in α-tocopherol and PBN, then a parallel reduction in neuronal damage provides strong evidence that oxidative stress and lipid peroxidation in a causal way mediate seizures and the corresponding injury. One limitation to the potential therapeutic application of this type of substance is that to be effective, the drugs need to be administered prophylactically before the onset of seizures. Future research should address the efficacy of these agents in preventing seizure-induced oxidative and dendritic changes and potentially reducing resultant neurocognitive deficits when they are administered at higher concentrations, either during or possibly even after seizures.

NMDA Receptor Antagonist (Memantine)

As excitotoxicity-induced neuronal damage in the model of anti-AChE-induced seizures is explained by the excessive release of glutamate that activates both NMDA and non-NMDA postsynaptic receptors, antagonism of the excitotoxicity mechanism may protect the CNS from the deleterious effects of anti-AChE agents. Several NMDA receptor antagonists have been shown to exert anticonvulsant effects against nerve agent-induced seizures when administered either as a pretreatment or after the seizure has been initiated, usually terminating the convulsions after an initial period of epileptical activity (Shih, 1990; Sparenborg et al., 1992). NMDA receptor antagonists do not modify the events responsible for the early phase of the seizure, but they block the subsequent recruiting of glutamate receptor activation, and hence the maintenance of seizure activity and irreversible functional and structural brain damage.

Among promising candidates as antidotes against CNS intoxication by OP nerve agents, memantine has been shown to pose both antiexcitotoxic and antiepileptic properties. Memantine is an uncompetitive NMDA receptor antagonist, clinically used for the treatment of Alzheimer's disease, Parkinson's disease and spasticity, in the absence of serious side effects (Lipton, 2005; Ozsuer et al., 2005). From a series of rat *in vivo* experiments, it is evident that pre-administration of memantine significantly protects AChE activity from inhibition caused by AChE inhibitors, including OP and CM insecticides and OP nerve agents (Gupta and Kadel, 1990; Gupta and Dettbarn, 1992; McLean et al., 1992; Gupta and Dekundy, 2005). By now, it is well established that memantine exerts various pharmacological effects by multiple pharmacological mechanisms: (i) blockage of nicotinic ACh receptor-ion channel complex (Masuo et al., 1986), (ii) reduced reflex excitability of both flexors

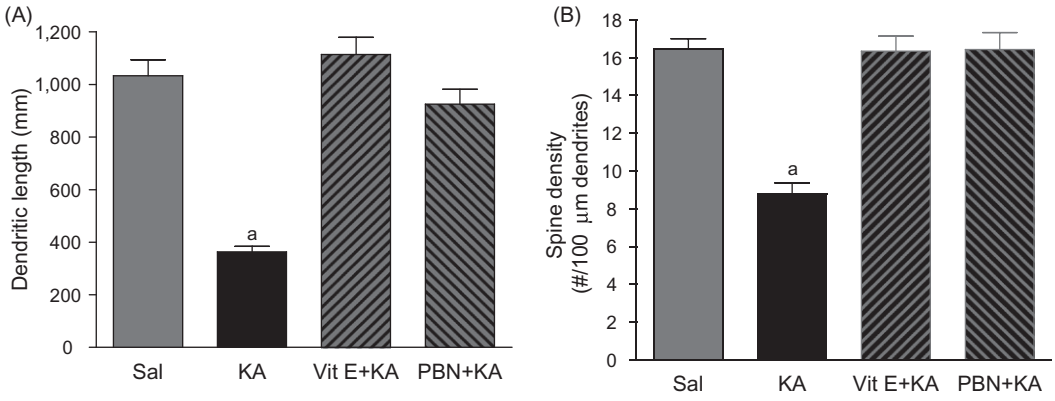

FIGURE 48.9 Dendritic length (A) and spine density (B) of pyramidal neurons from the CA1 hippocampal area of mice following ICV KA with or without vitamin E or PBN pre-treatment. Brains from mice exposed to KA were collected 30 min post-injection ($n \geq 5$ for each group). One-way ANOVA had $p < 0.001$ with Bonferroni's multiple comparison tests significant for KA versus control, vitamin E + KA or PBN + KA treatment.

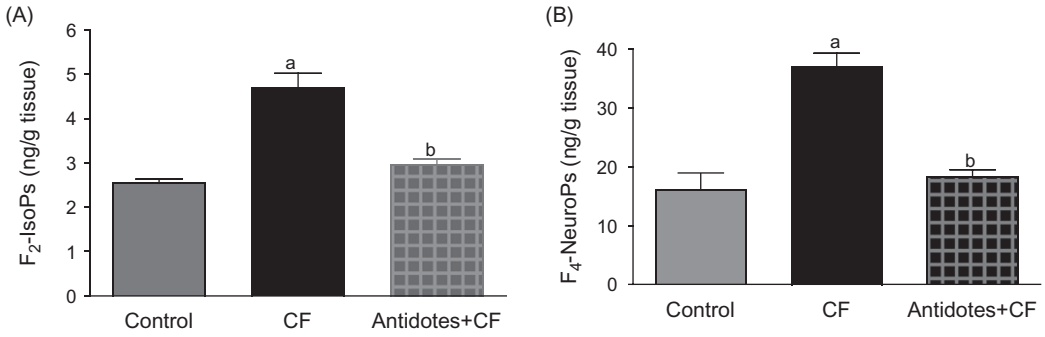

FIGURE 48.10 Cerebral F_2-IsoPs (A) and F_4-NeuroPs (B) concentrations following CF (1.5 mg/kg, s.c.) with or without antidote pretreatment (memantine, 18 mg/kg, and atropine, 16 mg/kg, given prophylactically, 60 and 15 min, respectively, before CF administration). Brains from rats exposed to CF were collected 60 min postinjection ($n \geq 5$ for each group). One-way ANOVA had $p < 0.0001$ with Bonferroni's multiple comparison tests significant for CF versus control (a), and for CF versus antidote + CF (b).

and extensors (Wand et al., 1977), (iii) prevention of neural hyperexcitability (McLean et al., 1992), (iv) central muscle relaxation (Grossman and Jurna, 1997), and (v) prevention of AChE inhibitor-mediated energy loss from muscle cells (Milatovic et al., 2005a). Memantine is also able to prevent the pathogenic calcium influx caused by continuous mild activation by low-level glutamate. On the other hand, memantine allows the physiological activation of the NMDA channels by high concentrations of glutamate, a phenomenon necessary for synaptic plasticity underlying normal learning and memory (Parsons et al., 1999).

Previous studies have also demonstrated that memantine treatment significantly reduces lipid peroxidation (Figure 48.10) and alterations in citrulline and HEP levels in muscles and brain of rats intoxicated with CF (Milatovic et al., 2005a; Gupta et al., 2007; Zaja-Milatovic et al., 2009).

No significant alterations in biomarkers of neuronal damage, citrulline, HEP, and their metabolite levels were seen in any of the brain regions receiving memantine and atropine. In addition, memantine and atropine exposure did not induce any alteration in neuronal morphometry, but when given as pre-treatment, it did provide protection against CF-induced morphometric changes in hippocampal neurons (Figure 48.11). Memantine, in combination with atropine, completely suppressed reduction in both dendrite length and in spine density of pyramidal neurons from the CA1 hippocampal area from CF-exposed rats (Figure 48.11).

In conclusion, the data demonstrated that synergistic mechanisms of cellular disruption caused by anti-AChE agents led to cellular dysfunction and neurodegeneration. It has also been demonstrated that preventing CF-induced neuronal hyperactivity by pretreatment with memantine and atropine blocks pathways associated with oxidative damage in rat brain. The documented ability of memantine therapy to reduce free radical generation and lipid peroxidation, prevent HEPs, and attenuate the morphological injury provides further support for the role of ROS and RNS in anti-AChE-induced seizures.

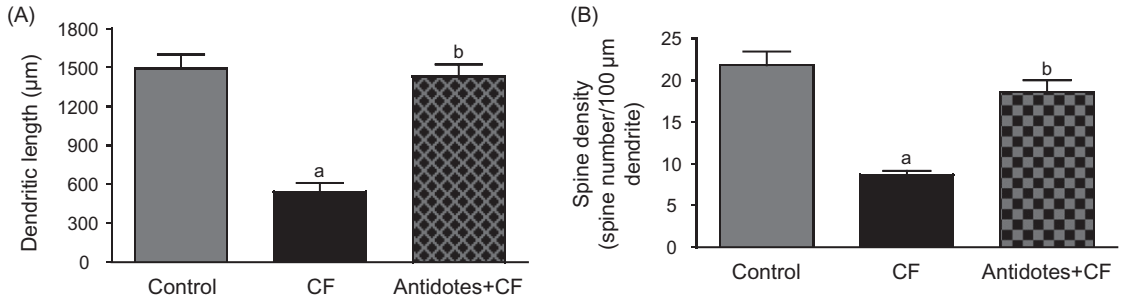

FIGURE 48.11 Dendritic length (A) and spine density (B) of pyramidal neurons from the CA1 hippocampal area of mice following CF (1.5 mg/kg, s.c.) with or without antidote pre-treatment (memantine, 18 mg/kg and atropine, 16 mg/kg given prophylactically, 60 and 15 min, respectively, before CF administration). Brains from rats exposed to CF were collected 60 min post-injection ($n \geq 5$ for each group). One-way ANOVA had $p < 0.0001$ with Bonferroni's multiple comparison tests significant for CF versus control (a), and for CF versus antidote + CF (b).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Exposure to OP nerve agents induces seizures, rapidly progressing to SE and profound structural brain damage. The progression of events includes initial high cholinergic activity followed by activation of glutamatergic neurons as a result of release of glutamate. Moreover, glutamate stimulates the continuous release of ACh, contributing to further excitatory stimulation, prolongation of the seizures, and excitotoxic neurodegeneration in vulnerable brain areas. The ensuing neuronal damage is thought to result from intense transient influx of calcium, which leads to mitochondrial functional impairment, cytochrome c-inactivation, depletion of ATP, simultaneous formation of free radical species, and oxidative stress. Therefore, control of excitotoxicity and oxidative stress, better understanding of the mechanisms of noncholinergic-mediated activities, and pathways that protect or promote neuronal survival are essential for the development of efficacious treatments and preventive therapies associated with OP exposures.

We have explored mechanisms associated with OP-induced neurotoxicity by probing their effects on oxidative stress and associated dendritic degeneration of pyramidal neurons in the CA1 hippocampal area. We have also investigated different pathways to attenuate biomarkers of oxidative damage associated with anti-AChE exposure and the extent to which such attenuation is accompanied by rescue from neurodegeneration. Results from our studies suggest that vitamin E, PBN, and memantine efficiently suppress oxidative injury. Future studies should be directed at deciphering the mechanisms of protection, addressing the ability of these agents to attenuate OP neurotoxicity via radical scavenging, AChE inhibition, suppression of neuroinflammation, glutamate antagonism, or any combination. Additional studies should also determine whether a combination of these treatments improve the therapeutic index against OP poisoning (compared to administration of each alone). Complementary studies should also investigate not only the prophylactic, but also the therapeutic effects of these neuroprotectants. Successful identification of safe and effective neuroprotectants that suppress noncholinergic activities associated with anti-AChE exposure will provide new pharmacological modalities to protect and treat both the acute and delayed effects of nerve agent poisoning.

CHAPTER

49

Blood–Brain Barrier Damage and Dysfunction by Chemical Toxicity

Ramesh C. Gupta, Jason Pitt and Snjezana Zaja-Milatovic

INTRODUCTION

Direct evidence for the existence of the blood–brain barrier (BBB) came at the dawn of the twentieth century from the observations of Nobel Laureate Paul Ehrlich. When he injected colored dyes, including trypan blue, into the blood stream, they leaked out of capillaries in most regions of the body to stain the surrounding tissue, but the brain and spinal cord remained unstained. Further support for the existence of the BBB came from the work of the Russian neurophysiologist Lina Stern in 1921, who called this barrier a "hematoencephalic" barrier. Since then, doubts have been cast over the actual existence of the BBB, until the emergence of electron microscopic data demonstrating the presence of the tight junctions between the endothelial cells that form brain capillaries (Abbott et al., 2010; Palmer, 2010). The BBB is formed and maintained through a dynamic interaction between cerebral and endothelial cells constituting the anatomical basis of the BBB and other neighboring cells, such as astroglia, pericytes, perivascular microglia, and neurons (Deli et al., 2005). The cross-talk between these cells endows endothelial cells with a unique BBB phenotype comprising not only the morphological barrier of endothelial tight junctions, but also the enzymatic and metabolic barriers, as well as the uptake and efflux transport systems (Abbott et al., 2010).

The term BBB describes a series of mechanisms that control the internal environment of the brain (Saunders et al., 2008). Stability of this environment is essential for normal brain development and function. Underlying the cellular mechanisms that determine the brain's internal environment is a fundamental physical barrier at the level of intercellular tight junctions between cells forming the interface between blood and brain (BBB) and in the choroid plexuses (blood–cerebrospinal fluid barrier, BCSFB). These tight junctions severely attenuate or occlude movement of chemicals and proteins through intercellular spaces between endothelial cells in the BBB and epithelial cells in the choroid plexus BCSFB.

The BBB formed by the endothelium of cerebral blood vessels is one of the three main barrier sites protecting the central nervous system (CNS). The barrier is not a rigid structure, but rather a dynamic interface with a range of interrelated functions, resulting from extremely effective tight junctions, transendothelial transport systems, enzymes, and regulations of leukocyte permeation, which thereby generates the physical, transport, enzymatic, and immune regulatory functions of the BBB (Abbott and Friedman, 2012). In addition, recent studies have revealed important stages, cell types, and signaling pathways involved in BBB development. Several enzymes (monoamine oxidase, epoxy hydrolase, endopeptidases, acetylcholinesterase, dopa decarboxylase, γ-glutamyl transpeptidase) are known to be present in endothelial cells and are important elements of the BBB phenotype constituting the so-called metabolic barrier, and they participate in the regulation of brain penetration of drugs (Fenstermacher, 1989; Pardridge, 2002). The role of the BBB as a metabolic barrier was further ascertained by the presence of mitochondria in cerebral endothelial cells (Fenstermacher, 1989). Thus, the BBB may be considered a physical as well as a metabolic barrier.

Because the involvement of brain barriers is apparent in neurodegenerative diseases, neurotrauma, chemical-induced neurotoxicity, and delivery of drugs of use and abuse, renewed interest in this area of research has emerged (Neuwelt et al., 2008; Palmer, 2010). In physiological conditions, the BBB regulates the exchange of nutrients, waste, and immune cells between the blood

Handbook of Toxicology of Chemical Warfare Agents.

and the nervous tissue of the CNS and is the most important component preserving CNS homeostasis and neuronal function (Abbott et al., 2010). Dysfunctional brain barrier mechanisms contribute to the pathology of neurological conditions, ranging from trauma to neurodegenerative diseases, and provide obstacles for successful delivery of potentially beneficial pharmaceutical agents (Saunders et al., 2008; Palmer, 2010; Erickson and Banks, 2013). Interestingly, modulations in the BBB can be the cause and/or consequence of non-CNS diseases, such as diabetes, chronic inflammatory pain, and obesity, but they are not discussed in this chapter because of chapter size constraints. This chapter describes, in brief, the structure and function of the BBB and modulations of its components and permeability by chemical warfare agents (CWAs) and other toxicants, Gulf War Illness (GWI), stress, blasts, excitotoxicity, and neurodegenerative diseases.

STRUCTURE AND FUNCTION OF THE BBB

The brain develops and functions within a strictly controlled environment resulting from the coordinated action of different cellular interfaces located between the blood and the extracellular fluids (interstitial fluid and the cerebrospinal fluid (CSF)) of the brain (Strazielle and Ghersi-Egea, 2013). The barrier between the blood and the brain or spinal cord parenchyma proper, referred to as the BBB, is formed by the endothelium of the cerebral microvessels. Several layers exist between the blood and brain: capillary endothelial cells, a basement membrane consisting of type IV collagen, fibronectin and laminin that completely cover the capillaries, pericytes embedded in the basement membrane, and glia/astrocytes that surround the basement membrane (Figure 49.1). Each of these layers could potentially restrict the movement of solutes (Hawkins et al., 2006; Alvarez et al., 2013).

de Boer et al. (1998) described that the BBB has narrow tight junctions, has no intercellular clefts, has minor pinocytotic activity, is not fenestrated, has a continuous basement membrane, contains many mitochondria, and has high electrical resistance (1,500–2,000 Ohm $\times$ cm^2). Next to the microvascular endothelial cells, pericytes, microglia, and neurons influence the functionality of the BBB, and there are also leukocytes (lymphocytes and monocytes) and, in the surrounding larger vessels, perivascular macrophages and mast cells. In addition to endothelial and epithelial cells, astrocytes and pericytes are involved in structure, functions, and regulation of brain barriers (Abbott et al., 2010; Armulik et al., 2010; Daneman et al., 2010; Mizee et al., 2013).

The BBB is to be distinguished from a second barrier component located between the blood and the ventricular CSF, and thus is called the blood–CSF barrier (BCSFB). The BCSFB interface is formed by the tight epithelium of the choroid plexuses, which are specialized structures projecting in all four ventricles of the brain and are responsible for the active secretion of CSF. The BBB develops a large surface area of exchange between the blood and the neutrophil, with an average of 100 cm^2/g of brain tissue in the adult mammal. In a 1-month-old rat, the apical surface area in contact with CSF has been estimated to be 75 cm^2 and close to the surface area developed by the BBB (Keep and Jones, 1990).

BBB tightness is maintained by various intercellular junctions, such as tight junctions, adherence junctions, gap junctions, and syndesmos, from which the tight junctions seem to be the most important ones in restricting passive hydrophilic transport. The BBB presents more possibilities for the transport of small molecules (molecular weight 400–600) compared with large ones, keeps the composition of electrolytes constant in the interstitial fluid of the brain, and prevents the passage of water-soluble drugs and proteins from the blood to the brain.

The BBB closely regulates the exchange of molecules in and out of the brain parenchyma to maintain its optimal homeostasis for a chemical environment that allows adequate brain functioning (de Vries et al., 2012). The ionic stability, neurochemical environment, and normal functioning of the brain are crucially dependent on the integrity of the brain barrier systems (Saunders et al., 2008). Without this stability, complex functions performed by the brain would be impossible. Saunders et al. (2008) further emphasized that dysfunction of brain barrier mechanisms in a variety of pathologies is more than a disruption of the normal (tight junction) diffusion restraint and that such dysfunction might be a part of the disease process, rather than a consequence. In a recent report, Erickson and Banks (2013) described that the BBB dysfunction is a cause as well as a consequence of neurological diseases, such as Alzheimer disease (AD).

IN VIVO AND *IN VITRO* MODELS TO STUDY THE BBB

The movement of compounds from the circulating blood into the brain is strictly regulated by the brain capillary endothelial cells, which constitute the BBB. The importance of the BBB is not only in the passage of toxicants but also in therapeutic drugs and antidotes. Brain capillary endothelial cells are connected to each other by continuous tight junctions and have a low number of pinocytotic vesicles. Several proteins (such as P-glycoproteins) and enzymes (such as monoamine oxidase, dopa decarboxylase, acetylcholinesterase, and others) are expressed by brain endothelial cells

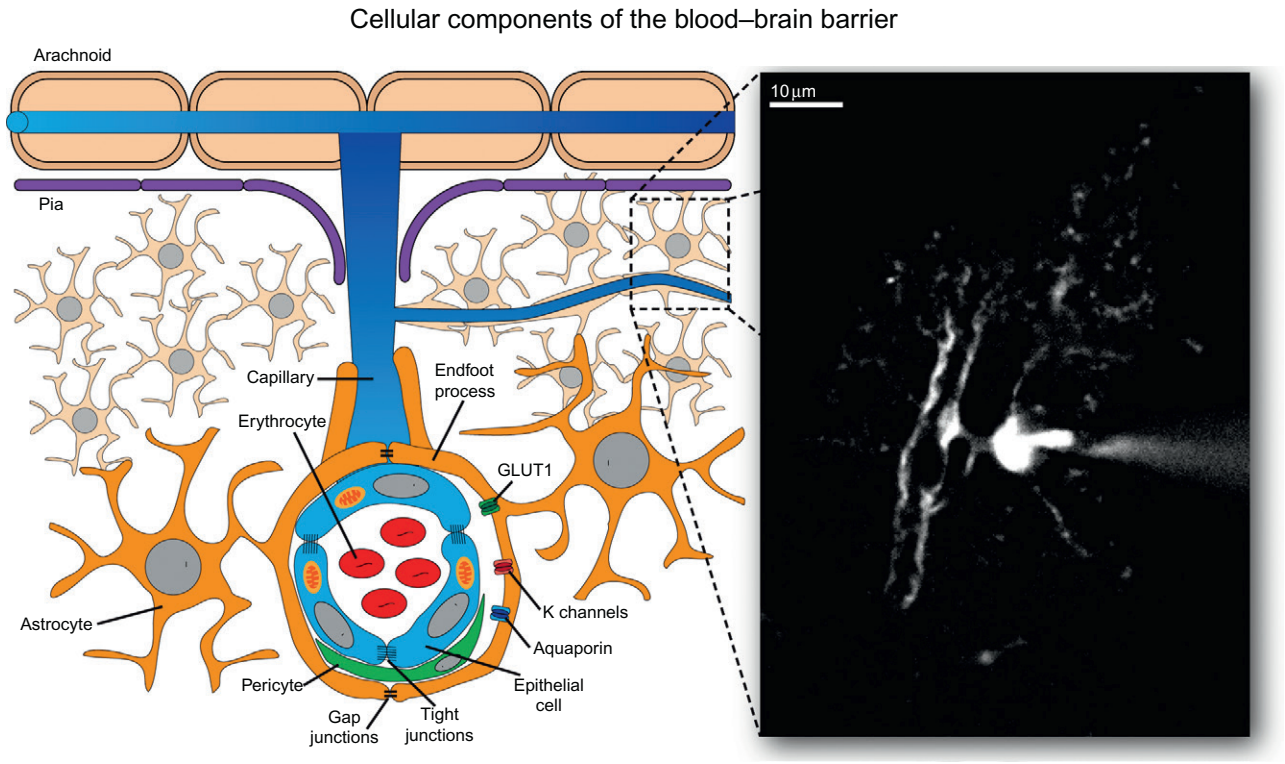

FIGURE 49.1 The BBB is a multicellular interface. The brain is a highly vascularized organ; blood vessels in the arachnoid space enter the brain and form a network of highly branched capillaries. Vascular epithelial cells are linked together through tight and adherens junctions. These intercellular junctions restrict the entry of blood-borne molecules from entering the CNS and form the BBB. Interactions between the epithelial cells are maintained by astrocytes, a type of glial cell that surrounds more than 99% of the vascular epithelium. Astrocytes ensheath blood vessels with specialized processes called endfoot processes, which express a variety of transporter proteins to maintain osmotic balance and uptake glucose from the blood. This intimate relationship between astrocytes and the vasculature is illustrated in the inset figure, which shows an astrocyte in an acute brain slice filled with a fluorescent dye. The patch pipette and blood vessel are visible to the right and left of the astrocyte, respectively. The buffering capacity of astrocytes is dramatically improved through a series of gap junctions between neighboring astrocytes.

and constitute the so-called metabolic barrier. Because of these characteristics, the BBB limits or impairs the delivery of certain drugs to the CNS. So, to understand the crossing of compounds of various classes, drugs, and antidotes, various *in vivo* and *in vitro* models have been developed.

In Vivo Model

Birngruber et al. (2013) reported a cerebral open flow microperfusion as a new membrane-free technique for measuring substance transport across the intact BBB in Sprague-Dawley rats. This *in vivo* technique is based on a probe that is inserted into the brain, thereby rupturing the BBB. The BBB is usually reestablished within 15 days, which then allows sampling of interstitial brain fluid under physiological conditions. This technique allows monitoring of BBB permeability, which can be useful for measuring pharmacokinetics across the BBB and pharmacodynamics in the brain. Using tracers, such as Evans blue (EB), horseradish peroxidase, and [^{131}I] albumin, breakdown of the BBB in humans and experimental animals has been studied under many conditions, such as hypoglycemia, hypertension, seizures/convulsions, and inflammation (Öztaş, 1996).

In Vitro Models

In vitro reconstituted models of the BBB from different mammalian species have been used since the late 1970s. However, their comparison is difficult because of the different species and methods used for isolation, culture, coculture, and characterization of the models. Lundquist et al. (2002) confirmed that the epithelial cells might not represent a valid and reliable *in vitro* BBB model, because results obtained on epithelial monolayers correlated poorly with *in vivo* BBB permeability values. Bowman et al. (1983) introduced the first *in vitro* BBB filter model. The insert was made of nylon mesh and polycarbonate tubing, and bovine brain endothelial cells were seated on it for studying the effect of calcium-free medium and osmotic shock on sucrose flux. Since then, a variety of

chambers and inserts from different materials and with diverse pore size have become commercially available. Garberg et al. (2005) used an *in vitro* model for BBB permeability based on the use of a continuous cell line and to investigate the specificity of this model. These authors developed a coculture procedure that mimics the *in vivo* situation by culturing brain capillary endothelial cells on one side of a filter and astrocytes on the other. Under these conditions, endothelial cells retain all the endothelial cell markers and the characteristics of the BBB, including tight junctions and enzymes activities (γ-glutamyl transpeptidase and monoamine oxidase). Raub (1996) identified the signaling pathways involved in the barrier-enhancing effects of C6 glioma cells, suggesting that the action is not mediated through cAMP, but rather by protein kinase C (PKC) activation via phospholipase D, independent of intracellular calcium increase.

Deli et al. (2005) presented permeability data from various *in vitro* BBB models by measuring transendothelial electrical resistance (TEER) and by calculation of permeability coefficients for paracellular or transendothelial tracers. These authors summarized the results of primary cultures of cerebral microvascular endothelial cells or immortalized cell lines from bovine, human, porcine, and rodent origin. This also described the effect of coculture with astroglia, neurons, mesenchymal cells, blood cells, and conditioned media, as well as the physiological influence of serum components, hormones, growth factors, lipids, and lipoproteins on the BBB function.

The strong correlation between the *in vivo* (Oldenhorf method) and *in vitro* (coculture) drug transport, the relative ease with which such cocultures can be produced in large quantities, and the reproducibility of the system provide evidence for an efficient system for the screening of drugs that are active in the CNS (Dehouck et al., 1997). These authors suggested that the coculture method is a useful system for investigating passive diffusion, carrier-mediated transport, and P-glycoprotein-dependent drug transport. The *in vitro* permeabilities of propranolol and cyclosporine A were parallel with indications from *in vivo* extraction, showing that transporters and P-glycoprotein are expressed in the coculture system. For further details, readers are referred to the work by Deli et al. (2005), who reviewed various *in vitro* models covering bovine, human, porcine, and rodent (murine and rat) brain endothelial cell-based systems. Bovine systems provide a high yield of brain endothelial cells sufficient for pharmacological screening, and they are widely used in basic as well as in applied research. Mouse brain yields the least endothelial cells compared with other species.

Some examples of the modulators of BBB permeability in *in vitro* models are: both cAMP elevator peptide hormone adrenomedulin and calcitonin gene-related peptide decrease paracellular permeability; a glucocorticoid hormone, hydrocortisone, improves the barrier properties; insulin exerts a tightening effect on tight junctions; and catecholamines (adrenaline and noradrenaline) increase the sodium fluorescein flux.

In essence, *in vitro* models have been widely used in pharmacological research for screening drugs and drug candidate molecules for either modifying BBB permeability or investigating brain penetration (Deli et al., 2005). This area of research is very important for permeability screening during drug development in the pharmaceutical industry.

GENDER DIFFERENCES IN THE BBB

For more than a quarter of a century, evidence has suggested that the BBB differs in males and females in terms of morphology, metabolism, and permeability. Interest arose from previous studies suggesting that women had higher cerebral blood flow than men, and the differences were more pronounced in the frontal regions (Mathew et al., 1986). Follow-up studies further confirmed the finding of higher cerebral blood flow in females as compared with males (Rodriguez et al., 1988).

In animal studies, although Saija et al. (1990) found no substantial difference in the permeability of the BBB between male and female rats, fluorescein penetrated to a greater extent in the brains of females as compared with males, but only into those regions that reside outside the BBB. Öztaş (1998) investigated the gender effects on the BBB permeability during bicuculline-induced seizures in female and male rats and found the extravasation of EB-stained albumin in a more pronounced manner in the brains of females as compared with males. In a similar study, Öztaş (1996) noted that disruption of the BBB permeability during pentylenetetrazol-induced seizures was asymmetric between the right and left hemispheres in female rats but not in male rats. Interestingly, ovariectomy decreased the BBB permeability during seizures, suggesting the involvement of estrogen because endothelial cells have been shown to contain estrogen receptors (Colburn and Buonassivi, 1978).

Furthermore, the distribution of serotonin is different in the brain and in the cerebral endothelial cells of males and females (Fischette et al., 1983), and serotonin is an important modulator of BBB permeability (Sharma and Dey, 1986). The sex hormone-related differences in the serotonin and other neurotransmitter levels in endothelial cells may cause different responses under pathological conditions. Öztaş (1998) hypothesized that if BBB permeability can increase more easily in females, then this increased breakdown may result in higher incidences of neurodegenerative diseases, such as AD and multiple sclerosis (MS) in women.

THE BBB IN YOUNG AND ADULT BRAINS

Structure and function of the BBB substantially differ in young and adult brains. In general, the BBB is immature in fetuses and newborns. This may be partly because of the fact that the blood vessels in the immature brain are more fragile than in the adult. Astrocytes in the developing brain are also responsible for the induction of tight junctions in the cerebral endothelial cells as well as other features of brain barrier mechanisms (Janzer and Raff, 1987). Saunders et al. (1999a,b) provided evidence that barriers to proteins at blood–brain and blood–CSF interfaces (tight junctions) are present from very early in development. Immunocytochemical and permeability findings revealed that proteins are largely excluded from extracellular space in the developing brain. In addition to tight junctions present at the BBB and BCSFB, the immature brain also has a mixture of other junctions present at the outer CSF–brain barrier (plate junctions, strap junctions, and wafer junctions). These barriers are not present in the adult (Saunders et al., 1999b). It was suggested that both the functional and the morphological properties of the BBB develop progressively from the onset of intraneural vascularization. However, the morphological characteristics of the BBB do not fully develop until the neonatal period. Because the BBB in fetal and early neonatal life is not fully developed, it allows for the diffusion of blood-borne macromolecules and toxins that are normally excluded from the mature CNS. Apparently, the fetus and the neonate are at greater risk for brain injury from toxicants, such as CWAs, metals, pesticides, and other environmental contaminants.

TRANSPORT OF MOLECULES ACROSS THE BBB

Brain capillary endothelial cells form the BBB. They are connected by extensive tight junctions and are polarized into luminal (blood-facing) and abluminal (brain-facing) plasma membrane domains (Hawkins et al., 2006). A pivotal function of the endothelial cells is to express transporters at the BBB and regulate the selective transport and metabolism of substances from blood to brain (Daneman et al., 2010). These transporters may be utilized to target specific molecules for delivery into the brain for therapeutic purposes. Figure 49.2 depicts various transport mechanisms for amino acids, glucose, proteins, and other molecules.

