SECOND EDITION

HANDBOOK OF TOXICOLOGY OF CHEMICAL WARFARE AGENTS

EDITED BY

RAMESH C. GUPTA

HANDBOOK OF TOXICOLOGY OF CHEMICAL WARFARE AGENTS

THE UNCERTAINTY OF THE DANGER BELONGS TO THE ESSENCE OF TERRORISM

Jürgen Habermas (1929–Present)

HANDBOOK OF TOXICOLOGY OF CHEMICAL WARFARE AGENTS

SECOND EDITION

Edited by

Ramesh C. Gupta, DVM, MVSc, PhD, DABT, FACT, FACN, FATS

Professor and Head, Toxicology Department
Breathitt Veterinary Center
Murray Sate University
Hopkinsville, Kentucky
USA

Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Contents

List of Contributors **xi**

I
INTRODUCTION, HISTORICAL PERSPECTIVE, AND EPIDEMIOLOGY

1. Introduction 3
   RAMESH C. GUPTA

2. Historical Perspective of Chemical Warfare Agents 7
   NATHAN H. JOHNSON, JOSEPH C. LARSEN AND EDWARD MEEK

3. Global Impact of Chemical Warfare Agents Used Before and After 1945 17
   JIRI BAJGAR, JOSEF FUSEK, JIRI KASSA, KAMIL KUCA AND DANIEL JUN

4. The Tokyo Subway Sarin Attack: Acute and Delayed Health Effects in Survivors 27
   TETSU OKUMURA, KENJI TAKI, KOUICHIRO SUZUKI, TAKEMI YOSHIDA, YUKIO KUROIWA AND TETSUO SATOH

5. Early and Delayed Effects of Sulfur Mustard in Iranian Veterans After the Iraq–Iran Conflict 37
   MAHDI BALALI-MOOD

6. Epidemiology of Chemical Warfare Agents 47
   LINDA A. MCCAULEY

7. Chemical Weapons of Mass Destruction and Terrorism: A Threat Analysis 55
   RENÉ PITA AND ARTURO ANADÓN

II
AGENTS THAT CAN BE USED AS WEAPONS OF MASS DESTRUCTION

8. Mustards and Vesicants 69
   ROBERT A. YOUNG AND CHERYL B. BAST

9. Organophosphate Nerve Agents 87
   ANNETTA WATSON, DENNIS OPRESKO, ROBERT A. YOUNG, VERONIQUE HAUSCHILD, JOSEPH KING AND KULBIR BAKSHI

10. Russian VX 111
    VLADIMIR REMBOVSKIY, ANDREY RADILOV, ELENA SAVELIEVA, SERGEY KUZNETSOV, IGOR MINDUKSHEV, DARIA PROKOFIEVA, NADEZHDA KRIVOROTOVA, NATALIA KHLEBNIKOVA, RICHARD O. JENKINS AND NIKOLAY GONCHAROV

11. Riot Control Agents 131
    COREY J. HILMAS

12. Psychotomimetic Agent BZ (3-Quinuclidinyl Benzilate) 151
    JOSEF FUSEK, JIRI BAJGAR, JIRI KASSA, KAMIL KUCA AND DANIEL JUN

13. Neurological Effects and Mechanisms of Blast Overpressure Injury 159
    DOROTHY L. DOBBINS AND XIAOPING PAN

14. Thallium 167
    LARRY J. THOMPSON

15. Arsenicals: Toxicity, Their Use as Chemical Warfare Agents, and Possible Remedial Measures 171
    SWARAN J.S. FLORA

16. Fluoroacetate 193
    NIKOLAY GONCHAROV, ELENA SAVELIEVA, VALERIY ZINCHENKO, SERGEY KUZNETSOV, IGOR MINDUKSHEV, MAXIM VINOKUROV, PAVEL AVDONIN, NATALIA VOITENKO, ANTON UKOLOV, TATIANA ORLOVA, RICHARD O. JENKINS AND ANATOLIY KUZNETSOV

17. Strychnine 215
    JIRI PATOCKA

18. Superwarfarins 223
    MICHAEL J. MURPHY AND ANDRES M. LUGO

19. PCBs, Dioxins and Furans: Human Exposure and Health Effects 239
    BOMMANNA G. LOGANATHAN AND SHIGEKI MASUNAGA

20. Polycyclic Aromatic Hydrocarbons: Implications for Developmental, Molecular, and Behavioral Neurotoxicity 249
CLAIRE E. BOLLINGER, MONIQUE MCCALLISTER, RYAN CLARK, RAINA RHOADES, MARK MAGUIRE, RUSSELL E. SAVAGE, YUQIN JIAO, ARAMANDLA RAMESH AND DARRYL B. HOOD

21. Carbon Monoxide: From Public Health Risk to Painless Killer 267
DAYA R. VARMA, SHREE MULAY AND SYLVAIN CHEMTOB

22. Methyl Isocyanate: The Bhopal Gas 287
DAYA R. VARMA AND SHREE MULAY

23. Cyanide Toxicity and its Treatment 301
RAHUL BHATTACHARYA AND SWARAN J.S. FLORA

24. Chlorine 315
SYLVIA MILANEZ

25. Phosgene 327
CHERYL B. BAST AND DANA F. GLASS-MATTIE

26. Other Toxic Chemicals as Potential Chemical Warfare Agents 337
JIRI BAJGAR, JIRI KASSA, JOSEF FUSEK, KAMIL KUCA AND DANIEL JUN

27. Ricin 347
RUSSELL DORSEY, GEORGE EMMETT AND HARRY SALEM

28. Botulinum Toxin 361
JAIME ANDERSON AND COREY J. HILMAS

29. Anthrax 387
COREY J. HILMAS AND JAIME ANDERSON

30. Onchidal and Fasciculins 411
ARTURO ANADÓN, MARIA ROSA MARTÍNEZ-LARRAÑAGA AND LUIS G. VALERIO JR.

31. Cyanobacterial (Blue-Green Algae) Toxins 421
DEON VAN DER MERWE

32. Radiation and Health Effects 431
KAUSIK RAY AND MELISSA STICK

33. Depleted Uranium 447
GEORGE C-T JIANG AND MICHAEL ASCHNER

III
TARGET ORGAN TOXICITY

34. Chemical Warfare Agents and the Nervous System 463
JING LIU, CHIBUZOR UCHEA, LINNZI WRIGHT AND CAREY POPE

35. Behavioral Toxicity of Nerve Agents 477
JIRI KASSA, JIRI BAJGAR, KAMIL KUCA AND DANIEL JUN

36. The Respiratory Toxicity of Chemical Warfare Agents 489
ALFRED M. SCIUTO AND URMILA P. KODAVANTI

37. Cardiovascular System as a Target of Chemical Warfare Agents 519
CSABA K. ZOLTANI

38. Ocular Toxicity of Chemical Warfare Agents 535
PATRICK M. MCNUTT AND TRACEY L. HAMILTON

39. Dermal Toxicity of Sulfur Mustard 557
JOSHUA P. GRAY, MICHAEL P. SHAKARJIAN, DONALD R. GERECKE AND ROBERT P. CASILLAS

40. Skeletal Muscle 577
RAMESH C. GUPTA, SNJEZANA ZAJA-MILATOVIC, WOLF-D. DETTBARN AND JITENDRA K. MALIK

41. Reproductive Toxicity and Endocrine Disruption of Potential Chemical Warfare Agents 599
TIMOTHY J. EVANS

42. Liver Toxicity of Chemical Warfare Agents 615
SHASHI K. RAMAIAH AND ATRAYEE BANERJEE

43. Renal System 627
SHARON M. GWALTNEY-BRANT

44. The Immune System as a Target for Chemical Warfare Agents 639
KAVITA GULATI AND ARUNABHA RAY

45. Alternative Animal Toxicity Testing of Chemical Warfare Agents 657
GOPALA KRISHNA AND SARYU GOEL

IV

SPECIAL TOPICS

46. Genomics and Proteomics in Brain Complexity in Relation to Chemically Induced PTSD 677
BEENA M. KADAKKUZHA, XIN-AN LIU AND VALERIO RIZZO

47. Clinical and Cellular Aspects of Traumatic Brain Injury 691
JASON PITT AND YIUKA LEUNG

48. Excitotoxicity, Oxidative Stress, and Neuronal Injury 709
SNJEZANA ZAJA-MILATOVIC AND RAMESH C. GUPTA

49. Blood–Brain Barrier Damage and Dysfunction by Chemical Toxicity 725
RAMESH C. GUPTA, JASON PITT AND SNJEZANA ZAJA-MILATOVIC

50. Neuropathologic Effects of Chemical Warfare Agents 741
RANDALL L. WOLTJER

51. The Effects of Organophosphates in the Early Stages of Human Muscle Regeneration 751
TOMAZ MARS, KATARINA MIS, SERGEJ PIRKMAJER, MAJA KATALINIC AND ZORAN GRUBIC

52. Cholinesterase Inhibitors: From Molecular Mechanisms of Action to Current and Future Prospects 761
NIR WAISKOPF AND HERMONA SOREQ

V

RISKS TO ANIMALS AND WILDLIFE

53. Potential Agents That Can Cause Contamination of Animal Feedstuffs and Terror 781
ROBERT W. COPPOCK AND MARGITTA DZIWENKA

54. Chemical Warfare Agents and Risks to Animal Health 791
TINA WISMER

55. Threats to Wildlife by Chemical and Warfare Agents 809
ROBERT W. COPPOCK AND MARGITTA DZIWENKA

VI

TOXICOKINETICS, TOXICODYNAMICS AND PHYSIOLOGICALLY-BASED PHARMACOKINETICS

56. Toxicokinetic Aspects of Nerve Agents and Vesicants 817
HARALD JOHN, FRANK BALSZUWEIT, KAI KEHE, FRANZ WOREK AND HORST THIERMANN

57. Toxicokinetics and Toxicodynamics of DFP 857
MIGUEL SOGORB, JORGE ESTEVEZ AND EUGENIO VILANOVA

58. Physiologically Based Pharmacokinetic Modeling of Chemical Warfare Agents 875
JEFFERY M. GEARHART, PETER J. ROBINSON AND EDWARD M. JAKUBOWSKI

59. Biotransformation of Warfare Nerve Agents 883
MILAN JOKANOVIĆ

VII

ANALYTICAL METHODS, BIOSENSORS AND BIOMARKERS

60. On-Site Detection of Chemical Warfare Agents 897
YASUO SETO

61. Laboratory Analysis of Chemical Warfare Agents, Adducts, and Metabolites in Biomedical Samples 915
M.J. VAN DER SCHANS

62. Biosensors for the Detection of OP Nerve Agents 925
JUN-ICHI ANZAI

63. Neuropathy Target Esterase as a Biomarker and Biosensor of Delayed Neuropathic Agents 935
RUDY J. RICHARDSON, R. MARK WORDEN, SANJEEVA J. WIJEYESAKERE, NICHOLE D. HEIN, JOHN K. FINK AND GALINA F. MAKHAEVA

64. Biomarkers of Exposure to Organophosphorus Poisons: A New Motif for Covalent Binding to Tyrosine in Proteins That Have No Active Site Serine 953
OKSANA LOCKRIDGE, LAWRENCE M. SCHOPFER AND PATRICK MASSON

65. Monitoring of Blood Cholinesterase Activity in Workers Exposed to Nerve Agents 967
DANIEL JUN, JIRI BAJGAR, KAMIL KUCA AND JIRI KASSA

VIII
PROPHYLACTIC, THERAPEUTIC AND COUNTERMEASURES

66. Pharmacological Prophylaxis Against Nerve Agent Poisoning: Experimental Studies and Practical Implications 979
JIRI BAJGAR, JOSEF FUSEK, JIRI KASSA, KAMIL KUCA AND DANIEL JUN

67. Prophylactic and Therapeutic Measures in Nerve Agents Poisoning 989
TROND MYHRER AND AAS PÅL

68. Medical Management of Chemical Toxicity in Pediatrics 1003
ELORA HILMAS AND COREY J. HILMAS

69. Physiologically Based Pharmacokinetic/Pharmacodynamic Modeling of Countermeasures to Nerve Agents 1035
ELAINE MERRILL, CHRIS RUARK, JEFFERY GEARHART AND PETER J. ROBINSON

70. Strategies to Enhance Medical Countermeasures After the Use of Chemical Warfare Agents on Civilians 1049
DAVID A. JETT AND DAVID T. YEUNG

71. Pyridinium Oximes in the Treatment of Poisoning with Organophosphorus Compounds 1057
MILAN JOKANOVIĆ

72. Novel Cholinesterase Reactivators 1071
KAMIL MUSILEK, JAN KORABECNY, DANIEL JUN, JIRI KASSA AND KAMIL KUCA

73. Paraoxonase (PON1) and Detoxication of Nerve Agents 1089
LUCIO G. COSTA, TOBY B. COLE AND CLEMENT E. FURLONG

74. The Role of Carboxylesterases in Therapeutic Intervention of Nerve Gases Poisoning 1099
SIGRUN HANNE STERRI AND FRODE FONNUM

75. Catalytic Bioscavengers: The New Generation of Bioscavenger-Based Medical Countermeasures 1107
PATRICK MASSON

IX
DECONTAMINATION AND DETOXIFICATION

76. Rapid Decontamination of Chemical Warfare Agents from the Skin 1127
EDWARD D. CLARKSON AND RICHARD K. GORDON

Index 1141

CHAPTER

1

Introduction

Ramesh C. Gupta

For centuries, extremely toxic chemicals have been used in wars, conflicts, terrorist and extremist activities, malicious poisonings, and executions. Natural toxins from plants or animals were one of the earliest forms of chemical warfare agents (CWAs). These were used to coat arrowheads and were commonly referred to as "arrow poisons." Ancient use of some CWAs and riot control agents (RCAs) dates back to the fifth century BC, during the Peloponnesian War, when the Spartans used smoke from burning coal, sulfur, and pitch to temporarily incapacitate and confuse occupants of Athenian strongholds. The Spartans also used bombs made of sulfur and pitch to overcome the enemy. The Romans used irritant clouds to drive out adversaries from hidden dwellings. In the fifteenth century, Leonardo da Vinci proposed the use of an arsenic sulfide powder as a chemical weapon. Modern use of CWAs and RCAs or incapacitating agents dates back to World War I (WWI).

With advancements in science and chemistry in the 19th century, the possibility of chemical warfare increased tremendously. The first full-scale use of CWAs began in April 1915, when German troops launched a poison gas attack in Ypres, Belgium, using 168 tons of chlorine gas, killing approximately 5000 Allied (British, French, and Canadian) soldiers. During WWI, the deployment of CWAs, including toxic gases (chlorine, phosgene, cyanide, and mustard), irritants, and vesicants in massive quantities (approximately 125,000 tons), resulted in approximately 90,000 fatalities and 1.3 million nonfatal casualties. The majority of deaths during WWI were a result of exposure to chlorine and phosgene gases. During the Holocaust, the Nazis used carbon monoxide and the insecticide Zyklon-B, which contains hydrogen cyanide, to kill several million people in extermination camps. Poison gases were also used during the Warsaw Ghetto Uprising in 1943. In November 1978, religious cult leader Jim Jones murdered more than 900 men, women, and children with cyanide.

Before, during, and after World War II, anticholinesterase organophosphate (OP) nerve agents/gases were developed in Germany, the United States, the United Kingdom, and Russia. They were also produced in large volumes in many other countries. During the "Cold War" period, they were maximally produced and stockpiled. These nerve agents have been used in wars and by dictators, extremists, cult leaders, and terrorist groups as chemical weapons of mass destruction (CWMD) on many occasions. In 1980, Iraq attacked Iran using mustard gas and OP nerve gas. During the period of the Iraq and Iran conflict (1980–1988), Iran sustained 387 attacks and more than 100,000 troops were victims, as were a significant number of civilians. Thousands of victims still suffer from long-term health effects. Soon after the end of the Iraq–Iran war in 1988, the brutal dictator of the Iraqi regime, Saddam Hussein, used multiple CWAs against the Kurdish minorities in a Halabja village, killing more than 10% of the town's 50,000 residents. To date, mustards have been used in more than a dozen conflicts, killing and inflicting severe injuries in millions of military personnel and civilians.

During the Persian Gulf War, exposure to OP nerve agents occurred from the destruction of munitions containing 8.5 metric tons of sarin/cyclosarin housed in Bunker 73 at Khamisyah on March 4, 1991, and during additional destruction of these nerve agents contained in rockets in a pit at Khamisyah on March 10, 1991. Although exposure levels to nerve agents were too low to produce signs of acute toxicity, military personnel serving in and around the Khamisyah area still suffer from long-term adverse health effects, most notably "Gulf War Syndrome." In 1996, approximately 60,000 veterans of the Persian Gulf War claimed to suffer from "Gulf War Syndrome" or "Gulf Veterans' Illnesses," possibly because of low-level exposure to nerve agents, mustard, pyridostigmine bromide, and pesticides. Exposed veterans had an increased incidence of chronic

DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00001-4

myelocytic leukemia and increased risk of brain cancer deaths compared with unexposed personnel.

In the mid 1990s, two terrorist attacks by a fanatic religious cult Aum Shinrikyo (Supreme Truth), known as Aleph since 2000, took place in Japan (Matsumoto in 1994 and Tokyo Subway in 1995). In both incidents, the OP nerve agent sarin was used as a CWA. An estimated 70 tons of sarin was manufactured by Aum Shinrikyo in Kamikuishiki, Japan. Although the total fatality count involved not more than 20 civilians, injuries were observed in more than 6000 and millions were terrified. These acts of chemical terrorism were unprecedented and the impact propagated not only throughout Japan but also throughout the entire world. In the past few decades, many incidents have also occurred with biotoxins such as ricin and anthrax. Publicity surrounding frequent recent use attributable to easy access and copycat crimes increase the possibility of future use of these chemicals and biotoxins, thus warranting advancement in emergency preparedness planning at the federal, state, and local government levels.

It is interesting to note that toxic chemicals have been used by governmental authorities against rebels or civilians. In the 1920s, Britain used chemical weapons in Iraq "as an experiment" against Kurdish rebels seeking independence. Winston Churchill strongly justified the use of "poisoned gas against uncivilized tribes." The Russian Osnaz Forces used an aerosol containing fentanyl anesthetic during the Moscow theater hostage crisis in 2002. RCAs were frequently used in the United States in the 1960s to disperse and control crowds.

At present, more than 25 countries and possibly many terrorist groups possess CWAs, and many other countries and terrorist groups are seeking to obtain them because of their easy access. Some of these agents are stockpiled in enormous quantities and their destruction and remediation are not only expensive but also associated with significant health risks. There is also the possibility of accidental release of CWAs or CWMD at the sites of their production, transportation, dissemination, and deployment. The intentional or accidental release of highly toxic chemicals, such as the nerve agent VX (Dugway Proving Ground, Utah, USA, 1968), Agent Orange (Vietnam, 1961–1972), PBB (Michigan, USA, 1973), dioxin (Seveso, Italy, 1976), and methyl isocyanate (Bhopal, India, 1984), has caused injuries in more than one million people and deaths in several thousands. A 1968 accident with VX nerve gas killed more than 6000 sheep in the Skull Valley area of Utah.

After September 11, 2001, the chances for the use of CWMD by extremist and terrorist groups, such as Al Qaeda, have been greater than ever, thus presenting great risks to humans, domestic animals, and wildlife in many parts of the world. On November 26, 2008, Pakistani Islamic terrorists attacked Mumbai City in India at 10 different sites, including two luxury hotels, a Jewish center, a train station, hospitals, and cafes. Approximately 200 innocent people died and approximately 300 people were injured by bullets and smoke. It is more likely that terrorist groups such as these may use toxic industrial chemicals (agents of opportunity) either in this way or as a precursor for more deadly CWMD. At present, many countries have established Defense Research Institutes with two major missions: (i) to understand the toxicity profile of CWAs/CWMDs and (ii) to develop strategic plans for prophylactic and therapeutic countermeasures. By the turn of the twenty-first century, the United States established the Department of Homeland Security. Many other countries also developed similar governing branches and agencies at the state and national levels to protect people and property from terrorist attacks. Among chemical, biological, and radiological weapons, the possibility of CWMD is more likely because of their easy access and delivery system. It is important to mention that understanding the toxicity profile of CWAs/CWMD is very complex, because these chemical compounds are of a diverse nature and, as a result, treatment becomes very difficult or, in some cases, impossible.

In the past, many accords, agreements, declarations, documents, protocols, and treaties have been signed at the international level to prohibit the development, production, stockpiling, and use of CWAs, yet dictators and terrorists produce and/or procure these chemicals to harm or kill enemies, create havoc, and draw national and international attention. In 1907, The Hague Convention outlawed the use of chemical weapons; however, during WWI, many countries used these chemicals. The first international accord on the banning of chemical warfare was agreed upon in Geneva in 1925. Despite the General Protocol, the Japanese used chemical warfare against China in 1930. In 1933, the Chemical Weapon Convention banned the development, possession, and use of CWAs. The document was signed and implemented by more than 100 countries. However, during WWII many chemicals of warfare were developed, produced, and used by several countries. In 1993, another global convention banning the production and stockpiling of CWAs was signed by more than 100 countries.

It is highly likely that these agents will be used in wars, conflicts, and terrorist attacks with malicious intent. In such scenarios, these extremely toxic agents continuously pose serious threats.

This first edition of *Handbook of Toxicology of Chemical Warfare Agents* was prepared to offer the most comprehensive coverage of every aspect of the deadly toxic chemicals that can be used as CWAs/CWMD. In addition to the chapters on radiation, several chapters were included on deadly biotoxins (ricin, abrin, strychnine, anthrax, and botulinum toxins) that can be weaponized in chemical, radiological, and biological warfare. Many

special and unique topics were offered that were not covered in other books. This was the first book to offer detailed target organ toxicity in the area of toxicology. In every chapter, all factual statements were substantiated with appropriate references.

Since the publication of the first edition of this handbook, concerns regarding the use and misuse of CWAs and biological warfare agents (BWAs) are greater than ever before. The delayed health effects from CWAs used during the Iraq–Iran conflict of the 1980s, during the sarin subway attacks in Japan and during the first Gulf War in the 1990s are still not well-understood. Recently, the Syrian government stockpiled more than 1300 metric tons of chemical agents, including sarin, VX, and sulfur mustard. In August 2013, the Syrian military repeatedly attacked civilians with chemical weapons, including sarin. More than 1300 people died and thousands were injured. Again, during April 11–13, 2014, Syrian military forces attacked civilians in Hama province with chlorine gas, killing and injuring an unaccounted number of people. Of course, the Syrian government has denied use of either sarin or chlorine gas.

The second edition of the *Handbook of Toxicology of Chemical Warfare Agents* is prepared to meet today's challenges of academicians and lay persons alike. The format used is user-friendly and easy to understand. Standalone chapters on individual chemical and biological agents, target organ toxicity, biosensors and biomarkers, risks to humans, animals, and wildlife, and prophylactic and therapeutic countermeasures are just a few of the many novel topics covered in this volume. The chapters are enriched with historical background as well as the latest information and up-to-date references. With 76 chapters, this book serves as a reference source for biologists, toxicologists, pharmacologists, forensic scientists, analytical chemists, local/state/federal officials in the Department of Homeland Security, Department of Defense, Defense Research Establishments, Department of Veterans Affairs, physicians at medical and veterinary emergency care units of hospitals, poison control centers, medical and veterinary diagnostic laboratories, environmentalists and wildlife interest groups, researchers in the areas of nuclear, chemical, and biological agents, and college and university libraries.

Contributors to the chapters in this book are the most qualified scientists in their particular areas of CWAs and BWAs. These scientists are from around the globe and are regarded as authorities in the fields of pharmacology, toxicology, and military medicine. The editor sincerely appreciates the authors for their dedicated hard work and invaluable contributions to this volume. The editor gratefully acknowledges Robin B. Doss and Michelle A. Lasher for their technical assistance. Finally, the editor remains indebted to Molly McLaughlin, Rhys Griffiths, and Kristine Jones, the editors at Elsevier, and Caroline Johnson, Susan McClung and Heather Turner in the production department of Elsevier for their immense contributions to this book.

CHAPTER

2

Historical Perspective of Chemical Warfare Agents

Nathan H. Johnson, Joseph C. Larsen and Edward Meek

The opinions and assertions contained herein are the private views of the authors, and are not to be construed as reflecting the views of the US Department of Defense, the US Air Force, or the US Department of Health and Human Services.

INTRODUCTION

The employment of chemicals in war has a long history (Silvagni et al., 2002; Romano et al., 2008). Just as the use of chemicals brought about tremendous advances in society, the concept of using chemicals to help win wars has been pursued for centuries (Joy, 1997; Smart, 1997). There are many examples of the exploitation of chemicals in warfare and conflict dating back to ancient times. Primitive humans may have been the first to use chemical compounds in both hunting and battle scenarios. The use of smoke from fires to drive animals or adversaries from caves may have been the earliest use of chemical weapons. Natural compounds derived from plants, insects, or animals that were observed to cause sickness or death were likely used by our distant ancestors in attempts to gain or maintain superiority (Hammond, 1994). Natural toxins from plants or animals on arrowheads, as well as the poisoning of water or food, could increase casualties and cause fear in opposing military forces or civilian populations. These early uses of chemicals paved the way for more lethal chemical weapons. For example, in the fourth century BC, smoke containing sulfur was used in the war between Sparta and Athens (Joy, 1997). Chinese manuscripts indicate arsenic-based compounds were used in battle (Joy, 1997). A few hundred years later, toxic smoke was employed by the Romans in Spain (Coleman, 2005). During the second siege of Constantinople, the Byzantine emperor Leo III used "Greek fire" in his quest for military victory (Coleman, 2005). During the ensuing years, there were many instances of the limited and attempted use of chemicals and toxins on the battlefield. Many of these examples may have been influenced by the intentional poisonings occurring in civilian settings (Joy, 1997; Smart, 1997; Newmark, 2004; Coleman, 2005). The earliest known treaty to ban poisons in warfare was signed between the French and Germans in the seventeenth century (Smart, 1997). In the siege of Groningen, European armies employed incendiary devices to release belladonna, sulfur, and other compounds. This led to the Strasbourg Agreement in 1675, which prohibited poison bullets (Smart, 1997; Coleman, 2005).

As science and chemistry advanced in the nineteenth century, the possibilities of chemical warfare increased exponentially. Advancements were made in industrial applications of sulfur, cyanide, and chlorine (Joy, 1997). In addition, the concept of delivering chemicals via projectiles was introduced. During the Crimean War, the British refused to use cyanide-based artillery shells against the Russians on the grounds that it was a "bad mode of warfare" (Smart, 1997). This was an early example of the ethical questions surrounding chemical use in warfare that continued into the twentieth century (Vedder and Walton, 1925). During the US Civil War, both the Northern and Southern armies seriously considered using various chemicals in their pursuit of operational victories (Smart, 1997). Early attempts at international treaties met with mixed results. The United States prohibited any use of poison during the Civil War. The Brussels Convention on the Law and Customs of War of 1874 prohibited poisons or poison-related arms (Smart, 1997). The first Peace Conference at the Hague

prohibited projectiles filled with asphyxiating or deleterious gases (Smart, 1997). The employment of chemicals as asphyxiating warfare agents was vigorously discussed there (Joy, 1997). However, some countries, including the United States, were not signatories to this agreement. Arguments again were made against chemicals based on moral grounds. However, counterarguments were made based on the assumption that chemicals lead to death without suffering (Vedder and Walton, 1925; Joy, 1997; Coleman, 2005). Individuals who advocated chemicals did not view their use as an unfair advantage; rather, it was just one of a series of technological advances which, if mastered, could provide strategic, operational, and tactical advantages on the battlefield. The second Peace Conference at the Hague, held eight years later, prohibited both poisons and poisoned weapons (Smart, 1997). The British use of picric acid–filled shells during the Boer War and the Japanese use of arsenical rag torches in the Russo-Japanese War further illustrate that chemical warfare was considered by some a legitimate form of warfare at the turn of the twentieth century (Smart, 1997). During the early twentieth century, technological advancements in the chemical industry made the possibility of sustained military operations using chemicals a realistic possibility. The murder of Archduke Franz Ferdinand at Sarajevo in June 1914, which sparked World War I, set the stage for what would become the first widespread use of chemical weapons to date (Harris and Paxman, 2002).

THE FIRST SUSTAINED USE OF CHEMICALS AS AGENTS OF WAR

The talk and rhetoric of the late nineteenth century should have prepared the countries on both sides of World War I for chemical warfare. However, that was not the case (Smart, 1997). World War I clearly demonstrated the deadly and destructive nature of chemicals in modern warfare. Both sides of the war experimented with novel forms of warfare, including chemical weapons, and followed the lead of their adversary (Hay, 2000). It is little wonder that this war is known as the "chemist's war" (Fitzgerald, 2008). Initially, the French used gas grenades with little effect, followed by the German use of shells filled with tear gas (Joy, 1997). The Germans, capitalizing on their robust chemical industry, produced shells filled with dianisidine chlorosulfate (Smart, 1997). These shells were used in October 1914 against the British at Neuve-Chapelle, but with little effect. In the winter of 1914–1915, the Germans fired 150-mm howitzer shells filled with xylyl bromide (Smart, 1997). These shells were fired on both the eastern and western fronts, with disappointing effects. Despite this inauspicious start, efforts were continued to develop new uses of chemical warfare. It would soon be evident that chemical weapons would be devastating on the battlefield (Coleman, 2005; Tucker, 2006). In late 1914, Fritz Haber, a German scientist who later won the Nobel Prize in Chemistry, proposed the possibility of releasing chlorine gas from cylinders (Joy, 1997). Chemical warfare was attractive to Germans for two reasons: the shortage of German artillery shells and the ability to defeat the trench system of the enemy (Smart, 1997). After consideration and debate, the Germans released chlorine in April 1915 at Ypres, Belgium (Coleman, 2005). The German military was not prepared for the tremendous operational advantage the chlorine release provided, however. It did not take long for the British and French forces to respond in kind to the German offensive (Vedder and Walton, 1925; Joy, 1997; Smart, 1997; Coleman, 2005). In the fall of 1915, a British officer, William Livens, introduced a modified mortar (Figure 2.1) that could project gas-filled shells of chlorine or phosgene, the two agents of choice at that time (Joy, 1997). Both chlorine and phosgene caused extreme respiratory problems to those soldiers who were exposed to them (Vedder and Walton, 1925; Joy, 1997; Smart, 1997; Coleman, 2005; Hurst et al., 2007) (Figure 2.2).

FIGURE 2.1 British Livens Projector, western front, World War I.

As the United States entered the war in the spring of 1917, an obvious concern of its military command was the effect of chemical warfare on standard operations. Chemistry departments at universities were tasked with investigating and developing novel chemical agents (Joy, 1997). Protective equipment (Figure 2.3) and basic studies of the biological effects of chemical agents were assigned to the US Army Medical Department (Joy, 1997). In the fall of 1917, the army began to build an industrial base for producing chemical agents at Edgewood Arsenal, MD (Joy, 1997). As the effects of chlorine and phosgene became diminished by the advent of gas masks (Figure 2.4), the Germans turned to dichlorethyl sulfide (mustard) at Ypres against the British (Joy, 1997). As opposed to the gases, mustard remained persistent in

FIGURE 2.2 Australian infantry in trench with gas masks donned, Ypres, Belgium, September 1917.

FIGURE 2.3 US Army captain wearing a gas mask in training, 1917.

FIGURE 2.4 World War I soldier and horse, both wearing gas masks.

FIGURE 2.5 British soldiers temporarily blinded by tear gas awaiting treatment at the Battle of Estaires, April 1918.

the area, and contact avoidance was the major concern (Joy, 1997). It is worth noting that almost 100 years after it was first used on the battlefield, mustard still has no effective treatment; research continues into developing effective therapeutics (Babin et al., 2000; Baskin et al., 2000; Casillas and Kiser, 2000; Hay, 2000; Schlager and Hart, 2000; Hurst et al., 2007; Romano et al., 2008). It has been estimated that there were over 1 million chemical casualties (Figure 2.5) of World War I, with almost 8% being fatal (Joy, 1997). The Russians on the eastern front had a higher percentage of fatalities than other countries in the war, primarily due to the later introduction of a protective mask (Joy, 1997). The relatively low rate of chemical deaths in World War I demonstrated the most insidious aspect of the use of such weapons—namely, the medical and logistical burden that it placed on the affected army. The eventual Allied victory brought a temporary end to chemical warfare. In 1919, the Treaty of Versailles prohibited the Germans from producing or using chemical weapons.

INITIAL COUNTERMEASURES

The concept of a protective mask against chemical attack dates back over 500 years, to Leonardo da Vinci (Smart, 1997). By the mid-nineteenth century, protective masks were proposed in the United States and Europe for both industrial and military use. The modern gas mask was developed by the Germans with sodium thiosulfate- and bicarbonate-soaked pads, and it was used during World War I (Joy, 1997). The French and English soon followed with their own versions of gas masks (Joy, 1997). In 1916, the Germans introduced a mask that incorporated a canister through which the soldiers breathed (Joy, 1997). Initially, the American forces in World War I used gas masks obtained from allies already fighting in the war (Smart, 1997). In 1918, the Americans introduced Richardson, Flory, and Kops (RFK) mask, a modified version of the British mask. In addition, masks were developed for the animals, such as horses, that supported the war efforts. Decontamination efforts during World War I were rudimentary and included chemical neutralization and aeration of clothing and equipment. Although the need to detect chemical agents was clearly identified, very little progress was made during World War I. Medical treatment included removal of the patient from the source, decontamination, and palliative care (Smart, 1997).

EVENTS AFTER WORLD WAR I

By the time World War I ended, the world had been introduced to chemical warfare on an unprecedented level. While some groups thought that humanity had learned a lesson about the cruel nature of chemical warfare, others prudently went to work on improving chemical defenses (Vedder and Walton, 1925). The thoughts of many professional military officers were that future wars would be fought under the new paradigm of chemical warfare (Vedder and Walton, 1925; Vedder, 1926; Smart, 1997). New gas masks were developed, and training in chemical environments was introduced (Vedder and Walton, 1925; Vedder, 1926; Joy, 1997). Textbooks and manuals, such as those written by US Army Colonel Edward B. Vedder (Figure 2.6), were introduced into the military medical community (Vedder and Walton, 1925). In addition, the civilian medical community gained valuable insight into toxicology from the events of World War I (Vedder, 1929; Johnson, 2007). Despite the firsthand experience with chemical warfare, some countries, including the United States, struggled to fund their offensive and defensive programs adequately during demobilization (Smart, 1997).

It did not take long for chemical warfare to appear in other conflicts. Chemical agents were used to subdue rioters and suppress rebellions. For example, the British used chemical agents to suppress uprisings in Mesopotamia in the early 1920s by dropping bombs in cities throughout the area (Coleman, 2005). The Soviet Union used chemical agents to quell the Tambov peasant rebellion in 1921, and France and Spain used mustard-gas bombs to subdue the Berber rebellion in the 1920s (Werth et al., 1999). Italy and Japan used mustard in several small regional conflicts (Joy, 1997). The Italian conflict in Ethiopia was particularly noteworthy because mustard was sprayed and dropped from planes, and some experts think that the agent's use contributed significantly to the Italian victory (Smart, 1997). This use demonstrated the contemporary belief that chemicals were viable alternatives to traditional combat.

FIGURE 2.6 Captain Edward B. Vedder, the "father" of the United States Army Medical Research Institute of Chemical Defense (USAMRICD).

The Japanese also used chemical weapons during the 1930s against regional foes. Mustard gas and the vesicant lewisite were released against Chinese troops and were also used in Southeast Asia (Coleman, 2005). Lewisite is an arsine that was usually produced as an oily brown liquid that was said to smell like geraniums (Spiers, 1986; Hammond, 1994). It was developed in the United States by Winford Lee Lewis in 1918 and was found to be effective at penetrating clothing. The United States produced approximately 20,000 tons of lewisite but only used small quantities of the chemical in World War I (Coleman, 2005). Dimercaprol, more commonly called *British antilewisite*, was developed as an effective treatment for the vesicant (Goebel, 2008). In the period between the two world wars, mustard was a key part of defensive planning (Coleman,

2005). New stores of mustard were produced in many countries. Work continued on many fronts to improve protective equipment. For example, the US Chemical Warfare Service introduced the M1A2 mask, an improvement on the M1 mask (Smart, 1997). In the Geneva Protocol of 1925, 16 of the world's major nations pledged never to use gas as a weapon of warfare; however, it was not ratified in the United States until 50 years later, in 1975 (Hammond, 1994). There has long been vigorous debate on the merits of treaties with nations that balance military needs against the potential irrational concept of chemical warfare (Vedder, 1926).

WORLD WAR II

In the lead-up to World War II, the Germans forever changed chemical warfare with the discovery of the organophosphorus nerve agents (Goebel, 2008). These agents inhibit cholinesterase enzymes in the nerve synapse responsible for the breakdown of the neurotransmitter acetylcholine (ATSDR, 2008). This results in the accumulation of the neurotransmitter in the synapse and overstimulation of the nervous system. This can result in subsequent respiratory failure and death (ATSDR, 2008).

In 1936, Gerhard Schrader, a German chemist working on the development of insecticides for IG Farben, developed a highly toxic organophosphate compound, which he named *tabun* (Hersh, 1968; Hammond, 1994). Schrader and an assistant became casualties of their discovery when a drop of the neurotoxicant was spilled in the lab, exposing both of them (Tucker, 2006). Had the amount of tabun spilled been greater, both researchers would have certainly succumbed to the effects of the poison. Tabun was the first of a series of compounds termed *nerve gases* (Coleman, 2005). The correct terminology, however, is *nerve agents*, as these substances are not gases; rather, they are liquids dispersed as fine aerosols. Tabun was extremely toxic in small amounts, and it was invisible and virtually odorless (Tucker, 2006). The compound could be inhaled or absorbed through the skin. These characteristics made it too dangerous to be used as an insecticide by farmers. German law required that any discovery having potential military applications be reported to military officials (Tucker, 2006). Schrader was not overly excited about producing chemical agents for the military; however, the Germans placed him in a secret military research facility with the emphasis on producing these nerve agents and discovering new agents (Tucker, 2006). Subsequently, Schrader and his team of researchers discovered a more lethal organophosphate compound similar to tabun, which he named *sarin* in honor of the team members: Schrader, Ambrose, Rudriger, and van der Linde (Coleman, 2005).

FIGURE 2.7 Gas mask production—Detroit, Michigan, 1942.

FIGURE 2.8 A private trains using protective gear during World War II.

At the onset of World War II, both the Allies and the Germans anticipated that chemical agents would be deployed on the battlefield (Tucker, 2006). This expectation intensified research into the development of new agents, delivery systems, and methods of protection (Figures 2.7 and 2.8). The Allied forces were unaware of the Germans' new nerve agent, tabun, at the beginning of the war. The German Army advanced very rapidly across Europe using their Blitzkrieg method of maneuvering. As a result, German military leaders were reluctant to use chemical weapons, fearing that their forces would lose momentum waiting for contaminated areas

to clear. (Tucker, 2006). Nevertheless, the Germans produced and stockpiled large amounts of nerve agents throughout the war (Spiers, 1986). The production of these organophosphate agents was complex, required custom equipment, and was hazardous to those involved in its production (Tucker, 2006). If workers got exposed, they would be dunked in a bath of sodium bicarbonate (Harris and Paxman, 2002; Goebel, 2008). It is also interesting to note that some members of the German workforce were given rations containing higher percentages of fat (Harris and Paxman, 2002). This was done because authorities observed that workers with higher-quality rations seemed protected against exposure to low levels of tabun. Many detainees were used in the manufacture and testing of chemical agents in Germany (Harris and Paxman, 2002; Tucker, 2006). It is not known how many chemical casualties resulted from prisoners of war being forced to work at producing nerve agents, but some fatalities were documented. The discovery of tabun and sarin was followed by the discovery of soman in 1944 by Richard Kuhn and Konrad Henkel at the Kaiser Wilhelm Institute for Medical Research (Tucker, 2006). This class of nerve agents is collectively termed "G" agents; the *G* stands for *German*, since German researchers discovered this class of compounds. A second letter is included as the specific identifier of each compound: GA (tabun), GB (sarin), GD (soman), and GF (cyclosarin) (ATSDR, 2008). These agents were mass-produced by the Nazi regime throughout the war, but they were not used (Tucker, 2006). There has been considerable debate about why the Germans did not employ their chemical weapons in World War II. While it may never be known conclusively, several possible reasons include lack of intelligence regarding the German superiority in chemical weapons, fear of retaliation, and Adolf Hitler's personal exposure to chemical agents on the battlefield in World War I (Harris and Paxman, 2002; Tucker, 2006).

Other chemical agents that had been produced during and following World War I were still being produced. On December 2, 1943, German planes sank several American ships off the coast of Italy. At least one of the ships contained mustard, which was to be used in retaliation if the Germans unleashed a large-scale chemical weapons attack (Tucker, 2006). Many casualties resulted from exposure to the mustard, some of which included civilian merchant seamen (US Navy, 2008). The presence of the agent on the ship was classified, resulting in physicians incorrectly treating many of the victims (Tucker, 2006).

POST–WORLD WAR II

By the conclusion of World War II, both the Allies and Germany had stockpiled large amounts of chemical agents (Tucker, 2006). The Allied forces divided up the stockpiles of agents discovered in German facilities. Following the end of the war, many of the Allied countries continued to conduct research on the German nerve agents. The rise of the Soviet Union as a power and adversary prompted the United States and other countries to continually search for novel chemical and biological warfare agents (Tucker, 2006). The research and resources that were allotted for these efforts were not trivial, even though they were often overshadowed by the research and development of thermonuclear weapons (Hersh, 1968; Goebel, 2008).

The post–World War II era ushered in the nuclear age. Some felt the age of chemical warfare was over (Smart, 1997), but subsequent events would prove this to be a hasty conclusion. In the United States, research on the G-series agents and medical countermeasures against these agents was accomplished by the late 1940s. Research and intelligence gathering was further hastened by the impressive gains that the Soviet Union made in chemical warfare capability in the years after World War II. By the early 1950s, production of sarin had been initiated in the United States (Smart, 1997). At nearly the same time, Ranajit Ghosh, a chemist at the British company Imperial Chemical Industries plant, developed a new organophosphate compound to use as a potential insecticide (Tucker, 2006). Like with Gerhard Schrader, this compound was deemed too toxic to be used in the field as a pesticide. The compound was sent to researchers in Porton Down, England, synthesized, and developed into the first of a new class of nerve agents, the V agents (Goebel, 2008). Like the G agents, the V agents have a second letter designation: VE, VG, VM, and VX (Coleman, 2005). Of these, VX was the most common. The V series of agents are generally more toxic than the G agents (ATSDR, 2008). In a deal brokered between the British and US governments, the British traded the VX technology for the thermonuclear weapons technology of the United States (Tucker, 2006). The United States produced and stockpiled large quantities of VX after that (Hersh, 1968; Hammond, 1994).

Throughout the 1950s and 1960s, advancements were made in the production and delivery of chemical weapons to include sarin and VX (Smart, 1997). While work on improving masks continued, a renewed concern was the inability to detect nerve agents. Several prototypes were developed in the mid-1950s. Great advancements were made in the therapeutics of agents that inhibited the enzyme acetylcholinesterase (Taylor, 2006; Gupta, 2008; Klaassen, 2008). Atropine was introduced in the early 1950s. Oximes were added as an adjunct to speed up reactivation of the enzyme (Smart, 1997). The autoinjector was developed to overcome user fear of self-injection of atropine. Major advances were made in the use of chemical weapons in artillery (Figure 2.9). For example, the United States developed both short- and long-range rockets filled with chemical agents. But it

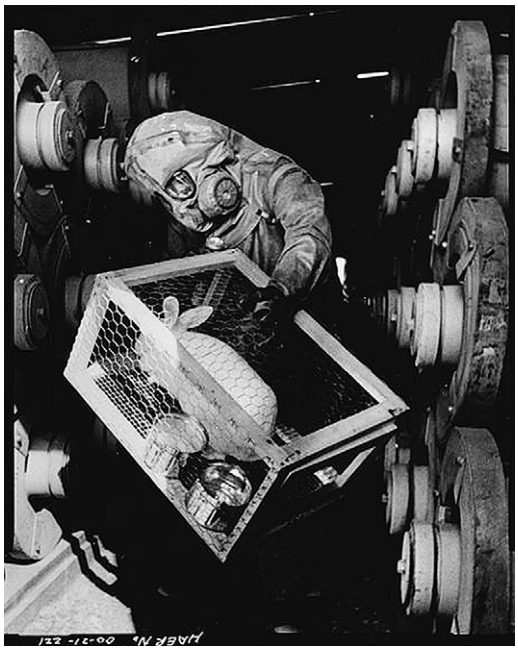

FIGURE 2.9 Testing for leaks at sarin production plant, 1970.

disposed of stockpiles of its chemical weapons in the late 1960s in an operation termed CHASE (which stood for "cut holes and sink 'em") in the sea (Coleman, 2005). In 1969, nerve agent stockpiles were discovered in US depots in Japan after several US military members became ill while doing maintenance (Tucker, 2006). This stockpile, which had been kept secret from the Japanese, created an uproar that later resulted in the disposal of the agents in the Johnston Atoll in the Pacific Ocean.

Defensive equipment, such as improved field alarms and drinking tubes for gas masks, were introduced in the 1960s (Smart, 1997). Great strides were also made in collective protection during the 1960s and 1970s. Although not used extensively since World War I, chemical agents have nonetheless been used for military purposes. The Egyptians allegedly used mustard and possibly nerve agents in the North Yeman civil war in the 1960s (Joy, 1997; Smart, 1997). This was the first reported use of nerve agents in armed conflict. There were allegations that chemical agents were used by the Vietnamese in Laos and Kampuchea in the late 1970s (Coleman, 2005). In the Vietnam War, the United States used defoliants and tear gas, and the Soviet Union was accused of using chemical agents in their war in Afghanistan (Joy, 1997).

INCAPACITANTS AND TOXINS

Incapacitating agents have long been considered an intermediate between chemical and traditional warfare. The Germans investigated the military use of lacrimators in the 1880s followed shortly thereafter by the French (Smart, 1997). The English and French considered using lacrimators in World War I (Smart, 1997). Japanese forces used tear gas against the Chinese in the late 1930s. The US Army used riot control agents and defoliants in the Vietnam War (Smart, 1997). The defoliant known as *Agent Orange* was later potentially linked to several forms of cancer (Stone, 2007). During the 1950s and 1960s, the United States had an active incapacitant program (Smart, 1997). These agents were thought of as more humane than traditional chemical agents because the intent was not to kill. These agents were designated *K agents* and included tetrahydrocannabinol and lysergic acid (Smart, 1997). One of the most extensively studied incapacitating agents was 3-quinuclidinyl benzilate, designated *BZ* by the US Army (Ketchum, 2006). Like many incapacitating agents, BZ was not adopted due to difficulty producing reproducible effects, unwanted side effects, latency in its effects, and difficulty in producing a dissemination that was free of smoke (Smart, 1997; Ketchum, 2006).

There have been multiple attempts to use the toxins from plants and living organisms to develop viable weapon systems. Two that are noteworthy are ricin and botulinum toxin. Ricin, a very potent toxin derived from the castor bean plant, has been recognized as a potential biological weapon since World War I. While the British were developing the V agents, US military researchers patented a procedure for purifying ricin (Harris and Paxman, 2002). The development of a method of disseminating ricin as a chemical weapon proved problematic, which made its use very limited. In 2003, ricin was detected on an envelope processed in a postal facility in Greenville, South Carolina. Postal workers did not develop symptoms of ricin exposure, and the individual who mailed the letter remains at large (Shea, 2004). The development and use of botulinum neurotoxin as a biological weapon was initiated at least 60 years ago (Smart, 1997; Arnon et al., 2001). In the 1930s, during Japan's occupation of Manchuria, the Japanese biological warfare group Unit 731 purportedly fed cultures of *Clostridium botulinum* to prisoners, killing them. The US Army biological weapons program produced botulinum neurotoxin during World War II in response to Germany's biological weapons program (Coleman, 2005). In fact, more than 100 million toxoid vaccine doses were prepared in time for the D-Day invasion of Normandy (Arnon et al., 2001).

RECENT EXPERIENCE

The 1980s proved to be a very significant time for the employment of chemical weapons on the battlefield. In 1980, Iraq invaded Iran (Smart, 1997). The Iraqi armed forces, advised by the Soviet Union, possessed chemical agents and were trained in their use. The war was

FIGURE 2.10 Aftermath of Iraqi chemical weapon attack (1980s).

unequivocally barbarous, and neither side gained an advantage. In many ways, this war had similarities to World War I. By 1983, Iran formally protested to the United Nations (UN) about the Iraqi use of chemical agents. The general consensus was that Iraq used mustard agents and possibly tabun in this war (Figure 2.10). It is estimated that 5% of Iranian casualties, totaling approximately 45,000, can be attributed to chemical agents; the Iraqi Army used chemical agents against the Kurdish minority in northern Iraq as well; and Libya was suspected of using chemical agents when it invaded Chad in 1986 (Smart, 1997).

The late 1980s also saw improvements in defensive equipment, such as the M40 gas mask developed by the United States (Smart, 1997). Other advancements were made in collective protection, decontamination, and detection. In 1984, US president Ronald Reagan issued a statement calling for an international ban on chemical weapons (Tucker, 2006). Subsequently, on June 1, 1990, President George H.W. Bush and Soviet leader Mikhail Gorbachev signed a treaty banning the production of chemical weapons and initiated the destruction of the stockpiles of both nations (Tucker, 2006). In 1993, the Chemical Weapons Convention was convened and signed, and it was implemented in 1997 (Hammond, 1994). As of 2008, the vast majority of UN member states had joined the Chemical Weapons Convention (OPCW, 2008).

In 1990, the Iraqi Army invaded neighboring Kuwait. Subsequently, the United States, at the request of Saudi Arabia, led a coalition to send forces to the area (Smart, 1997). These forces were the largest to operate in a potential chemical environment since World War I. They were provided with atropine autoinjectors, an acetylcholinesterase reactivator, and a nerve agent pretreatment (pyridostigmine bromide). Fortunately, chemical weapons apparently were not used in this conflict, although multiple false alarms were reported. The failure of the Iraqi military to use chemical weapons could be attributed to fear of retaliation, breakdown of communication, changing wind patterns, the surprising speed of the coalition attack, or the fact that Iraqi chemical infrastructure was attacked during the initial portion of the conflict. Since the conflict ended, many coalition veterans have reported a myriad of symptoms that have been commonly referred to as *Gulf War syndrome.* The etiology of this syndrome is unclear despite multiple epidemiological studies (Coleman, 2005). The most recent example of chemical weapons use is the ongoing Syrian civil war (Pellerin, 2013).

TERRORIST USE

One of the reasons why chemical weapons have been used relatively infrequently in combat over the past century is the fear of retaliation by opposing countries. In less organized asymmetrical conflicts, this fear is not as dangerous. At the same time, the potential exploitation of chemical weapons by terrorists is of great worldwide concern. The appeal of these weapons to terrorists lies largely in the fact that many of these chemical agents are cheap and relatively easy to produce, transport, and release. These characteristics, along with the fear associated with the idea of a chemical attack, make chemicals an ideal weapon for terror attacks (Romano and King, 2001). In 1974, Muharem Kurbegovic attacked several public buildings with firebombs in California and claimed to have developed sarin and some other nerve agents (Tucker, 2006). The search of his home resulted in the discovery of various precursor materials for chemical agents and a large amount of sodium cyanide. In 1994, the Aum Shinrikyo, a Japanese religious cult, carried out several attacks both in the subway and in residential areas using sarin produced by the cult's members (Tucker, 2006). A total of 19 people were killed, and over 6,000 received medical attention. Some of those who sought medical attention may have done so due to a fear of exposure. Psychological stress is a common aftermath of a chemical or biological attack (Romano and King, 2001). In the twenty-first century, chemicals that once had been used exclusively by the military have reemerged as contemporary threats. In the fall of 2006, Al Qaeda and associated groups used chlorine combined with traditional car and truck bombings to spread panic in Iraq (Garamone, 2007). These attacks were followed by similar incidents in the subsequent months.

CONCLUDING REMARKS AND FUTURE RESEARCH

So long as there are legitimate uses for chemicals in our society, the risk of chemical agents in conflict and

terrorist activity will always be present. Research continues across the globe for better detection, protection, and treatment of chemical agents. While many countries have denounced and indeed are signatories to various treaties to limit the use and production of chemical warfare agents, nonstate and terror organizations are under no such restrictions. Luckily, chemical weapon use has been limited in both warfare and less formal conflicts. As we progress into the twenty-first century, the use of established chemical warfare agents is a real possibility. The potential use of legitimate industrial chemicals (e.g., the Iraqi burning of petroleum fields in the first Gulf War) and the potential synthesis of new agents should also be recognized. History has demonstrated that chemicals have been used in both organized and asymmetrical conflicts, and preparations for defense and therapy for such encounters is prudent. Chemicals represent a unique force multiplier that simply cannot be ignored in the twenty-first century.

CHAPTER

3

Global Impact of Chemical Warfare Agents Used Before and After 1945

Jiri Bajgar, Josef Fusek, Jiri Kassa, Kamil Kuca and Daniel Jun

INTRODUCTION

The threat of chemical weapons (CWs), used either by States or Parties to the Chemical Weapons Convention (CWC; Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and on their Destruction) or by terrorists, has never attracted so much public attention as it has in the past 10 years. Despite the existing legal documents dealing with prohibition of CWs, for example, Geneva Protocol 1925 and CWC, some incidents of the use of CWs in different conflicts and terroristic attacks have been observed. Moreover, alleged use of CWs was noted during the period from 1925 to the present. It must be emphasized that the theoretical and practical basis for production, storage, and use of CWs still exists. Also, it must be clearly stated that CWs are applicable at any time, in any place, and in large quantities.

CWs consist of chemical warfare agents (CWAs) and the means to deliver to the target. They are characterized by high effectiveness for use against large targets and are known as area weapons or silent weapons. They are relatively low-cost and it is possible to achieve destruction of everything that is living while avoiding destruction of materials and buildings. They are also called the nuclear weapons of poor countries—"poor man's nuclear weapon." It should be pointed out that the use of CWs is connected with the use or release of toxic chemicals; thus, chemical warfare can be considered part of generally observed situations in which toxic chemicals are used or released and influence the environment and humankind.

A number of causal reasons for these events exist but, apart from accidents connected with the release of toxic chemicals from a natural source (e.g., volcanoes), the factors shown in Figure 3.1 or their combinations can be involved.

For military purposes a number of chemicals were tested, but only a few are contained in military arsenals. However, according to the definition in the CWC, any toxic chemical intended for military use must be considered a CW; in other words, the aim is to limit the designation of the compound in question for use as a CW. However, it is possible for terrorists to choose any chemicals with high toxicity.

BACKGROUND

The use of toxic chemicals against humankind is as old as any warfare conflict. The use of the poisoned arrow against humans—not animals—can be considered as the beginning of chemical warfare and is characterized as the intentional use of chemicals.

At the very beginning, chemical warfare was more closely connected with fire. "Greek fire" was an excellent naval weapon because it would float on water and set fire to the wooden ships. There are other examples from history; for example, toxic smoke was used in China in 2000 BC. In Thucydides' *History of the Peloponnesian War* (the fifth century BC war between Athens and Sparta), we find the first description of chemical warfare—the formation of toxic sulfur oxide by burning sulfur. In the year 184 BC, Hannibal of Carthage used baskets with poisonous snakes against his enemy. Both Socrates and Hamlet's father were poisoned with koniin. Aqua Toffana containing arsenic was also a known poison in ancient Italy. Leonardo da Vinci proposed a powder of arsenic sulfide in the fifteenth century. There are many more examples of the use of CWAs (Bajgar et al., 2007b).

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00003-8

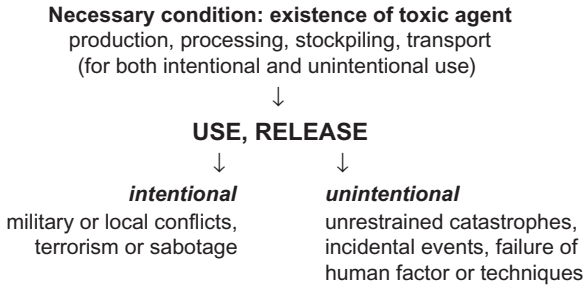

FIGURE 3.1 Possible reasons for release/use of toxic chemicals.

Modern history shows us that terrorists have used other chemicals, such as ricin (Bulgarian G. Markov was poisoned in 1978) or dioxin (the President of Ukraine Viktor Andriyovych Yushchenko was poisoned in 2004).