There are two major pathways for molecules and cells to cross the BBB: the paracellular (junctional) route and the transendothelial route (Deli et al., 2005). One of the hallmarks of the BBB phenotype is the restrictive paracellular pathway, which is regulated by interendothelial tight junctions. Tight junctions not only restrict paracellular flux but also maintain the polarity of enzymes and receptors on luminal and abluminal membrane domains. The most important integral tight junction proteins include occludin, claudin-1, claudin-5, and junctional adhesion molecules. Daneman et al. (2010) identified several tight junction molecules whose expression was found at the BBB, including marveld2, cingulin-like-1, and pard3, that might play a crucial role in the formation of BBB tight junctions.

It is established that the brain environment signals brain endothelial cells to form the BBB, but the identity of these signals is unknown. Paracellular permeability is regulated by diverse signaling cascades (Krizbai and Deli, 2003). Among many signaling pathways, some are noteworthy, such as Wnt/β-catenin signaling (Leibner et al., 2008; Daneman et al., 2010), sonic hedgehog (Shh) signaling (Alvarez et al., 2011), intracellular stabilization signals mediated VE-cadherin (Rudini et al., 2008; Taddei et al., 2008), and retinoic acid signaling (Mizee et al., 2013). Daneman et al. (2010) have generated a comprehensive data set describing the transcriptome of the BBB, which will provide a valuable resource for understanding the development and function of this crucial barrier, as well as its role in modulating CNS function.

The transendothelial pathways also exist at the brain microvasculature. In contrast to peripheral endothelium, the rate of pinocytosis is minimal, and free membrane diffusion applies mainly to small lipophilic molecules, for example, ethanol or nicotine (Pardridge, 2002). Daneman et al. (2010) utilized ingenuity pathway analysis (IPA) software to analyze the CNS endothelial enriched transcripts to identify signaling pathways that are enriched at the BBB or in peripheral endothelial cells. Various transport systems are present at the BBB to transport compounds in and out of the brain (de Boer et al., 1998). Active transport systems can be divided into three groups. First is carrier-mediated bidirectional transport, which is responsible for nutrient uptake in the brain. These transporters include glucose transporter GLUT-1, monocarboxylic acid transporter MCT1, large neutral amino acid transporter LAT1, or sodium-coupled nucleoside transporter CNT2 (and others). Second is efflux transport, which is unidirectional and delivers metabolites and xenobiotics from brain to blood. Third is receptor-mediated transport by endocytosis and transcytosis, which is important for the brain supply of peptides and proteins, such as low-density lipoproteins, transferrin, leptin, and insulin (Pardridge, 2002). Bidirectional transporters include glucose transporter GLUT-1, monocarboxylic acid transporter MCT1, large neutral amino acid transporter LAT1, or sodium-coupled nucleoside transporter CNT2 (and others) (Pardridge, 2002). P-glycoprotein and MRP-1 multidrug resistance proteins, brain multidrug resistance proteins (ABCG2/BCRP), or organic anion-transporting

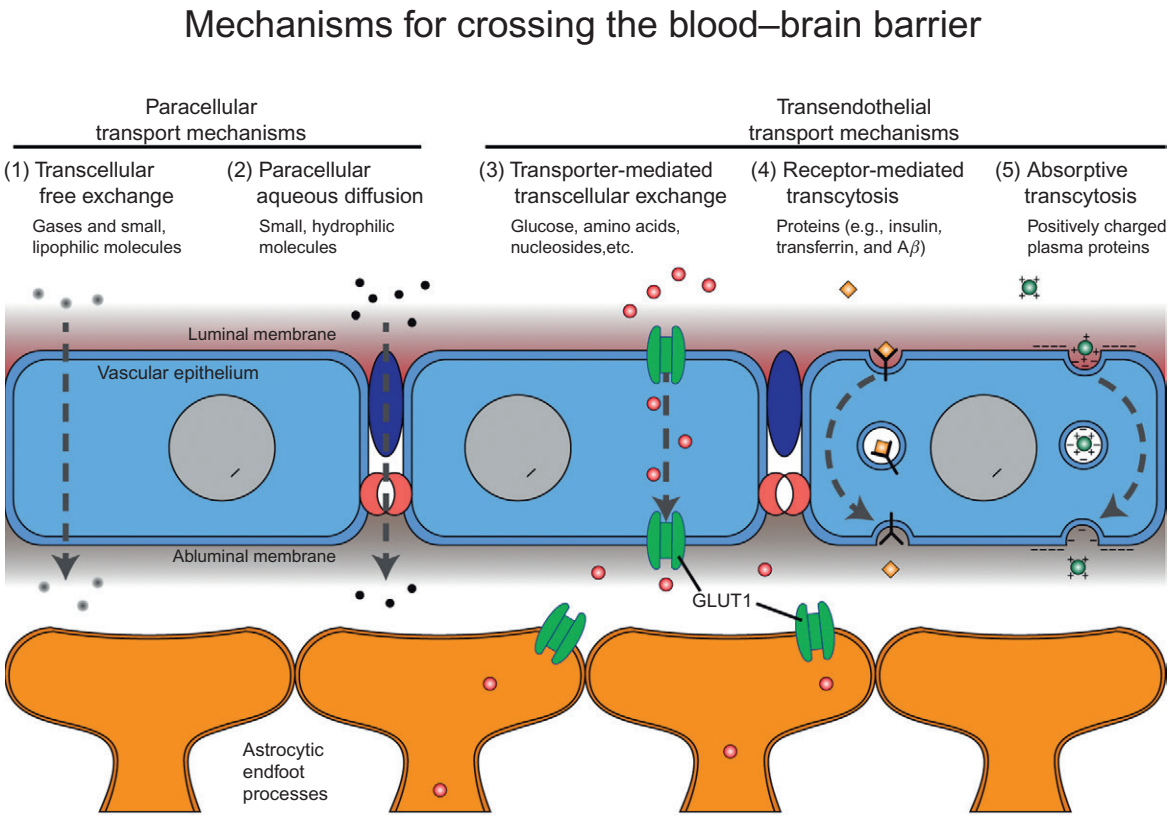

FIGURE 49.2 **Transport across the BBB occurs through a variety of mechanisms.** Gases and small lipophilic molecules enter and exit the CNS freely through transcellular exchange. Very small hydrophilic molecules are able to permeate the tight junctions (dark blue ovals) and adherens junctions (salmon crescents) between vascular epithelial cells that restrict the entry of larger molecules into the CNS. Instead, larger hydrophilic molecules are transported through transmembrane pores, receptor-mediated transcytosis, or absorptive transcytosis. After crossing the BBB, solutes are then transported through the astrocytic endfoot processes and shuttled to neurons.

polypeptide OATP2 belong to the rapidly growing group of efflux transporters at the BBB (de Boer et al., 2003; Chan et al., 2013).

A number of cellular and molecular factors can influence transport of molecules across the BBB. For most solutes and macromolecules, permeability is largely dependent on their lipophilicity. Hydrophilic solutes and macromolecules are believed to cross the barrier through specific carrier mechanisms or facilitated diffusion (Aschner, 1998). Some of these carriers are symmetrically distributed both on the luminal and abluminal membranes of the endothelial cells, whereas others have an asymmetric distribution. For example, the carriers for the essential neutral amino acids, which are required in the brain for neurotransmitter synthesis, are localized on both luminal and abluminal membranes. In contrast, the carrier for the amino acid glycine appears to be located only on the abluminal membrane. The function of this asymmetric distribution is to remove glycine from the CNS and to keep its concentration low in the brain. The polar distribution of proteins maintains amino acid homeostasis in the brain. The existence of two facilitative transporters for neutral amino acid on both membranes provides the brain access to essential amino acids. By now, it is well-established that the BBB participates in the active regulation of the amino acid content of the brain. These comprise various amino acid transport systems (System L1, System ASC, System A, acidic amino acid transporter, peptide transporter) (Begley, 1995). In addition to these transporters, P-glycoprotein (Pgp) is one of the transporters of great interest (Chan et al., 2013).

In recent studies, Daneman et al. (2010) and Geier et al. (2013) stated that the transporters and neuroprotective function of the BBB present major challenges for therapeutic drug delivery to the CNS. Critical to this function, BBB membrane transporters include the ATP-binding cassette (ABC) transporters, which limit drug penetration across the BBB, and the less studied solute carrier (SLC) transporters. These authors demonstrated expression of profiling of 359 SLC transporters and immunoassays in microvessels at the human BBB. In some situations, to be more effective, osmotic opening of the BBB has been used clinically to enhance entry of water-soluble drugs from the blood into the brain.

Daneman et al. (2010) also asserted that IPA software can be used to identify metabolic pathways enriched at the BBB or in peripheral endothelial cells. Glycolysis/gluconeogenesis and amino acid metabolism are enriched at the BBB, suggesting that brain endothelial cells may be intimately involved in the production of energy metabolites and amino acids for neurons, a function that has been thought to be uniquely served by astrocytes (Bélanger et al., 2011).

EFFECTS OF TOXIC AGENTS ON THE BBB

Breakdown of the BBB in humans and experimental animals in various conditions (stress, hypertension, convulsions, seizures, ischemia, hypoglycemia, inflammation) has been well-documented. The BBB is incapable of preventing the exchange of toxins/toxicants from the blood to the brain when its integrity (structure, function, or permeability) is compromised by chemicals or their toxicity.

Anticholinesterase Nerve Agents

Drewes and Singh (1985) reported that the cerebral transendothelial carrier-mediated transport of glucose and amino acids was not affected in mongrel dogs poisoned by soman, an irreversible acetylcholinesterase (AChE) inhibitor. Carpentier et al. (1990) investigated acute changes in BBB permeability to proteins using EB-labeled serum albumin and plasmatic gamma-immunoglobulin G (IgG) as indicators in rats. An increased BBB permeability to the EB–albumin complex was macroscopically observed in two-thirds of the convulsive rats intoxicated by 85 µg/kg of soman. Soman produced seizures and reversible BBB opening to a greatest extent after 30–60 min of paroxysmal electroencephalographic (EEG) discharges when signs of cerebral hyperactivity (epileptic EEG pattern, hyperoxia) were also at their height. Topographically, the protein leakage was bilateral and restricted to anatomically defined brain structures, some of which were sites of parenchymal edema and neuronal damage. Vascular damage occurred approximately when toxic symptoms began to reduce and was nearly concomitant to the highest level of brain oxygenation and to the maximal intensity of seizures. Interestingly, the first signs of increased BBB permeability were shown to precede the onset of edema. Carpentier et al. (1990) detected the BBB opening in the amygdaloid complex and in some cortical regions (cingulum, entorhinal, and piriform complex). The thalamus was the most frequently and intensely affected structure, and the hippocampus remained free of exudated immunoreactive IgG.

Observations from various studies suggest that soman-induced brain alterations are predominantly related to seizures or brain hyperactivity or to a direct cytotoxic action of soman or acetylcholine (ACh) itself, or because of ChE inhibition (McDonough et al., 1987).

Domer et al. (1983) found increased permeability of the BBB by systemic administration of ACh. Of course, brain hyperactivity alone appears inadequate to be responsible for the BBB opening. Obviously, the short duration of the transient protein leakage (Carpentier et al., 1990) contrasted with the well-known long-lasting brain AChE inhibition induced by soman (Petrali et al., 1985). Several other anti-ChE compounds, such as physostigmine and paraoxon, are also known to produce the BBB opening for macromolecules that was seizure-dependent, reversible, and unrelated to brain ChE inhibition. Ashani and Catravas (1981) observed that in soman-intoxicated rats, induced damage to BBB integrity was significantly reduced, despite a high degree of AChE and BChE inhibition, and protected from seizures by nembutal or atropine. In essence, endothelial AChE or BChE plays no role in BBB opening, although it may function as an "enzymatic barrier" to ACh.

Although the exact mechanism is unknown, various contributing factors, such as increased electrical activity, oxidative/nitrosative stress, decreased energy supply and store, deleterious action of excitatory amino acids, enhanced calcium intrusion, and brain edema, seemed to play significant roles in the brain damage (Misulis et al., 1987; Carpentier et al., 1990; Solberg and Belkin, 1997; Gupta et al., 2001a,b; Zaja-Milatovic et al., 2009; Prager et al., 2013). Other mechanisms in soman-induced damage to BBB integrity may be related to vasoactive substances (ACh, amines, amino acids, peptides, free radicals, and steroid hormones of the pituitary adrenal axis) and vasogenic events (acidosis, increased blood flow, and hypertension).

OP nerve agents, which are small lipophilic molecules, can easily penetrate the BBB by free diffusion and thereby inhibit AChE in the CNS (Mercey et al., 2012). Increased BBB permeability by OP nerve agents or other ChE inhibitors may lead to their enhanced entry into the brain, resulting in greater AChE inhibition and possibly resulting in subsequent maintenance of seizures and aggravation of their pathological consequences, such as edema and neuronal loss in certain brain structures. Evidently, increased BBB permeability may facilitate the entry of an antidote (oxime class) to the brain, which otherwise has limited access because of the BBB.

Oxime Reactivators of AChE Inhibited by OPs and the BBB

AChE reactivating oximes can be categorized into four groups: charged or noncharged and one-ring or two-ring compounds (Worek and Thiermann, 2013; Esposito et al., 2014). Commonly used AChE reactivators

(2-PAM, MMB-4, and HI-6) against OP nerve agents/pesticide-induced AChE inhibition are permanently charged cationic compounds that do not appreciably cross the BBB (Melchers et al., 1994; Cassel et al., 1997; Mercey et al., 2012; Esposito et al., 2014). These oximes reactivate AChE in peripheral sites, but they are not effective in the CNS and, consequently, they provide little or no protection against the neurological/neurotoxic effects of OP nerve agents. However, BBB-penetrating uncharged oximes, such as monoisonitrosoacetone (MINA), diacetylmonooxime (DAM), and dihydropyridine 2-pralidoxime (pro-2-PAM), act centrally and abrogate brain OP-induced seizure activity. But these compounds have a much lower propensity for reactivation of ChEs in peripheral tissues and blood compared with 2-PAM and other quaternary oximes, and they are too toxic for use (Skovira et al., 2010; Demar et al., 2010). Okuno et al. (2008) examined the BBB penetration of novel PAM-type oximes (alkylPAMs) using brain microdialysis with LC-MS/MS. Findings revealed that 4-[(hydroxyimino) methyl]-1-octylpyridinium bromide (4-PAO) may be effective for the reactivation of inhibited ChE in the brain; however, its toxicity was greater than that of 2-PAM. Recently, Okolotowicz et al. (2014) reported that uncharged amidine-oxime reactivator, (z)-*N*-((E)-1-(dimethylamino)-2-(hydroxyimino)ethylidine)butan-1-aminium chloride, is more lipophilic, chemically and metabolically stable, nontoxic, and can penetrate the BBB in animals and protect from the toxicity of nerve agents. Recently, Chambers et al. (2013) have synthesized some novel phenoxyalkyl pyridinium oximes that are more lipophilic than currently approved oximes against OP nerve agent surrogates. Being more lipophilic, these oximes may penetrate the BBB easily and thereby reactivate the OP-inhibited AChE. Furthermore, Esposito et al. (2014) have developed QSAR models to understand and improve physicochemical properties for the reactivation of OP-inactivated AChE, and these novel oximes may have easy access to cross the BBB as well.

Other strategies to deliver oximes across the BBB may include facilitative transport where sugar-oxime conjugates could be transferred by glucose transporters (Mercey et al., 2012; Bhonsle et al., 2013). Bhonsle et al. (2013) developed and validated molecular models for AChE reactivation by sugar oximes, which appear to be relatively nontoxic with a guinea pig LD_{50} of 1,590 mg/kg. By now, it is well-demonstrated that sugar oximes are relatively better reactivators of AChE inhibited by OPs compared with monoamine quaternary pralidoxime derivatives.

In OP nerve agent poisoning, a combination of AChE reactivating oximes provides better therapeutic efficacy compared with an individual oxime (Kassa et al., 2010, 2011a,b). Also, oximes (pralidoxime, trimedoxime, obidoxime, HI-6, HLo-7) provide greater neuroprotection against OP nerve agents when given in combination with an antimuscarinic drug (e.g., atropine sulfate) and an anticonvulsant drug (e.g., diazepam). In such scenarios, oximes alone or in combination, with and without atropine sulfate/diazepam, need to be evaluated at the BBB for their mechanisms of transport.

Karasova et al. (2010) evaluated 30 AChE reactivating oximes for BBB penetration using an *in vitro* model. Findings revealed that monoquaternary AChE reactivators were able to penetrate the BBB, and their molecular structure and molecular weight appeared to be the influencing factors for passive transport. Regarding the transport of bisquaternary oximes, the connecting linker plays a key role in penetrating into the BBB, for example, short linkers tend to facilitate penetration. Furthermore, the location of the oxime group on the pyridine ring influences passive transport into the brain. The optimum position of the oxime group was found to be at position four (i.e., para).

In essence, novel oxime reactivators (alone or in combination) that are capable of crossing the BBB and efficiently reactivating ChEs within the CNS are of great interest for protection of military personnel and civilians from nerve agents and OP pesticides.

NMDAR Antagonist Memantine and the BBB

Currently, an NMDA receptor (NMDAR) antagonist memantine is widely used in neurodegenerative diseases, but is more commonly used in moderate to severe AD. In a series of experimental studies, memantine has also been shown to protect animals from seizures, lethality, AChE inhibition, oxidative/nitrosative stress, high-energy phosphates depletion, cytotoxicity, and morphological alterations in the dendritic system of the brain against OP nerve agents or their surrogates (McLean et al., 1992; Gupta et al., 2007; Zaja-Milatovic et al., 2009). To protect or reverse OP-induced effects in the brain, memantine has to cross the BBB. Yet, the exact mechanism by which memantine crosses the BBB remains unknown. Recently, Mehta et al. (2013) identified the putative transporter involved in memantine disposition in the brain in mice. The findings implicate the involvement of an organic cation transporter regulated by proton antiport mechanisms in the transport of memantine across the mouse BBB, possibly the organic cation/carnitine transporter, OCTN1. Furthermore, memantine brain uptake was markedly reduced by various cationic transporter inhibitors (such as amantadine, quinine, tetraethylammonium, choline, and carnitine), suggesting the need for further investigation in patients using memantine and other medications (multidrug regimens). In the case of OP nerve agent poisonings, memantine is given in combination with atropine sulfate, which does not easily penetrate the BBB, and the interaction of memantine and atropine sulfate needs to be investigated at the BBB.

Melatonin and the BBB

CWAs are known to generate excess free radicals and cause excitotoxicity and neuroinflammation. Melatonin (*N*-acetyl-5-methoxytryptamine), being an indirect antioxidant and free radical scavenger, can modulate and control oxidative stress. Melatonin is also involved in vasomotor control and adrenal function. It possesses antiexcitatory actions, regulates immune function and energy metabolism, and exerts anti-inflammatory properties. Melatonin is highly lipophilic and, consequently, easily crosses cell membranes, including the BBB. Taking all these properties into consideration, melatonin could be an excellent and suitable candidate molecule to prevent CWA-induced tissue damage (Pita et al., 2013).

Drugs of Abuse-Induced BBB Damage

Currently, a large number of drugs of abuse are consumed by civilians as well as military personnel around the world. Among these illicit drugs, cocaine, morphine, and amphetamines (methamphetamine (METH), amphetamine, and methcathinone) are most commonly used (Multani et al., 2013). Because of its small size and lipophilicity, METH readily crosses the BBB by nonspecific diffusion. METH can induce BBB dysfunction in rodents, particularly in the limbic region including the hippocampus (Bowyer and Ali, 2006). Recently, Multani et al. (2013) described BBB disruption by using protein tracers, such as EB, iodine, and albumin immunohistochemistry of IgG1 in the cortex, hippocampus, thalamus, hypothalamus, cerebellum, and amygdala, and METH-induced neurotoxicity. The appearance of albumin immunoreactivity in the neuropil and leakage of serum albumin into the brain tissue had been observed as a consequence of METH-induced BBB breakdown, further leading to neuronal damage, myelin degeneration, reactive astrocytosis in the parietal and occipital cortices, extensive degeneration of pyramidal cells, and activation of microglia in the amygdala and hippocampus of rats (Sharma et al., 2007). It is suggested that, in addition to direct damage of monoaminergic nerve terminals, the deregulation of the BBB in these areas potentially contributes to widespread METH-induced neurotoxicity. METH directly damages dopaminergic and serotonergic nerve terminals, but also induces BBB dysfunction, which is thought to contribute to its neurotoxicity (Silva et al., 2010). Martins et al. (2013) provided mechanistic evidence that BBB breakdown was attributable to endothelial nitric oxide synthase (eNOS) activation and enhanced transcytosis. The neurotoxic effects of METH-induced BBB damage have been linked to hyperthermia, because METH causes dose-dependent temperature increases. Antioxidant H-290/51 pretreatment prevented hyperthermia, neuronal damage, myelin degradation, glial response, and leakage of serum albumin into brain tissue, establishing the role of free radicals in BBB damage and oxidative stress in METH neurotoxicity (Multani et al., 2013).

ElAli et al. (2012) reported that repeated administration of low-dose METH induces a transient parenchymal stress response, reflected by JNK1/2 and p38 MAPK activation, accompanied by the induction of pro-inflammatory cell adhesion molecules ICAM-1 and VCAM-1 in cerebral microvessels. Although tight junction proteins occludin and claudin-5 were expressed at high levels, a differential regulation of ABC transporters was observed after METH administration. The luminal ABCB1, which carries its substrates from the vessel into the blood, was upregulated, whereas the abluminal ABCC1, which carries its substrates from the vessel into the brain (Kilic et al., 2008), was downregulated in brain capillary cells (ElAli et al., 2012). These studies confirmed that METH modifies the structure of the BBB. JNK signaling has been shown to be involved in BBB breakdown associated with cerebral ischemia and subarachnoid hemorrhage. Recently, Urrutia et al. (2013) demonstrated that METH-induced changes in BBB integrity were attributable to JNK1/2-mediated activation of MMP-9 and laminin degradation. These effects were observed after acute exposure to METH at doses comparable with those used by consumers, for example, doses ingested typically in the range of 50–500 mg.

Metals

Metals, such as manganese (Mn), lead (Pb), and mercury (Hg), are transported on endogenous carriers, which otherwise function in the transport of essential macromolecules (Aschner, 1998; Song et al., 2014). Mn binds readily to transferrin without displacing iron (Fe) in plasma. Brain areas (pallidum, thalamic nuclei, and substantia nigra) with high Mn levels differ from those with high levels of transferrin receptors (nucleus accumbens and caudate putamen), suggesting that perhaps these sites may accumulate Mn through neuronal transport. Like Fe, Mn-loaded transferrin is taken up by receptor-mediated endocytosis at the luminal membrane of brain capillaries.

Pb can enter the CNS by more than one mechanism. The transport of Pb may occur either via the exchange of $PbCO_3$ with an anion or via exchange of an anion-ternary complex of $PbCO_3$ with another anion. Kinetic studies with ^{203}Pb continuously infused intravenously into adult rats revealed that ^{203}Pb uptake into different brain regions was linear with time up to 4 h after infusion (Bradbury and Deane, 1993). In the absence of organic ligands for Pb, the metal readily entered the CNS. However, the presence of albumin, L-cysteine, or EDTA during the vascular perfusion completely abolished the measurable uptake of ^{203}Pb. It was also suggested that Pb may passively enter the CNS in the form of $PbOH^+$.

It is well-established that Pb accumulates in the choroid plexus of humans as well as animals, suggesting that the choroid plexus is a primary target for Pb-induced neurotoxicity. Behl et al. (2009) demonstrated that exposure to Pb results in a significantly increased accumulation of intracellular amyloid-β ($A\beta_{1–40}$) in rat choroid plexus tissues *in vivo* and in immortalized choroidal epithelial Z310 cells *in vitro*. Several mechanisms may lead to an increased Aβ level at the BCSFB: a diminished expulsion of Aβ molecules from the plexus cells to the extracellular milieu; an increased uptake of Aβ from the CSF, blood, or both; an increased synthesis of Aβ; and/or a reduced metabolism or degradation of Aβ. Pb-induced inhibition of the production of LRP1 (a key intracellular Aβ transport protein in the choroid plexus) may be responsible for the accumulation of Aβ, and may be a major risk factor for AD.

Developing fetuses and neonates are most sensitive to methyl mercury (MeHg)-induced neurotoxicity, because MeHg is more readily transported across the immature BBB and because of its inhibitory effects on cell division. Aschner et al. (1990) demonstrated that MeHg conjugated to cysteine is transported across the BBB via the neutral amino acid transport L-system. It was reported that the structural similarity of the L-cysteine–MeHg conjugate with the structure of methionine suggested that, because of the broad specificity of the L-system, it should transport cysteine–MeHg conjugates efficiently across the BBB.

Copper (Cu) and Fe are trace minerals that are essential for normal brain function. They play important roles as catalysts, gene expression regulators, and second messengers. Recently, Monnot et al. (2011) investigated how BBB and BCSFB regulated Cu transport and how Fe levels altered brain Cu homeostasis. The findings demonstrate that both the BBB and BCSFB contribute to maintaining a stable Cu homeostasis in the brain and CSF. Cu appears to enter the brain primarily via the BBB and is subsequently removed from the CSF by the BCSFB. Fe deficiency has a more profound effect on brain Cu levels than Fe overload. Fe deficiency increases Cu transport at the brain barriers and prompts Cu overload in the CNS. The BCSFB plays a key role in removing excess Cu from the CSF.

BACTERIAL TOXIN-INDUCED BBB DAMAGE

Bacteria, their cell wall components, and their toxins can induce severe damage and dysfunction to the BBB (Deli et al., 2005). Lipopolysaccharide (LPS) is the primary endotoxin involved in inflammatory processes, sepsis, and multiorgan failure caused by Gram-negative bacteria like *Escherichia coli* (*E. coli*) or *Haemophilus influenzae*. LPS has been found to affect the CNS and damage the BBB by either direct or indirect means (Wispelwey et al., 1988; Shukla et al., 1996). Wispelwey et al. (1988) reviewed several studies dealing with LPS-induced damage to the BBB. In one study, intracarotid injections of *E. coli* LPS in rabbits caused diffuse breakdown of the BBB. In a second study, intracarotid LPS injections in rabbits were followed by an injection of colloidal Fe 4 h later. Electron microscopy of the brains of the LPS-treated animals revealed a large quantity of Fe within the endothelial cells, basement membrane, and glial process; however, in the saline controls, the Fe remained confined to the vascular lumen. In a third study, microscopic evaluation of brains from cats that had received intracisternal injection of *E. coli* LPS revealed evidence of profound inflammatory cell infiltration and microcirculatory impairment in both meningeal and cortical microvessels. Free radicals and nitric oxide (NO) appear to play a role in the LPS-induced increase in BBB permeability because stimulation with LPS not only produces superoxide radicals, but also enhances NO production. Minami et al. (1998) investigated the roles of NO and prostaglandins (PGs) in the development of damage to the BBB induced by LPS by using NOS and cyclooxygenase (COX) inhibitors. These authors concluded that both the NO produced by NOS (especially by iNOS) and the PGs produced by COX participate in the LPS-induced increase of BBB permeability. In *in vitro* BBB models, LPS induced a concentration-dependent and time-dependent increase in monolayer permeability (de Vries et al., 1996; Gaillard et al., 2003). Interestingly, glial cells protected cerebral endothelial cells from LPS-mediated injury in a coculture model.

Pertussis toxin, a virulence factor of *Bordetella pertussis*, severely compromises the integrity of brain endothelial monolayers in a dose-dependent and time-dependent manner and is possibly mediated by the PKC pathway (Brückener et al., 2003).

Meningitis-causing bacteria interact with brain endothelium and can cross the BBB as live bacteria either transcellularly or paracellularly and subsequently multiply inside the CNS (Kim, 2008). *Bacillus anthracis*, the etiologic agent of anthrax, has been shown to penetrate the BBB *in vivo*, and expression of the anthrax toxins was essential for this transmigration (Van Sorge et al., 2008). A more recent study demonstrated that anthrax toxins contributed to BBB disruption, invasion, trafficking, and the development of meningitis during live bacterial infection (Ebrahimi et al., 2011).

GWI AND THE BBB

After the first Persian Gulf War, many soldiers reported a variety of symptoms designated as Gulf War

Illness (GWI). The long-term symptoms include chronic fatigue, musculoskeletal pain, and cognitive–psychological disturbances, such as memory loss, confusion, inability to concentrate, mood swings, irritability, and somnolence. Among several factors, the use of pyridostigmine bromide (PB) pills, given to protect troops from the effects of AChE-inhibiting OP nerve agents (such as sarin, soman, tabun), and pesticides used during deployment, is highly likely (Amourette et al., 2009). PB is a reversible AChE-inhibiting carbamate that has been recommended by most military health services for prophylaxis against intoxication with irreversible AChE-inhibiting nerve agents. The toxic signs associated with PB are due to overstimulation of nicotinic and muscarinic receptors in the peripheral nervous system (PNS). Because of its quaternary amine structure, PB has limited access to the CNS. So, no effects on the CNS are described at doses currently recommended, unless BBB permeability is compromised.

Stress can disrupt the BBB and thereby can increase the neurotoxicity induced by chemicals in many cerebral areas (Sharma and Dey, 1986). Therefore, involvement of stress during PB treatment may allow PB to enter the brain and produce inhibition of brain AChE activity. It has been hypothesized that combat stress combined with PB treatment may have induced central penetration of PB, leading successively to the following: brain AChE inhibition; stimulation of muscarinic ACh receptors; rapid induction of c-fos oncogene; and selective regulatory effects on the long-lasting activities of genes involved in ACh metabolism (Amourette et al., 2009). Experimental studies have shown an increase in BBB permeability and inhibition of brain AChE activity after exposure to a combination of stress and PB (Friedman et al., 1996). At high doses, PB crosses the BBB in the hypothalamus to induce cholinergic and noncholinergic changes in nonstressed mice (Ropp et al., 2008). It is also suggested that the neurological symptoms of GWI are linked to neurodegeneration in some discrete brain areas, as clearly demonstrated in rats subjected to daily restraint stress and combined exposure to a repellent (*N*,*N*-diethyl-*m*-toluamide; DEET), an insecticide (permethrin), and PB (Abdel-Rehman et al., 2004).

EFFECTS OF BLASTS ON THE BBB

In recent military conflicts, the incidence of explosive blast-induced traumatic brain injury (TBI) has substantially increased. BBB disruption associated with TBI results in brain edema and increased cerebrovascular permeability, both of which affect morbidity and mortality in patients with head injury (Ling et al., 2009; Shetty et al., 2014). Brain edema after TBI is thought to be initiated by BBB rupture, permitting the influx of protein-rich exudate through compromised endothelial tight junctions that may lead to delayed neuronal dysfunction and degeneration (Shlosberg et al., 2010). In TBI, elevation of glutamate results in neuronal death primarily because of NMDAR-mediated excitotoxicity (Zhou and Sheng, 2013). In a recent study, Hue et al. (2013), using an *in vitro* model, reported the impact of primary blast on the BBB. By multiple measures, the barrier function of an *in vitro* BBB model was disrupted after exposure to a range of controlled blast loading conditions. Trans-endothelial electrical resistance (TEER) decreased acutely in a dose-dependent manner that was most strongly correlated with impulse, as opposed to peak overpressure or duration. Significantly increased hydraulic conductivity and solute permeability after injury further confirmed acute alterations in BBB function. Compromised zonula occludens-1 (ZO-1) immunostaining identified a structural basis for BBB breakdown. After blast exposure, TEER remained significantly decreased 2 days after injury, followed by spontaneous recovery to preinjury control levels by day 3. A study conducted on breachers (a military and law enforcement population that is routinely and repeatedly exposed to low-level blasts) showed changes in serum brain biomarker levels (ubiquitin C-terminal hydrolase-L1, αII-spectrin breakdown product, and glial fibrillary acidic protein), neurocognitive performance, and self-reported symptoms, suggesting brain injury and possibly damage to the BBB (Tate et al., 2013).