In a region of Bohemia, a "form" of CW was used as early as 600 years ago. It was in 1422 when the castle of Karlstein, the property of King Charles IV, was besieged and 1822 kegs containing the cesspools of the streets of Prague were hurled into the castle. Allegedly, the stench in the castle was unbearable. According to historical sources, the castle defenders were probably intoxicated with hydrogen sulfide released from the contents of the cesspools and therefore showed typical symptoms of poisoning (Bajgar, 2006).

There were some attempts to prohibit CWs by international agreement or law. Most of the early attempts were bilateral or unilateral agreements directed at the use of poisons. These included the 1675 agreement between France and Germany, signed in Strasbourg, to ban the use of poison bullets.

The first international attempt to control chemical and biological weapons took place in Brussels in 1874, when the International Declaration was signed and included a prohibition against poison and poisoned arms. Despite the first and second Brussels and Hague Conventions (1899 and 1907 signatories agreed not to use projectiles that could spread asphyxiating or deleterious gases), the world witnessed the application of chemicals during warfare to an unprecedented extent during World War I (WWI). A brief summarization of the events connected with the use/release of toxic chemicals is given in Table 3.1.

MILITARY USE OF CWS

The intentional use of CWs for military purposes can be found in both global and local conflicts. A typical example is the warning "Gas! Gas!" This was common in WWI and it is well-known from the E.M. Remarque novel *All Quiet on the Western Front* in which Remarque suggestively describes a chemical attack with chlorine.

During WWI, many chemicals were used, including mustard and asphyxiating and irritant agents. Approximately 45 types (27 more or less irritating and 18 lethal) of toxic chemicals were used. During the latter part of 1914, irritants were used by Germany and France; the effect was insubstantial. In late 1914, Nobel Prize winner Fritz Haber of the Kaiser Wilhelm Physical Institute in Berlin (chemical synthesis of ammonium in 1918) came up with the idea of creating chlorine, although this idea of using toxic chemicals in war was expressed by Admiral Dundonald as early as 1855. Chemical warfare really began in 1915, when German troops launched the first large-scale poison gas attack at Ypres, Belgium, on April 22, using 6000 cylinders to release 168 tons of chlorine gas, killing 5000 British, French, and Canadian soldiers. The date is recognized as "the birthday of modern chemical warfare," and thereafter the belligerent parties frequently used chemical gases against each other. Phosgene was introduced by Germany in late 1915. Soon after the first chlorine attack, the Allies used primitive emergency protective masks. In May 1916, the Germans started using diphosgene, while the French tried hydrogen cyanide 2 months later and cyanogen chloride the same year. The first time mustard gas was used by German troops was July 12, 1917. After its use near Ypres, it was also called yperit.

By the end of the WWI, approximately 124,200 tons of CWAs (chlorine, phosgene, mustard, etc.) had been released, causing at least 1.3 million casualties, of which more than 90,000 were fatal. The threat of the use of CWAs led to the development of protective means not only for humans but also for horses and dogs. The effectiveness of CWs in comparison with classic munition was evident: 1 ton of classic explosives caused 4.9 casualties; 1 ton of chemical munition caused 11.5 casualties; and 1 ton of yperite caused 36.4 casualties (Bajgar, 2006).

THE PERIOD BETWEEN WORLD WAR I AND WORLD WAR II

The terrible casualties of CWs used during WWI and the dangerous consequences for humans and the environment led to the signing of the "Geneva Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous and other Gases and Bacteriological Methods of Warfare" on June 17, 1925. This is recognized as one of the unique and famous international treaties on the prohibition of CWs. However, it neither comprises provisions for effective verification nor prohibits development, stockpiling, and transfer of CWs. Moreover, no definition of CWs was included. Despite the provisions of the Geneva Protocol, during 1935 to 1936 Italian troops used CWs during their invasion of Abyssinia (Ethiopia). This first major use of CWs after WWI came

TABLE 3.1 Some Milestones Related to the Use/Release of CWs and Toxic Chemicals

Year(s)	Event
2000 BC	Toxic smoke in China inducing sleep
Fourth century BC	Spartacus—toxic smoke
184 BC	Hannibal—baskets with poison snakes
1168	Fustat (Cairo) —use of "Greek fire"
1422	Bohemia region—cesspools (H_2S)
1456	Belgrade—rats with arsenic
Nineteenth century	Admiral Dundonald—proposed the use of chemicals in war
1914–1918	WWI—start of chemical war
1918–1939	Development of new CWs and protective means
June 17, 1925	Geneva Protocol
December 23, 1936	Lange and Kruger—synthesis of tabun
1940–1945	Concentration camps—cyanide
1943	Synthesis of sarin
1943	Hoffmann and Stoll—synthesis of LSD-25
1945	Kuhn—synthesis of soman
1950	V agents are begun
1961–1968	Production of VX
1961–1971	Vietnam War—herbicides (impurity dioxin)
1962	BZ was introduced into military arsenals
1970	Bicyclic phosphates considered as potential CWAs
1976	Seveso—release of dioxin
1980	Some rumors on intermediate volatility agent
1984	Bhopal incident—release of methylisocyanate
1985	Decision on production of binary CWs
1986, 1987	Demonstration of USA CWs (Tooele) and Soviet Union CWs (Shikhany) to the CD in Geneva
1987	Production of binary CWs
1988	Halabja—use of mustard
1980–1990	Rumors of new nerve agent Novichok
1989	Conference on chemical disarmament, Paris
1991	Persian Gulf War—veteran's syndrome
1992	BZ military stocks of the USA were destroyed
1992	Finalization of the rolling text of the CWC at the CD—Geneva
1993	Signing CWC in Paris
1993	Preparatory Commission on OPCW
1994	CWs of Iraq were destroyed
1994	Aum Shinrikyo—sarin attack in Matsumoto
1995	Aum Shinrikyo—sarin attack in Tokyo
April 29, 1997	CWC—entry into force; establishment of OPCW in The Hague
2000	Research on nonlethal weapons intensified
2002	Moscow theater—Fentanyl derivatives used against terrorists
April 29, 2012	CWs of the State Parties to the CWC will be destroyed but it was prolonged; this period varies from 2015 to 2023 years.
August 2013	Syria—use of sarin

after October 3, 1935, when Mussolini launched an invasion of this country. Despite the Geneva Protocol (Italy had ratified in 1928), the Italians used mustard gas with horrible effects. Later, CWs were used between Japan and China during 1937 to 1945. The Japanese attacked Chinese troops with mustard gas and lewisite. The Japanese, in addition to their biological program, had an extensive CWs program and were producing agent and munitions in large quantities by the late 1930s.

WORLD WAR II

Despite the storing and stockpiling of CWs by the great powers engaged in World War II (WWII), these fatal weapons were not practically used (except small examples) during WWII (probably because of the fear of massive retaliatory use of CWs). An example of intentional use, but not during military conflict, was the killing of prisoners in concentration camps in Nazi Germany. The agent first used in the camps was carbon monoxide, followed by the more "effective" hydrogen cyanide released from Zyklon B. Some experiments with aconitine-impregnated shells and some other toxic compounds including biological agents were tested on prisoners.

However, during WWII, an important step in the preparation of the most dangerous CWA was observed in Germany. In Schrader's group, organophosphates (OPs) were synthesized, primarily with the aim of obtaining more effective insecticides. Between 1934 and 1944, Schrader's team synthesized approximately 2,000 OPs, including two well-known OP compounds, parathion and paraoxon. As early as 1935, the government of Nazi Germany insisted that Schrader switch the primary aim from OP insecticides to CWAs. At present, OPs are widely used in agriculture, medicine (human and veterinary), and industry. These compounds also include nerve agents (the most toxic compounds of the OP group). Nerve agents such as sarin, tabun, soman, and VX are the main compounds of CWAs. The Germans were also the greatest producers of nitrogen mustard and produced approximately 2,000 tons of HN-3.

This part of history is well-known (Koelle, 1963, 1981; Bajgar, 2006; Tuorinsky, 2008; Klement et al., 2013). First synthesis of OP was described in the second half of the eighteenth century. For a long time the first OP (its toxicity was described later) was considered to be TEPP, which was synthesized by Clermont (1854–1855). Philippe de Clermont was a well-known chemist in Sorbonna. Charles Adolph Wurtz dedicated his work to the synthesis of esters of pyrophosphoric acid. These data were specified by Petroianu (2008), and thus he contributed to the discovery that the first synthesis of this OP—TEPP—was performed by Vladimir Moshnin of Moscau. These data are depicted in the work of Patočka (2010). New trends in the synthesis of nerve agents have been described by Halamek and Kobliha (2011).

Tabun was synthesized in 1936, followed by others (sarin at the end of WWII, followed by soman), and production of these agents for the military in large quantities and their stockpiling were recognized after WWII in Dyhernfurth, Poland (e.g., stocks of tabun and some quantities of sarin). The technology was subsequently transferred to Russia, and research and development of new OP nerve agents was continued. During this period, British and American scientists were evaluating the toxic properties of DFP.

THE PERIOD AFTER WORLD WAR II AND THE COLD WAR

At the end of WWII, many Allied nations seized the CWs. Most of the CW manufacturing plants in Germany were taken over and moved to new sites in Russia, such as the military area of Shikhany. This "takeover" prompted other states to begin even more research of CWs. Despite the Allies' own research into CWs, very important technologies and "know-how" were obtained from Nazi Germany for both the United States and the former Soviet Union.

The interest in CW technology was probably one reason for the change of the future border: according to Churchill's history of WWII, the proposed future boundary between Poland and Germany had been primarily agreed to consist, in part, of the Oder River flowing to the Baltic Sea, and its tributary, the Neisse River. Before their confluence, the Neisse consisted of two branches, the East Neisse and the West Neisse. The East Neisse should be the boundary, resulting in slightly more territory for Germany. Stalin held for the West Neisse and progress was delayed. No one knows why Stalin was so insistent in this matter. The reason was probably very simple: the small town of Dyhernfurth (now Brzeg Dolny), a few kilometers north of Breslau (Wroclaw) in the disputed territory, contained a factory for the production of nerve agents. It was estimated that when Dyhernfurth was captured it contained stockpiles of 12,000 tons of tabun, 600 tons of sarin, and an unknown amount of soman. Presumably, the factory was dismantled and, along with their stockpiles, transported to the Soviet Union (Koelle, 1981). It has been documented that the Soviets were ready to conduct a chemical attack and their research and development of CWs were intensified.

In the United States during the 1950s, the chemical corporations concentrated on the weaponization of sarin. At the same time, they became interested in developing CWs that incapacitated rather than killed the targets. Mescaline and its derivatives were studied

but without practical output. Five years later, the new project "Psychochemical Agents" (later K-agents) was established. The objective was to develop a nonlethal but potent incapacitant. Nonmilitary drugs like LSD-25 and tetrahydrocannabinol were also examined. None of these agents was found to be of military importance. The first and only incapacitant was BZ, developed in 1962; however, its stocks were destroyed in 1992, as declared by the US delegation to the Conference on Disarmament in Geneva (Document of CD, 1991). These agents, intended not to kill but to induce incapacity, are covered under the class of nonlethal weapons (Hess et al., 2005).

In the former Soviet Union as a whole during 1940–1945, approximately 110,000 tons of first-generation toxic chemicals were produced, and most of them were yperite, lewisite, and irritating agents. Second-generation CWs were composed of nerve agents such as sarin, soman, V agents, and, to a lesser degree, tabun. The development of new third-generation CWs comprised traditional and nontraditional CWs, for example, blister and irritant agents and nerve gases, including new types such as Novichok 5, whose exact chemical structure is unknown, although some assessments have been made (Bajgar, 2006). It could be a nerve agent having high toxicity, and its effects are difficult to treat using common antidotes.

An example of the unintentional use of CWs has also been observed. In March 1968, thousands of dead sheep were discovered in the Skull Valley area in Arizona in the United States. This area was adjacent to the US Army's Dugway open-air testing site for CWs. Nerve gas had drifted out of the test area during aerial spraying and killed the sheep. One year later, on July 8, 1969, the Army announced that 23 US soldiers and one civilian had been exposed to sarin in Okinawa during the clearing of sarin-filled bombs (Sidell and Franz, 1997).

There are a number of examples of localized conflicts during which CWs have been intentionally used but cannot be verified: from 1951 to 1952 during the Korean War; in 1963, the Egyptians used mustard bombs against Yemeni royalists in the Arabian peninsula; during the Indo-China War (see Vietnam War); in 1970, in Angola, antiplant agents were almost certainly used; and in former Yugoslavia, there were rumors of the use of psychotomimetic agents.

Iraq–Iran and Afghanistan War

On September 22, 1980, Iraq launched its invasion against Iran. There has been mention of the large-scale use of CWAs in the Iran–Iraq war. In November 1983, Iran informed the United Nations that Iraq was using CWs against Iranian troops. Soon after, the use of CWs was unleashed. In addition, mustard and tabun were used. It is well-known that the Iraqi Government used these agents against its own citizens, more conspicuously at Halabja in March 1988. The CWs attack was the largest against a civilian population in modern times. More than 100,000 Iranians were poisoned with CWAs; sulfur mustard was the most frequently used and has induced a number of delayed complications in Iranian veterans (pulmonary, dermal, ocular, immune system depression, reproduction, malignancy, etc.) (Afshari and Balali-Mood, 2006). Other localized conflicts involving alleged use of CWs are described in detail in an extensive review (Robinson, 1971).

The Soviet Union probably used mustard (and nerve gas) in Afghanistan. The Afghanistan war was considered the Soviet Union's "Vietnam." The use of CWs was described by Sidell and Franz (1997). The use of CWs by Soviet forces was also significant and has been confirmed against unprotected subjects. Despite the use of CWs, the withdrawal of Soviet troops from Afghanistan was realized at the beginning of 1989.

Vietnam War

After WWII, the main use of CWs was recorded during 1961 to 1972, when the US Army used defoliants. The herbicide Agent Orange was used during the Vietnam War and led to the injury of more than one million Vietnamese and Americans. Agent Orange (a mixture of 2,4-dichlorophenoxy acetic acid and 2,4,5-trichlorophenoxy acetic acid) contained the chemical contaminant dioxin as an impurity that caused many deaths on both sides. There were other herbicide mixtures such as Agent White (2,4-D and picloram) and Agent Blue (cacodylic acid). The biological effects of dioxin were described by Sofronov et al. (2001). The first major operation of this type was conducted over the Ca Mau peninsula during September–October 1962. The areas sprayed with defoliants were five-times larger and 10-times larger in 1965 and 1967, respectively. The scale of the use of defoliants was approximately in proportion to the overall involvement of US troops. In 1970, herbicides and defoliants were used in tens of tons, especially 2,4,5-T. The area sprayed enlarged from 23 km^2 in 1962 to 22,336 km^2 in 1969. The area exposed to spraying was assessed to be 58,000 km^2 and the number of people exposed was assessed to be more than one million; there were more than 1000 deaths. In addition to defoliants used to destroy vegetation concealing the North Vietnamese, the United States used tear gas for clearing tunnels and bunkers. The irritants CS, CN, and DM were reported to be used. The total CS procured was approximately 7,000 tons from 1963 to 1969.

Development of VX Agent

VX was synthesized in the 1960s on the basis of the results of Tammelin and Aquilonius (Tammelin, 1957;

Aquilonius et al., 1964). The manufacturing of VX began in the United States in 1961. Construction of the United States' VX agent production plant at Newport, Indiana, was completed in 1961, when the first agent was produced. The production facility only operated for 7 years and was placed on standby in 1968 (Smart, 1997).

During the same period, Soviet scientists developed the so-called Russian VX (VR, RVX, R 033) (Kassa et al., 2006; Kuca et al., 2006). The chemical structure of VX was unknown for a long time. Therefore, some attempts to resolve this question have been made (Bajgar, 1968). Because of these ambiguities and difficulties in synthesis, model V agent [EDMM, *O*-ethyl *S*-(2-dimethylaminoethyl) methylphosphonothioate] was initially used in the Eastern Block to study antidotal treatment. Another structural analog of VX known as Chinese VX (CVX) was also developed and studied (Eckert et al., 2006).

A very important step in the development in CWs has been the production of "binary munitions," in which the final stage of synthesis of the agent from precursors is performed in the munition (bomb, shell, or warhead) immediately before or during delivery to the target. In the 1950s, armed forces had begun looking at binary weapons. Until this time, CWs were unitary—the toxic agent was filled in the munition and then stored ready to be used. The binary concept—mixing or storing two less toxic chemicals and creating the nerve agent within the weapon—was safer during storage. The production of binary projectiles began on December 16, 1987, at the Pine Bluff Arsenal in Arkansas.

PERSIAN GULF WAR

On August 2, 1990, Saddam Hussein sent Iraqi troops into Kuwait, allegedly in support of Kuwaiti revolutionaries who had overthrown the emirate. Iraq was known to have a large stockpile of CWs during its conflict with Iran and confirmed that they would use CWs.

President George H.W. Bush ordered US forces to be sent to Saudi Arabia at the request of the Saudi Government (Operation Desert Shield); this was the build-up phase of the Persian Gulf War. As a consequence, in 1996, almost 60,000 veterans of the Persian Gulf War claimed certain medical problems related to their war activities. Some were caused by exposure to nerve agents (released after the bombing and destruction of the sarin production facility). Unexplained "Gulf War Syndrome" with low-dose exposure to CWAs was suggested as a possible cause. Extensive research failed to find any single case of the problem. However, some health effects, including alterations to the immune system 3 months after the exposure to low concentrations of sarin, were demonstrated (Kassa et al., 2001, 2003). In the desert, during the autumn and winter of 1990–1991, the threat of chemical warfare became very real to allied military personnel. It was demonstrated by the UN Commission that major Iraqi agents were mustard, tabun, sarin, and cyclosarin. Mustard agent was relatively pure, but nerve agents were a complex mixture of the agent and degradation products. During the period from June 1992 to June 1994, the Commission's Chemical Destruction Group destroyed 30 tons of tabun, 70 tons of sarin, and 600 tons of mustard, which were stored in bulk and in munitions.

Suddenly, it became clear to the whole world that there were countries with CWs and biological weapons, and there were other countries that might obtain or produce them.

SYRIA

The conflict in Syria has been the last conflict in which the use of CWs was confirmed by the UN Mission (UN, 2013). Nerve agent sarin was used in an attack on the Ghouta area of Damascus (August 21, 2013). It is not the intention of this chapter to evaluate political situations; however, it was not possible to decide exactly who used sarin (current government or FSA) against civilian victims. First complex reactions were published in October 2013 in the CBRNe World (Higgins, 2013; Johnson, 2013; Kaszeta, 2013; Winfield, 2013). For the Mission, there were not ideal conditions: difficult political situation, chaotic scene, and timing that was not ideal. However, the report was well-structured and conclusions were clear: sarin was present in some samples and rocket remains, and selected survivors showed symptoms supporting sarin exposure (Johnson, 2013).

There are different data regarding the number of victims, initially varying from hundreds to thousands. The Syrian Observatory for Human Rights reported more than 500 deaths and thousands of patients displaying "neurotoxic symptoms," including civilian people and children. Medicine Sans Frontiers said at least 3600 patients had these symptoms and, of those patients, 355 had died. UN Mission selected 36 from 80 survivors who met the criteria established by the Mission. Symptoms consistent with organophosphate intoxication were observed: decreased consciousness (78%), dyspnea (61%), blurred vision (42%), eye irritation or inflammation (22%), lacrimation (8%), miosis (14%), salivation (22%), vomiting (22%), and convulsion (19%). Johnson (2013) did not mention the postmortem samples or data regarding dead persons. Treatment of victims and the course of poisoning, including laboratory results, have not been specified. However, laboratory examinations would be useful, as in case of Tokyo victims (Polhuis et al., 1997). It would be possible to use other methods

of laboratory diagnoses of nerve agent intoxication, as described previously (Noort et al., 2009; Schans van der, 2009; Bajgar, 2013). Autopsies of victims were not conducted but would have been useful, as would postmortem examinations of dead animals. Regarding CWs of Syria, they will be destroyed under the supervision of Organization for Prohibition of Chemical Weapons (OPCW) (for Syria, CWC entered into force on October 14, 2013) and with international assistance.

UNINTENTIONAL USE OF TOXIC CHEMICALS

There are two main accidents connected with the release of toxic chemicals. In July 1976, in Seveso, Italy, more than 40,000 people were exposed to dioxin, a persistent and highly toxic chemical. The first signs were skin lesions appearing on children, and after some months there was evidence of chloracne. Health consequences have been observed from that time to the present. The Seveso accident was possibly the most systematically studied dioxin contamination incident. A similar contamination of one building of the Spolana company in Neratovice (a town in the former Czechoslovakia) was also observed (Bajgar et al., 2007a; Pelclová et al., 2011). Another example, the Bhopal accident, is probably the greatest industrial disaster in history. In 1984, on December 2 and 3, water inadvertently entered the methylisocyanate storage tank (containing approximately 40 tons of this chemical). As a result, methylisocyanate was released into the surrounding area. There was no warning. Many people who inhaled high concentrations of toxic gas asphyxiated because of extensive lung damage. Approximately 150,000 people were intoxicated (50,000 seriously poisoned) and more than 2500 people died (Bajgar, 2006).

TERRORIST USE OF CWS

Terrorists have expressed an interest in nerve agents and have deployed them in attacks on unprotected civilians (Rotenberg and Newmark, 2003). A Japanese religious cult, Aum Shinrikyo, independently manufactured numerous chemical and biological agents. The first such attack with sarin occurred in Matsumoto in 1994 and in the Tokyo subway in 1995. Thousands of people were affected and dozens of people died (Ohtomi et al., 1996; Nagao et al., 1997; Okomura et al., 1998; Yokoyama et al., 1998). In Matsumoto (1994), 600 people were poisoned and hospitalized and seven died (Morita et al., 1995; Nakajima et al., 1997; Yoshida, 1994). The attack in the Tokyo subway (1995) resulted in 5500 people seeking hospital evaluation and 12 deaths (Bajgar, 2006). An interesting terroristic act was described by Tsuchihashi et al. (2005)—a fatal intoxication with VX administered percutaneously.

Nerve agents belong to the group of OPs. These compounds in the form of pesticides are commercially available and are used in agriculture, which can lead to professional, suicidal, or accidental intoxication. The mechanism of action, diagnosis, and treatment of intoxication with OP pesticides and nerve agents are very hot topics at present. Moreover, some principles of the effects, diagnosis, and therapy are very similar for OP and highly toxic nerve agents; therefore, the principle of action and effective treatment can be applied in general for the civilian sector, too.

The use of these chemicals was observed in Moscow in 2002. The Moscow theater hostage crisis was the seizure of a crowded theater on October 23, 2002 by approximately 40 armed Chechen militants who claimed allegiance to the separatist movement in Chechnya. They took 850 hostages and demanded the withdrawal of Russians from Chechnya and an end to the Chechnya war. The leader of the terrorists was 22-year-old Movsar Baraev. After 2.5 days of waiting, Russian forces used an unknown gas pumped into the ventilation system. Officially, 39 terrorists and at least 129 of the hostages (nine of them foreigners) were killed. Some estimates have put the civilian death toll at more than 200. It was thought that the security services used an aerosol of a CWA, first assessed as BZ, but later it was specified that an aerosol anesthetic of the Fentanyl type was used (Bajgar and Fusek, 2006).

In the hospitals, the survivors were cut off from any communications with the outside and their relatives were not allowed to visit them. An incorrect list of hospitals for victims was released. The main problem was the lack of information about those dealing with the identification and characterization of the chemical used and the unavailability of known antidotes (e.g., naloxon) by medical staff treating the victims (Bajgar et al., 2007a). It appeared from this event that there were compounds not explicitly enumerated in the CWC and therefore not controlled by this Convention. Fentanyl can be considered as a nonlethal weapon (a group of so-called calmatives) and these chemicals can also be used to incapacitate animals; of course, its use against humans is not excluded (Bajgar, 2006; Hess et al., 2005).

NEGOTIATIONS

Although the Cold War was continuing, the political situation led to increased activities in international negotiations. At the Conference on Disarmament in Geneva, some attempts to negotiate a ban of CWs were begun, first as the ad hoc Working Group, and later as the ad hoc

Committee on Chemical Weapons with the mandate to negotiate the text of a convention banning CWs.

The discussions in Geneva were more intensive from 1987 and, in 1992, the elaboration of the so-called rolling text of future CWCs was finished. During these negotiations, the text of future Conventions ("rolling text") was enlarged: the final report (CD/342) of February 2, 1983 contained 23 pages; the same report of August 23, 1985 (CD/636) had 46 pages; and CD/952 of August 18, 1989 contained 134 pages. Simultaneously with the Geneva negotiations, in September 1989, the Memorandum of Understanding between the Governments of the United States and the USSR regarding a bilateral verification experiment and data exchange related to prohibition of CWs, otherwise known as the Wyoming Meeting, started negotiations between two main possessors of CWs. These countries also contributed to the negotiations in Geneva: they demonstrated their CWs to the Conference on Disarmament in the United States in November 1986 (Tooele) and in the USSR in October 1987 (Shikhany). The final document of the Convention is approximately 200 printed pages. The Convention was then agreed on in New York at the UN General Assembly and signed in Paris in 1993. The CWC (Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and on their Destruction) entered into force on April 29, 1997, 180 days after the deposit of the 65th instrument of ratification of the Convention by Hungary. At this time, 87 countries ratified the CWC and became original States Parties to the Convention. Simultaneously, the OPCW in The Hague started its work of supervising the destruction of CW stocks and monitoring the world's chemical industry to prevent future misuse. There are many activities of the OPCW, for example, training of the inspectors for control of destruction of CWs including their medical protection, research, and supported activities, solving problems due to practical implementation of the CWC, control of chemical and military facilities, and other activities. Russia and the United States were unlikely to meet the final stockpile destruction deadline of April 29, 2012. By the middle of 2008, 183 signing States and 194 recognizing States had adhered to the Convention (Davey, 2008). However, there are still States that are nonsignatories to the Convention. CWs have a long and ancient history. A lack of CW use in WWII suggested that "gas warfare" had ended. However, further development and the utility of chemicals in Vietnam and in terrorist attacks have maintained a military interest in CWs.

Current information of OPCW provides the status of the destruction of CWs. April 29, 2012 was suggested to be the prolonged period for CW destruction. Seven State Parties declared they possessed CWs (Albania, India, Iraq, South Korea, Libya, Russia, and the United States). The stocks of Albania, India, and South Korea were destroyed. Until this date, 73.72% of all declared CWs (the sum of 71,195.086 tons) were destroyed (Streda, 2013). On the basis of the Conference of the State Parties (16th Session, December 2011), the destruction period was prolonged for Russia (2015), Libya (2016), and the United States (2023). Simultaneously, CW-producing facilities were also destroyed or dismantled—13 State Parties declared 70 of these facilities (Bosnya and Hercegovina, China, France, India, Iraq, Iran, Japan, South Korea, Libya, Russia, Serbia, Great Britain, and the United States) and 43 of these objects were destroyed and 21 were dismantled for peaceful purposes.

It is clear that the use (incidental or otherwise) of toxic chemicals has impacts on different spheres of human existence, such as state structures and infrastructure, economics, psychic and public behavior, and the environment. Toxic chemicals are a great consumer of natural sources, both renewable and nonrenewable. They also consume raw materials and energy and, as a consequence, cause pollution of the environment and lead to deficiency of raw materials throughout the world and therefore an unequal distribution of the world's natural sources. The impact on the psychology of humankind is also important, following either chemical wars (both global and local) or use of these chemicals by terrorists. The development of new technologies is equally important because they influence, positively and negatively, further human development. Research in this direction not only can contribute to "improvement" of chemicals to obtain more effective CWAs but also can improve our knowledge of basic sciences (toxicology, neuropharmacology, etc.) and allow us to better understand physiological functions in general. It is appropriate to recall the history of cholinesterases and their inhibitors. The existence of cholinesterases was predicted by H.H. Dale in 1914, 14 years before acetylcholine was demonstrated as a natural constituent of animal tissues. This research approach was changed during WWII and cholinesterases acquired a special significance in the context of chemical warfare and nerve agents (Silver, 1974). Another publication in this area (Koelle, 1963) can be considered as the first to deal with anticholinesterase agents including CWAs—nerve agents. One can only hope that in the future the only physiological and pharmacological research will be performed in a nonmilitary framework, but that may not be the case.

CONCLUDING REMARKS AND FUTURE DIRECTION

The threat of the use (either military or terroristic) of CWAs (and other toxic chemicals) still exists. The military use of these agents is limited, but their terroristic use is unlimited. The spectrum of these agents is very large and the ability to be prepared against the use of toxic chemicals is necessary.

CHAPTER

4

The Tokyo Subway Sarin Attack: Acute and Delayed Health Effects in Survivors

Tetsu Okumura, Kenji Taki, Kouichiro Suzuki, Takemi Yoshida, Yukio Kuroiwa and Tetsuo Satoh

INTRODUCTION

The Tokyo subway sarin attack occurred in 1995. Prior to the disaster in Tokyo, Matsumoto sarin attack happened on June 27 in 1994 in Matsumoto city, Nagano Prefecture at the center of Japan main land. Sarin was dispersed into the open air using an electric heater fan to direct it to the target apartment. Eventually, eight people died and 660 were injured. In addition to these injured patients, one woman exposed to sarin died after 14 years hospitalization. This was the first terrorist attack using sarin on the general public in the world, an incident which served as a wake-up call for anti–nuclear, biological, and chemical (NBC) terrorism policy throughout the world. In the 10 years since the attack, efforts to combat NBC terrorism have focused on rapid and effective measures to respond to attacks employing nerve agents such as sarin.

SARIN TOXICITY AND MECHANISM OF ONSET

Sarin is an organophosphate compound. Within the context of chemical weapons, organophosphates are collectively referred to as "nerve agents," of which sarin, tabun, soman, and *O*-ethyl *S*-[2-(diisopropylamino) ethyl] methylphosphonothioate (VX) are examples. Organophosphates inhibit the enzyme acetylcholinesterase (AChE), which degrades acetylcholine (ACh), a neurotransmitter substance that acts locally on nerve synapses. Once organophosphates bind to the phosphorylate AChE to inhibit its activity, ACh accumulates at nerve terminals, resulting in enhanced ACh activity at receptor sites. ACh effects can be functionally classified based on their site of action and can have muscarinic, nicotinic, and central nervous system (CNS) effects. These effects cause the major symptoms associated with an acute organophosphate toxicity. Muscarinic effects increase parasympathetic nerve activity and cause miosis, visual disturbances (accommodation disorder), increased salivary and bronchial secretions, bronchospasm, bradycardia, and increased gastrointestinal peristaltic activity (e.g., abdominal pain, nausea, vomiting, and diarrhea). Nicotinic effects, due to hyperstimulation of neuromuscular junctions, cause fasciculations, muscle weakness, and respiratory paralysis, and increased sympathetic nerve activity leads to miosis, sweating, tachycardia, and hypertension. CNS effects due to ACh, when severe, include anxiety, headaches, excitement, ataxia, somnolence, disorientation, coma, and seizures.

Well-known symptoms of sarin toxicity include miosis, hypersecretions, bradycardia, and fasciculations. However, the mechanism of organophosphate toxicity seems to involve conflicting actions. For example, mydriasis or miosis, and bradycardia or tachycardia may occur. Acute respiratory insufficiency is the most important cause of immediate death. Early symptoms include (i) tachypnea due to increased airway secretions and bronchospasm (a muscarinic effect), (ii) peripheral respiratory muscle paralysis (a nicotinic effect), and (iii) inhibition of respiratory centers (a CNS effect), all of which lead to severe respiratory deficiency. If left untreated at this stage, death will result. Cardiovascular symptoms may include hypertension or hypotension. Various arrhythmias can also occur, and caution is required when the QT interval is prolonged. In particular, if hypoxemia is present, fatal arrhythmias may occur with intravenous administration of atropine

Handbook of Toxicology of Chemical Warfare Agents.

sulfate, which means that this drug should be given intramuscularly to victims of sarin poisoning. Common gastrointestinal symptoms of this poisoning include nausea, vomiting, and diarrhea.

An intermediate syndrome lasting 1–4 days after sarin exposure appears to exist (De Bleecker, 1992). This is due to prolonged AChE inhibition, and it is associated with acute respiratory muscle paralysis, motor nerve paralysis, and cervical flexor and proximal muscle paralysis. Recumbent patients who have difficulty raising the head and neck require particular care. However, the intermediate syndrome has not been reported with nerve agent toxicity in animals or humans (Sidell, 1997), although this syndrome is well documented in humans following large exposure to organophosphate and carbamate pesticides (Gupta, 2005; Paul and Mannathukkaran, 2005; Gupta and Milatovic, 2012). The cause of the intermediate syndrome may be toxicity due to massive organophosphate exposure or inadequate treatment of such exposure (intestinal decontamination, antidote administration, and respiratory management). In organophosphate-induced delayed neuropathy (OPIDN), seen 2–3 weeks after exposure and characterized by distal muscle weakness without fasciculation, the pathophysiology is not well understood. OPIDN was first reported in the 1930s due to contamination of Jamaican ginger (nicknamed *Jake*) by organophosphates. This incident (so-called ginger jake paralysis) caused lower limb paralysis in about 20,000 victims. OPIDN symptoms have also recently been reported in Matsumoto and Tokyo subway sarin victims (Sekijima et al., 1997; Himuro et al., 1998). Inhibition and aging of neuropathy target esterase plays a role in OPIDN, but despite several basic research studies, the detailed pathophysiology has not yet been established, making OPIDN difficult to treat.

OVERVIEW OF THE TOKYO SUBWAY SARIN ATTACK

The attack took place during the morning rush hour, at about 8 a.m. on March 20, 1995, the day before the Spring Equinox holiday. The attack was carried out by members of a cult known as Aum Shinrikyo to distract police from carrying out a raid on the group's headquarters. The terrorist target was government buildings in Kasumigaseki in the heart of Tokyo. Most offices in Kasumigaseki open for business at 9:30 a.m., but the early-morning rush hour was unusually heavy because it was a Monday. Some believe that the time of 8 a.m. was chosen because some cult members had inside information about the government offices. Police suspected, based on an undercover investigation that they were conducting, that Aum Shinrikyo was manufacturing sarin for use in a terror attack, but few people, even within the police department, were aware of this fact. The police did not have personal protective equipment (PPE), which meant that they had to borrow PPE and receive training on use of the equipment from the Self-Defense Forces. Members of the Self-Defense Forces were alerted to some of Aum Shinrikyo's planned activities, but the general public, including healthcare providers and fire department personnel, knew nothing of these activities (Figure 4.1).

According to a subsequent police report, the terrorists placed sarin in five subway trains in the following way.

FIGURE 4.1 Scene from a sarin attack at Tsukiji station.

Approximately 600 g of sarin at a concentration of 33% was mixed with hexane and *N*, *N*-diethylaniline and placed in a nylon/polyethylene bag. Five terrorists then wrapped the bags in newspaper, punctured the bags with the tips of their umbrellas, and left the bags on the trains. In this way, the sarin seeped out of the bags and vaporized, but no other active means of dispersal were used. In this sense, as well as the relatively low number of deaths, the Tokyo subway sarin attack was not considered a full-scale attack.

Of the bags of sarin used in the attack, two bags were not punctured. These bags were returned to the police laboratory for analysis. At Kasumigaseki, one of the subway stations on the Chiyoda subway line, two station employees collapsed and died on the platform after they cleaned and removed one of the bags that didn't get punctured, even though they were wearing gloves. The number of victims of this attack varies depending on the source, but all known information confirms that 12 people died in the attack, and it is generally believed that at least 5,500 victims suffered mild to serious injuries. Firefighting agencies estimate 5,642 victims, and the police, 3,796 victims, while official figures released by the subway company put the total number of victims at 5,654. This includes the 12 who died (10 passengers, 2 employees), those hospitalized (960 passengers, 39 employees), and those treated for minor injuries (4,446 passengers, 197 employees).

Thus, the way in which we use the lessons learned from this attack will affect our ability to deal adequately with future terrorist attacks using sarin, which could be even greater and more serious with respect to the number of victims. Can we really assume that only 12 of the approximately 5,500 victims died because the Japanese medical system was particularly well prepared for such an eventuality? Probably not. It is more likely that the relatively small number of fatalities was due to the low concentration of sarin and the passive means of dispersing it. From this perspective, the Matsumoto sarin attack one year earlier was more aggressive than the Tokyo subway sarin attack. In a trial after the Matsumoto incident, it was revealed that a 70% concentration of sarin was actively volatilized using an electric heater and dispersed using an electric fan. A total of 7 victims died and 660 were injured and one victim died 14 years after sarin exposure. In other words, if the Tokyo subway sarin attack had been conducted using the same means as those employed in the Matsumoto sarin attack, the number of fatalities may have been 50 or 60. So humanity has not yet experienced the effects of a full-scale sarin attack in a major city.

Even if it did not rise to the level of a major attack, this incident was the first chemical terrorist attack in a large city. There were few first-responders who could even have conceived of such an attack, let alone be prepared to rapidly evacuate victims from the subway stations. Many passengers who had difficulty walking rushed out of the trains and onto the subway platform and fell down, which would have increased their exposure to the sarin permeating the stations. In addition, the site to which many of the victims were finally evacuated at ground level, where they could lie down, was close to an air exhaust vent from the subway below, so the exposure continued.

The first call for an ambulance came 9 minutes after the 8 a.m. attack, with the first report of a "victim with seizures at Kayabacho Station." By 8:15 a.m., the reports of victims started to increase. Around this time, the fire department received a report from Tsukiji Station stating that "an explosion occurred and several people were injured." Calls for ambulances eventually came from 19 subway stations, and after 8:30 a.m., victims began to pour into local clinics and hospitals. According to the Tokyo Fire Department, 5,493 people were treated at 267 medical institutions in Tokyo, and 17 people were treated at 11 medical institutions outside Tokyo. Among the victims, 53 were seriously injured (Ieki, 1997). Another source states that a total of 6,185 people were treated at 294 medical institutions (Chigusa, 1995). The discrepancy in the number of victims reported by different agencies attests to some of the confusion at the time. St. Luke's Hospital received the largest number of victims (640 on the day of the attack), probably because of its close proximity to the Hibiya line, where a large number of victims were located, and because of a report on television stating that "St. Luke's Hospital has the antidote for treatment."

EMERGENCY TREATMENT OF SARIN TOXICITY

The standard treatment for sarin toxicity includes (i) maintaining the airway, (ii) assisting breathing, and (iii) supporting circulation. In victims of the Tokyo subway sarin attack, endotracheal intubation was performed frequently. However, in the Matsumoto sarin attack, endotracheal intubation was more difficult to do in many victims because of airway hypersecretion and bronchospasm. This difference in symptoms is attributable to the 70% concentration and the active means by which the sarin was dispersed at Matsumoto, as opposed to the much lower 33% concentration and passive means of dispersal employed in Tokyo. Dr. Frederick Sidell, an expert on chemical terrorism in the United States, advocated decontamination, drugs, airway, breathing, and circulation (DDABC) as the basic treatment for nerve agent poisoning. Even if the advised emergency treatment is followed, initial efforts to achieve adequate ventilation may be in vain. Efforts to achieve adequate ventilation should be made after at least initial administration of atropine to control the buildup of airway secretions and bronchoconstriction (Sidell, 1997). If healthcare

professionals learn from the Matsumoto attack, they can better recognize early parasympathetic nervous symptoms, including miosis, hypersecretion, and rhinorrhea, as common indications of chemical terrorism due to nerve agents, and therefore be able to institute appropriate treatment with antidotes in time. In large-scale disasters with many victims, treatment is often deferred in those with cardiopulmonary arrest (CPA; so-called black tag). However, at St. Luke's Hospital, one in three persons with CPA and two patients with respiratory arrest made a full recovery and were discharged. This high rate of recovery and return to the community is unlike that seen in other types of disasters. Therefore, if medical resources are available, all victims of a sarin attack should be aggressively treated, including cardiopulmonary resuscitation (CPR) when necessary.

The global standard for the treatment of sarin toxicity is the administration of (i) atropine, (ii) an oxime agent like 2-PAM, and (iii) diazepam (Medical Letter, 2002).

Recommended doses of atropine are 2 mg in patients with mild symptoms that are primarily ocular, but without respiratory symptoms or seizures; 4 mg in patients with moderate symptoms, including respiratory symptoms such as dyspnea; and 6 mg in patients with severe symptoms, including seizures and respiratory arrest. The standard administration route should be intramuscular. As mentioned previously, intravenous administration of atropine in the treatment of severe symptoms such as hypoxemia can induce ventricular fibrillation; thus, intramuscular administration is advised. Oxime agents such as 2-pralidoxime methiodide (2-PAM), or 2-formyl-1-methylpyridinium iodide oxime should also be given. The recommended dose for 2-PAM in moderate and severe cases of inhalation, or for liquid exposure to a nerve agent, is 1 g by intravenous infusion over 20–30 min. Further continuous administration of 500 mg/h may also be required in severe cases. Since the rate of aging of the nerve agent–enzyme bond is correlated with time until 2-PAM is administered, if the aging half-life of sarin is 5 h, then 2-PAM must be administered before this time. The oxime of choice for sarin and VX is 2-PAM, but asoxime chloride (HI-6) should be used for soman and obidoxime for tabun. Seizures are treated with diazepam. This three-drug combination (atropine, 2-PAM, and diazepam) is the global recommendation for sarin toxicity, and autoinjectors are available in several countries (Vale et al., 2006) (Figure 4.2).

After the Tokyo subway sarin attack, St. Luke's Hospital, which treated 640 victims, used about 700 ampules of 2-PAM and 2,800 ampules of atropine (Okumura et al., 1998). This calculates out to 550 mg of 2-PAM and 2.2 mg of atropine per victim. The route of administration was intravenous in all cases, with a total dose of 1.5–9 mg of atropine in severe cases (Okumura et al., 1996); this range of dose reflects the low concentration and passive means of sarin dispersal used in the Tokyo attack.

However, in Tokyo, no one was saved by administration of 2-PAM; conversely, no one died because they did not receive it. In other words, if the victims' survival was the ultimate goal, there was no clinical evidence that 2-PAM was effective. The only reported finding was a more rapid return of plasma pseudocholinesterase levels to normal in patients who received 2-PAM, as compared to those who did not. But in terms of long-term prognosis, this does not rule out the effectiveness of oxime

FIGURE 4.2 Sarin victims at St. Luke's International Hospital.

therapy. Ideally, detailed studies are needed to evaluate the efficacy of 2-PAM, including for long-term prognoses. To date, however, there has been no sophisticated study of the Tokyo subway sarin attack in this vein.

One piece of evidence supporting the efficacy of 2-PAM to treat sarin toxicity has been the clinical benefit associated with it when treating toxicity due to organophosphorus pesticides. However, some experts now doubt whether such a benefit really exists. For example, Peter et al. (2006), using meta-analytic techniques, reevaluated the effects of oxime therapy in organophosphate poisoning. Not only did they find no beneficial effects, they reported possible adverse effects. The Cochrane Reviews for clinical evidence-based medicine (Buckley et al., 2005) reported no risk/benefit evidence supporting the use of oxime agents in organophosphate poisoning, but they did conclude that further detailed investigations are necessary.

According to reports about Iranian physicians who treated sarin toxicity during the Iran–Iraq war (Newmark, 2004), 2-PAM was not available on the front lines, and atropine alone was used for treatment. The doses of atropine used were considerably higher than those used in the Tokyo subway sarin attack, or that are generally recommended in the United States (Medical Letter, 2002). The Iranian protocol called for initial administration of 4 mg intravenously. If no atropine effects (improvement in dyspnea or decrease in airway secretions) were seen after 1–2 min, 5 mg was then administered intravenously over the next 5 min while the heart rate was monitored. A rise in heart rate of 20–30 beats per minute was diagnosed as an atropine effect. In severe cases, 20–200 mg was given. Regardless of the dose, the key to saving lives, according to this protocol, was how soon the atropine was administered.

Thus, treatment without the use of an oxime agent is possible. Of course, in countries where this is economically possible, treatment should use the combination of atropine, an oxime agent like 2-PAM, and diazepam. In addition, the use of autoinjectors for administration is also helpful. Unfortunately, terrorist attacks using sarin are also carried out in less economically developed countries; and even if the drugs are available, performance relative to cost needs to be considered. In this sense, preference should be given to the availability of atropine and diazepam. In other words, unless it is economically feasible, funds should be used to obtain atropine and diazepam rather than oxime agents, whose cost–benefit ratio is still inconclusive.

ACUTE AND CHRONIC SYMPTOMS OF SARIN TOXICITY

Based on data from 627 victims treated at St. Luke's Hospital (Okumura et al., 1998), the symptoms, listed in order of prevalence, were miosis (pupillary constriction; 90.5%), headache (50.4%), visual impairment (37.6%), eye pain (37.5%), dyspnea (29.2%), nausea (26.8%), cough (18.8%), throat pain (18.3%), and blurred vision (17.9%). Cases were categorized as severe if they involved seizures or respiratory arrest requiring mechanical ventilation, moderate for respiratory distress or fasciculations, and mild for eye symptoms only. Of 640 cases reported by St. Luke's Hospital, the degree of intoxication was severe in 5 victims, moderate in 107, and mild in 528, with nicotinic effects observed in those with moderate or severe symptoms.

In the Tokyo subway sarin attack, decontamination was not performed on site, and first-responders and healthcare workers initially did not wear PPE. As a result, of 1,364 firefighting personnel, 9.9% became secondary victims. At that time, TV, and newspapers reported on the sarin attack every day, and many people in Japan were scared of the sarin incident surrounding them. At St. Luke's Hospital, 23% of the hospital staff became secondary victims (Okumura et al., 1998). The percentage of secondary victims by hospital occupation was as follows: nursing assistants (39.3%), nurses (26.5%), volunteers (25.5%), doctors (21.8%), and clerks (18.2%). Thus, increased contact with a primary victim increased the risk of becoming a secondary victim. The percentage of secondary victims by hospital location were the chapel (45.8%), the intensive care unit (38.7%), the outpatient department (32.4%), the general ward (17.7%), and the emergency department (16.7%). The high rate of secondary victims in the chapel was attributed to poor ventilation and the large number of victims sheltered there. Because it was during the winter, victims entered the chapel fully clothed. When they removed their coats, and every time they moved thereafter, some of the sarin trapped inside the clothing probably escaped, causing secondary exposure. Fortunately, none of the secondary victims died. However, if a higher concentration of sarin and more effective means of dispersion had been employed in the Tokyo attack, as had been done in the Matsumoto incident, then it is likely that some of the secondary victims would have died.

Within the context of risk communication, the so-called worried-well, who were concerned about having been exposed to the nerve agent, and those complaining of symptoms even though actual exposure was unlikely, also flocked to hospitals seeking treatment (Bloch et al., 2007). As previously mentioned, among patients treated at St. Luke's Hospital on the day of the attack, 90.5% had miosis, an objective finding due to sarin exposure, but the remaining 9.5% were considered to be worried-well patients.

The reason or reasons for the small number of worried-well patients in the Tokyo subway sarin attack are unclear. Given the extensive coverage by the news media, who

mentioned that victims were crowding into St. Luke's Hospital, persons without definitive symptoms, or those who were unsure whether they had been exposed but who did not want to add to the confusion, likely avoided going to that hospital, which created a kind of natural selection process. Another contributing factor may have been that the target of the attack was the government buildings in Kasumigaseki in the heart of Tokyo, which meant that many of the victims were probably well educated. Conversely, unfamiliarity with sarin and toxic gases in general may also have contributed to the low number of such patients. In either case, these observations should be reviewed from the perspective of risk communication.

Only one victim from the Matsumoto and Tokyo subway sarin attacks has still not regained consciousness; that person remains in a vegetative state due to anoxic brain damage (Yanagisawa et al., 2006). Sarin victims treated at St. Luke's Hospital were regularly followed for the development of chronic symptoms. One year after the incident, a survey was conducted, and 303 of 660 victims responded (Ishimatsu et al., 1996). A total of 45% of the respondents reported that they still experienced symptoms. In terms of physical symptoms, 18.5% of the victims still complained of eye problems, 11.9% of easy fatigability, and 8.6% of headaches. Regarding psychological symptoms, 12.9% complained of fear of subways, and 11.6% still had fears related to escaping the attack. In another survey conducted after 3 years, 88% of the respondents reported several aftereffects (Okumura et al., 1999). Unfortunately, these surveys may lack objectivity. For example, the response rate may have been higher among victims still complaining of symptoms.

Murata et al. (1997) performed a controlled comparison study in victims 6 to 8 months after the attack, with evaluations of event-related and visual-evoked potentials (VEP), brainstem auditory evoked potentials, electrocardiographic R–R interval variability (CVRR), and scores on a posttraumatic stress disorder (PTSD) checklist. In the sarin victims, P300 and VEP (P100) latencies were significantly prolonged, and CVRR was abnormal, indicating depression of cardiac parasympathetic nervous activity. The findings suggested persistent effects of sarin in the higher and visual nervous systems. In another study, Yokoyama et al. (1998a) reported a delayed effect on the vestibulo-cerebellar system induced by acute sarin poisoning. Yokoyama et al. (1998b) also reported a chronic effect on psychomotor performance. In addition, Miyaki et al. (2005) described the chronic effects associated with psychomotor and memory function up to 7 years after exposure. As mentioned previously, two victims with OPIDN were reported (Sekijima et al., 1997; Himuro et al., 1998).

As part of a series of scientific studies sponsored by the Japanese Ministry of Health, Labor, and Welfare, Matsui et al. (2002) conducted two studies 7 years after the sarin attack. The first was a case control study comparing victims treated at St. Luke's Hospital with a non-sarin-exposed patient group. Statistical analysis showed significantly higher rates of chest pain, eye fatigue, presbyopia, eye discharge, nightmares, fear, anxiety, difficulty in concentrating, and forgetfulness in the victim group. Moreover, in the victim group, there were even significantly higher rates of visual blurring, myopia, problems with focal convergence, abnormal eye sensations, flashbacks, fear of returning to the attack site, and not wanting to watch news about the attacks. The rate of PTSD, as evaluated by several diagnostic criteria, was also higher in the victim group. The second research consisted of a cohort study comparing a group who required medical intervention after the attack with a group who did not. For lethargy, diarrhea, myopia, presbyopia, problems with focal convergence, eye discharge, and apathy, there were no significant differences between the groups; however, for other evaluated parameters, scores were significantly higher in the nonintervention group. Comparison of PTSD incidence, based on whether intervention was received or not, showed that the nonintervention group had a significantly higher rate of masked PTSD. There was a higher incidence of eye symptoms in the victim group than in the nonvictim group, but there was no difference between the intervention and nonintervention groups. Thus, eye symptoms are probably long-term physical aftereffects of sarin exposure. In some Matsumoto cases, persistent electroencephalogram changes without seizure activity have been reported up to 5 years later (Yanagisawa et al., 2006).

The results of these studies suggest some long-term effects of sarin toxicity and careful follow-up and observation are indicated in these victims.

LONG-LASTING INDEFINITE COMPLAINTS OF SARIN-EXPOSED VICTIMS

In 1996, the supporting group for sarin-attack victims was formed. The group members, who consist of medical doctors and volunteers, are committed to treating victims. In 2001, the group was reconstructed into the nonprofit Recovery Support Center (RSC). The RSC has followed up the long-lasting complaints of these victims up to 2012, looking at the aftereffects and indefinite complaints of the sarin victims. The psychiatric term "indefinite complaints" means one patient complains and many indefinite patients also complain without particular reasons.

As shown in Table 4.1, the AChE activity of the long-lasting victims has returned to normal levels. However, they continue to suffer from sustained "indefinite complaints" even 19 years after the disaster.

TABLE 4.1 The Sequelae of Indefinite Complaints of Sarin Victims

Complaints of the Sarin Victims	2008 (137) (%)	2010 (121) (%)	2012 (113) (%)
Sluggish	67.1	43.8	34.5
Fatigue	78.8	48.8	33.6
Easy to catch cold	30.6	22.3	12.4
Low grade fever	14.5	7.4	10.6
Dyspnea	20.4	16.5	21.2
Constricting chest pain	22.6	16.5	22.1
Palpitation	27.7	22.3	17.7
Nausea	8.0	9.1	0.7
Diarrhea	26.2	14.9	16.8
Abdominal pain	17.5	14.1	11.5
Appetite loss	5.8	10.7	0.4
Dizziness	45.9	29.8	23.9
Headache	61.3	33.1	24.8
Eye strain	83.9	66.9	46.0
Dim	76.6	60.3	43.4

Numbness	49.6	26.4	32.7

Numbers in parenthesis indicate sarin victims who received medical examinations. (%) means the percent of victims who suffered from the complaints. Sarin victims who could not attend to consult medical examinations with similar numbers or more were taken separately by inquiries of questionnaire survey and their sequelae answered had similar tendency with respect of indefinite complaints.

Table 4.1 also shows a higher incidence of eye symptoms, including eye fatigue, eye discharge, chest pain, nightmare, fear, anxiety, and so on. Additionally, blurred vision, problems with focal convergence, abnormal eye sensations have been raised with higher rates compared to the non-exposed group.

In the medical examinations carried out on 2008, over 50% of the responding victims claimed a high incidence of symptoms such as sluggishness, fatigue, headache, eye strain, and difficulties seeing distant objects. These results suggest that victims still suffer from these indefinite complaints in their daily lives. Fortunately, comparing the data from 2010 and 2012 shows that these indefinite complaints tend to be going down each year. However, many sarin victims still live with discomfort. Thus, it is necessary to find therapeutic treatment methods to improve such long-lasting and intractable medical conditions.

LABORATORY FINDINGS IN SARIN TOXICITY

According to inpatient records from St. Luke's Hospital, the most common laboratory finding related to sarin toxicity was a decrease in plasma cholinesterase (ChE) levels in 74% of patients. In patients with more severe toxicity, plasma ChE levels tended to be lower, but a more accurate indication of ChE inhibition is the measurement of erythrocyte ChE, as erythrocyte acetylcholinesterase (AChE) is considered "true ChE" and plasma ChE is "pseudo-ChE." However, erythrocyte ChE is not routinely measured, whereas plasma ChE is included in many clinical chemistry panels; thus, it can be used as a simple index for ChE activity. In both the Matsumoto and Tokyo subway sarin attacks, plasma ChE served as a useful index of sarin exposure. In 92% of hospitalized patients, plasma ChE levels returned to normal on the following day. In addition, inpatient records from St. Luke's Hospital showed an elevated creatine phosphokinase and leukocytosis in 11% and 60% of patients, respectively. In severe cases such as the Matsumoto attack, hyperglycemia, ketonuria, and low serum triglycerides due to the toxic effects of sarin on the adrenal medulla were observed (Yanagisawa et al., 2006).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

This chapter has discussed sarin toxicity based on experiences of the attacks in Matsumoto and the Tokyo subway, as well as the Iran–Iraq war. This section provides some conclusions drawn from the toxicological issues related to sarin.

Given the low concentration and poor means of dispersal, the Tokyo subway sarin attack can be referred to as a "passive" attack. The implication of such an assumption, therefore, is that no one has yet witnessed a full-scale sarin attack in any major city. While valuable information can be gained from the Tokyo subway sarin attack, the experience obtained from the more aggressive Matsumoto sarin attack and the Iran–Iraq war should also be considered when developing initiatives directed at dealing with a potential full-scale attack in the future, in which the effects would be more serious.

Importantly, reliable epidemiologic data is lacking regarding the long-term effects of sarin toxicity, the question of whether low exposure to sarin has any long-term effects, and specific effects on children, pregnant women, and fetuses (Sharp, 2006). The sporadic and limited epidemiological surveys undertaken to date suggest that some long-term effects are present. The RSC has clearly shown that sarin victims still suffer from persistent aftereffects of indefinite complaints, even 19 years later. Thus, well-designed international epidemiologic studies should be conducted in victims exposed to sarin in Japan, Iran, and during the Persian Gulf War.

Several issues regarding treatment need to be resolved. Before the Tokyo subway sarin attack in 1995, the treatment of chemical weapons victims was exclusively regarded as a military issue. However, since then, the deliberate release of nerve agents against the general public has become a serious public safety issue. Treatment of chemical weapon injuries in a military setting assumes that one is dealing with healthy males who have received basic and ongoing training, and who are wearing PPE. An attack on the general public, however, involves a heterogeneous population from many different backgrounds, and the victims are likely to include women (including those who are pregnant), children, and persons who are elderly, sick, and disabled. Furthermore, the public is defenseless against chemical weapons because of their lack of knowledge of dangerous chemical substances and their lack of experience with wearing PPE. Taken together, there is the potential for thousands of victims if nerve agents are deliberately released against ordinary citizens.