EXCITOTOXICITY, STRESS AND THE BBB

Glutamate excitotoxicity has been linked to chronic neurodegenerative disorders, including amyotrophic lateral sclerosis (ALS), MS, and Parkinson disease (PD), as well as in ischemia and TBI (Deli et al., 2005; Marmiroli and Cavaletti, 2012). Škultétyová et al. (1998) reported stress-induced increase in BBB permeability in control and monosodium glutamate-treated rats. Glutamate administration in neonatal rats causes reversible changes in BBB permeability and known neurotoxic lesions. These investigators evaluated whether glutamate repeatedly administered to neonatal rats influences properties of the developing BBB with consequences on adult BBB function. In control rats, 30 min of immobilization stress resulted in increased endogenous albumin extravasation in the hypothalamus, hippocampus, brain stem, and cerebellum, but not in the cortex and striatum. Basal levels of albumin in adult glutamate-treated rats (4 mg monosodium glutamate/g body weight, intraperitoneal, five times during neonatal period) were significantly lower in the hypothalamus compared with that in controls. Stress-induced increase in albumin levels was

lower in the brain stem, higher in the hypothalamus, and similar in other brain regions in glutamate-treated rats in comparison with controls. In conclusion, short-lasting immobilization stress increased BBB permeability in some, but not all, brain regions. Glutamate treatment of neonatal rats resulted in low basal albumin levels in the hypothalamus but did not exert a pronounced influence on adult BBB function. BBB vulnerability in glutamate-treated rats during stress exposure was increased in the hypothalamus and decreased in the brain stem.

In *in vitro* studies, although no permeability change was found in the case of basolateral application on a bovine coculture (Gaillard et al., 1996), apical glutamate treatment increased the flux of 70 kDa FITC-dextran (Collard et al., 2002) and decreased TEER (Sharp et al., 2003) in human brain endothelial monolayers. These findings support that brain endothelial cells express functional glutamate receptors (Krizbai et al., 1998; Sharp et al., 2003).

BRAIN BARRIERS AND CNS DISEASES

Involvement of brain interfaces, such as BBB and BCSFB, has been implicated in various neurodegenerative diseases, such as AD (Deane and Zlokovic, 2007; Zisper et al., 2007; Agyare et al., 2013; Burgmans et al., 2013), PD (Shaltiel-Karyo, et al., 2013), motor neuron disease (Garbuzova-Davis et al., 2007), and MS (Minagar and Alexander, 2003; van Horssen et al., 2007; Basivireddy et al., 2013). Modulation of the BBB permeability has also been reported in stroke, TBI, epilepsy (Abbott and Friedman, 2012; de Vries et al., 2012), autism, schizophrenia and other psychiatric disorders (Shalev et al., 2009; Palmer, 2010), GWI (Amourette et al., 2009), and edema, hypoxic-reoxygenation, or ischemic conditions (Deli et al., 2005; Kaur and Ling, 2008).

Impaired cognitive function and short-term memory are characteristic clinical features of AD. Underlying pathological features of this disease include neuronal and synaptic loss in the cerebral cortex as well as amyloid-β (Aβ)-containing diffuse and neuritic plaques (senile plaques), intraneuronal neurofibrillary tangles, and cerebral amyloid angiopathy (Zisper et al., 2007; Agyare et al., 2013). A prevailing hypothesis in the AD field was the amyloid cascade hypothesis that Aβ deposition in the CNS initiates a cascade of molecular events that cause neurodegeneration, leading to AD onset and progression. However, because of poor correlation between insoluble amyloid and cognitive impairment, increased *in vitro* toxicity of Aβ in the presence of antifibrillogenic agents and the synaptic localization of soluble oligomeric polymers, many experts now support the soluble Aβ oligomer cascade hypothesis (reviewed in Wilcox et al., 2011). Amyloid plaques may instead act as Aβ sinks, plaques that are surrounded by a halo of oligomers, which then attach to synapses and eventually cause synapse loss (Koffie et al., 2009). The loss of synapses is highly relevant to cognitive impairments, and is the best correlate with AD dementia severity (Terry et al., 1991).

Zisper et al. (2007) provided evidence that in advanced AD, plasma proteins like prothrombin can be found within the microvessel wall and surrounding neuropil, and that leakage of the BBB may be more common in patients with at least one APOE4 allele. Agyare et al. (2013) demonstrated that DutchAβ40 shows preferential accumulation in the BBB endothelial cells because of its inefficient blood-to-brain transcytosis. Consequently, DutchAβ40 establishes a permeation barrier in the BBB endothelium, prevents its own clearance from the brain, and promotes the formation of amyloid deposits in the cerebral microvessels. In a recent review, Burgmans et al. (2013) presented ample evidence for interplay between Aβ and BBB function in AD and reiterated that accumulation of the Aβ and disruption of the BBB can initiate cerebral microangiopathy, which has frequently been associated with vascular dementia. Although Aβ and BBB dysfunction have both been associated with AD and vascular dementia, respectively, they coexist in most demented patients. In fact, increasing evidence suggests that Aβ and BBB disruption may interact and facilitate each other in their effect on neurodegeneration. Recently, Erickson and Banks (2013) published a review of BBB dysfunction as a cause and consequence of AD. Paganetti et al. (2014) demonstrated that oral treatment with pirenzepine dose-dependently reduced brain Aβ level by its enhanced clearance in AβPPS1, hAβPP$_{st}$, and AβPP/PS1 transgenic mice by selective inhibition of muscarinic ACh receptors on endothelial cells of brain microvessels at the BBB.

It appears that the BBB does not play a major role in the etiology of PD, but its disruption may be beneficial in drug development. The neuropathological hallmarks of PD are progressive loss of dopaminergic neurons in the substantial nigra pars compacta accompanied by inclusions termed Lewy bodies and dystrophic Lewy neuritis in surviving neurons. The main constituent of the Lewy bodies is the α-synuclein protein. The etiology of these proteins is thought to involve major conformational changes leading to their misfolding, followed by production of β-sheet structures that have a strong tendency to aggregate into small oligomers and protofibrils that elongate into mature fibrils (Leong et al., 2009). One of the main obstacles in drug development is the inability of most drugs to pass across the BBB into the CNS. Mannitol, a nonmetabolized FDA-approved osmotic diuretic mediator, can also be used to open the BBB by producing osmotic shrinkage of the endothelial cells and mechanical separation of the tight junctions that form the BBB. Shaltiel-Karyo et al. (2013) demonstrated that mannitol interferes with α-synuclein aggregation without

exerting adverse effects, and suggested that mannitol administration in combination with other drugs could be a promising novel approach for treating PD or other brain-related diseases.

In neurologic disorders such as MS, epilepsy, capillary cerebral amyloid angiopathy, and AD, a profound dysfunction of the BBB is apparent (de Vries et al., 2012). In stroke and TBI, acute BBB dysfunction causes vasogenic edema with the danger of transtentorial herniation, and the effects of chronic BBB impairment are involved in neuroinflammatory disorders, such as MS, AD, and epilepsy (de Vries et al., 2012). Studies have led to the belief that BBB disruption represents an early event in MS lesion formation, preceding the massive infiltration of leukocytes (mainly T lymphocytes and monocyte-derived macrophages), leading to myelin degradation and nervous tissue destruction (Minagar and Alexander, 2003). *In vitro* and *in vivo* animal studies and patient tissue studies showed a significant involvement of the disruption of BBB integrity and function in MS pathology. Alterations not only involved the modulations of the tight junction but also included a reduced expression of the efflux pumps and the ABC transporters (Kooij et al., 2011).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The CNS is composed of various interfaces, such as the BBB, the BCSFB, and the blood–spinal cord barrier (BSCB). Brain capillary endothelial cells form the tight junctions and are referred to as the BBB. Currently, there are many *in vivo* and *in vitro* models to understand the mechanistic aspects of BBB functionality and permeability. Under physiological conditions, brain barriers protect the brain from pathogens, toxins, toxicants, proteins, and neurotransmitters. Disruption of the normal function of the BBB to circulating solutes and toxicants is usually the result of widened interendothelial junctions and/or alterations in one of the transporters localized within the BBB. Structure and function of the BBB and its permeability can be modulated by CWAs, toxins/toxicants, adverse conditions, and induced pathological conditions. Disruption of the BBB can also be the cause and/or consequence of neurodegenerative diseases, such as AD and MS. In future studies, novel *in vitro* and *in vivo* methods need to be developed to screen the compounds with properties of easy access to the BBB and those that can be used as therapeutic agents against CWAs.

Neuropathologic Effects of Chemical Warfare Agents

Randall L. Woltjer

INTRODUCTION

Nerve agents exert their effects through binding and irreversible inactivation of acetylcholinesterase (AChE), the enzyme that hydrolyzes acetylcholine (ACh), leading to a toxic accumulation of ACh at nicotinic (skeletal muscle and preganglionic autonomic) receptors, muscarinic (mainly postganglionic parasympathetic receptors), and central nervous system (CNS) synapses. Exposure to symptomatic doses of these agents leads to characteristic neuropathologic effects that have been examined in a variety of animal models. In addition, it is becoming increasingly recognized that even lower levels of exposure to these agents, even in the absence of seizures or other manifestations of acute toxicity, may be associated with more subtle forms of toxicity. Historically, this has been of concern in organophosphate (OP) and carbamate insecticide exposure among farm workers; however, it is likely that use of nerve agents in civilian populations or against military personnel would likely result in a range of exposures that stem from both the proximity of various groups to the site of deployment as well as the persistence of residues of some agents in the environment. This chapter will describe what is known about the neuropathologic consequences of both symptomatic and asymptomatic exposure to these agents and touch upon underlying mechanisms that may account for some of the regional specificity of their effects in nervous tissues.

BACKGROUND

Common nerve agents developed for chemical warfare purposes include the G-series (so named because they were first developed by German scientists in the mid-1930s) and V-series (a designation of ambiguous origin) weapons. The G agents includes tabun (GA), sarin (GB), soman (GD), and cyclosarin (GF); the V-series includes *O*-ethyl *S*-[2-(diisopropylamino) ethyl] methylphosphonothioate (VX), first synthesized by the British in 1954, which is approximately an order of magnitude more potent than agents of the G-series. The other V agents include Russian VX and Chinese VX. The G-series compounds are volatile liquids at room temperature, are soluble in both fat and water, and are absorbed readily through the eyes, respiratory tract, and skin. V-series agents are oilier, and therefore toxic mainly via skin exposure, and pose a lower inhalation hazard than G agents. However, their persistence in the environment has implications for chronic exposures, including low-level exposures, that may also lead to more subtle toxicities.

Nerve agents are organic esters of phosphorus-based acid derivatives that are potent inhibitors of AChE. Many toxicological and medical studies have been conducted since their development, and it has been helpful to classify exposure-associated health effects in terms of four general clinical classifications (Brown and Brix, 1998). These are:

1. Acute cholinergic effects that occur within minutes to hours, which may be lethal or lead to at least some degree of recovery.
2. Long-term neurological and neuropsychological effects that sometimes follow recovery from acute toxicity, and which may persist for years.
3. A delayed peripheral polyneuropathy, known as *organophosphate-induced delayed neuropathy (OPIDN)*, from which recovery may be poor.

4. A delayed syndrome of muscle weakness (so-called intermediate syndrome) that occurs within days of recovery from severe acute effects and that is typically reversible.

In addition, new research supports the hypothesis that even asymptomatic exposures to these agents, especially if they occur over a prolonged period of time, may lead to effects on nervous tissue. This would be an obvious concern in the event that populations are exposed to nerve agents, as unrecognized exposure and repeated low-dose exposure during the course of inappropriately conducted decontamination procedures could lead to these effects. Furthermore, the possibility of additional susceptibilities of pregnant women and children to low doses of nerve agents in these circumstances are additional areas of concern that we know little about.

Nonneurologic effects of nerve agent exposure have also been reported and include psychiatric and cardiac disease (Brown and Brix, 1998). However, this chapter will focus on the known neuropathologic effects, which are highly correlated with the cognitive effects of nerve agent exposure (Myhrer et al., 2005). For the purpose of this chapter, the clinical classification of exposure effects presented here will be used as an approximate scaffold for the description of lesions, predominantly in the CNS, that have been encountered in approximately equivalent stages of exposure in animal models. In addition, the limited amount of data regarding lesions encountered in humans who have been exposed to these agents will be reviewed.

ACUTE EFFECTS OF SYMPTOMATIC EXPOSURE

Ischemic/Hypoxic Injury

A large number of studies using experimental animals, including rodents, cats, and nonhuman primates, have been carried out to characterize the neurobehavioral effects of nerve agent exposure and their histopathologic correlates in brain tissue (Petras, 1981, 1994; Lemercier et al., 1983; Churchill et al., 1985; Carpentier et al., 1990; Hymowitz et al., 1990; Baze, 1993; Kadar et al., 1995). Acute exposure to nerve agents is associated with a range of clinical symptoms, varying from abnormal movements and salivation, to limb tremor and muscle fasciculation, to convulsions. In general, axonal degeneration was present in the cerebrum of all animals with convulsions and in the majority of animals with tremor and fasciculations. In a variety of animals, especially rodents, the test subjects that survived seizures tended to manifest extensive bilateral brain neuronal necrosis affecting predominantly the forebrain, thalamus, tegmentum, and spinal cord. In monkeys, the striatum, globus pallidus, substantia nigra, amygdala, hippocampus, and optic pathway (including the lateral geniculate bodies, pretectum, and superior colliculi) also sustained injury that progressed to necrosis.

Acute injury may be attributable to several mechanisms. Ischemic hypoxia may derive from respiratory insufficiency during prolonged seizures, and evidence of cellular ischemia is present in the brains of exposed animals. This consists of shrinkage of the cell soma and proximal dendrites, cytoplasmic microvacuolation due to mitochondrial swelling, dispersion of Nissel substance (cytoplasmic ribonucleic acid/RNA), increased cytoplasmic eosinophilia, nuclear changes (including displacement of the nucleus to an eccentric position in the neuron), shrinkage, and darkening. Generally, these nerve agent–associated lesions were described as being indistinguishable from those associated with brain ischemia or anoxia (Brown and Brierley, 1966, 1972; Brierley et al., 1973; McLeod et al., 1984).

Subsequent data argued against the hypothesis that hypoxic injury, at least in isolation, primarily accounts for the patterns of injury observed with acute nerve agent–induced brain injury. Although the presence of prolonged seizure activity is highly correlated with nerve agent–associated brain damage (Lemercier et al., 1983; McDonough and Shih, 1997; Carpentier et al., 2000), the changes in blood or brain oxygenation preceding or during nerve agent–induced seizures are minimal (Clement and Lee, 1980; Lynch et al., 1985; Carpentier et al., 1990; Goldman et al., 1993), and in rat experimental models, increases in regional blood flow and glucose uptake are actually observed (Pazdernik et al., 1985; Samson et al., 1985; Goldman et al., 1993). In addition, hippocampal slices exposed in culture to soman at levels that elicited spontaneous epileptiform activity were found to have earliest morphologic changes that recapitulated those seen in soman-treated intact animals; these included nuclear indentations and a decrease in nuclear size (Sikora-VanMeter et al., 1985, 1987). These findings differed from the dilated endoplasmic reticulum and mitochondrial alterations observed in hippocampal slices maintained in hypoxic conditions, and they support the argument that some other aspect of seizure activity, apart from hypoxic injury, contributes mechanistically to at least part of the damage to cerebrum associated with nerve agent exposure.

Nerve Agent-Associated Excitotoxic Injury

Within minutes after exposure to nerve agents, there is a marked decrease in AChE activity and associated rise in ACh. The earliest seizure activity begins in the absence of other significant neurotransmitter alterations and is prevented by anticholinergic drugs. These observations suggest that seizure-associated neuropathologic findings that occur upon nerve agent exposure are

caused primarily by a mechanism of cholinergic toxicity. However, if seizures progress untreated, other neurotransmitter systems display secondary alterations, and the involvement of these has been invoked in models of injury to the cerebrum that involve mechanisms of excitotoxic injury. Specifically, they refer to the involvement of glutamate, an excitatory amino acid transmitter that increases intracellular calcium mobilization. In excitotoxicity, overstimulation of glutamatergic synapses leads to marked neuronal calcium dyshomeostasis that in turn leads to neuronal injury (reviewed in Aarts and Tymianski, 2004). Excitotoxic injury contributes to neuronal pathology in a variety of conditions, including epilepsy, stroke, traumatic brain injury, multiple sclerosis, and an assortment of neurodegenerative diseases.

Protein expression changes support the involvement of glutamate receptors in nerve agent exposure. Hippocampal lysates from soman-exposed guinea pigs were found not to differ in their content of neurofilament or synaptophysin, but showed significant increases in subunits of a variety of glutamate and *N*-methyl D-aspartate (NMDA) receptors (Johnson et al., 2008) that mediate excitatory neurotransmission. Experiments in which nerve agents were injected directly into various brain sites established that the areas most sensitive to seizure induction lie generally in the ventrolateral aspects of the forebrain that contain high concentrations of AChE (McDonough et al., 1987, 1993). Following activation of these areas, seizures can propagate to sites distant from the area of injection, and these areas may demonstrate morphologic evidence of neuronal injury. Importantly, pre-treatment or early post-exposure treatment of experimental animals with anticonvulsants (for example with the benzodiazepine diazepam) blocks nerve agent–associated seizures that in turn prevents or diminished neuropathologic effects (Martin et al., 1985; McDonough et al., 1989, 1995; Hayward et al., 1990; Clement and Broxup, 1993). This occurs in the absence of a direct effect on cholinergic processes. Moreover, a pro-drug derivative of the 2-pralidoxime oxime, which produced a dose-dependent reactivation of OP-inhibited AChE, was found to block seizures 16–33% of the time, and seizure inhibition was highly correlated with neuropathologic effects of OPs in guinea pigs (Shih et al., 2011). A similar correlation of anti-seizure efficacy and prevention of markers of brain tissue injury was reported with the use of a kainate receptor antagonist (Figueiredo et al., 2011). These observations, taken together, suggest strongly that excitotoxic mechanisms contribute largely to the structural changes observed in cerebrum upon nerve agent exposure. Abrogation of these mechanisms by anticholinergic drugs within 20–40 min of the onset of seizures is sufficient in most cases to significantly diminish neuropathologic lesions (McDonough and Shih, 1997). The failure of anticholinergic drugs to prevent nerve agent–associated pathologic changes after this time period has been attributed to the recruitment and dominance of noncholinergic mechanisms of excitotoxicity, and perhaps to secondary loss of the integrity of the blood-brain barrier (McDonough and Shih, 1997).

Additional Acute Effects of Nerve Agents on Brain Tissue

Review of the literature on excitotoxicity suggests a variety of subsequent mechanisms by which calcium dyshomeostasis leads to neuronal dysfunction and injury. It is conceivable that pathologic effects of nerve agents could also arise via additional, as yet incompletely characterized, mechanisms that are independent of excitotoxicity, or that involve a variety of self-reinforcing cycles of brain tissue injury. A toxicogenomic study of messenger RNA (mRNA) expression changes after acute sarin exposure provided evidence for increased free radical stress and neuroinflammation in the cerebrum, as well as anticipatable changes in the expression of genes involved in calcium flux and binding, neurotransmission, synaptic activity, and glial activation (Damodaran et al., 2006). In a more recent study, increases in transcription of especially inflammatory markers were found to be widespread throughout the cerebrum (Spradling et al., 2011). One factor secreted by activated glia during the first days after OP exposure is vascular endothelial growth factor, and angiogenesis, the formation of new blood vessels, has also been described in the months after soman administration in mice (reviewed by Collombet, 2011). Consistent with an etiologic role for inflammation in OP-induced injury, one recent report showed that alpha-linolenic acid, an omega-3 fatty acid with antidepressant and anti-inflammatory properties, protects against soman-induced neuropathologic effects (Pan et al., 2012). Roles for oxidative injury and neuroinflammation have been hypothesized in a host of other neurologic conditions, including neurodegenerative diseases, and the demonstration of their involvement in nerve agent–associated neuropathologic changes in the brain may suggest additional prophylactic or therapeutic opportunities that are being explored in other neurologic disease. Hence, the possibility of modulation of the effects of AChE inhibitors on brain tissue by antioxidant and anti-inflammatory drugs has been the subject of investigations by a number of research groups (e.g., Gupta et al., 2000, 2001a,b; Dettbarn et al., 2001; Klaidman et al., 2003; Milatovic et al., 2006).

The morphologic manifestations of immune activation upon exposure of soman-treated rats include a rapid increase in glial fibrillary acidic protein staining, which is a marker of gliosis, as well as subsequent (1–4 h post-exposure) microglial activation in susceptible areas, including the piriform cortex and hippocampus (Zimmer

et al., 1997). This is accompanied by increased expression of central neuroinflammatory genes (Levy et al., 2004). These observations have led to the development of a novel class of anti-inflammatory, anti-cholinesterase (anti-ChE) drugs that may have utility in treating nerve agent poisoning (Amitai et al., 2005). In a rat model of AChE inhibitor intoxication, markers of reactive oxygen species (ROS) and reactive nitrogen species (RNS) were found to be elevated in susceptible regions of brain within 15 min to 1 h of exposure (Gupta et al., 2007; Zaja-Milatovic et al., 2009); this was accompanied by dendritic damage to the hippocampus, a sensitive morphologic marker of neuronal injury (Gupta et al., 2007; see also Figure 50.1). Consistent with an excitotoxic contribution to neurotoxicity, the NMDA receptor antagonist memantine, in combination with the anticholinergic drug atropine, prevented increases in ROS and RNS, as well as dendritic damage. Taken together, these findings suggest that novel combination therapies that target a variety of processes of nerve agent toxicity may offer enhanced protection, or at minimum may offer a degree of protection if post-exposure treatment is delayed past the point at which anticholinergic drugs have lost much of their effectiveness.

PROLONGED EFFECTS OF SYMPTOMATIC EXPOSURE

A number of studies describe the long-term effects of nerve agent exposure on the cerebrum (Lemercier et al., 1983; Kadar et al., 1992; McDonough et al., 1998; Collombet et al., 2005a, 2006; Grauer et al., 2008). Inflammatory changes are pronounced and may occur in two phases—namely, an initial response to cholinergic cell death, as well as a second, delayed inflammatory process that begins approximately 1 month after exposure and persists for at least several months (Grauer et al., 2008). Morphologically, reactive changes that may be seen with many etiologies of brain tissue injury may be observed if survival is sufficiently prolonged after exposure. Subpial astrogliosis with hyperplastic, swollen astroctyes may be observed, as may reactive microgliosis with microglial lipidosis. Focal calcification of brain parenchyma may also be observed, along with localized associated gliosis.

Other long-term changes may be more particular to nerve agent exposure. After acute soman exposure in mice, neuronal degeneration in the hippocampus begins within 1 day. After initial neuronal losses, a subpopulation of degenerating neurons persists for approximately 30–90 days before many of these are lost as well (Collombet et al., 2006). These losses are accompanied by a dramatic decline in spatial memory, with a slight recovery at 90 days that may reflect partial neuronal regeneration (Collombet et al., 2006). Similar changes were described in the amygdala (Collombet et al., 2008).

Neurogenesis has also been described in cerebrum in response to focal or global ischemia and epilepsy-associated neurotoxicity (Nakatomi et al., 2002; Scharfman et al., 2000). After soman-induced toxicity, neural progenitor cells in the subgranular zone of the dentate gyrus and the subventricular zone of the cerebrum undergo a transient reduction (Collombet, 2011), followed by a more prolonged expansion (Collombet et al., 2005a) and migration to sites of brain injury (Collombet et al., 2005b), where they engraft and differentiate into neurons and astrocytes within approximately 34 days after exposure (Collombet et al., 2005b). Whether neurotrophic treatments that have been proposed and are under investigation in models of neurodegenerative diseases may have a place in the therapy of nerve agent exposure remains a speculative matter, but one that will surely be investigated in the future.

The only published study of the brain structural effects of nerve agent exposure in a human population, focused on long-term changes induced in victims of a sarin attack in the Tokyo subway system that occurred in 1995 (Yamasue et al., 2007). In this event, which resulted in 12 deaths, approximately 5,500 victims were exposed to sarin, and all patients exhibited typical symptoms of acute intoxication. A variety of somatic, ocular, and cognitive symptoms were reported to persist among victims even 5 years after the attack (Kawana et al., 2001). Magnetic resonance imaging revealed decreased regional brain volumes in the insular cortex, neighboring white matter, and hippocampi of victims (Yamasue et al., 2007); and reduced regional white matter volume was significantly correlated with decreases in serum cholinesterase levels and with victim symptoms (Yamasue et al., 2007). Although these findings are compatible with sites of susceptibility reported in the nonhuman primate studies cited previously, the findings reported were from purely imaging studies, and the precise histopathologic correlates of these findings remain unknown.

ORGANOPHOSPHATE-INDUCED DELAYED NEUROPATHY

OPIDN is defined as a delayed-onset central and peripheral distal sensorimotor polyneuropathy caused by exposure to nerve agents (Brown and Brix, 1998), typically within 1–2 weeks, and no more than 4 weeks, after exposure. Symptoms attributable to effects on sensory (numbness, tingling, and pain) and motor (fatigue, weakness, and paralysis) functions are present and display a typical axonal length-associated pattern (e.g., predominantly lower extremities, with upper extremities affected at higher agent exposure). No treatment exists, and recovery is slow and rarely complete.

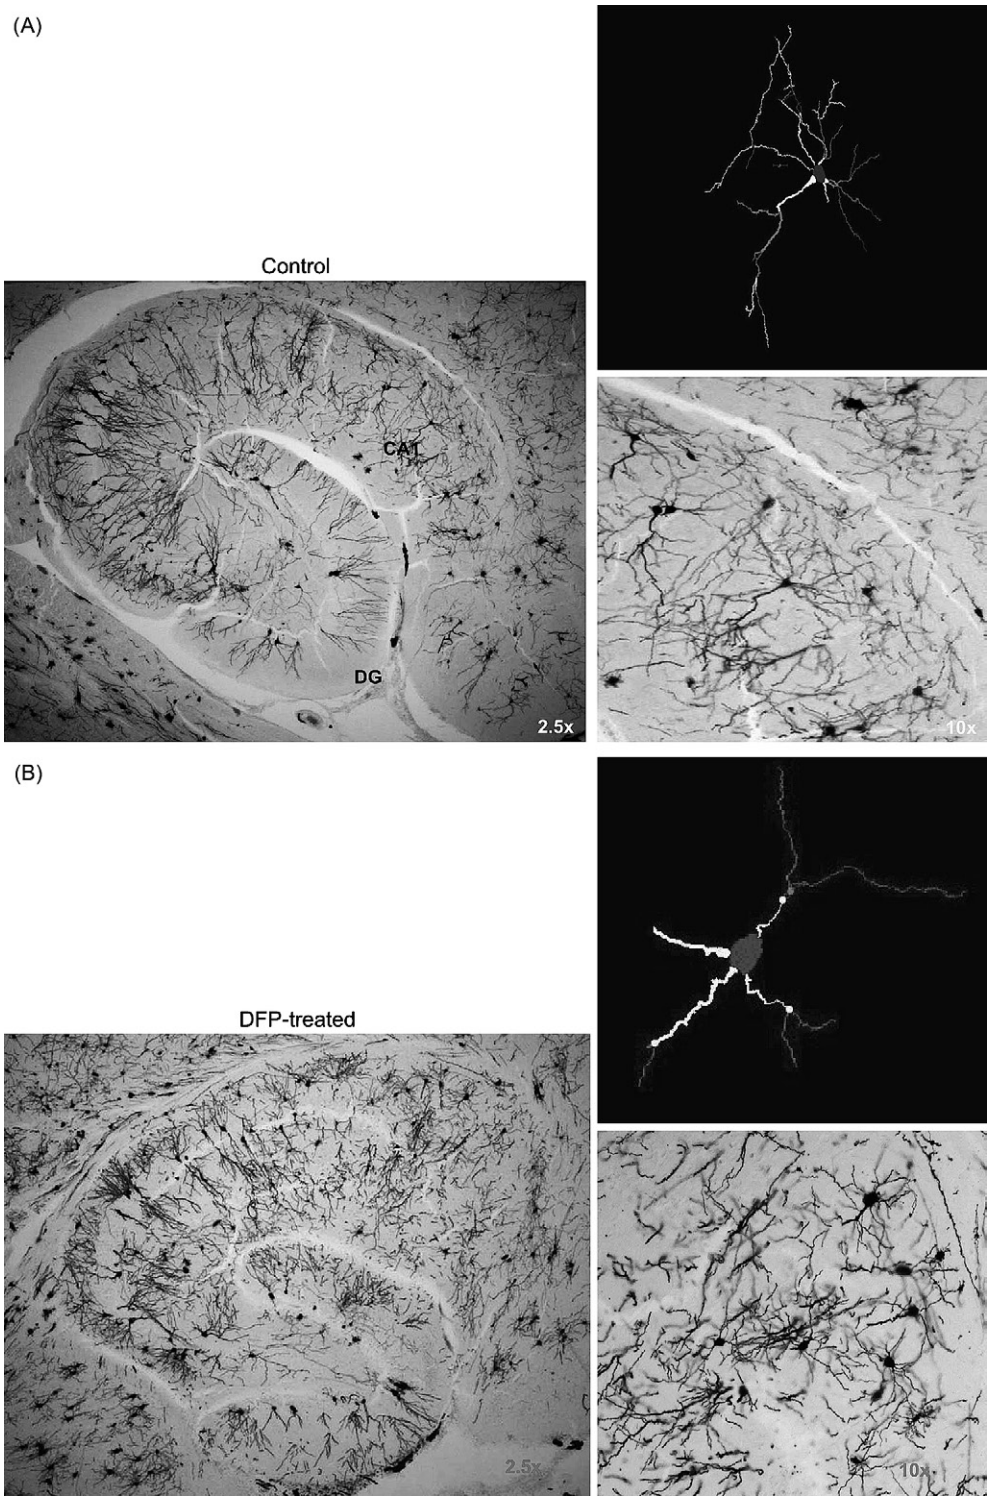

FIGURE 50.1 Photomicrographs of rat hippocampi with pyramidal neurons and their tracings from CA1 hippocampal area (DG, dentate gyrus) of rat brains 1 h after saline (control, panel A) or diisopropyl phosphorofluoridate (DFP, 1.5 mg/kg, s.c.) injections (panel B). DFP is an OP compound which acts as a potent AChE inhibitor with similar structure to OP nerve agents. Morphological correlates of anticholinesterase exposure were investigated using the structural integrity of the CA1 dendritic system, the neuronal compartment most sensitive to both age-related and disease-related degeneration (Uylings and de Brabander, 2002), as an experimental endpoint. Golgi impregnation of 50-μm-thick rat brain sections from paraffin-embedded blocks were carried out according to the manufacturer's specifications (FD Rapid GolgiStain Kit). Golgi-impregnated pyramidal neurons with no breaks in staining along the dendrites from CA1 sector of hippocampus were selected and spines counted according to the methods by Leuner et al. (2003). Tracing and counting were carried out with a Neurolucida system at × 100 objective magnification under oil immersion (MicroBrightField, VT). In each panel, the lower left view is a low (2.5× original objective) magnification of the hippocampus, the lower right view shows dendritic structure at higher magnification (10× original objective), and the upper right view shows a Neurolucida tracing of dendritic structure. Anti-AChE-induced seizures is accompanied by rapid evolution of dendritic abnormalities, apparent in a significant decrease in the dendritic length and spine density of pyramidal neurons as early as 1 h after DFP. Dendritic degeneration seen in this model of DFP-induced seizures is similar to neurodegeneration of pyramidal neurons in CA1 hippocampal area in mouse models of kainic acid (KA)–induced excitotoxicity (Zaja-Milatovic et al., 2008) and activated innate immunity (Milatovic et al., 2003). *Source: Courtesy of Dr. Dejan Milatovic, Department of Pediatrics, Vanderbilt University School of Medicine.*

OPIDN has been attributable to inhibition of neuropathy target esterase (NTE), rather than AChE, as inhibition of AChE is not necessary for the development of OPIDN (Pope et al., 1993; Wu and Casida, 1996; Jamal, 1997). Hence, since nerve agents target AChE much more than NTE (Gordon et al., 1983), the degree to which OPIDN would emerge as a significant consequence of nerve agent exposure alone is questionable; rather, doses that could potentially lead to OPIDN would, as a practical matter, cause lethal acute anti-AChE effects first. As a practical matter, unlike many other OPs, VX has not been shown to induce OPIDN and is reported to be at least 1,000 times less effective than sarin in inhibiting NTE (Gordon et al., 1983). However, several therapies, such as the anticonvulsant agent diazepam, that are used to minimize or prevent injury to the central nervous effects of nerve agents have less significant effects in the periphery; specifically, they have no effect on the targeting of NTE at peripheral sites. Therefore, it is conceivable that OPIDN could be a significant effect in treated survivors of nerve agent exposure. Indeed, exposure of humans to OP insecticides has led in some instances to OPIDN, even in the absence of symptoms associated with acute toxicity (Barns, 1975). Experimentally, OPIDN has been induced in hens treated with subsymptomatic doses of OPs if the time of dose administration is not prolonged (Barns, 1975).