Therefore, the medical treatment required for responding to a chemical terrorist attack on the general public will require a different strategy than that employed for such attacks in a military setting. This is because even though numerous lessons can be learned from military experiences, there will be measures that are useful in those settings that may not be applicable to an attack on the general public. An important issue is the means by which appropriate drugs can be safely and reliably supplied to a large number of victims. In addition, it is unrealistic to expect that first-responders wearing PPE will be able to establish intravenous lines in large numbers of victims at the scene of a terrorist attack. Thus, the use of autoinjectors for intramuscular or intraosseous access is more realistic (Ben-Abraham et al., 2003). In this regard, what is needed are not the standardized autoinjectors issued to military personnel, but rather, a variety of autoinjectors that are uncomplicated and easy for victims in normal settings to use. Research on the drugs used to treat victims of chemical terrorism is being conducted in several countries in both military and private situations. However, unlike drugs that are designed for treating diseases, clinical trials cannot be performed in humans due to the fact that it is unethical to subject participants in experiments to poisonous substances. Conducting a randomized control study is also difficult because there is an insufficient number of cases of organophosphate poisoning to establish a reliable sarin toxicity model. A prime example is the oxime agent HI-6. It was developed and in existence for more than 10 years before its widespread use. From the standpoint of international security, collaborative research on drugs for treating chemical terrorism and a global agreement on standard treatment are needed. These are important issues in clinical toxicology that require international cooperation.

Acknowledgments

We wish to thank the many people who have devoted their lives to the research into treating exposure to chemical weapons since the Tokyo subway sarin attack and who provided valuable advice in preparing this chapter. This chapter is dedicated to the memory of Dr. Frederick Sidell at the United States Army Medical Research Institute.

CHAPTER

5

Early and Delayed Effects of Sulfur Mustard in Iranian Veterans After the Iraq–Iran Conflict

Mahdi Balali-Mood

INTRODUCTION

Brief Chemistry

Sulfur mustard (SM), which is bis(2-chloroethyl) sulfide and is also known as mustard gas, was first synthesized in 1822 by Despretz. SM is an oily liquid that is colorless if pure, but it normally ranges from pale yellow to dark brown. Iranian veterans have described it as having a slight garlic or horseradish odor. It has a density of 1.27 g/mL, a melting point of 14.4°C, and a boiling point of 217°C. SM is only 0.05% soluble in water (Kikilo et al., 2008; Pechura and Rall, 1993).

SM is generally regarded as a "persistent" chemical agent because of its low volatility. In cool weather there is little vapor; however, mustard's evaporation increases as the temperature increases. At higher temperatures, such as those in the Middle East during the hot season (38–49°C), mustard vapor becomes a major hazard (Pechura and Rall, 1993; Sidell et al., 1997; Kikilo et al., 2008).

SUMMARIZED HISTORICAL USES

SM has been the most widely used chemical warfare agent (CWA) of the past century. It was first used extensively in World War I (WWI) between 1914 and 1918. Despite the Geneva Protocol in 1925 on the prohibition of CWA, SM was used by Italian troops in Ethiopia (1935–1936) and by Egyptian forces in Yemen (1963–1967). The greatest military use of SM was by the Iraqi Army against the Iranian soldiers and even civilians in Sardasht and Halabjah between 1983 and 1988, resulting in more than 100,000 chemical casualties (Balali-Mood and Hefazi, 2005; Salem et al., 2008).

TYPES AND ROUTES OF EXPOSURE

Based on the situation involved, several types of exposure including single, multiple, secondary, subclinical, and chronic may occur. Most human cases of SM poisoning have occurred during armed conflicts and most accidents involved a single exposure (Pechura and Rall, 1993; Sidell et al., 1997; Balali-Mood and Hefazi, 2005; Kikilo et al., 2008; Salem et al., 2008). Multiple low SM exposures occurred occupationally, during WWI and in the Iran–Iraq conflict (Balali-Mood and Hefazi, 2005; Salem et al., 2008). First aid workers and nursing and medical staff who cared for SM casualties in the field clinics and hospitals during the Iraq–Iran War without proper personal physical protection have become intoxicated. Some of them (between 5% and 25%) are now suffering from the delayed toxic effects of SM and have disabilities (Balali-Mood and Hefazi, 2005).

Low-level SM exposure with or without symptoms but with delayed or long-term health effects has been described in detail (Mandel and Gibson, 1917; Hurst and Smith, 2001; Balali-Mood et al., 2005a,b; Balali-Mood and Hefazi, 2006). Subclinical exposure to SM in some Iranian combatants induced delayed toxic effects (Ghanei et al., 2004a–c). Chronic SM exposure is usually occupational. Some factory workers in Japan and in the United Kingdom were reported to have had SM

poisoning and even malignancies attributable to SM (Brown, 1949; Nishimoto et al., 1970).

Inhalation is the major route of exposure that induces respiratory and systemic toxicity after absorption across the lung surface (Sidell et al., 1997; Balali-Mood and Hefazi, 2005; Hefazi et al., 2005). However, SM is a vesicant or blistering agent that has direct toxic effects on the skin, producing erythema, blistering, epidermolysis, and necrosis. It is a lipid-soluble compound and thus can be readily absorbed across the skin (Balali-Mood and Hefazi, 2005; Hefazi et al., 2006).

The eyes are the organs most sensitive to SM. This marked susceptibility is attributed to ocular features, including the aqueous–mucous surface of the cornea and conjunctiva as well as the high turnover rate and intense metabolic activity of the corneal epithelial cells (Pickard, 1919; Etezad-Razavi et al., 2006).

SM may also enter the body via oral ingestion. Some Iranian combatants were observed during the Iran–Iraq War who had ingested food contaminated by SM and subsequently became intoxicated. They experienced nausea, vomiting, hematemesis, abdominal pain, and dyspnea. SM may also be absorbed through the lower gastrointestinal (GI) tract (Balali-Mood and Hefazi, 2005). Injection is a very rare route of SM intoxication and has not been reported in humans.

HUMAN TOXICITY

Exposure to very high doses of SM in the field may induce convulsions and death in less than 1 h (WHO, 1970; Balali-Mood et al., 1986; Sidell et al., 1997; Balali-Mood and Hefazi, 2005). Such observations have not been reported during the Iran–Iraq War. Acute toxic effects generally appear after variable periods of latency depending on the dose, mode of exposure, the environmental temperature, and the individual (Anslow and Houk, 1946; WHO, 1970; Balali-Mood et al., 1986; Pechura and Rall, 1993; Balali-Mood and Hefazi, 2005).

Subacute exposure occurred during the Iran–Iraq War and in the workers in SM munitions factories. However, this type of exposure may present as mild acute SM intoxication, as a complication in the respiratory tract, or even as malignancy (Balali-Mood and Navaeian, 1986; Easton et al., 1988).

Delayed toxic effects of SM have been documented. The first report of delayed toxic effects in Iranian veterans was reported in 1986 (Balali-Mood, 1986). Several articles on the delayed toxic effects and complications of SM in Iranian veterans have since been published (WHO, 1970; Balali-Mood, 1986; Ghanei et al., 2004a–c; Balali-Mood et al., 2005a,b; Hefazi et al., 2005; Etezad-Razavi et al., 2006; Hefazi et al., 2006).

The workers who were chemically exposed to mustard agents in British and Japanese munitions factories developed chronic respiratory effects, including chronic bronchitis, bronchiectasis with progressive emphysema, and narrow attenuated bronchioles (Brown, 1949; Nishimoto et al., 1970; Easton et al., 1988).

MAIN MECHANISMS OF TOXICITY

The monofunctional mustards have one alkylating site and, therefore, can attack and break the DNA at specific nucleotides. Although SM reacts with RNA, proteins, and phospholipids, the general consensus is that a DNA alkylate plays an important role in delayed toxic effects (Walker, 1971; Ball and Robert, 1972). The major alkylating site of nucleic acids of mammalian origin is the nitrogen residue of guanine (Wheeler, 1962). Cell death from DNA cross-linking is delayed until the cell replicates its DNA or undergoes division. At higher cellular exposures, however, mechanisms other than DNA cross-linking become important and produce more rapid cell death. The acute damage to the cornea, mucous membranes, and skin seen after SM exposure is probably generated by one or more of these other mechanisms. One mechanism that may be involved in acute damage is nicotinamide adenine dinucleotide depletion. Other potential mechanisms of cell death are related to rapid inactivation of sulfhydryl containing proteins and peptides, such as glutathione. These sulfhydryl compounds are critical in maintaining the appropriate oxidation reduction state of cellular components. Glutathione is also thought to be critical in reducing reactive oxygen species in the cell and preventing peroxidation and loss of membrane integrity (Rankin et al., 1980; Eklow et al., 2004). Tumor necrosis factor-α is involved in SM-induced skin lesions (Worsmer et al., 2005).

TARGET ORGANS AND ACUTE CLINICAL FEATURES

Acute toxic effects of SM are mostly observed in the eyes, respiratory tract, and skin. These organs are thus known as the target organs, because their involvement is more prominent here than in the other organs. However, neuropsychiatric symptoms and signs and digestive and cardiovascular dysfunctions were also observed. Frequencies of clinical features of acute SM intoxications in 233 Iranian patients treated in Mashhad, Iran, are shown in Figure 5.1.

Eyes are the organs that are most sensitive to SM. The first symptoms of SM exposure usually occur in the eyes. The Iranian patients with SM exposure reported itching and burning sensation of the eyes, leading to acute

conjunctivitis, blepharospasm, and even keratitis. In the acute stage, the limbal region frequently presents a marbled appearance in which porcelain-like areas of ischemia are surrounded by blood vessels of irregular diameter.

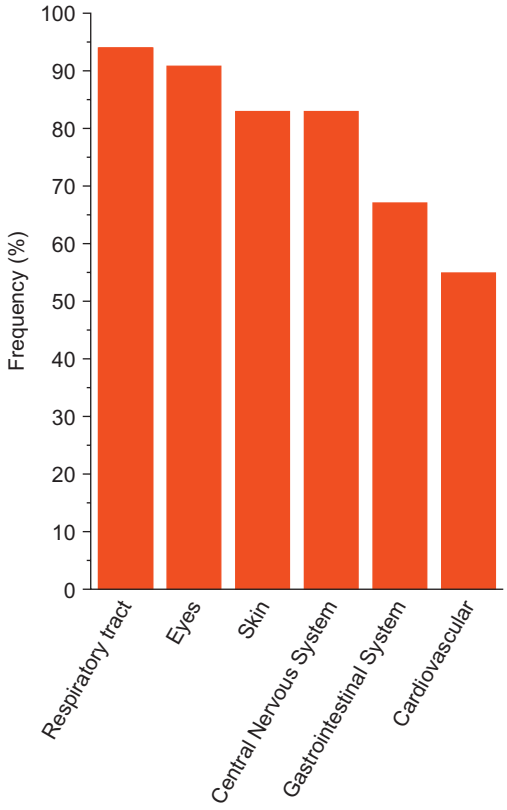

FIGURE 5.1 Frequency of clinical features of acute SM poisoning in different organs of 233 Iranian patients treated in Mashhad, Iran, a few days after exposure.

Later, the vascularized scars of the cornea often contain deposits of cholesterol, calcium, and fat (Giraud, 1917; WHO, 1970; Balali-Mood and Navaeian, 1986; Balali-Mood et al., 1986; Balali-Mood and Hefazi, 2005).

Respiratory effects occur in a dose-dependent manner from the nasal mucosa to the terminal bronchioles (WHO, 1970; Balali-Mood et al., 1986). Acute pulmonary effects commence with a tracheobronchitis, followed by bronchopneumonia, adult respiratory distress syndrome, and even pulmonary emboli in severely intoxicated patients, which may lead to death, mostly during the second week after SM exposure. Chest X-ray (CXR) of the Iranian SM-intoxicated patients revealed fewer abnormalities than the clinical manifestations. However, the severely intoxicated patients showed abnormal CXR results. CXRs of an Iranian patient with bronchopneumonia caused by acute SM poisoning before and after treatment in 1985 are shown in Figure 5.2.

Direct toxic effects of SM on the skin are the main apparent effects that lead to it being called a vesicant or a blistering agent. Erythema and blisters are the most common skin manifestations caused by SM exposure. A soldier who had a separate suit and face mask suffered from skin erythema and blisters on his neck 3 days after SM exposure, as shown in Figure 5.3.

A German and an Iranian medical toxicologist (first author) classified the cutaneous mustard gas lesions as described under the clinical manifestations (Helm and Balali-Mood, 1988).

GI effects after SM exposure have been documented in some studies. Destruction of the mucosa and shedding of the epithelial elements, however, begin days after exposure, resulting in the loss of large volumes of

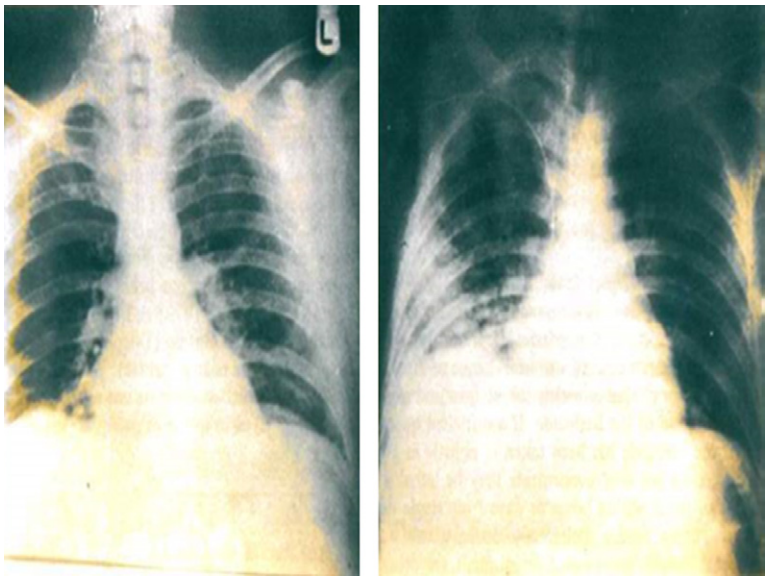

FIGURE 5.2 Chest X-rays of an Iranian patient with bronchopneumonia due to acute SM poisoning before (right) and after (left) treatment 8 days and 19 days after exposure in 1985.

FIGURE 5.3 A soldier who had a separate suit and face mask revealed skin erythema and blisters on his neck 3 days after SM exposure in 1985.

fluid and electrolytes (Papirmeister et al., 1991). Acute gastroduodenitis with hemorrhagic erosions, acute desquamative enteritis, and severe hemorrhagic necrotic colitis were reported in WWI veterans (Canelli, 1918) but were not observed in the Iranian veterans.

Extremely heavy exposure to SM can cause central nervous system (CNS) excitation, leading to convulsions in animals (Anslow and Houk, 1946). Balali-Mood and Navaeian (1986) reported convulsions in six Iranian veterans who were hospitalized during the early stages of their intoxication (Balali-Mood and Navaeian, 1986). Most casualties from WWI and from the Iran–Iraq conflict, however, revealed mild and very nonspecific neurological effects, such as headache, anxiety, restlessness, confusion, and lethargy (Canelli, 1918; Balali-Mood and Navaeian, 1986). A frequent long-term complication in patients exposed to SM is delayed neuropathic toxicity, which was underrepresented in most previous studies (Thomsen et al., 1988).

HEMATOIMMUNOLOGICAL COMPLICATIONS

SM, as an alkylating agent, is particularly toxic to rapidly proliferating cells such as lymphoid and bone marrow cells. Leukocytosis is common within the first few days after exposure. White blood cell (WBC) counts then begin to decrease starting from the third or fourth day after exposure and reach their minimum level at approximately the ninth day. This leukopenia is followed by a decrease in megakaryocytes and, finally, in the erythropoietic series (Willems, 1989; Tabarestani et al., 1990; Balali-Mood et al., 1991). Bone marrow biopsies have shown hypocellular marrow and atrophy involving all elements (Tabarestani et al., 1990). If cytopenia is not marked and there are still remaining stem cells, then recovery will occur as the patient recovers (Krumbhaar and Krumbhaar, 1919; Tabarestani et al., 1988; Tabarestani et al., 1990; Balali-Mood et al., 1991; Mahmoudi et al., 2005). The bone marrow studies reveal a severe decrease in cellularity and fat replacement and also nuclear changes, such as budding, binuclear, and karyorrhexis in erythrocyte precursors. The toxic effects of SM on the hematopoietic system are dose-dependent, and it is concluded that SM causes aplastic or ineffective hematopoiesis (Tabarestani et al., 1988). Severe leukopenia, however, is an ominous sign, leading to secondary infections and higher mortality rates in these patients. SM victims with WBC counts of 200 cells/mL or less died during their initial admissions (Willems, 1989).

SM poisoning could result in the impairment of both humoral and cellular immune functions (Dayhimi et al., 1988; Zandieh et al., 1990; Ghotbi and Hassan, 2002). Along with the appearance of clinical disorders, both C3 and C4 titers showed an increase, followed by a gradual decrease, over 1 year. The majority of SM-exposed patients had increased levels of IgG and IgM during the first weeks and up to 6 months after exposure (Ghotbi and Hassan, 2002).

A decrease of cell-mediated immunity has been observed in Iranian veterans 1, 2, and 3 years after exposure (Zandieh et al., 1990). Natural killer (NK) cells, which are known to be one of the most important components of cellular immunity, have been found to be significantly lower in patients with severe respiratory complications 10 years after exposure (Ghotbi and Hassan, 2002).

Hematological and immunological complications of 40 patients 16–20 years after severe SM intoxication in comparison with 35 controls were reported (Balali-Mood et al., 2005a,b; Mahmoudi et al., 2005). Total WBC and red blood cell (RBC) counts and hematocrit (HCT) levels were significantly higher in the patients than in the control group. The percentages of monocytes and $CD3^+$ lymphocytes were significantly higher, and the percentage of CD16+ 56 positive lymphocytes (NK cells) was significantly lower in patients than in the control group. Other hematological and flow-cytometric parameters did not show any significant difference between the two groups. Serum IgM and C3 levels were significantly higher in the patients in comparison with the controls. Other immunoglobulins and complement factors did not show any significant difference between the two groups, as shown in Table 5.1.

DELAYED CLINICAL COMPLICATIONS

The main target of the long-term complication of SM poisoning is the respiratory system. In a study of incidence of common late complications of SM poisoning in

TABLE 5.1 Hematological and Immunological Changes in 40 Patients, 16–20 Years After Severe SM Intoxication Comparing with 35 Healthy Subjects

Parameters	Patient Mean ± SD	Control Mean ± SD	*P*-value

Skin	29	72.5
Eyes	27	67.5

lungs, eyes, and skin in 34,000 Iranians, the lungs were found to be the most affected organ (Khateri et al., 2003). In another study, the most common clinical complications of SM in different organs of 40 Iranian veterans 16–20 years after exposure showed that the respiratory tract was involved in 95% of the patients, as shown in Table 5.2 (Balali-Mood et al., 2005a,b).

RESPIRATORY TRACT

Respiratory complications are the greatest cause of long-term disability among people with SM exposure. A pulmonologist who investigated the pulmonary complications in Iranian veterans in 2007 named it mustard lung (Ghanei and Adibi, 2007).

A triad of cough, expectoration, and dyspnea has been found to be present in more than 80% of Iranian veterans 3 years after their initial exposure (Balali-Mood, 1992; Balali-Mood and Hefazi, 2006). Hemoptysis (mainly streaky), chest tightness, chest pain, and nocturnal dyspnea are also frequent. The main objective clinical findings are generalized wheezing (the most common sign), crackles, decreased lung sounds, clubbing, and cyanosis (Balali-Mood, 1992; Balali-Mood and Hefazi, 2006; Ghanei and Adibi, 2007).

Pulmonary function testing has revealed more obstructive patterns than restriction, and approximately half of these obstructive spirometric results are reversible in response to inhaled bronchodilators. FVC, FEV1, and FEV1/FVC (FEV1%) have all been found to be significantly lower in SM-intoxicated veterans in comparison with healthy nonexposed subjects and CWA survivors who had used a gas mask at the time of attack (Balali-Mood, 1992; Balali-Mood and Hefazi, 2005; Balali-Mood et al., 2005a,b; Ghanei and Adibi, 2007).

Abnormal spirometric findings in general and restrictive patterns in particular tend to increase over time (Balali-Mood and Hefazi, 2005; Balali-Mood et al., 2005a,b; Ghanei and Adibi, 2007). A study of 77 subjects who were present in a contaminated area and had no acute signs and symptoms at the time of exposure, but who now have respiratory disorders, indicates that subclinical exposure to SM can be responsible for the occurrence of delayed respiratory complications such as bronchiectasis and bronchiolitis obliterans (Ghanei et al., 2004a–c).

CXR findings in patients with late respiratory complications of SM have been described as increased bronchovascular markings, hyperinflation, bronchiectasis, pneumonic infiltration, and radiologic evidence of pulmonary hypertension (Balali-Mood et al., 2005a,b; Ghanei and Adibi, 2007). However, CXR is not sensitive enough for the detection of respiratory complications in these patients and high-resolution computed tomography of the chest may be required as the diagnostic imaging procedure of choice (Bagheri et al., 2003; Balali-Mood et al., 2005a,b; Bakhtavar et al., 2008). A study of 197 Iranian veterans 10 years after a single heavy exposure to SM revealed the development of a series of delayed destructive pulmonary sequelae, such as chronic bronchitis (58%), asthma (10%), bronchiectasis (8%), large airway narrowing (9%), and pulmonary fibrosis (12%). Each of these complications is described in more detail (Emad and Rezaian, 1997).

Chronic Bronchitis

Several studies have reported chronic bronchitis as the most common late complication of the respiratory system resulting from war exposure to mustard gas (Balali-Mood, 1992; Emad and Rezaian, 1997; Ghanei et al., 2004a–c, 2005, 2006a,b; Balali-Mood et al., 2005a,b).

Hypoxemia and hypercapnea are commonly observed in moderate to severe cases, leading to cor pulmonale and respiratory failure in the final stages of the disease (Emad and Rezaian, 1997; Balali-Mood and Hefazi, 2005; Balali-Mood et al., 2005a,b). Infection of the respiratory tract, resulting in bronchopneumonia, is also a common problem that is often complicated by septicemia (Balali-Mood et al., 1986, 2005a,b; Balali-Mood and Hefazi, 2005).

Asthma

Airway hypersensitivity, manifested as typical attacks of breathlessness, wheezing, and nocturnal cough, as well as a reversible obstructive pattern on pulmonary function tests, have been reported between 4 weeks and 20 years after SM inhalation. Patients with chronic bronchitis may also have some degree of bronchospasm, which does not respond to bronchodilators. Attacks of bronchospasm are characteristically triggered by respiratory infections, environmental allergens, and cold weather (Emad and Rezaian, 1997; Bijani and Moghadamnia, 2002; Ghanei et al., 2004a–c, 2005, 2006a,b; WHO, 2004; Balali-Mood et al., 2005a,b). New techniques, such as impulse oscillometry (IOS), have been used for evaluation of airway dysfunction. However, it was found to be less sensitive than spirometry in spotting small airways obstructions. IOS is a good diagnostic method in the detection of pulmonary involvement in uncooperative patients (Ghanei et al., 2004a–c).

Bronchiectasis

Direct effects of SM on the bronchial wall mucosa and more recurrent respiratory infections after inhalation of SM are known to be responsible for the development of bronchiectasis. Both the severity and frequency of bronchiectatic lesions tend to increase over the long-term, as evidenced by a study of 40 Iranian veterans with severe late complications of SM poisoning. These lesions usually begin bilaterally in the lower lobes and then progress toward the middle lobe and the lingula.

In severe cases with extensive bronchiectatic lesions, pulmonary hypertension and, ultimately, cor pulmonale may occur (Sohrabpour, 1992; Hosseini, 1998; Aslani, 2000; Ghanei et al., 2004a–c; Balali-Mood et al., 2005a,b).

Large Airway Narrowing

Airway narrowing, attributable to scarring or granulation tissue, is late sequelae of acute injuries to the trachea and large bronchi, usually developing 2 years after exposure (Aslani, 2000; Sohrabpour, 1992; Ghanei et al., 2004a–c). A study of 19 Iranian veterans with large airway narrowing caused by SM revealed stenosis in the trachea (seven cases), main bronchi (eight cases), and lobar bronchi (four cases) (Ghanei et al., 2004a–c). In contrast to stenosis caused by prolonged intubations, there is no predilection in the right main bronchus (Balali-Mood et al., 2005a,b). The major problem in these patients is the recurrence of the lesion, which usually occurs 6 months after treatment (Aslani, 2000).

Pulmonary Fibrosis

Late-onset pulmonary fibrosis has been reported in several Iranian veterans with combat exposure to SM (Aslani, 2000; Balali-Mood et al., 2005a,b). The analysis of bronchoalveolar lavage fluid from patients with mustard gas inhalation showed that these patients have an ongoing local inflammatory process of the lower respiratory tract, resulting in the development of pulmonary fibrosis years after the initial exposure. Histopathological examination of transbronchial lung biopsy (TBLB) samples of SM-exposed veterans revealed variegated fibrosis, diffuse fibrosis, and an absence of fibrosis in 86%, 4%, and 10% of the patients, respectively. Usual interstitial pneumonitis accounted for 97% of all cases of fibrosis (Emad and Rezaian, 1997). In another study, electron microscopic examination of seven TBLB specimens was performed in a WHO research center in Japan. Abnormal findings included: (i) proliferation, desquamation, and degeneration of the bronchial epithelial cells; (ii) interstitial fibrosis or fibrosing alveolitis; and (iii) increased type I and type II alveolar epithelial cells as well as hyperplasia of ciliated and goblet cells (Sohrabpour, 1992). Inflammation and fibrotic processes in the lung tissue of SM-exposed patients may be progressive (Ghanei et al., 2004a–c). Diffusing lung capacity could be used as an objective monitor of the degree of fibrosis and also as a good predictor for prognosis (Emad and Rezaian, 1997).

PERIPHERAL NEUROMUSCULAR COMPLICATIONS

Electromyography (EMG) and nerve conduction velocity (NCV) of 40 Iranian veterans with severe late manifestations of SM poisoning revealed abnormalities in the peripheral nervous system of 77.5% of the patients. NCV disturbances were more common in sensory nerves compared with motor nerves and were more prevalent in the lower extremities than in the upper extremities. EMG recordings revealed a normal pattern in 24 (60%) patients, incomplete interference with normal amplitude in 6 (15%) patients, and incomplete interference with low amplitude in 10 (25%) patients. NCV and EMG disturbances in both upper and lower extremities were

mostly symmetric (Ghanei et al., 2004a–c; Balali-Mood et al., 2005a,b).

DERMAL DELAYED EFFECTS

The occurrence and persistence of lesions after SM exposure are directly related to the duration and severity of exposure. Injury that results in erythema and edema without vesicle formation is almost always followed by complete healing and nonresidual effects (Chiesman, 1944; Balali-Mood and Hefazi, 2005). Blistering and necrotic wounds, however, cause permanent residual effects. The first report of delayed toxic effects of SM poisoning in 236 Iranian veterans 2 years after exposure revealed late skin effects such as hyperpigmentation (34%), hypopigmentation (16%), and dermal scarring (8%) (Balali-Mood and Navaeian, 1986). The most common skin symptom among these patients was itching, followed by a burning sensation and desquamation. These symptoms are basically caused by dryness of the skin and become worse in dry weather and after physical activity. A more recent study of 40 Iranian veterans who were heavily exposed to the gas 16–20 years previously revealed the most common cutaneous lesions to be hyperpigmentation, erythematous papular rash, dry skin, multiple cherry angiomas, atrophy, hypopigmentation, and hypertrophy. These lesions were found on the genital areas (48%), the back (48%), the front thorax and abdomen (44%), lower extremities (mainly inguinal) (44%), upper extremities (mainly auxiliary) (41%), and the head and neck (15%). Dry skin was more prominent in the extremities. Hyperpigmentation in some patients had the appearance of pigmented xerodermoid, which is a diffuse hyperpigmented area with superimposed macular hypopigmentations and hyperpigmentations (Balali-Mood et al., 2005a,b; Hefazi, et al., 2006).

In another study, the cutaneous lesions of 500 SM-exposed Iranian veterans were compared with 500 unexposed veterans. An association was found between SM exposure and late skin lesions such as severe dry skin, hyperpigmentation and hypopigmentation, localized hair loss, eczema, and chronic urticaria. There was also a higher incidence of vitiligo, psoriasis, and discoid lupus erythematosus among SM-poisoned patients. This could be attributable to the immunological basis of these disorders and to the fact that SM has adverse long-term effects on the immune system. Previously injured sites have been reported to be sensitive to subsequent mechanical stimulation and showed recurrent blistering after mild injury (Fekri and Janghorbani, 1992).

Histopathological examination of skin biopsy samples has revealed nonspecific findings including epidermal atrophy, keratosis, and basal membrane hyperpigmentation. Nonspecific fibrosis and melanophages have also been observed within the dermis (Fekri and Janghorbani, 1992; Balali-Mood et al., 2005a,b; Hefazi et al., 2006). Occupational exposure to SM has been demonstrated to cause a variety of skin changes, including pigmentary disorders, skin ulcers, and cutaneous cancers (Khehr, 1984).

OPHTHALMOLOGIC COMPLICATIONS

In less than 1% of patients with battlefield exposure to SM, a delayed type of ulcerative keratopathy may develop, leading to late-onset blindness (Hughes, 1942; Blodi, 1971; English and Benett, 1990; Pleyer et al., 1999; Javadi and Kazemi-Moghadam, 2000). The maximum delayed toxic effects usually occur 15–20 years after initial exposure, although latency periods as long as 40 years or as short as 6 years have also been reported (Solberg et al., 1997; Javadi and Kazemi-Moghadam, 2000; Etezad-Razavi et al., 2006). Patients are usually symptom-free for an indefinite number of years when delayed keratitis develops, characterized by photophobia, lacrimation, and failing vision (Pleyer et al., 1999). Vascularized scars of the cornea are covered with crystal and cholesterol deposits, leading to a worsening of the opacification, recurrent ulcerations, and sometimes corneal perforation. Opacification of the cornea is seen predominantly in the lower and central portions, whereas the upper part is often protected by the eyelid (Solberg et al., 1997; Pleyer et al., 1999). Surprisingly, lesions even recur after corneal transplantation (Javadi and Kazemi-Moghadam, 2000). The exact pathogenesis of this condition is unknown, but degenerative processes and immune reactions against corneal proteins (collagen–mustard compound) have been suggested as the cause of long-term damage (Solberg et al., 1997). Unfortunately, there has been no report of any long-term studies of mustard gas workers to determine their ocular status after prolonged occupational exposure.

PSYCHIATRIC COMPLICATIONS

Casualties from WWI and from the Iran–Iraq conflict were noted to be long-term mood and anxiety disorders, as well as posttraumatic stress disorder (Balali-Mood, 1986; Tabatabaee, 1988; Hashemian et al., 2006). Debility, loss of vitality, impaired concentration, sensory hypersensitivity, diminished libido, weakened potency, neuralgic symptoms, and disorders in autonomic regulation are common manifestations. Neuropsychiatric evaluation of 1,428 Iranian veterans 3–9 years after exposure to SM revealed anxiety (15%), depression (46%), personality disorders (31%), convulsions (6%), and psychosis (3%) (Tabarestani et al., 1988). Disorders of

consciousness (27%), attention (54%), emotion (98%), behavior (80%), thought process (14%), and memory (80%) were studied in 70 patients 3–5 years after SM exposure (Balali-Mood, 1986). Depression and posttraumatic stress in Iranian survivors of chemical warfare, mostly SM exposure, were also reported (Javadi and Kazemi-Moghadam, 2000). In another study, decreased libido and impotence were recorded in 52% and 9% of patients, respectively. Quite interestingly, 10% of the patients revealed an increased libido. Functional photophobia and aphonia and effort syndrome have also been reported (Balali-Mood et al., 2005a,b).

CARCINOGENICITY

SM is genotoxic because of its reactions with DNA, which is an important first step in carcinogenesis. Although most cells possess effective DNA repair mechanisms, these are not always effective in the case of SM damage. Alkylation of *O*6-guanine by SM seems to be critical. *O*6-ethylthioethylguanine is a poor substrate for the DNA repair enzyme *O*6-alkylguanine-DNA alkyltransferase (Ludlum et al., 1986). Therefore, this *O*6 lesion may be the most important mutagenic lesion. However, only limited data are available regarding the specific mutations produced by SM. Mutations in a tumor suppressor or an oncogene gene can favor a proliferate advantage of a clonal cell. Notably, alterations in the p53 tumor suppressor gene have been described in Japanese mustard gas workers (Takeshima et al., 1994). However, most of the lesions in this population were similar to smoking-related mutations. Mutations in lymphocytes at the hypoxanthine phosphoribosyltransferase (hprt) gene locus have also been reported (Yanagida et al., 1988).

REPRODUCTIVE

The effects of SM exposure during pregnancy are unknown. Data addressing the productive toxicities of SM in human models are both lacking and contradictory (Azizi et al., 1995).

CARDIOVASCULAR COMPLICATIONS

Cardiovascular complications such as myocardial perfusion abnormalities and coronary ectasis have recently been observed in some patients (Gholamrezanezhad et al., 2007). Further, more detailed studies of larger groups of veterans and controls are now being undertaken, especially in regard to cardiovascular complications.

RECENT ADVANCES IN SM POISONING AND ITS COMPLICATIONS

Because there are still several hundred Iranian veterans suffering from the long-term complications of SM poisoning, research of these patients is continuing. Attaran et al. (2010) have found a significant positive correlation between interleukin-6 and airflow limitation in SM-exposed patients with chronic obstructive pulmonary disease (Attaran et al., 2010). Another Iranian research group (Abolghasemi et al., 2010) has demonstrated a significant association between overall frequency of physical abnormalities in children and paternal SM exposure. They have concluded that SM exposure may have a lasting and important effect on generations to come (Abolghasemi et al., 2010).

Razavi et al. (2012) published a systematic review of the delayed complications of SM poisoning in Iranian veterans. They have reported numerous late complications among the victims and listed a wide range of respiratory, ocular, dermatological, psychological, hematological, immunological, GI, and endocrine complications, all which influence the quality of life of the exposed veterans. Although the mortality rate attributable to SM poisoning was 3%, morbidity was high, with variety and chronicity of toxic effects and complications (Razavi et al., 2012).

Karami et al. (2013) studied the effects of delayed complications of SM poisoning on the mental health of Iranian veterans 25 years after exposure and found a wide range of psychiatric complications, including neurotic and psychotic disorders. They have recommended that psychological state should be considered more often in SM-exposed veterans and that it is important to provide more mental health centers for these patients (Karami et al., 2013).

Unfortunately, there is no antidote or effective treatment for SM poisoning. Poursaleh et al. (2012) studied the treatment of SM poisoning in Iranian veterans and have found that mustard lung has an ongoing pathological process and is an active disorder even years after exposure. They concluded that there are no curative modalities for mustard lung; therefore, primary prevention and, if injury has occurred, secondary prevention for SM victims should be considered. They recommended studies that investigate underlying physiopathology and pharmacokinetics of drugs, as well as those that conduct more surveys and controlled clinical trials to obtain more effective treatments (Poursaleh et al., 2012).

Despite two centuries of research on SM in experimental animals and in humans, the animal studies are still ongoing. Mishra et al. (2010) showed that dermal SM exposure in euthymic hairless guinea pigs induced infiltration of both $CD4^+$ and $CD8^+$ T cells into the exposed skin. They also found strong upregulated expression of

pro-inflammatory cytokines and chemokines (TNF-α, IFN-γ, and IL-8) in distal tissues such as the lung and the lymph nodes. They claimed to report for the first time that SM induced a specific delayed-type hypersensitivity response that is associated with splenomegaly, lymphadenopathy, and proliferation of cells in these tissues. Their results suggest that dermal exposure to SM leads to immune activation, infiltration of T cells into the SM-exposed skin, delayed-type hypersensitivity response, and molecular imprints of inflammation in tissues distal from the site of SM exposure (Mishra et al., 2010). These immunological responses may contribute to the long-term sequelae of SM toxicity, as evident in many reports of the SM-exposed Iranian veterans (Krumbhaar and Krumbhaar, 1919; Dayhimi et al., 1988; Tabarestani et al., 1988; Zandieh et al., 1990; Ghotbi and Hassan, 2002; Mahmoudi et al., 2005).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

A wide range of early and delayed toxic effects of SM can be categorized into two major groups: (i) direct toxic effects on the skin, eyes, and respiratory system with subsequent long-term complications such as chronic obstructive pulmonary disease (COPD), bronchiectasis, pulmonary fibrosis, large airway narrowing, hypopigmentation and hyperpigmentation of the skin, chronic conjunctivitis, and delayed keratitis and (ii) systemic toxicities, particularly the immunohematopoietic complications, that are believed to be responsible for the increased risk of infections and malignancies in these patients. However, there are still major gaps in SM literature and further studies of human subjects who have been exposed to the agent are required. Immunological and psychological dysfunctions, as well as the relationship between SM exposure and carcinogenesis and teratogenesis, are important fields that need further investigation. Recent findings of cardiovascular complications in some of these patients also require further investigations, particularly on a molecular basis to discover the mechanisms of early and delayed toxic effects of SM in humans. Future experimental and human studies may lead to a better understanding of SM poisoning and more effective treatment.

CHAPTER

6

Epidemiology of Chemical Warfare Agents

Linda A. McCauley

INTRODUCTION

While chemical warfare agents have been used in military conflict for decades, it is only in the last two decades that increased attention has been paid to the acute and chronic health effects associated with exposure to these agents. The subsequent reports of ill-defined illnesses in the veterans of the Gulf War of 1991, followed by the 1995 sarin terrorist attack in the Japanese subway system, focused attention on the capacity of deliberate or accidental exposure to chemical warfare agents, resulting in significant human death and subsequent disability.

Epidemiological studies of chemical warfare agents have suffered problems in determining exposure. Other than epidemiological investigations following the Japanese terrorist event, little objective epidemiological evidence is available. In this chapter, the major studies that have been conducted on populations exposed to the chemical warfare agents are discussed and methodological issues summarized.

PRE-WORLD WAR II

The first full-scale deployment of chemical agents in battle was during World War I in 1915, when the Germans used them against French, Canadian, and Algerian troops. Casualties were relatively heavy, though there were few deaths. A total of 50,965 tons of pulmonary, lachrymatory, and vesicant agents were deployed by both sides of the conflict, including chlorine, phosgene, and mustard gas. Official figures declare about 1,176,500 nonfatal casualties and 85,000 fatalities directly caused by chemical agents during the course of the war (Heller, 2005). In 1925, 16 of the world's major nations signed the Geneva Protocol, pledging never to use gas in warfare again; however, there were subsequent reports of its use. In 1935, Italy used mustard gas during the invasion of Ethiopia in the Second Italo-Abyssinian War with 15,000 chemical casualties reported. In this military conflict and subsequent wars in which chemical agents were used, no systematic attempt was made to accurately describe the epidemiology of the exposures, nor were any accurate data collected to monitor the health of exposed populations after the acute exposures.

Concern regarding the potential long-term effects of these exposures continued to be an issue, and in 1975, a longitudinal follow-up study of the mortality experience of three samples of World War I veterans was conducted to determine if a single exposure to mustard gas with respiratory injury was associated with increased risk of lung cancer in later life (Norman, 1975). Rosters of men born between 1889 and 1893 (2,718 exposed to mustard gas, 1,855 hospitalized with pneumonia in 1918, and 2,578 with wounds of the extremities (controls)) were traced via the Veterans Administration's death records. The 4,136 deaths reported were 95% of that expected. Observed deaths from lung cancer numbered 69 (2.5%) for the mustard gas group, as compared to 33 (1.8%) for the pneumonia group and 50 (1.9%) for the controls. The risk of death from lung cancer among men who were gassed relative to that for the controls was estimated as 1.3, with 95% confidence limits of 0.9–1.9.

WORLD WAR II

In 1938, the chemical structure of sarin nerve gas was discovered by the Germans, followed by the discovery

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00006-3

of the nerve agent soman in the spring of 1944 (Schmaltz, 2006). However, chemical warfare agents were not extensively used by either side, due in part to fear of a devastating Allied retaliatory attack. There was one account of an exposure to mustard gas among Allied troops when several US ships were sunk by the Germans in 1943, including one carrying mustard gas intended for use in retaliation by the Allies if German forces initiated gas warfare. Because the presence of the gas was highly classified, authorities treating casualties ashore had no idea that they were seeing the effects of mustard gas; as a result, they prescribed improper treatment. This incident was not uncovered for many years, and military records indicate that 628 of the casualties hospitalized after the raid suffered from mustard gas exposure and 69 deaths were attributed in whole or in part to this cause (US Naval Historical Center, 1943). The due impact of the gas exposure to military and civilian populations was not accurately reported because of the high secrecy regarding the exposure and the difficulty discerning the effect of gas exposure from other types of injuries.

During the Holocaust, the Nazis used the insecticide Zyklon B containing hydrogen cyanide to kill several million people in extermination camps and reportedly used poison gases during the Warsaw ghetto uprising in 1943. In addition, experiments were conducted on concentration camp prisoners using mustard gas and phosgene.

In 1994, a US Senate report, entitled "Is Military Research Hazardous to Veterans' Health? Lessons Spanning a Half Century," stated that US military personnel were used as human subjects in the 1940s to test two chemical agents, mustard gas and a similar compound, Lewisite. This testing was done to determine how to best protect military troops from the effects of chemical warfare agents (Pechura and Rall, 1993).

During the war, the US military conducted a secret research program aimed at determining how best to protect military personnel against the effects of mustard gas and Lewisite (Pechura and Rall, 1993). Up to 4,000 men took part in the program, which required participants to wear gas masks and clothing that had been treated in an attempt to keep the gas from reaching the skin. Men were required to remain in the sealed test room from 1 to 4 h. Some men were tested in the field, where they were required to stay in an area that had been bombed with mustard gas anywhere from 1 h to 3 days. In 1992, the US Department of Veterans Affairs (VA) began to allow compensation for seven conditions that can result from mustard gas exposure: laryngitis, chronic bronchitis, emphysema, asthma, chronic conjunctivitis, chronic keratitis, and corneal opacities. Following publication of a report by the National Academy of Sciences (Pechura and Rall, 1993), the VA extended the list to include respiratory cancers (nasopharyngeal, laryngeal, and lung except for mesothelioma), skin cancer, chronic obstructive pulmonary disease, and acute nonlymphocytic leukemia.

Bullman and Kang (2000) conducted a 50-year mortality follow-up study of veterans exposed to low levels of mustard gas. The subjects were World War II Navy veterans who received low-level nonlethal exposures to mustard gas while participating in mustard gas chamber tests at Bainbridge, MD, between 1944 and 1945. These veterans were exposed to mustard gas while wearing protective clothing and masks. A control group consisted of 2,663 Navy veterans who served at the same location and time as the exposed people, but did not participate in chamber tests. The investigators found no excess of any cause-specific mortality associated with varying levels of mustard gas exposures that were sufficient to cause skin reactions. A significant strength of this study was that the length of time in the exposure chamber, the dose of exposure, and documentation of any observable acute effect were available for each of the exposed subjects so that a dose–response analysis could be done.

Schnurr et al. (2000) reported on the prevalence of current posttraumatic stress disorder (PTSD) associated with participation in these secret military tests of mustard gas exposure. Using the registry established by the VA, 363 male military veterans were randomly sampled and found to have a current prevalence of 32% for full PTSD and 10% for partial PTSD. Prevalence of PTSD varied as a function of risk and protective factors, including volunteering, physical symptoms during the tests, and prohibited disclosure. Veterans with full PTSD reported poorer physical health, a higher likelihood of several chronic illnesses and health-related disability, greater functional impairment, and higher likelihood of health-care use than those with no PTSD. Veterans with partial PTSD also had poorer outcomes than did veterans with no PTSD in a subset of these domains.

Schnurr et al. (1996) postulated that these exposures involved elements of "contamination stressors," in which information about the exposure or the lack of information serve as the stressors, rather than the actual exposure to the chemical. Lack of information during the time of exposure, and the notification decades later could have led to vague or diffuse fear with unknown consequences, contributing to the development of PTSD. The contamination stressor led to a future orientation; a worry about what problems will develop as a result of the previous exposure.

POST-WORLD WAR II

Development of other agents, such as the *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX) nerve agent continued during the 1950s, and in

1961, the United States was producing large amounts of VX and performing its own research into nerve agents. In 1952, the US Army patented a process for developing the powerful toxin ricin.

In 1969, 23 US servicemen and one US civilian stationed in Okinawa, Japan, were exposed to low levels of the nerve agent sarin while repainting the depot's buildings. When the exposure was publicized, the United States moved the weapons in 1971 to Johnston Atoll. Between 1951 and 1969, various chemical and biological agents were tested at the Dugway Proving Ground. From 1962 to 1973, more than 5,800 military personnel participated in a series of tests on the vulnerability of warships to biological and chemical attacks. Only some of the involved military personnel consented to these tests. Many of them used chemical warfare simulants, which were thought at the time to be harmless. The results of the tests were reported in classified documents (SHAD report). In 2000, the US Department of Defense (DoD) released the names of the participants and information about the testing that occurred. In 2002, the Institute of Medicine (IOM) agreed to undertake a scientific study of potential long-term health effects associated with these exposures. The IOM assembled a comparable control group and conducted a health survey by telephone. Mortality records were also examined. The primary outcomes of interest were mortality, general health, and medical conditions. The SHAD participants were divided into four groups:

- Group A consisted of 3,000 participants whose exposure was limited to either *Bacillus globigii* (BG) or methylacetoacetate (MAA).
- Group B consisted of 850 participants whose only potential exposure was to trioctyl phosphate (TEHP) and contained a large number of Marines.
- Group C consisted of 720 participants who were in tests where active chemical warfare agents were used.
- Group D consisted of 850 subjects potentially exposed to simulants who were not in group A, B, or C.

Control groups were assembled for each of the exposed groups. Of the nearly 12,500 Navy and Marine subjects, 9,600 were assumed alive (i.e., no evidence of death from available records sources) and were surveyed. The response rate for the SHAD participants was 60.8% and 46.6% for controls. No differences were observed in all-cause mortality between SHAD participants and controls, although the SHAD participants had a statistically significant higher risk of death due to heart disease. Lack of cardiovascular risk factor data makes this difference difficult to interpret. SHAD participants also reported statistically significantly worse health than controls, but no specific patterns of illness were found. Group C, the only group with potential exposure to active chemical or biological agents, reported the smallest differences in overall health compared to controls. Small differences in memory and attention as well as somatization were observed and SHAD participants had higher levels of neurodigenerative conditions. SHAD participants also reported higher rates of symptoms, thought to be related to reporting bias. There were no significant differences in self-reported hospitalizations.

This report was significant in that it was the first epidemiological investigation of a military population with documented exposure to chemical agents or stimulants. The survey was conducted, however, 30 years after the exposure and, with the exception of mortality records, was limited to self-reported measures of health. A mortality follow-up study of the SHAD cohort was published by Kang and Bullman (2009) in which the cause-specific mortality of 4,927 SHAD veterans was compared to 10,927 other Navy veterans of that era. The SHAD veterans had an increased risk of overall mortality, due primarily to heart disease; therefore, this heightened risk was not attributed to exposure to active chemical or biological warfare agents. This study was limited due to lack of information on other potential exposures, particularly exposure to Agent Orange, a defoliant used in Vietnam, and the possibility of error was introduced by exposure misclassification.

In 2012, the IOM was commissioned to conduct a second epidemiological study comparing the health status of the SHAD veterans with a comparison population. This research, currently underway, will build on knowledge gained from the first study and use veteran and Medicare data as well as death certificate data. The anticipated date for completion of the study is February 2015.

IRAN–IRAQ WAR

Saddam Hussein received chemical weapons from many countries, including the United States, West Germany, the Netherlands, the United Kingdom, France, and China (Lafayette, 2002). In 1980, Iraq attacked Iran, employing mustard gas and tabun, in a war that lasted 8 years. A total of 5% of all Iranian casualties were directly attributable to the use of these agents. Iran sustained approximately 387 chemical attacks during this war (Shemirani et al., 1993). About 100,000 Iranian soldiers, along with significant numbers of civilians, were chemical warfare victims. Nerve gas agents killed about 20,000 Iranian soldiers immediately. Shortly after the war ended in 1988, the Iraqi Kurdish village of Halabja was exposed to multiple chemical agents, resulting in the death of 10% of the 50,000 residents.

The extensive assault on military and civilian populations, terrible as it was, has resulted in some of the

best-designed epidemiological studies of the effects of exposure to chemical warfare agents in recent years. Hashemian et al. (2006) reported on the results of a cross-sectional, randomized survey of 153 civilians in three towns exposed to military conflict in northwestern Iran: Oshnaviveh (low-intensity conventional warfare), Rabat (high-intensity conventional warfare), and Sardasht (both high-intensity conventional warfare and chemical weapons). The surveys measured full or partial PTSD diagnosis and symptoms of anxiety and depression. Compared with individuals exposed to low-intensity warfare, those exposed to high-intensity warfare and chemical weapons were at a higher risk for lifetime PTSD (odds ratio (OR), 18.6; 95% confidence interval (CI), 5.8–59.4), current PTSD (OR, 27.4; 95% CI, 3.4–218.2), increased anxiety symptoms (OR, 14.6; 95% CI, 6.0–35.6), and increased depressive symptoms (OR, 7.2; 95% CI, 3.3–15.9). Exposure to high-intensity warfare but not to chemical weapons was also significantly associated with lifetime PTSD (OR, 5.4; 95% CI, 1.7–17.6), compared with those in the low-intensity warfare group. Further, compared with individuals exposed to high-intensity warfare alone, those exposed to both high-intensity warfare and chemical weapons were at higher risk for lifetime PTSD (OR, 3.4; 95% CI, 1.5–7.4), current PTSD (OR, 6.2; 95% CI, 2.0–20.1), increased anxiety symptoms (OR, 5.6; 95% CI, 2.5–12.6), and increased depressive symptoms (OR, 3.7; 95% CI, 1.8–7.2).

Sulfur mustard is rated by the International Agency for Research on Cancer (IARC) as a human carcinogen and is a known risk factor for occupational lung cancer (Nishimoto et al., 1987; Ghanei and Vosoghi, 2002). Zafarghandi et al. (2012) described the incidence of cancer in 7,570 Iranian sulfur mustard-exposed veterans compared to 7,595 unexposed subjects in a 25-year follow-up study. Cancer incidence was significantly increased with exposure to sulfur mustard. The incidence rate ratio for cancer was 1.81 (95% CI 1.15–2.34); however, no increased risk of site-specific cancers were found. The hazard ratio of cancer occurrence was 2.02 (95% CI 1.41–2.88).

The long-term clinical consequence of sulfur mustard exposure was looked at by the Sardasht-Iran Cohort Study (Ghazanfari et al., 2009), which included 372 individuals from Sardasht as the exposed group and 128 non-exposed individuals from Rabat. As part of this research, Ghanei et al. (2010) studied pulmonary complications and found that blistering at the time of exposure was associated with more respiratory symptoms and worse lung function, but not with air trapping, bronchiectasis, and mosaic parenchymal attenuation detected with computed tomography (CT) of the thorax. This cohort was also used to examine the long-term effects of sulfur mustard on civilian's mental health 20 years post exposure. There were significant differences in somatization, obsessive-compulsion, depression, anxiety, and hostility between the exposed and unexposed groups, suggesting significant long-term effects of sulfur mustard exposure.

Comparisons of the effects of sulfur mustard and nerve agents have also been conducted in this population. Emadi et al. (2012) compared late cutaneous complications between the two exposure groups of 154 sulfur mustard-exposed cases and 175 nerve agent exposed cases. Only 18.1% of the mustard-exposed group was asymptomatic, compared to 62.4% of the nerve agent exposures. A number of mustard-induced dermatologic lesions were reported, including scars, intertrigo, xerosis, cherry angioma, hyperpigmentation, pilar keratosis, poikiloderma, and malignant tumors.

1991 GULF WAR

Given the past use of chemical weapons of Iraq on its own citizens, there was much concern that Saddam Hussein would again employ these weapons during the conflict against coalition forces. The only known exposure to anticholinesterase chemical warfare agents during the Gulf War was during the destruction of munitions containing 8.5 metric tons of sarin/cyclosarin housed in Bunker 73 at Khamisyah, Iraq, on March 4, 1991, and additional destruction of sarin/cyclosarin rockets in a pit at Khamisyah on March 10, 1991. The US DoD reported that the exposure levels were too low to activate chemical alarms or to cause symptoms at the time of the detonation; however, several studies have been conducted to assess long-term health effects associated with this exposure. The DoD conducted modeling of the air plume that resulted from the detonation and estimated the extent of troops potentially exposed to the plume.

McCauley et al. (1999) conducted a computer-assisted telephone survey of 2,918 Gulf War veterans from Oregon, Washington, California, North Carolina, and Georgia to evaluate the prevalence of self-reported medical diagnoses and hospitalizations among this potentially exposed population and among comparison groups of veterans who were deployed and not deployed to the Southwest Asia theater of operations. Troops reported to be within 50 km of the Khamisyah site did not differ from other deployed troops in terms of reporting any medical conditions or hospitalizations in the 9 years following the Gulf War. Hospitalization rates among deployed and nondeployed troops did not differ. Deployed troops were significantly more likely than nondeployed troops to report diagnoses of high blood pressure (OR = 1.7), heart disease (OR = 2.5), slipped disk or pinched nerve (OR = 1.5), PTSD (OR = 14.9), hospitalization for depression (OR = 5.1), and periodontal disease (OR = 1.8). There was a trend for deployed veterans to report more diagnoses of any cancer (OR = 3.0).

Smith et al. (2003) investigated postwar morbidity for Gulf War veterans, contrasting those who may have been exposed to low levels of nerve agents at Khamisyah and those unlikely to have been exposed. Cox regression modeling was performed for hospitalizations from all causes and hospitalizations from diagnoses within 15 categories during the period March 10, 1991 through December 31, 2000, for the duration of active-duty status. Veterans possibly exposed to nerve agents released by the Khamisyah demolition were not found to be at increased risk for hospitalization from most chronic diseases nearly 10 years after the Gulf War. Only 2 of 37 models suggested that personnel possibly exposed to subclinical doses of nerve agents might be at increased risk for hospitalization from circulatory diseases, specifically cardiac dysrhythmias.

Bullman et al. (2005) reported the results of a mortality study of troops exposed to chemical warfare agents based on the air plume models that were developed after the detonation. The cause-specific mortality of 100,487 exposed veterans was compared with that of 224,480 unexposed US Army Gulf War veterans. The risks for most disease-related mortality were similar for exposed and unexposed veterans. However, exposed veterans had an increased risk of brain cancer deaths (relative risk = 1.94; 95% CI = 1.12, 3.34). The risk of brain cancer death was larger among those exposed 2 or more days than those exposed 1 day when both were compared separately to all unexposed veterans.

This same team of investigators also conducted a study to examine the association of exposure to the Khamisyah plume with subsequent self-reported morbidity (Page et al., 2005). The study sample included 1,056 deployed Army Gulf War veterans who responded to the National Health Survey of Gulf War Era Veterans in 1995 and who were resurveyed in 2000. Half of the subjects had been notified of potential exposure to chemical warfare agents. Comparing notified and nonnotified subjects, there were no statistically significant differences with respect to bed days, activity limitations, clinic visits, or hospital visits. Among 71 self-reported medical conditions and symptoms, there were five statistically significant differences, four of which were for lower rates of illness among notified subjects.

Page and colleagues also published a similar study undertaken to investigate whether possible chemical warfare exposure was associated with morbidity among Army Gulf War veterans using morbidity data for 5,555 Army veterans who were deployed to the Gulf region (Page et al., 2005). Responses to 86 self-assessed health measures, as reported in the 1995 National Health Survey of Gulf War Era Veterans, were evaluated. They found little association between potential exposure and health after adjusting for demographic variables. The investigators concluded that potential exposure to sarin or cyclosarin at Khamisyah did not seem to have adversely affected self-perceived health status, as evidenced by a wide range of health measures.

More recently, Heaton examined the association between modeled estimates of sarin/cyclosarin exposure levels and volumetric measurements of gross neuroanatomical structures in 1991 Gulf War veterans with varying degrees of possible low-level sarin/cyclosarin exposure (Heaton et al., 2007). A total of 26 veterans recruited from the Devens Cohort Study participated. Magnetic resonance images (MRIs) of the brain were acquired and analyzed using morphometric techniques, producing volumetric measurements of white matter, gray matter, right and left lateral ventricles, and cerebrospinal fluid. Volumetric data were analyzed using exposure estimates obtained from refined models of the presumed exposure hazard area in Khamisyah. No differences were observed in the 13 exposed veterans when compared to 13 nonexposed veterans in volumetric measurements of discrete brain tissues. However, linear trend analyses showed a significant association between higher levels of estimated sarin/cyclosarin exposure and both reduced white matter (adjusted parameter estimate = 4.64, $P < 0.0001$) and increased right lateral ventricle (adjusted parameter estimate = 0.11, $P = 0.0288$) and left lateral ventricle (adjusted parameter estimate = 0.13, $P < 0.0001$) volumes. These findings suggest subtle but persistent central nervous system pathology in Gulf War veterans potentially exposed to low levels of sarin/cyclosarin.