Morphologically, OPIDN is manifested as classic neuropathologic lesions associated with Wallerian-type, or dying-back degeneration of axons, with secondary demyelination. Briefly, this begins with swelling of the axolemma (the membrane of the axon), and is followed by granular disintegration of intraaxonal organelles and cytoskeleton, including the microtubular network. Schwann cells react rapidly, stopping synthesis of new myelin initially, and clearing degenerating myelin debris and subsequently recruited macrophages. In the recovery phase, which may be initiated within days after injury, Schwann cells proliferate and release neurotrophic factors that encourage the growth of proximal axonal sprouts from intact axons. This pattern is a nonspecific response to axonal injury and in the absence of a history of exposure to nerve agents, the clinical and neuropathologic differential diagnosis is fairly broad; it includes amyotrophic lateral sclerosis, as well as a variety of toxic neuropathies attributable to exposure to heavy metals, solvents, and other substances (Barrett and Oehme, 1985; Longstreth, 1994). Hence, the history of nerve agent exposure is critical in establishing the diagnosis.

OP-ASSOCIATED MUSCLE WEAKNESS

The term *intermediate syndrome* refers to a delayed onset of muscle weakness that occurs shortly after recovery from severe acute effects of OP exposure and is typically associated with full recovery within approximately 4 weeks (Marrs, 1993). Although details of the mechanism by which this occurs are not known, it is believed to be attributable to the accumulation of ACh at the neuromuscular junction (Karalliedde and Henry, 1993). Consistent with this, morphologically, one finds a necrotizing myopathy that appears somewhat localized to regions of nerve endplate regions (Ariens et al., 1969; Fenichel et al., 1972, 1974; Kawabuchi et al., 1976; Good et al., 1993). Ultrastructural studies reveal vacuolated myofibers in association with nerve terminals containing swollen mitochondria (Petras, 1981, 1994). In these studies, a large degree of variability both between experimentally treated animals and within affected muscles was observed; hence, it is clear that unknown additional factors mediate susceptibility. Separation of nerve terminals from the muscle surface was attributable to progressive myofiber vacuolar swelling and insertion of Schwann cell or macrophage processes into the region. This appears likely to be incompatible with effective neurotransmission at this site, and the reversibility of this process may account for the transient nature of OP-associated muscle weakness.

EFFECTS OF SUBSYMPTOMATIC EXPOSURE TO NERVE AGENTS

The classic neuropathologic lesions of nerve agent exposure, as described previously, are greatly associated with the induction of clinically and electrographically apparent seizure activity. Recently, however, concern has been raised about even low levels of exposure to nerve agents that may not be sufficient to result in symptoms at the time of exposure, but may nevertheless lead to clinical symptoms or neuropathologic effects after long delays, perhaps in the context of chronic or repeated exposure. One scenario in which this might occur invokes an urban exposure to an agent such as VX, followed by incomplete decontamination with prolonged evaporation from persistently contaminated surfaces (Bloch-Shilderman et al., 2008). In addition, practical experience with nerve agent exposure has shown that most episodes involve small or asymptomatic doses (for example, to emergency and medical treatment personnel), as opposed to acute symptomatic toxicity (Levin and Rodnitzky, 1976; Morita et al., 1995; Gray et al., 1999).

Concern about effects of low doses of nerve agents are founded in part on observations in populations, such as agricultural workers, with chronic occupational exposure to OP compounds, such as pesticides. Many reports relate neurologic changes to these exposures, and relevant biochemical alterations have been described in these subjects, including changes in antioxidant status (López et al., 2007). Other investigators have shown

biochemical changes, including muscarinic receptor decreases and mRNA cytokine expression changes in affected cerebrum in animal models (Henderson et al., 2002). In a rat model of subsymptomatic exposure, repeated exposure to sarin at a dose that induced a 30% inhibition of erythrocyte AChE led eventually to ataxic gait, increased stereotyped behavior, and increased CNS excitability following administration of the convulsive drug pentamethylenetetrazol (Kassa et al., 2001). Repeated low-dose sarin exposure also led to a disrupted electroencephalogram (EEG) sleep pattern (Shih et al., 2006) and decreased locomotor activity and cognitive performance tests in rats and mice (Russell et al., 1986; Nieminen et al., 1990; Sirkka et al., 1990; Baille et al., 2001). Interestingly, some endpoints, such as temporal perception, were initially impaired by low-dose soman treatment but led to tolerance later, whereas others, such as nociceptive sensory and perceptual thresholds, became elevated throughout the course of treatment (Russell et al., 1986). In nonhuman primates treated with subtoxic doses of sarin (Burchfiel et al., 1976), as well as humans with symptomatic but limited exposure to nerve agents (Metcalf and Holmes, 1969; Wadia et al., 1974; Duffy et al., 1979), EEG changes were significant and persisted many months after exposure.

No study of subsymptomatic nerve agent exposure found significant neuropathologic lesions, as determined by standard histopathologic techniques, to be associated with behavioral or biochemical endpoints. However, it remains to be determined whether more sensitive morphologic endpoints, such as hippocampal dendritic structure (as illustrated in Figure 50.1), are altered by exposures of this nature. Having said that, the data presented here illustrate the difficulty of determining safe levels of nerve agent exposure in human populations.

It is conceivable that the prenatal period may represent a time of special sensitivity to OP exposure. Recently, a review of epidemiologic and animal data pertaining to chlorpyrophos, a common OP insecticide, was undertaken (Li et al., 2012), with the conclusion that there was insufficient evidence to conclude that adverse neurobehavioral effects occurred in humans exposed to this agent. This, of course, leaves open the question of the developmental effects of higher doses of this agent or the effects of other agents. Reviews of animal studies suggest mixed results for prenatal exposure and behavioral effects on rodents exposed during the first few days of life. Morphologic effects on brain tissue were similar to those described in adult animals and occurred when significant AChE inhibition was present in brain tissue or red blood cells. Interestingly, red cell AChE inhibition was more pronounced in dams than in offspring, suggesting a maternal protective effect (Maurissen et al., 2000). The longer-term effects of lower doses were not determined.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The neuropathologic effects of chemical warfare agents (CWAs), particularly nerve agents, have been characterized and related to a variety of central and peripheral clinical syndromes. The most prominent of these are neuronal losses at characteristic sites in the cerebrum that follow nerve agent–induced seizure activity, with accompanying glial reaction and a subsequent, incomplete neuroregenerative response. Recent progress in the scientific understanding of excitotoxic, neuroinflammatory, and oxidative processes that may contribute to the development of neurotoxicity provides a conceptual link to other neurologic diseases. Therapies that prove successful in preventing or treating these diseases might also be translated into neuroprotective strategies that might be useful in treating populations exposed to CWAs. Conversely, if novel, effective treatments for nerve agent exposure can be developed, the possible value of their application to a host of neurological illnesses, especially age-related neurodegenerative diseases that are becoming increasingly prevalent in Western societies, should be considered.

CHAPTER

51

The Effects of Organophosphates in the Early Stages of Human Muscle Regeneration

Tomaz Mars, Katarina Mis, Sergej Pirkmajer, Maja Katalinic and Zoran Grubic

INTRODUCTION

Organophosphate (OP) poisoning is a complex clinical condition. Increased acetylcholine (ACh) concentration in the cholinergic synapses attributable to acetylcholinesterase (AChE) inhibition leads to altered signaling in these synapses, causing various pathological effects, including failure of respiratory muscles and cardiac arrhythmias. Hypoxia that develops as a combination of impaired exchange of gases in the lungs and bradycardia is an especially threatening complication. However, there is now substantial evidence that inhibition of AChE is not the exclusive mechanism underlying a wide variety of adverse consequences of OP exposure described previously (Terry, 2012). It is known that cholinesterases (ChEs) are not the only targets of OPs and that various intracellular mechanisms are modified because of direct or indirect OP actions (Jett and Lein, 2006; Terry, 2012; Lima et al., 2013). For instance, DNA microarray analysis of cells treated with OP diazinon disclosed overwhelming modulation (upregulation or downregulation) of a wide range of genes (Mankame et al., 2006). Although still poorly understood, such noncholinergic OP actions might directly or indirectly modify functioning of the complex intracellular mechanisms and importantly contribute to the effects of OP poisoning.

OP poisoning frequently results in myopathy (Preusser, 1967; Wecker et al., 1978). Its pathophysiology is complex and is a combination of muscular hyperactivity and consequent alterations in oxidative processes in the muscle fibers. During sustained seizures and fasciculations, the flow of oxygen through the muscle is greatly increased at a time when the demand of ATP is greater than the rate of its generation. Under such conditions, production of reactive oxygen species is greatly increased and exceeds the protective capacity of the cellular defense system so that their damaging effects result in muscle injury (Dettbarn et al., 2001, 2006; Gupta et al., 2002).

Skeletal muscle responds to the injury by the activation of the regeneration process (Bischoff, 1979). Muscle regeneration shares its basic features with embryonic myogenesis, although it also differs from it in some respects (Charge and Rudnicki, 2004; Collins, 2006; Bentzinger et al., 2012; Yin et al., 2013). The regeneration process starts from the dormant mononucleated satellite cells located between the basal lamina and cell membrane of the adult skeletal muscle fiber. Final outcome of the muscle damage therefore depends not only on the extent of the damage itself, but also on the efficiency of the regeneration process. Especially with high OP intake, typically found with suicide attempts, poisoning is often complicated by respiratory failure combined with metabolic and respiratory acidosis (Emerson et al., 1999). These patients must be treated in intensive care units and often require mechanical ventilation. Critically ill patients frequently have development of skeletal muscle dysfunction (de Letter et al., 2001; Bolton, 2005) that often persists even after hospital discharge. Insufficient muscle regeneration might directly contribute to such myopathies (Prelovsek et al., 2006); therefore, it is important to know whether OPs interfere in any way with the mechanisms involved in this process. This aspect of

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00051-8

OP poisoning has not been approached yet in human muscle. In this chapter, we provide evidence that the mechanisms underlying early stages of human muscle regeneration are affected by OPs.

Recently, we have identified the neuropathy target esterase–related enzyme (NRE) as a novel OP target in human skeletal muscle. NRE is highly homologous to the neuronal neuropathy target esterase (NTE), which was originally identified as a target enzyme for highly toxic OPs that cause delayed paralyzing syndrome (Richardson et al., 2013). If targeted by OPs *in vivo*, NRE might be involved in OP poisoning-related myopathy.

One of the key steps in the process of muscle regeneration is myoblast proliferation, which decisively determines the mass of regenerated muscle tissue. Our investigations of the effects of OPs on muscle regeneration were therefore focused on these early precursors of muscle fibers. All experiments were performed in the *in vitro* model in which the process of human muscle regeneration is genuinely reproduced. We describe various OP influences on the early precursors of muscle development and discuss their potential effects on muscle regeneration. Because AChE is the most thoroughly characterized target of OPs, we also approached the question of its role and expression in the mononuclear myoblasts. Diisopropylphosphorofluoridate (DFP) was used throughout our studies.

REGENERATION PROCESS IN HUMAN SKELETAL MUSCLE

The process of human muscle regeneration in many respects follows the process of embryonic development of skeletal muscle (Figure 51.1A). The earliest myogenic precursors in this development are mononuclear myoblasts (Charge and Rudnicki, 2004; Bentzinger et al., 2012; Yin et al., 2013). These still mononucleated, but already committed, cells proliferate several times to reach sufficient density before they fuse into multinucleated myotubes. Once formed, myotubes enter into a long-term and complex process of muscle differentiation that results in development of fully functional mature myofiber. An important step in the transition from myotube to myofiber is its innervation and formation of the complex structure of the neuromuscular junction (NMJ) (Emerson and Hauschka, 2004; Witzemann et al., 2013).

All these steps are repeated during the postnatal regeneration process, except that adult mononuclear myoblasts are derived from the satellite cells. These primordial cells failed to enter developmental and differentiation process during embryonic myogenesis, but retained the capacity to enter myogenic process and self-renewal when activated by the muscle damage (Collins, 2006). As such, they serve as mononuclear muscle precursors of muscle fibers formed *de novo* during muscle regeneration (Figure 51.1A).

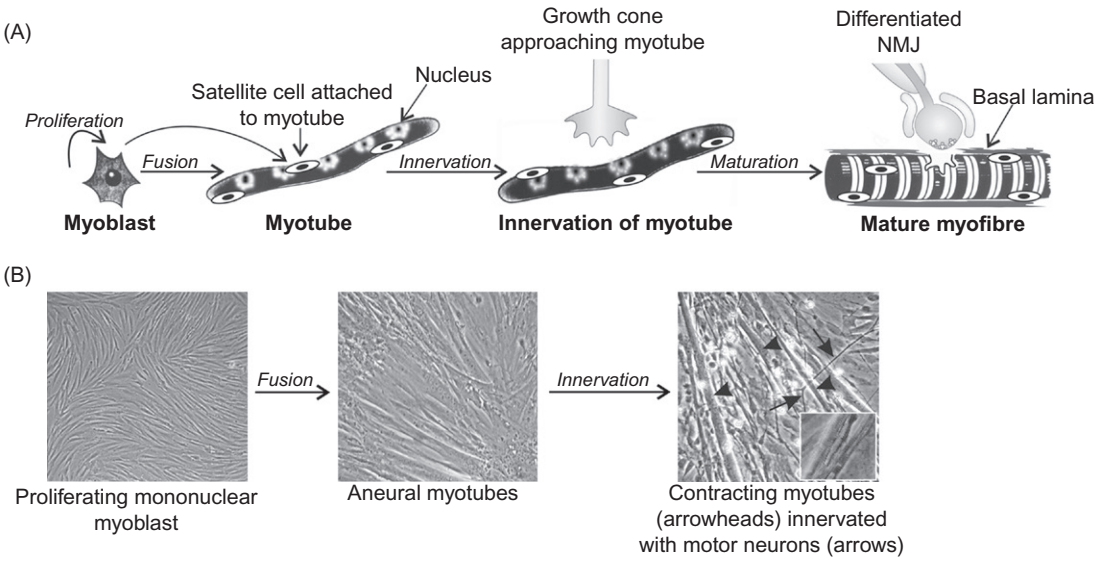

FIGURE 51.1 (A) Schematic presentation of the stages of muscle development. (B) Reproduction of these stages under *in vitro* conditions. (A) Stages of muscle development from mononuclear myoblast to the mature innervated myofiber. Nuclei, which are still centrally located in myotubes, move to the periphery in the mature fiber as a result of the synthesis of contractile elements in the sarcoplasm. Mature fibers contract and exhibit cross-striations. Only mononuclear myoblasts still have the capacity to divide and proliferate. Some of them do not fuse and become entrapped as mononuclear satellite cells under the basal lamina of the mature fiber. (B) Reproduction of this process in the experimental model of the *in vitro* innervated human muscle; axons are labeled by arrows and functionally innervated myotubes by arrowheads. Cross-striations could be seen in the innervated myotubes at higher magnification (insert).

All stages of muscle regeneration can be reproduced in the experimental model of the *in vitro* innervated human muscle (Figure 51.1B). This system was first described in the 1980s (Kobayashi and Askanas, 1985; Askanas et al., 1987) and then was further characterized in the studies in various laboratories, including ours. In this experimental model, satellite cells are released by trypsinization from small pieces of adult human muscle routinely removed at orthopedic operations. The experiments using human muscle cells were approved by the National Medical Ethics Committee of the Ministry of Health of the Republic of Slovenia (permit numbers 63/01/99 and 71/05/12) and were conducted in accordance with the Declaration of Helsinki and Good Laboratory Practice regulations. Satellite cells released by trypsinization are the source of mononucleated myoblasts that then proliferate and, at certain density, start to fuse and form multinucleated myotubes. To establish innervation, an explant of the rat embryonic spinal cord is placed on a monolayer of muscle cells. After 6–10 days of co-culture, motor neurons functionally innervate myotubes, which then start contracting. Such co-cultures are long-lived and contract for up to 6 months. Morphology of the NMJs closely resembles the NMJ *in vivo* (Askanas et al., 1987). Also, glial cells in the embryonic spinal cord explant recapitulate temporally regulated developmental steps observed *in vivo* (Mars et al., 2001). For details of preparation and various applications of this model, see the works by Grubic et al. (1995), Mars et al. (2003), Jevsek et al. (2004), Pirkmajer et al. (2010), Pegan et al. (2010), and Mis et al. (2013).

NONCHOLINERGIC EFFECTS OF DFP IN REGENERATING HUMAN SKELETAL MUSCLE

The Effect of DFP on IL-6 Secretion from the Mononuclear Myoblasts and Myotubes

Cultured human myoblasts fusing myoblasts and myotubes used in our experiments constitutively secrete interleukin-6 (IL-6). IL-6 is a major cytokine released from the skeletal muscle under various conditions (Febbraio and Pedersen, 2005). We found that IL-6 secretion from cultured muscle cells is stimulated by the major proinflammatory agents like tumor necrosis factor (TNF-α) and endotoxin lipopolysaccharide (Prelovsek et al., 2006). Because IL-6 is a potent stimulator of myoblast proliferation (Austin and Burgess, 1991; Austin et al., 1992; Cantini et al., 1995; de Letter et al., 2001; Baeza-Raja and Munoz-Canoves, 2004; Serrano et al., 2008), it is assumed that the physiological meaning of myoblast IL-6 secretion under such conditions is promotion of muscle regeneration, so that the myopathy attributable to septic conditions is, at least to some extent, compensated by muscle regeneration.

As mentioned, OP poisoning resulting in severe hypoxia often causes critical illness that is often accompanied by myopathy diagnosed as critical illness myopathy (CIM). Development of CIM is even more likely in the setting of OP poisoning because OPs directly lead to development of myopathy (Dettbarn et al., 2006). It is therefore important to find out whether the OP intoxication affects IL-6 signaling and, consequently, muscle regeneration. The effects of OP on IL-6 secretion from human myoblasts can be expected because it has already been reported that OPs drastically interfere with cytokine signaling in the mouse immune system (Alluwaimi and Hussein, 2007).

We show that IL-6 secretion from human myoblasts is significantly inhibited by DFP (Figure 51.2). IL-6 secretion was decreased by 50% in myoblasts, which might significantly reduce the efficiency of muscle regeneration process in damaged muscle. The mechanism underlying this effect of DFP remains to be established and is probably complex. In our culture medium, DFP is hydrolyzed quickly and becomes practically inactive in less than 1 h (Worek et al., 2004). Despite rapid hydrolysis, DFP-induced intracellular alterations may persist beyond the period during which DFP is still active. In our recent study, we observed 53% decrease in IL-6 secretion from human myoblasts after treatment with 10^{-5} M tabun (Katalinic et al., 2013). Our experiments are in accordance with the study of Zabrodskii et al. (2012), who demonstrated reduced concentrations of blood IL-6 in rats exposed to 30 days of sub-lethal doses of sarin and methylparathion.

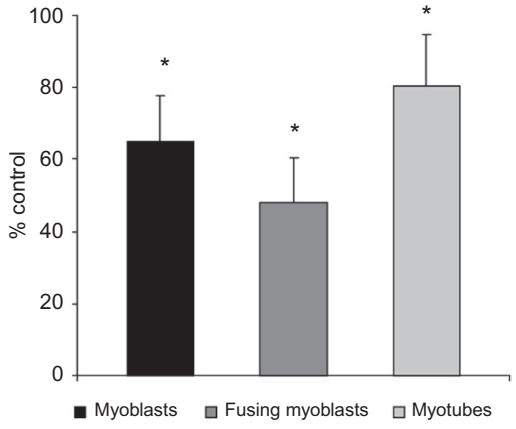

FIGURE 51.2 IL-6 secretion from myoblasts, fusing myoblasts, and myotubes. Cultured human myoblasts, fusing myoblasts, and myotubes were exposed to DFP (10^{-5}M). Concentration of IL-6 (expressed per 100,000 nuclei) was determined 24 h later with ELISA (Endogen, Rockford, IL). *Significant difference (Student *t* test, $P < 0.05$; $n = 3$) between control and treated cultures was observed at all stages studied, but was most prominent in the myoblasts.

Heat Shock Proteins in Human Myoblasts and Myotubes After Treatment with DFP

One of the most prominent cellular responses to stress is a rapid upregulation of heat shock proteins (HSPs), a family of highly conserved proteins that exert cytoprotective effects attributable to their chaperone functions in protein folding and protein degradation (Welch, 1992; Morimoto, 1993; Kiang and Tsokos, 1998; Kregel, 2002). Various physical, chemical, and biological environmental stress factors including xenobiotics can induce this response (Wu and Tanguay, 2006). Because OP pesticides are among inducers of HSP response *in vivo* and *in vitro* (Bagchi et al., 1996), we tested whether DFP actions include HSP-mediated stress response in myogenic precursors. We measured expression of HSP 27 and HSP 70, which are typically induced by various stress factors. The expression of stress factor HSP 27, but not of HSP 70, was slightly but significantly increased in DFP-treated human myoblasts (Figure 51.3), which is consistent with the reported selectivity of HSP induction in various tissues (Wu and Tanguay, 2006). We observed the DFP-stimulated increase in HSP 70 expression in myotubes, which indicates that HSP response to DFP becomes more prominent during the myotube stage (Figure 51.3). This pattern of effects is just the opposite to the observed decrease in IL-6 secretion (Figure 51.2), indicating that stress response at the HSP level does not result in increased IL-6 secretion. Increase in HSP70 was also demonstrated in several organs of common carp exposed to chlorpyrifos (Xing et al., 2013), suggesting a conservative mechanism unrelated to specific species, tissue, or OP. From the standpoint of muscle regeneration, it remains to be investigated whether the observed HSP response to DFP in any way protects proliferative potential of myoblasts that may be hampered by DFP-induced decrease in IL-6 secretion. These results are again indicative of the wide spectrum of effects that OPs induce by direct action on muscle tissue.

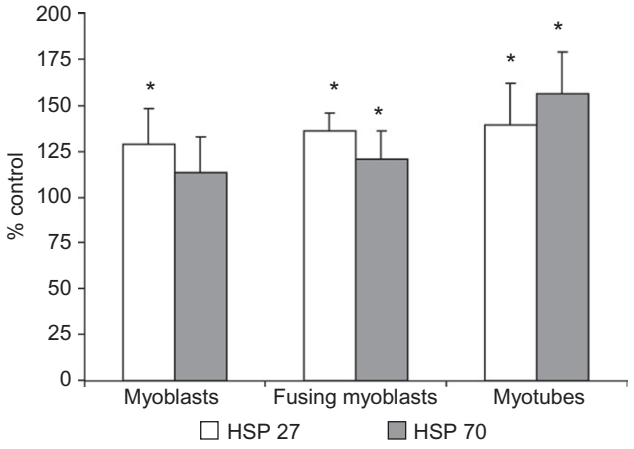

FIGURE 51.3 The effects of DFP on the HSP 27 and HSP 70 levels in myoblast, myoblasts in fusion, and myotube cultures. Levels of HSP 27 and HSP 70 were determined 24 h after addition of DFP (10^{-5} M). They were quantitated by Western blot with Chemi Genius BioImaging System (Syngen, Cambridge, UK). *Significant difference (Student *t* test, $P < 0.05$; $n = 4$) between control and DFP treated cultures was observed in all determinations except for HSP 70 in myoblasts.

Response of Human Myoblasts to Hypoxia

Severe OP poisoning can result in respiratory failure with arterial oxygen partial pressures less than 50–60 mmHg (6.65–7.99 kPa) (Tsao et al., 1990). In such circumstances, peripheral tissues, including skeletal muscle, become extremely hypoxic, which might have important effects on the myogenic precursors during regeneration. Central to the cellular response to hypoxia is hypoxia-inducible factor-1 (HIF-1), a heterodimeric transcription factor consisting of oxygen-regulated α-subunit (HIF-1α) and oxygen-independent β-subunit (HIF-1β). HIF-1α, which is normally almost undetectable because of its continuous degradation in the ubiquitin–proteosome pathway, rapidly accumulates in hypoxia and translocates to the nucleus, where it dimerizes with HIF-1β to form a functional transcription factor that controls expression of hundreds of genes related to cellular adaptation to hypoxia (Manalo et al., 2005; Semenza, 2007a). Through its effects on gene expression, HIF-1α not only increases oxygen delivery to hypoxic tissues by stimulating erythropoiesis and angiogenesis, but also promotes cell survival by redirecting cellular energy metabolism toward glycolysis (Pasteur effect) (Seagroves et al., 2001; Semenza, 2007b). Because of its central role in hypoxic response, we tested whether such adaptation also takes place in human myoblasts *in vitro*. We exposed human myoblasts to acute hypoxia (1% O_2 for 4 h) and found markedly increased HIF-1α levels compared with normoxic control (Figure 51.4). This result suggests that human myoblasts respond to hypoxia in a fashion similar to that of other cell types (Pirkmajer et al., 2010).

Myoblast proliferation is accompanied by apoptosis, which reduces the number of myogenic precursors and therefore affects the final outcome of the regeneration process. To determine if hypoxia affects muscle regeneration by altering the extent of myoblast apoptosis, the apoptotic markers were followed in human myoblasts under hypoxic conditions. We found that the activity of effector caspases in myoblasts remained unaltered during 48 h exposure to 1% oxygen, suggesting low susceptibility to hypoxia-induced apoptosis (unpublished results).

The Effects of DFP on the NRE in Human Myoblasts

NRE, a trans-membrane serine esterase linked to the endoplasmic reticulum, has been identified as a

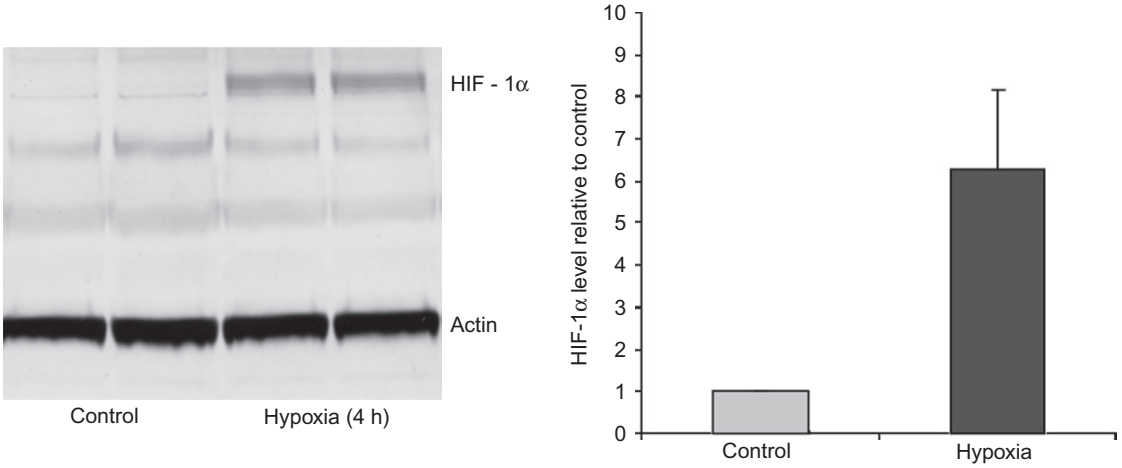

FIGURE 51.4 The effect of acute hypoxia on HIF-1α expression in human myoblasts. Human myoblasts were exposed to 1% O_2 for 4 h. A representative Western blot is shown on the left. Relative expression level of HIF-1α (three independent experiments) is shown on the right (arbitrary units, control = 1) (Student *t* test, $P = 0.004$). Quantification was performed with Chemi Genius BioImaging System (Syngen, Cambridge, UK).

member of the patatin domain–containing enzymes family (Kienesberger et al., 2008). It has high homology to neuronal NTE. The interactions of NTE with highly toxic OPs have been reported as a cause of delayed paralyzing syndrome observed in OPs intoxications (reviewed in Richardson et al., 2013). Three major isoforms of NRE, 102, 150, and 225 kDa, were detected in different stages of skeletal muscle regeneration *in vitro* (Figure 51.5A). Notably, the 150 kDa isoform was markedly upregulated on fusion of myoblasts into myotubes, suggesting NRE might have a role in differentiation of myogenic precursors. However, NRE activity was decreased in human myoblasts exposed to DFP (Figure 51.5B). Taken together, these results indicate that OPs may impair myogenesis via NRE inhibition. Inhibition of NRE may represent a novel mechanism underlying OP poisoning-related myopathy (paper in preparation).

EXPRESSION AND ROLE OF ACHE IN HUMAN MYOBLASTS

Most of the contractile and synaptic muscle proteins cannot be detected before formation of myotubes. Conversely, AChE is already expressed in the myoblast stage (Tennyson et al., 1971; Grubic et al., 1995). Although its function in this earliest stage of muscle ontogenesis is not known, it can only be noncholinergic or noncatalytic because other components of the cholinergic system are not present in myoblasts (Meshorer and Soreq, 2006).

To further explore the role of AChE in myoblasts, we followed various functional parameters in human myoblasts after selective elimination of AChE expression by siRNA.