This investigative team also compared previous neurobehavioral performance results collected prior to notification of veterans who were potentially exposed during the Khamisyah detonation (Proctor et al., 2006). They hypothesized that the exposure to sarin and cyclosarin would be associated with poorer performances on objective neurobehavioral tasks in specific functional domains (particularly in visuospatial abilities and psychomotor functioning) in a dose-dependent manner. They found that sarin and cyclosarin exposure was significantly associated with less proficient neurobehavioral functioning on tasks involving fine psychomotor dexterity and visuospatial abilities 4–5 years after exposure. They concluded that the findings suggest a dose–response association between low-level exposure to sarin and cyclosarin and specific functional central nervous system effects 4–5 years after exposure.

To determine the generalizability of these findings in the Devens Cohort, investigators from the University of California, San Francisco studied a second cohort of Gulf War veterans with suspected sarin/cyclosarin exposure (Chao et al., 2010). They studied 40 Gulf War veterans categorized as exposed to sarin/cyclosarin at Khamisiyah in comparison to a control group of 40 nonexposed veterans. MRI data of the brain were analyzed, with

volumetric measurements of gray matter, white matter, cerebrospinal fluid and hippocampus. Exposed veterans had reduced total gray matter and hippocampal volumes compared to controls ($P < 0.01$). While no group differences were observed on measures of cognitive function or total white matter volume, there were significant positive correlations between total white matter volume and measures of executive function and visuospatial abilities in exposure sarin/cyclosarin. While limited in accurate exposure assessment and specific unit information, the authors argue that these findings in conjunction to those found by Heaton, Proctors, and colleagues point to the need for a follow-up study with more subjects and more sophisticated imaging technology.

TERRORISM

Two terrorist attacks with the nerve agent sarin affected populations in Matsumoto and Tokyo, Japan, in 1994 and 1995, killing 19 and injuring more than 6,000. Morita et al. (1995) described the acute effects, including instantaneous death by respiratory arrest in four victims in Matsumoto. In Tokyo, 2 people died in station yards, and another 10 victims died in hospitals within a few hours to 3 months after the poisoning. A total of six victims with serum cholinesterase (ChE) below 20% of the lowest normal levels were resuscitated from cardiopulmonary arrest (CPA) or coma with generalized convulsion. Of those, five recovered completely and 1 remained in a vegetative state due to anoxic brain damage. Electroencephalogram (EEG) abnormalities were observed for up to 5 years in certain victims. Miosis and copious secretions from the respiratory and gastrointestinal tracts (muscarinic effects) were common in severely to slightly affected victims. Weakness and twitches of muscles (nicotinic effects) appeared in severely affected victims. Neuropathy and ataxia were observed in a small number (less than 10%) of victims, in which findings disappeared between 3 days and 3 months. Leukocytosis and high serum creatine kinase (CK) levels were common. Hyperglycemia, ketonuria, low serum triglycerides, and hypokalemia were observed in severely affected victims, and these abnormalities were attributed to damage of the adrenal medulla.

The Matsumoto government assembled a committee of city government, local hospitals and physicians from Shinsu University to monitor the immediate and long-term effects of the exposure, resulting in the most comprehensive epidemiological studies of acute and residual effects of exposure to chemical warfare agents. Three weeks after the attack, community residents ($n = 2052$) residing in an area within 1,000–850 m of the attack were surveyed and categorized as severely affected if they were admitted to the hospital, moderately affected if treated in outpatient clinics, and slightly affected if they had symptoms but did not seek medical attention. At the time of this follow-up survey, 28% of the affected residents remained symptomatic (69% of the severely affected, 42% of the moderately affected, and 14% of the slightly affected). The most frequent persisting symptoms were fatigue, dysesthesia of extremities, and ocular pain. Visual problems continued in about 10% of severely affected victims (Yanagisawa et al., 2006).

In the Tokyo subway attack, 640 victims were seen within hours of the incident. Of these people, 5 were critically injured and required mechanical ventilation, and another 107 were moderately injured with systemic symptoms and signs of respiratory, digestive, or neurological damage, in addition to ocular problems. The large majority ($n = 528$) had only eye damage or symptoms and were released after several hours of observation (Yanagisawa et al., 2006).

There have been a number of investigations of the health of the survivors of the Tokyo subway attack. Yokoyama et al. (1998a) conducted a study of 18 victims 6–8 months after the attack. At that time, their mean plasma ChE was 72.1, lower than the normal range of 100–250 IU/L. In neurobehavioral testing at that time, sarin cases had significantly lower scores on the digit symbol test than the control group. Cases were more likely to have higher scores on both the General Health Questionnaire, an indication of psychological distress, and fatigue measures than controls, and PTSD scores were also increased. Postural balance was also different in victims, suggesting that integration of visual input might have been impaired (Yokoyama et al, 1998b). P300 and VEP (P100) latencies in the sarin cases were significantly prolonged in these victims compared with the matched controls (Murata et al., 1997). In the sarin cases, the CVRR (electrocardiographic R-R interval variability) was significantly related to serum ChE levels determined immediately after exposure; the PTSD score was not significantly associated with any neurophysiological data despite the high PTSD score in the sarin cases. These findings suggest that asymptomatic after effects to sarin exposure, rather than PTSD, persist in the higher and visual nervous systems beyond the turnover period of ChE.

The National Police Academy (1999) conducted a survey of 1,247 residents who reported to the police department that they had contact with sarin at the incident. More than half complained of physical symptoms, such as asthnopia and decrease in visual acuity; and 17% reported psychological trauma from the event, with 14% still unable to ride on subways 3 years after the incident.

There continue to be follow-up studies describing the residual effects of the attack. Ohtani et al. (2004) followed 34 victims 5 years after the attack. Not only PTSD, but also nonspecific mental symptoms, persisted in the victims at a high rate. A total of 11 victims were diagnosed with current

or lifetime PTSD. Victims with PTSD showed higher anxiety levels and more visual memory impairment.

Yamasue et al. (2007) conducted a 5 year follow-up study to identify persistent morphological changes subsequent to the attack. In the research, 38 victims of the sarin attack who had been treated in the emergency department for sarin intoxication and 76 control subjects underwent weighted and diffusion tensor MRIs. ChE values were compared to levels immediately after the attack. The voxel-based morphometry exhibited smaller than normal regional brain volumes in the insular cortex and neighboring white matter, as well as in the hippocampus, in the victims. The reduced regional white matter volume correlated with decreased serum cholinesterase levels and with the severity of chronic somatic complaints related to interoceptive awareness. Voxel-based analysis of diffusion tensor MRIs further demonstrated a significantly lower than normal fractional anisotropy in the victims. These findings suggest that sarin intoxication might be associated with structural changes in specific regions of the human brain.

Rescue and safety workers have also been studied. Nishiwaki et al. (2001) looked at 27 male rescue team staff and 30 police officers 3–45 months after the event. The subjects showed decreased performance on the digit span test; however, no effects on stabilometry and vibration perception threshold were found. Li et al. (2004) followed 27 male firefighters and 25 male police officers 3 years after the attack for genotoxic effects. They found an elevated frequency of sister chromatid exchanges in lymphocytes of the victims, which were related to the percentage of ChE inhibition observed just after the attack.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

This chapter described the major epidemiological studies of populations who have been exposed to chemical warfare agents. Many of the studies of military populations have suffered from inaccurate exposure assessment and lack of clinical data. However studies in the past decade of terrorist attacks, as well as the Iran–Iraqi cohort studies, provide the most comprehensive data to date on the scope of health outcomes associated with these exposures. These reports point to the need for long-term follow-up studies of victims of such events. The data from the terrorist events and military assaults point to the prevalence of PTSD in populations with real or threatened exposure.

CHAPTER

7

Chemical Weapons of Mass Destruction and Terrorism: A Threat Analysis

René Pita and Arturo Anadón

INTRODUCTION

Terrorism is a contested concept because there is not an international legal consensus regarding its definition. Barile defines terrorism as the threat or implementation of violent means to undermine, destabilize, inflict harm, or cause panic in a society (Barile, 2010).

After the September 11, 2001 (9/11) terrorist attacks in the United States, the high risk of possible attacks with chemical weapons (CWs), especially by groups linked to jihadist terrorism, has been perceived. Before 9/11, in 1994 and 1995, Aum Shinrikyo, a religious organization in Japan, used sarin (a nerve agent) in attacks in Matsumoto and on the Tokyo subway, causing a large number of casualties. These terrorist attacks had a big impact on the international chemical defense and intelligence communities but not on other circles, perhaps because a chemical attack by a religious organization in Japan seemed something far removed from the reality of the rest of the world. But this changed after 9/11, when the mailing of letters containing *Bacillus anthracis* spores accompanied by images of the attacks on New York City's World Trade Center towers increased the concern about weapons of mass destruction (WMD) attacks, including attacks by CWs.

In this chapter, information is analyzed from open sources regarding the possible use of CWs by terrorist groups, especially by those affiliated with or associated with the Al Qaeda terrorist network, as well as by supporters of the global jihad movement. As religious terrorist groups, Al Qaeda and the global jihad movement do not fit the assumption made by Brian Jenkins in 1975 that "terrorists want a lot of people watching and a lot of people listening, and not a lot of people dead" (Jenkins, 1975). This statement fits better with secular terrorist groups. But for religious terrorist groups like Al Qaeda, "divine duty" results in disappearance of moral restraints that would justify "a lot of people dead" in their terrorist attacks, such as the 9/11 attacks. And if CWs are part of the WMD concept because they can cause a large number of casualties, they could be very good tools for jihadist terrorist groups to achieve their goals.

CWs FOR TERRORIST ACTIONS

"Classical" Chemical Warfare Agents: Vesicants and Nerve Agents

The two main chemical warfare agents (CWAs) are vesicants and nerve agents (Table 7.1). The first chemicals used as weapons in World War I included toxic industrial chemicals (TICs) that were widely available in the chemical industry. These included lung-damaging agents like chlorine and phosgene, as well as cyanides that were named "blood agents." When these agents proved to be effective at the tactical level, research and development programs of CWAs started (Pita, 2008). These programs tried to obtain chemicals that would be effective in battle because of the physico-chemical and toxicological properties of the chemicals, although they had no use in the industrial field.

First, sulfur mustard, a vesicant warfare agent, was produced and used in World War I. Mustards alkylate a wide range of biologically important molecules producing cytostatic, mutagenic, and cytotoxic effects. In 1936, just before the start of World War II, tabun was synthesized and then produced as the first nerve CWA. Nerve agents inhibit acetylcholinesterase (AChE) throughout

Handbook of Toxicology of Chemical Warfare Agents.

TABLE 7.1 Some Potential Chemical Agents for Terrorist Actions

Vesicants	Sulfur mustards
	Nitrogen mustards
	Lewisites
Nerve agents	Tabun (GA)
	Sarin (GB)
	Soman (GD)
	VX
Incapacitating agents	BZ
	Opioids
RCAs	CS
	CN
	CR
	Capsaicin
TICs	Chlorine
	Phosgene
	Cyanides
Toxins	Ricin

FIGURE 7.1 A jihadist manual dealing with CWs available on the Internet.

the body, causing an accumulation of acetylcholine (ACh), which produces overstimulation at muscarinic receptors, nicotinic receptors, and in the central nervous system (CNS).

Vesicant agents (sulfur mustards, nitrogen mustards, and lewisites) and nerve agents (tabun, sarin, soman, and VX, among others) are included in the Chemical Weapons Convention (CWC) Schedule 1 of chemicals for the application of verification measures (http://www.opcw.org, accessed February 21, 2014). This schedule features chemicals that have little or no use in the industry and have been developed, produced, stockpiled, or used as CWs.

Nerve agents can be considered as the most important CWAs because of their high toxicity and their high versatility for tactical use. This high versatility is attributable to the fact that although all nerve agents are liquid at room temperature, some can be considered persistent agents (e.g., VX) because of their low volatility, whereas others can be considered nonpersistent (e.g., sarin) because their volatility is higher. Persistent agents would be useful against targets with no occupational interest that would be contaminated for a certain period of time. On the contrary, nonpersistent agents would evaporate faster and would be the choice against targets that need to be occupied.

Toxicological and physico-chemical properties of nerve agents would also make this group the CWs of choice for terrorist groups. However, the synthesis process requires some level of expertise and is far more complex than the recipes featured in the "do it yourself" (DIY) manuals available on the Internet (Figure 7.1). Even Aum Shinrikyo—which had excellent financial resources and personnel with the required expertise and performed their attacks before the entry into force of the CWC—had some difficulties in synthesizing sarin (Tu, 2002).

The recent use of sarin on August 21, 2013, during the Syrian conflict was confirmed by the UN Mission, and it shows that nerve agents are still a real threat. Despite the limitations the UN Mission found while investigating the use of CWs in Syria, hopefully some interesting conclusions for the medical community will eventually emerge (Pita and Domingo, 2014).

Incapacitating Agents

Incapacitating agents are chemicals that produce a disabling condition that persists for hours to days after exposure has occurred. These were studied during the Cold War when it was assumed that incapacitating the enemy would cause damage not only because casualties would become unavailable for duty but also because they would need to be evacuated and would consume more logistical resources. Incapacitating agents include depressants and stimulants of the CNS. The main incapacitating agent is BZ (3-quinuclidinyl benzilate), a CNS depressant included in Schedule 2 of the CWC because it is produced in small commercial quantities for biomedical purposes.

Opioids have also been studied as incapacitating CWAs. In October 2002, a fentanyl derivative was used by Russian Special Forces to end a hostage crisis during

which Chechen terrorists had taken approximately 800 hostages at a Moscow theater (Wax et al., 2003). The dissemination of this opioid through the theater ventilation system killed approximately 130 people and injured more than 600. The fact that medical services did not have information about the identity of the chemical resulted in a lack of antidotal treatment of the poisoned hostages.

Riot Control Agents

Riot control agents (RCAs), popularly referred to as "tear gas" or "pepper spray," should not be confused with incapacitating agents. Unlike the latter, RCAs are local irritants with disabling effects that disappear within a short time after the exposure. Most important, RCAs do not act at the CNS level; therefore, they have lower toxicity and a wide margin of safety when compared with incapacitating agents. In fact, RCAs are not listed in the CWC schedules. Although the Convention prohibits its use as a method of warfare, it does not prohibit its use for law enforcement purposes.

Toxic Industrial Chemicals

TICs are of special interest in the chemical terrorism context because of the fact that they are widely available in large quantities, and even an attack against a chemical plant or transport vehicle may result in a release with potentially catastrophic consequences similar to the release of methyl isocyanate (a chemical used in the production of carbamate pesticides, as well as in the production of rubbers and adhesives) in Bhopal (India) in 1984.

The importance of TICs is reflected in the fact that the CWC features a schedule that includes chemicals that may be produced in large commercial quantities for industrial purposes, but that have been produced, stockpiled, or used as CWs. Schedule 3 includes phosgene, a lung-damaging agent, and some cyanides. Cyanides are commonly named "blood agents," something that may cause confusion, leading one to think that cyanides affect the oxygen transportation in the blood. The reason for calling cyanides blood agents was because chlorine and phosgene were toxic chemicals with local effects in the respiratory tract, whereas cyanides had to be absorbed in the lungs and passed to the blood to produce systemic effects. Although the toxicological mechanism of action of cyanides is well-known now, it is not rare to see them as blood agents when mentioned in the CWs or chemical terrorism context.

Toxins

Toxins are chemical substances of biological origin, although synthesis procedures for some nonprotein toxins that have been studied as weapons are widely available (Jacobi et al., 1984; Tanino et al., 1977). Toxins are included in the CWC because it covers toxic chemicals "regardless of their origin or of their method of production." Actually, two toxins, ricin and saxitoxin, are explicitly included in Schedule 1 of the CWC. However, toxins are also included in the Biological and Toxin Weapons Convention (http://www.opbw.org, accessed February 21, 2014). For these reasons, toxins can be considered CWs, biological weapons, or mid-spectrum agents.

EXTORTION ACTIVITIES WITH CWs

Throughout history, there have been extortion activities during which toxic chemicals have been used. For example, at the end of 1982, there were seven fatal cases of cyanide poisoning after the ingestion of acetaminophene-tampered capsules. McNeil Consumer Products had to destroy approximately 22 million units and changed the production from capsules to tablets that were more difficult to tamper with (Dunea, 1983; Wolnik et al., 1984). Those responsible were never identified, and some imitators in the United States started contaminating medicines and food products with toxic chemical substances.

In some cases blackmailers have even attacked governments. For example, on March 2, 1989, an anonymous person called the US and Japanese embassies in Santiago, Chile, alerting them that cyanide had been injected in fruit destined to be exported to those countries (Grigg and Modeland, 1989; Spiers, 2000; Wilkening, 1999). Although countermeasures were not taken initially, after a second call to the US embassy on March 17, the US Food and Drug Administration (FDA) decided to start inspections at the Philadelphia port, the port of entry of approximately 80% of the fruit from Chile. After an extensive search, only two grapes that had been injected with a small quantity of sodium cyanide were found. However, as a preventive measure, on March 13, all fruit coming from Chile was placed on quarantine. Subsequent searches did not find more tampered fruit and the quarantine ended on March 17. Although the event ended without any poisoning cases, it meant losses of approximately $300 million for Chile's fruit export market.

Since 2009, there have been suspected mass poisoning attacks on girls' schools in Afghanistan (Pita and Gunaratna, 2010). The victims have suffered nausea, vomiting, and unconsciousness, but there have been no deaths reported or confirmations that chemical attacks had taken place. The Taliban, which opposes female education, has denied responsibility.

STATE TERRORISM

CWs have also been used in the assassination of selective targets by Secret Services. The defection of KGB's Capt. Nikolai Khohhlov in February 1954 brought to light some of the devices created for this type of attack. In fact, Khohhlov defected in the middle of a mission to assassinate Georgi Okolovich, a Soviet dissident living in West Germany, by using a cigarette pack that concealed a hydrogen cyanide ampoule (Andrew and Gordievsky, 1990). Similar cases include the killing of two Ukrainian exiles in Munich in 1957 and 1959 by a KGB agent who used a special gun device to disperse hydrogen cyanide. According to Vadim Birstein, since the 1920s and at least until the late 1970s, different laboratories in the Soviet Union were in charge of the development of assassination devices for their Secret Services (Birstein, 2001). The 2004 dioxin poisoning of Viktor Yushchenko, former Ukrainian president, and the 2006 polonium-210 poisoning of Alexander Litvinenko show that these type of activities are not something of the past (le Polain de Waroux et al., 2011; Sorg et al., 2009).

One of the most bizarre stories of assassination is the murder of Georgi Markov, a Bulgarian journalist exiled in the United Kingdom, with an umbrella that delivered ricin (Crompton and Gall, 1980; Knight, 1979). The umbrella was allegedly modified to fire a small pellet filled with approximately 500 μg of ricin. On September 7, 1978, Markov was waiting for a bus on Waterloo Bridge when he felt a strong puncture in the back of his right thigh. When he turned around, a man with an umbrella apologized. The next day he was hospitalized with fever, vomiting, speaking difficulties, and a white cell count of 10,600/mm^3 that increased to 33,200/mm^3 3 days later. On September 11, Markov died of cardiac failure. The autopsy revealed the presence of a small spherical pellet with a diameter of 1.53 mm that had two holes of 0.34 mm. Days before Markov was attacked, on August 26, another Bulgarian exiled in Paris, Vladimir Kostov, also felt a puncture in his back and had to be hospitalized for 12 days, although he finally recovered. On September 26, a similar pellet—spherical, of 1.52 mm diameter, with two holes of 0.34 mm—was extracted from his back.

No public reports about the identification of ricin have been published, but the ricin link was made based on the (Birstein, 2001; Waller et al., 1966) differential diagnosis by the United Kingdom's Ministry of Defense scientists (they even administered ricin to a pig to compare the clinical signs of the poisoning with the ones observed in Markov), histopathological findings that were similar to those found in different *in vivo* tests with animal models, and intelligence regarding a ricin program in the Soviet Union and perhaps other Warsaw Pact nations.

Years later, former KGB members stated that the umbrella was provided by the KGB to the Bulgarian Secret Services, and previous attempts to kill Markov had been unsuccessful (Andrew and Gordievsky, 1990; Kalugin, 1994). Because Bulgarian documents about the Markov case seem to have been destroyed, only future KGB document releases would disclose more information about this murder (Carus, 2002). However, the former Warsaw Pact Secret Services were not the only ones to perform such programs, as seen during the appearances of CIA officials in the Senate Committee known as the Church Committee, which took place during September 16–18, 1975. Former CIA Director William Colby explained that the CIA had an incapacitating agents program (known as MKULTRA) and provided documents detailing the CIA stock of CWs at that time, which included small quantities of BZ, toxins, and cyanide pills, among others (Select Committee to Study Governmental Operations with Respect to Intelligence Activities, 1976).

NATIONALIST AND SEPARATIST TERRORIST GROUPS

Secular terrorist groups have not showed special interest in CWs, perhaps thinking that its use may be rejected by their own followers (although many of them have performed terrorist attacks with conventional explosives that produced a high number of casualties). There are some reported cases indicating that nationalist and independent groups have used chemical substances in sabotage actions. For example, in 1992 the Kurdistan Workers' Party (PKK) allegedly contaminated several water tanks with sodium cyanide in an air base near Istanbul. The attack was aborted when the recipients of 25 kg of potassium cyanide were found next to the tanks (Karasik, 2002).

Another example can be found in the Liberation Tigers of Tamil Eelam (LTTE) in Sri Lanka. Although the LTTE was a secular terrorist group, their members showed a level of veneration for their leader, Velupillai Prabhakaran, akin to that of a religious cult, and even used tactics used by jihadist terrorist groups. LTTE members were known to carry sodium cyanide capsules that had to be used to commit suicide in case of capture. There are also some reports about the use of sodium cyanide against Sri Lanka's economic interests (Carus, 2002; Wilkening, 1999). The first report is from 1986, which mentions attempts to sabotage tea exporting by informing different embassies that some lots were contaminated with cyanide. US authorities analyzed different lots but did not find anything strange. The second report is from December 1996, when potassium cyanide was

allegedly applied to stamps used by the Sri Lanka Army. But the most important LTTE chemical attack occurred in June 1990, using drums of chlorine against a military camp located at east Kiran, although there is no information about the number of casualties (Hoffman, 2009).

LEFT-WING TERRORIST GROUPS

In May 1975, the Baader-Meinhof Gang, also known as the Red Army Faction (RAF), a left-wing terrorist group based in West Germany, threatened to use mustard gas in Stuttgart and other cities in Germany if imprisoned members were not freed. However, in-depth studies of this incident have found no evidence of the access of the RAF to mustard gas (Claridge, 2000). The terrorist organization was taking advantage of media reports indicating that old mustard gas containers from World War I had disappeared from a CW destruction facility.

Colombian guerrillas (initially left-wing terrorist groups but today are considered narcoterrorism groups because of their association with organizations that deal with illicit traffic of drugs of abuse) have performed small attacks with CWs. On December 2, 2001, members of the Revolutionary Armed Forces of Colombia (FARC) attacked a police station in San Adolfo (Huila), probably with cyanogen chloride, killing four policemen. Since then, munitions charged with cyanide have been found in raids against FARC camps. In fact, in November 2007, Colombia's National Police showed their concern after finding a clandestine FARC laboratory near the frontier with Ecuador that was working on the filling of rockets with toxic chemicals (Pita, 2008). The chemicals included ammonia, chlorine, and cyanide compounds.

RIGHT-WING TERRORIST GROUPS AND LONE WOLVES

It is not uncommon to find criminal activities using CWs linked with right-wing groups or sympathizer lone wolves. The two most common agents used have been cyanides and ricin. Actually, hydrogen cyanide production and ricin extraction procedures are commonly found in "cookbooks," publications that are popular among members of white supremacist groups and in "amateur terrorist" circles. Some of these titles include *Assorted Nasties*, *The Preparatory Manual of Chemical Warfare Agents*, *The Poisoner's Handbook*, and *Silent Death*.

Although hydrogen cyanide gas (boiling point at 760 mmHg, 25.7°C; vapor pressure at 20°C, 600 mmHg) is easy to obtain by mixing the right cyanide salt and acid, transporting and mixing the reagents without being discovered constitutes one of the biggest hurdles in terrorist attacks. Regarding the ricin extracted with procedures included in cookbooks, it is not able to achieve a good product for causing a large number of casualties by any exposure route, mainly because of the low content of toxin of the final extracts (Pita et al., 2004).

In the mid 1980s, a group named the Covenant, the Sword, and the Arm of the Lord obtained potassium cyanide to contaminate water supplies of different US cities (Stern, 2000). In a raid that took place on one of their facilities, authorities found a drum with 30 gallons of potassium cyanide. When one of its members was told that the attack would kill not only those he considered enemies (Jews and "mud-people") but also other people, including members or sympathizers of the group, his reply was: "We felt that God would take care of this [and] that those who were meant to die would be poisoned" (Stern, 2000). And when he was told that 30 gallons were not enough to obtain a toxic concentration in the city's water reservoir he answered: "God would… make sure the poison got to the town" (Stern, 2000). He even explained that they had decided to act because there were signs of the arrival of the Armageddon: "You get tired of waiting for what you think God is planning" (Stern, 2000). These statements make it clear that terrorist groups with religious motivations most of the time have no moral restraints in performing attacks to cause a large number of casualties. In fact, Christian-identity right-wing groups and lone wolves have also carried out terrorist attacks that have caused a large number of casualties, like the April 19, 1995 bombing of the Alfred P. Murrah Federal building in Oklahoma that caused 168 fatalities and more than 500 nonlethal casualties.

In 1991, four members of the Minnesota Patriots Council, an anti-government right-wing group, obtained a kit called "Silent Tool of Justice" that contained approximately one dozen castor plant seeds and a toxin extraction procedure that one of the members followed. The plan was to mix the toxin with dimethyl sulfoxide (DMSO) and aloe vera gel and apply it on doorknobs of different individuals that were considered enemies of the group (Tucker and Pate, 2000). The four members were arrested in 1994.

Cases of lone wolves with intentions of using CWs are not rare. For example, in the mid 1970s, authorities found 25 pounds of sodium cyanide at the apartment of Muharem Kurbegovic, the "Alphabet Bomber" (Simon, 2000). Other chemicals and documents found showed a special interest in CWs. Kurbegovic had threatened to use nerve agents, but he did not have any when arrested. A good example of a lone wolf linked to right-wing groups is Thomas Leahy (Carus, 2002). In 1997, an enforcement officer in Wisconsin responded to a report of spousal abuse made by Leahy's wife. When the officer arrived, the wife opened the door wearing a mask and explained the reason to the officer: "Because my husband is in the basement making poison gas" (Gurr and Cole, 2000). Among

the items found in the laboratory were some cookbooks, ricin extracts, and three spray bottles with a mix of nicotine and DMSO. Also, in 2004, an arms trader with white supremacist group connections was sentenced to 11 years in prison (Kosal, 2006). In April 2003, authorities had raided his Texas warehouse arsenal and found that he was building an improvised chemical device (ICD) based on the mixing of sodium cyanide and an acid.

APOCALYPTIC CULTS: AUM SHINRIKYO

Although Aum Shinrikyo sarin attacks are detailed in Chapter 4, the Japanese cult is a clear example of how difficult it is to produce a CWA and use it as a weapon with an efficient dissemination system, especially taking into account that the cult had adequate financial resources and technological means. The cult also benefited from the 1951 Religious Corporation Law that grants tax exemptions to religious organizations in Japan and protection against possible interference of the state in their activities. This advantageous situation allowed Aum Shinrikyo, when it started its chemical, biological, and toxin programs, to enjoy a position that would be similar to that within a proliferating state—where there is no need to hide these activities from the security forces because the program is integrated within government activities—rather than a terrorist organization.

But sarin was not the only CW used by the cult, which even had a biological weapons program, although it was less successful than the chemical one. After the Tokyo sarin terrorist attacks in 1995, Aum Shinrikyo cult members tried an attack with hydrogen cyanide. On May 5, they used an ICD in Shinjuku's Tokyo subway station that consisted of two plastic bags, one with sodium cyanide suspended in 2L of water and another one with 1.5L of a sulfuric acid solution (Dolnik and Gunaratna, 2008; Tu, 2002). The activation system consisted of two condoms, one with sodium chlorate and another with sulfuric acid, so when the latter ate the latex the fire produced would break the plastic bags and allow the mixing of the cyanide salt and the acid, producing hydrogen cyanide. However, the quantities were not well-calculated and the fire destroyed the ICD. On July 4 and 5, another two attacks occurred in Tokyo, this time using an ICD in which the activation of an electrical device with blades would break the plastic bags. One ICD failed, while the other only produced one case of mild poisoning.

JIHADIST TERRORISM: AL QAEDA

Al Qaeda's WMD Intentions

There are three phases in the statements of Al Qaeda members related to WMD. In the first phase, Al Qaeda tended to justify the acquisition and possession of these weapons from the point of view of deterrence. This phase goes as far back as 1998, when Osama bin Laden had stated that acquiring WMD was a "religious duty" (Pita, 2007). This and similar statements were made by bin Laden in different interviews after the US attack on the Al Shifa Pharmaceutical Industries factory in Khartoum on August 20, 1998. This attack was part of Operation Infinite Reach in retaliation for the bombings of the US embassies in Kenya and Tanzania on August 7, 1998, for which the bin Laden terrorist network was blamed by US officials. The Al Shifa target was justified in the finding of *O*-ethyl methylphosphonothionate, a precursor of the nerve agent VX, in soil samples outside the factory, and in the financial contributions of bin Laden to the production of CWs. Soon after 9/11 and the mailings of envelopes with *B. anthracis* spores in the United States, bin Laden was interviewed again; when asked about reports claiming that he was trying to acquire WMD, he answered: "We have the weapons as deterrent" (Pita, 2007).

The second phase of statements of Al Qaeda members related to WMD began soon after the overthrow of the Taliban regime in Afghanistan. Al Qaeda's reasoning was that the Coalition Forces had used conventional weapons (e.g., missiles) that had caused a large number of casualties and destruction, and for this reason these weapons could be considered WMD. This interpretation justified the use of chemical, biological, radiological, and nuclear (CBRN) weapons as retaliation for similar attacks. The most well-known statement in this second phase was made by Suleiman Abu Gheith, Al Qaeda's spokesman, who wrote in his 2002 electronic article "In the Shadow of the Lances" that based on this reasoning they had the "right to kill four million Americans—two million of them children—and to exile twice as many and wound and cripple hundreds of thousands" (Pita, 2007).

The third phase started in May 2003, when Shaykh Naser bin Hamad Al Fahd, a Saudi cleric who supports the global jihad movement, issued a fatwa justifying and authorizing the use of WMD (Paz, 2005). Al Fahd used arguments based on reciprocity, stating that the United States had used weapons that caused a large number of casualties and mass destruction. But what was new in this fatwa was that Al Fahd's arguments were also based on Islamic texts that supposedly justify that it is permissible to use WMD if those engaged in jihad decide there is benefit in using them. And this is the case of Al Qaeda's influential strategist Mustafa Setmarian Nasar, better known as Abu Musab Al Suri, who posted a letter on the Internet in December 2004 stating that the use of WMD was "a necessity."

Al Qaeda's interest in WMD may also be based on their important psychological effects. An objective of using these weapons in a military scenario is not only to

cause physical casualties but also to demoralize troops. Similarly, in a terrorist attack on civilians, one of the primary goals is to create a general sense of panic and fear, resulting in psychological trauma and disruption of economic and social activities (Zanders, 2003). For these reasons, WMD can also be regarded as "weapons of mass *disruption*." For instance, it is frequently asserted that the Aum Shinrikyo sarin subway attack caused more than 5,000 casualties, but actually only approximately 1,000 patients had clinical signs of sarin exposure (Woodall, 1997). That means that approximately 4,000 people who sought attention in medical facilities were, in fact, mainly psychological casualties with psychogenic symptoms. Based on a book by Abu Walid Al Misri, editor of a magazine for the Taliban, quoted in Peter Bergen's book *The Osama bin Laden I Know* (2006), Al Qaeda has been aware of the psychological effects of WMD since they first thought about acquiring them.

Al Qaeda's CWs Capabilities

The first information of Al Qaeda's CWs programs came from Jamal Ahmed Al Fadl (an Al Qaeda member who defected and became a US government informer in 1996), who claimed that in the early 1990s he and other Al Qaeda members discussed the start of a manufacturing program of CWs with a Sudanese army officer (Bergen, 2001; Clarke, 2004; Tucker, 2006). In fact, the Al Shifa facility would have been part of this program.

Since October 2001, reporters and military forces in Afghanistan found written and electronic documents with rudimentary procedures for the production and use of toxic chemicals (Pita, 2007). These procedures are similar and, in some cases, word-for-word translations from the ones included in the cookbook publications mentioned previously. Actually, two well-known cookbooks were found in Afghanistan, *Assorted Nasties* and *The Poisoner's Handbook*. This material came mostly from the Abu Khabab camp located in the Darunta training camp complex that specialized in explosives and toxic chemicals training (Gunaratna and Acharya, 2006). This camp was named after the man who ran it, the Egyptian Midhat Mursi, commonly known as Abu Khabab, who was killed in a US air strike on the Pakistan–Afghan border in July 2008.

Ahmed Ressam, an Algerian arrested by US authorities for carrying explosives that he intended to use in a bombing against the Los Angeles International Airport, explained in court in July 2001 that he had been trained in the Darunta training camp complex in 1998 to prepare hydrogen cyanide by mixing a cyanide salt and sulfuric acid (Pita, 2007). He was told to release it near the air intake vents of buildings and even participated in live training exercises using dogs. In August 2002, Cable News Network aired several Al Qaeda videotapes obtained in Afghanistan that revealed experiments with chemical agents on dogs. One of those tapes showed several men—apparently after having mixed several chemical reagents—rushing out of an enclosure, inside which was a tied-up dog. Soon, a white vapor appeared and a few moments later the dog started showing the first clinical signs of exposure. The quality of the images was not good enough to identify a toxidrome, but the videotape was reminiscent of what Ahmed Ressam said about his training with hydrogen cyanide in Afghan camps. These experiments were allegedly recorded by Abu Khabab in the Darunta training camp complex. In November 2006, a book published by Nasiri (2006), the pseudonym of an alleged informer of the British and French intelligence services, explained his participation in experiments with animals using cyanide at the Khalden training camp. Nasiri describes the failed attempts to develop mustard gas munitions in Khalden. He states that after many trials, finally the camp members celebrated when the shell produced a "thick cloud of smoke." However, this does not mean that the munition was effective in disseminating mustard gas.

One of the most relevant discoveries in Afghanistan regarding the chemical and biological weapons program was made by *Wall Street Journal* reporter Alan Cullison, who obtained two computers from a looter who allegedly stole them from Al Qaeda's central office in Kabul on November 12, 2001 (Cullison, 2004; Cullison and Higgins, 2001). The looter told Cullison he had found the computers in the office of Al Qaeda's military commander Muhammad Atef (aka, Abu Hafs), a strong supporter of Al Qaeda's acquisition of WMD, who was killed in a US air strike that same month. Computer files included information of Al Qaeda's effort to start a chemical and biological weapons program code-named "Al Zabadi" ("yogurt") in May 1999 with an initial budget of only $2,000–4,000. Based on Cullison's analysis of the computer files, Ayman Al Zawahiri—Al Qaeda's second-in-command at that time—and Abu Hafs (assisted by Abu Khabab) started the program after studying different books and articles from biomedical journals.

According to former CIA Director George Tenet, Al Qaeda became interested in chemical and biological weapons after Aum Shinrikyo's 1995 sarin attack on the Tokyo subway (Tenet and Harlow, 2007). But an electronic message sent by Al Zawahiri to Hafs in 1999 stated that it was "the enemy" who brought these weapons to his attention, possibly US Secretary of Defense William Cohen (Leitenberg, 2004, 2005). In November 1997, Cohen appeared on television showing a 5-pound sugar package and saying that if it were to contain spores of *B. anthracis* and were spread over Washington, DC, half the city's population would die. A photograph of Cohen holding the 5-pound sugar package was allegedly also found in Afghanistan (Leitenberg, 2004).

No public report of sophisticated CBRN means or production facilities found in Afghanistan has yet been made. Only a centrifuge and an "oven" found near Kandahar have been presented by the US Department of Defense as the equipment Al Qaeda intended to use to produce chemical and biological weapons (Miller, 2002). This material was part of a laboratory that was being built for the production of *B. anthracis* spores (Pita and Gunaratna, 2009).

Based on intelligence assembled from collected documents, detainee interviews, and reconnaissance of Al Qaeda facilities during Operation Enduring Freedom, the Commission on the Intelligence Capabilities of the United States Regarding Weapons of Mass Destruction (US WMD Commission) concluded in its unclassified report that Al Qaeda did not have large-scale chemical and biological weapons capability (US WMD Commission, 2005). Still, past and current chemical and biological programs are said to be not fully understood, especially because of difficulties in penetrating the terrorist network and, therefore, in collecting human intelligence (HUMINT).

After the disappearance of the Afghan training camps, the Internet and jihadist websites have acquired more relevance. Al Suri's book, *The Global Islamic Resistance Call*, posted on the Internet in 2005, suggests an asymmetric approach that includes the use of WMD as well as a decentralized and diffused global jihad in which autonomous cells play an important role. Autonomous cells were to be self-sufficient, including having training capabilities. For these reasons, jihadist websites are important tools providing autonomous cells with training manuals as well as lessons learned from attacks by other cells. These electronic training manuals include information and procedures about toxic chemicals similar to those found in Afghanistan, that is, similar to the information included in cookbooks. Some of these websites offer scanned copies of these cookbooks.

Al Qaeda Plots with CWs

A detailed study of incidents with CWs linked to Al Qaeda shows that cyanides, ricin, and TICs have been the main choices of jihadist terrorists (Pita, 2007). Nerve agents also seem to be of interest, especially because of their toxicological and physico-chemical properties, which make them ideal for tactical use in terrorist attacks. However—and as previously mentioned—the synthesis process requires some level of expertise and is far more complex than the recipes featured in jihadist manuals.

Nerve Agents

Open sources have reported jihadist cells planning terrorist attacks with nerve agents and showing interest in these CWAs; in any case, they had the chemical agent or proved that they had acquired the capability to produce it.

The *Daily Telegraph* (London) reported that members of an Al Qaeda cell based in the United Kingdom were arrested while planning to release sarin in the European Parliament building in Strasbourg in February 2001, although no actual evidence of sarin was found (Bamber et al., 2001). Also, in February 2001, the *Daily Telegraph* reported that British police had foiled a plot involving sarin against the London underground (Hastings and Bamber, 2001). Once again there was no evidence of the actual presence of the nerve agent. Both incidents seemed to be linked and related to a transnational network of Al Qaeda cells in the United Kingdom, Germany, Italy, Belgium, France, and Spain. What these cells had in common was that their key members had been trained in Afghan camps in the mid to late 1990s. The network was planning terrorist attacks with conventional weapons and chemical substances. In a conversation on March 13, 2001 that was bugged, a member of the Italian cell mentioned "an extremely efficient liquid that suffocates people," suggesting it could be placed in tomato cans, exposing people when the cans were opened (Finn and Delaney, 2001). Referring to the German cell, he mentioned, "They arrested them while they were preparing the gas." The chemicals this cell possessed were acquired in 48 separate purchases at pharmacies but were, in fact, intended to be used in improvised explosive devices (IEDs), not in nerve agent production (Finn, 2002; Finn and Delaney, 2001; Pita, 2007).

On November 14, 2003, the following headline appeared in the Spanish newspaper *La Razón* (Madrid): "The FBI believes that the Salafists intended to mix napalm with sarin gas" (Arnuero, 2003). This was in reference to the chemical substances found in possession of a supposed Al Qaeda–related cell whose members were arrested in Barcelona in January 2003. However, sarin was not present among the chemicals, nor were any of its precursors. Later, it was made public that the Spanish cell, helped by other cells based in France and the United Kingdom, was planning a chemical attack against a naval base in Rota (Spain), used jointly by Spain and the United States (Martínez and Muñoz, 2005).

Based on Iraq Survey Group investigations, the special advisor to the director of central intelligence on Iraq's WMD reported on September 30, 2004, that the Al Abud network (a network of Iraqi insurgents) attempted to produce tabun, nitrogen mustard, and ricin from late 2003 to mid 2004 (Duelfer, 2009; Iraq Survey Group, 2004). These attempts failed, but they did fill nine mortar rounds with malathion, an organophosphate insecticide.

Based on an internal British police document and on information disclosed by a UK senior officer, the *Sunday Times* (London) reported in August 2005 that Scotland

Yard had thwarted an Al Qaeda attack on the House of Commons with "chemicals, a dirty bomb, and sarin gas" (Leppard and Winnett, 2005). The report mentioned that the plot was discovered after decoding encrypted e-mail messages in 2004, but there was no mention of the actual presence of the agents. This report was presumably linked to the arrest of eight men in August 2004 in the United Kingdom who were charged with conspiracy to commit public nuisance by the use of "radioactive materials, toxic gases, chemicals, and/or explosives" (Pita, 2007). No chemicals were found, although one of the arrested men, Dhiren Barot, had two notebooks with information of explosives and toxic chemicals as well as reconnaissance information of financial facilities in the United States. Later, Barot was reported to have been a trainer in Afghanistan camps in the late 1990s.

More recently, in June 2013, the Iraqi Defense Ministry said that they foiled a plot by an Al Qaeda cell to use remote-controlled toy planes to disseminate CWs, including sarin and mustard gas (Roggio, 2013). The cell was allegedly planning to execute the attacks in the Middle East, Europe, and North America. However, when the five cell members were arrested they had not yet been able to produce any CWA.

Cyanides

The first case of an Al Qaeda terrorist attack linked to chemical terrorism is the February 1993 World Trade Center bombing, as it is commonly believed that the explosives were mixed with a cyanide compound. The reason is that during the trial the judge stated: "You had sodium cyanide around, and I'm sure it was in the bomb. Thank God the sodium cyanide burned instead of vaporizing. If the sodium cyanide had vaporized, it is clear what would have happened is the cyanide gas would have been sucked into the north tower and everybody in the north tower would have been killed. That to my mind is exactly what was intended" (Parachini, 2000).

This was based on the idea that the terrorists considered the tactic of using a toxic chemical in the attack and on the fact that the FBI found a small bottle of a sodium cyanide solution in a storage shed. However, hydrogen cyanide was never detected in the attack and even a detailed case study of this event concludes that no toxic chemical was mixed with the explosives (Parachini, 2000).

On February 19, 2002, four Moroccans, members of the Salafi Group for Preaching and Combat (GSPC, now Al Qaeda in the Islamic Maghreb) were arrested in Rome (Pita, 2007). They had approximately 4 kg of potassium ferrocyanide that they intended to use to contaminate the water supplies near the US embassy. Nevertheless, that particular substance is widely used as a food additive (E 536) and, because of its toxicological properties, was probably not the best choice to use in a chemical attack.

Based on information in Ron Suskind's *The One Percent Doctrine*, an Al Qaeda cell based in Saudi Arabia planned an attack on the New York City subway with Al Mubtakkar devices (Suskind, 2006). Basically, the Al Mubtakkar device is an ICD supposed to work as a crude binary munition (a binary chemical munition is one in which chemical substances held in separate containers react when mixed or combined as a result of being fired, launched, or otherwise initiated to produce a CW). It produces hydrogen cyanide when a barrier that separates the cyanide salt (potassium cyanide) and the acid (hydrochloric acid) is broken. Potassium permanganate is also included for the device to potentially produce a mix of hydrogen cyanide, cyanogen chloride, and chlorine. The device can be activated manually or by using the explosive triacetone triperoxide (commonly known as TATP) and a detonator. The detonator can be activated remotely or with a temporizer, allowing terrorists to escape; however, the probability is high that, if not well-regulated, the explosion will inactivate the chemical reagents and obviate production of the cyanogen agent.

Suskind (2006) states that the cell members had traveled to New York City from North Africa in the autumn of 2002, and had even carried out reconnaissance missions to identify targets. Surprisingly, when Al Qaeda's leader in Saudi Arabia, Sheikh Yousef Al Ayiri, told Al Zawahiri about the plot in January 2003, the latter decided to cancel the operation. Suskind's book claims that this decision was made just 45 days before the intended attack.

Ricin

Ricin was reported to have been detected in January 2003 in an apartment in the north of London where North African Al Qaeda sympathizers were living. The raid took place when the United Kingdom received a tip-off from the Algerian intelligence services indicating that "poison" had been prepared there. This ricin finding turned out to be a false positive, because subsequent analyses of samples by the British reference laboratory did not identify ricin (Leitenberg, 2005). However, 20 *Ricinus communis* seeds and a written ricin extraction procedure—copied from a cookbook and downloaded from the Internet—were found (Stenersen and Lia, 2007). The alleged plot was to use ricin on door handles (perhaps with DMSO). The fingerprints on the material and the handwriting analysis identified Kamal Bourgass, an Algerian refugee who had applied for asylum in the United Kingdom in 2000. It seems (but is not clear) that he attended training camps in Afghanistan. Of all the arrested men, only Bourgass was convicted, on April 8, 2005, of conspiring to commit a public nuisance by the use of poisons and/or explosives. At an earlier trial in 2004, he had been convicted of killing a police officer

during his capture in an apartment in Manchester on January 14, 2003.

Intelligence reports from 2010 mentioned that Al Qaeda in the Arabian Peninsula was trying to acquire large quantities of *R. communis* seeds in Yemen to produce ricin (Schmitt and Shanker, 2011). No further information about this has been made public.

Toxic Industrial Chemicals

On March 30, 2004, anti-terrorism police in the United Kingdom arrested eight alleged sympathizers of Al Qaeda who were supposedly planning to use osmium tetroxide against Gatwick Airport, the London subway, and other enclosed high-traffic areas, although they did not have the chemical when arrested (Baker and Kosal, 2004). Osmium tetroxide is often used as a stain in biology laboratories. One month later, Jordanian authorities announced that they had defeated an Al Qaeda plot to use explosives and large quantities of TICs such as sulfuric acid, cyanide salts, and pesticides against the US embassy in Amman, the Jordanian prime minister's office, and the headquarters of the Jordanian General Intelligence Department (Levitt and Sawyer, 2004).

From October 2006 until mid 2007, suicide terrorists in Iraq detonated vehicle-borne IEDs carrying chlorine cylinders (Pita, 2012). This new tactic clearly shows that the use of TICs is an option that may yield better results than following the crude and rudimentary procedures of Al Qaeda–related publications for the production of CWs. However, the chlorine attacks in Iraq were still rudimentary in their means of delivery. In most of the attacks casualties were not caused by chlorine exposure, but rather because of the mechanical and thermal effects of the explosion. Also, in some attacks chlorine was not released because the low mechanical effect of the explosion was not enough to break the cylinders.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Nerve agents are the most important CWs because of their high toxicity and versatility in tactical use. However, the production difficulty seems to be their most important drawback. Amateur production of CWAs or extraction of toxins by using cookbooks and Al Qaeda–related manuals has commonly been overrated, leading to supposedly catastrophic consequences of terrorist attacks. In fact, CWs are frequently described as "the poor man's atomic bomb," but this description was used at the end of World War II to explain that for a state actor tying to acquire WMD capability, chemical and biological weapons would be a more feasible option than nuclear weapons, which require more complex technical resources.

An additional problem for terrorists is the need to have a reliable delivery system. Effective dissemination may be even more difficult than obtaining the agent, especially if the objective is to cause a large number of casualties. The "art" of CWs includes the research and development of special munitions that, among other things, do not inactivate the agent by the thermal effect of the explosion. Aerosolization dispersal systems are another option. Luckily, another gap in the information in the Al Qaeda–related publications and cookbooks is the often inaccurate information regarding delivery systems.

We should also take into account advances in science and technology, because some of the drawbacks in the production of CWs and dissemination systems may disappear in the future, making re-evaluation of threat assessments necessary. The lack of adequate procedures and programs for the production of CWs may explain why, until now, jihadist terrorists have not been capable of achieving an effective chemical attack. But it is clear that they are both interested in CW capability and are actively trying to obtain it. For this reason, it should not be dismissed that options other than self-production may also be attempted, for example, resorting to sponsoring states or black-market arms trafficking networks. In fact, the possibility that Syrian CWs could have fallen into the hands of terrorist groups during the ongoing civil war should be seriously considered.

The ready access to TICs in the chemicals industry makes them attractive to nonstate actors also. The threat of insiders who work with toxic chemicals and whose integrity may be compromised by terrorist groups is one of the main concerns of intelligence services today. Insiders who decided to participate in chemical terrorism could have a variety of motivations, from ideological to financial. Advances in science and technology have also increased the number of people working with toxic "dual-use" chemicals and with the explicit and tacit knowledge that could be used for terrorist purposes.

In conclusion, analysis of the chemical terrorism threat shows how important it is that medical personnel consider CWs poisoning in the differential diagnosis in cases of suspected chemical terrorist attacks and have knowledge of CWAs, including their effects and medical treatment.

CHAPTER

8

Mustards and Vesicants

Robert A. Young and Cheryl B. Bast

INTRODUCTION

In the simplest terms, vesicants are chemicals that cause tissue blistering. Their toxic activity is not limited to the skin, however, and their mode of action is complex. These cytotoxic alkylating agents were initially developed as chemical weapons used to induce ocular, dermal, and respiratory damage that results in immediate casualties, reduction in fighting efficiency, and demoralization. Depending on the exposure, injury may be local or systemic. This chapter will focus on sulfur mustards, nitrogen mustards, and lewisite. (Although occasionally classified as a vesicant due to its action as a skin, eye, and respiratory tract irritant, phosgene oxime (CX) is more appropriately considered an urticant, or nettle agent, and is not discussed here.) Extensive information regarding the chemistry and toxicology of vesicants is available in several publications (Papirmeister et al., 1991; Somani, 1992; USACHPPM, 1996; ATSDR, 2003; Romano et al., 2008). In response to a request by the U.S. Department of Veterans Affairs (VA), a panel of experts extensively reviewed and evaluated the medical and scientific literature on mustard agents and lewisite, as well as the military testing programs relative to these agents (IOM, 1993).

The term *sulfur mustard* may refer to distilled mustard (bis(2-chloroethyl)sulfide; HD, sesqui mustard (SM)), Levenstein mustard (H), agent HT (a mixture of HD and bis(2-chloroethylthioethyl)ether), or a sulfur mustard–lewisite mixture (HL). Distilled mustard (HD) is relatively pure (97%) bis(2-chloroethyl)sulfide and results from the vacuum distillation of HD. Generic references to sulfur mustard usually mean HD. Levenstein mustard (H) is a mixture of HD and sulfur impurities (generally in a 70:30 ratio), and as its name implies, it was produced by the Levenstein process, which involves reacting ethylene with sulfur chloride. Agent H may contain sulfur impurities imparting a yellowish color and sweet, garliclike odor.

Agent HT is generally a mixture of 60% HD and 40% bis(2-chloroethylthioethyl)ether (T), although this ratio may vary. Agent HL is a mixture of sulfur mustard (HD) and lewisite (L) that was developed for cold weather or high-altitude use due to its lower freezing point. SM is 1,2-bis(2-chloroethylthio) ethane and is considered a more potent vesicant than HD, but its very low vapor pressure limits its effectiveness as a warfare agent. That condition is remedied by combining it with HD to form agent HQ. The removal of one chlorine from sulfur mustard results in "half-mustard" (2-chloroethyl ethyl sulfide, or CEES), a monofunctional sulfur mustard analog. Although retaining some alkylating properties, half-mustard is not as highly regulated as sulfur mustard and is frequently used in sulfur mustard research. Most of the discussion of sulfur mustards in this chapter will be about distilled sulfur mustard (HD).

Nitrogen mustards include HN1 [bis(2-chloroethyl) ethylamine], HN2 (2,2′-dichloro-N-methyldiethylamine), and HN3 [tris(2-chloroethyl)amine hydrochloride]. As will be discussed later in this chapter, some of these were used in therapeutic arenas rather than in warfare.

Lewisite [L or L-1; dichloro(2-chlorovinyl) arsine] is an arsenical vesicant developed early in the twentieth century. Lewisite occurs as cis- and trans-isomers, the typical ratio being 10:90. Several impurities, including bis(2-chlorovinyl)chloroarsine (L-2) and tris(2-chlorovinyl)arsine (L-3), are typically present. The chemical and physical properties of cis- and trans-isomers are similar.

Sulfur Mustards

Sulfur mustards are chemical vesicants capable of causing severe skin and eye damage at very low concentrations. Table 8.1 shows the chemical name, synonyms, identification codes, chemical formula, and structural formula for sulfur mustard.

Handbook of Toxicology of Chemical Warfare Agents.

TABLE 8.2 Selected Physical and Chemical Properties of Sulfur Mustard

	Value	References
Physical state	Oily liquid	MacNaughton and Brewer (1994)
Molecular weight	HD: 159.08	DA (1996)
Density	5.4	DA (1996)
Boiling point	HD: 215–217°C	Budavari et al. (1989); DA (1996)
Freezing point	HD: 14.5°C	DA (1996)
Vapor pressure (mmHg)	HD: 0.072 mmHg at 20°C; 0.11 mmHg at 25°C	DA (1996)
Water solubility (g/L)	Sparingly soluble in water; soluble in organic solvents	Budavari et al. (1989); DA (1996)

Although frequently referred to as "mustard gas," the chemical is a liquid at normal ambient temperatures. Due to its oily consistency and low aqueous solubility, sulfur mustard is persistent in the environment. Information on the half-life of HD in air is unavailable. As previously noted, impurities may impart a garliclike odor to sulfur mustard. Odor thresholds ranging from 0.15 to 0.6 mg/m^3 have been reported for sulfur mustard (Dudley and Wells, 1938; Bowden, 1943; Fuhr and Krakow, 1945; Ruth, 1986).

Watson and Griffin (1992) have summarized information on the distribution of unitary chemical weapon stockpiles in the United States. The chemical and physical properties of sulfur mustard (agent HD) are shown in Table 8.2.

The water solubility of sulfur mustard has been reported as 0.092 g/100 g water at 22°C (DA, 1974), and 5×10^{-3} M at room temperature (MacNaughton and Brewer, 1994). In dilute aqueous solutions, sulfur mustard hydrolyzes almost completely to thiodiglycol and hydrochloric acid (Papirmeister et al., 1991). For dissolved HD, the hydrolysis half-life ranges from about 4 to 15 min for temperatures of 20–25°C. Bulk HD may persist in water for up to several years (Small, 1984). It has been estimated that it takes 15 days for the mass of a 1-cm droplet of HD in quiescent water to decrease by half (Small, 1984). The Henry's law constant for HD has been estimated to be 2.1×10^{-5} atm m^3/mol (MacNaughton and Brewer, 1994), indicating a moderate potential for evaporation from water.

The persistence of sulfur mustard in soil depends on the soil type, pH, moisture content, and whether the agent is at the soil surface or buried. Small (1984) reported that HD applied to the soil surface volatilized and would likely be the main route of HD loss (with a half-life of about 30 min). In wet soil, however, hydrolysis would be the primary loss pathway. When sprayed onto soil, a vesicant action may persist for about 2 weeks, but when the agent continually leaks into the soil, vesicant action may be present after 3 years (DA, 1974). Rosenblatt et al. (1995) state that the persistence of sulfur mustard in soil is due to the formation of oligomeric degradation products that coat the surface of the mustard agent and that are resistant to hydrolysis. This may greatly enhance the environmental persistence of sulfur mustard. Sulfur mustard has a log K_{ow} of 1.37 and a K_{oc} of 133, indicating that binding to soil organics would limit transport through soil to groundwater (MacNaughton and Brewer, 1994). MacNaughton and Brewer (1994) also calculated a leaching index of 7.2 for HD (i.e., the number of leachings required to reduce the HD soil concentration to one-tenth of the original amount, assuming that for each leaching, 1 kg of soil is in equilibrium with 1 L of water).

Nitrogen Mustards

Nitrogen mustards are tertiary bis(2-chloroethyl) amines with vesicant activity (NDRC, 1946). Tables 8.3 and 8.4 summarize the nomenclature and chemical and physical properties of HN1, HN2, and HN3. Due to their toxicity and various physical–chemical properties, initial interest in these chemicals as warfare agents developed shortly before and during World War II. Although HN2 and HN3 were specifically developed as military agents, HN1 was originally developed as a pharmaceutical. HN2 (mechlorethamine) later found use as an antineoplastic agent. Nitrogen mustards and derivatives such as melphalan, chlorambucil, and cyclophosphamide are alkylating agents used as cancer therapeutic agents (Somani, 1992).

TABLE 8.3 Nomenclature, Chemical Formulae, and Chemical Structures of Nitrogen Mustards

HN-1	
Synonyms	Ethyl-bis(2-chloroethyl)amine; bis-(2-chloroethyl)ethylamine

Lewisite

Lewisite is composed of cis- and trans-isomers in the ratio of 10:90 and several impurities including bis(2-chlorovinyl)chloroarsine (L-2) and tris(2-chlorovinyl) arsine (L-3) (Rosenblatt et al., 1975). The chemical and physical properties of the cis- and trans-isomers are similar. The nomenclature and chemical and physical properties of L-1, L-2, and L-3 are presented in Tables 8.5 and 8.6, respectively. In pure form, lewisite is colorless and odorless, but it usually occurs as a brown oily liquid with a distinct geraniumlike odor. Gates et al. (1946) reported an odor threshold of 14–23 mg/m^3 for lewisite.

TABLE 8.5 Nomenclature, Chemical Formulae, and Chemical Structure of Lewisites

Lewisite (L)	
Synonyms	2-Chlorovinyldichloroarsine; (2-chlorovinyl)arsenous dichloride; beta-chlorovinyldichloroarsine; dichloro(2-chlorovinyl) arsine; chlorovinylarsine dichloride; EA 1034
CAS No.	541-25-3
Chemical formula	$ClCH{=}CHAsCl_2$
Chemical structure	L-2	
Synonym	Lewisite-2
CAS No.	40334-69-8
Chemical formula	$(ClCH{=}CH)_2AsCl$
Chemical structure	L-3	
Synonym	Lewisite-3
CAS No.	40334-70-1
Chemical formula	$(ClCH{=}CH)_3As$
Chemical structure	
Information regarding the atmospheric transformation of lewisite is limited. MacNaughton and Brewer (1994) reported that some photodegradation may take place and that hydrolysis may also occur in the gas phase. Lewisite is only sparingly soluble in water; 0.5 g/L (Rosenblatt et al., 1975). Hydrolysis of lewisite results in the formation of lewisite oxide and HCl and this may occur rapidly. The hydrolysis of lewisite is complex and includes several reversible reactions (Epstein, 1956; Rosenblatt et al., 1975; Clark, 1989; MacNaughton and Brewer, 1994). Under slightly acidic conditions, lewisite initially undergoes rapid and reversible conversion to dihydroxy arsine, 2-chlorovinyl arsine oxide, and two equivalents of hydrogen chloride:

TABLE 8.6 Physical and Chemical Properties of Lewisite

	Value	References
LEWISITE		
Physical state	Oily, amber brown liquid	Lindberg et al. (1997)
Molecular weight	170.08	USACHPPM (1996)
Boiling point	190°C	Trammell (1992)
Freezing point	−18°C; varies depending on purity	Watson and Griffin (1992)
Vapor pressure (mmHg)	0.34 mmHg at 25°C; 0.22 mmHg at 20°C	USACHPPM (1996)
Water solubility (g/L)	0.5 g/L in water; soluble in most organic solvents	USACHPPM (1996)

$$Cl—CH{=}CH—AsCl_2 + 2H_2O \rightarrow Cl—CH{=}CH—AsCl_2 + 2HCl$$

The production of two equivalents of chloride occurs within 3 min at 20°C; at 5°C, the reaction is 90% complete within 2 min, and the completion of the reaction requires several hours. The hydrolysis rate constant is reported as $1\,min^{-1}$ at 20°C. Hydrolysis of 2-chlorovinyl arsine oxide is slower, resulting in lewisite oxide (chlorovinyl arsenous oxide) and polymerized lewisite oxide:

$$Cl—CH{=}CH—As(OH)_2 + H_2O \rightarrow Cl—CH{=}CH—AsO + (Cl—CH{=}CH—AsO)_n$$

The forward reaction is favored because lewisite oxide and polymerized lewisite oxide are insoluble. In a basic solution, the trans-lewisite isomer is cleaved by the hydroxyl ion to give acetylene and sodium arsenite; this reaction may occur even at low temperatures (Rosenblatt et al., 1975; Clark, 1989). Cis-lewisite heated to over 40°C reacts with sodium hydroxide to yield vinyl chloride, sodium arsenite, and acetylene (Rosenblatt et al., 1975). In aqueous solution, the cis-isomer undergoes a photoconversion to the trans-isomer (Rosenblatt et al., 1975). Epstein (1956) reported that the toxic trivalent arsenic of lewisite oxide in standing water is converted to the less toxic pentavalent arsenic.

Lewisite in soil may rapidly volatilize or may be converted to lewisite oxide due to moisture in the soil (Rosenblatt et al., 1975). The low water solubility suggests intermediate persistence in moist soil (Watson and Griffin, 1992). Both lewisite and lewisite oxide may be slowly oxidized to 2-chlorovinylarsonic acid (Rosenblatt et al., 1975). Possible pathways of microbial degradation in soil include epoxidation of the C=C bond and reductive dehalogenation and dehydrohalogenation (Morrill et al., 1985). Due to the epoxy bond and arsine group, toxic metabolites may result. Additionally, residual hydrolysis may result in arsenic compounds. Lewisite is not likely to bioaccumulate. However, the arsenic degradation products may bioaccumulate (Rosenblatt et al., 1975).

HISTORY AND BACKGROUND

Sulfur Mustards

Sulfur mustard was synthesized and its biological activities first characterized in the 1800s (Guthrie, 1860; Niemann, 1860; Despretz, 1992). By the early 1900s, its synthesis was further refined and its use as a warfare agent had been established when used as a warfare agent (as Levenstein mustard) during World War I. More recent use occurred during conflicts in the Middle East. Its oily nature makes it persistent on surfaces it makes contact with. Because sulfur mustard exerts toxic effects following dermal, ocular, and inhalation exposure, its use necessitated full body protection which, in turn, required the development of protective clothing and significant changes in warfare operations.

Minute quantities of sulfur mustard are used by various military and contract laboratories for defense research purposes, and for verification of Chemical Weapons Convention compliance. Bulk quantities of sulfur mustard are no longer manufactured in the United States. Military stockpiles of sulfur mustard are awaiting destruction or are in the process of being destroyed. Some sulfur mustard may also be found buried or abandoned at former defense sites. Sulfur mustard was frequently loaded into artillery shells and aerial bombs (often with lewisite). Various quantities of sulfur mustard also exist in other countries. Large amounts of sulfur mustard have been disposed of at sea.

Outside of military conflicts, exposure to sulfur mustard has occurred or may occur in work environments that involve chemical weapon materials (e.g., storage depots, demilitarization facilities, and research laboratories), during emergency response operations or remediation and decontamination activities, or during treaty verification activities in support of the Chemical Weapons Convention. Chemical weapons such as vesicants are still considered potential military threats and terrorist targets. The most likely route of exposure to sulfur mustard is via aerosol/vapor exposure of the skin, eyes, and respiratory tract.

Nitrogen Mustards

Due to the toxicity and various physical–chemical properties of nitrogen mustards (which are structurally similar to sulfur mustard), initial interest in these chemicals as warfare agents began shortly before and during World War II. Like sulfur mustard, all are alkylating agents. This chapter only discusses the nitrogen mustards

referred to as HN1, HN2, and HN3; selected chemical and physical properties of these substances are summarized in Tables 8.3 and 8.4. Although HN2 and HN3 were initially investigated as military agents, HN1 was originally developed as a pharmaceutical. HN2 (mechlorethamine) later found application as a pharmaceutical. Nitrogen mustards and derivatives such as melphalan, chlorambucil, and cyclophosphamide are alkylating agents used as cancer therapeutic agents (Somani, 1992). HN1 and HN3 are among the chemical agents found in Chemical Agent Identification Sets (CAIS), which are considered a component of nonstockpiled material. Generally, nitrogen mustards have not had the interest or high profile that sulfur mustard and lewisite have.

Lewisite

Lewisite, an organoarsenic compound, was developed in an attempt to create a more effective blister agent than sulfur mustard. Its development is generally credited to Winford Lewis at the Catholic University, Washington DC, and is based upon a thesis by Julius Nieuwland, who described the synthesis of lewisite from arsenic trichloride, acetylene, hydrochloric acid, and mercuric chloride. Early on, the compound was frequently referred to by the vividly descriptive term "Dew of Death." Like sulfur mustard, it is both a vesicant and a systemic poison with target tissues not limited to the skin. In an attempt to develop an antidote to lewisite, British anti-lewisite (BAL), also known as dimercaprol, was developed (Peters et al., 1945) which later became invaluable in the treatment of arsenic poisoning. Late in World War I and into World War II, large quantities of lewisite were manufactured by Germany, the United States, Italy, the Soviet Union, and Japan (reviewed by Trammell, 1992). Large amounts of lewisite were manufactured (up to 2 tons/day by Japan) and stored prior to and during World War II (Tanaka, 1988; Trammell, 1992). Lewisite was frequently a component (often mixed with sulfur mustard) of artillery shells and aerial bombs (often mixed with sulfur mustard). Like sulfur mustard, there are reports of large amounts of the compound being disposed of at sea (Spiers, 1968). With the possible exception of its use against Iranian soldiers during the Iran–Iraq conflict (Perera, 1985), there has been little or no use of lewisite in battle. Goldman and Dacre (1989) have reviewed the chemistry and toxicology of lewisite.

TOXICOKINETICS

Sulfur Mustards

With its high lipophilicity, toxicologically relevant amounts of sulfur mustard are absorbed in epithelial tissue (Papirmeister et al., 1991). Dermal absorption depends on the thickness of the epidermis and on the presence of moisture, which enhances penetration. Absorption tends to be greater at the base of hair shafts and in the hair follicle, where the epithelial tissue is thinner than the surrounding surface area (Papirmeister et al., 1991). Approximately 20% of sulfur mustard applied to skin may be rapidly absorbed, while 12–50% of this may react and remain at the application site (Somani and Babu, 1989). About 12% of the absorbed material remains at the contact site; the rest enters the circulation (Renshaw, 1947). Renshaw (1947) noted that the rate of penetration is 1–4 μg/cm^2/min at 75°F.

For dermal exposure, penetration rates over 2–8 h ranged from 2.9 to 6.7% and rates of absorption ranged from 1.2 to 4.0% following application of 400 μg of radiolabeled sulfur mustard per cm^2 of isolated perfused porcine skin (Riviere et al., 1995). The average total recovery of the radiolabel was 9.3% (3.8–17.7%), suggesting substantial loss due to volatilization.

Relative to dermal absorption, little is known about absorption in the respiratory tract. Cameron et al. (1946) calculated the absorption of sulfur mustard vapor in the noses of rabbits and rhesus monkeys. The concentration of the agent in the nasal passages was 10–30% of the chamber concentrations (40, 100, and 500 mg/m^3), implying an absorption of approximately 70–90%.

Several studies using radiolabeled sulfur mustard have shown that sulfur mustard and its metabolites may be widely distributed in the body after percutaneous or intravenous exposure. Maximum levels of radioactivity were detected in the kidneys, lungs, and livers of rabbits following intravenous administration (Boursnell et al., 1946). At 15 min following percutaneous exposure of rats, sulfur mustard–derived radioactivity was found in all examined tissues except the eyes (Young et al., 1944). Similarly, Clemedson et al. (1963) noted uniform distribution of radioactivity in mice after either percutaneous or intravenous exposures, with most radioactivity occurring in the nasal region, kidneys, liver, and intestine. Hambrook et al. (1993) reported on the uptake and distribution of radiolabeled sulfur mustard in the skin and blood of rats after cutaneous application. It was found that much of the agent entering the blood binds to hemoglobin and, to some extent, with glutathione (GSH). Results of studies with rabbits showed that sulfur mustard was concentrated in the cornea and, to a lesser extent, in the iris, lens, and conjunctiva within 5 min after application (Axelrod and Hamilton, 1947).

The biotransformation of sulfur mustard after intravenous or intraperitoneal injection of radiolabeled compound in rats has been examined. Following intravenous injection, the major urinary metabolite was GSH-bis-chloroethyl sulfide conjugates (45% of total urinary radioactivity) and smaller amounts of sulfone conjugates

(7%) and thiodiglycol and its conjugates (14.4%) (Davison et al., 1961). Roberts and Warwick (1963) found the major urinary product of cysteine-bis-(β-chloroethyl)sulfone after intraperitoneal injection of sulfur mustard in rats. Papirmeister et al. (1991) concluded that hydrolysis to thiodiglycol and reaction with GSH are the most important routes of detoxification. This is supported by human data showing that thiodiglycol is present in the urine for one week or more after exposure (Wils, 1987).

Nitrogen Mustards

The effects of time, temperature, and humidity on the vapor penetration of HN1 and HN3 into the forearm skin of human male volunteers were reported by NDRC (1945). Results of this research showed similar effects of temperature and humidity as observed for sulfur mustard (e.g., greater absorption with increased temperature and humidity). The penetration of HN1 and HN3 was found to be linear with time (5–20 min for HN1 and 30–60 min for HN3). At 71–72°F and 50–52% relative humidity, the HN1 penetration rate was 2.8 μg/cm^2/min; and for HN3, it was 0.18 μg/cm^2/min at 72–73°F and 45–48% relative humidity. At 86–87°F and 47–49% relative humidity, the HN1 penetration rate increased to 5.2 μg/cm^2/min, and the HN3 penetration rate increased to 0.3 μg/cm^2/min at 85°F and 47–48% relative humidity. Excretion via the urine is likely a major route of elimination, especially due to the water solubility of the immonium ion (see "Mechanism of Action" section).

Lewisite

Little information is available regarding the toxicokinetics of lewisite. It is readily absorbed by mucous membranes and, because of its lipophilicity, dermal absorption is significant (HSDB, 2004). Dermal absorption reportedly occurs faster for lewisite than for sulfur mustard (Hurst and Smith, 2008). Axelrod and Hamilton (1947) reported that radiolabeled (^{74}As) lewisite applied to a 0.43 cm^2 area of human skin was primarily fixed on the epidermis and that very little was found in the dermis; most was detected in hair and hair follicles. In experiments with guinea pigs, histological examination revealed that lewisite applied to skin entered the epidermis within 2 min and penetrated the dermis within 10 min (Ferguson and Silver, 1947). Only trace amounts were detectable in the dermis at 24 h post-application.

MECHANISM OF ACTION

Sulfur Mustards

Sulfur mustard is a bifunctional alkylating agent. The mechanism of action of sulfur mustard is multifaceted and complex, and has been reviewed in some detail by Papirmeister et al. (1991); Hurst and Smith (2008); Smith et al. (2008); Shakarjian et al. (2010), and Ghanei and Harandi (2011). Efforts to understand the mechanisms of sulfur mustard toxicity are ongoing. Basically, sulfur mustard disrupts the interface of the epidermis and basement membrane causing blistering between the epidermis and dermis. Both immediate (immediate cell membrane damage) and delayed phases (secondary effects resulting from inflammatory responses, deoxyribonucleic acid (DNA) damage, and vascular leakage) have been described for sulfur mustard-induced dermal effects (Somani and Babu, 1989). Sulfur mustard may initiate intramolecular and intermolecular crosslinks that provide many targets, including proteins, nucleic acids, and lipids. Many of the toxic effects of sulfur mustard also appear to be attributed to oxidative stress resulting from the disruption of normal cellular metabolism.

Among the most studied mechanisms of sulfur mustard toxicity are thiol depletion, resulting in intracellular calcium imbalance and subsequent cell death; alkylation of DNA and other cellular macromolecules; lipid peroxidation resulting from sulfur mustard-induced gluthathione depletion; and induction of an inflammatory response. The overall mechanism of sulfur mustard toxicity likely involves an interlinking of the aforementioned processes which are briefly described below.

A key component of sulfur mustard toxicity is the formation of a sulfonium ion and resulting episulfonium intermediate that may react with sulfhydryl-containing macromolecules. Damage may include Ca^{2+} translocases (Ca^{2+}-stimulated, Mg^{2+}-dependent ATPase), which depend on thiol groups to maintain cellular Ca^{2+} homeostasis, and microfilamentous proteins. The resulting increase in intracellular calcium levels ultimately causes a decrease in cellular integrity and induction of apoptosis. Oxidative stress in sulfur mustard toxicity has been reviewed by Smith et al. (2008).

The role of DNA alkylation and the poly(ADP-ribose) polymerase (PARP) hypothesis theory for sulfur mustard toxicity has been reviewed by Papirmeister et al. (1991). In this mechanism, DNA is the initial target of the mustard agent. Alkylated DNA purines are enzymatically depurinated, creating apurinic sites that are cleaved by apurinic endonucleases, resulting in DNA strand breaks. The accumulation of DNA breaks leads to activation of the chromosomal enzyme PARP, which utilizes NAD^+, causing a severe reduction in cellular NAD^+. Depletion of NAD^+ results in the inhibition of glycolysis, and stimulation of the nicotinamide adenine dinucleotide phosphate ($NADP^+$)–dependent hexose monophosphate shunt, ultimately resulting in the induction and secretion of proteases and subsequent cellular changes. Kehe et al. (2009) has reviewed dermal toxicity

mechanisms of sulfur mustard. Sulfur mustard-induced apoptosis and activation of inflammatory mediators such as various interleukins (ILs) such as IL-1alpha, IL-1beta, IL-6, IL-8, as well as tumor necrosis factors, also appear to be involved in the toxic response to sulfur mustard.

In the review by Papirmeister et al. (1991), it was noted that sulfur mustard-induced cytotoxicity is dose-dependent and that DNA appeared to be more sensitive to mustard-induced alkylation than are other cellular constituents. The low-dose effects of sulfur mustard are characterized by genotoxicity and inhibition of mitosis. The loss of cellular reproduction may be due to bifunctional alkylation that ultimately prevents normal DNA replication. It was hypothesized that monofunctional DNA damage might be responsible for low-dose mutagenic and possibly carcinogenic effects.

Sulfur mustard-induced lipid peroxidation is a function of GSH depletion. For this mechanism, depletion of GSH results in an accumulation of reactive oxygen species via hydrogen peroxide–dependent processes (Miccadei et al., 1988). The oxygen radicals react with membrane phospholipids, forming lipid peroxides that alter membrane structure, causing it to break down.

Additional work has focused on the identification of possible biomarkers of sulfur mustard exposure and injury (Buxton et al., 2000, 2001; Danne et al., 2000). More recently, the role of metalloproteinases and collagen degradation (Gerecke et al., 2005), platelet-activating factor (Clark et al., 2005, 2006), and interaction with cytochrome P450 processes (Brimfield and Hodgson, 2005; Brimfield et al., 2006; Mancheco and Brimfield, 2006) is being investigated relative to the mechanism of action of sulfur mustard.

Nitrogen Mustards

A key component of nitrogen mustard toxicity is analogous to that of sulfur mustard: the formation of a cyclic onium cation. This occurs in the presence of polar solvents such as water (Somani, 1992). The immonium ion may react with nucleophiles (such as nitrogen) in the base components of nucleic acids and with sulfhydryl groups in proteins and peptides. The precise mechanism of nitrogen mustard activity is unclear, but several have been proposed: DNA/RNA alkylation and resultant effects, effects on GSH, membrane effects (protein cross-linking, ion transport effects), and cytoplasmic effects (release of lysosomal enzymes). The possible mechanisms of nitrogen mustard have been reviewed by Gray (1989). Results of preliminary work by Elsayed and Omaye (2006) in mice given HN2 intraperitoneally showed pulmonary alterations indicative of oxidative stress and impaired detoxification processes that are consistent with the aforementioned mechanisms.

Lewisite

Dermal or intravenous exposure to lewisite leads to local skin edema and pulmonary edema due to increased capillary permeability. The increased capillary permeability results in blood plasma loss and resultant physiological responses collectively referred to as *lewisite shock*. Lewisite shock may be likened to shock observed in severe burn cases. It has been hypothesized that functional changes in the lungs, kidneys, respiratory tract, and cardiovascular and lymphatic systems may be the result of a disturbance of osmotic equilibrium (Goldman and Dacre, 1989).

Lewisite-induced vesicant and systemic toxicity are likely due in part to interactions with thiol groups (Goldman and Dacre, 1989). The interaction with enzyme sulfhydryl groups may cause inhibition of enzyme by the formation of stable cyclic structures with arsenic. These thiol interactions result in energy depletion, leading to cell death (Young, 1999).

TOXICITY

Sulfur Mustard

The toxic effects of sulfur mustard in humans and animals have been extensively reviewed by Sidell and Hurst (1992); Somani (1992); Watson and Griffin (1992); IOM (1993); ATSDR (2003); NRC (2003); Romano et al. (2008); and Ghanei and Harandi (2011). Sulfur mustard affects the skin, respiratory tract, and eyes. The acute effects include edema, ulceration, and necrosis of epithelial tissue. Systemic toxicity may also occur and is characterized by nausea and vomiting, fever, and malaise. There is evidence of systemic toxicity (gastrointestinal tract) following dermal exposure only (Dacre and Goldman, 1996). Delayed effects include conjunctivitis and blindness following ocular exposure and chronic bronchitis following inhalation exposure. Affected tissues may have an increased susceptibility to secondary infections, and possibility of carcinogenicity of the skin and respiratory tract. However, the often-observed latency between acute exposure and late-onset tissue damage is not fully understood. Of the approximately 100,000 casualties of sulfur mustard exposure during the Iran–Iraq war (1983–1988), approximately 45,000 are still experiencing long-term effects of exposure over 20 years later (Ghanei et al., 2010).

Ambient temperature and humidity govern the degree of toxicity of sulfur mustard; in hot and humid conditions, lower mustard concentrations are required to produce debilitating effects. The severity of sulfur mustard effects is also greater in areas of the body with greater moisture (e.g., the axilla, groin, and eyes). Information regarding the toxic effects of long-term exposure to low

levels of sulfur mustard that are not acutely toxic is limited. Ghanei et al. (2010) have reviewed the acute and long-term cutaneous effects of sulfur mustard.

Available data suggest that the location and severity of damage resulting from exposure to sulfur mustard are concentration-dependent and a function of the highly reactive nature of sulfur mustard (Papirmeister et al., 1991). The eyes are generally considered to be the most sensitive and rapidly responding target (Reed, 1918; Reed et al., 1918; Anderson, 1942). For low exposures, sulfur mustard-induced injury appears to be limited to the upper respiratory tract (Eisenmenger et al., 1991) and eyes (Reed, 1918; Reed et al., 1918; Guild et al., 1941; Anderson, 1942). In work with informed volunteer subjects, Anderson (1942) reported that Ct values of 60–75 mg-min/m^3 would result in conjunctivitis, photophobia, and ocular irritation, while Ct values of 75–90 mg-min/m^3 would cause a high proportion of casualties, as determined by more severe ocular damage requiring several weeks of treatment. A chronic ocular injury known as *mustard gas keratopathy (MGK)* has been identified in some individuals following moderate- to high-level exposure. A weak positive correlation between severity of ocular and pulmonary involvement was found in a study of 292 Iran–Iraq conflict veterans (Ghasemi et al., 2012). McNutt et al. (2013) provided insight into the progression and pathophysiological correlates for this injury.

At exposure concentrations higher than those causing ocular damage, pulmonary effects would be expected (Eisenmenger et al., 1991). Regardless of the target tissue, there is a latency period between initial exposure and development of effects. The eyes and respiratory tract appear to have the shortest latency period, with effects appearing within hours depending on the exposure level. Later-onset lung injury is often referred to as mustard lung (ML) because the injury differs somewhat from more typical chronic obstructive pulmonary disease. In a review of the mechanisms of sulfur mustard-induced lung injury, Ghanei and Harandi (2011) found that oxidative stress and apoptosis may be more relevant mechanisms regarding ML than for other chronic obstructive pulmonary diseases.

In addition to the acute toxic effects on the eyes, skin, and respiratory tract, both acute and longer-term neuropsychiatric effects (e.g., depression, anxiety, neurasthenia, insomnia, and posttraumatic stress syndrome/PTSD) have been documented for individuals exposed to sulfur mustard (Romano et al., 2008). Many of these effects have been documented for individuals exposed during noncombat conditions (e.g., those of munitions plant workers) and are not always the result of high-level exposure that result in serious overt effects. Longer-term effects, such as chronic bronchitis, have been associated with occupational exposures that included episodes of acute toxicity, and delayed or recurrent keratitis may occur 8–40 years after a severe vapor exposure. Sulfur mustard-induced immunosuppression resulting in greater susceptibility to infections has also been reported.

TABLE 8.7 Acute Lethality of Sulfur Mustard in Laboratory Species Following Inhalation Exposure

Species	Lethality Value	Concentration (mg/m3) and Exposure Duration (min)	References
Rat	2 min LCt_{50}: 1512 mg-min/m^3	756 mg/m^3 (2 min)	Fuhr and Krakow (1945) (not verified)
	30 min LCt_{50}: 990 mg-min/m^3	33 mg/m^3 (30 min)	
	60 min LCt_{50}: 840 mg-min/m^3	14 mg/m^3 (60 min)	
Mouse	2 min LCt_{50}: 4140 mg-min/m^3	2070 mg/m^3 (2 min)	Fuhr and Krakow (1945) (not verified)
	30 min LCt_{50}: 1320 mg-min/m^3	44 mg/m^3 (30 min)	
	60 min LCt50: 860 mg-min/m^3	14.3 mg/m^3 (60 min)	
Mouse	60 min LCt_{50}: 42.5 mg/m^3	42.5 mg/m^3 (60 min)	Vijayaraghavan (1997)
Monkey	10 min LCt_{50}: 800 mg-min/m^3	80 mg/m^3 (10 min)	Rosenblatt et al. (1975)
Dog	10 min LCt_{50}: 600 mg-min/m^3	60 mg/m^3 (10 min)	Rosenblatt et al. (1975)
Cat	10 min LCt_{50}: 700 mg-min/m^3	70 mg/m^3 (10 min)	Rosenblatt et al. (1975)
Goat	10 min LCt_{50}: 1900 mg-min/m	190 mg/m^3 (10 min)	Rosenblatt et al. (1975)
Guinea pig	5 min LCt_{50}: 800 mg-min/m^3	160 mg/m^3 (5 min)	Langenberg et al. (1998)
	10 min LCt_{50}: 1700 mg-min/m^3	170 mg/m^3 (10 min)	Rosenblatt et al. (1975)

Acute lethality data in animals are summarized in Table 8.7. Based upon the animal data, interspecies variability in the lethal response to sulfur mustard vapor is less than an order of magnitude. For nonlethal effects, the animal data suggest that test species exhibit signs of toxicity that are qualitatively similar to humans when acutely exposed to sulfur mustard vapor. Ocular and respiratory tract irritations are clearly evident in studies using dogs, rats, mice, rabbits, and guinea pigs.

Effects of orally administered sulfur mustard in rats were studied by Sasser et al. (1996a). Repeated gavage administration of sulfur mustard in sesame oil produced epithelial hyperplasia of the forestomach at the highest dose tested, but no deaths and no other treatment-related

pathological lesions or changes in clinical chemistry or hematological parameters.

Results of a multigeneration study in rats given sulfur mustard by gavage showed no significant adverse effects on reproductive parameters at any dose level, but revealed dose-related lesions of the squamous epithelium of the forestomach (acanthosis and hyperplasia) (Sasser et al., 1996b). It is likely that the forestomach lesions were a function of the treatment regimen, whereby the bolus dose in an oil vehicle (sesame seed oil) would enhance the effects of sulfur mustard having direct contact with the forestomach tissue. Studies by Hackett et al. (1987) in which rabbits were gavage-dosed with sulfur mustard were equivocal regarding reproductive/developmental effects, due in part to the dose regimen and overt maternal toxicity.

Studies in animals have shown that sulfur mustard may induce developmental and reproductive effects (reviewed in NRC, 1999, 2003). Acute exposures resulting in systemic uptake may have effects on reproductive organs, including inhibition of spermatogenesis. Fetal anomalies were observed in tests with rats given sulfur mustard during gestation, but only at maternally toxic doses.

The genotoxicity of sulfur mustard is well documented. The chemical is known to produce DNA cross-links, mutations following replication or repair errors, chromosomal breaks, and chromosomal aberrations. Occupational exposures have been associated with increased frequencies of somatic cell mutations, sister chromatid exchanges, and chromosome abnormalities. Studies with rats indicate that subchronic inhalation or oral exposures can produce dominant lethal effects.

The carcinogenicity of sulfur mustard in animals has been reviewed in IARC (1975); Watson et al. (1989); IOM (1993); NRC (1999) and USACHPPM (2000). McNamara et al. (1975) studied the potential carcinogenicity of sulfur mustard in rats, mice, rabbits, guinea pigs, and dogs exposed via inhalation for up to one year. No tumors were detected in the mice, rabbits, guinea pigs, or dogs, but skin tumors (i.e., basal and squamous cell carcinomas, trichoepitheliomas, and keratoacanthomas) were associated with sulfur mustard exposure at the highest exposure tested (0.1 mg sulfur mustard/m^3 for 6.5 h, followed by 0.0025 mg sulfur mustard/m^3 for 17.5 h/day, 5 days/week). An increased incidence of pulmonary tumors in Strain A mice was observed following intravenous injections (4 doses over 2 days) of sulfur mustard (Heston, 1950), and an increase in injection site tumors in mice given subcutaneous injections of sulfur mustard over a 6-week period (Heston, 1953).

In a cohort study reported by Easton et al. (1988), there was a significant excess of laryngeal, pharyngeal, upper respiratory tract, and lung cancers in workers at a sulfur mustard manufacturing facility during World War II. A study of the Iranian military veterans exposed to sulfur mustard under battlefield conditions during the Iran–Iraq conflict at levels sufficient to cause severe signs of toxicity indicated a potential increased incidence of chronic myelocytic leukemia (CML). In several earlier studies on World War I veterans who were exposed to sulfur mustard, leukemia was not identified as a possible effect, although it is unclear if examination for CML had ever occurred in those populations. Confounders, such as exposure to benzene or radiation which complicate the analysis, have not yet been ruled out in the ongoing epidemiologic study of Iranian veterans. Two cases of CML were reported for Japanese workers exposed to sulfur mustard (Shakil et al., 1993) but the incidences of CML in the entire population of sulfur mustard–exposed workers and in an unexposed control population were not reported. Studies in animals provide supporting evidence for the carcinogenicity of sulfur mustard, although the results of some studies are compromised by insufficient exposure durations and injuries resulting from caging situations.

Nitrogen Mustards

Information regarding the toxicity of nitrogen mustards is less extensive as that for sulfur mustard. Limited lethality data in animals are summarized in Table 8.8. Like sulfur mustard, exposure to nitrogen mustards may cause skin blistering, as well as respiratory tract injury and ocular damage. Response data from tests with informed human volunteer subjects (NDRC, 1944) suggested a relative potency of HN3 > HN1 > HN2 for vesicant effects, although the differences were minor. Like sulfur mustard, dermal effects were enhanced by moisture (as from sweating). Estimated thresholds for skin blistering and ocular injury are summarized in Table 8.9. Ocular injury (irritation resulting in compromised operational effectiveness of military personnel) was detected at exposures much lower than those causing dermal effects. All of the toxic effects of nitrogen mustard appear to involve a latency period of several hours for ocular responses and several days for dermal blistering. Nitrogen mustards are alkylating agents with known mutagenicity, but there are no animal cancer bioassays and no human carcinogenicity data.

Nitrogen mustard and its hydrochloride salt have been shown to be teratogenic in mice and rats. Intraperitoneal administration of HN2-hydrochloride/g to mice during gestation resulted in serious teratogenic effects (Danforth and Center, 1954). Haskin (1948) and Murphy et al. (1958) reported similar findings in rats given HN2-hydrochloride/kg subcutaneously during gestation.

Nitrogen mustards are bifunctional alkylating agents that produce a carcinogenic response (primarily lung tumors and lymphomas) in mice following subcutaneous,

TABLE 8.8 Lethality of Nitrogen Mustard (HN2)

Route	Species	Dose (mg/kg)	Exposure Time	Effect	References

TABLE 8.9 Estimated Effects Thresholds in Humans Exposed to Nitrogen Mustard Vapors

HN1	HN2	HN3	Effect
–	0.012 mg-min/m^3	–	No observable effect level during therapeutic use of HN2 (Van Vloten et al., 1993)
90 mg-min/m^3	70 mg-min/m^3	42 mg-min/m^3	Moderate but reversible ocular effects (Porton Report, 1942a,b, 1943a–d; U.S. Army Med. Div., 1945a,b; NDRC, 1946)
>21,170 mg-min/m^3	5,800 mg-min/m^3	1,800 mg-min/m^3	Median blistering Ct (10 or 20 min exposure) for normal skin
		31,300 mg-min/m^3	Median blistering Ct (20 min exposure) for sweating skin (NDRC, 1944)

intraperitoneal, and intravenous administration, as well as by skin painting (IARC, 1987). Intravenous administration of nitrogen mustard to rats produced tumors in multiple organs (IARC, 1987). Information in humans is limited to reports of squamous cell carcinomas of the skin following therapeutic application of nitrogen mustard in the treatment of mycosis, fungoides, and psoriasis (IARC, 1987).

Lewisite

The toxicology of lewisite has been reviewed by Goldman and Dacre (1989); Trammell (1992); Watson and Griffin (1992); Hurst and Smith (2008) and NRC (2013). Because lewisite L-2 and L-3 are of lower volatility than L-1, occur in lesser amounts, and are toxicologically similar to L-1, the discussion of toxicity is limited to lewisite (NRC, 2013). Its characteristic geraniumlike odor is detectable at 14–23 mg/m^3 (Gates et al., 1946). Lewisite may be lethal in humans following inhalation, or dermal, or oral exposure. It is reportedly immediately highly irritating at estimated concentrations of 6–8 mg/m^3. Gates et al. (1946) estimated an LC_{50} of 3,300 mg/m^3 for 30 min for lewisite vapor absorption through the bare skin and an inhalation LC_{50} of 120 mg/m^3 for 10 min and 50 mg/m^3 for 30 min. Inhalation of 10 mg/m^3 lewisite for 30 min may result in severe intoxication and incapacitation lasting for several weeks, and inhalation of 10 mg/m^3 for 15 min caused inflammation of the eyes and swelling of the eyelids (Franke, 1977). Like sulfur mustard, moist tissues are particularly sensitive to lewisite. The eyes exhibit the greatest sensitivity (IOM, 1993).

The vesicant properties of lewisite result from direct contact with the skin. Signs of dermal toxicity (pain, inflammation) may be experienced within a minute after exposure. Acute lethality is usually the result of pulmonary injury. Ocular exposure may result in corneal necrosis. Due to its lipophilicity, percutaneous absorption of lewisite is rapid and, at a sufficient exposure, may be associated with systemic toxicity characterized by pulmonary edema, diarrhea, agitation, weakness, hypothermia, and hypotension (IOM, 1993). The threshold for severe systemic toxicity in humans following dermal exposure to lewisite has been estimated at 10 mg/kg (9.1–13.4 mg/kg) (Sollman, 1957).

Eldridge (1923) conducted tests on human volunteers to assess the effects of dermal exposure to lewisite vapor.

The arms of men (1–7 men with previously determined average sensitivity to lewisite) were exposed to varying concentrations of lewisite vapor for periods ranging from 10 min to 3 h for the purpose of determining the concentration of lewisite required to create blistering. The resulting dermal responses ranged from reddish discoloration to a clear, watery blister over the entire burned area, accompanied by reddening, swelling, and hardening of the surrounding skin. The burns reached maximum severity in 36–48 h, and healing was complete in 6 days to 2 weeks. The men also reported that the healed skin remained sensitive for several weeks after the healing was complete.

It has been hypothesized that fatalities following dermal exposure to lewisite may be due to blood plasma loss resulting from extensive capillary damage (lewisite shock; Cameron et al., 1946). Sollman (1957) estimated that an oral dose of as little as 2 mL in an adult human (equivalent to 37.6 mg/kg) may be fatal within several hours. The target tissues and organs for systemic toxicity of lewisite include the liver, gallbladder, urinary bladder, lung, and kidneys (Cameron et al., 1946; Snider et al., 1990). Generally, there is a data deficiency regarding definitive exposure–response data for lewisite.

In studies with rats, Silver and McGrath (1943) found little difference in the acute lethality of cis- or trans-lewisite exposed for 10 min. Ten-minute mouse LC_{50} values for the cis- and trans-isomers were 190 and 200 mg/m^3, respectively. All mice exposed to 240 mg/m^3 lewisite for 10 min died. Clinical signs in dogs exposed for 7.5 or 15 min included immediate continual eye blinking, followed by excessive nasal secretion, lacrimation, and sneezing (Armstrong, 1923). Ocular inflammation and vomiting also occurred in some dogs by the end of the 7.5- and 15-min exposures. Dogs exposed for 30 min or longer exhibited frequent retching, vomiting, extreme salivation, labored breathing, and inflammation of the entire respiratory tract. Necropsy revealed a thick membrane in the nostrils, larynx, and trachea, which was accompanied by purulent bronchitis, hemorrhage, pneumonia, edema, and congestion of the lungs.

Similar to the work on sulfur mustard, Sasser et al. (1989a) conducted experiments in rats given lewisite by gastric intubation (in sesame oil) at doses of 0.01, 0.1, 0.5, 1.0, or 2.0 mg/kg, 5 days/week for 13 weeks. A dose-related response was observed for lethality (deaths in the three highest dose groups) and frequency and severity of forestomach lesions. The forestomach lesion incidence and severity were due, at least in part, to the bolus of dosing and the sesame oil vehicle.

Multigeneration reproductive studies in rats (Sasser et al., 1989b) and teratology studies in rats and rabbits (Hackett et al., 1987) given lewisite by gastric intubation were negative or compromised by concurrent maternal toxicity.

The carcinogenic potential of lewisite is not well understood. In a long-term follow-up study, Krause and Grussendorf (1978) reported the formation of a malignant lesion at the site of contact 8 years following a single, acute dermal exposure of a German soldier accidentally exposed to liquid lewisite on his lower right leg in 1940. The lesion was diagnosed as malignant 8 years later, and 38 years after exposure, the area of contact remained ulcerated and diagnosed as Bowen's disease (an intradermal squamous cell carcinoma). Bowen's disease was also diagnosed in workers at a Japanese lewisite production facility (Inada et al., 1978). Findings in these workers were not conclusive due to concurrent exposure to diphenylcyanoarsine and sulfur mustard. Furthermore, no quantitative estimates of dose or exposure rates were available (Inada et al., 1978).

Increased incidences of cancer mortality (respiratory tract: 14%; digestive tract: 9.6%) in workers from the Okuno-Jima poison gas factory were reported by Wada et al. (1968). When cancer rates were correlated with job classifications, the frequency of respiratory and gastrointestinal tract neoplasms was highest in workers who were involved in the production of sulfur mustard or lewisite, followed by those who worked indirectly with sulfur mustard or lewisite. The lowest frequency occurred in the group having no direct contact with the vesicant agents (Yamakido et al., 1985). Similar to the Bowen's disease findings, the cancer incidences were confounded by the fact that workers were also exposed to sulfur mustard, hydrocyanic acid, diphenylcyanoarsine, chloroacetophenone, and phosgene.

RISK ASSESSMENT

Sulfur Mustards

Noncancer

Various standards and guidelines have been developed for sulfur mustard. These values are applicable to occupational exposures, emergency planning and response efforts, and remediation efforts. Airborne exposure limits (AELs) and health-based environmental screening levels (HBESLs) for sulfur mustard have been developed by the U.S. Army (USACHPPM, 1999, 2000). Most health-based criteria for sulfur mustard vapor exposure are based upon protection of the eyes and respiratory tract, which are the most sensitive targets.

Acute exposure guideline levels (AEGLs) for sulfur mustard have been developed for emergency planning and emergency response applications (NRC, 2003; US EPA, 2012). The AEGLs represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min

TABLE 8.10 Inhalation Standards and Guidelines for Sulfur Mustard

	Exposure Duration				
Guideline	**10 min**	**30 min**	**1 h**	**4 h**	**8 h**
AEGL-1[a]	0.06 ppm	0.02 ppm	0.01 ppm	0.003 ppm	0.001 ppm
AEGL-2[a]	0.09 ppm	0.03 ppm	0.02 ppm	0.004 ppm	0.002 ppm
AEGL-3[a]	0.59 ppm	0.41 ppm	0.32 ppm	0.08 ppm	0.04 ppm
Dept. of the Army/Civilian Occupational WPL[b]					0.0005 ppm (24-h)
Dept. of the Army/Civilian GPL[c]					$1.5 \times 10 \times 10^{-5}$ ppm (24-h)
CDC-CSEPP[d]					0.3 ppm

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure. The AEGL-1 values for sulfur mustard are based upon minor ocular irritation in informed human volunteers (Anderson, 1942). AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. The AEGL-2 values for sulfur mustard are based on marked conjunctivitis, edema, photophobia, and eye irritation in informed human volunteers (Anderson, 1942). AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death. The AEGL-3 values for sulfur mustard are based on a lethality threshold estimated in mice (Kumar and Vijayaraghavan, 1998).

[a]*AEGL (NRC, 2002) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels—AEGL-1, AEGL-2, and AEGL-3—are developed for each of five exposure periods (10 and 30 min, 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects.*

[b]*Worker population exposure limit (DA, 1991, 1997; DHHS, 1988), 8-h TWA, 5 days/week.*

[c]*General population limit (no observable effects), 24-h TWA, 5 days/week.*

[d]*Recommended acute effect levels for determining emergency evacuation distances in the Chemical Stockpile Emergency Preparedness Program (CSEPP); no specified exposure duration.*

to 8 h (Table 8.10). The AEGLs for nitrogen mustards are interim status values that have not undergone final review and publication by the National Research Council/National Academy of Sciences. Provisional Advisory Levels (PALs) are developed by the U.S. Environmental Protection Agency (EPA) as public emergency exposure limits for three severity levels (PAL 1, PAL 2, and PAL 3) and for exposure durations of 24 h, 30 days, 90 days, and 2 years for both oral and inhalation exposure (Young et al., 2009). Oral PALs for sulfur mustard are not recommended due to insufficient data and because of the chemical nature of sulfur mustard (Bast et al., 2013). Inhalation PAL 1 values for sulfur mustard are 0.00083 mg/m^3 for 24 h and 0.00010 mg/m^3 for 30 days, 90 days, and 2 years. Inhalation PAL 2 values are 0.0042 mg/m^3 for 24 h, 0.0029 mg/m^3 for 30 days, and 0.00097 mg/m^3 for 90 days and 2 years. PAL 3 values are 0.088 mg/m^3 for 24 h, but are not recommended for longer durations (Bast et al., 2013).

An interim reference dose (RfDi), an estimate of a daily dose to humans that is likely to be without appreciable risk of deleterious health effects during a lifetime, of 7×10^{-2} mg/kg/day has been developed for sulfur mustard (NRC, 1999).

Inhalation standards and guidelines for sulfur mustard are summarized in Table 8.10. Other standards and guidelines for sulfur mustard have been summarized by ATSDR (2003).

Cancer

The International Agency for Research on Cancer (IARC) classified sulfur mustard as a Group 1 carcinogen (carcinogenic to humans) (IARC, 1987). The National Toxicology Program (NTP) considers mustard gas to be a substance "known to be a human carcinogen" (DHHS, 1988). These assessments are based upon human and animal data.

Studies of occupational exposures to sulfur mustard indicate an elevated risk of respiratory tract and skin tumors following long-term exposure to acutely toxic concentrations. Overall, several factors are important regarding the assessment of the carcinogenicity of sulfur mustard. Increased cancer incidence in humans appears to be associated only with exposures that caused severe acute effects, and occupational exposures tended to involve repeated exposures and repeated injury of the same tissues. Although numerous individuals suffered sulfur mustard-induced injuries in various conflicts over the years, incidences of skin cancer are rarely reported (Firooz et al., 2011). Evidence for lung cancers resulting from sulfur mustard exposure are well documented with most cases associated with long-term exposures, although there is emerging evidence for the involvement of acute and short-term exposure (Ghanei and Harandi, 2010). Because the therapeutic use of the sulfur mustard analog nitrogen mustard is associated with an increased incidence of CML, the reports of CML in HD-exposed individuals appear to be relevant to the carcinogenicity of sulfur mustard.

TABLE 8.11 AEGLs for Nitrogen Mustards (HN-1, HN-2, HN-3)

	Exposure Duration				
Guideline	**10 min**	**30 min**	**1 h**	**4 h**	**8 h**
AEGL-1[a]	NR	NR	NR	NR	NR
AEGL-2[a]	0.13 mg/m^3	0.044 mg/m^3	0.022 mg/m^3	0.0056 mg/m^3	0.0028 mg/m^3
AEGL-3[a]	2.2 mg/m^3	0.74 mg/m^3	0.37 mg/m^3	0.093 mg/m^3	0.047 mg/m^3

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure. No AEGL-1 values for nitrogen mustards are currently recommended due to insufficient data. AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. A threshold for ocular irritation in informed human volunteers is the basis for the AEGL-2 values for nitrogen mustards. AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death. The AEGL-3 values for nitrogen mustards are based on an estimated lethality threshold in rats.
[a]AEGL (NRC, 2002) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels—AEGL-1, AEGL-2, and AEGL-3—are developed for each of five exposure periods (10 and 30 min, 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects.

Cancer slope factors and unit risk values for sulfur mustard have been summarized by ATSDR (2003).

Nitrogen Mustards

Noncancer

Very few standards and guidelines are available for nitrogen mustards. AEGL values for the nitrogen mustards (HN1, HN2, and HN3) have been developed and are based upon ocular irritation in human volunteers (AEGL-2) and lethality in rodents (AEGL-3), as shown in Table 8.11. Data were insufficient for derivation of level AEGL-1 values. The AEGL values are currently awaiting finalization. The U.S. army (USACHPPM, 1996, 2004) has developed worker population limit (WPL) values and general population limit (GPL) values for nitrogen mustard (USACHPPM, 1996, 2004).

Cancer

Data are not available with which to quantitatively assess the cancer risk from nitrogen mustards. However, IARC (1987) considers nitrogen mustard a Group 2A carcinogen based upon limited evidence in humans and sufficient evidence in animals.

Lewisite

Noncancer

The U.S. Army has developed HBESLs for lewisite (USACHPPM, 1999). Additionally, a chronic oral reference dose (RfD) of 1×10^{-4} mg/kg/day is available (NRC, 1999; USACHPPM, 1999), as are inhalation and dermal RfDs (USACHPPM, 1999). Acute Exposure Guidelines Levels (AEGLs) have been developed for lewisite (NRC, 2013), and are presented in Table 8.12. Inhalation PAL 1 values are not recommended for lewisite. Inhalation PAL 2 and 3 values for 24-h exposure durations are 0.01 mg/m^3 and 0.037 mg/m^3, respectively (Bast et al., 2013). Exposure values for longer PAL-specific durations (30 days, 90 days, and 2 years) are not recommended.

Cancer

Data regarding the potential carcinogenicity of lewisite are anecdotal and insufficient for a quantitative assessment. Although quantitative data are lacking, the position maintained by the Centers for Disease Control and Prevention (CDC) (DHHS, 1988) is that some evidence suggests that lewisite may be a carcinogen. For environmental exposure and remediation concerns, the arsenic component and/or arsenic-containing degradation products, however, are relevant.

Although the carcinogenicity of lewisite is equivocal and a quantitative assessment is not feasible, several lewisite degradation products are known carcinogens. Combustion products of lewisite include the inorganic arsenicals, arsenic trichloride, arsenic trioxide, and vinyl chloride. Inorganic arsenic is carcinogenic in humans and animals and is classified as a Group A carcinogen by U.S. EPA (2008). Arsenic trioxide and vinyl chloride are both considered Group A carcinogens by U.S. EPA (1984) and Group 1 carcinogens by IARC (1987).

TREATMENT

Sulfur Mustard

Medical management of sulfur mustard exposure begins with preventing exposure. As previously noted in

TABLE 8.12 AEGLs for Lewisite

	Exposure Duration				
Guideline	**10 min**	**30 min**	**1 h**	**4 h**	**8 h**
AEGL-1[a]	NR	NR	NR	NR	NR
AEGL-2[a]	1.3 mg/m^3	0.47 mg/m^3	0.25 mg/m^3	0.070 mg/m^3	0.037 mg/m^3
AEGL-3[a]	3.9 mg/m^3	1.4 mg/m^3	0.74 mg/m^3	0.21 mg/m^3	0.11 mg/m^3

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure. No AEGL-1 values for lewisite are currently recommended due to insufficient data. AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. A 3-fold reduction of the AEGL-3 values for lewisite were considered an appropriate and defensible estimate for the AEGL-2 values (NRC, 2013). AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death. The AEGL-3 values for lewisite were based upon an estimated LC_{01} in dogs (Armstrong, 1923).

[a]*AEGL (NRC, 2002) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels—AEGL-1, AEGL-2, and AEGL-3—are developed for each of five exposure periods (10 and 30 min, 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects.*

this chapter, the military use of sulfur mustard necessitated full body protection. As a result, considerable effort has been expended in the development and evaluation of protective clothing and equipment (Schier and Hoffman, 2005). In general, these include air-purifying and atmosphere-supplying respirators and chemical-protective clothing (e.g., chemical and vapor impermeable coverings and clothing treated with adsorbing or neutralizing chemicals). Following exposure, rapid decontamination is essential and may include removal of contaminated clothing and removal or neutralization of the agent. Ocular exposure will require rapid removal of the agent from the eyes by flushing with water. Vapor exposure may necessitate respiratory support. Because there are no antidotes for sulfur mustard poisoning, medical management must rely on prevention, decontamination, and palliative treatment of signs and symptoms. The use of possible antidotes (e.g., antioxidants) has been reviewed by Smith et al. (2008) and Laskin et al. (2010). Polyurethane sponges containing detoxification additives are being developed and evaluated for decontamination and detoxification (Gordon et al., 2006). The medical management of sulfur mustard (and other vesicant agents) has been reviewed by Munro et al. (1990); Keyes et al. (2005) and Laskin et al. (2010).

Nitrogen Mustards

Medical management of nitrogen mustard exposure is similar to that for sulfur mustard. It involves preventing exposure and, where exposure has occurred, decontamination and support therapy. The use of antioxidants in the treatment of nitrogen mustard toxicity is under investigation (Hardej and Billack, 2006).

Lewisite

Similar to the mustard agents, exposure prevention is the first line of defense against lewisite. Rapid decontamination is especially relevant to lewisite exposure due to the rapid development of pain (1–2 min) associated with lewisite exposure. Unlike other vesicants, an effective antidote for lewisite toxicity exists in the form of BAL (2,3-dimercaptopropanol), which binds with arsenicals, thereby countering the lewisite-induced damage. Such chelation therapy is associated with notable side effects (e.g., renal effects) and requires careful medical management. More effective analogs of BAL have been developed that have less significant side effects.

Mouret et al. (2013) reported that for the SKH-1 hairless mouse model, topical application of dimercapto-chelating agents such as BAL and meso-2,3-dimercaptosuccinic acid (DMSA) were more effective than subcutaneous administration in the attenuation of lewisite vapor-induced injury. Although both agents reduced neutrophil infiltration, wound size, and necrosis of the skin barrier, BAL was found to be more effective than DMSA.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

As chemical warfare agents, vesicants have received considerable attention over the last two decades due to concerns regarding destruction of agent stockpiles, remediation of contaminated sites, the documented and speculated use of these agents in regional conflicts, and possible use in subversive/terrorist activity. This elevated interest profile has resulted in summaries of

older toxicological data, generation of new data, and a greater understanding of the effects of these agents on biological systems. Application of these data has been invaluable in the development of various health-based criteria, standards, and guidelines for use in remediation efforts, risk planning, and emergency response activities.

In accordance with the Chemical Weapons Convention, the United States is destroying (via chemical neutralization followed by biotreatment or supercritical water oxidation) the remaining sulfur mustard stored at the Blue Grass and Pueblo Army Depots (PEO ACWA, 2014). The sulfur mustard occurs in artillery projectiles and mortar rounds. Destruction is scheduled for completion by 2019 at Pueblo Army Depot and 2023 at Blue Grass Army Depot.

Future directions appear to focus on acquiring additional in-depth understanding of the mechanism of action of these agents through the development of experimental models for vesicant-induced injury, as well as an application of this information in the development of therapeutic measures for the prevention and treatment of vesicant-induced injury.

CHAPTER

9

Organophosphate Nerve Agents

Annetta Watson, Dennis Opresko, Robert A. Young, Veronique Hauschild, Joseph King and Kulbir Bakshi

INTRODUCTION

The chemical warfare (CW) nerve agents primarily addressed in this chapter include the anticholinesterase nerve agents tabun (GA), sarin (GB), soman (GD), cyclosarin (GF), and VX, all of which are, or have been, part of the US domestic munitions inventories (Carnes, 1989; Opresko et al., 1998; NRC, 1999). Russian VX (often represented as VR) is evaluated in Chapter 10 by Rembovskiy et al. (2015). Other less well-characterized nerve agents such as compound GE, VG (Amiton™), or V_x are evaluated as data allow.

These agents are potent anticholinesterase compounds deliberately formulated to induce debilitating effects or death during wartime hostilities and have been used by military authorities of several nations to develop munitions (e.g., Germany during the Nazi era, the United States, the former Soviet Union). US military stockpiles of CW munitions manufactured as a Cold War deterrent decades ago await demilitarization at designated stockpile sites and have been the subject of extensive emergency preparedness and response planning. Additional planning has been necessary at other current and formerly used military sites where containers and buried munitions have been inventoried (the "nonstockpile" sites) (Opresko et al., 1998; NRC, 1999, 2003). More recent global events have focused attention on the potential threat of chemical terrorism, especially at transportation hubs (Tucker and Raber, 2008). The deliberate release of nerve agent sarin at lethal concentrations in the Japanese cities of Matsumoto (1994) and Tokyo (1995) by a Japanese domestic terrorist group has illustrated that such attacks can be a reality and require advance emergency preparedness planning (Morita et al., 1995; Okumura et al., 1996, 2007; Sidell, 1996; Cannard, 2006; Yanagisawa et al., 2006; Tu, 2007).

Information provided on agent toxicity, risk assessment, treatment options, and other related topics will be useful to communities and facilities developing and updating emergency preparedness plans for accidental or intentional release of nerve agents; this information can also be used to support environmental decision-making where nonstockpile material and military gear have been found. In response to various public laws and international agreements such as the Chemical Weapons Convention (PL 99-145, 1986; PL 102-484, 1993; CWC, 1997), existing emergency guidance and military policy documents currently reflect the identified criteria and information (OASA, 1999; CSEPP, 2003, 2006a,b; NRT, 2008).

Although there are different applications for the information provided in this evaluation, in general the toxicological focus for emergency preparedness and response applications is that of acute exposures associated with a one-time release. Typically, the scenarios considered include a single-source airborne release from either an intentional terrorist attack, or accident involving an agent container or munition from a military site. It is widely recognized that vapor inhalation is the exposure route of greatest concern for such an event (Sidell, 1997; ATSDR, 2007). In contrast, the toxicological focus of environmental site remediation plans for military installations and formerly used defense sites where buried CW agent residues may occur requires consideration of long-term release and potential incidental ingestion of media such as soil particles or water with relatively low levels of contamination. To reflect these critical applications and information needs, the current evaluation will also primarily focus on

- single-source, one-time nerve agent releases and exposure routes involving agent vapor inhalation or direct ocular vapor exposures.

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00009-9

- long-term (chronic or subchronic) exposure from residual nerve agent contamination.

It is acknowledged that there exists a rich and valuable body of repeat-exposure studies using serial vapor or serial injection exposures for the nerve agents soman (GD), sarin (GB), and VX (see recent excellent reviews and analyses by Shih et al., 2006; McDonough and Romano, 2008; and experimental studies by Dabisch et al., 2005, 2007a); the interested reader is encouraged to examine these and related resources, because the current evaluation does not highlight experiments that apply serial exposure protocols.

BACKGROUND

Development of Organophosphate Formulations as CW Agents

The G-series nerve agents evaluated are all toxic ester derivatives of phosphonic acid containing either a cyanide (GA) or a fluoride (GD, GE, GF) substituent and are commonly termed "nerve" agents as a consequence of their anticholinesterase properties as well as their effects on both the peripheral nervous system (PNS) and central nervous system (CNS). The "G" series military nomenclature used by NATO member nations has historically been considered to be an abbreviation for "German," with the second letter of the code ("A", "B", and so on) identifying the order in which these compounds were found and analytically identified by Allied forces investigating materials found in captured German military facilities at the close of WWII (Sidell, 1997). Agent VX, a phosphonic acid ester with a sulfur substituent, was industrially synthesized in the United Kingdom in the early 1950s; the code letter "V" is a reported reference to "venom" (Sidell, 1997). Other, less well-characterized V-series compounds include Vx, VE, VM, and VG (trade name Amiton™ when commercially introduced as a miticide in the mid 1950s).