Recovery of AChE mRNA Expression and AChE Activity After Gene Silencing of AChE and After Exposure to DFP

The *de novo* AChE synthesis importantly contributes to the recovery of AChE activity after OP poisoning (Grubic et al., 1981). Thus, we explored recovery of AChE mRNA and activity after gene silencing of AChE or DFP exposure. Although AChE level (determined on the basis of its catalytic activity) decreased to approximately 50% of control after siRNA treatment (Figure 51.6), we could not detect any functional or morphological changes in myoblast cultures in comparison with control. Addition of DFP to siRNA-treated myoblasts, which blocked practically all AChE catalytic activity, also resulted in no visible changes in myoblast cultures. This observation suggests that complete loss of AChE catalytic activity is not conducive to alterations that could be observed at the morphological level.

We then followed and compared the levels of AChE mRNA and AChE activity in siRNA-treated myoblasts and estimated the relationship between AChE expression at the mRNA and mature protein level. Because AChE is polymorphic and alternative splicing of primary transcript gives rise to three AChE mRNA species, tailed (T), hydrophobic (H), and read-through (R), which encode differently targeted AChE catalytic subunits (Massoulie, 2002), we followed these mRNA species separately in these experiments.

Three stages could be distinguished during a 170 h (approximately 7 day) period, during which we followed AChE activity:AChE mRNA ratio in the siRNA-treated myoblasts. During the first 10 h after siRNA treatment, AChE mRNA already decreased to approximately 60%

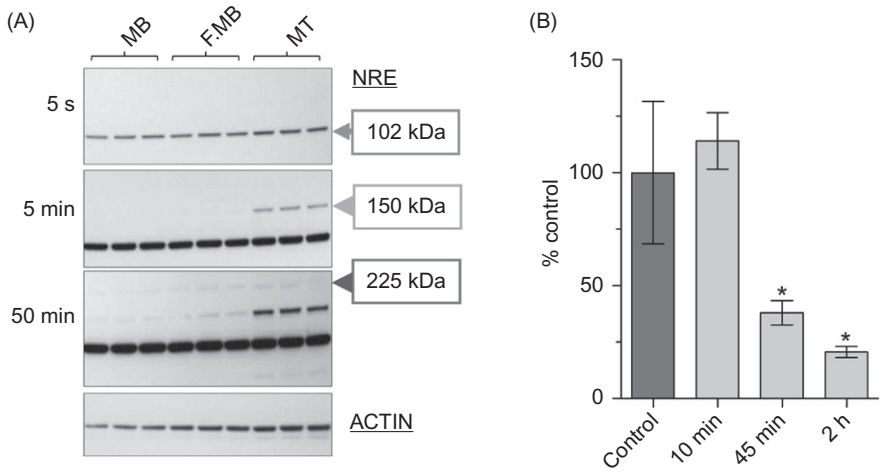

FIGURE 51.5 (A) Expression of NRE in cultured human muscle. (B) Inhibition of NRE by DFP. (A) Expression of NRE in cultured human myoblasts (MB), fusing myoblasts (F.MB), and myotubes (MT). NRE-specific bands were detected at 102, 150, and 225 kDa (note different times of film exposure) with a significant increase of 150 kDa isoform between fusing myoblasts and myotubes. (B) Time-dependent inhibition of NRE-specific esterase activity by DFP. Myoblasts were exposed to 10^{-5} M DFP for 10, 45, and 120 min. NRE-specific esterase activity was measured in myoblast homogenates using *p*-nitrophenyl valerate as a substrate. Data shown represent means ± SE (n = 4–6). *$P \leq 0.05$ versus control.

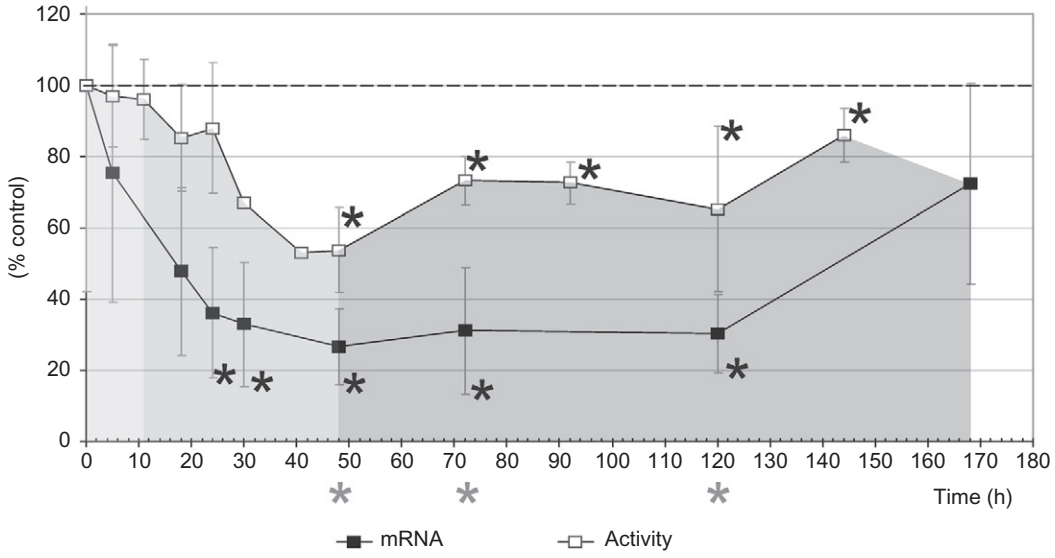

FIGURE 51.6 Relative changes of AChE-T mRNA and AChE activity in lysates of human myoblasts during the first week after siRNA application. Cultures of control and treated myoblasts were prepared from the satellite cells of the same donor and were processed in parallel. Gene silencing was achieved by lipofection of siRNA (Dharmacon); for details see Mis et al. (2006). Q-PCR with TaqMan chemistry was used for mRNA measurements. AChE mRNA levels were standardized to GAPDH mRNA. AChE activity levels determined by Ellman technique were expressed per 10,000 cells, the number of which was determined on the basis of Hoechst 33258 nuclear staining. Each point represents mean of three to seven measurements, and in each of which we determined the AChE-T mRNA or AChE activity ratio between control and siRNA-treated levels (% control). *The statistically significant (Student t test, $P < 0.05$) differences relative to the starting point. The statistically significant (Student t test, $P < 0.05$) percent differences between AChE activity levels determined by Ellman technique and mRNA levels at the same time point are indicated by * under the x-axis. Three shades of grey correspond to three stages discussed in the text.

of control level, whereas AChE activity remained practically unchanged. During the second stage (hours 10–50), AChE mRNA decreased to approximately 30% of control. AChE activity followed this decline and reached its lowest level of approximately 50% of control 50 h after siRNA treatment. From hour 50 onward, a new (more or less) constant relationship between AChE and its mRNA is established (Figure 51.6).

Of the three mRNA species, AChE-H and AChE-T mRNA followed practically the same pattern of

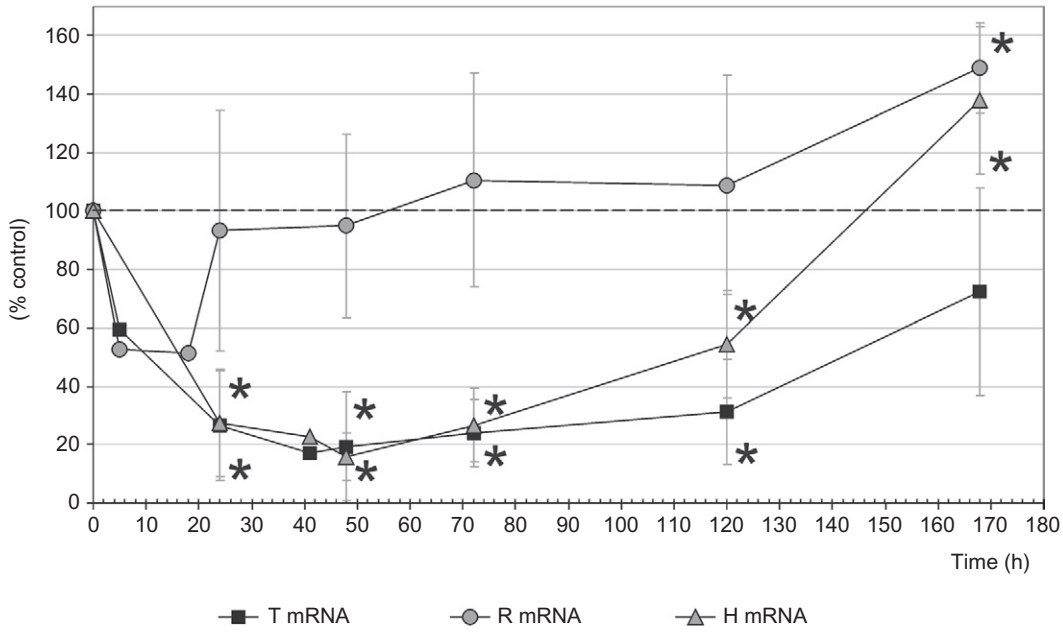

FIGURE 51.7 Relative changes of AChE-H, AChE-R, and AChE-T mRNAs in human myoblasts during the first week after siRNA application. Q-PCR with TaqMan chemistry was used (standardized to GAPDH mRNA). Each point represents mean of five separate siRNA experiments. In absolute terms, the levels of AChE-T mRNA were approximately 50-times higher than the levels of H and R. The differences regarding starting point (*) were statistically significant (Student *t* test, $P < 0.05$).

expression after siRNA treatment of human myoblasts, whereas AChE-R mRNA behaved in a completely different and less reproducible manner (Figure 51.7). In comparison with the other two mRNA species, which decreased to approximately 20% of control after siRNA treatment, AChE-R mRNA never decreased to less than 50% of control. It quickly recovered and then increased so that 7 days after siRNA treatment, its level was almost 1.5-times higher than that in controls. After approximately 150 h, but not earlier, we also observed similar overshoot for AChE-H, but never for AChE-T. All three AChE mRNA species could be detected at all developmental stages. Patterns of their expression were developmental stage–dependent, but AChE-T was the predominat species in all stages.

At present, we have no explanation for the different expression pattern of R-mRNA species in comparison with the other two. Increased AChE-R mRNA levels have been reported in mouse brain after exposure to stress (Nijholt et al., 2004). However, under *in vivo* conditions, external factors not present *in vitro* could be responsible for changed expression of this mRNA. There have been several reports from the Soreq group in which AChE-R variant was specifically induced by various stressors (Cohen et al., 2003; Grisaru et al., 2006; Ofek et al., 2007; Evron et al., 2007; Shapira-Lichter et al., 2008; Shaltiel et al., 2013). However, we do not know whether our results obtained in an artificial environment in which systemic stress response is absent are related to these findings. In any case, R-species represent only a very small fraction of AChE mRNA, and it is not known whether it is translated.

No significant changes in the levels of any of the three AChE mRNA species could be observed at any of the developmental stages of human muscle after treatment with DFP, suggesting that OPs have no direct influence on AChE expression in human muscle during the regeneration process.

The Role of AChE in Myoblast Apoptosis

One of the frequently reported noncholinergic AChE functions is its participation in apoptosis. There is evidence that reduced expression of AChE decreases apoptotic markers in hematopoietic stem cells (Soreq et al., 1994), human neuroblastoma cells (Yang et al., 2002), and various cell lines (Zhang et al., 2002). In addition, it has also been demonstrated that AChE overexpression results in increased apoptosis (Yang et al., 2002) and that cells that otherwise do not express AChE do so when entering apoptosis (Zhang et al., 2002). As for the molecular mechanism underlying these effects, there is evidence that AChE participates in apoptosome formation (Park et al., 2004). To investigate if early AChE expression in myoblasts reflects its role in the development of the apoptotic apparatus, we followed the effect of siRNA-mediated AChE silencing on the apoptotic markers after staurosporine-induced apoptosis in cultured human

myoblasts. Decreased apoptosis in siRNA-transfected myoblasts and increased AChE expression in staurosporine-treated myoblasts confirmed AChE involvement in apoptosis (Pegan et al., 2010).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Myopathies are one typical consequence of OP poisoning (Dettbarn et al., 2001, 2006). They might be additionally complicated by reduced efficiency of muscle regeneration. Our findings demonstrate that various intracellular mechanisms are influenced by exposure of precursors of muscle regeneration to DFP. Our experiments revealed significantly reduced IL-6 secretion after DFP treatment, which might hamper myoblast proliferation and the efficiency of muscle regeneration. Increased levels of HSPs in DFP-treated myoblasts suggest that cellular response to stress is induced after DFP treatment. The increased level of HIF-1α after exposure to hypoxia shows that adaptation mechanisms against hypoxia are also organized during the early stages of muscle regeneration.

Cholinesterase Inhibitors: From Molecular Mechanisms of Action to Current and Future Prospects

Nir Waiskopf and Hermona Soreq

INTRODUCTION

The classical functions of the cholinesterase enzymes, acetylcholinesterase (AChE), and butyrylcholinesterase (BChE), involve regulation of cholinergic signals by acetylcholine (ACh) hydrolysis. However, their presence in locations where no ACh is released suggests that cholinesterases (ChEs) have additional, context-dependent nonclassical functions. Our understanding of the essential roles of these enzymes in the central nervous system (CNS), neuromuscular junctions (NMJ), and the autonomic nervous system predicts severe consequences following interference with their functions (Taylor, 1996; Soreq and Seidman, 2001; Darvesh et al., 2003; Silman and Sussman, 2005). The acute and life-threatening manifestations of anti-ChE toxicity were observed following the use and misuse of nerve agents, pesticides, and therapeutic anti-ChEs. These span dysregulated molecular interactions, as well as severe and potentially fatal clinical presentations. The immediate negative physiological consequences associated with critical deficiency in ACh hydrolysis are readily explained by the well-characterized role of cholinesterases in terminating the cholinergic signal. Yet the long-term outcomes of sublethal exposure to anti-ChEs may reflect complex alterations in cholinergic functions, including modified cholinesterase concentrations and composition, that are also associated with diverse disease states. Studies of the structure, functions, and natural regulation of cholinesterases allow better understanding of the molecular mechanisms and consequences of anti-ChEs poisoning and can lead to development of improved therapeutic agents. Hence, this chapter starts with an overview on human cholinesterases.

HUMAN CHOLINESTERASES

Decades of research led to a widely accepted view of cholinesterases as a family of enzymes that hydrolyze choline esters, including ACh, thereby terminating neurotransmission in the CNS, NMJ, and the autonomic nervous system. The ChE family members share more than 50% sequence homology and have basically similar folding patterns. However, their substrate and inhibitor specificities divide them into two distinct entities: AChE, which mainly hydrolyzes ACh (hence also called the *specific cholinesterase*) and BChE which is 20-fold less efficient than AChE in ACh hydrolysis but can hydrolyze a considerably wider range of substrates (hence called *pseudocholinesterase* or *nonspecific cholinesterase*). AChE is the primary ChE in the nervous system, whereas BChE is found in higher concentrations in peripheral systems. For example, AChE concentration is 10-fold higher than BChE in the brain, whereas in the circulation, BChE concentration is 100-fold higher than AChE. Hence, the total capacity to hydrolyze ACh, also termed *cholinergic status*, depends on the cumulative sum of AChE and BChE activities, which balance each other to maintain homeostasis (Figure 52.1A; Ben Assayag et al., 2010; Shenhar-Tsarfaty et al., 2014).

Human Cholinesterases: The Common Core

The existence of the two distinct cholinesterases and their functional definition as specific cholinesterase and pseudocholinesterase was first introduced by Mendel and Rudney in the early 1950s. By the early 1990s, these definitions were well complemented by theoretical

and experimental structural-molecular observations. Cloning of cholinesterase genes from plants, invertebrates, and vertebrates (including humans) and the consequent elucidation of the three-dimensional structure of cholinesterases (Figure 52.1B and C; Nicolet et al., 2003; Ngamelue et al., 2007; Dvir et al., 2010; Nachon et al., 2011; Nachon et al., 2013) allowed a better understanding of the structure-function relationship in these enzymes, while opening new and yet-unsolved questions.

The cholinesterases were found to be serine hydrolases, belonging to the α/β-fold superfamily. Their three-dimensional crystal structures revealed a globular core, penetrated by a narrow groove (the "gorge") lined by aromatic residues, at the bottom of which lies the active site. Several functional subsites in the active site gorge were identified. These include: (i) the catalytic triad, composed of glutamic acid, histidine, and serine residues, which catalyze substrate hydrolysis by a charge relay mechanism; (ii) the acyl pocket, which interacts with the substrates' acyl group; and (iii) the anionic choline binding site, which interacts with the substrates' cationic groups. Another important component is the oxyanion hole, which stabilizes the transition state by accommodation of the negatively charged carbonyl oxygen.

At the functional level, the structural differences between the enzymes in the active site gorge can explain

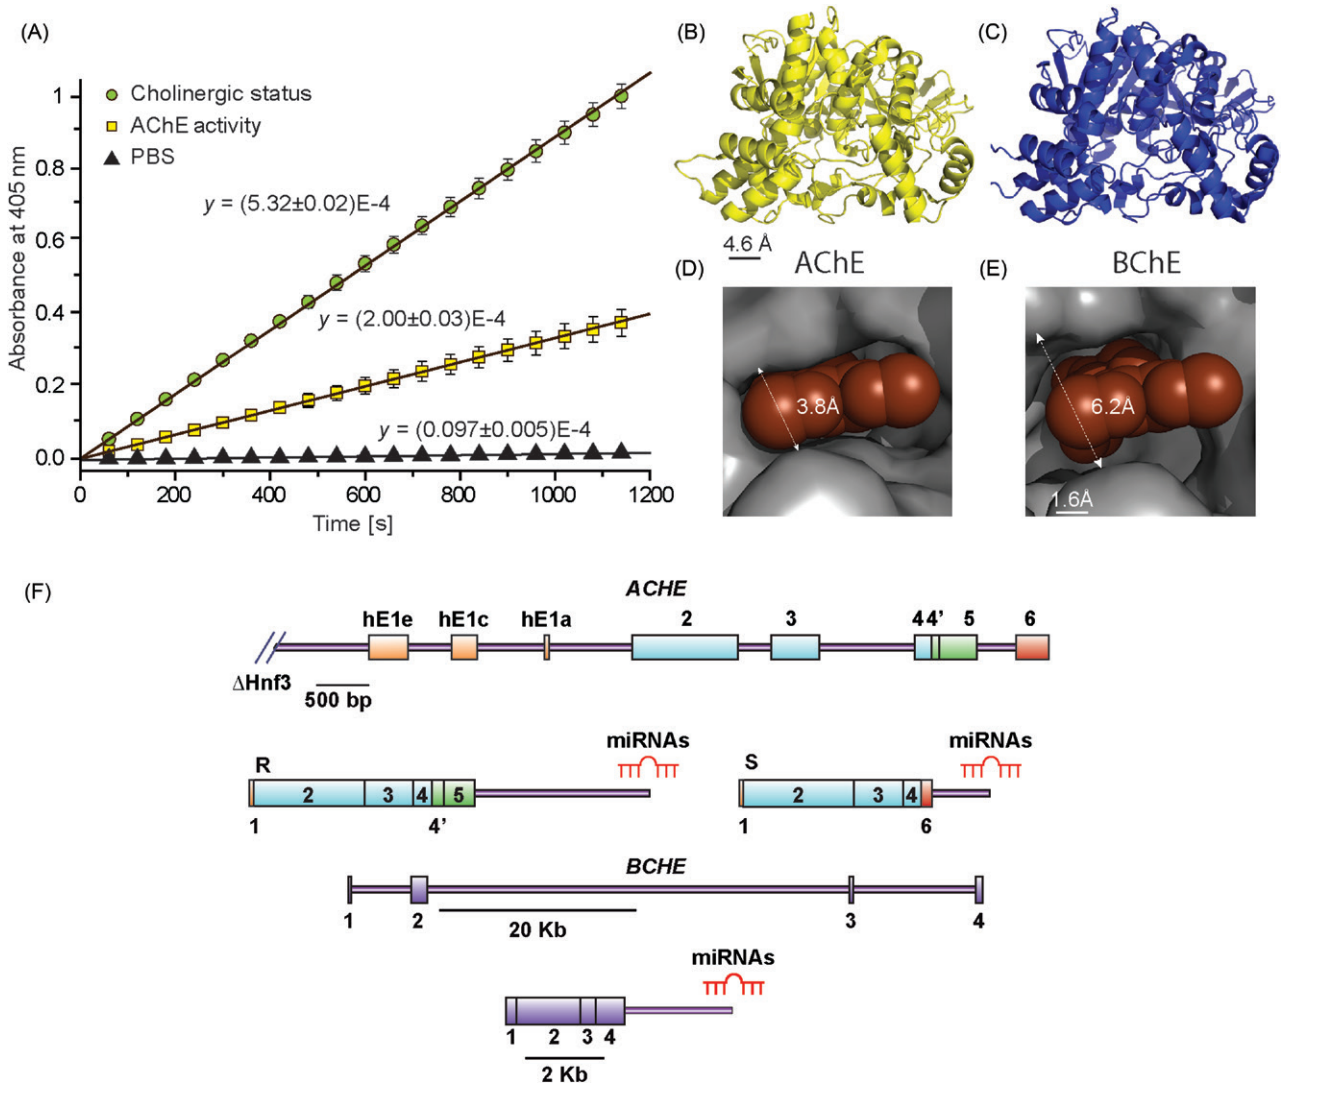

FIGURE 52.1 Cholinesterase enzymes. (A) Measurement of cholinesterase activity in human serum. The quantification of substrate hydrolysis as absorption changes over time shows that both AChE and BChE contribute to the total capacity to hydrolyze ACh, termed *cholinergic status*. (B) and (C) Cholinesterase homology, as observed in their crystallographic structures. (D) and (E) Modeling cholinesterases with the inhibitor donepezil demonstrates the differences in the volume of the active site gorge and explains the differences in substrate specificity and catalytic efficiency between AChE and BChE. (F) *ACHE* and *BCHE* genes and mRNAs. Alternative promoter usage of the 5′ of the *ACHE* gene and alternative splicing contribute to the diversity in AChE mRNA and protein isoforms. *Source: (A)–(E) and (F) are based on Arbel et al. (2014) and Nadorp and Soreq (2014), respectively.*

the differences in substrate specificity and hydrolysis efficiency. For example, BChE has less aromatic residue lining at the gorge, resulting in enlargement of the active site gorge volume by approximately 200 $Å^3$ compared to AChE; this affects the accessibility and accommodation of different substrates and inhibitors to the active site (Figure 52.1D and E; Nicolet et al., 2003; Ngamelue et al., 2007). Moreover, replacement of two phenylalanines in the entrance to the AChE's acyl pocket by two smaller amino acids, leucine and valine, in the BChE's acyl pocket, allows the accommodation of larger acyl groups and hence larger substrates (Darvesh et al., 2003). These differences explain why BChE has a broader catalytic spectrum with preference for longer-chain substrates, whereas AChE is characterized by its substrate specificity, which is essentially limited to ACh, but with 20-fold greater efficiency in ACh hydrolysis compared to BChE (Soreq and Seidman, 2001; Darvesh et al., 2003).

In addition to the catalytic active site, there exists a secondary substrate-binding site, referred to as the *peripheral anionic site (PAS)*, residing in proximity to the active site gorge. This site contributes to the first step of the catalytic pathway, to allosteric modulation of the catalytic activity, to mediation of many inhibitor interactions, and to some of the nonhydrolytic functions of AChE (Soreq and Seidman, 2001; Dvir et al., 2010). However, BChE's PAS lacks three out of the four aromatic residues that compose the AChE's PAS, resulting in different reactions toward ligand binding. For example, in the presence of excess substrate, ACh binding to AChE's PAS results in substrate inhibition, whereas its binding to BChE's PAS inversely results in substrate activation (Darvesh et al., 2003).

Additional differences between the cholinesterases and their isoforms results from variable posttranslational modifications which depend on (among other factors) cell type and physiological state (Silveyra et al., 2006). These include glycosylation, oligomerization, proteolytic processing, and (for one of the AChE variants) attachment to a glycosylphosphatidylinositol (GPI) anchor. For example, with human AChE, all three potential glycosylation sites are occupied, and with human BChE, at least eight of the nine potential sites are occupied (Darvesh et al., 2003).

Human Cholinesterases: Myriad Molecular Forms

The classic view of two cholinesterases whose sole function is to terminate cholinergic signals at the synapse has been repeatedly challenged by observations that were incongruent with this view and suggested a far more complex picture of multiple molecular forms with distinct temporal and spatial expression patterns. This complexity mainly results from alternative splicing in the case of AChE, but largely reflects frequent single nucleotide polymorphisms (SNPs) in the *BCHE* gene.

Humans possess two cholinesterase genes at two separate loci: *BCHE* (3q26) with four exons and three introns (Darvesh et al., 2003); and *ACHE* (7q22) with six exons and four introns (Soreq and Seidman, 2001). In the *BCHE* gene, more than 40 SNPs were identified. Some of these were found to produce isoforms with modified catalytic activity, sensitivity to inhibitors, and protein interaction (Podoly et al., 2009; Howard et al., 2010). For example, the common (wild type/WT) variant of BChE shows greater catalytic activity than the atypical BChE (D70G), K variant (A539T), J variant (E497V), and H variant (V142M) (Darvesh et al., 2003). The different BChE isoforms can construct distinct molecular forms, such as hydrophilic monomers and disulfide-bonded dimers, which may further form dimer-dimer soluble globular tetramers. BChE multimers can also possess distinct amphiphilic features and form asymmetric multimers of membrane-bound forms composed of tetramers anchored to the membrane by proline-rich domains. For example, the collagen Q (ColQ) in NMJ, the proline-rich membrane anchor (PRiMA) in the CNS or the proline-rich peptides derived from lamellipodin in serum (Li et al., 2008), all of which interact with the C-terminal domain of BChE.

In the human *ACHE* gene, only 19 SNPs were identified to date. As with BChE, these SNPs can affect AChE activity and interactions (Valle et al., 2011). However, the plethora of AChE protein isoforms results mainly from the translation of several messenger RNA (mRNA) variants arising through highly regulated epigenetic, transcriptional, and posttranscriptional processes (Figure 52.1F). Alternative splicing at the 3′-end of the *ACHE* pre-mRNA yields three different mRNA transcripts, which encode proteins with distinct carboxyl termini (Soreq and Seidman, 2001). The synaptic form, AChE-S (also known as *T*, for "tailed"), is generated by splicing out exon 5. This is the dominant transcript in most tissues. AChE-S mRNA translation gives rise to a 40-amino-acid C-terminal extension of the core AChE of 534 amino acids. This C-terminal peptide contains a key cysteine residue, which allows the formation of dimers through disulfide bonds. These in turn are able to form, similar to BChE, tetramers stabilized by hydrophobic interactions between tryptophan amphiphilic tetramerization (WAT) domains, which can later bind ColQ at the NMJ or the structural subunit PRiMA in the CNS, forming membrane-bound multimers (Noureddine et al., 2008). Impaired ColQ binding to AChE due to ColQ mutations leads to congenital myasthenia (Engel, 2012), highlighting the importance of this interaction.

A second form, the readthrough AChE-R, is encoded by a transcript containing pseudointron 4′ and exon 5 as an alternative 3′ terminal exon. This variant accumulates

under various stressful insults through a feedback response that activates ACH transcription and shifts splicing in the brain, muscle, spermatocytes, hematopoietic cells, intestine, and other parts of the body (Kaufer et al., 1998; Lev-Lehman et al., 2000; Meshorer et al., 2002; Grisaru et al., 2006; Meshorer and Soreq, 2006; Pick et al., 2006; Gilboa-Geffen et al., 2007; Mor et al., 2008). AChE-R has a shorter C-terminal peptide than AChE-S, which lacks the cysteine residue responsible for dimerization; hence, AChE-R remains monomeric and soluble (Soreq and Seidman, 2001; Zimmermann, 2013).

The third form, AChE-E (also known as H, for "hydrophobic"), is incoded by a transcript with exon 5 as the 3′ terminal exon but its C-terminal peptide is subsequently cleaved after amino acid 14 of E5 (557 from the N-terminus). The newly generated C-terminus is GPI-anchored to the erythrocytic membrane and includes cysteine residue which allows AChE-E dimerization (Soreq and Seidman, 2001).

Although the protein products of these mRNAs differ in their C-terminal peptide sequence and capacity to oligomerize, all of the molecular forms of AChE carry an identical active site and display similar catalytic properties. Importantly, the distinct C-termini dictate dissimilar subcellular localizations, biological roles, and noncatalytic properties.

The 5′-end of the AChE pre-mRNA is also subject to alternative promoter usage, together yielding five and three alternative transcripts in mice and humans, respectively (Figure 52.1F; Meshorer et al., 2004). The alternative 5′- and 3′-end significantly increase the combinatorial complexity of AChE. Most of the identified 5′ exons produce alternative untranslated regions. However, at least one of those exons in humans is translated to a protein, with an extended N-terminus (N-AChE; Meshorer et al., 2004; Toiber et al., 2008). Based on the combinations of the 3′ and 5′ alternative transcripts, N-AChE-E, N-AChE-R, and N-AChE-S might all exist (Meshorer and Soreq, 2006). Since N-AChE was shown to associate with the plasma membrane of blood cells (Meshorer et al., 2004), it might have the capacity to directly dock the soluble AChE-R to synaptic membranes, without ColQ or PRiMA.

Regulation of Cholinesterase Gene Expression

The regulation of cholinesterase enzymes primarily occurs at the epigenetic, transcriptional, and posttranscriptional levels (Soreq and Seidman, 2001; Shaked et al., 2009; Sailaja et al., 2012; Shaltiel et al., 2013). *ACHE* transcription is subject to epigenetics regulation via modulation of histone methylation events in the *ACHE* promoter (Sailaja et al., 2012). This explains the long-lasting increases in AChE levels following exposure to inhibitors (Friedman et al., 1996) or stressful events (Kaufer et al., 1998; Meshorer et al., 2005). The transcriptional control of the *ACHE* gene is principally regulated by two proximal promoters, one that is clearly dominant and another alternative promoter (Soreq and Seidman, 2001). Additionally, enhancers are present distally and within the first intron (Camp et al., 2008), as well as proximally to the four alternative first exons (Meshorer and Soreq, 2006). The upstream region of the *ACHE* locus contains numerous putative transcription factor binding sites, including those that potentially bind NF-κB and AP-1, as well as a glucocorticoid response element binding site (Soreq and Seidman, 2001). An increase in *ACHE* transcription is noted as a consequence of various stimuli as diverse as differentiation, anti-ChE exposure, and transiently reduced levels of AChE (Friedman et al., 1996; Kaufer et al., 1998; Evron et al., 2007). Inversely, decreases in *ACHE* transcription are seen in mice deficient in the neural growth factor TrkA (Soreq and Seidman, 2001).

One example is the transcriptional regulation of the collagen-tailed AChE-S variant, which is primarily detectable under normal conditions, in vertebrate skeletal muscle. Muscle-specific expression of AChE is believed to be controlled by the transcription factors MyoD and myocyte enhancer factor-2 acting on the regulatory region located within the first intron (Camp et al., 2008). This region is exceptionally well conserved between higher vertebrates, suggesting a generalization of this phenomenon. Negative regulation of *ACHE* transcription has been shown via a calcitonin gene-related peptide (CGRP)–dependent mechanism. CGRP is secreted from motor neurons and binds to the calcitonin receptor located in the NMJ (Rossi et al., 2003). Receptor activation results in increased intracellular cyclic adenosine monophosphate (cAMP), and subsequent attenuation of *ACHE* transcription through a cAMP-response element in the *ACHE* promoter. It has been shown that CGRP also reduces synthesis of PRiMA, which is required for the assembly and localization of skeletal muscle AChE, and that overexpression of PRiMA itself can drive *ACHE* transcription (Xie et al., 2007).