As Cold War deterrents, nerve agents began to be manufactured and weaponized by the United States in the 1950s. When the US CW agent production program was terminated by the Nixon presidential "Statement on Chemical and Biological Defense Policies" of November 1969 (National Security Decision Memorandum 35), the US stockpile of unitary munitions included bulk ("ton") containers, underwing spray tanks, projectiles, rockets, bombs, land mines, and rockets (Carnes, 1989; Sidell, 1997). Nerve agent unitary munitions contained GA, GB, or VX. The US CW agent munition stockpile is obsolete and is presently undergoing destruction and disposal by the US Army Chemical Materials Agency (see www.cma.army.mil) at each of the several unitary stockpile sites, for compliance with the CWC to eliminate the risk of continued storage for these aging CW munitions; current nerve agent stockpile sites are located in Alabama, Arkansas, Indiana, Kentucky, Oregon, and Utah. In December 2008, the US Army Chemical Materials Agency announced that 58% of the US unitary chemical munitions stockpile had been successfully destroyed.

Physical and Chemical Properties of Nerve Agents

The G-agents are all viscous liquids of varying volatility (vapor density relative to air between 4.86 and 6.33) with faint odors ("faintly fruity" or "spicy," "odor of camphor"). Agent VX is an amber-colored liquid with a vapor density of 9.2, and it is considered odorless. Thus, nerve agent vapors possess little to no olfactory warning properties (Table 9.1).

The vapor pressures and acute toxicity of these agents are sufficiently high for the vapors to be rapidly lethal. Within the G-series, GB is considered to present the greatest vapor hazard (order of vapor hazard approximates GB > GD > GF > GA). Agent VX was deliberately formulated to possess a low volatility; VX is approximately 2,000-times less volatile than nerve agent GB (DA, 1990a,b). As a consequence, agent VX is considered a persistent "terrain denial" military compound with the potential to be a contact hazard or generate off-gas toxic vapor concentrations over a period of days after surface application, particularly under cold weather conditions or when bulk-release quantities of liquid agent are involved. Although not readily volatile, VX vapors (if allowed to accumulate) are nevertheless considered more acutely potent than those of agent GB or the other G-series agents (Mioduszewski et al., 1998).

As a consequence of the volatilities exhibited by G-series nerve agents (Table 9.1), the most likely exposure route (and source of primary hazard) is via direct vapor exposure to the eyes and upper respiratory tract tissues and vapor inhalation (with consequent systemic absorption) (Cannard, 2006; Dabisch et al., 2008a); G-agents are considered "nonpersistent" as per definitions used by the US Department of Defense (DOD, 2008). Nerve agent VX is widely considered to present a greater threat from the percutaneous exposure route (when compared with the G-series agents) as well as a vapor inhalation threat at elevated ambient temperatures (e.g., >40°C) (Craig et al., 1977; Sidell, 1997; Benton et al., 2005, 2006a).

Nerve agent V_x exhibits volatility (76.4 mg/m^3 at 25°C) intermediate to that of agents GA and VX, and a vapor density (7.3) intermediate to that of agents GF and VX; V_x is also considered "persistent." There are few data from which to characterize nerve agents VE (*O*-ethyl-*S*-[2-(diethylamino) ethyl]ethylphosphonothioate, CAS No. 21738-25-0) or VM (*O*-ethyl-*S*-[2-(diethylamino) ethyl]methylphosphonothioate, CAS No 21770-86-5).

MECHANISM OF ACTION

All of the OP nerve agents under consideration are anticholinesterase compounds and induce accumulation of the neurotransmitter acetylcholine (ACh) at neural synapses and neuromuscular junctions (NMJs) by phosphorylating acetylcholinesterase (AChE). Depending on the route of exposure and amount absorbed, the PNS and/or CNS can be affected and muscarinic and/or nicotinic receptors may be stimulated. Interaction with other esterases may also occur, and direct effects to the nervous system have been observed.

Exposure to acutely toxic concentrations of nerve agents can result in excessive bronchial, salivary, ocular, and intestinal secretions, sweating, miosis, bronchospasm, intestinal hypermotility, bradycardia, muscle fasciculations, twitching, weakness, paralysis, loss of consciousness, convulsions, depression of the central respiratory drive, and death (Grob and Harvey, 1953; Grob, 1956; Sidell, 1997; Yanagisawa et al., 2006; Marrs, 2007; Okumura et al., 2015). Minimal effects observed at low vapor concentrations include miosis (contraction of the pupils of the eye, with subsequent decrease in pupil area), tightness of the chest, rhinorrhea, and dyspnea (Dunn and Sidell, 1989; Dunn et al., 1997). Pupillary contraction, resulting in varying degrees of miosis characterized by measures of pupil diameter, is consequent to local inhibition of ocular AChE activity with pupillary sphincter contraction (Dabisch et al., 2007b, 2008a,b; Dabisch and Taylor, 2010).

Reactivation of inhibited cholinesterase by dephosphorylation is not possible once the nerve agent–cholinesterase complex undergoes "aging," which is thought to be the consequence of the loss of an alkyl or alkoxy group. Agent GD ages very rapidly when bound to red blood cell cholinesterase (RBC–ChE), with a $t_{½}$ (time required for 50% of the enzyme to become resistant to reactivation) of 1.3 min (Harris et al., 1978). The aging half-time for agent GA with RBC–ChE is 46 h (calculated; De Jong and Wolring, 1978), and the $t_{½}$ for agent GB with RBC–ChE is 5 h (Sidell and Groff, 1974). The complex formed between RBC–ChE and agent VX does not age significantly (half-life of approximately 48 h) (Sidell and Groff, 1974; Dunn et al., 1997).

Direct Nervous System Effects

Although nerve agents exert toxic effects on the CNS and PNS indirectly through AChE inhibition (Koelle, 1975, 1981), nerve agents may also affect nerve impulse transmission by additional mechanisms at NMJs (see reviews by Somani and Husain, 2001; Marrs, 2007; Gupta and Milatovic, 2010) and at neurotransmitter receptor sites in the CNS (Myhrer and Aas, 2010; Weissman and Raveh, 2010). Rao et al. (1987) reported that VX caused an increase in ACh release at NMJs in the frog by an interaction with the nicotinic ACh receptor–ion channel complex. Aas et al. (1987) reported alterations in muscarinic receptors in rat bronchi and lung tissue after subacute inhalation exposures to agent GD. In the CNS, nerve agents may act directly on muscarinic, nicotinic, and glutamate receptors in manners unrelated to cholinesterase inhibition (Bakry et al., 1988; Chebabo et al., 1999; Lallement et al., 1991a,b; Rocha et al., 1998, 1999). Chebabo et al. (1999) reported that 0.3–1 nM of agent GB reduced the amplitude of GABA-mediated postsynaptic currents (GABA; neurotransmitter γ-aminobutyric acid), but had no effect on the amplitude of glutamatergic-mediated postsynaptic currents; this selective reduction in action potential–dependent release of GABA might account for GB-induced seizures. Lallement et al. (1991a,b) had suggested that GD-induced overstimulation of glutamatergic receptors contributed to maintenance of seizures.

Although these electrophysiological data indicate that nerve agents may have direct effects on the nervous system unrelated to AChE inhibition, the data do not provide a means of determining a dose conversion to an integrative whole-body endpoint such as lethality or qualitative/quantitative comparisons directly relevant to adverse effects.

It should be further noted that the effects of nerve agents on GABAergic transmission in the CNS may have implications for behavioral effects in laboratory animals and humans, and may also contribute to the induction of convulsions at higher doses (Bakshi et al., 2000). Nevertheless, given the present undefined application of noncholinergic data to whole-body estimations, reliance on the primary assumption of AChE action is consistent with recognized opinion (Bakshi et al., 2000).

Binding with Blood Cholinesterases

The activity of RBC–ChE, as well as that of plasma cholinesterase (plasma–ChE, plasma butyrylcholinesterase or BuChE), has been used to monitor exposure to, and recovery from, anticholinesterase pesticides as well as nerve agents. There is some historical evidence that RBC–ChE can be as sensitive as brain–ChE to the anticholinesterase effects of nerve agents. Grob and Harvey (1958) reported that *in vitro* concentrations producing 50% activity depression of brain–ChE and RBC–ChE were equivalent in the case of GA (1.5×10^{-8} mol/L), and comparable in the case of GB (3.0×10^{-9} versus 3.3×10^{-9} mol/L). The *in vivo* animal studies conducted by Jimmerson et al. (1989) disagree, which is further supported by the fact that blood ChE activity may not always be correlated with exposure or with signs and symptoms of toxicity (Holmstedt, 1959; Sidell, 1992, 1997) (Table 9.2). This was also observed during clinical treatment of cases after the Matsumoto and Tokyo

TABLE 9.2 Human Experimental Data for Single Exposures to GB Vapor

Concentration (mg/m^3)	Exposure Duration	Ct ($mg\,min/m^3$)	Signs and Symptoms	Reference
0.05	20 min	1	Headache, eye pain, rhinorrhea, tightness in chest, cramps, nausea, malaise	Harvey (1952)
0.05	20 min	1	Threshold (<1 mm pupil diameter decrease) to mild (1–2 mm pupil diameter decrease) miosis[a] in test subjects	Johns (1952)
0.06	20 min	1.2	No reported effects	McKee and Woolcott (1949)
0.06	40 min	2.4	Miosis; slight tightness in chest ($n = 4$)	McKee and Woolcott (1949)
0.3	0.5 min	0.15	Rhinorrhea in 16/16; chest tightness in 7/16	Fairley and Mumford (1948)
0.5	30 min	15.0	Miosis, dyspnea, photophobia, 40% inhibition of RBC–ChE, subclinical SFEMG[b] changes	Baker and Sedgwick (1996)
0.6	1 min	0.6	Miosis and slight tightness in chest	McKee and Woolcott (1949)
2	2 min	4	Miosis "moderate"; no other signs of ChE inhibition	Rubin et al. (1957)
NA	10 min to 5 h	3.13	50% pupil area decrement	Callaway and Dirnhuber (1971)
NA	10 min to 5 h	13.85	90% pupil area decrement	Callaway and Dirnhuber (1971)
4.19 (average)	2 min	8.38	Average 47% inhibition of RBC–ChE; no other effects (breathing rate 5.6–8.4 L/min through nose or mouthpiece)	Oberst et al. (1968)
20.7 (average)	2 min	41.4	Average 49% inhibition of RBC–ChE; no other effects (breathing rate 47–65 L/min through nose or mouthpiece)	Oberst et al. (1968)
2.8–4.3	1–2.25 min	4.5–5.0	Miosis of unprotected (unbandaged)[c] eyes of 10 military servicemen; min pupil size of 1.8 mm	Sim (1956)
4.0–4.5	2–2.25 min	8.3–9.8	Miosis of unprotected (unbandaged)[c] eyes of 22 military servicemen; min pupil size of 1.6 mm	Sim (1956)
9.5	1 min, 3 s	10	Miosis of unprotected (unbandaged)[c] eyes of 12 military servicemen; min pupil size of 1.7 mm	Sim (1956)
5.5–7.6	1.75–2.5 min	13.1–15.4	Miosis of unprotected (unbandaged)[c] eyes of 54 military servicemen; min pupil size of 1.5 mm	Sim (1956)
12.8–15.3	1–1.2 min	14.4–15.0	Miosis of unprotected (unbandaged)[c] eyes of 38 military servicemen; min pupil size of 1.5 mm	Sim (1956)

chemical terrorist incidents of GB exposure to the public (Nozaki et al., 1997; Yanagisawa et al., 2006).

It is generally considered that systemic effects in humans after acute nerve agent exposures are likely when RBC–ChE is inhibited by 75–80% (e.g., to 20–25% of normal activity levels) (Sidell, 1992). Nevertheless, it is well-known that local signs and symptoms of the eye and nose in humans and animals (e.g., miosis, rhinorrhea) can occur in the absence of any measurable change from baseline ChE activity in the blood after vapor or aerosol nerve agent exposure (Harvey, 1952; Craig and Woodson, 1959; Sidell, 1992) and are attributable to the local and direct effects of agent on tissues of the eye and upper respiratory tract (Grob, 1956; Dabisch et al., 2008a) (Table 9.2). When systemic exposure (e.g., other than direct ocular or direct nasal) occurs, miosis and rhinorrhea are not usually observed as first noticeable effects (NRC, 2003; Dabisch et al., 2008a).

EPA science policy guidelines regarding use and application of cholinesterase activity inhibition data generally consider blood ChE activity inhibition to be an imperfect measure, and there appears to be no fixed

percentage of blood ChE activity change that can distinguish adverse from nonadverse effects (Storm et al., 2000; USEPA, 2000). A number of investigations have noted the poor association between blood (RBC and plasma) cholinesterase activity and nerve agent intoxication (Rubin and Goldberg, 1957; Sidell, 1992, 1997; Koelle, 1994; Mioduszewski et al., 2002a; Cannard, 2006; Yanagisawa et al., 2006); minimal blood ChE activity has been observed in association with normal tissue function (Sidell, 1992). In a clinical situation, measurement of blood ChE activity has forensic utility and is helpful as a measure of recovery but is not a quantitative measure of absorbed dose (Cannard, 2006).

Binding with Other Enzymes

Nerve agents also interact with detoxification enzymes such as carboxylesterases (CarbE) and A-esterases (e.g., arylesterase and paraoxonase), and the degree of such interaction can alter the magnitude and extent of the toxic cascade after AChE inhibition (Gupta et al., 1991; Pope, 1999; Pope and Liu, 2002; Fonnum and Sterri, 2006) as well as species-specific characteristics. Observed spontaneous reactivation of soman-inhibited plasma CarbE in the rat indicates that "aging" does not occur for the GD–plasma CarbE complex (in contrast to that observed for GD and RBC–ChE) (Dunn et al., 1997), and further suggests that endogenous plasma CarbE may be a principal functional scavenger for agent GD (Maxwell and Brecht, 2001). Recent studies indicate that full characterization of the OP-protective capabilities of CarbEs requires assessment not only of the amount, but also of the affinity exhibited by CarbEs for the inhibitor, as well as the total CarbE activity unlikely to be inhibited (inhibitor resistant esterase activity) (Chanda et al., 2002). The detoxification potential of CarbEs is multifaceted and is an area requiring further experimental characterization (Fonnum and Sterri, 2006, 2015).

TOXICITY

Effects

Nerve agents are toxic anticholinesterase compounds by all routes of exposure and exhibit a steep dose–response. Detailed descriptions of nerve agent toxicity may be found in reviews by Munro et al. (1994), Mioduszewski et al. (1998), Opresko et al. (1998), Sidell (1997), NRC (1999, 2003), Bakshi et al. (2000), Somani and Husain (2001), Marrs (2007), and Weissman and Raveh (2010).

Anticholinesterase effects of nerve agent exposure can be characterized as muscarinic, nicotinic, or CNS. Muscarinic effects occur in the parasympathetic system and, depending on the amount absorbed, can be expressed as conjunctival congestion, miosis, ciliary spasm, nasal discharge, increased bronchial secretion, bronchoconstriction, anorexia, emesis, abdominal cramps, sweating, diarrhea, salivation, bradycardia, and hypotension. Nicotinic effects are those that occur in somatic (skeletal/motor) and sympathetic systems, and can be expressed as muscle fasciculations and paralysis. CNS effects may be manifested as confusion, reflex loss, anxiety, slurred speech, irritability, forgetfulness, depression, impaired judgment, fatigue, insomnia, depression of central respiratory control, and death (Sidell and Groff, 1974; Sidell, 1992, 1997; Opresko et al., 1998; Bakshi et al., 2000). Minimal effects observed at low concentrations in human subjects include miosis, a feeling of "tightness" in the chest, rhinorrhea, and dyspnea (Dunn and Sidell, 1989) (Table 9.2).

Although RBC–ChE inhibition in the blood is considered an operationally acceptable surrogate for CNS inhibition, plasma ChE is more labile and is a less reliable reflection of enzyme activity change at neuro-effector sites (Young et al., 1999; USEPA, 2000).

In the whole-body agent vapor exposure studies of Mioduszewski et al. (2002a; SD rat single exposures to GB vapor) and Benton et al. (2006a; SD rat single exposures to VX vapor), miosis was usually not correlated with or accompanied by reductions of circulating AChE, BuChE, or CarbE. For the VX vapor exposure study of Benton et al. (2006a), and among those rats exhibiting only one sign (either whole-blood AChE activity inhibition or miosis), miosis developed in the absence of blood AChE activity depression "90% of the time." The findings of Mioduszewski et al. (2002a) for SD rats are consistent with those for human volunteers exposed to GB vapor in the study by Rubin and Goldberg (1957). These results further document the fact that miosis alone, and in the absence of signs such as ChE or CarbE activity inhibition, is a local effect and reflects an exposure much less than that required for generation of systemic clinical effects. Thus, consideration of a local effect such as miosis as a critical endpoint for decision criteria and exposure guideline determination allows a useful margin of protection against the potential for agent exposures sufficiently large to generate systemic effects.

Minimal Potential for Delayed Neuropathy

A continuing area of public concern regarding nerve agent exposure is the possibility of chronic neurological effects, particularly delayed neuropathy, given that neuropathic effects have been observed after high levels of occupational exposure to the lipophilic agricultural pesticides. Exposure to some OP anticholinesterase compounds results in delayed neurotoxic effects (ataxia, distal neuropathy, paralysis), which are collectively described as organophosphate ester–induced delayed

neuropathy (OPIDN). OPIDN is characterized by myelin sheath and axon degeneration and was once thought to be the consequence of inhibition and aging of neuropathy (or neurotoxic) target esterase (NTE) (Abou-Donia, 1993; Ehrich and Jortner, 2002; Gupta and Milatovic, 2012). With greater knowledge and recent data pointing out that NTE-knockout mice may also develop OPIDN (Abou-Donia, 2003; O'Callahan, 2003; Winrow et al., 2003), the NTE theory has been replaced with one involving a noncholinergic, proteolytic mechanism involving cytoskeletal proteins found in neurofilaments (De Wolff et al., 2002). The resulting proteolysis, accompanied by perturbed ionic gradients, cellular edema, and myelin debris, can generate neuropathy.

A number of well-conducted studies using USEPA guidelines for experimental determination of delayed neurotoxicity (USEPA, 1998) have been performed for the G-agents and agent VX (Gordon et al., 1983; Willems et al., 1984; Goldman et al., 1988; Wilson et al., 1988). The USEPA protocol requires toxicological testing with the domestic hen, an OPIDN-sensitive laboratory animal. In general, exposure to the standard threat nerve agents (e.g., GA, GB, GD, GF, VX) is not considered neuropathic in humans (Marrs, 2007) given that agent VX is not neuropathic in standard challenge tests with hens and that G-agent concentrations necessary to induce OPIDN would be supralethal, and human survival would be highly unlikely.

Evaluation of Other Potential Effects

Animal data from vapor, oral, and injection exposure studies for the G-series nerve agents and agent VX indicate that these agents do not induce reproductive or developmental effects in mammals (Van Kampen et al., 1970; Denk, 1975; Schreider et al., 1984, 1988; LaBorde and Bates, 1986; Goldman et al., 1988; Bates et al., 1990; Bucci et al., 1993; LaBorde et al., 1996). Incidental data from the Tokyo subway incident (Ohbu et al., 1997) documenting the birth of healthy children to women who had received exposures to toxic GB concentrations at 9–36 weeks of gestation support this finding.

Neither agent GB nor agent VX was genotoxic in a series of microbial and mammalian assays (Crook et al., 1983; Goldman et al., 1987, 1988), whereas agent GA has been reported to be weakly mutagenic in similar cellular assays (Wilson et al., 1994). Experimental results indicate that agents GB, GA, and VX have no carcinogenic potential (Weimer et al., 1979; Goldman et al., 1988; Bucci et al., 1992a,b).

Inhalation/Ocular Toxicity in Human Subjects

It is noted that the most complete experimental data set for the nerve agents evaluated in all species is that for agent GB. The following analysis reflects that emphasis (Table 9.2). Human study reports evaluated have been previously judged by the US Environmental Protection Agency National Advisory Committee for Acute Exposure Guideline Levels for Hazardous Substances and the National Research Council (NRC) Committee on Toxicology to be consistent with acceptable criteria and procedures regarding informed consent and appropriate clinical supervision (NRC, 2001, 2003).

Agent GB

Fairley and Mumford (1948) exposed 16 male volunteers to 0.3 mg GB/m^3 for 0.5 min. Nine of the test subjects reported that they could detect the agent by smell; seven reported tightness of the chest and 16 reported rhinorrhea.

McKee and Woolcott (1949) evaluated the effects of low concentrations of agent GB on 14 male volunteers. A single exposure to 0.6 mg GB/m^3 for 1 min or 0.06 mg GB/m^3 for 40 min resulted in miosis and slight tightness of the chest; within 24 h, signs and symptoms resolved in subjects exposed for 1 min, whereas more than 48 h was required for resolution in subjects exposed for 40 min.

In a study reported by Harvey (1952), 128 adult male volunteers were exposed in a chamber to GB concentrations ranging from 0.05 to 3.0 mg/m^3 for 2–20 min. The corresponding cumulative exposures ranged from 1.0 to 6.0 mg min/m^3. The most common signs and symptoms resulting from the GB exposures were headaches, eye pain, rhinorrhea, tightness in the chest, cramps, nausea, and concentration difficulties.

When evaluating data from the Harvey (1952) study, Johns (1952) reported on the occurrence of miosis in exposed individuals. Regression analysis of 150 observations, including 55 controls, indicated that the concentration at which a 50% decrease in pupil diameter would be attained was approximately 4.1 mg min/m^3, with 90% confidence limits of approximately 2.7 and 5.7 mg min/m^3. Johns (1952) defined "mild miosis" as a "decrease of 1–2 mm" in pupil diameter, which usually disappeared within 24 h. Although mild miosis as defined was observed in some subjects at the lowest Ct tested (Ct = 1.0 mg min/m^3), other subjects exhibited mean maximal pupil decreases of less than 1 mm, indicating attainment of a response threshold at this level of exposure. Untreated controls exhibited a pupil diameter decrease of 0.33 mm or more; Johns (1952) attributed this difference to observer bias and pointed out that there was still a relative difference between the control group and the exposed groups.

Oberst et al. (1968) conducted inhalation studies in which 125 volunteers were exposed to low concentrations of GB vapor to measure levels of GB retention and changes in RBC–ChE activity. In one series of tests in which resting subjects were exposed to GB for 2 min,

the calculated retained dose was 3.4–3.8 μg/kg and the percent inhibition of RBC–ChE activity was 39–63% (average 49%). In a second series of tests in which exercising men were exposed to GB for 2 min, the calculated retained dose was 3.2–4.0 μg/kg and the percent inhibition of RBC–ChE activity was 29–58% (average 47%). The reported 2 min ChE_{50} dose for all 125 subjects (grouped data) was 3.95 μg GB/kg. From these data, the 2 min EC_{50} for cholinesterase inhibition can be estimated as approximately 21 mg/m^3 for resting men breathing approximately 7 L/min and approximately 4 mg/m^3 for exercising men breathing approximately 50 L/min.

Baker and Sedgwick (1996) exposed eight human volunteers to 0.5 mg GB/m^3 for 30 min in a chamber; test subjects walked at a rate of 96 paces per minute while breathing normally. The exposure resulted in a 60% inhibition of RBC–AChE activity; subjects exhibited miosis, some photophobia and mild dyspnea. Respiratory symptoms resolved within minutes and the ocular effects within 48 h after exposure. There were no clinical neuromuscular signs or symptoms; however, small and nonclinical changes in single fiber electromyography (SFEMG) of the forearm were measured at 3 h and 3 days after exposure; SFEMG changes were not detectible 15–30 months after exposure.

The results of agent GB vapor exposure studies conducted with human volunteers indicate that the threshold for miosis and other minimal toxic effects is in the range of 0.05–0.5 mg/m^3 for 10 min to 30 min exposures (Table 9.2 and summaries).

Rubin et al. (1957) evaluated the effects of agent GB on the visual threshold of three adult volunteers. The test individuals were exposed to 2 mg GB/m^3 for 2 min with the eyes exposed or protected. With the eyes unprotected, the exposure resulted in moderate miosis with no other obvious signs of cholinesterase activity inhibition, but with a significant elevation of the absolute visual threshold in the dark-adapted eye.

Callaway and Dirnhuber (1971) evaluated the "miotogenic potency" of GB vapor in humans (62 miosis responses in 26 human volunteers). Exposure time periods ranged from 10 min to 5 h. Callaway and Dirnhuber reported 50% and 90% decrements in pupil area (Table 9.2). There are acknowledged weaknesses in the protocol and data of Callaway and Dirnhuber (1971), such as limited 1970s-era capabilities for measuring agent vapor concentrations, semi-subjective protocols for measuring miosis in human eyes, and incomplete documentation of miosis incidence.

Based on human and animal data, McNamara and Leitnaker (1971) estimated that the EC_{50} for miosis in humans would be 0.0083 mg/m^3 for 8 h exposure duration or 0.0028 mg/m^3 for 24 h exposure duration. McNamara and Leitnaker (1971) did not expect miosis to occur at 0.001 mg/m^3 for 8 h or 0.0003 mg/m^3 for 24 h.

Agents VX and Vx

No experimental data are available for direct characterization of acute VX vapor toxicity in humans after inhalation exposure. Based on lethality data for several animal species, Bide and Risk (2000, 2004) estimated the 10 min LCt_{50} value for a VX aerosol to be 7 mg min/m^3 for a 70 kg man breathing 15 L/min for 10 min.

One of the few experimental attempts to evaluate human exposure to VX vapor for durations longer than a few minutes is the historically important study of Bramwell et al. (1963), in which eight individuals were exposed to VX vapor concentrations ranging from 0.23 mg/m^3 to 5 mg VX/m^3 for durations ranging from 2.25 s to 24 min (Cts = 0.7–25.6 mg min/m^3). The Bramwell et al. (1963) study is not considered credible because of its seriously flawed exposure protocol; both C and t were varied (resulting in no replicate cumulative exposures), and the organic solvent benzene was used to help disperse the agent in the exposure (carrier solvent may have altered agent absorption) (Reutter et al., 2000).

Koon et al. (1959) evaluated the minimum odor detection limits of VX in 16 volunteers. Each subject sniffed the agent both during the morning and afternoon on 2 successive days (presumably only one sniff at each time point). The estimated total doses for the four exposures ranged from 0.01 to 0.13 μg/kg. No significant changes in RBC or plasma ChE activity were observed in the test subjects. Three subjects reported headaches the evening of the last test, and three other subjects reported slight chest tightness, dryness of the mouth, and nasal irritation for 30 min after the test.

Recent multiservice (Army, Marine Corps, Navy, and Air Force) guidance on agent-specific exposure limits estimates the VX ECt_{50} for mild toxicity in humans (miosis, rhinorrhea) to be 0.10 mg VX-min/m^3 for 2–360 min exposures (DA, 2005). The inhalation/ocular ECt_{50} for severe effects in humans (i.e., muscular weakness, tremors, breathing difficulty, convulsions, paralysis) was estimated to be 10 mg min/m^3 for 2–360 min exposures for a respiratory minute volume of 15 L/min (DA, 2005).

Agent V_x is considered toxic via inhalation exposure or direct contact with the eye and/or skin (DA, 2005) but has been poorly studied. Because of lack of data suitable for analysis, DA (2005) has determined that no toxicity estimates for Vx can be developed at this time.

Inhalation/Ocular Toxicity in Laboratory Species

G-Series Agents

Lethal Levels

There are considerable data regarding the acute lethality of G-series agents for short-term exposures (Table 9.3) (see also NRC, 2003 for a detailed review).

TABLE 9.3 Acute Inhalation Lethality (LC_{50}; LCt_{50}) for Nerve Agent Vapor in Laboratory Animals

[a]*Lethality assessed over 14 days.*
[b]*LCt_{50} values summarized from numerous obscure sources by Gates and Renshaw (1946).*

In studies conducted by Mioduszewski et al. (2001, 2002a), acute lethality of agent GB to male and female SD rats was evaluated for time periods of 10, 30, 60, 90, 240, and 360 min in a whole-body dynamic chamber. GB concentrations ranged from approximately 2–56 mg/m^3, and lethality was assessed at 24 h and at 14 days after exposure. Female rats were reported to be significantly ($P < 0.01$) more sensitive than males to GB vapor toxicity over the range of exposure concentrations and durations studied.

In studies conducted by Bide and Risk (2004), male CD-1 strain mice were exposed to whole-body GB for time periods ranging from 20 to 720 min. LC_{50} values for 3–12 h were progressively higher (toxicity lower) than that predicted by either Haber's rule or the Ten Berge relationship (Ten Berge et al., 1986). In studies conducted by Anthony et al. (2004), male and female SD rats were exposed to whole-body agent GF for 10, 60, or 240 min, and lethality was assessed 24 h and 14 days after exposure (Table 9.3). Females were more sensitive than males.

Hulet et al. (2006b) exposed male and female Göttingen minipigs to whole-body lethal concentrations of agent GF vapor for 10, 60, or 180 min (Table 9.3). No significant gender differences were observed in the GF lethality values.

In the latter years of WWII, agent GE underwent acute inhalation toxicity characterization at a number of research facilities managed by the Office of Scientific Research and Development (National Defense Research Committee). These results, for which the research protocols and exposure concentrations are not available for comparison, were summarized by Gates and Renshaw (1946) and are provided in Table 9.3 as LCt_{50} values.

Sublethal Levels

A consistent endpoint for sublethal effects determination is miosis. This information is summarized in Table 9.4.

Van Helden et al. (2003, 2004a,b) exposed male and female marmosets (Callithrix jacchus, Harlan, UK) (whole-body) to mean GB vapor concentrations of 0.27–0.91 μg/m^3 and male Dunkin–Hartley guinea pigs to 0.02–0.43 μg/m^3 for 5 h. The lowest cumulative exposure at which the internal dose became measurable (based on fluoride-regenerated GB from blood BuChE) was 0.04 ± 0.01 mg min/m^3 in marmosets and 0.010 ± 0.002 mg min/m^3 in guinea pigs.

Miosis, EEG effects, and visual-evoked response (VER) were examined after 5 h exposures at concentrations ranging from 7.5 to 150 μg GB/m^3. Significant miosis (as measured by the ratio of pupil diameter to iris diameter; $P < 0.05$) was attained for marmosets and guinea pigs (Table 9.4) (Van Helden et al., 2003; 2004a). Significant ($P < 0.05$) threshold change in EEG parameters for marmosets occurred at 0.2 mg min/m^3, whereas significant threshold VER changes occurred at 25 mg min/m^3 (Van Helden et al., 2004b).

Mioduszewski et al. (2002a,b) exposed young adult (8- to 10-week-old) male and female Sprague–Dawley (SD) rats to whole-body GB vapor concentrations of 0.01–0.48 mg/m^3 for three exposure periods of 10, 60, and 240 min in a dynamic airflow inhalation chamber. Rat pupil diameters were assessed and blood samples were also collected for RBC–AChE, BuChE, and plasma carboxylesterase (CarbE) activity determinations. Animals were also observed for development of clinical signs during a 7-day postexposure period; EC_{50} values for miosis were reported (Table 9.4; miosis EC_{50} points defined as the statistical concentration required for postexposure pupil diameters of 50% or less of the pre-exposure pupil diameter in 50% of the exposed population) (Mioduszewski et al., 2002a,b). Gender differences (females more susceptible) were observed. Whole-body exposure to GB vapor did not result in significant activity inhibition for any blood enzyme monitored (RBC–AChE, plasma–BuChE, or CarbE) for any GB vapor concentration and duration tested. Mioduszewski et al. (2002a,b) concluded that clinical signs associated with whole-body GB vapor exposure were limited to miosis.

Kassa et al. (2001) exposed male albino Wistar rats for 60 min in an inhalation chamber once, or repeatedly to GB concentrations of 0.8, 1.25, or 2.5 mg/m^3. Animals exposed to the lowest concentration (level 1) were asymptomatic based on clinical and laboratory

measurements. Animals exposed to the second concentration (level 2) were asymptomatic based on clinical signs but experienced significant inhibition of RBC–AChE activity (by 30%). The highest test concentration (level 3) was reported to be a nonconvulsive symptomatic exposure. Three months after exposure, control and exposed animals were evaluated for GB-induced effects using biochemical, hematological, neurophysiological, behavioral, and immunotoxicological methods. None of the exposed animals showed any clinical signs of intoxication; their body weight did not differ significantly from control values, and there were no changes in hematological or biochemical parameters, including blood and brain cholinesterase activity. The only significant effect ($P < 0.05$) observed in rats exposed once to 1.25 mg GB/m^3 (level 2) was an increase in stereotypical behavior. In a continuation of these studies, Kassa et al. (2004) reported that at 3 months after exposure, the level 3 animals showed significant increases in two biochemical markers of stress, plasma corticosterone, and liver tyrosine aminotransferase activities. The latter was also significantly increased in level 2 test animals. In spatial discrimination tests, animals tested at all three GB concentrations showed significant increases in reaction time up to 2 h after exposures. In the level 3 animals, the effects lasted for 3 weeks.

Walday et al. (1991) exposed male Wistar rats to 0.05 or 0.2 mg GD/m^3 for a single 40 h period. No clinical

signs of toxicity were seen during the exposures. AChE, BuChE, and CarbE activities were significantly inhibited in airway and lung tissue at both doses. Brain BuChE and CarbE activity exhibited significant effects at either dose; brain AChE activity did not significantly change from baseline at 0.05 mg GD/m^3, but did so at 0.2 mg GD/m^3.

Genovese et al. (2004) evaluated cognitive and general performance effects of GB on adult male SD rats. The test animals received a single whole-body exposure for 60 min once at 1.7–4.0 mg GB/m^3. Cognitive and behavioral performance testing began 48 h after inhalation exposure and was conducted during 55 sessions occurring over approximately 11 weeks after exposures. Single exposures did not significantly affect performance and no delayed performance onset was observed.

Genovese et al. (2008) characterized the miosis EC_{50} for sarin in a nonhuman primate (African green monkey; *Chlorocebus aethiops*) after 10 min exposures (Table 9.4). Evaluation of potential behavioral change by performance on a serial probe recognition test indicated no change from baseline for all subjects. No other clinical sign was observed.

Genovese et al. (2006) also evaluated cognitive and general performance effects of GF on adult male SD rats using the same protocol as that for GB. The test animals were exposed for 60 min to 0, 1.6, 3.7, or 5.2 mg GF/m^3. The highest test concentration resulted in a significant decrease in the response rate in the behavioral task for the first two postexposure sessions; however, the deficit was not persistent and recovery occurred rapidly. None of the exposures to GF caused a significant effect on completion time in the maze (cognitive) task.

In tests conducted by Allon et al. (2005), freely moving male albino SD rats were exposed to whole-body 34.2 ± 0.8 μg GB/L for 10 min, after which electrocardiograms of exposed and control animals were monitored every 2 weeks for 6 months. One and 6 months after exposure, rats were challenged with epinephrine under anesthesia and the threshold for cardiac arrhythmia was determined. Surviving treated rats displayed agitation, aggression, and weight loss compared with nonexposed rats, and approximately 20% experienced sporadic convulsions. GB-challenged rats with severe signs demonstrated QT segment prolongation during the first 2 to 3 weeks after exposure. Epinephrine-induced arrhythmias appeared at a significantly lower blood pressure in the treated group during the first month after exposure and lasted for up to 6 months.

Callaway and Dirnhuber (1971) evaluated the miotogenic potency of GB vapor in rabbits exposed to GB under goggles (43 miosis responses in ten albino rabbits). Exposure time periods ranged from 10 min to 5 h (Table 9.4).

Bartosova-Sevelova and Bajgar (2005) exposed rats to agent GB vapors for 4 h at four different concentrations (0.30, 0.43, 0.58, and 0.82 mg/m^3) in a whole-body exposure chamber. Convulsions and hypersalivation were observed in one animal exposed to 0.82 mg/m^3. There was a significant decrease in blood AChE activity in all but the low-dose test groups and the controls. AChE activity in the brain was significantly decreased only in animals exposed to 0.58 mg/m^3, and only in the pontomedullar area. No significant alterations in AChE activity were seen in the frontal cortex or in the basal ganglia. AChE activity in the pontomedulla was lowest at the greatest dose (0.82 mg/m^3), but the data were too variable for statistical significance.

Sekowski et al. (2004) evaluated gene and protein level changes in the brain of male and female SD rats exposed to low-level doses (0.004–0.033 mg/m^3) of aerosolized agent GB and GF via whole-body inhalation for 4 h. Preliminary results indicate that exposure to nerve agents results in differential expression of a number of neuronal genes, including a group that affects cellular processes critical to neurological injury and regeneration, and gender-associated differences in the level and type of gene expression response were significant.

Whalley et al. (2004) exposed adult male and female SD rats to a series of whole-body agent GF vapor concentrations for 10, 60, or 240 min. Miosis (defined as a 50% reduction in pupil area compared with baseline) measured approximately 30 min after exposure indicates that females were significantly more sensitive than males ($P < 0.05$) (Table 9.4).

In studies conducted by Hulet et al. (2006a,c, 2007), male and female Göttingen minipigs were exposed to whole-body agent GB or GF for 10, 60, or 180 min (Table 9.4). Male minipigs were significantly ($P = 0.022$) more sensitive to the effects of GF exposure than females.

Conn et al. (2002) exposed male F344 rats to 0, 0.2, or 0.4 mg GB/m^3 for 1 h/day for 1 or more days. Animals were maintained at either 25°C or 32°C to evaluate the effects of heat stress. Body temperature and activity were monitored by telemetry continuously during exposure and for 1 month after the exposures. Although RBC–ChE activity was reduced in the exposed animals (quantitative data not provided), the test protocol did not significantly alter temperature regulation or locomotive activity of the rats.

Agent VX

Lethal Levels

Benton et al. (2006b, 2007) experimentally determined the LCt_{50} and LC_{50} in male and female adult SD rats exposed to whole-body VX vapor for 10, 60, and 240 min in a dynamic exposure chamber (Table 9.3); study protocol was similar to that for agent GB in the studies conducted by Mioduszewski et al. (2001, 2002a). Experiments testing the role of decontamination

less than 24 h after exposure provided clear evidence for percutaneous toxicity induced by whole-body vapor exposure to the persistent nerve agent VX. For severe and lethal VX vapor exposure effects, females were not more susceptible than males for the exposure durations examined.

Bide and Risk (2000) exposed outbred male CD1 (SD) BR rats, outbred male CD1 (ICR) BR mice, and outbred male (HA) BR guinea pigs to NaCl aerosols containing entrained VX in a nose-only inhalation system for an exposure time of 12 min. Observed LCt_{50} values are summarized in Table 9.3.

Bide and Risk (2000, 2004) also cite several previous studies in which LCt_{50} values for mice, guinea pigs, rabbits, hamsters, and dogs were reported (Table 9.3).

For exposure to VX vapors, Koon et al. (1960) reported 10 min LCt_{50} values for mice with exposure to either whole-body or head only, as well as for goats. Carroll et al. (1957) also reported female mouse LCt_{50} values for nose-only and whole-body protocols. However, Carroll et al. (1957) reported that the concentration of VX in the exposure chamber was not measured directly but was estimated from the mortality level, which was correlated with the LD_{50} for i.v. injection.

Sublethal Level

Benton et al. (2005, 2006a, 2007) have characterized miosis as well as severe effects (severe tremors and/or prostration, convulsions and/or gasping) in male and female SD rats exposed to whole-body VX vapor (0.00037–0.016 mg VX/m^3) under study protocols similar to those for agent GB in the studies conducted by Mioduszewski et al. (2001, 2002a). Miosis EC_{50} endpoints were derived for VX vapor exposure durations of 10, 60, and 240 min (Table 9.4). At the highest VX concentrations tested for each exposure duration, significant (>99.9% confidence) differences between control and experimental whole-blood AChE activity were observed; no other signs (e.g., tremors, salivation) were observed and delayed pupil effects were minimal. For the miosis endpoint, female rats are considered more susceptible than males to VX vapor exposure.

For severe effects (tremors, prostration, etc.), the ECt_{50} values (mg min/m^3) reported by Benton et al. (2007) were as follows: 10 min, 40.9 (female) and 35.2 (male); 60 min, 30.0 (female) and 31.2 (male); and 240 min, 31.5 (female) and 29.9 (male). EC concentrations were not reported.

After single 60 min VX vapor exposures in the range of 0.016–0.45 mg VX/m^3, Genovese et al. (2007) examined blood AChE activity, dose estimation by regeneration assay, transient miosis, and behavior parameters in adult male SD rats. Behavioral evaluation included a radial maze task and a variable-interval schedule-of-reinforcement task. At all concentrations tested, transient miosis and AChE activity inhibition were observed and some subjects exhibited transient ataxia and slight tremor. After 3-month postexposure evaluations of behavior, the authors concluded that performance deficits were minor and transient at these concentrations. Further, no delayed effects were observed.

RISK ASSESSMENT

Application of standard risk assessment methods by numerous authorities and agencies to the toxicological data summarized has generated exposure guidelines that provide objective and health-based foundations for responsible and efficient response after nerve agent release, as well as a basis for site recovery and decontamination decision criteria. The health-based nerve agent exposure guidance summarized here has been derived in an open and transparent manner and judged scientifically valid and protective (Opresko et al., 1998, 2001; NRC, 1999, 2001, 2003; Krewski et al., 2004, Watson et al., 2006a,b; see also www.epa.gov/oppt/aegl/). Although initially developed to facilitate disposal of the US stockpile of CW munitions and to support remediation or closure at sites where CWs were historically processed, nerve agent exposure guidance became a subject of interest for homeland defense applications after the events of September 2001.

For reasons described previously, the air exposure pathway has been a primary focus of risk assessment activity for nerve agents (NRC, 2003; Cannard, 2006; ATSDR, 2007; Dabisch et al., 2008a; others). In situations where long-term agent release is a concern, and where agent residuals may be found, potential exposure to relatively low levels of ingested agents is a priority.

In all cases, it is important to appropriately safeguard public health without defaulting to overly conservative actions (e.g., to "nondetect") that would divert limited resources without significant benefit. The following sections summarize toxicological support and developmental rationale for the two primary criteria of interest to community decision-makers managing response to an intentional, or accidental release of nerve agent(s) to the environment.

Acute Exposure Guideline Levels

Credible short-term nerve agent exposure limits, designed to aid state and local government agencies in developing emergency response plans in the event of accidental or deliberate atmospheric release, have been derived. These short-term values have also proved useful in deployed force health protection, and in establishing health-based CWA performance goals for detection system development (USACHPPM, 2004, 2008).

TABLE 9.5 Summary of AEGL Values for G-series Nerve Agents and VX (mg/m^3)

Agent	Classification	10 min	30 min	1 h	4 h	8 h

Acute exposure guideline levels (AEGLs; expressed in units of mg/m^3 or ppm) are vapor exposure guideline values for numerous hazardous compounds (primarily toxic industrial compounds) that have been published by the National Academy Press (e.g., NRC, 2003, 2007). For each hazardous compound, guideline levels are developed for vapor exposure durations of 10 and 30 min, 1, 4, and 8 h, as well as for three gradations of toxic effect severity. AEGL-1 concentrations are the mildest effect category, whereas AEGL-3 concentrations represent the most severe effect category (NRC, 2001). The point above the AEGL-3 concentration at which level 3 effects would initiate for any given human exposure duration is not identified in the AEGL assessment protocol.

Typically, the AEGL concentration established for any given effect level is often less than the known experimental concentration at which such toxicological effects occur. This protective nature of the AEGL process and values was demonstrated for each of the nerve agents, where observed human thresholds for reversible effects occur at air concentrations greater than AEGL-1 levels (Watson et al., 2006a,b).

Selection protocols for critical effects and studies, AEGL derivation, time scaling, use and selection of uncertainty and modifying factors, and a description of the lengthy and deliberative review process used are all described in NRC (2001) as well as in recent articles by Krewski et al. (2004) and Bruckner et al. (2004). Development of AEGL values includes consideration of uncertainty factors as well as the need for any modifying factors. Because exposure–response data are usually not available for each AEGL-specific exposure duration (NRC, 2001), temporal extrapolation is used in the development of values for some AEGL-specific time periods. The concentration–exposure time relationship for many systemically acting vapors and gases may be described by $Cn \times t = k$, where the exponent n ranges from 0.8 to 3.5 (Ten Berge et al., 1986; NRC, 2001). Some investigators refer to the Ten Berge extrapolation as the "toxic load model" and n as the "toxic load exponent" (Sommerville et al., 2006; Dabisch et al., 2008a). The excellent data collected by investigators at Edgewood Chemical Biological Center (Aberdeen Proving Ground, MD), characterizing nerve agent vapor exposure miosis and lethality endpoints for multiple agents and species, has allowed agent-specific determination of n (summarized in Dabisch et al., 2008a). In the case of swine exposed to G-agents and rats exposed to VX, the experimentally determined n values for these endpoints are 1.6 or less, which are less than the n of 2 assumed during AEGL development for these same compounds in 2001–2003 (NRC, 2003), and based on then-available data for SD rats exposed to agent GB (Mioduszewski et al., 2002a,b). It thus appears that G-agent and VX dose response for the miosis and lethality endpoints are less steep than previously indicated and that the published nerve agent AEGL values (Table 9.5) are more protective than originally considered (NRC, 2003; Watson et al., 2006a,b).

For comparison, it is useful to consider other common guideline sources applicable to short-term nerve agent release events. The US Department of Energy, in their development of 1 h Protective Action Concentrations/Temporary Emergency Exposure Levels (PAC/TEELS), has chosen to replicate the published nerve agent-specific 1 h AEGL-1, AEGL-2, and AEGL-3 values as tier 1, tier 2, and tier 3 PAC/TEEL values, respectively (see http://hss.energy.gov/HealthSafety/WSHP/chem_safety/teel.html).

Application of AEGL Values

The AEGL process does not include specific implementing or application guidance, and specific approaches for using the values are left to the discretion of risk managers and appropriate authorities (NRC, 2001). Nevertheless, AEGL application is already broad and continues to expand.

The utility of AEGL values for CW agent emergency preparedness planning was recognized by the Chemical Stockpile Emergency Preparedness Program (CSEPP), when FEMA and Army representatives adopted final nerve agent AEGL concentrations to replace previous agent toxicity criteria for emergency response decision-making (CSEPP, 2003). As of February 2003, standing CSEPP policy guidance for each of the communities hosting agent demilitarization facilities in the US, recommends application of AEGL-2 concentrations as the protective action level for evacuation or shelter-in-place, and application of AEGL-1 concentrations as notification levels (CSEPP, 2003). Since publication of final AEGL levels by NRC (2003) and enactment of the CSEPP Policy Paper (CSEPP, 2003), multiple stockpile states and counties have incorporated the Policy Paper recommendations into their individual community emergency response plans, and used them in making regulatory decisions permitting agent munition disposal operations (CSEPP, 2006a,b).

In February 2008, the US National Response Team (NRT) posted Quick Reference Guides for the G-series nerve agents and VX for public access on its website (www.nrt.org) (NRT, 2008). These Quick Reference Guides are useful summaries of agent characteristics and advisories and are provided as national guidance. While acknowledging that site-specific clean-up decision criteria will be the result of multi-agency agreements and site-specific factors, the NRT considers that attainment of agent-specific air concentrations less than 8 h of AEGL-1 is an acceptable criterion for verification of site decontamination.

In general, agent concentrations less than AEGL 2 are considered to be in a range that poses relatively negligible health consequences for acute exposures.

Other AEGL applications performed or recommended include use as hazard assessment plume modeling criteria for the US Nonstockpile Chemical Material Program and Homeland Defense scenarios, as testing criteria for personal protective equipment intended for use by first responders in a single weapon-of-mass-destruction scenario, as detection performance goals for advanced equipment acquisition and development, and as a tool for assessing potential exposures during military missions such as peacekeeping (USACHPPM, 2008).

Estimated Oral Reference Doses

Development of nerve agent–specific reference dose estimates is critical to remediation and restoration at existing and closing military sites, which is a priority activity for DOD (Opresko et al., 1998, 2001).

A reference dose (RfD; mg/kg/day) was originally designed for estimating noncancer health risks at CERCLA (Comprehensive Environmental Response, Compensation, and Liability Act of 1980) Superfund sites (USEPA, 1989). As such, it is an essential component of the site risk assessment used to assess potential long-term exposures to contaminated media such as soil, where RfDs address the pathway of incidental ingestion of soil particles (USEPA, 1989; Dourson, 1994; Cicmanec et al., 1996; Abernathy et al., 2004).

Methods used to derive oral RfDs for nerve agents follow standard USEPA protocols (USEPA, 1989; Dourson, 1994), use appropriate toxicological data and uncertainty factors, and have undergone review for consistency by the National Research Council (Opresko et al., 1998, 2001; NRC, 1999; Bakshi et al., 2000). Because EPA has not officially verified the derived values for nerve agents, they are identified as estimated RfDs (RfDe) (Table 9.6).

These criteria are selected by the Office of the Army Surgeon General as the most appropriate oral toxicity reference values for use in environmental risk assessments and represent the Army's position (Opresko et al., 2001). The RfDe values have been input to USEPA risk models along with accepted chronic vapor exposure limits (as cited in Watson and Dolislager, 2007) to generate agent-specific Health Based Environmental Screening Levels (HBESLs). These HBESLs are endorsed by military policy as criteria to assess potentially contaminated soils (Table 9.6) (USACHPPM, 1999; OASA, 1999; Watson and Dolislager, 2007).

TREATMENT

Critical Role of Decontamination

Before discussion of antidotes and treatment regimens, it is noted that affected individuals should be removed from the site of agent exposure as quickly as possible, and undergo rapid decontamination to remove

TABLE 9.6 Estimated Reference Doses (RfDe), RfD Uncertainty Factors, and Health-Based Environmental Screening Levels for Nerve Agents

Nerve Agent	RfDe (mg/kg/day)	Composite Uncertainty	Residential Soil Preliminary Remediation Goal (mg/kg)	Industrial Soil Preliminary Remediation Goal (mg/kg)
VX	6E-7	100	0.042 (est.)	1.1 (est.)
GA	4E-5	3,000	2.8 (est.)	68.0 (est.)
GB	2E-5	3,000	1.3 (est.)	32.0 (est.)
GD	4E-6	3,000	0.22 (est.)	5.2 (est.)

potential for continued personal exposure and to prevent secondary exposure to responders, health care workers, medical transport vehicles, and treatment facilities (Sidell, 1997; Cannard, 2006; ATSDR, 2007; Okumura et al., 2007; Pulley and Jones, 2008). Decontamination of CW agents is discussed more fully by Gordon (2015) in Chapter 76 of this volume.

Signs and Symptoms Guiding Medical Management

Depending on concentration and duration of exposure, cases of nerve agent intoxication can exhibit a dose-dependent "constellation" of clinical signs and symptoms representing a variety of parasympathetic effects, functional change at NMJs, and altered CNS function (Cannard, 2006). As a consequence, critical care personnel and others responsible for developing and administering treatment protocols should take into account the totality of the case presentation. A good example is drawn from observations made by medical personnel treating subway passengers presenting at Tokyo area hospitals and clinics on day 1 of the sarin release incident. In decreasing order of frequency, the following clinical signs and symptoms were noted: miosis (observed in most patients), headache, dyspnea, nausea, vomiting, muscular weakness, cough, rhinorrhea, chest oppression, muscular fasciculations, and psychological disturbances such as anxiety (Lillibridge, 1995). Similar distributions were observed among subway passengers treated at St. Luke's International Hospital (Okumura et al., 1996, 2007) as well as residents affected in the Matsumoto incident of 1994 (Yanagisawa et al., 2006), and are consistent with classic descriptions of nerve agent intoxication (Sidell, 1997; Leikin et al., 2002; Cannard, 2006). Miosis was found to be a more responsive exposure index than RBC–ChE activity inhibition (Nozaki et al., 1997) or serum cholinesterase activity (Yanagisawa et al., 2006) in cases of sarin vapor exposure during the Tokyo and Matsumoto incidents, respectively (Okumura et al., 2015).

Yanagisawa et al. (2006) classified individuals exhibiting a pupil diameter larger than 3.0 mm as without miosis and not affected by nerve agent vapor exposure given that simultaneous serum ChE activity measurements taken during treatment of the Matsumoto cases displayed no inhibition (e.g., largely ≥100% of normal serum ChE activity with two cases exhibiting activity <90% of normal). This, and additional miosis data from Matsumoto, can be used in determining appropriate treatment for individuals without known or confirmed nerve agent vapor exposure (Cannard, 2006; Yanagisawa et al., 2006); for these individuals, examination, observation without treatment, and discharge are appropriate actions and were successfully implemented during medical responses to the Tokyo subway incident (Lillibridge, 1995; Okumura et al., 2015).

Nerve Agent Antidotes

The choice of appropriate treatment for nerve agent intoxication depends on the agent as well as extent and route(s) of exposure. Very mild exposure to nerve agent vapor may necessitate only decontamination and observation; severe exposure to vapor or liquid requires immediate decontamination, antidote administration, artificial respiration, monitoring, and supportive therapy over hours to multiple days (Sidell, 1997; ATSDR, 2007; Vale et al., 2007; Pulley and Jones, 2008). Convenient triage classifications have been developed by ATSDR (2007) in collaboration with the US Army Medical Research Institute of Chemical Defense.

In cases of massive inhalation exposure, immediate care is vital to prevent death from respiratory failure and because the agent–AChE complex becomes resistant to reactivation by oxime-type antidotes. "Aging" is compound-specific; aging half-times range from minutes (agent GD) to days (agent VX) (Sidell and Groff, 1974; Sidell, 1997). Standard antidotes clinically available in the United States are atropine (anticholinergic) and pralidoxime (Protopam or 2-PAM-Cl). In addition, CNS active drugs such as diazepam (Valium) are strongly recommended if convulsions occur; anticonvulsant treatment is critical for protection against lethality and brain pathology (Shih et al., 2003).

Individuals exposed to vapor and exhibiting miosis only or miosis and rhinorrhea only do not usually require antidote treatment and will resolve without medical intervention (Cannard, 2006; ATSDR, 2007), but they should be observed. If rhinorrhea is problematic in these vapor-only cases, then ATSDR (2007) advises intramuscular atropine (0.05 mg/kg pediatric; 2.0 mg adult) to relieve signs, followed by patient discharge. If eye pain/headache or nausea is problematic in vapor-only

TABLE 9.7 Recommended Antidote Protocol for Emergency Nerve Agent Exposure Therapy[a]

	Antidotes		
Patient Age	**Mild/Moderate Signs and Symptoms[b]**	**Severe Signs and Symptoms[c]**	**Other Treatment**
Infant (0–2 years)	Atropine: 0.05 mg/kg i.m. or 0.02 mg/kg i.v. 2-PAM-Cl: 15 mg/kg i.v. slowly	Atropine: 0.1 mg/kg i.m. or 0.02 mg/kg i.v. 2-PAM-Cl: 15 mg/kg i.v. slowly	Assisted ventilation as needed Repeat atropine (2 mg i.m. or 1 mg i.m. for infants) at 5–10 min intervals until secretions have diminished and breathing is comfortable or airway resistance has returned to near normal Phentolamine for 2-PAM induced hypertension (5 mg i.v. for adults; 1 mg i.v. for children) Diazepam for convulsions (0.2 to 0.5 mg i.v. for infants up to 5 years; 1 mg i.v. for children >5 years; 5 mg i.v. for adults)
Child (2–10 years)	Atropine: 1.0 mg i.m. 2-PAM-Cl: 15 mg/kg i.v. slowly	Atropine: 2.0 mg i.m. 2-PAM-Cl: 15 mg/kg i.v. slowly	
Adolescent (>10 years)	Atropine: 2.0 mg i.m. 2-PAM-Cl: 15 mg/kg i.v. slowly	Atropine: 4.0 mg i.m. 2-PAM-Cl: 15 mg/kg i.v. slowly	
Adult	Atropine: 2.0–4.0 mg i.m. 2-PAM-Cl: 15 mg/kg (1 g) i.v. slowly	Atropine: 6.0 mg i.m. 2-PAM-Cl: 15 mg/kg i.v. slowly	
Elderly, frail	Atropine: 1.0 mg i.m. 2-PAM-Cl: 5–10 mg/kg i.v. slowly	Atropine: 2.0 mg i.m. 2-PAM-Cl: 5–10 mg/kg i.v. slowly	

[a]*Contents reproduced from ATSDR (2007) (public domain).*
[b]*Mild/moderate signs and symptoms include localized sweating, muscle fasciculations, nausea, vomiting, weakness, dyspnea.*
[c]*Severe signs and symptoms include unconsciousness, convulsions, apnea, flaccid paralysis.*

cases, then ATSDR (2007) further advises administration of topical atropine or homatotropine to the eye for relief, eye protection from bright light, and discharge.