Yet more recently, AChE has been shown to be subject to microRNA (miRNA) regulation at the posttranscriptional level. MiRNAs are small molecules (20–25 nucleotides long) that can target and bind many mRNA transcripts, each leading to their posttranscriptional silencing (Bartel, 2009). *In silico* screening identified 244 miRNAs that can target the 3′-untranslated regions of different cholinesterase transcripts: 116 for BChE, 47 for the AChE-S splice variant, and 81 for the normally rare splice variant AChE-R. Of these, 11 and 6 miRNAs target both AChE-S and AChE-R, and AChE-R and BChE transcripts, respectively (Hanin and Soreq, 2011). To date, the evolutionarily conserved miRNA-132 and the primate-specific miRNA-608 have both been experimentally

validated as targeting AChE, with consequences for both inflammatory responses (Shaked et al., 2009; Maharshak et al., 2013) and cognition (Shaltiel et al., 2013; Hanin et al., 2014). Importantly, carriers of a common SNP in the *ACHE* gene that disrupts miRNA-608 suppression show a 60% elevation in brain AChE activity (Hanin et al., 2014). Other cholinesterase-targeting miRNAs are currently being investigated and show promising results.

In addition to the regulation on cholinesterase production, other regulation pathways keep the cholinergic system in balance. For example, acute exposure to anti-ChEs induces brain increases in AChE transcripts accompanied by massive decreases in the vesicular ACh transporter, which together compensate for at least part of the exposure consequences (Kaufer et al., 1998). Also, increased hydrolysis of ACh in AChE-overexpressing transgenic mice was at least partially counterbalanced by a parallel daytime increase in ACh synthesis (Farchi et al., 2003).

Cholinesterases Primarily Function as Acetylcholine-Hydrolyzing Enzymes

The cholinesterases are mainly known for their classical role—catalyzing the hydrolysis of choline esters such as ACh, thus terminating neurotransmission in the NMJ, CNS, and autonomic nervous system. NMJ cholinesterases are anchored to the cell membrane and organized in a spatially related manner close to the nicotinic ACh receptors (nAChRs), a superfamily of ligand-gated ion channels. Within the muscle, axons branch to innervate multiple muscle fibers, each fiber receiving a single synaptic input. The postsynaptic membrane of the skeletal muscle forms deep invaginations called *junctional folds*. Nicotinic AChR are clustered at the peaks of the folds, close to the neuronal presynaptic active zone enriched in ACh-releasing vesicles. The synaptic cleft is filled by the basal lamina of the NMJ, highly enriched in AChE, whereas BChE is concentrated in subsynaptic folds (Blondet et al., 2010). Depolarization of the nerve terminal due to a neuronal impulse is followed by an influx of calcium ions into the terminal via voltage-gated calcium channels. This influx results in the exocytosis of many synaptic vesicles and the release of a corresponding number of ACh quanta into the synaptic space. Binding of two ACh molecules to the nAChR multisubunit complex opens the AChR channel, allowing the inward flux of cations along their electrochemical gradient and producing endplate potential. If this depolarization exceeds the threshold required to open the voltage-gated sodium channels at the depths of the folds, an action potential is generated, leading to muscle contraction. The evoked responses that can be recorded from the surface of the muscle following nerve stimulation are called *compound muscle action potential*, which represents the cumulative action potentials of all muscle fibers activated. The cholinesterases contribute to the regulation of this signal transduction by ACh hydrolysis. Part of the resulting choline pool is recycled with the aid of a high affinity transporter in the pre-synaptic nerve terminal, and is being used as substrate by choline acetyltransferase (ChAT) to generate new ACh molecules (Sarter and Parikh, 2005).

The catalytic activity of cholinesterases is important not solely for regulating neurotransmission, but also for modulating the cholinergic anti-inflammatory reflex. This term was coined after recognition of the ability of excessive stimulation of nAChRs to prevent the secretion by macrophages of the pro-inflammatory cytokines TNFα, interleukin (IL)-1β, IL-6, and IL-18, but not the anti-inflammatory cytokine IL-10 (Tracey, 2010). More specifically, upon inflammatory stimuli, the α7 nicotinic ACh receptor (α7nAChR) is activated by ACh, which results in the inhibition of NF-κB nuclear translocation and suppression of cytokine release by monocytes and macrophages (Tracey, 2010).

The importance of AChE to this process is evident in that low-dose lipopolysaccharide induces a 10-fold increase in miRNA-132 levels, which in turn reduces AChE protein levels and activity in the human serum, potentiating the anti-inflammatory reflex (Shaked et al., 2009; Waiskopf et al., 2014). Thus, ACh hydrolysis by ChEs interferes with the ACh anti-inflammatory effect, and their regulation can rebalance it.

Cholinergic Hyperexcitation and Induction of AChE-R Production

Acute psychological stress induces cholinergic stimulation, yielding neuronal hyperexcitability. Immediate reactions to such cholinergic stimulation include a dramatic increase in neuronal c-fos mRNA (Kaufer et al., 1998; Lev-Lehman et al., 2000). The c-fos protein further binds and regulates the promoters of the *CHAT*, *VCHAT*, and *ACHE* genes. A consequent decrease in ChAT and VChAT then suppresses ACh synthesis and packaging, while enhanced AChE mRNA synthesis and translation facilitates ACh hydrolysis, together yielding an effective restraint on the hypercholinergic response. The larger AChE activity observed in both brain and NMJ following stress further reflects a change in alternative splicing and the induction of a soluble AChE variant, AChE-R (Kaufer et al., 1998). This profound feedback response serves well in the short term to quickly reduce the cholinergic hyperactivity following an acute insult. However, repeated cholinergic stimulation may induce long-term hypersensitization, with potentially damaging consequences. Supporting this notion, transgenic mice overexpressing AChE in the CNS present delayed

cognitive and neuroanatomical pathologies (Soreq and Seidman, 2001; Cohen et al., 2002; Farchi et al., 2003). In humans, traumatic stress with a severe stress response is often followed by long-term pathological changes (McEwen and Morrison, 2013). Under extreme conditions, such changes are clinically referred to as the anxiety-associated *posttraumatic stress disorder.* Physiological relevance of AChE-R to these increases was reported in healthy human volunteers, where higher blood AChE-R levels occurred in association with the subjects' state of anxiety (Sklan et al., 2004). It is still unknown whether the stress-induced alternative splicing of AChE occurs as a cause or an outcome of anxiety, or both. However, in either case, this phenotype may reflect physiological relevance of the overexpressed AChE-R in reaction to stress. Apart from this apparent association, AChE-R may mediate at least some of the adverse cellular changes associated with delayed stress responses (e.g., neuronal spine loss or glial hyperactivation; Soreq and Seidman, 2001).

Under normal conditions, AChE-S is an essential component of functional NMJ, but AChE-R is not. Compatible with this notion, the loss of the ColQ collagen-like structural subunit linking AChE-S to the NMJ leads to congenital myasthenia (Engel, 2012), and modified AChE levels were associated with muscle dystrophy in both chickens and mice (Comim et al., 2011; Vidal et al., 2013).

Similar to its regulation in the brain, AChE-R accumulates in neuromuscular tissues under conditions of disease and stress. AChE-R levels rise both in the serum and muscles of experimental autoimmune myasthenia gravis (EAMG) rats and in the serum of myasthenia gravis (MG) patients (Angelini et al., 2013). In the primate spinal cord, AChE-R accumulated under handling stress in a cell size–dependent manner, suggesting that the characteristic response of shift in the alternative splicing of AChE pre-mRNA spans different cell types and is pivotal for controlling motor functions. Cholinergic spinal cord interneurons innervate large spinal cord neurons, but not the motor neurons themselves, and they respond to stress conditions by elevating AChE-R and by reducing the translocation of AChE-S mRNA into neurites. This is compatible with the shift in alternative splicing toward AChE-R and its transport to neural extensions, where it replaces the normally expressed transcript, AChE-S (Meshorer et al., 2002). A rapid and transient elevation in serum AChE-R following stress responses further suggests a mechanism for suppressing ACh-mediated excitation under stress. However, prolonged elevation in AChE-R (for example, under chronic stress) may damage cholinergic signaling and exert noncholinergic effects. A direct role for AChE-R in MG symptoms likely involves several functional levels. The first is the clear cholinergic function of AChE-R in controlling ACh levels at the NMJ. The second is interference with the anti-inflammatory role of ACh, exacerbating the outcome of the autoimmune origin of the disease. The third may involve changes in the levels of AChE-targeting miRNAs, which can secondarily modify the levels of other targets of such miRNAs (Hanin et al., 2014; Tay et al., 2014).

Nonclassical Cholinesterase Functions

In addition to the traditional roles of ChEs as regulators of cholinergic transmission, many nonclassical roles have been proposed for them (Soreq and Seidman, 2001; Birikh et al., 2003; Darvesh et al., 2003). These include protein–protein interactions and unusual hydrolytic activities. BChE was thought to have additional roles ever since the first evidence of its ability to catalyze the hydrolysis of noncholine esters and the discovery of silent BChE variants that do not possess hydrolytic capacity (Darvesh et al., 2003). For example, BChE was found to have aryl acylamidase activity and was proposed to attenuate amyloid plaque formation and contribute to neurogenesis. In this respect, the K variant of BChE shows weakened protein interactions and lower stability and hydrolytic activity, in spite of an intact active site (Podoly et al., 2009; Shenhar-Tsarfaty et al., 2011).

The first discovered noncatalytic role of AChE-S was the enhancement of embryonic neurite extension, both in cell cultures and in *Xenopus* motor neurons that express human AChE-S (Soreq and Seidman, 2001). Since then, the most significant advances in understanding the nontraditional roles of ChEs emerged through AChE-R studies (Meshorer et al., 2002). AChE-R was first recognized as a stress-induced, soluble AChE variant, but researchers quickly noticed that it contributed to numerous important processes, from fear to hematopoiesis and inflammation. Specifically, both AChE-S and AChE-R were found to interact with the scaffold protein RACK1 (Birikh et al., 2003; Waiskopf et al., 2014). These interactions are important in the regulation of inflammation and fear memory and long-term fear potentiation (Birikh et al., 2003; Nijholt et al., 2004; Waiskopf et al., 2014). Moreover, a proliferation function of AChE-R has been recognized in hematopoietic cellular processes and osteogenesis (Soreq and Seidman, 2001; Pick et al., 2006), whereas excess of AChE-S was inversely shown to interfere with lymphopoiesis (Perry et al., 2007).

Another potential function is based on AChE's sequence homology to cell surface adhesion molecules such as neuroligin (Bourne and Marchot, 2014), suggesting that it may be involved in synaptogenesis and synaptic maintenance (Silman and Sussman, 2005). In brain synapses, AChE-R might compete with neuroligin upon interaction with its partners (i.e., neurexin), interfering with and even modifying the postsynaptic signaling pathway. Such interference may serve as a potential mediator

of cytoarchitectural changes in CNS synapses (Soreq and Seidman, 2001). Both neuroligin and neurexin are also expressed and function at the NMJ, suggesting parallel relevance to the NMJ architecture. Within the NMJ, synaptic differentiation is induced by axon-derived agrin and muscle-derived laminin. Laminin 1 was suggested as a potential partner for AChE (Paraoanu and Layer, 2004) and for the cleavable C-terminal AChE-R peptide, ARP (Johnson and Moore, 2007).

AChE-S was also suggested to play a role in accentuating amyloid plaque formation (Soreq and Seidman, 2001). On the other hand, AChE-R was found to be drastically up-regulated in amyloid beta-treated cell culture (Li et al., 2013) and to inversely attenuate plaque formation through its C-terminal domain (Berson et al., 2008). Importantly, AChE-R elevation in the serum of stressed mice was associated with an apparent cleavage of ARP. This peptide contributes to hematopoietic proliferation and pro-inflammatory cytokine production (Grisaru et al., 2006; Pick et al., 2006; Gilboa-Geffen et al., 2007), contextual fear and long-term potentiation enhancement (Nijholt et al., 2004; Farchi et al., 2007), neuronal development, plasticity, and inflammation-associated neuropathies (Dori et al., 2007).

ANTI-ChEs AND THE CHOLINERGIC SYSTEM

The vital role of the acetylcholine-hydrolyzing enzyme AChE in terminating cholinergic neurotransmission has been recognized for almost as many years as ACh has been recognized as a neurotransmitter. For nearly the same amount of time, AChE research was intimately linked to the study of its inhibitors. The vulnerability of cholinesterases to the natural toxins of many organisms, including fungi, plants, and animals, promoted the discovery and synthesis of new anti-ChEs for use as pesticides, therapeutics, and, unfortunately, as chemical warfare agents (CWAs; Gupta, 2006). These inhibitors helped to elucidate the enzymatic mechanism of action and this knowledge, in turn, was used to design even more potent or more specific anti-ChEs.

Molecular Mechanisms of Cholinesterase Inhibition

The therapeutic/toxic action of cholinesterase inhibitors is targeted at well-known domains of cholinesterases, such as the catalytic site at the bottom of the gorge (Nachon et al., 2013), the anionic peripheral site (Silman and Sussman, 2005), or both (Cheung et al., 2012). Given the structural differences between cholinesterases, their inhibitors can be classified by their selectivity to particular ChEs. For example, phenserine, huperzine A, and BW284c51 are selective AChE inhibitors and tetra(monoisopropyl)pyrophosphoramide (Iso-OMPA) and ethopropazine are selective BChE inhibitors, whereas paraoxon and rivastigmine inhibit both. Alternative classifications may be based on the origin of the inhibitors (whether natural (e.g., galantamine, onchidal, and coumarins) or synthetic compounds (e.g., tacrine, donepezil)), reversibility, or according to their chemical nature. The last divides most of them into two main groups: carbamates and organophosphates (OPs).

Carbamates are used as pesticides (e.g., aldicarb, carbofuran, carbaryl, ethienocarb, and fenobucarb); medications to elevate ACh levels in diverse pathologies such as Alzheimer's disease, MG, glaucoma (e.g., neostigmine, rivastigmine, physostigmine, and pyridostigmine); and in veterinary medications. Some of the members in this group, similar to ACh, can undergo acylation (carbamylation) to form a carbamoyl-enzyme intermediate. The subsequent hydrolysis rate of this hemi-substrate is very slow, occupying the enzyme carbamoylated for a long time and competing with the natural substrate, hence often regarded as pseudo-irreversible inhibition (Figure 52.2A). Interestingly, atypical BChE was found to be far less sensitive than the WT BChE to inhibition by pyridostigmine and several other carbamate anti-ChEs (Loewenstein-Lichtenstein et al., 1995), thus some of the carbamates are variant-specific inhibitors.

The second major group of ChE inhibitors, the OP compounds, was introduced as CWAs in World War II (e.g., tabun, sarin, and soman). Since then, they were developed as CWAs (e.g., nerve agents such as VX, VE, VG, and VM), but also as agricultural pesticides (e.g., malathion, parathion, diazinon, fenthion, dichlorvos, trichlorfon, chlorpyrifos, dimethoate, triazophos, and ethion), flame retardants (e.g., triphenyl phosphate), therapeutics to elevate ACh levels (e.g., echothiophate and diisopropyl fluorophosphate, DFP), and veterinary medications. Similar to carbamates, OPs react with the active site of ChEs and other serine esterases due to the structural resemblance to their substrates (Nachon et al., 2011). The phosphorylated enzyme can be reactivated at a considerably slower rate than the carbamylated enzyme, and certain OPs can further undergo dealkylation following their interaction with the enzyme, which completely blocks its reactivation (known as *aging*; Taylor, 1996; Wandhammer et al., 2013) (Figure 52.2A).

Importantly, whereas most OPs pass the blood–brain barrier (BBB), carbamate anti-ChEs can be divided into those that penetrate the BBB, such as physostigmine and rivastigmine, and those that are unable to cross it under normal conditions, such as pyridostigmine, neostigmine, and ambenonium. Hence, CNS toxicity symptoms are less common with carbamate poisoning. For anti-ChE toxicity and BBB dysfunction and damage, see Chapter 49.

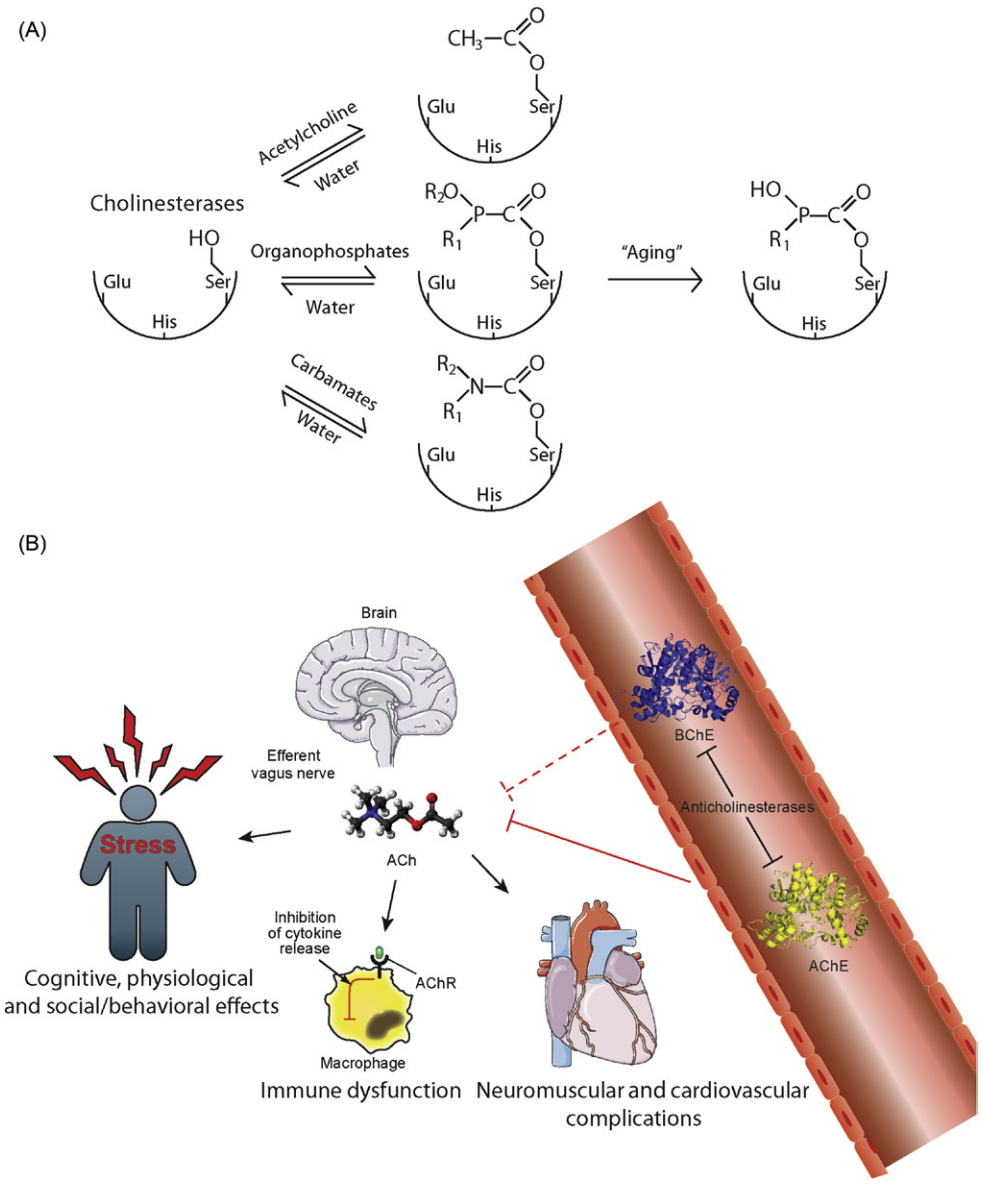

FIGURE 52.2 Anti-ChEs and the cholinergic system. (A) Cholinesterase catalytic triad interactions with acetylcholine and anti-ChEs. (B) Schematic representation of the long-term effects of exposure to anti-ChEs. *Source: (B) is based on Arbel et al. (2014).*

Short-Term Effects of Anti-ChE Exposure

ACh accumulation under exposure to ChE inhibitors and the subsequent nonregulated overstimulation of nicotinic and muscarinic ACh receptors initiates a variety of detrimental processes, including cholinergic hyperexcitation and neuromuscular malfunctioning, which can culminate in severe consequences for the exposed patient (Yanagisawa et al., 2006). In the peripheral nervous system (PNS), the short-term effects of anti-ChE exposure commonly involve autonomic dysfunction, including excessive stimulation of secretory organs, resulting in salivation, lacrimation, urination, and defecation, and muscle fasciculations, and can even include complete paralysis of different muscles. CNS exposure is usually accompanied by symptoms such as CNS depression, anxiety, restlessness, and confusion. Moreover, severe exposure can cause seizures, coma with decreased respiration, and even death, commonly due to cardiac effects or respiratory insufficiency due to muscle weakness even a few days after the exposure (Taylor, 1996).

Anti-ChEs also exert deleterious effects on immune functions (Corsini et al., 2013). OP-mediated suppression of TNF-α, IL-1β, and iNOS has been shown, as well as a confirmation of decreased humoral immunity through suppression of IL-4 (Singh and Jiang, 2003).

This, in turn, has led to investigation of OP-mediated suppression of the hypothalamic-pituitary-adrenal axis (Pena-Philippides et al., 2007). However, anti-ChEs were also found to initiate acute immune responses. For example, the nerve agent soman induces an increase in the pro-inflammatory cytokine TNFα, IL-1β, and IL-6 in rats, including in the brain, where IL-1β is thought to contribute to irreversible brain damage (Banks and Lein, 2012). This bidirectional impairment of immune functions may reflect systemic responses that affect more than the cholinergic system alone.

Therapeutic anti-ChEs have also been shown to exert anti-inflammatory properties (Tyagi et al., 2007), presumably through their role in increasing ACh levels. Specifically, the cholinergic anti-inflammatory pathway has profound implications for excessive nAChR stimulation in the context of an infected host by increasing the susceptibility to initial infection or therapeutically reducing the host overreaction seen in sepsis. Therefore, it is important to consider also treating those anti-ChEs-exposed patients who do not exhibit acute cholinergic symptoms in order to reduce the likelihood of opportunistic infection following survivable anti-ChEs intoxication.

Long-Term Effects of Anti-ChEs

Intoxication, when surviving an acute exposure, also induces long-term consequences, including OP-induced cardiac complications, delayed neuropathy, cognitive, social and behavioral effects, and delayed muscle weakness (Figure 52.2B). The effects of anti-ChEs, like many other stressful insults, are mediated by the accumulation of the early immediate protein c-fos, followed by up-regulation of *ACHE* gene expression (Friedman et al., 1996) and a 3′ alternative splicing shift from AChE-S to AChE-R (Kaufer et al., 1998; Meshorer et al., 2002). This prolonged overexpression of AChE-R due to the intoxication causes dramatic deleterious consequences, parallel to those observed after acute psychological stress; those also span degenerated synaptic folds in the NMJ, enlarged motor endplates, disorganized muscle fibers, and branded terminal nerves, accompanied by physiological malfunctioning (Lev-Lehman et al., 2000; Farchi et al., 2003).

AChE-R mRNA levels remain elevated for several weeks following a daylong exposure, even to exceedingly low doses of the AChE inhibitor, DFP (Lev-Lehman et al., 2000; Meshorer et al., 2002). In the striatum, exposure to AChE inhibitors predictably increased AChE-R mRNA by threefold, but it did not affect AChE activity or total AChE mRNA, possibly suggesting the arrested translation or production of inactive AChE-R (Perrier et al., 2005), most likely due to miRNA effects (Shaked et al., 2009; Shaltiel et al., 2013; Hanin et al., 2014). In the hippocampus, exposure to AChE inhibitors could not be rebalanced by subsequent cholinergic stimulation due to a limited ability for additional AChE-R induction (Meshorer et al., 2002), which may reflect epigenetic modulation of *ACHE* transcription (Sailaja et al., 2012). Intriguingly, AChE-R mRNA was found in the apical dendrites of neurons from all cortical layers following exposure to cholinesterase inhibitors (Kaufer et al., 1998; Meshorer et al., 2002), suggesting possible local regulation and translation of AChE in the synapse and in noncholinergic neurons. Engineered mice overexpressing AChE-R model these changes and display significant deficits in both normal and social behavior and memory (Cohen et al., 2002; Nijholt et al., 2004; Farchi et al., 2007), compatible with the assumption that excess of AChE-R is causally involved with the long-term effects of anti-ChE exposure.

Two weeks following DFP exposure for 4 days, mouse tongue muscles show significant increase in AChE catalytic activity (Lev-Lehman et al., 2000). The punctuated expression pattern of NMJ-related AChE-S mRNA remains unchanged, but AChE-R mRNA is significantly induced and exhibits a diffuse, extrajunctional distribution. AChE-S overexpressing TgS mice, which also show host AChE-R mRNA overexpression, presented a similar expression pattern (Lev-Lehman et al., 2000). Furthermore, in control animals, histochemical activity staining localized the signal to motor endplates, whereas in TgS mice, the soluble AChE-R presented dispersed staining in muscle fibers, which is not restricted to the endplate region, parallel to its pattern of distribution in muscles of myasthenic rats.

In both TgS mice and strain-matched controls chronically treated with DFP, AChE-R overexpression was accompanied by neuromuscular pathology. This neuropathology was exhibited as a chaotic fiber disorder with severe atrophy and vacuolization, compared to control mice where fiber organization was conspicuous (Lev-Lehman et al., 2000). A significant increase was observed by silver staining in small unbundled neurites, but not in large nerve bundle fibers, both in TgS mice overexpressing the synaptic AChE variant and following chronic DFP treatment, compared to strain-matched controls. Compatible with the neurite-promoting activity of AChE, these findings indicate axon branching under the influence of AChE-R overexpression and suggest that the affected muscles were subjected to denervation-reinnervation processes. Importantly, nontransgenic mice treated with DFP and untreated TgS mice exhibited a significant increase in the number of endplates in their diaphragm muscle compared to FVB/N controls (Lev-Lehman et al., 2000). These endplates were smaller in diameter, supporting the notion that reinnervation occurred. Intact TgS muscles stimulated directly via the phrenic nerve examined *ex vivo* demonstrated rapid

fatigue following initial stimulation, accompanied by enlarged decrements and delayed recovery compared to strain-matched controls; this finding was attributed to both neuronal and muscle impairments (Farchi et al., 2003).

The persistent hypercholinergic transmission due to cholinesterase inhibition also results in rapid internalization of the AChR, with homeostasis being restored through the simultaneous process of AChE replacement (Krejci et al., 2006). OP exposure has been shown to induce nAChR desensitization, validating the concept of receptor-level compensation (Katz et al., 1997). In an elegant experiment, a one-time blockade of AChE resulted in a 54% internalization of the AChR at the NMJ within 3 days, presumably in an attempt to mitigate the increased synaptic ACh. Hence, the long-term effects of anti-ChE exposure result from interference with the regular functioning of different cholinergic components.

Anti-ChEs as Therapeutic Agents

Plant-originated anti-ChEs, such as huperzine A, have been used for thousands of years in the treatment of aging-induced memory impairment (Haviv et al., 2007). In 1877, prior to the discovery of ACh as a neurotransmitter in the brain, physostigmine (eserine)—a carbamate extracted from the seeds of *Physostigma venenosum*—became the first cholinesterase inhibitor used therapeutically to control increased ocular pressure caused by wide-angle glaucoma (Taylor, 1996).

Anti-ChEs, such as neostigmine and physostigmine, were also the first effective treatments for MG already in common use in 1935 (Engel, 2012). However, since physostigmine is capable of crossing the BBB, neostigmine was the preferred therapeutic agent. Pyridostigmine bromide (Mestinon) became available in the 1950s as a longer-lasting agent, active for 3–6 h with fewer side effects and the ease of oral administration. Medical forces in Western armies also have used it as a prophylaxis in anticipation of anti-ChE exposure (Friedman et al., 1996). Longer-lasting agents, including OP inhibitors, were not used since they accumulated to overdose levels. Subsequently increased interest in anti-ChE for Alzheimer's disease therapeutics led to the development of tacrine, as the first ChE inhibitor approved in 1993 by the US Food and Drug Administration (Giacobini and Gold, 2013). More recently, second-generation anti-ChEs, such as rivastigmine, donepezil, and eptastigmine, have shown higher efficacy, lower toxicity, and easier administration (Ringman and Cummings, 2006).

Importantly, anti-ChE therapy can also cause a variety of side effects, including gastrointestinal problems, salivation, sweating, and cardiac and hypotension effects. Hence, further research and development of anti-ChEs for therapeutics is required.

DETECTION AND PREVENTION OF ANTI-ChE TOXICITY

The toxicity of anti-ChEs led to their development as CWAs, with the most recent example being the Syrian use of nerve agents to oppress in-land citizens (Sample, 2013). This and the effects of daily life exposure to anti-ChEs in agriculture and industry led to the development of detection methods and therapeutic agents to prevent the lethal effects of anti-ChEs (Periasamy et al., 2009; Masson, 2011; Worek and Thiermann, 2013).

Detection and Use of Nanoparticles and Other Technologies

Different technologies and methods based on cholinesterases have been developed for low cost and fast detection of anti-ChEs with high sensitivity, accuracy and storage stability (Periasamy et al., 2009). These include a novel development of cholinesterases conjugated to nanomaterial-based sensors. In such systems, the cholinesterases are conjugated to nanomaterials such as carbon nanotubes (CNTs), metallic nanoparticles (NPs), or semiconductor NPs, which enable the use of their unique properties, in the nano regime, to achieve the requirements from satisfactory sensors.

Various strategies were examined for the preparation and modification of multiwall CNT (MWCNT) for applications such as electrochemical sensors, solar cells, and photovoltaic devices with advantages such as high electrical conductivity, mechanical strength, and stability (Zhang et al., 2013). This was utilized for the development of anti-ChE sensors based on cholinesterases deposited on electrodes (Periasamy et al., 2009; Cevik et al., 2013). In most of these systems, thiocholine, the hydrolysis product of substrates such as acetylthiocholine or butyrylthiocholine, participates in a redox reaction that allows amperometric and cyclic voltammetry measurements. The comparison of the response with and without anti-ChEs allows the detection and quantification of their concentrations. For example, using such systems, the impressively low sensitivity limits of 4×10^{-13} M for paraoxon and 5×10^{-9} M for triazophos were measured with glassy carbon electrode (GCE)–MWCNT-AChE (Periasamy et al., 2009). In parallel, developments in the synthesis, surface engineering, and conjugation of metallic and semiconductor NPs to proteins for imaging, sensing, and delivery opened this platform for anti-ChE sensors as well.