If liquid/droplet exposure is known or suspected in an individual exhibiting miosis only or miosis and rhinorrhea only, it is recommended that the individual receive no antidote treatment but be closely observed for at least 18 h, because toxic effects of liquid percutaneous exposure may not manifest for several hours (Sidell, 1997; Cannard, 2006). Toxic effects from vapor-only exposure usually occur quickly (within minutes) (Sidell, 1997). Current medical management guidelines and recommended medication protocols are summarized in ATSDR (2007), Vale et al. (2007), and Pulley and Jones (2008). The ATSDR antidote treatment protocol for civilian emergency management is summarized in Table 9.7. For additional information about antidotal treatment, readers are referred to Chapters 67, 68, and 71 of this volume.

Ongoing Antidote Development

Given that termination of seizure activity protects against development of neuropathological lesions (especially neuronal necrosis) in brain tissues of experimental animals (Martin et al., 1985; Shih et al., 2003; Marrs and Sellström, 2007), focus on anticonvulsant therapy is critical. Reduced potential for permanent brain damage in human cases by preventing or limiting the duration of status epilepticus is a primary goal. In challenge tests against multiple LD_{50} doses of agents GA, GB, GD, GF, VX, and VR in guinea pigs, the anticonvulsants midazolam and trihexyphenidyl were more effective than diazepam for seizure control, and midazolam was the most rapidly effective (Shih et al., 2003). The diazepam pro-drug avizafone is also effective (Lallement et al., 2000, 2004) and is available via auto-injector administration (as is diazepam). For more rapid seizure control during acute treatment phases, Marrs and Sellström (2007) recommend midazolam administered intramuscularly because of its more rapid intramuscular absorption.

Although pralidoxime is an effective and well-tolerated reactivator, it is not very potent. The search has thus continued for oximes that would combine high reactivator effectiveness against nerve agents with low toxicity and good chemical stability; several promising drugs (the oxime HI6; trimedoxime, or TMB-4; and obidoxime, or LüH-6) have emerged but are not equally effective against all agents and forms of exposure (Dawson, 1994; Marrs et al., 2006; Antonijevic and Stojiljkovic, 2007; Eyer and Worek, 2007; Wetherell et al., 2007; Kuca et al., 2009; Kassa and Kuca, 2010). Marrs et al. (2006) point out that, in the absence of pyridostigmine pretreatment, there are at present "no clinically important differences" between the standard oxime pralidoxime and the alternative oximes HI-6 and obidoxime in the treatment of nerve agent intoxication.

As a combinatorial drug with atropine, galantamine has been effective and safe in counteracting lethal GD and GB doses in the guinea pig (Albuquerque et al., 2006; Pereira et al., 2008); galantamine also protects against neurodegeneration at doses of LD50 or more in the guinea pig, and it shows promise as a pretreatment before GD or GB exposures.

Lethality was prevented by treatment with nasal atropine (atropine methyl nitrate), and postexposure treatment with atropine methyl bromide instillation, in combination with pulmonary therapeutic surfactants or liquevents in guinea pigs exposed to approximate LC_{50} concentrations of VX aerosol (Nambiar et al., 2007). This concept shows promise for operational application in emergency response.

Pretreatment When Exposure Is Likely

In certain military deployment settings when threat of nerve agent exposure exists, pretreatment with an anticholinesterase carbamate compound has been fielded to protect personnel. The pretreatment carbamate of current choice, pyridostigmine bromide (PB), reversibly sequesters (and thereby protects) a fraction of AChE from bonding with circulating nerve agents; the carbamate moiety spontaneously hydrolyzes from the AChE molecule within hours and allows AChE to again become available for normal physiological function. Such a pretreatment concept and drug enhances the effectiveness of atropine and oximes in treating lethal doses of GA, GB, and VX (Gall, 1981; Inns and Leadbeater, 1983). US combat units already supplied with atropine and pralidoxime have been equipped with 30 mg PB tablets for oral administration every 8 h; the current maximum pretreatment period is 21 days (Sidell, 1997; Scott, 2007).

A related carbamate, physostigmine, has been shown to protect animals against not only nerve agent lethality but also incapacitation (Leadbeater et al., 1985). When co-administered with hyoscine, physostigmine effectively reduced incapacitation and prevented death in guinea pigs exposed to agent GD (Wetherell, 1994), and prevents lethality and reduced/prevented incapacitation in guinea pigs exposed to GA, GB, GD, GF, and VX (Wetherell et al., 2002). Transdermal patch administration of physostigmine and hyoscine, or physostigmine alone, in the guinea pig has protected against GD intoxication (Meshulam et al., 1995).

Other developmental pretreatment options include NMDA receptor antagonist memantine in combination with atropine sulfate (Gupta and Dettbarn, 1992; McLean et al., 1992), pre-exposure loading with an excess of circulating ChE or BuChE (Bajgar et al., 2007; Lenz et al., 2008; Podoly et al., 2008; Saxena et al., 2008; Van der Schans et al., 2008; Masson, 2015), or CarbEs (Maxwell et al., 1987) to bind nerve agent before the agent can reach tissue AChE sites.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

A good deal of nerve agent toxicity research performed and published since the mid 1990s has served to bring a more widespread awareness of the knowledge that detectable (either by means of devices or manifestation of signs) low-level nerve agent exposures under a variety of scenarios are both sublethal and also potentially without significant long-term adverse health impact. Although such points are also inherent in the development of LD_{50}s and related values, much of the original focus of nerve agent toxicological work was, not surprisingly, on lethal or severe toxicological endpoints. To the extent that it adds detail and rigor to the estimation of exposure levels for nonlethal effects as well as insightful information on specifics of the mechanisms of nerve agent action, the more recent research has been highly useful in validating past conclusions on the subject. These recent data also further direct attention toward responsible consideration of the consequences for transient presence of residual, low-level agent concentrations in a number of scenarios. Having a transparent, robust, and strongly data-based framework within which to evaluate likely consequences of potential low-level nerve agent exposures, will greatly aid in planning and evaluating response operations, and reducing the magnitude of disruption to affected communities and facilities.

It is hoped that additional species and agents will be evaluated under comparable experimental protocols for the endpoints of miosis and lethality, as well as for more intermediate toxicological endpoints.

Standard treatment and pretreatment guidance is also summarized, as well as consideration of novel antidote development and promising approaches. Additional clinical trials will assist in developing protocols and practices for expanding available treatment options. Fielding of improved seizure management drugs and protocols should be expedited. The detoxification potential of CarbEs is multi-faceted and is an area that would benefit from further characterization.

Acknowledgments

Analysis contained in this evaluation was originally prepared for two agencies of the US Department of the Army: the US Army Center for Health Promotion and Preventive Medicine under Interagency Agreement 2207-M135-A1, and the US Army Environmental Command under Interagency Agreement 2134-K006-A1. The Oak Ridge National Laboratory (ORNL) is managed and operated by UT-Battelle, LLC, for the US Department of Energy under contract DE-AC05-00OR22725.

The critical advice of our colleagues Dana Glass and Robert Ross (Leader, Toxicology and Hazard Assessment Team, Environmental Sciences Division, ORNL) in the preparation of this chapter is thankfully acknowledged.

The views expressed in this chapter do not necessarily represent official Federal agency position or policy. Mention of trade names or commercial products does not constitute endorsement or recommendation of use.

Russian VX

Vladimir Rembovskiy, Andrey Radilov, Elena Savelieva, Sergey Kuznetsov, Igor Mindukshev, Daria Prokofieva, Nadezhda Krivorotova, Natalia Khlebnikova, Richard Jenkins and Nikolay Goncharov

INTRODUCTION AND BACKGROUND

One of the most abundant and most toxic agents in the chemical arsenals of the United States and Russia is VX and Russian VX (RVX), respectively, whose development in the middle of the twentieth century indicated the peak of warfare chemistry. V-gases are low-volatile liquids with high boiling points, so they are much more persistent than the higher-volatility organophosphorus nerve agents, such as sarin or soman. V-series compounds are more toxic that other organophosphates (OPs). For example, in comparison with sarin (GB), VX is estimated to be approximately twice as toxic by inhalation, 10 times as toxic by oral administration, and approximately 170 times as toxic by skin exposure (Munro et al., 1994). V-series nerve agents are quite effective when exposed through skin contact (especially as tiny drops) and commonly cause death. Poisoning occurs regardless of exposure method (specifically inhalation, ingestion of vaporous and liquid agents through intact or injured skin or eye mucosa, and contact with contaminated surfaces).

The name *VX* relates to a group of *O,S*-diesters of methylphosphonic acid $ROPO(CH_3)S(CH_2)_2N(R1)_2$. *O*-isobutyl *S*-2-(diethylamino)ethyl methylphosphonothioate (R = *i*Bu, R1 = Et), produced since 1972 exclusively in the former Soviet Union, was generally referred to as *RVX* (CAS #159939-87-4). The synonyms for this substance are as follows:

- VR
- VA
- Phosphonothioic acid methyl-, *S*-[2-(diethylamino) ethyl] *O*-(2-methylpropyl) ester
- *O*-isobutyl *S*-2-(diethylamino)ethyl methylthiophosphonate
- *O*-isobutyl *S*-(*N,N*-diethylaminoethyl) methylphosphonothioate
- Russian V-gas

The brutto formula of RVX is $C_{11}H_{26}SNPO_2$ (MW 276.37). The structural formula of RVX is presented in Figure 10.1.

RVX is a colorless transparent liquid resembling glycerol in mobility, with a boiling point of 300.0°C, melting point of 35.0°C, ρ^{20} of 1.0083 g/cm^3, and volatility of C_{max}^{20} 0.0105 mg/dm^3. The agent is poorly soluble in water (less than 5% at 20°C) and highly soluble in organic solvents. Technical products can be colored from yellow to dark brown and smell like fried sunflower seeds.

Research into the environmental behavior of highly toxic chemicals is an important branch of analytical toxicology. We take the word *behavior* to mean the persistence, mechanisms of possible transformation, composition of such transformation products, and toxicity of these substances. Among known toxicants, V-series compounds tend to undergo perhaps the most varied transformations due to their unique structure. Possessing both high reactivity and polyfunctionality, these compounds incorporated into multicomponent matrices are capable of concurrently reacting with several components. Therewith, the reactions may involve different active centers within the same molecule. The routes and results of such reactions cannot be predicted in advance. The situation is even more complicated by the fact that active components of a natural or technogenic matrix are not always known. In view of this, research aimed at identifying transformation products of

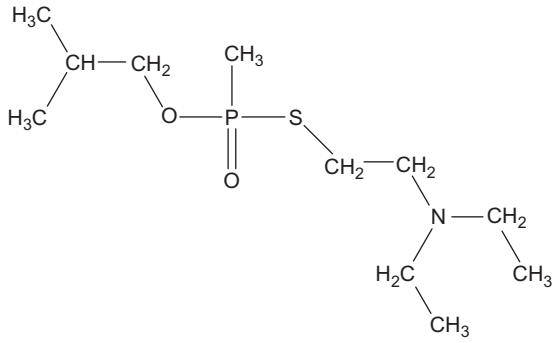

FIGURE 10.1 Structural formula of Russian VX.

VX in various media are of particular importance. The degradation of such compounds is suggested to be initiated by electron addition to phosphorus *via* reaction with anionic nucleophiles (Yang, 1999), such as hydroxide ion, water, alcohols, amines, or unsaturated organic compounds. The problem of determination of RVX in complex matrices and identification of RVX transformation products is still more complicated by the scarcity of available reference information.

Cholinesterases (ChEs) are well-known targets for OPs, and RVX is no exception. Much less information is available about other enzymes that could be primary targets upon exposure to low doses of OP, and on biochemical markers of possible delayed effects of OP intoxication when the level of ChE activities is the same as the control. However, this problem is very important for various reasons, among which is fulfillment of chemical warfare agents (CWAs) nonproliferation conventional programs, and the inherent possibility of accidental exposure of personnel to RVX, as well as the chronic effects of subsymptomatic concentrations of RVX that could arise from the stockpiles of chemical agents. Among other reasons, the terrorist threat is a well-recognized reason for concern.

MONITORING OF RVX

A group of measures for assessing levels of toxic chemicals in the environment is called *ambient monitoring*. The possible objects of ambient monitoring are air, water, soil, food, wastes, building materials, and other media through which toxicity factors can be delivered to the human organism. Biomonitoring is based on sampling and analysis of body fluids and tissues and is an indicator of internal dose that provides a measurement of exposure to a toxic chemical. It is quite understandable that toxicological studies are mainly focused on biomonitoring rather than on the levels of toxic compounds in environmental media. At the same time, ambient monitoring is the only tool for revealing sources of toxic pollutants affecting an organism.

Ambient Monitoring and Environmental Persistence of RVX

The composition of VX degradation products and admixtures has been studied in detail by hybrid chromatography–mass spectrometry (MS) methods. The objects of admixture studies were the contents of containers in which VX had been stored for a long time. Dozens of admixtures and stabilizers could be identified. There has been much work on the identification of admixtures in VX and its degradation products. A systematic review of VX transformation products is presented by Munro et al. (1999), but there are no such systematic data for RVX. The degradation of RVX in various media always produces complex mixtures of products that commonly contain dozens of both volatile and nonvolatile organic compounds. The prevalent volatile products are phosphorus-free alkyl diethylaminoethyl monosulfides and polysulfides. The electron impact (EI) mass spectra of these compounds are quite similar to each other and most commonly contain a single strong peak at *m/z* 86, formed by the $[(Et)_2NCH_2]^+$ ion. Among phosphorus-containing products, methylphosphonic acid (MPA) and its monoisobutyl and diisobutyl esters (iBuMPA and iBu_2MPA) are almost always detected in certain quantities. These compounds are also present as admixtures in technical RVX samples in varied amounts (from tenths of a percent to several percent). The P–S bond cleavage in RVX forms diethylaminoethanethiol and iBuMPA. The latter slowly hydrolyzes to form MPA. Conditions favoring P–O bond cleavage to form the highly toxic *S*-2-(diethylamino)ethyl methylphosphonothioic acid are unknown.

The most hazardous known VX hydrolysis products are persistent bis[2-(diisopropylamino)ethyl] disulfide, and highly toxic and persistent *S*-[2-(diisopropylamino) ethyl] methylphosphonothioate. The decomposition of RVX gives rise to structural analogs of the above products: bis[2-(diethylamino)ethyl] disulfide and *S*-[2-(diethylamino)ethyl] methylphosphonothioate. The latter is commonly called *monothiol*. Systematic data on the behavior of these products in the environment, as well as on their acute and chronic toxicity to humans and mammals and ecotoxicity, are lacking. Components of the complex mixture of RXV decomposition products present as low-informative EI mass spectra; therefore, these compounds are hardly possible to identify solely on the basis of mass spectral data. Chemical-ionization (CI) mass spectra are much more characteristic, but CI mass spectra—in view of their irreproducibility and lack of databases—are of limited use for identification. Like VX, RVX does not possess a strong electron-acceptor center favoring decomposition but still is not a complete analog of VX in this respect. In dilute aqueous solutions, RVX proved to be much more persistent: a half-life of 12.4 days as

opposed to 4.8 days for VX (Crenshaw et al., 2001). The mechanism of the neutralization of VX and RVX with an equimolar amount of water was first described by Yang et al. (1996). It was found that autocatalytic hydrolysis is possible exclusively in V-series nerve agents since it should involve the protonated amino group.

We performed experimental research on the stability assessment of RVX and identification of its transformation products under the action of equimolar or excess amounts of water. The method for analysis was gas chromatography–electron impact mass spectrometry (GC-EIMS). In a dilute aqueous solution (10 mg/mL) in the presence of 5% phosphoric acid, the concentration of RVX after exposure for 20 days at room temperature without stirring was 2.7 mg/mL, or 27% of the initial amount. Since among RVX hydrolysis products both volatile and nonvolatile compounds could be expected, we chose three schemes for sample preparation: (i) evaporation to dryness followed by silylation; (ii) organic solvent extraction; and (iii) silylation of the extract obtained by procedure (ii).

Table 10.1 lists the principal products of RVX hydrolysis with excess water in an acid medium, with specified analytical fractions with the highest contents of each compound. It should be noted that even after 100-day exposure, we could detect 1% of the initial amount of RVX in the solution, which implied a fairly uniform hydrolytic degradation.

Experiments on RVX hydrolysis with an equimolar amount of water were performed as follows. A mixture of 74 μL of RVX and 5.6 μL of water was exposed at room temperature for 3.5 months without stirring. An ash-gray thick uniform material formed after hydrolysis and completely dissolved in 5 mL of acetonitrile. The solution was diluted 100 times with acetonitrile and analyzed by GC-EIMS (sample D). An aliquot of this sample was mixed with an equal volume of bis-trimethylsilyltrifluoroacetamide (BSTFA), and the mixture was heated at 70°C for 30 min and then analyzed by GC-EIMS (sample E). The autocatalytic hydrolysis of RVX was almost complete by the end of the experiment, since the RVX content in the sample was no more than 0.01%. Qualitatively, the reaction mixture in the latter case was much poorer than in the hydrolysis with excess water. Among the volatile hydrolysis products, the following were detected by GC-EIMS in sample D: 2-(diethylamino)ethanethiol (4%), diisobutyl methylphosphonate (2%), bis[2-(diethylamino)ethyl] sulfide (2%), RVX (<0.01%), and bis[2-(diethylamino)ethyl] disulfide (80%). Of nonvolatile products in sample E, MPA (3%) and isobutyl ester of MPA (isobutyl MPA) (96%) were identified as trimethylsilyl ester. Isobutyl MPA, which catalyzes RVX degradation, was detected as the major components of the reaction mixture. As the second most abundant component we expected 2-(diethylamino)ethanethiol, according to Yang et al. (1996), but we found instead that it almost completely converted into bis[2-(diethylamino)ethyl] disulfide. This result seems feasible since once the autocatalytic degradation of RVX was complete, nothing would prevent thiol from being converted into disulfide. In a dilute aqueous solution of RVX, this conversion occurs less rapidly, and even after 100 days, the solution contains much less 2-(diethylamino) ethanethiol than bis(2-diethylaminoethyl) disulfide.

The Chemical Weapons Convention requires signatory states to completely destroy not only their

stockpiled chemical weapons (CWs), but also the corresponding industrial facilities, including buildings and other constructions. Toxicity and hazard assessment of demolition wastes of former VX production facilities is quite a challenging problem in view of the high absorption capacity of building materials for VX-series agents. Whether V-series agents are possible to detect in one or another material is difficult to predict because of the paucity of data on their persistence in various media. An ion-trap secondary ionization MS study showed that VX undergoes complete degradation when in contact with concrete surfaces (Groenewold et al., 2002). The process follows first- or pseudo-first-order kinetics, and the half-life of VX is about 3 h. The affinities and persistence of VX in certain materials were studied by Love et al. (2004). The test materials included powdered activated charcoal, as well as natural iron and aluminum oxyhydroxide minerals: goethite (yellow ochre) and montmorillonite (clay), respectively. It was shown that VX has a high affinity for charcoal, a moderate affinity for montmorillonite, and a very low affinity for goethite. The adsorption on goethite was increased in the presence of dissolved organic matter. VX degraded rapidly on a dry goethite than in the presence of water. We performed experiments with RVX applied on the soil, concrete, bricks, and a polymeric material (polyisobutylene used in hydroinsulation) at concentration ranges of 10^{-6}–10^{-5} mg/kg, which corresponded to the tentative maximum allowable concentrations accepted in the Russian Federation. Conditions for the effective extraction of RVX could not be found for any of the materials tested. The extremely low recoveries of RVX from materials of various natures can be explained by both irreversible sorption and degradation. The problem of simulating the behavior of V-series nerve agents, including RVX, in various materials is complicated by the fact that such factors as the presence of water, organic compounds, or both strongly affect both RVX sorption and degradation kinetics. In any case, in alkaline materials (concrete, cement, plaster, or lime), RVX undergoes fast degradation, especially in the presence of water, whereas in organic hydrophobic media (polymers, lubricants), it can persist for a long time.

During the operation of an RVX production or destruction facility, its inner surfaces might have been treated with various reagents, and therefore it is quite difficult to predict the transformation routes and degradation products of the toxic agent. These products may include previously unknown toxic compounds. We faced problems in assessing the toxicity and hazard of samples (specifically wall and ceiling fragments) from a former RVX production facility (Radilov et al., 2007). This research was required for developing technical regulations for demolition of the facility. Table 10.2 lists compounds isolated from the sample building materials, taken in working areas of the former RVX production facility, which might have contacted RVX. Aqueous and organic extracts of the samples were prepared according to the Organization for the Prohibition of Chemical Weapons recommended operational procedures (Rautio, 1994). Analysis was performed via GC-MS in the EI and positive chemical ionization (reactant gas methane) modes. According to the procedures, aliquots of all extracts were subjected to BSTFA silylation and diazomethane methylation.

Along with RVX transformation products, the samples contained more than 100 organic compounds that are matrix components of building materials, solvents, plasticizers, reaction products of degassing agents with matrix components, among other materials. In brick and concrete samples, we detected in high concentrations (up to 10 g/kg) so-called fyrols (components of foam fire-extinguishing compositions). In terms of chemical composition, fyrols are mixtures of tris(dibromoalkyl) phosphates with phosphoric acid. Among the RVX transformation products in Table 10.2, components with RI 1,685, 1,888, and 2,241 were relatively abundant (up to 5 mg/kg) and were assigned two almost equally probable structures (which appear in bold in the table). Such products could not be expected in advance; as a result, they were not detected by target analysis. However, their detection can be considered as evidence that the samples in hand were contaminated with RVX in the past.

Environmental monitoring of RVX chemical weapon storage and destruction facilities (CWDFs) is carried out by sanitary regulation units, and development of highly sensitive and productive biochemical analytical express methods for such monitoring is of great significance for governmental bodies. An alkali-peroxide formulation is applied at CWDF as a basic degassing solution for decontamination of RVX. In our first study on determination of warfare nerve agents with microplate biochemical methods, we showed that hydrogen peroxide at concentrations in the micromolar range substantially distorted results obtained with the Ellman method. For the Hestrin method, the IC_{50} for hydrogen peroxide was shown to be about 2.5 orders of magnitude higher than that found via the Ellman method, so the former method was considered more specific for quantitative determination of OPs in the samples containing hydrogen peroxide (Prokofieva et al., 2010). In our next study, to quantitatively determine RVX in aqueous solutions for the purposes of environmental monitoring at places of storage or destruction of CWs, we developed new microplate versions of the Ellman and the Hestrin methods in order to avoid interferences from admixtures that could otherwise give rise to false results (Prokofieva et al., 2012). The linear range of the Hestrin method (74.8–1,120 pM) was 3.1-fold wider than that of the Ellman method (37.4–374 pM). Limits of detection

TABLE 10.2 RVX-Related Organic Compounds Identified in Samples of Building Materials (Radilov et al., 2007)

RT (min)	Compound	Structural Formula, Molecular Weight (MW)	RI
4.19	Triethylamine	 MW 101	
7.35	Diethyl disulfide	 MW 122	929

23.20	*O,O*-Diisobutyl *S*-[(3-isobutylsulfanyl)propyl] phosphorodithioate or *O,S*-Diisobutyl *S*-[(3-isobutylsulfanyl)propyl] phosphorodithioate	 or  MW 372	2,241

and quantification of RVX for both methods were below the maximal allowable concentration of RVX in water-soluble washouts. One of the early products of RVX hydrolysis, *N*,*N*-diethylaminoethanethiol, caused false negative results via the Ellman method at >10 μM; individual blanks were necessary to eliminate these effects. The Hestrin method showed greater specificity (about 3 orders of magnitude) for analysis of samples containing mercaptans. Thus, the principal merit of the Hestrin-based approach is that potentially dangerous false negative results can be avoided. A new biochemical procedure of RVX determination at technological surfaces were certified and introduced to the Federal Register of measurement procedures.

TABLE 10.3 Characteristics of the Procedures for Determination of *O*-isobutyl MPA as a Marker of Exposure to RVX, in Urine and Blood Plasma

Method	Detection Limit (ng/mL)	Matrix	Total Analysis Time per Sample (h)
GC-MS	10	Plasma	10
SPME-GC-MS	5	Urine	1.5
GC-MS-MS	1	Plasma	10
HPLC-MS	1.0	Plasma	1.5
HPLC-MS-MS	0.8	Plasma	1.5

Biomonitoring and Toxicokinetics of RVX

GC-MS and HPLC-MS Analyses of RVX Metabolites

Identification and quantitative assessment of toxic chemicals and their metabolites in biomedical samples can be performed by the following methods: (i) establishment of the fact and factor of exposure of humans and animals to chemical accidents; (ii) clinical diagnosis of poisoning; (iii) forensic expertise; and (iv) biomonitoring of people that deal with highly toxic chemicals. RVX, like other highly toxic readily metabolizing chemicals, is difficult to detect in body fluids and tissues even for very short periods after exposure. Successful identification and quantitative assessment of the toxicity factor in biomedical samples is possible under the following conditions (Savelieva et al., 2003):

- Right choice of biological matrix (the object for analysis)
- Right choice of a biomarker pertinent to the level and nature of exposure
- Measurable biochemical or physiological effect
- Availability of a reliable and sufficiently selective and sensitive analytical procedure
- Availability of reference compounds and criteria for correct data interpretation.

Analytical procedures applied to diagnosis and retrospective verification of exposure to OP include (Worek et al., 2005): (i) biochemical determination of ChE activity; (ii) identification of unbound OP; (iii) identification of decomposition products; (iv) fluoride-induced reactivation of inhibited ChE, followed by analysis of the inhibitor; and (v) analysis of phosphyl-protein-adducts after tryptic digestion of the protein. The last procedure is regarded to be the most specific and sensitive, but it has the drawback of being strongly dependent on the analysis of butyrylcholinesterase (BChE), the most abundant plasma serine esterase with a half-life of about 16 days.

It is well known that hydrolysis is the major metabolism pathway of G-series agents (Beck and Hadad, 2008). The enzymatic hydrolysis of these agents primarily involves phosphorylyl phosphatases and produces *O*-alkyl methylphosphonic acids (*O*-alkyl MPA). V-series agents (VX, RVX) are not typical substrates for phosphorylyl phosphatases, which probably explains the higher persistence of these agents in the organism. Free *O*-alkyl MPAs formed by hydrolysis of OP agents can be detected in body fluids and tissues and are used as markers of exposure to these agents. The final hydrolysis product is MPA, but its fraction is smaller compared to *O*-alkyl MPA. The low-molecular RVX hydrolysis products are actively excreted within the first few days after intoxication and can serve as suitable targets for retrospective analysis for no longer than 2–3 weeks. However, 2–3 days after exposure, the body levels of *O*-alkyl MPA and MPA become much more demanding in terms of detection sensitivity. We have developed a series of procedures for identification and quantitative assessment of *O*-isobutyl MPA as a marker of exposure to RVX in urine and blood plasma. Characteristics of the procedures are presented in Table 10.3.

The GC-MS procedure involves sample deproteinization, purification, evaporation to dryness, *tert*-butyldimethylsilylation of redissolved dry residue, and GC-EIMS analysis in the Selective Ion Monitoring (SIM) mode. The solid-phase microextraction (SPME)-GC-MS procedure involves extraction of *O*-alkyl MPA from urine on the microfiber, their *tert*-butyldimethylsilylation directly on the microfiber, and thermodesoption of the resulting derivatives in a GC injector. SPME of *O*-alkyl MPA on microfiber is an effective approach for urine since it allows one to avoid the stage of sample desalination associated with the inevitable losses of target compounds. However, SPME is much less effective with plasma because of its high protein content. The high-performance liquid chromatography with mass spectrometry (HPLC-MS) procedure involves sample centrifuging, solid-phase extraction on Diapak C16M

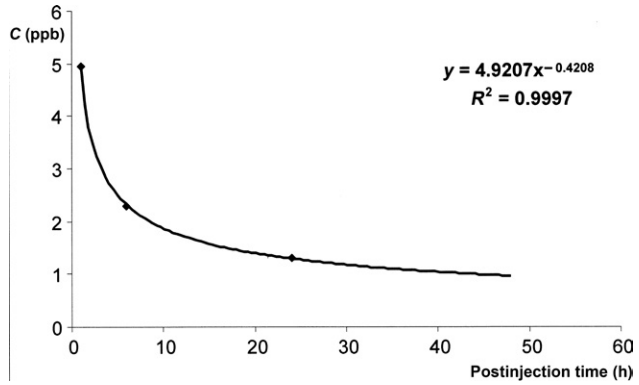

FIGURE 10.2 Concentration of *O*-isobutyl MPA in blood plasma versus time after intramuscular injection of RVX in rats at a dose of 0.8 LD_{50}

cartridges, elution with an acidic (pH 3.0–4.0) methanol, evaporation and redissolution of the eluate, and HPLC-MS analysis in the chemical ionization mode at atmospheric pressure with registration of negative ions (Rodin et al., 2007). The latter procedure has been used in toxicokinetic experiments for measuring the concentration of *O*-alkyl MPA in rat plasma 1, 6, 24, and 48 h after intramuscular (i.m.) injection of OP agents at a dose of 0.8 LD_{50} (0.0144 mg/kg). The toxicokinetic curve for *O*-isobutyl MPA is presented in Figure 10.2.

The HPLC-MS (quadrupole analyzer) and HPLC-MS-MS (medium-class ion-trap analyzer) procedures for the determination of OP metabolites in blood plasma were found to be comparable in terms of sensitivity, accuracy, and performance, but HPLC-MS is preferred in terms of the availability and cost of equipment and maintenance.

MS/MS Analysis of Human Albumin

Albumin has been demonstrated to be an OP hydrolase (Sogorb et al., 1998). Bovine albumin binds diisopropylfluorophosphate (DFP) in equimolar proportions (Murachi, 1963), and binding of DFP to Tyr was shown simultaneously (Sanger, 1963). MS identified the active site to be Tyr410 for bovine albumin and Tyr411 for human albumin (Schopfer et al., 2005; Li et al., 2007). A characteristic feature of this Tyr is a low pK_a (near 8), in contrast to pK_a values of almost 10 for other tyrosines (Means and Wu, 1979), which is believed to be due to a pocket with nearby basic residues of Arg410 and Lys414 in human albumin (Sugio et al., 1999; Li et al., 2007). Various warfare agents were shown to readily bind to Tyr411, though VX needs more time and a higher concentration for this chemical binding, which is explained by a lower potential of the $SCH_2CH_2N(iPr)_2$ substituent in VX to leave in a noncatalyzed reaction, as compared with F^- or CN^- (Williams et al., 2007).

In order to determine the specificity of RVX binding with albumin, we first obtained a mass spectrum of human albumin after *in vitro* incubation of blood serum with RVX, and the shift in the spectrum of about 400 Da suggested at least two sites of RVX binding to albumin (Radilov et al., 2009). To locate the binding sites, we incubated RVX with commercially available human albumin (Sigma), and then digested it with trypsin to obtain MS/MS peptide spectra. Two sites of binding RVX to human albumin were revealed, one of them being the well-known Tyr411 and the second site being an unexpected Tyr150. Taking into consideration that 144–160 amino acids in human albumin are RRHPYFYAPELFFAKR (http://myhits.isb-sib.ch/cgi-bin/motif_scan), we suggest that Tyr150 could be activated by positively charged RRH and KR, which could serve to lower its pK_a.

Up to recently, studies of V-agents degradation in *in vivo* or even *in vitro* experiments (under conditions maximally approximated to those *in vivo*) were quite problematic because of methodological and technical difficulties: there were no analytical equipment with sufficient sensitivity for assessment and quantitative analysis of metabolic transformations of these OPs in complex protein mixtures. There is only one study (Tsuchihashi et al., 1998) on identification of VX metabolites in blood serum of a human victim, where metabolic pathways of VX degradation were designated. The analysis of blood serum revealed ethyl methylphosphonic acid (EMPA), as well as methyl thioether of 2-(diisopropylamino) ethanethiol, in contrast to thiol alone, which was not revealed because of its high reactivity. There is evidence to suggest that thiols in human organism are rapidly methylated via thiol *S*-methyltransferase (Weisinger and Jakoby, 1980), leading Tsuchihashi et al. (1998) to conclude that VX is hydrolyzed to produce EMPA and thiol, which was then methylated by the enzyme. However, the pH of human blood and intercellular and intracellular fluids are within a narrow span of 7.2–7.4. Therefore, one can suppose that hydrolysis of V-agents could proceed not only by breaking the P–S bond, but also by breaking the P–O bond. Indeed, the formation of EA-2192 was shown first, both in *in vivo* and *in vitro* experiments, by Reiter et al. (2011).

In the human or animal body, nerve agents are rapidly bound with their targets, so analysis of blood samples for presence of the intact agents is possible soon after poisoning with rather high doses. A more helpful approach can be the analysis of biological samples for presence of alkyl methylphosphonic acids (AMPAs), which are the major products of nerve agent hydrolysis (Noort et al., 2002; Riches et al., 2005). Besides AMPA, the long-living biochemical markers are considered to be covalent adducts of nerve agents with blood proteins (Riches et al., 2005). In this case, the half-life of the marker depends not only on the quantity of a nerve

agent entering the organism, but also on metabolic stability of the adduct and the lifetime of the protein (Noort et al., 2002).

All the adducts of nerve agents with proteins that can be revealed presently are derivatives of a corresponding AMPA and serine and/or tyrosine amino acids (Bao et al., 2012; Read et al., 2010). In the case of G-agents, these adducts are the only ones to be formed. In contrast, V-agents are broken up so that two parts with similar molecular weights are produced, such as AMPA and the corresponding thiol. Therefore, in the case of intoxication with RVX, one should seek not only adducts of isoBMPA with serine and tyrosine residues, but also adducts of *N*,*N*-diethyl-2-aminoethanethiol (hereinafter referred to as *thiol*) with cysteine residues. From the point of view of its diagnostic value, the adduct of thiol with cysteine would be less specific than adducts of isoBMPA and tyrosine residue of albumin or serine residue of ChEs, but its sensitivity should be much higher than these adducts due to high reactivity of the thiol.

A molecule of albumin has several disulfide bonds and also one reduced cysteine residue, Cys34. It is well known that most thiol groups present in blood plasma belong to Cys34 of albumin (Ogasawara et al., 2007; Oettl and Stauber, 2007). That is why in order to obtain *in vitro* preparation of covalent adducts of proteins with RVX, we have mixed RVX solutions not only with undiluted blood serum and ethylenediaminetetraacetic acid (EDTA)–plasma, obtained from two outbreed male rats and nine healthy human volunteers, but also with human and rat serum albumins (HSA and RSA, respectively, in amounts of 50 mg/mL). Samples of human plasma/serum were pooled, and albumin solutions were prepared in 10 mM phosphate buffer saline (PBS) and pH 7.2, containing 137 mM NaCl and 2.7 mM KCl. The final concentrations of RVX in the samples were 37 nM, 0.37 μM, 3.7 μM, and 37 μM. The samples were incubated at 37°C for 24 h and then hydrolyzed by pronase according to Read et al. (2010). Solutions of RVX served as control samples, with PBS as the blank sample. HPLC-MS/MS analysis was carried out on a Thermo Scientific LTQ Orbitrap Velos mass spectrometer coupled with an Accela 1250 LC system and an autosampler. Data were acquired and processed using Xcalibur software. Chromatographic separation was carried out on a Hypersil Gold C18 column (150 mm × 4.6 mm i.d., particle size 1.8 μm): mobile phase, 0.05% trifluoroacetic acid (TFA) in water (A) and 0.05% TFA in acetonitrile (B); flow rate 400 μL/min; gradient elution conditions, 55% B (0–1.5 min), 5–90% B (1.5–10.0 min), 90% B (10–30 min), 5% B (30.01–35.0 min); injection volume 10 μL. The MS conditions were as follows: heated electrospray ionization (HESI-II) probe, positive ionization mode, spray voltage 3 kV, ion transfer tube (capillary) temperature 400°C, and sheath gas and auxiliary gas flow rates of 50 and 17 arbitrary units, respectively. Transitions were monitored at the collision energy 18 eV.

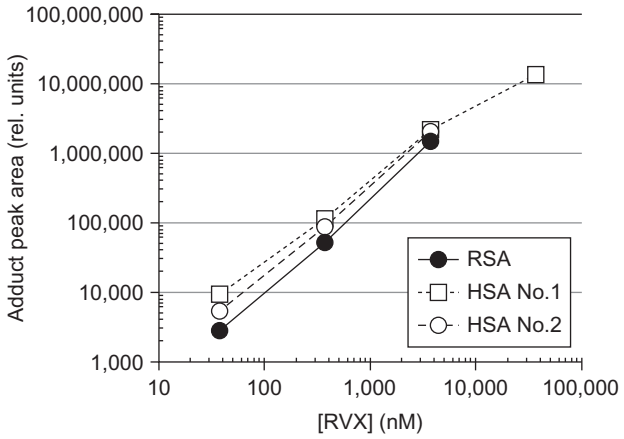

FIGURE 10.3 Relationship between thiol–cysteine adduct formation and amount of RVX introduced into albumin solution. Logarithmic coordinates.

Analysis for detection and quantification of the adduct was preceded by *in situ* synthesis of an RVX adduct with cysteine. To this end, we incubated a mixture of RVX with L-cysteine in PBS at 37°C for 24 h in molar ratios of about 10:1 and then analyzed the resulting mixture by HPLC-MS/MS. Along with RVX and L-cysteine spikes, a new strong peak at 4.4 min was detected in the reconstructed mass chromatograms of the reaction mixtures at the exact mass corresponding to a protonated molecular ion of the thiol–cysteine adduct: *m/z* 253.10161 ($[(C_2H_5)_2NCH_2CH_2S\text{-}SCH_2CH(NH_2)COOH^+H]^+$; theoretical mass 253.10389). The structure was confirmed by the primary transition *m/z* 253.10161→*m/z* 132.08307 ($((C_2H_5)_2NCH_2CH_2S^+$; theoretical mass 132.08469) and secondary transition *m/z* 132.08307→*m/z* 86.09697 ($[(C_2H_5)_2NCH_2]^+$; theoretical mass 86.096974) (not shown in this chapter).

Then we detected the thiol–cysteine adduct in the samples obtained after joint incubation of HSA and RSA (50 mg/mL) and RVX for 24 h, followed by pronase hydrolysis. The data reflecting the ability of these albumins to bind RVX are given in Figure 10.3. As seen, both RSA and HSA cysteine residues showed a similar ability to form adducts with RVX. Taking HSA as an example, we analyzed two different samples (HSA №1, HSA №2) at two different times and obtained good reproducibility of results. Figure 10.4 shows data on thiol adduct formation with cysteine residues of blood plasma or serum proteins, obtained after their reaction with different quantities of RVX. We observed a linear correlation between the initial concentration of RVX and the amount of the thiol–cysteine adduct. In contrast to albumin solutions, a greater spread of data was obtained for different concentrations of RVX. Moreover, there was

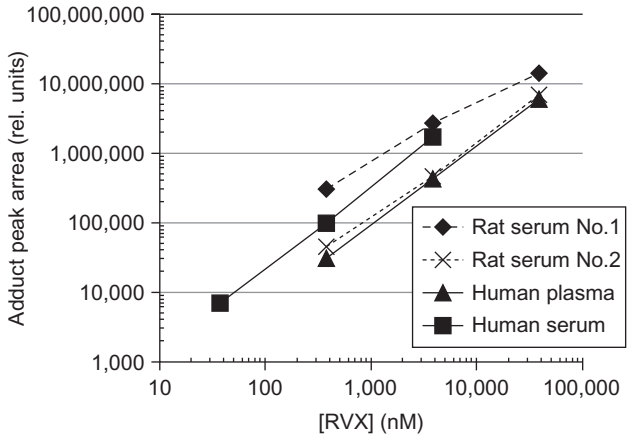

FIGURE 10.4 Relationship between the adduct formed and the amount of RVX introduced into serum/plasma. Logarithmic coordinates.

a considerable variability in the abilities of sera obtained from different animals (rats 1 and 2 in Figure 10.4) to form thiol adducts. The peak areas of the thiol–cysteine adduct differ from each other by an order of magnitude relative units, which could be attributed to different redox status of the animals' serum samples.

Thus, we have revealed a new thiol–cysteine adduct, produced by interaction of plasma/serum proteins with RVX *in vitro*. We have also shown that cysteine of serum albumin plays the major role in this formation. However, there is a need for further increase of sensitivity for the sake of solid-phase microextraction, which makes it possible to concentrate the sample before HPLC-MS/MS analysis. Presently, the sensitivity of the method is not high enough to reveal the adduct in rat serum samples two days after the sublethal poisoning with RVX.

MECHANISMS OF ACTION AND PRINCIPLES OF THERAPY

Three types of damages induced by OPs have been identified: acute poisoning, the so-called intermediate syndrome (IS), and OP-induced delayed polyneuropathy (OPIDP) (Ray, 1998). The IS symptoms and signs usually occur after apparent recovery from the acute cholinergic syndrome, but before OPIDP develops (Karalliedde et al., 2006). OPIDP also occurs almost exclusively in patients with preceding acute cholinergic toxicity related to severe acute exposure to an OP compound; neuropathy target esterase (NTE) is considered to be the principal molecular target for OPIDP (Lotti and Moretto, 2005). However, there is no data to indicate that VX has any potential at high or low doses for the induction of OPIDP in its classic manifestation in humans or other species, either with acute or long-term exposure. The reason could be that the ability of VX to inhibit NTE is near 1,000-fold less than that of GB (Vranken et al., 1982; Gordon et al., 1983). Single i.m. injections of VX at 5 LD_{50} in atropine-protected chickens produced neither inhibition of NTE nor histological or behavioral evidence of OPIDP (Wilson et al., 1988a). There was no ability of VX at subchronic exposure (0.04 mg/kg for 90–100 days) to induce OPIDN in antidote-protected chickens (Wilson et al., 1988b). According to other data, NTE activity in brain areas and soleus muscles of rats was significantly depressed after they were subacutely exposed to VX in the absence of supporting therapy for 14 days at doses at the LD_{50} level and higher, and surviving animals exhibited muscle myopathy in the soleus muscles (Lenz et al., 1996). Blood AChE activity was depressed to zero throughout the experiment, so there is no contradiction on the lack of clear OPIDP signs under severe intoxication with VX.

Thus, molecular mechanisms of delayed and chronic effects of VX are still poorly understood, and scientific data on these effects under RVX intoxication is much scarcer. It seems that chronic intoxication should be a separate type of damage with OPs. The problem requires searching for new criteria to determine intoxication. One should differentiate at least two aspects of this problem: molecular and functional. The former concerns revealing new molecular targets of OP action. For instance, plasma and liver carboxyesterases (CarbEs) may be more sensitive targets compared to AChE in cases of chronic action of OP low concentrations (Ray and Richards, 2001). Although CarbE are responsible for the metabolism of a variety of xenobiotics, this fact has been ignored over a long period of time. Another esterase is involved in testosterone biosynthesis metabolizing cholesterin esters in the testis (Jewell and Miller, 1998); one more (surfactant convertase) is also involved in cholesterin metabolism in the lung (Krishnasamy et al., 1997); and a number of brain CarbE and other hydrolases are also sensitive to OPs (Chemnitius and Zech, 1983; Richards et al., 2000; Nomura et al., 2005). Various OPs are potent inhibitors of fatty acid amide hydrolase and monoacylglycerol lipase (Quistad et al., 2001, 2006), the principal enzymes of the endocannabinoid system.

The second (functional) aspect of this problem concerns the development of pathologic symptoms, the molecular causes of which are not due to AChE inhibition. One of the first cases of OP non-ChE effects (when the association between the OP molecular target and the functional disturbance has been proved) involved inhibition of kinurenin formamidase of the hen egg yolk sac membrane responsible for teratogenic effects (Seifert and Casida, 1978). Another example of the OP teratogenic effect is abnormal development of the conjunctive tissue of Xenopus embryos due to inhibition of lysyloxidase and incomplete post-translational modification of collagen (Snawder and Chambers, 1993).

Acute Intoxication with RVX

A contributing factor to the high toxicity of VX may be its preferential reaction with AChE. Moreover, unlike the G-agents, VX depresses AChE activity significantly more than BChE in humans (Sidell and Groff, 1974); the result is that more VX is available to react specifically with the target enzyme, AChE. At the same time, indirect primary (connected with AChE inhibition) and secondary (not connected with AChE inhibition) effects of RVX have also been described. Development of after-intoxication immunodeficient or immunotoxic states relate to the first group of effects (Germanchuk and Zabrodskii, 2005). In experiments with rats that were administered RVX at a dose of 0.75 LD_{50}, a suppression of immune reactions was found: Th-1 cells significantly lost their functions and T-dependent immune reactions were depressed. In addition, an optimal balance of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) in lymphocytes necessary for their proliferation and differentiation was disturbed (Zabrodskii et al., 2007). On the other hand, after a severe intoxication of laboratory rats with RVX (2 LD_{50} with therapeutic treatment), there were no aftereffects concerning the capability of the central nervous system (CNS) to produce conditioned reflex reactions, neither in the early post-intoxication period (2 weeks) nor at remote terms (1–6 months) (Novikova et al., 2007). Four different effects of RVX were ascribed to the second group (Prozorovskii and Chepur, 2001): (i) sensitization and desensitization of cholinoceptors to acetylcholine that is characteristic of M-cholinoceptors; (ii) influence on acetylcholine release by nerve terminals: an inhibition after stimulation of M-cholinoceptors and facilitation after stimulation of N-cholinoceptors; (iii) direct interaction with cholinoceptors, mainly with nicotinic ones, leading either to their activation or inactivation; (iv) interaction with ionic channels, mainly with that of N-cholinoceptors.

Hypoxic syndrome is one of the principal clinical manifestations under acute intoxication with RVX. It is triggered by disturbance of ventilation, which in its turn is caused by bronchospasm, bronchorrhea, convulsions, and central deregulation of respiration. A series of pathological mechanisms leads to reduction of circulating blood volume, decrease of blood vessel tone, and deregulation of vessel wall permeability. Abnormalities of blood rheology, caused by the loss of body fluids (salivation, bronchorrhea, etc.), and aggregation of blood cells significantly increase the dynamic viscosity of blood and aggravate disturbances of microcirculation. Disturbances of oxygen transport and its delivery to tissues induce secondary metabolic disorders and involvement in a pathological process of related biological systems that facilitates oxygen utilization by the tissues (Shestova and Sizova, 2005). An imbalance of electrolytes has also been described: in blood plasma under acute intoxication, there was decrease of sodium and potassium, the latter being more expressed than the former (Rybalko et al., 2005). Indirect secondary effects of OP agents, including RVX, can be induced by excessive amounts of ACh in blood, with its action on cells having no cholinergic innervations. This can lead to deformation of red blood cells and endothelial cells, activation of basophiles and degranulation of mast cells (Prozorovskii and Chepur, 2001). In this content, one should keep in mind that endothelial cells have got all the attributes of autonomic cholinergic regulation. There have been not only M-cholinoceptors, but also N-cholinoceptors revealed (Hsu et al., 2005), as well as activity of AChE (Carvalho et al., 2005; Santos et al., 2007), the system of synthesis of acetylcholine (cholinacetyl transferase) and vesicular system of ACh transport out of the cells (Kirkpatrick et al., 2003).

Delayed Effects: Chronic and Subchronic Intoxication with RVX

In the context of realization of the conventional programs for CW destruction, chronic effects of subsymptomatic concentrations of RVX are of particular interest, since risk of exposure of personnel of the CW destruction facilities to chemical agents cannot be completely ruled out. In addition, members of the rescue service engaged in the decontamination process are regarded to be a group at high risk of exposure. The difficulty of diagnosis of delayed effects and chronic intoxication with RVX relates to polymorphism of the clinical manifestations (Savateev et al., 2001). Long-term monitoring of personnel staff engaged in production of RVX revealed slowly progressing signs of chronic intoxication (Gur'eva et al., 1997). The clinical signs of this may consist of functional and organic disorders of the CNS together with vegetative dysregulations, such as peripheral angiodystonic syndrome, vegetosensory polyneuropathy or complex motor-sensory-vegetative pathology of axonopathic or myelinopathic type. Neuromuscular effects, visual and gastrointestinal disorders, immunodeficiency, and metabolic disorders have also been described (Gur'eva et al., 1997; Yanno et al., 2000). Cessation of contact with RVX does not lead to involution of the clinical picture of chronic intoxication. Along with nervous, gastrointestinal, and motor disorders, there can be visual and cardiovascular diseases. Moreover, the chronic occupational pathology of the former workers of the facilities may develop in 3–6 years, even though they were exposed to no more than 10 times the maximum allowable concentrations of RVX and had no acute intoxications in their anamneses (Filippov et al., 2005).

Experimental results were reported on exposing male and female rats to VX (0.00025, 0.001, or 0.004 mg/kg, s.c.) daily for 30, 60, and 90 days (Goldman et al., 1988). RBC-AChE activity was significantly depressed in rats at all VX doses for 30, 60, and 90 days. BChE was significantly depressed in rats given 0.001 mg/kg VX for 30 days and in both genders of the high-dose group for all exposure periods. No dose-related changes were reported in clinical chemistry and histopathology. The authors concluded that VX exposure sufficient to significantly depress RBC-AChE activity produced no subchronic toxic effects.

Taking into consideration these clinical manifestations of delayed and chronic effects of RVX, an experimental search was undertaken to seek new possible mechanisms of the pathogenesis and novel functional signs of intoxication (Goncharov et al., 2003; Mindukshev et al., 2005). To model chronic intoxication in experiments with animals, RVX was dissolved daily in drinking water to concentrations of 5×10^{-8}, 5×10^{-7}, and 5×10^{-6} g/100 mL. A group of 5 rats consumed 20 mL of RVX aqueous solution daily. So, during the 3-month test, animals of the first group consumed daily RVX with drinking water in a dose of 10^{-5} mg per 1 kg body weight (I), animals of the second group consumed a dose of 10^{-4} mg (II), and those of the third group consumed 10^{-3} mg (III). Measurement of AChE activity in red blood cells (RBC-AChE) was performed by Ellman's method, and the functional activity of platelets was investigated by a novel method of low-angle light scattering that allows all stages of the platelet transformation to be assessed (Mindukshev et al., 2005). Investigation of monosynaptic miotatic reflex and conduction rate through the peripheral nerve fiber was conducted with *N. tibialis.*

Comparative analysis of biochemical and physiological parameters studied is indicative of the complete absence of significant changes of RBC-AChE activity in rats of all three groups relative to the control, after exposure to the RVX doses given above (not shown in this chapter). On the contrary, platelets of test animals exposed to RVX differed from the control by their pronounced instability, an indication of which was development of their spontaneous activation and aggregation (Figure 10.5).

After 3 months of intoxication, two kinetic parameters of aggregation (namely, normalized maximal rate U_{max} and effective concentration EC_{50}) were significantly increased in groups II and III. Two months after cessation of the chronic intoxication with RVX (i.e., the rehabilitation period), significant differences of both kinetic parameters were found only for group III. Groups I and II showed significant increases of EC_{50}, but only a tendency ($P<0.1$) to increase U_{max}. The final estimation of kinetic parameters of aggregation, made 6 months after the rehabilitation, showed significant decrease of U_{max} in group III and increase of EC_{50} in all three intoxicated groups (Figure 10.6). Significant increase of U_{max} suggests the sensitization of platelets with the primary activation of signaling ways *via* protein kinases, the action of which tends to increase the expression of GPIIb/IIIa receptors (Shattil et al., 1998). The increase of the EC_{50} parameter with further elevation of U_{max} points to a partial desensitization of $P2X_1$ and $P2Y_1$ receptors, as does the growing activity of the abovementioned kinases.

Stimulation of the peripheral nerve trunk of intact animals leads to generation of muscle action potentials of three types. According to the duration of latent periods, they fall into the following order: (i) M-response

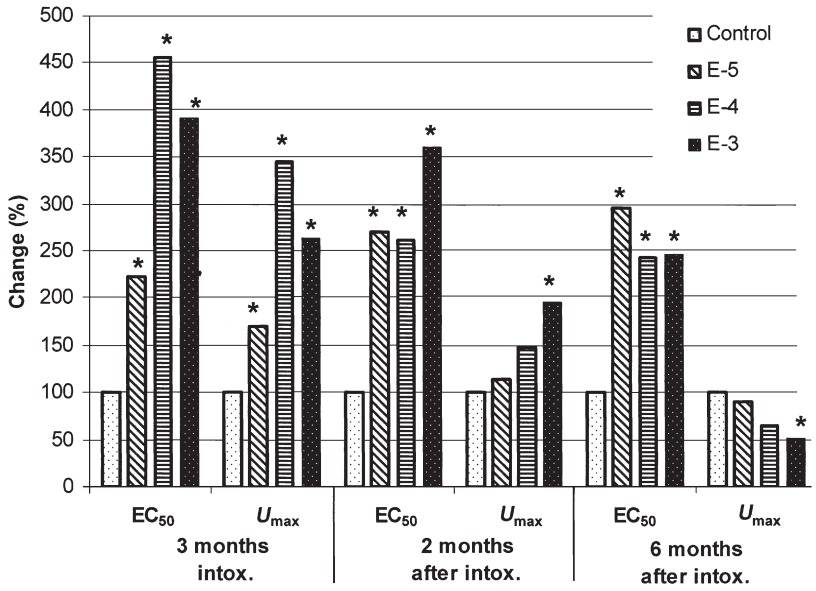

FIGURE 10.6 Kinetic parameters of rat platelet aggregation immediately after three months of RVX exposure, and at 2 and 6 months after cessation of the intoxication (*$P < 0.05$ relative to control). E-5, E-4, and E-3 relate to doses of RVX (1×10^{-5}, 1×10^{-4}, and 1×10^{-3} mg/kg) consumed by rats daily with drinking water.
Inscriptions: U_{max} means normalized maximum rate of platelet aggregation. *Source: Reprinted from Mindukshev et al. pp. 247–257. Copyright (2005), with permission from IOS Press.*

TABLE 10.4 Electrophysiological Parameters of the Peripheral Nervous System of Rats After RVX 3 Months' Chronic Exposure

	Control	I	II	III
t_M	1.36 ± 0.29	1.50 ± 0.19	1.72 ± 0.33[a]	1.07 ± 0.14[b]

(the result of the direct stimulation of α-motorneuron axons), (ii) H-response (the monosynaptic response), and (iii) polysynaptic responses with the variable latent period from 8–12 up to about 40 ms. In test animals of the III group, the changes of temporal parameters refer mainly to the latent period and duration of M-response (Table 10.4). Polysynaptic responses occur at all intensities of excitation and have a more pronounced character than in intact rats. A marked level and more distinct differentiation of the peaks of the complex action potential were noted.