Cholinesterases were conjugated by different bioconjugation techniques to colloidal NPs of different compositions, dimensions, and surface coating allowing fine tuning of the NPs to the desired application (Figure 52.3A; Waiskopf et al., 2011, 2013). Cholinesterases were also conjugated to NPs deposited on electrodes,

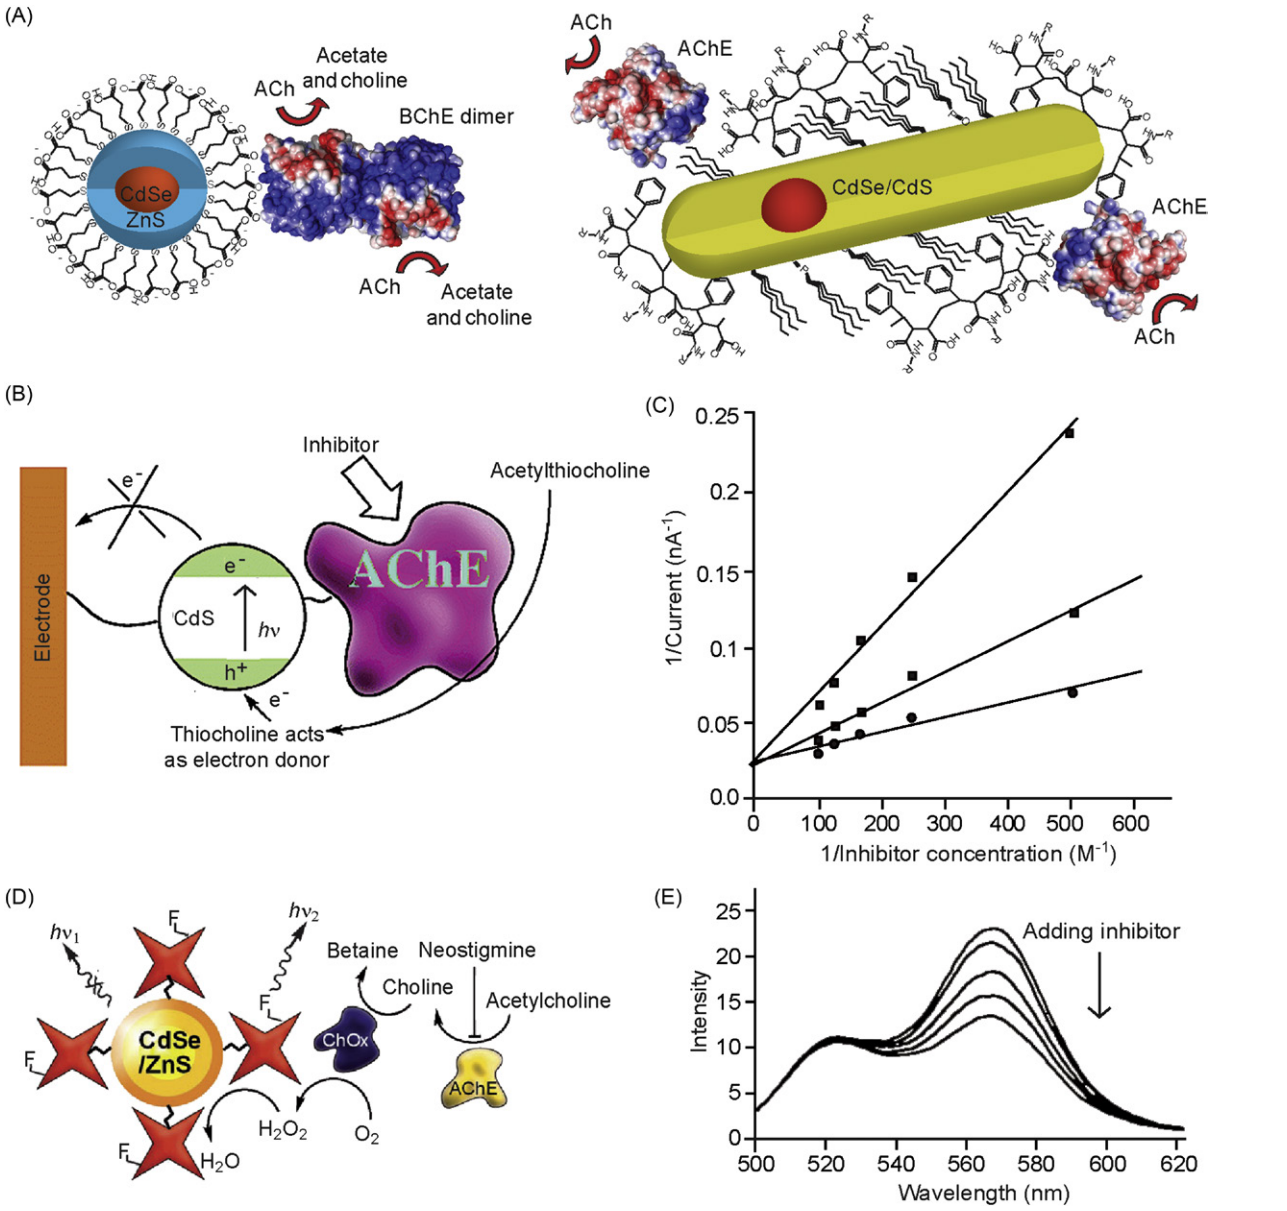

FIGURE 52.3 Cholinesterase-based sensors. (A) Cholinesterases conjugated to NPs of different composition, dimensions, and surface coating. (B) Illustration of a photoelectrochemical sensor of anti-ChEs using cholinesterases conjugated to NPs on an electrode. (C) Experimental data with different concentrations of ACh, which show the reduction in current with the increase in anti-ChE concentration. (D) Illustration of the anti-ChE sensing method based on interference with a chain reaction that starts with cholinesterase-driven hydrolysis of acetylcholine molecules and ends with emission from semiconductor NPs. (E) Experimental data showing the reduction in semiconductor NPs emission intensity with the increase in anti-ChE concentration. *Source: (A) was reprinted and adapted from Waiskopf et al. (2013) with kind permission from Springer Science and Business Media. (B) and (C); (D) and (E) reprinted and adapted with permission from Pardo-Yissar et al. (2003) and Gill et al. (2008), respectively. Copyrights (2003) American Chemical Society and (2008) John Wiley & Sons, respectively.*

increasing the number of conjugated enzyme molecules due to the large surface area/volume ratio. This, in addition to the tailoring of the NPs and the conjugation techniques, allows better charge transfer efficiency upon oxidation of the hydrolysis product thiocholine. This led to increased sensitivity to anti-ChEs in electrochemical sensors as compared with cholinesterase deposition on bare electrodes. For example, AChE conjugated to CdS or gold NPs showed sensitivity to 10^{-5} M BW284c51 and 5×10^{-10} M of trichlorfon or 7.6×10^{-6} M of methyl-parathion, respectively (Figure 52.3B and C; Pardo-Yissar et al., 2003; Periasamy et al., 2009). More complex systems combining several types of NPs on the electrode were also examined. For example, CdTe-AuNPs-chitosan microspheres-GCEs showed sensitivity to 1.34×10^{-9} M of monocrotophos (Periasamy et al., 2009).

In a different approach, the reduction properties of thiocholine were used to grow gold NPs on an AChE-chitosan-gold electrode using $HAuCl_4$ as a precursor. The growth of gold NPs upon substrate hydrolysis and its inhibition by anti-ChEs resulted in changes in cyclic voltammetry showing sensitivity to 6×10^{-11} M of malathion (Periasamy et al., 2009).

It is noteworthy that the high sensitivity of anti-ChEs detection in methods utilizing thiocholine also has some problems. For example, the thiol group has high affinity to metals such as gold and cadmium, which can affect the measurements. One suggested way to overcome this issue is to quantify anti-ChE concentrations without the use of thiolated substrates. This was achieved in a three-step procedure. First, phosphorylated cholinesterases were bound to ZrO_2 NPs deposited on an electrode due to specific interaction of the ZrO_2 with the phosphoric group. Second, cadmium-based NPs conjugated to antibodies for cholinesterases were added to the solution for binding the cholinesterases. Third, electrochemical stripping analysis of the cadmium after acid dissolution allowed the quantification of the OPs. Using this method, sensitivity levels of 8×10^{-12} M for phosphorylated AChE and 3×10^{-11} M for phosphorylated BuChE was achieved (Periasamy et al., 2009; Lu et al., 2011). In a similar method, phosphorylated cholinesterases were first mixed with magnetic-particle-antiphosphoserine polyclonal antibodies for magnetic separation, and then cadmium-based NPs conjugated to antibodies against cholinesterases were used. Using this approach, sensitivity to phosphorylated AChE and BChE of the order of 10^{-11} M was achieved (Zhang et al., 2013).

These conjugated cholinesterase systems are stable for long periods of time since the bound materials stabilize the cholinesterases and protect them against proteases and harsh environmental conditions. However, the conjugation procedure might damage the enzymatic activity (Waiskopf et al., 2013) and irreversible inhibition of cholinesterases activity upon use can prevent reuse of these sensors. Hence, different NP-based assays with nonconjugated cholinesterases were also developed. For example, colorimetric assays based on growth or aggregation of gold NPs upon substrate hydrolysis showed better detection limits than 10^{-10} M of anti-ChE concentrations (Periasamy et al., 2009; Wang et al., 2009; Sun et al., 2011; Wang et al., 2013).

Fluorometric assays emerge as an additional approach, in which different chain reactions starting from substrate hydrolysis and ending with change in semiconductor NP fluorescence may be used to detect anti-ChEs (Gill et al., 2008; Chen et al., 2013; Meng et al., 2013). An example for such a chain reaction can be seen in Figures 52.3D and E. The chain reaction starts with choline, the product of acetylcholine and butyrylcholine hydrolysis, which is used by choline oxidase (ChOx) as a substrate. ChOx oxidizes choline to betaine while generating hydrogen peroxide (H_2O_2). Then H_2O_2 quenches the fluorescence of quantum dots, allowing the detection of cholinesterase activities with sensitivity limits of 4.49×10^{-9} M to dichlorvos (Gill et al., 2008; Chen et al., 2013; Meng et al., 2013). This chain reaction has also been used in an electrochemical sensor sensitive to H_2O_2 formation for the detection of anti-ChEs. For example, screen-printed graphite electrodes modified with γ-MnO_2 nanostructures that show electrocatalytic activity toward the oxidation of H_2O_2 presented sensitivity up to 5×10^{-11} M of chlorpyrifos (Dontsova et al., 2011). More recently, this screen-printed graphite electrode-MnO_2 NPs system was also found to be sensitive to thiocholine, achieving sensitivity limits of 6×10^{-10} M to diazinon (Eremenko et al., 2012).

An additional novel approach to detect cholinesterase inhibitors is based on field effect transistor technology, with sensitivity to change in local pH or in protein structure upon ACh hydrolysis. An ion-sensitive field effect transistor with AChE bound to its gate showed sensitivity of up to 10^{-5} M of ACh and the ability to detect physostigmine concentrations in the range of 10^{-4} to 10^{-7} M, based on the decrease in the recorded current in comparison to the response without the inhibitor (Hai et al., 2006). In another study, AChE was bound to a floating gate-derived field effect transistor, with a response range of 10^{-2} to 10^{-9} M ACh and achieved a sensitivity to 10^{-8} M physostigmine (Goykhman et al., 2009).

Generally, few limitations for these systems have been explored in the literature, including damaging of the sensor by any factor that will affect the enzymatic activity or other reactions used in the method and the inability to recognize the inhibitor using such cholinesterase-based sensor. Therefore, in addition to cholinesterase-based sensors, many other sensors and methods have been developed and used to detect anti-ChEs in the past, each with its own advantages and disadvantages (reviewed by Kim et al., 2011). Anti-ChE detection methods thus should be tailored to the specific anti-ChEs and the requirements from the sensor.

Recombinant Cholinesterases as Therapeutic Agents

Current medical intervention in the case of acute exposure to anti-ChE agents includes the use of the muscarinic receptor antagonist atropine to block overstimulation, and oximes to reactivate OP-modified cholinesterases (Worek and Thiermann, 2013). However, these conventional treatments have limited effectiveness and may involve serious short- and long-term side effects (Worek and Thiermann, 2013). In fact, the routine treatments, while successfully decreasing anti-ChE-induced lethality, rarely alleviate post-exposure toxicity

and result in significant performance deficits and even permanent brain damage (Masson, 2011).

The shortcomings of the pharmacological approach to the problem prompted the development of an alternative approach (namely, the use of cholinesterases as anti-ChE-binding stoichiometric bioscavengers (Masson, 2011)). This approach is considered one of the inherent protection layers in which BChE acts as a natural scavenger of OP nerve agents and pesticides (Rosenberg et al., 2013). Several strategies for production of cholinesterases have recently been evaluated, including purification from outdated blood-banked human plasma (Lenz et al., 2005), from mammalian cell cultures, from the milk of transgenic goats (Podoly et al., 2009) or from transgenic plants (Evron et al., 2007; Geyer et al., 2010).

Administration of exogenous cholinesterases can provide protection against nerve agents, as was demonstrated in a variety of rodents (Lenz et al., 2005) and in primates (Rosenberg et al., 2013). Considerable success was achieved with polyethylene-glycol-conjugated recombinant BChE as an OP bioscavenger (Rosenberg et al., 2013). Nonetheless, this therapeutic approach depends on the availability of large amounts of recombinant human enzymes, which are required in stoichiometric rather than catalytic quantities. Indeed, the 1:1 stoichiometry necessary for anti-ChE bioscavenging by ChEs, stemming from the virtual irreversibility of the interaction of the enzymes with the inhibitors, is one of the major limitations of this approach. Co-administration of oximes to enhance regeneration of the bioscavengers after OP exposure is only partially effective (and it is not effective at all against some nerve agents, such as tabun and soman) and the chemistry involved in the process results in highly reactive and toxic phosphyloximes (Worek and Thiermann, 2013).

The effects of treating mice with plant-derived AChE-R in conjunction with their exposure to OPs were also tested (Evron et al., 2007). Interestingly, by 10 days post-exposure, AChE-R prophylaxis ameliorated the chronic effects of OP toxicity by mitigating the long-term up-regulation of *ACHE* gene expression; this treatment reduced plasma murine AChE-R levels and limited the NMJ dysmorphology. However, in addition to its capacity to restore the cholinergic balance immediately after acute intoxication, prolonged overproduction of AChE-R is associated with the overproduction of pro-inflammatory cytokines (Grisaru et al., 2006), behavioral impairments (Birikh et al., 2003), declarative memory loss (Nijholt et al., 2004; Farchi et al., 2007), muscle malfunctioning (Brenner et al., 2003), and excessive myelopoiesis (Pick et al., 2006; Gilboa-Geffen et al., 2007). Hence, pretreatment with the enzyme would predictably cause a transient elevation of inflammation markers. Nevertheless, the relatively rapid clearance of the plant-derived AChE-R_{ER}, which makes it transient, would limit the duration of such effects. Moreover, interference with the overproduction of endogenous AChE-R in the circulation should further limit the duration of such symptoms, avoiding much of the delayed post-poisoning phenotype, which is due to exposure-induced AChE-R accumulation. These findings highlight the advantages of plant-produced AChE-R_{ER} for both short- and long-term protection.

By utilizing AChE-R, a known positive modulator of inflammation, we have also demonstrated a means of counteracting the immunosuppressive actions of nicotinic AChR stimulation. AChE-R has been shown to induce a pro-inflammatory cytokine response, as well as an enhanced cellular response. We demonstrated that the effects of OP-induced immunosuppression in skeletal muscle are reversed following treatment with AChE-R.

Thus, the cholinesterases can be used not only as stoichiometric bioscavengers, but also as therapeutic proteins that are capable of preventing both the acute presentation and chronic dysmorphology and immunosuppression of OP toxicity.

Catalytic Bioscavengers

An ideal bioscavenger should be broad-acting, avoid aging, and present satisfactory reactivation kinetics; i.e., it should be catalytically active. Several enzymes from diverse organisms, ranging from bacteria to invertebrates and vertebrates, are known to hydrolyze anti-ChE compounds and their utility as catalytic bioscavengers of nerve agents and pesticides does not go unnoticed. The genetics and structure of these enzymes are diverse, but despite this, they are classed all together as OP hydrolases or as phosphotriesterases (Wales and Reeves, 2012). The most broadly active members of this artificial grouping are the enzymes from *Pseudomonas diminuta* and *Flavobacterium* sp.; their study yielded valuable structural and functional insights, but their utility for treating humans is questionable because of their bacterial origin (Wales and Reeves, 2012). On the other hand, mammals have several serum enzymes that reveal low, but significant, hydrolyzing activity toward OPs. These include not only paraoxonase (PON), but also members of the α/β-fold hydrolase family, particularly BChE and carboxylesterase (CarbE; Li et al., 2005).

Of the three members of the PON family, the most studied, and hence best known, is PON1. The genes encoding for the various PONs are more than 60% identical, and all three are mapped to nearby loci on the long arm of chromosome 7 (Bourquard et al., 2008), and, interestingly, only 5.5 Mb away from the *ACHE* locus (Sklan et al., 2004). Of the three, PON1 and PON3 are serum enzymes associated with high-density lipoprotein, whereas PON2 is expressed in many tissues (Bourquard et al., 2008). The three PONs can hydrolyze a variety of

esters and lactones, but despite their name, weak OP hydrolyzing activity is associated only with PON1 (Harel et al., 2004; Bourquard et al., 2008). Although the precise physiological roles of PONs remain elusive, epidemiogenomic studies, *in vitro* biochemical experiments, and *in vivo* experiments with knockout mice, build a compelling case for the involvement of at least PON1 in protection from atherosclerosis (Aviram and Vaya, 2013; Shenhar-Tsarfaty et al., 2013). At the same time, similar lines of evidence point to a much broader role in protection, especially neuroprotection. PON1, true to its name, is an OP hydrolase, but its hydrolytic capacity is quite promiscuous. Levels of serum PON activity, on the one hand, correlate well with polymorphisms in the *PON1* locus and, on the other hand, correlate with sensitivity to anti-ChE pesticides (Costa et al., 2013).

Based on biochemical data but mainly on the crystal structure of recombinant PON1 (Harel et al., 2004), Tawfik and coworkers offered a model for the architecture and function of the lactonase active sites of the PON enzymes (Khersonsky and Tawfik, 2006). PON has a six-bladed, β-propeller structure, with two calcium ions located in the central tunnel. One is buried and acts as a structural Ca^{2+}, whereas the second is catalytic Ca^{2+}, which is solvent-exposed and functions as a stabilizer of negatively charged intermediate products. The PON enzymes also have two His residues, the so-called His^{115}-His^{134} dyad, which mediates the lactonase and esterase activities of the enzymes. His^{115} acts as a general base to activate a water molecule attacking the carbonyl oxygen of the substrate and His^{134} activates His^{115} by a proton relay mechanism (Khersonsky and Tawfik, 2006). While the His dyad model is consistent with other data and nicely explains both lactonase activity and PON1's anti-atherosclerotic function, it fails to describe the phosphotriesterase activity of the enzyme. Nonetheless, molecular evolution experiments from the Tawfik laboratory, together with site-directed mutagenesis by that group and others, indicate that while the lactonase and OP hydrolase active sites are partially overlapping, substrates are oriented differently so that they face different chemically active residues (Khersonsky and Tawfik, 2006). Several mutations specifically increase the OP hydrolase activity. For example, H134Q increases it threefold to sixfold relative to WT, while significantly reducing the lactonase activity (Harel et al., 2004; Khersonsky and Tawfik, 2006). Even more dramatic, using directed evolution of PON1, Tawfik and coworkers achieved 340-fold increased catalytic efficiency in the hydrolysis of G-type nerve agents in comparison to WT-like recombinant PON1 (Gupta et al., 2011; Goldsmith et al., 2012).

It is noteworthy that the two enzymes that have thus far have been shown to provide the best protection against OP poisoning, AChE and BChE, belong to the α/β-fold hydrolase family. They bind OP anti-ChEs very efficiently, but the phosphorylated enzymes fail to reactivate. However, certain mutants of human BChE were shown to reactivate considerably faster, effectively making them OP hydrolases (Geyer et al., 2010). Unfortunately, although significant improvements were achieved, the process is still very inefficient, especially with the soman-inhibited enzyme, which is rapidly undergoing aging. In this context, it is interesting to note that murine BChE, but not its human counterpart, can spontaneously reactivate (Li et al., 2005). CarbE is another member of the same family, with broader catalytic activities and sensitive to OPs. CarbE can self-activate, and it is speculated that His residue within the sequence WI**H**GGGL plays a role in this process. The corresponding sequence of BChE (and AChE) is WI**Y**GGGF. One of the OP-hydrolase-enhancing mutations, G117H of BChE, is in the same region (WIYGG**H**F). (Note: the bold letters refer to changes in the amino acid sequence.) But unlike PON1 and the ChE enzymes, CarbE is not normally found in human serum (Li et al., 2005). The OP-hydrolyzing activities associated with native CarbEs, murine BChE, and recombinant human BChE raise the possibility of evolving these enzymes into more efficient phosphotriesterases.

Selective RNA-Targeted Suppression of AChE-R Overexpression Effects

The idea that anti-ChEs intoxication leads to prolonged overexpression of AChE-R, resulting in deleterious consequences, called for in-depth research. The effects of excess AChE-R in neuromuscular pathologies could be alleviated by small molecule inhibitors, as in MG; however, their effects were short-lived. This could be due to indiscriminate inhibition of both AChE-S and AChE-R, which would induce general increases in ACh and subsequent feedback overproduction of yet more AChE-R, exacerbating muscle weakness. Supporting this notion, MG patients, with elevated AChE-R levels, typically require oral drug administration every 4–6 h, and up to every 3 h in more refractory cases (Ropper and Brown, 2005). Antisense oligonucleotide suppression of nascent AChE-R mRNA transcripts emerged as an effective means for challenging the hypothesis that AChE-R was causally involved with these symptoms, as well as a promising therapeutic alternative. Known by the names *AS3*, *EN101*, *Monarsen*, and *BL-7040*, the AChE mRNA-targeted agent is a 20-residue-long antisense molecule, 2′-oxymethylated at its 3′-terminal position (Angelini et al., 2013). It is targeted at exon 2 of AChE mRNA, which is common to the different AChE mRNA splice variants (Soreq and Seidman, 2001; Meshorer and Soreq, 2006). Nevertheless, the nascent, relatively unstable AChE-R transcripts

demonstrated particular sensitivity to the antisense treatment compared to AChE-S mRNA. This was the case in cultured primary brain cells (Meshorer et al., 2002), live mice (Cohen et al., 2002; Birikh et al., 2003; Nijholt et al., 2004), and human-originated cell lines (Perry et al., 2004). Antisense suppression of AChE-R was also shown in EAMG rat muscles and in monkey spinal cord neurons, leaving AChE-S almost unaffected (Brenner et al., 2003; Angelini et al., 2013). Moreover, anti-ChEs induce a feedback response and up-regulation of the AChE-R variant, suggesting that they would actually exacerbate AChE-R overexpression in myasthenic muscles, perhaps explaining their short-lived effect. In contrast, antisense treatment should not activate this feedback loop, providing yet another added value to its use.

In muscle, AChE's catalytic activity increased 2 weeks after repeated DFP exposure for 4 consecutive days. This increase reflected the overexpressed AChE-R and could be significantly reduced by systemic antisense treatment. Antisense treatment brought down AChE's catalytic activity to the range of control animals (Lev-Lehman et al., 2000). Importantly, this treatment further prevented the increase in NMJ endplate density, supporting the notion that these plastic changes were also attributed to AChE-R. The muscle weakness, characteristic of AChE-R excess, resembles the reported weakness syndrome that follows continuous or repeated exposure to agricultural anti-ChE pesticides (Ross et al., 2013). Thus, excess AChE-R may be pivotal for rapid regaining of homeostasis following OP exposure, but its long-term accumulation entails multiple delayed damages.

The successful antisense treatment in animal models led to clinical trials in human MG patients. The agent is provided in a single daily oral dose, followed by measurable improvement in muscle functioning (Angelini et al., 2013). The reported effect lasts over 24 h, with a 100-fold lower required molar dose than that of pyridostigmine (Sussman et al., 2012). Thus, the antisense treatment seems promising for intoxication-induced effects of AChE-R overexpression.

Antagomir-Mediated Suppression of the AChE Targeting miRNA-132

Of note, OP poisoning victims show prolonged suppression of serum AChE activity that was attributed until recently to persistent exposure of the blood enzyme to the OP poison. Recently, we discovered that the post-exposure decline in AChE activity reflects drastic increases in the levels of miRNA-132, a natural regulator of AChE, and that conditional increase in miRNA-132 levels in engineered mice causes multiple brain and body pathologies. These findings offer a new explanation for the post-exposure decline in AChE activity and call for developing a new treatment strategy. We tested the feasibility of prophylactic protection against OP poisoning by injecting a chemically protected antisense oligonucleotide (AM132) targeted against miRNA-132 to mice exposed to increasingly lethal doses of the anti-ChE OP insecticide metabolite paraoxon. Muscle miRNA-132 levels were drastically reduced post-treatment; miRNA-132 increases were avoided, and treated mice exhibited fewer poisoning symptoms, faster recovery, and extended survival time compared to controls. Furthermore, 1 week after poisoning, treated mice demonstrated reduced anxiety reactions (in an elevated plus maze) and better navigation memory performance (in a Morris water maze). Taken together, these findings suggest that the post-poisoning decline in AChE activity, and possibly many of the delayed pathologies, are due to increases in miRNA-132, further suggesting that post-exposure treatment with AM132 may avoid such detrimental consequences (Ofek et al., 2011).

CONCLUDING REMARKS

Throughout this chapter, we have explored the current thinking and experimental data in support of the principal roles that cholinesterases play in maintaining synaptic and systemic cholinergic homeostasis. This view puts the various protein members of the cholinesterase family, especially the readthrough variant of AChE, at a crucial (and therefore vulnerable) intersection between the CNS and PNS and other body networks, such as the hematopoietic and immune systems. We presented an intricately balanced picture consisting of epigenetic, transcriptional, posttranscriptional, and posttranslational regulation. Aiming at mitigating the short- and long-term consequences of exposure to chemical stressors that interfere with cholinergic neurotransmission indeed requires systemwide actions. Through gain and loss of function experimental approaches and the use of various *in vivo*, *ex vivo*, and *in vitro* systems, a more coherent picture is beginning to emerge. This allows the development of both novel cholinesterase-based sensors to detect anti-ChE, and novel therapeutic strategies relying on enzyme supplementation in combination with RNAi agents to restore a healthy cholinergic status by carefully manipulating AChE levels to ameliorate the chronic effects of anti-ChE toxicity.

Potential Agents That Can Cause Contamination of Animal Feedstuffs and Terror

Robert.W. Coppock and Margitta Dziwenka

INTRODUCTION

Terror Objectives

Foodstuffs and feedstuffs (intended for human and animal consumption, respectively) are vulnerable to terrorist attacks and acts of crime. A terrorist attack is intended to cause injury, death, and economic loss to civilian populations (WHO, 2002). The organizations and individuals that commit acts of terror generally have multiple objectives (Carus, 2001). These motives include revenge, creation of panic and disorder, intimidation of the target population and governments, alteration of the form of governance, influence over government policy, toppling political leaders, and challenging economic stability. Criminal acts generally are committed for monetary gain, revenge, or a personal social–psychological agenda (Carus, 2001). Agri-terrorism and agri-crimes can target specific agricultural industries. Defense against agri-terrorism and agri-crimes requires diversion of resources that could otherwise be used for economic growth. Emergency preparedness must include infrastructure and professional personnel for all events and hazards inclusive of terrorism and criminal acts against the livestock, poultry, and companion animals and the animal-to-human food web. Timely decision-making is essential in determining if disease in livestock is attributable to exposure to chemical–physical agents or infectious agents (Neher, 1999; Kosal and Anderson, 2004). Most preparedness plans give disproportionate priority to infectious agents (WHO, 2002; Kosal and Anderson, 2004). Toxicologic focus of the investigation often lags until the likelihood of infectious etiology is considered low. Laboratory information that provides timely holistic scope and etiology of the incident is essential for timely decision-making (Crutchley et al., 2007). Laboratory capacity and expertise are essential for identification of chemical and physical agents. The required infrastructure for thorough emergency preparedness includes full-service government-subsidized diagnostic laboratories for animals. Acts committed by terrorist and criminal perpetrators can overwhelm laboratory, regulatory, public health, and other resources (WHO, 2002; Kosal and Anderson, 2004). Well-rehearsed multiple-hazard protocols to deal holistically with an attack on food-animal production and supply chain are essential for emergency preparedness and the coordinated prompt response. National defense organizations are keen to identify and separate terrorists with political and devout agendas from criminal lawbreakers (Carus, 2001).

A terrorist attack targeted at feedstuffs could have a remarkable impact on the feed and livestock industries and human health. Large handling and manufacturing facilities provide opportunities for point source act-of-terror–linked adulteration of feedstuffs that result in wide distribution of chemical and physical agents (Kosal and Anderson, 2004). The World Health Organization (WHO, 2002) believes that a local terrorist attack on food could have global impacts. Specific industries and livestock sectors can be targeted with significant economic losses (Crutchley et al., 2007). Terrorist attacks can also indirectly affect feedstuffs with collateral damage. For example, fallout from a dirty bomb can contaminate forages, cereals, and other feedstuffs, and emissions from a fire can be deposited over a large area. Consuming contaminated edible animal products exposes humans to acute, subacute, and chromic effects of a toxic substance. Persistent organic pollutants (POPs) can be

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00053-1

bioconcentrated and likely have multigenerational effects in humans (Blanck et al., 2000). Companion animals can be exposed through contaminated animal products being incorporated into pet foods (Brown et al., 2007). Attacks on companion animal feedstuffs resulting in illness and deaths in pets can have considerable emotional impacts on a community. The melamine–cyanuric acid contamination of pet food showed that a combination of adulterants caused sickness (Puschner et al., 2007).

Agricultural Food Ecosystem and Terror

A brief review of the agri-food ecosystem is important in the discussion of terrorist-linked toxicology of animal feedstuffs. Generally, the activities and technologies in the agro-ecosystem are maximized for human control and economic gain. All aspects of food production in the agro-ecosystem, including input supplements, chemicals, and fertilizers, can be the targets for terrorists. Harmful agents and organisms can be added directly or indirectly to feedstuffs. The vulnerability of animal feeds can be illustrated by the large-scale toxicological incidents inclusive of chemical residues in animal products that have been reported. Feed contamination incidents have important economic and human health consequences (Carter, 1976; Lok and Powell, 2000; Kosal and Anderson, 2004). There is likely an under-reporting of occurrences of feedstuffs-linked animal intoxications and there is generally fragmentary governmental infrastructure to collect, process, and use veterinary toxicoepidemiological data (Guitart et al., 2010).

Upsetting the Margins Between Safe and Unsafe Practices

The production of cereal grains, oilseeds, other commodities, and forage for the human food web essentially occurs in a manmade agroecosystem (Coppock and Jacobsen, 2009). Activities in the agroecosystem include seeding, growing, harvesting, storing, and transportation of feedstuffs and foodstuffs. The agronomic ecosystem is driven by economic decisions that generally maximize profitability and minimize labor and input costs. This ecosystem is dependent on management decisions that ensure all activities are performed in a timely manner, input costs are reduced, and all operations are conducted in a manner that generally ensures the quality and safety of foodstuffs and feedstuffs. The margin between safe and unsafe practices is generally close. The time-sensitive activities include seeding, watering, fertilization, weed and other pest control, harvest timing and methods, preservation, storage, and shipping. All aspects of the system require that chemical contamination of feedstuffs does not occur.

The agroecosystem is essentially unprotected and is vulnerable to attacks by terrorists. These attacks may not be directly focused on the agroecosystem, but they can indirectly narrow the margins between safe and unsafe practices. For example, the tactics used by terrorists can have huge impacts on foodstuffs and feedstuffs and can be as simple as, for example, disrupting the distribution of electrical and fossil fuel energy, availability of water, or targeting industries and infrastructure serving the agricultural sectors. A remarkable reduction in available and affordable energy can immediately alter practices traditionally used to harvest and preserve feedstuffs and increase the risk of growth of toxigenic fungi. Disruption of water availability can delay all of the input processes and increase the susceptibility of a crop to infection with mycotoxigenic fungi. The agroecosystem food web also includes manufacturing of feedstuffs and foodstuffs. Food-producing animals in the agroecosystem are vulnerable to heat-stable toxins and persistent chemicals that are bioconcentrated and relayed to humans in edible animal products. Animal by-products containing persistent chemicals can be used in food-animal feedstuffs and petfoods.

Examples exist when large incidents of animal intoxication occurred because of upsets in the agroecosystem and because of human error wherein chemical contamination not linked to terror had economic impacts (Kojima and Fujita, 1973; Kay, 1977; Fries, 1985; Coppock et al., 1988; Kosal and Anderson, 2004; Dorea, 2006; Burns, 2007). These incidents have long-term impacts on human health (Kojima and Fujita, 1973; Henderson et al., 1995; Blanck et al., 2000; Kosal and Anderson, 2004). Chemical-induced illness at the local level can have a significant impact on the health system, challenge the ability of government agencies to understand the scope of the incident, and strain intragovernmental relations (Kojima and Fujita, 1973; Green et al., 1987; Lok and Powell, 2000; Kosal and Anderson, 2004).

MYCOTOXINS AND TOXIGENIC FUNGI

Background

The alleged use of mycotoxins as a chemical weapon is a controversial subject (Tucker, 2001; Katz and Singer, 2007). Mycotoxins and toxigenic fungi can be used for terrorist attacks on both feedstuffs and foodstuffs (Scholthof, 2003; Tucker, 2003; Shannon, 2004; Klassen-Fischer, 2006). Veterinary and human medical professionals in North America do not commonly consider mycotoxicoses as disease entities in a differential diagnosis. In addition to low consideration as the etiology of disease, the clinical presentation caused by mycotoxins can easily be diagnosed as being caused by other

etiologies (Paterson, 2006). Thus, the delay in the identification of mycotoxins as the causal agent(s) could occur over a considerable period of time. Delay in recognition can increase the numbers of animals and humans intoxicated. There is an example of large-scale human and animal exposure to mycotoxins because the agroecosystem was disrupted by war (Joffe, 1978). There are endemic exposures to mycotoxins in Africa because of drought, economic hardships, wars, and agricultural practices (Marasas, 2001; Gnonlonfin, et al., 2013). Mycotoxin contamination of foodstuffs and feedstuffs can be an indirect effect of terrorism and war because of disruption of agricultural practices. In addition to adverse effects on human and animal health, substantial additional economic hardship would likely occur concurrently because of trade issues.

Applications of Biotechnology

It should be assumed that the effective use of mycotoxins as terrorist weapons can be increased with the use of biotechnology. Development of fungi for bioterrorism has been reported to share technologies with the military development of fungi for use as weapons (Paterson, 2006). The genetics of mycotoxin production are being elucidated and this knowledge is assumed to result in reduction of health risks. It is well-known that the conditions for mycotoxin production are the presence of toxigenic fungi having favorable growing conditions that include temperature, substrate, and moisture content (Woloshuk and Shim, 2013). It is possible for aggressive strains of toxigenic fungi to be isolated or developed that produce mycotoxins at lower temperatures and moisture levels than would be considered the usual limits for a particular fungal species (Moretti et al., 2013; Subramaniam and Rampitsch, 2013). Also, fungal varieties can be genetically modified (GM) in a manner that would enhance toxin production by removing the environmentally activated "restrictors" of toxin production. The adaptation of mycotoxigenic fungi and mycotoxins in terrorist activities likely follows the developments in fungal genetic research and biotechnology.

Potential Use of Fungal Biocontrol Agents

Fungal biocontrol agents (FBCAs) could be used in terrorist activities. Some FBCAs have been developed using bioselection and some have been developed using GM technologies (Paterson, 2006). A number of the FBCAs produce mycotoxins, and known toxigenic fungi have been used to control unwanted vegetation. Studies have been performed using FBCAs in plants used to produce illicit drugs (Charudattan et al., 2011). The same technologies can be used to target crops used as feedstuffs in livestock and poultry production.

Economic Losses from Use of Mycotoxins as Weapons

The use of toxigenic fungi and mycotoxins for bioterrorism can have economic consequences. Increasing the environmental prevalence of aggressive strains of toxigenic fungi could increase the losses due to mycotoxins from $2.5 billion to some substantially higher number (CAST, 2003). These losses may be underestimated because Robens and Cardwell (2003, 2005) projected the loss attributable to aflatoxins alone at $1.5 billion per year without including secondary industry and trade losses. International commodity trading of dry cereal grains could be used as a method of disseminating the spores of GM aggressive toxigenic strains of a particular fungus. Once released into the environment, the GM fungi would be difficult to control.

Use of Mycotoxin Contaminated Feedstuffs

Mycotoxin-contaminated feedstuffs could be purchased at a bargain price and used as a terrorist tactic in the manufacture of a completed feed. For example, horse or swine feeds could be formulated with a high level of grain by-products that are known to contain mycotoxins. Field incidences of mycotoxicoses not linked to terrorist activities have been reported from the use of mycotoxin-contaminated by-products in formulating ruminant, horse, and swine feeds (Wilson et al., 1990; Osweiler et al., 1992; Riet-Correa et al., 2013). Pet foods have been contaminated with aflatoxins and they caused illness and deaths of companion animals in regional areas (Arnot et al., 2012; Wouters et al., 2013).

Residues in Edible Tissues

Food-producing animals can ingest mycotoxin-contaminated feedstuffs and mycotoxin residues can be present in edible animal products (Coppock and Dziwenka, 2014). The concern for residues of mycotoxins in edible animal products has primarily been focused on residues of aflatoxins (Coppock et al., 2012). Residues of some mycotoxins in animal products can be regulated. Incidents of aflatoxin-contaminated feedstuffs being fed to milk-producing animals and subsequent contamination of foodstuffs are a public concern (Prandini et al., 2009). In North America there has been a consolidation of the dairy herds producing large volumes of milk and fewer and larger feed suppliers. Bioterrorism using aflatoxins to contaminate feedstuffs could contaminate a large volume of dairy products with aflatoxin M_1.

Mycotoxicology

A discussion of mycotoxicology is beyond the scope of this chapter. For further details on mycotoxicology, the reader is referred to other recent publications (CAST, 2003; Gupta, 2012).

MICROBIAL TOXINS

Botulism Toxin

Background

Botulism neurotoxins (BoNTs) are potential terrorist weapons in foodstuffs and feedstuffs chains and are given priority because of the extreme potency of BoNT (Wein and Liu, 2005; Woudstra et al., 2013). BoNT can easily be produced at low cost as a preformed toxin. Botulism can occur by *Clostridium botulinum* growing *in vivo* in the gut and wounds causing toxicoinfection (examples are infant botulism and visceral botulism in domestic animals) (Anniballi et al., 2013). *C. botulinum* produces environmentally resistant spores and exposures to BoNT and *C. botulinum* spores are spread through oral and cutaneous routes. Preformed BoNT can be added directly to foodstuffs and feedstuffs. The *C. botulinum* spores or substances with high spore counts can be added to foodstuffs and feedstuffs and, if favorable conditions exist, then the BoNT can be preformed in foodstuffs and feedstuffs before consumption occurs. The *C. botulinum* spores in foodstuffs and feedstuffs can, under favorable conditions, trigger *in vivo* formation of BoNT by toxicoinfection. Clinical reports have shown that botulism occurs in livestock and some outbreaks can be associated with feedstuff containing animal carcasses (Bienvenu et al., 1990; Kinde et al., 1991; Braun et al., 2005; Otter et al., 2006). Type D botulism has been identified in cattle fed chicken litter, type C has been associated with ensiled chicken litter, and type B has been associated with forages (Long and Tauscher, 2006).

Mechanism of Action

BoNT, after uptake, undergoes biotransformation within the neuron and subsequently binds with synaptic vesicular proteins and blocks the release of acetylcholine from the presynaptic membrane (Osborne et al., 2007). Clinical signs of botulism are weakness, tremors, recumbency, laryngeal paresis, and other signs of nervous system dysfunction (Braun et al., 2005). Botulism toxins do not appear to be excreted in milk (Galey et al., 2000).

Potential Production and Use

Botulism toxins can be produced and incorporated into ingredients used in feedstuffs. The use of dead rodents or other animals can serve as a substrate for *C. botulinum*, providing anaerobic conditions exist (Galey et al., 2000). Contamination of feedstuffs, especially silage, with the carcasses of dead mice or other small animals could be a method of producing and disseminating botulism toxins. There is some evidence that insect larva take-up BoNT and are unaffected. Insect larvae in carrion contain BoNT (Hubalek and Halouzka, 1991). The growth and use of insect larvae for use in animal and poultry feeds could be a terror tactic for botulism. For further details on toxicity of botulism toxins, readers are referred to Chapter 28.

PLANT TOXINS

Background

Poisonous plants and their seeds could be used to adulterate feedstuffs (Keremidis et al., 2013). Seeds of poisonous plants have been incorporated into animal rations and have resulted in animal intoxication (Burrows and Tyrl, 2001). For example, grain screenings that contain high levels of toxic plant seeds could be distributed as potential feed ingredients. Toxic seeds can be directly introduced into animal rations.

Castor Beans (Ricin)

Background

Castor beans (*Ricinus communis* L.) are grown commercially for castor oil, which is sought-after for cosmetics, coatings, industrial, and automotive applications (Millard and LeClaire, 2008). There is interest in its use in biodiesel. There is approximately 1 tonne of residual cake produced for every 0.5–0.6 tonne of oil produced. Castor bean cake is sold as fertilizer, soil enhancers, and other uses; in some countries, it is used as a feed supplement. The castor bean contains a cocktail of toxins (Worbs et al., 2011). Ricin, a potent toxin in castor bean, is water-soluble and is easy to extract from castor bean meal. Ricin is soluble in water over a wide range of pH values. The ricin content of castor bean varies with the growing conditions and genetics of the plant (Millard and LeClaire, 2008; Worbs et al., 2011). A general guide is 1–2 mg of ricin per gram of ground castor seed, and levels can be as high as 20 mg of ricin per gram of seeds. Ricin can be 5% of the total protein in castor beans and is present in the waste mash after the oil has been extracted. The ricin content of the waste mash generally is 1–10% (w/w). Ricin should be considered relatively heat-stable at temperatures used for food processing (Audi et al., 2005; Jackson and Halbert, 2006). The seed husks of *R. communis* are also poisonous and the recognized tolerable level is 10 mg of seed husks per kilogram of feed, and a fatal dose in cattle is estimated

to be 0.5 mg/kg body mass (Alexander et al., 2008). The ricinine piperidine alkaloid, a toxin of lesser potency, is found in all parts of the castor plant and is heat-stable. Ricinine stimulates the central nervous system.

Ricin as a Weapon

Ricin has been used to commit murder and kill animals. It captures the interest of both terrorist organizations and those involved in protecting populations from terrorists. It is available in tonne quantities by using inexpensive technologies to extract it in crude form from castor seed meal, a by-product that has a low sale value (Shea and Gottron, 2013).

Toxicity and Mechanism of Action

The seed coat of the castor bean needs to be fractured for the ricin to be released (Burrows and Tyrl, 2001). Ricin in waste mash is biologically available. Most animal species including birds are sensitive to castor bean poisoning (Jensen and Allen, 1981; Mouser et al., 2007). The degree of toxicity depends on the dose (number of seeds) ingested and liberation of ricin by degradation of the seed coat by some form of mastication. The liberated ricin is absorbed from the gastrointestinal tract. The estimated lethal dose of castor bean seeds by species is given in Table 53.1; however, it is likely that the lethal dose for some species is lower than the doses found in the literature. Ruminants are considered to be more resistant to ricin (Alexander et al., 2008) than are horses and dogs. The most likely reason is degradation of ricin by microbes in the rumen. This phenomenon also suggests that the dose in neonatal ruminants would likely be substantially lower than for mature ruminants.

Ricin is a lectin-type globular glycoprotein and has A and B chains (Doan, 2004; Audi et al., 2005). Ricin is considered a type 2 ribosome-inactivating protein (RIP). The ricin B chain attaches to the surface of the plasma membrane at the galactose-containing glycoproteins, pits are formed, and ricin is internalized by endocytosis and forms an intracellular vesicle. The vesicles containing ricin coalesce and form endosomes. The cellular uptake of ricin is a slow process and this can explain the lag time between exposure and onset of clinical signs. The internalized ricin can dissociate from the endosomes and can be transported to lysosomes for degradation or the vesicles can be removed from the cell by exocytosis. Ricin can bleb off the endosome and return to the cell surface by vesicular and tubular structures, or it is transported to the Golgi apparatus. In the Golgi apparatus, the A chain undergoes retrograde transport to the endoplasmic reticulum (Audi et al., 2005). Cleavage of the A and B chains occurs in the endoplasmic reticulum. From the endoplasmic reticulum, the ricin A chain is translocated to the cytosol. Here, the ricin A chain catalytically inactivates ribosomes. The A chain is an enzymic polypeptide that catalyzes the N-glycosidic cleavage of adenine from 28S rRNA loupe in the 60S ribosomal subunit. The removal of adenine from 28S rRNA in the ribosome destroys its

TABLE 53.1 Sensitivity of Different Species to Castor Bean Intoxication[a]

Species	Lethal Castor Bean Mass per kg of Body Mass (mg Ricin/kg Body Mass)	Comment
Horse	7–240 mg (7 mg)	Considered the most sensitive species.
Human	225 mg (20)	Dose altered by the degree of mastication.
Duck	0.7–1.2 g	1/8 duck died at 16 days after treatment. Grinding of the seeds by the proventriculus can be a variable in toxicity.
Chicken	10–14 g	Grinding of the seeds by the proventriculus can be a variable in toxicity and values could be considerably lower for macerated seeds.
Geese	400 mg	Grinding of the seeds by the proventriculus can be variable in toxicity.
Rabbit	1.2 g	Mastication considered to be required.
Pig	1.2 g	Mastication is required. 0.5 g husks per kg body mass is also fatal.
Goat	5 g	Age of ruminant can be a factor as the rumen may inactivate ricin. Inactivation by the rumen and mastication of seeds are factors in toxicity.
Sheep	1–2 g	Age of ruminant can be a factor as the rumen may inactivate ricin. 1.4–2.8 mg ricin containing cake fed for 8 months and caused intestinal pathology.
Cattle	1–2 g	Age of ruminant can be a factor as the rumen likely inactivates ricin. Considered to be more resistant to intoxication than sheep.

Source: Burrows and Tyrl (2001).

[a]*It is likely that the lethal dose for some species is lower than the doses found in the literature.*

functionality and thereby blocks protein synthesis. One A chain can enzymatically inactivate 1,500 ribosomes/min. Using other mechanisms, ricin causes the release of inflammatory mediators. Ricinine is a central nervous system stimulant and is theorized to inhibit the postsynaptic ϒ-aminobutyric acid receptor subtype A and to alter the release of glutamate.

Analytical Methods

Analytical methods used to identify ricin include immune methods (ELISA) and liquid chromatography/mass spectrometry (LC/MS). Gastric contents can be assayed and ricin can be detected in blood and body fluids by radioimmunoassay and LC/MS (Darby et al., 2001; Mouser et al., 2007). Ricinine levels can be assayed in serum and urine using LC/MS (Røen et al., 2013). Polymerase chain reaction methods are available to detect the DNA in castor beans.

Clinical and Pathological Findings

Clinical signs of ricin intoxication are high morbidity, abdominal pain, emesis, diarrhea, and lethargy. Hematemesis and melena may be observed. Clinicopathology includes elevated hepatic enzymes in serum, hyperphosphatemia, and sometimes hypoglycemia. Electrolyte imbalance can occur because of diarrhea and emesis. Pathological findings in a dog were hepatocellular necrosis, fibrosis of central veins and sinusoids, and lymphocytic infiltrate (Mouser et al., 2007). Jejunal mucosa can be eroded and infiltrated with leukocytes, and the tunica muscularis can also be affected. Hemorrhage can be observed in the mucosal and muscular layers. Necrosis can be seen in the spleen. Renal pathology has also been reported.

Other Plant Source Type 2 RIPs

Abrin is a plant source type 2 RIP. It is found in *Abrus precatorius* (rosary pea, Indian licorice, jequirity bean). The toxicology of abrin is considered to be very similar to ricin. A similar *Abrus* toxin is pulchellin, produced by *Abrus pulchellus* (Millard and LeClaire, 2008). The rosary pea has been reported to be more toxic than castor beans (Griffiths et al., 1994). Like castor beans, the rosary pea must be masticated to release the toxins (Burrows and Tyrl, 2001). Species sensitivity is variable and horses are considered to be the most sensitive. The mature goat is considered to be a more resistant species, and seed in the form of 2 g/kg body weight is reported as a lethal dose. The reported lethal dose of seeds for the horse is approximately 100 mg/kg body mass and for cattle it is reported to be 600 mg/kg body weight. It is likely that abrin is denatured in the rumen.

There is limited commercial production of the jequirity bean. The rosary pea is grown as an ornamental plant and has escaped into the wild in the warmer climate in the United States. *Abrus* sp. is not grown as an oilseed or for other large-scale commercial use.

For further details about ricin and abrin, readers are referred to Chapter 27.

RAPIDLY ACTING AND EASILY AVAILABLE SUBSTANCES

Cyanide

Cyanide (CN^-) is considered a terrorist weapon (Cameron and Pate, 2001; Ballantyne and Salem, 2008; Wismer, 2012). Cyanide has a history of use in controlling problem wildlife and unwanted feral animals, and it has alleged use as an agricultural terror agent in livestock drinking water (Wiemeyer et al., 1986; Cameron and Pate, 2001). Two common forms of cyanide salts are sodium cyanide and potassium cyanide. Cyanide can be used to adulterate feedstuffs and water.

Mechanism of Action

The toxicology of CN^- is complex (Ballantyne and Salem, 2008; Wismer, 2012). The lethal effect of cyanide is blockage of cytochrome C oxidase, which results in loss of electron transfer, and molecular oxygen is not utilized. In addition to cytochrome C, other cytochromes are adversely affected by forming complexes with the cytochrome iron. The oxidized cytochrome–CN complexes are stable, but the complex is relatively unstable in a reductive environment. The instability of the cytochrome–CN^- complex in a reductive environment is the focus of the majority of treatment regimes.

Plant Sources—Ruminants

Certain plants contain cyanogenic glycosides (Nicholson, 2012). Cyanogenic plants and trees are common in some geographical regions; for local criminal action, these could be placed in pastures. Plant parts containing cyanogenic glycosides, precursors that form hydrogen cyanide (HCN) in the rumen, could be placed in ruminant rations. Birds can be poisoned by consuming seeds and berries from cyanogenic plants (Woldemeskel and Styer, 2010).

Treatment of Cyanide Poisoning

Treatment of cyanide poisoning has been discussed in detail by Wismer (2012) and Nicholson (2012), and in Chapter 23.

Insecticides

Large numbers of cattle and other domestic livestock have been contaminated and poisoned with insecticides that were inadvertently incorporated and incorporated

by criminal intent into feedstuffs (Neher, 1999; Guitart et al., 2010). Coordinated effort is required to diagnose, contain, and eliminate insecticide poisoned and contaminated animals from the food web. There have been instances in which the same transport vessels have been used to transport/store insecticides, seeding crops, and silage, resulting in cross-contamination. Terrorists, to adulterate animal feedstuffs, could use insecticides. The use of insecticides that are persistent organic compounds (POCs) for terror actions may also present a residue problem in the surviving animals. The toxicology and treatment of insecticides have been discussed in detail by Gupta (2006, 2012).

PERSISTENT ORGANIC COMPOUNDS

Background

POCs, also known as POPs, could be candidates for a terrorist attack on livestock. Most POCs are biomagnified in the food web. The economic and political impact from their use in a terrorist attack would likely be huge based on the impacts from reported inadvertent contaminations of feedstuffs and feed ingredients. The majority of the POCs are bioconcentrated in body lipids. Most of these compounds require high doses to cause acute illness in livestock, poultry, and fish. At low doses the resultant illness is generally less evident, and there are residues in edible animal products and rendered products used in animal feedstuffs. The occurrences of POCs contaminating feedstuffs and feed ingredients are underappreciated (Kim et al., 2007). The lack of specific clinical signs and lesions increases the risk of elusive diagnosis, animals passing slaughter inspections, and their products being consumed by humans (Carter, 1976; Fries, 1985; Hayward et al., 1999; Bernard et al., 2002; Dorea, 2006). For the POCs, the safety of foodstuffs and feedstuffs are reliant on chemical analyses (Kim et al., 2007). The occurrences of POCs being relayed from contaminated food-producing animals and from animal-source foods to humans are known (Kay, 1977; Reich, 1983; Fries, 1985; Bernard et al., 2002; Huwe and Smith, 2005; Dorea, 2006; Kim et al., 2007). A historical incident occurred in Michigan when a flame retardant consisting of polybrominated biphenyls (PBBs) was mixed into livestock feeds (Carter, 1976; Reich, 1983). The flame retardant was manufactured for use in thermoplastics and was shipped to the feed manufacturer in place of magnesium oxide. Environmental sources of POCs are also important in the agroecosystem (Stevens and Gerbec, 1988). Ball clay contaminated with polychlorinated dibenzodioxins (PCDDs) and dibenzofurans (PCDFs) in animal mineral mixes and other incidents clearly show that these events can occur over a substantial period of time before low-level contamination is recognized and foodstuffs and feedstuffs are protected (Reich, 1983; Bernard et al., 2002; Kim et al., 2007). Proactive analytical surveillance for POPs requires substantial resources consisting of highly trained personnel, sophisticated laboratory procedures, and infrastructure to meet laboratory safety requirements. The analytical and personnel support for investigations into POCs contaminating livestock feedstuffs can challenge budgets, and there can be bureaucratic pressure to restrict or delay investigations because of budgetary targets and political approvals (Reich, 1983; Bernard et al., 2002). Some of the highest levels of POPs in consumed foodstuffs have occurred because of feedstuffs being contaminated. The health impacts of POPs in the human diet are likely underappreciated and there is evidence to show the effects can be multigenerational (Blanck et al., 2000).

Potential Economics of Terror Attack Using POCs

The history of incidents clearly shows that feedstuffs contaminated with POCs have caused remarkable economic loss (Reich, 1983; Bernard et al., 2002). Most POCs are biomagnified in the food web. If feedstuffs have a wide distribution, then the measurable economic impacts can be immense. For example, with the ball clay incident from two soybean meal manufactures, it was estimated that 1.7 million eggs per day (at that time approximately 1% of the US egg production) and 35% of the farm-reared catfish were contaminated with PCDDs/DFs (Hayward et al., 1999). These animal-source foodstuffs, contaminated with PCDDs/DFs, were consumed by humans (Fiedler et al., 1997; Rappe et al., 1998). Michigan suffered one the largest animal feed contamination incidents in the history of the United States. Feedstuffs were contaminated with PBBs and more than 500 farms were under quarantine (Carter, 1976). More than 865 tons of feedstuffs, 29,800 head of cattle, 5,920 hogs, 1,470 sheep, 1.5 million chickens, 34,500 kg dairy products, and 5 million eggs were destroyed (Carter, 1976). The total cost was estimated in 1983 currency value at more than $215 million (Reich, 1983). In the United States, more than 400 upright silos were coated with a polychlorinated biphenyl (PCB) containing resin and livestock and their edible products were contaminated with PCBs (Willett et al., 1987). In Belgium, a tank of animal fat (animal feed ingredient) feed was contaminated in January 1999 with a PCB (congener closely matched Aroclor 1260/1254) containing PCDDs/DFs and caused an unprecedented feed and food crisis (Lok and Powell, 2000; Bernard et al., 2002). It is estimated that 150 kg of PCBs with PCDDS/DFs contaminated the recycled animal fat. Nine feed manufactures used the contaminated oil to formulate poultry and livestock feeds. There was a considerable lag time

for the government to deal with this issue inclusive of political elections. Several countries banned imports of animal source foodstuffs and products containing animal source ingredients. Estimates losses from this disaster are US $1.5 billion (Lok and Powell, 2000).

Human Exposures

Human populations have been exposed to POPs by consuming contaminated animal-source foodstuffs. The health effects from exposure of the human population to POPs are likely underappreciated. The POPs are passed *in utero* from mother to fetus and postnatally to the neonate via breast milk. There is some evidence that adverse multigenerational effects occur (Blanck et al., 2000). The timing of exposure in life stages, from embryo to senility, can be important in the expression of adverse effects.

HEAVY METALS AND METALLOIDS

Heavy metals and metalloids have been used to maliciously poison livestock.

Lead

Lead is readily available in the form of spent lead acid batteries and shotgun shot. Because lead has been removed from paint, incidents with lead-acid batteries, gunshot, and environmental sources account for the majority of cattle poisonings in North America. Lead is excreted in milk, deposited in bones, liver, and kidney, and is considered a food safety issue (Bischoff et al. 2014; Coppock et al., 1991). Lead poisoning is likely underdiagnosed and can be confused with thiamin-responsive polioencephalomalacia in cattle. The favorable clinical response to thiamine therapy could result in failure to diagnose plumbism. When clinical signs of lead poisoning are observed, appropriate specimens should be taken and submitted to the laboratory for lead analyses.

Lead in Feedstuffs

A small amount of lead can poison a large number of livestock. Lead is solubilized by silage fluids and migrates in the liquid phase of silage (Coppock et al., 1988; Galey et al., 1990; Bischoff et al., 2014). Lead shot could be maliciously added to livestock feedstuffs.

Treatment of Lead Poisoning

Lead poisoning is responsive to thiamine and chelation therapy (Coppock et al., 1991).

Arsenic

Arsenic is used to maliciously poison livestock. Arsenic is readily available and can be mixed with feedstuffs and water. Arsenic can be present in production water from oil and gas field activities. Arsenic can be used for crimes of revenge. In acute arsenic poisoning, survival is generally low.

Toxicology

Readers are referred to other books for discussions of the toxicology of heavy metals (Gupta, 2012); and chapter 15 in this book.

CONTAMINATED TRANSPORT VESSELS

Historically, occurrences of feedstuffs becoming contaminated in transport vessels were primarily because of the failure to clean the vessels after use. Failure to clean transport vessels or leaving substances to be commingled with animal feedstuffs could be an act of terrorism or criminal action that could cause significant contamination of animal feed ingredients that could have broad dissemination in animal feedstuffs and contaminate human foods.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The agro-ecosystem is essentially unprotected and vulnerable to terrorist criminal activity using chemical substances. Emphasis has been placed on identification of infectious agents as the cause of disease in livestock and poultry. Few intoxicating substances produce pathognomonic signs, clinicopathologic profiles, and lesions. A holistic approach is required for prompt identification of the cause of disease in livestock and prompt identification of the etiology of animal disease is dependent on a full-service diagnostic laboratory infrastructure. Farm gate biosecurity protocols are becoming more common, but the majority of these programs do not include protection of the agroecosystem from chemical threats. The use of chemicals that are acutely toxic can kill a large number of livestock. When sick and dead livestock have been observed, actions are taken to divert the animals from the food web. Animals poisoned with chemicals that cause less overt and subtle signs of intoxication can enter the human food web. Most of the POCs are biomagnified in the food web and generally cause chronic toxicity. Review of published incidents shows that considerable time is generally required for the etiology of chronic intoxication with POCs to be identified. During this interval, animal products have passed inspections and entered the human food web, and animal by-products have been incorporated into animal and poultry feeds. Economic losses occurring from POPs

contaminating livestock feedstuffs, when they occur, are generally huge. The impact of POPs on human health is likely underappreciated and there is mounting evidence these effects can be multigenerational. The load demand on laboratories and personnel can be substantial when widespread contamination of feedstuffs/foodstuffs has occurred and the toxic substance is known. There is a neglected need to include the use of chemicals as terror agents in infrastructure development and response protocols. Clever use of chemical mixtures for a terrorist attack on food could delay identification of the etiology and reproducing the syndrome; melamine–cyanuric acid in pet foods is a good example. A delay in definitively defining the syndrome would help the terrorists to achieve their objective of maximizing psychological, sociological, economic, and political impacts by preventing governments and corporations from ensuring the public that food is safe.

CHAPTER

54

Chemical Warfare Agents and Risks to Animal Health

Tina Wismer

INTRODUCTION

Animals are susceptible to all four basic types of military agents: choking (such as chlorine gas and phosgene), blister (such as mustard, lewisite, and phosgene oxime), blood [such as cyanide and hydrogen cyanide (HCN)], and nerve agents [such as tabun, sarin, soman, and *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX)]. They can also be affected by incapacitating agents such as 3-quinuclidinyl benzylate (BZ), riot control agents (RCAs), ricin, and abrin. Since chemical warfare agents (CWAs) can be deployed by a variety of inexact methods (including bombs, spray tanks, rockets, missiles, land mines, and artillery projectiles), domestic and wild animals living in proximity to human populations can be affected (USACHPPM, 2001a). Americans own 83.3 million dogs and 95.6 million cats and more than 62% of American households own at least one pet (American Pet Products Association, 2013–2014). Due to the expansion of suburbia, human–wildlife interactions are also increasing. Livestock are very important potential targets of attack as they have secondary ramifications for human health and disruption of the food chain.

The Centers for Disease Control and Prevention (CDC) Strategic Planning Working Group, as part of their preparedness plan for possible terrorist attacks using biological or chemical weapons, has called for "prompt diagnosis of unusual or suspicious health problems in animals" (Anonymous, 2000a). The CDC recommended establishing "criteria for investigation and evaluation of suspicious clusters of human and animal disease or injury and triggers for notifying law enforcement of suspected acts of chemical terrorism." With many of the military agents, there are few initial indicators of a chemical attack. It has been proposed that animals could serve as sentinels for chemical terrorism. These animals would be similar to the canaries used by coal miners in the United Kingdom and the United States to provide early warning of deadly mine gases.

Throughout history, it has been noted that during chemical warfare attacks, animals may also be affected. A newspaper article from World War I gives details of the effects on animals during an unspecified type of gas attack (Anonymous, 1918):

> Results show that horses suffer much from the noxious fumes, and are subsequently thrown into a state of nervous terror on again scenting them. Mules are more inclined to stand their ground, and appear as if trying not to breathe … cats quickly scent the gas, and run about howling. Guinea pigs are first to succumb … Rats and mice emerge from their holds, and are found dead in quantities, which as the soldiers say, is the only advantage of a gas attack by the enemy.

The same account discusses how much these animals meant to the soldiers, as they even managed to fashion gas masks for several of these species to protect them during gas attacks (Anonymous, 1918). The soldiers believed that different species of animals may have been more sensitive to certain types of gas attacks than humans:

> … Poultry of all kinds are useful for giving warning, ducks and fowl becoming agitated 10 min or so before the oncoming gas clouds. Many kinds of wild birds are greatly excited, and the usually unruffled owl becomes, as it were, half demented. Only the sparrow seems to disregard the poisonous vapor, and sparrows chirp on where horses are asphyxiated, and bees, butterflies, caterpillars, ants and beetles die off in great numbers. The gas at once kills snakes, and earthworms are found dead in their holes many inches below the ground.