The results obtained after examining the rats in group II differ from the control group more significantly. Along with normal action potentials (of the "spike" type), there were slow waves of depolarization of up to 30 ms duration. Another significant difference is the absence of the "subthreshold border"; that is, graduation of the increase of the amplitude of the action potential when the irritation stimulus enhances (Figure 10.7). Such an event can usually take place in newborn animals and is caused by a slight differentiation of motor neurons (Bursian, 1983). The latent period of M-response, the rate of rising action potentials, and their duration increased significantly. The results of testing the rats of group I did not differ from the control. At the same time, some animals had the entire spectrum of pathologic reactions observed in rats of groups II and III: fasciculations, the presence of slow (local, depolarized) potentials, and paradoxical discharges. The opposite character of the changes in velocity of nerve impulse conduction within

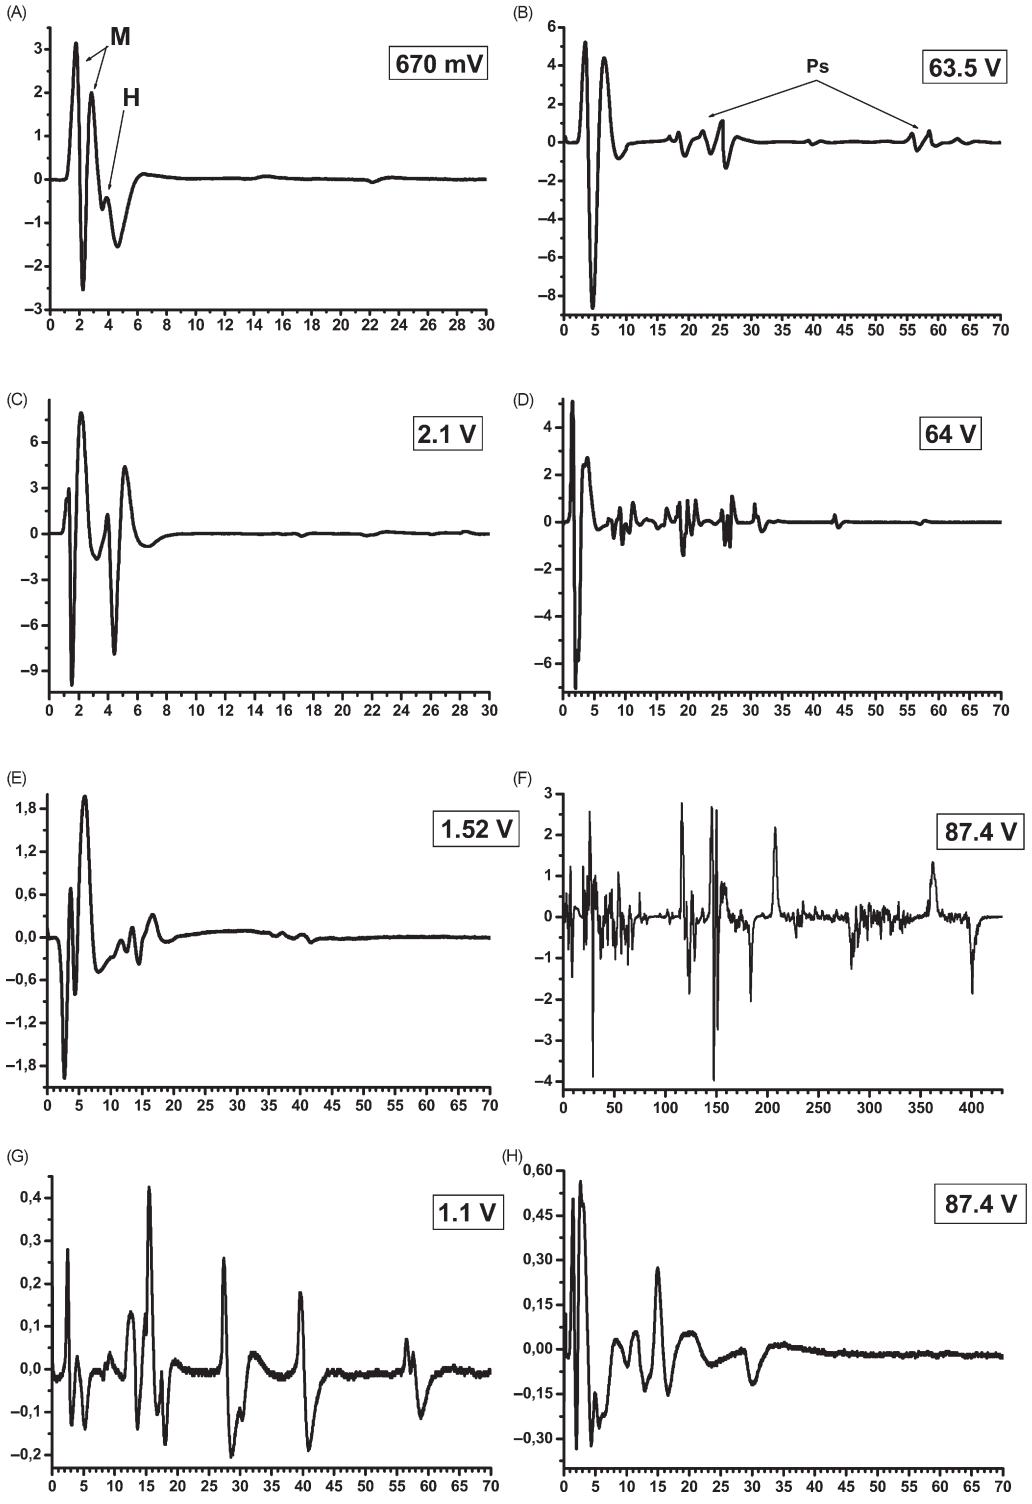

FIGURE 10.7 Action potentials of the rat gastrocnemius muscle under stimulation of *N. tibialis*: Effect of direct stimulation of the muscle (M-response, M), mono- (H-response, H), and polysynaptic (Ps) responses of control rats (A and B), rats of group III (C and D), II (E and F), and I (G and H). Ciphers within frames indicate value of the stimulus. The *x*-axis shows time of registration in ms; the *y*-axis shows amplitude of action potential in mV.

groups II and III could be caused by different intensities of demyelinization of nerve fibers with different diameters.

Earlier in this chapter, contradictory functional disorders in response to exposure to OPs were described, for which no appropriate interpretations were suggested from the point of view of molecular sources. For example, daily administration of DFP to rats for 20 days at a dose of 17% of LD_{50} caused an increase of velocity of nerve impulse conduction (Anderson and Dunham, 1985), although dimethoate or dichorphos treatment at subsymptomatic doses for at least 8 weeks caused reduction of peripheral nerve conductivity (Desi and Nagimajtenyi, 1999).

Delayed Effects: Embryo- and Gonadotoxicity, Mutagenesis, and Carcinogenesis

To study the embryotoxicity of RVX, it was administered to pregnant female rats perorally at a dose of 1/100 LD_{50} (Kiryukhin et al., 2007). RVX had a toxic effect in the females judged by a decrease in their RBC-AChE activity; at the same time, AChE activity in tissues of fetoplacental complex complied with age-specific control levels. These results may be regarded as evidence for impossibility (or at least low probability) of transplacental transfer of RVX from maternal organism to fetus. However, manifestation of intoxication symptoms by pregnant rats indicates that RVX can induce an embryotoxic effect, which is apparent from disorders of prenatal and postnatal ontogenesis (Tochilkina and Kiryukhin, 2007). It should be mentioned that embryotoxicity of VX to rat fetuses was also shown after single LD_{50} doses to the mother (Guittin, 1988), and after repeated doses of 0.005 mg/kg (near 1/5 LD_{50}) at varying times during fetal development (Guittin et al., 1987). On the other hand, no teratogenic potential of VX was found in sheep, rats, and rabbits (Van Kampen et al., 1970; Goldman et al., 1988).

Gonadotoxicity of RVX was investigated in chronic experiments for different methods of introduction. Dermal exposure of male rats to RVX demonstrated that general toxic effects were the governing factor of gonadotoxicity. There were no gonadotoxic effects at the level of threshold dose, which was estimated to be 4×10^{-6} mg/kg (Maslennikov and Kiryukhin, 2003). Other research has not revealed changes in the weight parameters of left and right testicles and epididymis, nor their total and specific weight parameters (Shabasheva et al., 2007). It has been concluded that RVX poses no danger concerning development of specific disorders of male reproductive function, and this is in agreement with available data on VX: neither acute nor chronic VX exposure had deleterious effects on reproductive potential (Van Kampen et al., 1970).

Studies of mutagenicity of RVX in the Ames test revealed no point mutations in the indicative bacteria. However, studies conducted by a micronuclear test have demonstrated that a single intragastric introduction of RVX at a dose of 1/10 LD_{50} stimulated in rats an enhancement of frequency of polychromatophilic erythrocytes with extranuclear inclusions. In cases when the cytotoxic effects were absent, these alterations could be interpreted as being of a mutagenic nature (Maslennikov and Ermilova, 2005). At the same time, the threshold dose of general toxic effect of RVX had neither mutagenic nor embryotoxic or gonadotoxic effects. Therefore, the delayed effects of RVX can appear at doses exceeding those that induce general toxic effects, indicating the nonspecific character of its action.

In studies involving bacteria or yeast, VX was tested both with and without metabolic enzyme activation to determine if VX metabolites might be mutagenic; the results were negative (Crook et al., 1983; Goldman et al., 1988). In addition, negative results were obtained for VX in the *Drosophila* mutagenicity assay (Crook et al., 1983), and VX was considered to be a nonmutagen in a test with mouse lymphoma cells (Goldman et al., 1988).

In the available literature, we could not find experimental data on the carcinogenicity of RVX. Nevertheless, epidemiologic data on tumor and pretumor diseases of the people that were engaged in production of RVX did not reveal an increase of oncological morbidity compared to a control group of human subjects (Fedorchenko et al., 2003). In agreement with this, McNamara et al. (1973) reported that there was no association of increased cancer in personnel working daily with VX.

Principles of Therapy

Acute toxicity of OPs in general and RVX in particular has been much more extensively investigated than chronic toxicity, so it is not surprising that an effective therapy has been developed for acute intoxications only. The most effective antidote complex for treating acute intoxications with RVX consists of an antagonist of M-cholinoceptors, a reversible inhibitor of ChE, and a reactivator of ChE; in addition, anticonvulsants can be used in cases where convulsions occur. In experiments with guinea pigs, they were pretreated with pyridostigmine (0.026 mg/kg, i.m.), and then immediately after RVX intoxication ($2 \times LD_{50}$), animals were given pralidoxime chloride (25 mg/kg, i.m.) and atropine sulfate (2, 8, or 16 mg/kg, i.m.); diazepam (5 mg/kg, i.m.) was administered to animals that displayed seizures and convulsions (Chang et al., 2002). It was also shown that in cases of acute intoxication with RVX, higher doses of atropine should be administered compared to those for VX. Of several oximes (pralidoxime, obidoxime, and

TABLE 10.5 Parameters of RVX Toxicity for Animals and Humans

Parameter	Rout of Exposure	Dose
LCt_{50} (human)	Inhalation	0.04 mg/min/dm^3
LC_{50} (mouse)	Inhalation	1.8–4.5 × 10^{-5} mg/kg
LCt_{50} (mouse)	Inhalation	0.011 mg/min/L
LD_{50} (rabbit)	Percutaneous	0.014 mg/kg
LD_{50} (cat)	Percutaneous	0.01 mg/kg
LD_{50} (dog)	Percutaneous	0.0157 mg/kg
LD_{50} (mice)	Percutaneous	0.016 mg/kg
LD_{50} (human)	Percutaneous	0.1–0.01 mg/kg

TABLE 10.6 RVX Safety Standards in the Russian Federation (Uiba et al., 2007)

MAC for working air (mg/m^3)	5 × 10^{-6}
MAC for reservoir water (mg/dm^3)	2 × 10^{-6}
TSEL for ambient air (mg/m^3)	5 × 10^{-8}
MPL for equipment surface (mg/dm^2)	2 × 10^{-6}
MPL for human skin (mg/dm^2)	3 × 10^{-8}
MAC for soil (mg/kg)	5 × 10^{-5}
EEL for ambient air (mg/m^3)	
After 1 h	1.6 × 10^{-5}
After 4 h	4.1 × 10^{-6}
After 8 h	2.0 × 10^{-6}
After 24 h	6.6 × 10^{-7}

Abbreviations: MAC, maximal allowable concentration; TSEL, tentative safety exposure level; MPL, maximal permissible level of pollution; EEL, emergency exposure limit.

HI-6), the most effective was HI-6, as it was in the case of VX, sarin, cyclosarin, and soman poisonings (Kassa et al., 2006).

Looking for therapies to treat chronic, low-dose intoxication, one should keep in mind that the VX-AChE complex has been found to undergo a significant degree of spontaneous reactivation in humans (at a rate of about 1%/h over the first 70 h after intravenous/i.v. administration of VX); another feature of VX toxicity is the lack of aging or stabilization of the VX-AChE complex and the relative ease of reactivation of VX-poisoned enzymes by oxime antidotes in humans (Sidell and Groff, 1974). Because there are no major differences in the reactivation process of both VX and RVX-inhibited ChE (Kuca et al., 2006), natural inactivation with plasma and liver paraoxonase (PON1) of RVX, VX, and other warfare agents could play a bigger role in prophylactic therapy of acute and chronic intoxications and their delayed effects (Costa et al., 2005). PON1 is a catalytic bioscavenger, in contrast to the stoichiometric bioscavenger BChE. A constituent of red wine, known as resveratrol, has been shown to be a natural and rather effective up-regulator of PON1, and it has good potential for protecting living cells against CWAs (Curtin et al., 2008).

TOXICOMETRY AND HYGIENIC REGULATIONS

In countries dealing with destruction of CWAs, control limits for exposure via surface contact of drinking water are needed, as are detection methods for their low levels in water, soil, or foodstuffs. Some of the toxicity parameters of RVX for humans and animals are available in the *Textbook of instructive and technical documentation on the problem of chemical weapon destruction* (Anon, 2001) and are given in Table 10.5.

In the event of contact of human skin with the fabric of a protective suit, toxicometric parameters of RVX have been experimentally estimated with laboratory rats (Zhukov et al., 2007): LD_{50}=0.55 ± 0.09 mg/kg, or 6.9 × 10^{-3} mg/cm^2; Lim ac (integr.) = 0.056 ± 0.001 mg/kg, or 7.0 × 10^{-4} mg/cm^2; Lim ac (sp) = 0.0051 ± 0.001 mg/kg, or 6.4 × 10^{-5} mg/cm^2; Lim ch = 4.75 × 10^{-5} mg/kg, or 5.9 × 10^{-7} mg/cm^2. The maximum concentration limit of RVX for the fabric of protective suits has been estimated to be 3.1 × 10^{-8} mg/cm^2, taking into consideration the reserve coefficient, an average body weight, and total area of the skin coverlet.

For the purposes of sanitary regulations, it has been estimated that RVX within the range of concentrations 0.01–1.0 mg/L has no negative influence on the natural purification of aquatic reservoirs, on growth and decay of saprophytic and pathogenic microflora, and on nitrification processes. The noneffective dose of RVX has been estimated to be 1 × 10^{-7} mg/kg, the threshold dose 1 × 10^{-6} mg/kg, and the effective dose 1 × 10^{-5} mg/kg (Maslennikov and Ermilova, 2006). Studies on RVX effects on the soil microflora have revealed that actinomyces and micromycetes proved to be the most vulnerable, whereas *Nitrobacteria* was the least vulnerable species (Gorbunova and Maximova, 2003). The hygienic regulations for RVX are presented in Table 10.6.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The ambient monitoring and biomonitoring of RVX and its destruction products within the areas of CW storage and destruction facilities is an important task for the State Sanitary Inspection Units of the Russian Federation. In this regard, development of chemical analytical and

bioanalytical methods and procedures should be among the main purposes of applied sciences. At the same time, estimation of probability of exposure to RVX and other CWAs calls for the solving of fundamental problems of molecular and functional diagnostics of the pathogenesis, as well as the development of effective therapy or prophylaxis.

In this chapter, we presented the principal products of RVX hydrolysis with excess water in an acid medium. It has been shown that after 3 months of exposure, nearly 1% of the initial amount of RVX in the solution could be detected. According to data on RVX hydrolysis with an equimolar amount of water, the autocatalytic hydrolysis of RVX was almost completed after 3 months since the RVX content in the sample was no more than 0.01%. Moreover, the reaction mixture was much poorer than in the case of hydrolysis with excess water. Isobutyl MPA, which catalyzes RVX degradation, was detected as the major component of the reaction mixture. Yang et al. (1996) found 2-(diethylamino)ethanethiol to be the second major component of the mixture, but in our experiment, it was almost completely converted into bis[2-(diethylamino)ethyl] disulfide.

We have not found conditions for effective extraction of RVX in experiments with its application on soil, concrete, bricks, and polyisobutylene at concentrations 10^{-6}–10^{-5} mg/kg. The extremely low recoveries of RVX from materials of various natures can be explained by both irreversible sorption and degradation. A summarized list of compounds isolated from samples of building materials was presented, which were taken from some areas of a former RVX production facility and might have contacted RVX. RVX degradation products were found, along with organic components of building materials, solvents, plasticizers, reaction products of degassing agents with matrix components, and other materials. High concentrations of fyrols were detected in some brick and concrete samples.

Procedures for identification and quantitative assessment of *O*-isobutyl MPA (a marker of exposure to RVX) in urine and blood plasma have been developed, and then toxicokinetic experiments for measuring *O*-alkyl MPA in rat plasma after intramuscular injection of RVX at a dose of 0.8 LD_{50}. In addition, we have obtained a mass spectrum of human albumin after *in vitro* incubation of blood serum with RVX. Incubation of commercially available human albumin with RVX with subsequent trypsinolysis and MS/MS analysis has revealed two sites of binding RVX to human albumin, Tyr411 and Tyr150. These data could contribute to development of sensitive and specific diagnostic methods.

Having analyzed our own experimental data and available scientific literature, we came to the conclusion that the toxicological features of RVX were not properly studied. On the one hand, pathogenesis of acute intoxication has been described, and toxicometric parameters and hygienic regulations have been developed. On the other hand, mechanisms of nonspecific effects and chronic intoxication, pathogenesis of delayed manifestations need further clarification. That is why there is a lack of effective prophylactic and therapeutic means of treating the delayed effects of RVX (and many other OPs) that cannot be equated or reduced to development of OPIDP. The search for non-ChE targets is still far from its final stage and not all the functional consequences of an OP exposure have been revealed. Various OPs can covalently bind to tyrosine residues of tubulin, near the GTP binding sites or within loops that interact laterally with protofilaments (Grigoryan et al., 2008), and this could partly explain an impairment of fast axonal transport and neuropsychological effects of chronic, low-dose exposure to OPs (Stephens et al., 1995; Terry et al., 2007). Previously, assumptions have been made about a direct influence of OPs on the humoral components of hemostasis and the complement system in terms of abundance of serine proteases in these systems (O'Neill, 1981). An interrelation of hemostasis and neuromuscular conduction is of undoubted interest considering the low "percentage" of endoneural capillaries in the structure of nerve fibers, and dependence of the trophism of any tissue upon the integrity of the endothelial monolayer and upon adequate functioning of hemostatic mechanisms. An idea about dependence of the trophism of nerve fibers upon the vascular bed comes from data on their ratio: the volume of capillaries amounts to just 2–4% of the total volume of nerve fiber (Odman et al., 1987). Moreover, peripheral nerves have no lymphatic vessels, which could provide an effective outflow of the capillary infiltrate and prevent development of edema (Low, 1984; Olsson, 1984).

Our data support the existence of a key role of nonsynaptic mechanisms in developing effects under chronic exposure to RVX. The morphofunctional changes at the level of the microcirculatory bed that influence the functional state of platelets may prove to be significant factors in the etiology of delayed effects of chronic intoxication. Since the life span of blood platelets is about 10 days, the changes observed are likely to reflect multiple microangiopathies, when clinically pronounced manifestations are prevented by compensatory mechanisms, such as receptor desensitization, endothelial and plasmatic proteases, and molecular effectors providing the feedback regulation.

It is well known that OPs cause the inhibition of several major enzymes, and this fact can be easily proved by simple methods of laboratory and clinical biochemistry. On the other hand, diagnostics of a chronic, low-dose action of OPs, or their delayed effects after subacute intoxication is a big problem because of lack of inhibition or recovery of the enzymes' activities. Determination of a peptide spectrum of blood plasma or serum could

serve as an alternative and more sensitive method for diagnosing the intoxications.

An adequate interpretation of the experimental data would lead to a proper understanding of the therapeutic approaches, which could prevent or even reverse the development of delayed effects of RVX and other warfare or pesticide OPs. Resveratrol, being an effective up-regulator of PON1, is now extensively studied in different laboratories as a possible remedy (Curtin et al., 2008). In view of our understanding of the pathogenesis of delayed effects, it is important to mention another property of resveratrol as a protector of endothelial progenitor cells, which contribute to renovation of injured blood vessels (Gu et al., 2006).

In conclusion, we outline some present and future areas of study on the analytical chemistry, biochemistry, and toxicology of RVX:

- Improvement of the methodology of chemical and biochemical monitoring in environmental objects and human organisms.
- Development of prognostic modeling for probable risk assessment in case of elevation of the allowable levels of RVX in various media.
- Studies on the quantitative relations dose-effect, time-effect, and dose-time-effect for ChE and non-ChE effects, for both acute and chronic exposure to RVX.
- Studies on novel molecular and functional effects under acute and chronic exposure to RVX.
- Studies on mechanisms of development of delayed effects after intoxication with RVX.
- Development of novel effective means for prophylaxis and treatment of delayed effects of intoxications with RVX.

Fulfillment of these studies surely would contribute to fundamental and applied knowledge well beyond the toxicology of RVX.

CHAPTER

11

Riot Control Agents

Corey J. Hilmas

INTRODUCTION

Nonlethal agents are a broad class of compounds intended to produce transient incapacitation of an individual or individuals. Both incapacitating agents and riot control agents (RCA) are separate classes of nonlethal agents. Although the two classes share the characteristic to incapacitate, a distinction must be drawn between these two types of agents. RCAs differ from incapacitating agents in several respects. RCAs possess relatively short onset and limited duration of action. RCAs induce short-term toxic effects that subside within minutes after termination of the exposure. Additionally, modern RCAs have a very high safety ratio compared with incapacitating agents and first-generation RCAs. Many incapacitating agents were developed during the Cold War that produced either limited lethality and/or prolonged morbidity. Consequently, incapacitating agents have been banned by international treaties recognized by the United States, including the Chemical Weapons Convention (CWC). Specifically, the CWC has placed a ban on the development, production, and possession of any chemical weapon intended to cause death or "temporary incapacitation." The United States considers these broad incapacitating agents as chemical warfare agents (CWAs). However, the United States does not recognize RCAs as CWAs; therefore, US policy considers them to be legal for use by civilian police or the military. The CWC does prohibit their use in times of war. Thus, the United States has opted not to utilize RCAs in Iraq during the early twenty-first century against organized and armed insurgents.

Although the field of nonlethal agents is diverse and interesting, we limit our discussion to only those agents considered to be RCAs. The goal of RCAs is to temporarily incapacitate through irritating the skin and mucosal membranes of the eyes, airways, and digestive tract. As a result of their short-term toxicity, they are effective agents used by military and law enforcement personnel to disperse crowds, clear buildings, and quell riots. Whereas RCAs are often thought of as "tear gas" or pulmonary irritants, they encompass more than this terminology would suggest. They are neither gases nor exclusively pulmonary irritants. Historically, RCAs were categorized as lacrimators, sternutators, and vomiting agents based on their predominant toxicity in the eyes, lungs, or digestive tract. This nomenclature is outdated because modern RCAs affect a wide variety of organ systems. This fact will be clearly evident in the subsequent discussion concerning their mechanism of action and toxicity. Today, RCAs comprise a diverse array of chemical compounds with similar toxic effects because of their introduction on the battlefield in the early part of the past century. Opinions, interpretations, conclusions, and recommendations are those of the author and are not necessarily endorsed by the US Food and Drug Administration.

HISTORY

The Chinese were perhaps the first to use pulmonary irritants with their stink bombs (Smart, 1996). The smoke emanating from them was a primitive sternutator designed to harass the enemy. RCAs were used during the Peloponnesian War in the fifth century BC when the Spartans used smoke from burning coal, sulfur, and pitch to temporarily incapacitate and confuse occupants of Athenian strongholds (Thoman, 2002). During antiquity, the Romans used irritant clouds to drive out their Spanish adversaries from hidden dwellings (Robinson, 1971). Almost all of these examples involved the use of incapacitating agents as an offensive tactical weapon as opposed to controlling crowds for defensive purposes.

World War I (WWI) marked the birth of RCAs as well as the modern age of CWAs (Figure 11.1). Both German

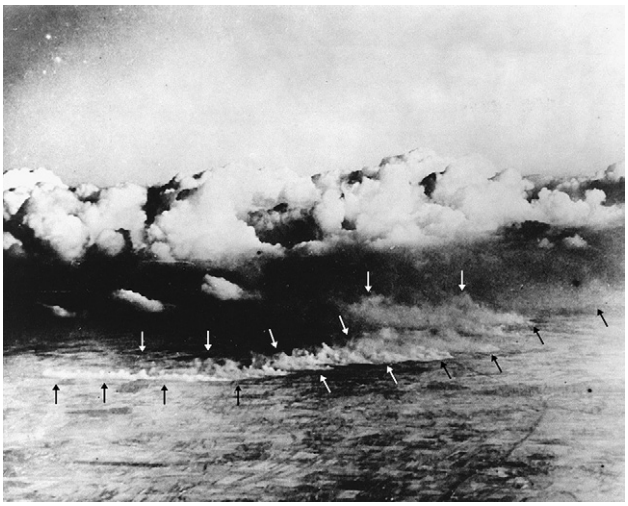

FIGURE 11.1 The birth of CWAs in WWI. The photograph depicts the initial chlorine gas attack by Germany at Ypres, Belgium, on April 22, 1915. The German Army released chlorine gas from cylinders to form a poisonous cloud (indicated by black and white arrows) directed toward the French lines by the prevailing winds.

and French forces used a wide variety of irritating agents, such as acrolein (papite), chloropicrin (PS), and diphenylaminearsine (DM; Adamsite); however, bromoacetone (BA) was the most widely used lacrimator agent at that time. At the end of WWI, the US military investigated the use of chloroacetophenone (CN) as a chemical irritant. First developed by Graebe in 1869 and formulated as Chemical Mace®, CN was the most widely used RCA until World War II (Olajos and Stopford, 2004).

Two chemists, Carson and Stoughton (1928), synthesized 2-chlorobenzylidene malononitrile (CS); however, it was not adopted by the military as an official RCA until 1959. As a more chemically stable compound and having a greater potency with less toxicity than CN, it gradually replaced CN as the preferred RCA. CS was widely used during the Vietnam War to flush the Viet Cong out of the labyrinth of underground tunnels and bunkers throughout Southeast Asia (Figure 11.2). In the years following the Vietnam War, other militaries adopted CS. Saddam Hussein's forces used it against Iran during the Iran–Iraq War of the 1980s. Today, CS is commonly used by law enforcement agencies and militaries for riot control training, respirator training in boot camps, temporary incapacitation of an assailant, and civil disturbances. A famous case of RCA use by the US Federal government involved CS dissemination on the Branch Davidian cult members in 1993. Because of its high flammability rating, CS was believed to be a large contributor to the inferno that burned down the Waco, TX, compound and its inhabitants. Even before fire broke out and destroyed the compound, it is believed that CS concentrations ranged from five-times to 60-times the amount required to deter individuals (Bryce, 2000).

FIGURE 11.2 Top: US Army Engineers unpack and test a Mitey-Mite blower in the jungles of Vietnam. The Mighty-Mite aerosolized and disperse smoke, CS powder, or other RCA as a means of tunnel denial. Bottom: American soldiers ("tunnel rats") wearing M28 protective masks just before entry into underground tunnels previously saturated with CS. *Source: Photograph (top): Courtesy of the US Army Engineer School, Fort Belvoir, VA.*

During the 1980s and 1990s, the use of CS gas was rapidly on the decline and slowly being replaced by oleoresin capsicum (OC) spray. OC, an extracted resin from *Capsicum* pepper plants, was first developed in the 1970s as an alternative to CN and CS agents. Commercially available OC sprays used by the public are approximately 1% capsaicin, whereas formulations used by law enforcement agencies can contain up to 15% capsaicin. Most recently, a synthetic form of capsaicin called nonivamide, marketed as Captor, gained popularity as a defensive aerosol in the early 1990s (Olajos and Stopford, 2004).

Under the CWC of 1997, RCAs were banned from use as a method of warfare because in high concentrations RCAs are toxic chemicals with the potential to incapacitate individuals for prolonged periods, produce long-term sequelae, and cause death. The CWC allows RCAs to be used in domestic riot control as well as for enforcement of domestic law and "extraterritorial law enforcement

activities undertaken by military forces" (Rosenberg, 2003). These boundaries and definitions, although vague, were clarified in 2003 by President George W. Bush (Wade and Schmitt, 2003). Bush authorized the use of tear gas against Iraqi troops for defensive purposes as allowed in Executive Order 11850 of 1975. Many experts believed this would violate the CWC (which was not signed by Iraq) and give Saddam Hussein the power to use chemical agents against the United States under the authority of the Geneva Protocol (Wade and Schmitt, 2003). In the end, RCAs were never used during that conflict.

BACKGROUND

The Agents and Their Physicochemical Properties

Unlike the majority of chemical agents that are liquid at room temperature, modern RCAs are crystalline solids with low vapor pressure (see Table 11.1). RCAs are typically administered as fine particles, aerosol sprays, or in solutions; therefore, they are not true gases. The inhalation toxicity of RCAs, as well as CWAs, is often indicated by the expression *Ct*. This term is defined as the product of concentration (*C*) in mg/m^3 multiplied by exposure time (*t*) in minutes ($mg\,min/m^3$). LCt50 and ICt50 are conventional terms used to describe airborne dosages that are lethal (L) or incapacitating (I) to 50% of the exposed population. The intolerable concentration (mg/m^3), ICt50, and minimal lethal concentration (mg/m^3) are provided in Table 11.1 for the most common RCAs. The ocular irritancy threshold (minimal irritant or minimal effective dose), estimated human LCt50, and safety ratio are provided in Table 11.2 for these same RCAs. The modern RCAs are characterized by a high LCt50, low effective Ct50, low ICt50, low minimal irritating concentration, and large safety index ratio (LCt50/irritancy threshold). As a rule of thumb, clinical signs and symptoms from RCA exposure generally subside within 30 min but may persist depending on dose and duration of exposure (Blain, 2003). Orthochloroacetophenone (CN) and chlorobenzylidene malononitrile (CS) are the classic representative agents of this class of compounds. The toxicity of CN and CS is discussed in depth because of the vast volume of literature available for these compounds.

Chloroacetophenone (CN)

CN is a crystalline solid with a strong, pungent odor (Figure 11.3). It is dispersed as a smoke, powder, or liquid formulation from grenades or other devices. It is perhaps better known under the trade name Chemical

TABLE 11.1 Physical Characteristics and Toxicity Data for the Common RCAs

		Physical Characteristics			Toxicity Data			
Agent	**Discovered in**	**Solubility**	**Vapor Pressure (mmHg at 20°C)**	**Vapor Density**	**Onset**	**Intolerable Concentration (mg/m^3)**	**ICt50 ($mg\,min/m^3$)**	**Minimal Lethal Concentration[a] (mg/m^3)**
CS	1928 (Carson and Stoughton)	Insoluble in water Soluble in organic solvents	0.00034	6.5	Immediate	5	3–10	2,500

FIGURE 11.4 US soldier in protective clothing disseminating CN aerosol using the M33A1 disperser.

Mace® and was once used widely for self-protection. It was also the standard tear gas used by the military (Figure 11.4) and police personnel. It has been replaced in favor of the less toxic CS for riot control and capsaicin pepper spray for self-defense.

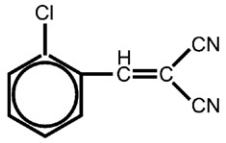
CN exhibits the greatest toxicity among RCAs in use today. Consequently, it has been replaced by compounds with higher safety ratios. CN is 3-fold to 10-fold more toxic than CS in rats, rabbits, guinea pigs, and mice (Ballantyne and Swanston, 1978). Pathological findings in the lungs tend to be more severe and CN causes far greater edema. CN typically causes an acute, patchy, inflammatory cell infiltration of the trachea, bronchi, and bronchioles, in addition to early bronchopneumonia. CN not only demonstrates greater irritation to the skin than CS but also is a more potent skin sensitizer (Chung and Giles, 1972). Patients frequently exposed to CN are at high risk for development of allergic dermatitis (Penneys, 1971).

Ortho-Chlorobenzylidene Malononitrile (CS)

The term CS was adopted after the two chemists, Carson and Stoughton, who synthesized the compound. CS is a white, crystalline powder with a pepper-like odor and low vapor pressure (Figure 11.5). It is rapidly hydrolyzed after contact with water but minimally soluble in ethyl alcohol. CS is the most widely used RCA today, although many countries are switching to even less toxic compounds. CS is used by the US Armed Forces for gas discipline training exercises to help new recruits learn the importance of donning their protective

CS

Structure:



Formula:	$C_{10}H_5N_2Cl$
MW:	188.6
MP:	93°C
BP:	310–315°C
Appearance:	white, crystalline solid
Odor:	pungent, pepper-like

UPAC name:

masks quickly (Figure 11.6). It was also used by the United States during the Vietnam War for tunnel denial and crowd control (Figure 11.7) and by police forces for dispersing violent protests and incapacitating assailants.

Dibenz(b,f)-1:4-Oxazepine (CR)

Dibenz(*b,f*)-1:4-oxazepine (CR) (Figure 11.8) is a potent sensory irritant with less toxicity than CS or CN (Ballantyne, 1977b). CR causes an immediate and effective irritation of the eyes, nose, and skin without persistent effects in these target organs. The irritation associated with CR is more transient compared with other RCAs. It is 5-times to 10-times greater in potency than CS; therefore, a smaller concentration is needed to cause irritation (low minimal irritant concentration or

dose) and incapacitation (low ICt50) (Tables 11.1 and 11.2). CR has a favorable safety ratio; it is safer than other RCAs based on its higher LCt50 (Table 11.1) and greater LCt50/irritancy threshold (safety ratio). In humans, the effects caused by CR are identical to CS. The LCt50 for humans is estimated at >100,000 mg min/m^3. Despite its reduced toxicity in humans, CR is not entirely without risk. CR is fairly stable, resists weathering, and persists in the environment (Sidell, 1997); therefore, enhanced toxicity may occur with prolonged exposure.

Diphenylaminechlorarsine (DM)

Diphenylaminechlorarsine (DM) (Figure 11.9) and Adamsite are pro-emetic agents used in WWI. DM has greater toxicity than other RCAs and has been abandoned in favor of compounds with less toxicity and greater safety ratios. Although toxicity is typically delayed with DM exposure, toxic signs and symptoms can occur within minutes after exposure. Systemic toxicity may also be more pronounced and prolonged.

Symptoms often subside hours after exposure. Because DM is an antiquated RCA, this compound is irrelevant today and will not be discussed further.

Oleoresin Capsicum

OC is an oily resin derivative from capsicums and composed of several related compounds. Capsicums are solanaceous (nightshade species) plants from the genus *Capsicum*. More than 20 species fall within the genus. Capsaicinoids are considered the active ingredients of OC. These active compounds are endocrine products of glands found in the plant placenta and are a mixture of two unsaturated and three saturated homologs (Figure 11.10). Capsaicinoids are isolated through a volatile solvent extraction of the dried, ripened fruit of chili peppers. The capsaicinoids are distilled, dried, and compounded together. The final oleoresin contains several branched-chain alkyl vanillylamides, in addition to capsaicin, the major component in OC. The predominant capsaicinoid components of OC are capsaicin (70%), dihydrocapsaicin (20%), norhydrocapsaicin (7%), homocapsaicin (1%), and homodihydrocapsaicin (1%) (Salem et al., 2006) (Figure 11.10).

Capsaicinoids cause dermatitis as well as nasal, ocular, pulmonary, and gastrointestinal effects in humans. OC gained popularity in the 1990s as a defensive weapon for civilians and law enforcement agencies because they produce immediate, temporary immobilization and incapacitation when sprayed directly into the face or eyes. It is important to note that hand-held pepper spray formulations can contain OC by themselves or a mixture of OC and CS.

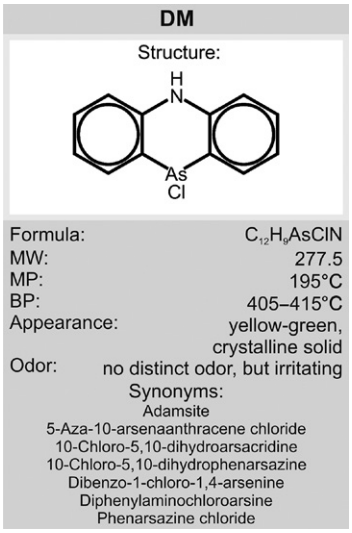

FIGURE 11.9 Chemical structure and physicochemical properties of diphenylaminechlorarsine (DM).

Pelargonic Acid Vanillylamide

Other capsaicinoids are available. Pelargonic acid vanillylamide (PAVA or nonivamide), shown in Figure 11.10, is a "synthetic" form of capsaicin. Nonivamide was first synthesized by Nelson (1919). Nonivamide was originally found to be a minor component in *Capsicum annum* peppers (Constant and Cordell, 1996); however,

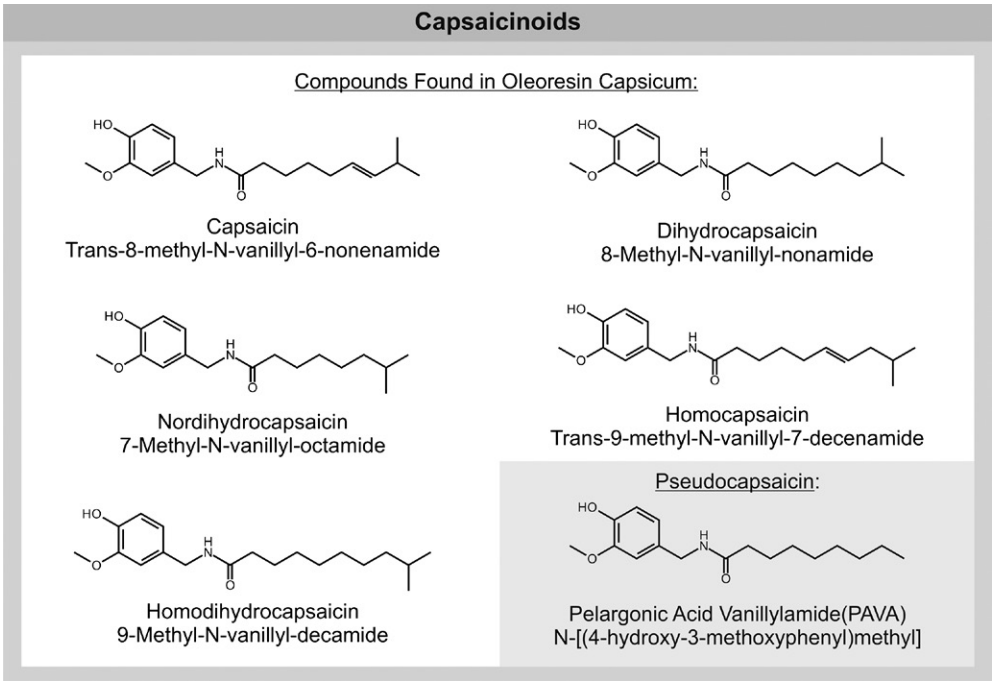

FIGURE 11.10 Chemical structures of the most common capsaicinoids found in OC.

the majority of PAVA is derived from synthesis rather than by extraction from natural plant sources. As a result, the composition and concentration of PAVA can remain consistent (Haber et al., 2007).

For PAVA to work, it must be directed at the subject's eyes. The pain in the eyes is reported to be higher than that caused by CS tear gas (Smith et al., 2004; Association of Chief Police Officers of England, Wales and Northern Ireland, 2006). The effects are immediate but will subside 15–20 min after exposure to fresh air. PAVA does display disadvantages. Although PAVA has a high rate of effectiveness, it has proven to be ineffective against those under the influence of alcohol (Association of Chief Police Officers of England, Wales and Northern Ireland, 2006). Additionally, the Smith et al. (2004) study mentions a number of cases in which PAVA was used without effect. The effect of PAVA was also reported to be almost instantaneous, with the undesirable effect that recovery was also immediate. PAVA is commercially available in two forms, captor I and captor II. Captor I contains 0.3% PAVA with a solvent of equal parts ethanol and water. Captor II contains 0.3% PAVA with propylene glycol, water, and ethanol (Committee on Toxicity of Chemicals in Food, Consumer Products, and the Environment, 2007).

MECHANISM OF ACTION

CS, CN, and CR

The mechanisms of action through which RCAs act are not completely understood. One explanation for the toxic effects of RCAs is the production of hydrochloric acid through reduction of chloride ions on mucosal membranes (Worthington and Nee, 1999). This may help explain the marked, focal irritation and burns on skin resulting from exposure to CS (Anderson et al., 1996). In addition, CS and CN are SN_2 alkylating agents (Cucinell et al., 1971; Ballantyne and Swanston, 1978); in contrast, the vesicant mustard is an SN_1 alkylating agent. The SN_2 moniker describes direct reaction of the agent with nucleophilic compounds in a bimolecular fashion. In particular, they react with intracellular thiol or SH-containing enzymes, thereby inactivating them (Ballantyne, 1977a). Mackworth (1948) first showed that CN and other first-generation lacrimators used during WWI (bromoacetophenone, ethyl iodoacetate, chloropicrin, bromobenzyl cyanide) strongly inhibited thiol-containing succinic dehydrogenase and pyruvic oxidase, major players of crucial metabolic pathways. Some suggest that lactic dehydrogenase is completely insensitive to lacrimators (Mackworth, 1948), but only lacrimators from the iodoacetate family were ever studied by this group. Another group reported that lactic dehydrogenase is, in fact, strongly inhibited by CS (Cucinell et al., 1971). Chloropicrin also interferes with oxygen transport to the tissues by reacting with SH groups on hemoglobin.

In addition, CS reacts with the disulfhydryl form of lipoic acid, a coenzyme in the pyruvate decarboxylase system (Olajos and Salem, 2001). Alteration in dihydrolipoic acid biochemistry can lead to decreased acetyl CoA levels, resulting in cellular injury. Therefore, tissue injury seems to be related to inactivation of these metabolic enzyme systems. The damage is transient because the enzymes can be rapidly reactivated if exposure is terminated (Beswick, 1983).

Based on these studies, it has been suggested that alkylation of nucleophilic sites, including SH-containing enzymes, is the underlying biochemical lesion responsible for lacrimator-induced toxicity. However, pain from RCA exposure can occur without tissue injury. It has been suggested that the irritant and painful effect of CS may be bradykinin-mediated (Cucinell et al., 1971; Olajos and Salem, 2001). CS causes bradykinin release *in vivo* in humans (Cucinell et al., 1971) and *in vitro* (Blain, 2003). Elimination of bradykininogen *in vivo* abolishes the systemic response to CS (USAMRICD, 2000; Salem et al., 2006).

The metabolism of CS to cyanide (see "Toxicokinetics") was once thought to be responsible for agent-induced lethality in animals (Jones and Israel, 1970; Cucinell et al., 1971). Despite reports of alleged fatality cases, mortality in humans after CS administration has not been authenticated (Ballantyne, 1977a; Olajos and Salem, 2001). CS has been demonstrated to cause death in dogs (Cucinell et al., 1971). CS is hydrolyzed to malononitrile and 2-chlorobenzaldehyde (Brewster et al., 1987). Further metabolism of malononitrile yields two potential cyanides, which could interact with sulfur thiols to yield thiocyanate. Cyanide typically causes death immediately, but animals administered CS by inhalation far more than the lethal C*t* do not die immediately; death occurs 12–24 h after exposure. In fact, death seems to be attributable to airway and lung damage (Ballantyne and Swanston, 1978). Studies to ascertain cyanide production after CS exposure in humans showed negligible levels of plasma thiocyanate (Leadbeater, 1973). Another study revealed low levels of cyanide production in mice administered carbon 14–labeled CS (Brewster et al., 1987). In short, cyanide is not liberated in sufficient quantity from CS metabolism to become toxic enough to cause death.

While cyanide inhibition of cytochrome *c* oxidase may not account for the full spectrum of toxicity in CS exposure, cyanide toxicity may include an array of biochemical interactions. These include lipid peroxidation (Johnson et al., 1987), cyanide release of endogenous opioids to cause respiratory paralysis, disruption of neuronal calcium homeostasis (Johnson et al., 1986), and phospholipid hydrolysis (Sakaida and Farber, 1990). The mechanism of action for CN follows very closely that of CS because they are both alkylating agents. The

effect of both agents on SH-dependent enzyme systems has been studied (Cucinell et al., 1971). Less is known regarding the mechanism of action for CR intoxication.

Capsaicinoids

Capsaicinoids interact with a population of neuropeptide-containing afferent neurons and activate a "vanilloid" receptor (Szallasi and Blumberg, 1990). There seems to be a requirement by the receptor for a vanilloid ring and an acyl chain moiety for activity (Szallasi and Blumberg, 1999). Vanilloid receptors are part of a superfamily of transient receptor potential cation channels. Binding of a vanilloid-containing ligand to the receptor causes channel opening, influx of Ca^{2+} and Na^{+}, depolarization of the neuron, and release of neuropeptides (Martling, 1987). In addition to transitory excitation of primary afferents, activation of these receptors leads to a prolonged refractory period, indicative of an apparent nonconducting and desensitized state of the receptor. In this refractory period, primary afferents become unresponsive to further application of capsaicinoids. Furthermore, it has been suggested that influx of Ca^{2+} and Na^{+} may lead to rapid cellular damage and eventual cell death (Jancso et al., 1984), possibly by Ca^{2+}-dependent protease activity. Administration of capsaicin in neonatal rats causes destruction of the dorsal root ganglion neurons (Jancso et al., 1977).

The biological actions of capsaicin are primarily attributable to release of the neuropeptide substance P, calcitonin gene–related peptide (CGRP), and neurokinin A from sensory neurons. These transmitters from primary sensory neurons communicate with other cell types. They produce alterations in the airway mucosa and neurogenic inflammation of the respiratory epithelium, airway blood vessels, glands, and smooth muscle. Alterations in multiple effector organs lead to bronchoconstriction, increased vascular permeability, edema of the tracheobronchial mucosa, elevated mucosal secretion, and neutrophil chemotaxis (Tominack and Spyker, 1987). Capsaicin-induced effects of bronchoconstriction, vasodilation, and plasma protein extravasation are mediated by substance P. In addition, substance P can cause bronchoconstriction through stimulation of c-fibers in pulmonary and bronchial circulation.

TOXICOKINETICS

The uptake, distribution, and metabolism of CS, CR, and capsaicins (but not CN) have been well characterized.

Uptake, Distribution, and Metabolism of CS

CS is rapidly absorbed and distributed throughout the body after inhalation exposure. Pharmacokinetic studies show that CS is removed from circulation quickly with first-order kinetics after inhalation exposure. CS half-life is just less than 30 s (Olajos, 2004). Short half-lives in the circulatory system are also demonstrated for the major CS metabolites (2-chlorobenzyl malononitrile and 2-chlorobenzaldehyde) (Leadbeater, 1973). Currently, it is thought that significant amounts of CS, near the tolerable concentration of approximately $10\,mg/m^3$, would not be absorbed after CS inhalation. The absorption of CS from the digestive tract in cases of exposure by ingestion is unknown at this time. Systemic toxicity has been noted after ingestion of CS pellets (Solomon et al., 2003).

In mammalian species, CS rapidly hydrolyzes to form 2-chlorobenzaldehyde and malononitrile (Leadbeater, 1973). The malononitrile intermediate is further metabolized from two cyanide moieties, which are converted to thiocyanate (Cucinell et al., 1971). The aldehyde intermediate undergoes oxidation to 2-chlorobenzoic acid or reduction to 2-chlorobenzyl alcohol. These metabolites are conjugated and excreted in the urine.

Uptake, Distribution, and Metabolism of CR

Absorption of CR after aerosol inhalation is rapid, with a plasma half-life of 5 min; this is consistent with half-life estimates after intravenous administration (Upshall, 1977) and gastrointestinal uptake (French et al., 1983). Corneal tissue has been demonstrated to take-up CR and to metabolize it to the lactam derivative (Balfour, 1978).

A number of studies have investigated the bioconversion, fate, and elimination of CR in various animal species (Balfour, 1978; French et al., 1983). Human metabolic studies of CR have not been performed because of the high degree of sensitivity of human tissues to CR. The maximum tolerated dosage is far too low to allow for detection in metabolic studies (Olajos, 2004). The lactam derivative dibenz[*b*, *f*]1:4-oxazepin-11-(10H)-one is a primary metabolic product of metabolism and a direct precursor of the urinary hydroxylated metabolites. In rats, the lactam, a dihydro-CR metabolite, an amino alcohol of CR, and an arene oxide are metabolites in CR degradation. In the rat, the major mechanism for elimination is sulfate conjugation and biliary excretion to a limited extent. Phase I metabolism by microsomal mixed-function oxidases involves reduction of CR to the amino alcohol, oxidation to form the lactam ring, and hydroxylation to form the hydroxylactams. Phase II conjugation reactions sulfate the hydroxylactam intermediates for renal elimination. Amino alcohol intermediates are conjugated with glucuronide for biliary secretion.

Uptake, Distribution, and Metabolism of CN

The uptake, distribution, and fate of CN have been poorly characterized despite numerous investigations reporting its toxicity. Inhalation of lethal CN, which does

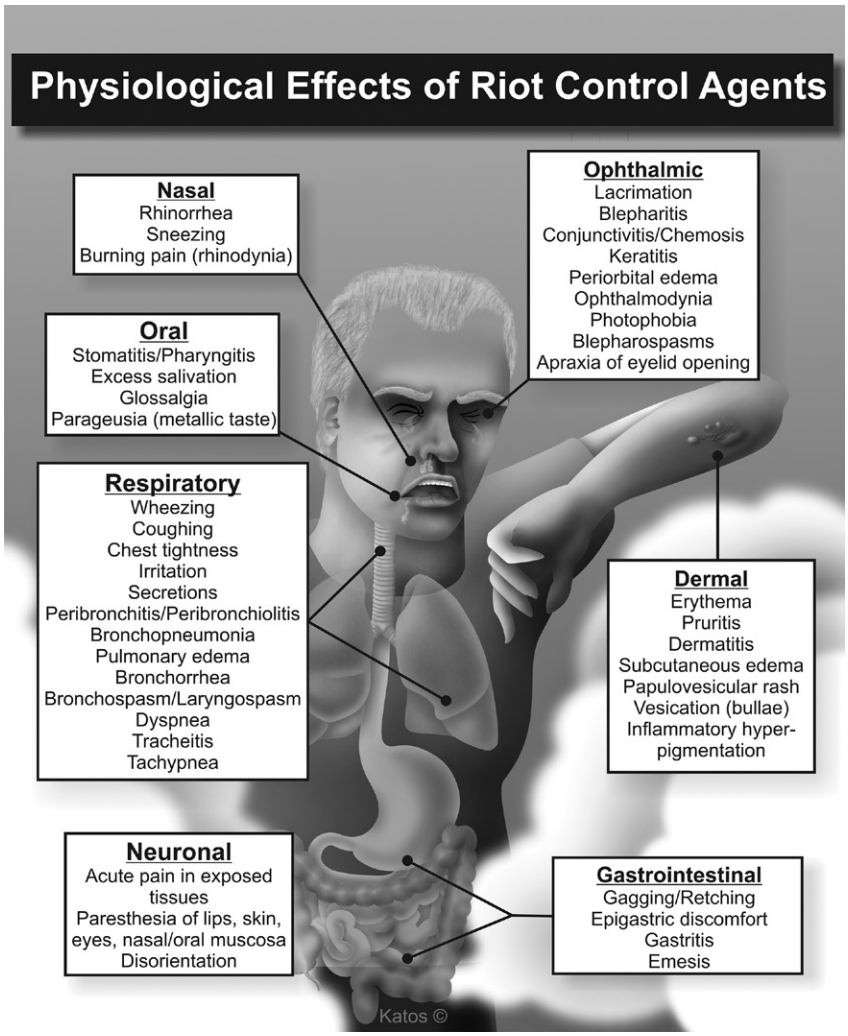

FIGURE 11.11 Physiological effects of RCAs. *Source: Illustrated, copyright protected, and printed with permission by Alexandre M. Katos.*

not metabolize to liberate cyanide, also causes death secondary to effects on the pulmonary system (pulmonary congestion, edema, bronchopneumonia, cellular degeneration in the bronchiole epithelium, and alveolar thickening) in mice, rats, guinea pigs, and dogs (Olajos and Salem, 2001). CN presumably reacts irreversibly with the free sulfhydryl groups of proteins and enzymes. It is thought that CN metabolically converts to an alkylating agent with this affinity for SH groups and nucleophilic sites in tissues (Mackworth, 1948; Olajos, 2004).

Uptake, Distribution, and Metabolism of Capsaicins

Capsaicin and capsaicinoids undergo phase I metabolic bioconversion to catechol metabolites via hydroxylation of the vanillyl ring moiety (Miller et al., 1983). Metabolism involves oxidative, in addition to nonoxidative, mechanisms. An example of oxidative conversion involves the liver mixed-function oxidase system to convert capsaicin to an electrophilic epoxide, a reactive metabolite (Olajos, 2004). Surh and Lee (1995) have also demonstrated the formation of a phenoxy radical and quinine product; the quinine pathway leads to formation of a highly reactive methyl radical (Reilly et al., 2003). The alkyl side chain of capsaicin also undergoes rapid oxidative deamination or hydroxylation (Reilly et al., 2003) to hydroxycapsaicin as a detoxification pathway. An example of nonoxidative metabolism of capsaicin is hydrolysis of the acid–amide bond to yield vanillylamide and fatty acyl groups.

TOXICITY

RCAs produce a wide variety of physiological effects in humans. Figure 11.11 illustrates these generalized toxic signs and symptoms of exposure. The clinical effects in

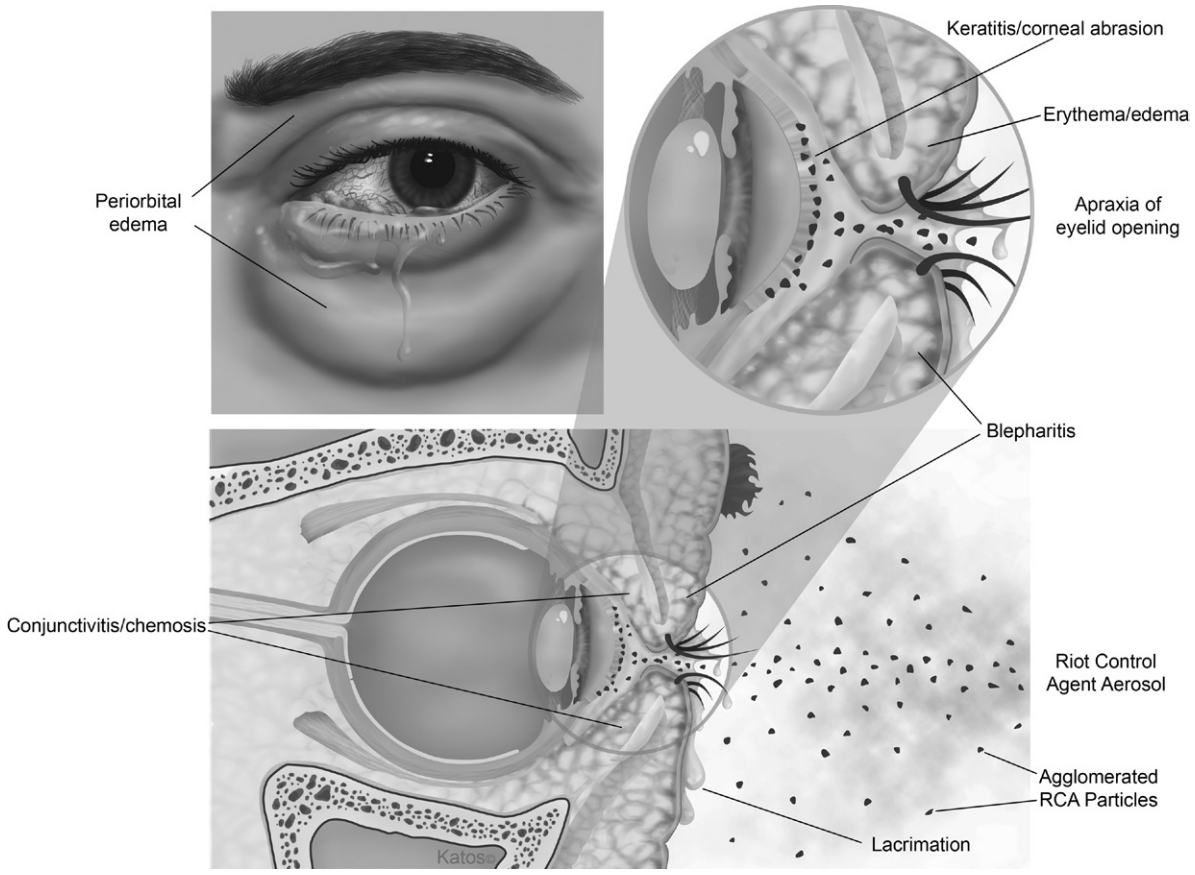

FIGURE 11.12 Exposure of the eye to CS aerosol. Top left panel: External view of left eye immediately after exposure to CS aerosol, showing scleral injection, periorbital edema, and lacrimation. Bottom panel: Penetration of CS aerosol into the eye, sagittal view. Following exposure to CS, the eye responds with inflammation, edema (chemosis), lacrimation, erythema, eye pain, and eyelid closure. Top right panel: Close-up of the eye and eyelids, sagittal view. Inflammation of the eyelids (blepharitis), conjunctivae (conjunctivitis), and cornea (keratitis) are apparent. The eye, in turn, responds with spasms of eyelid closure (blepharospasms) followed by an inability to open the eyelids (apraxia of eyelid opening). Agglomerated CS particles can penetrate the eye on initial contact and cause corneal abrasions. *Source: Illustrated, copyright protected, and printed with permission by Alexandre M. Katos.*

the figure are representative of those encountered after CN or CS exposure. CR causes effects qualitatively similar to those caused by CS, except it has greater potency. The predominant anatomical regions affected include eye, lung, and skin. RCAs also cause nasal, oral, neuronal, and gastrointestinal effects.

Ophthalmological Effects

CN and CS

The eyes are a major target for the short-lived toxic effects of RCAs. Eye findings from RCA toxicity can range in severity from conjunctival erythema to ocular necrosis. Lacrimation, conjunctival erythema/edema, blepharitis, and erythema are the most typical findings after exposure to all RCAs. Toxic signs may further include periorbital edema (Yih 1995), blepharospasm or spasms during eyelid closure (Grant, 1986; Blain, 2003), apraxia of eyelid opening, ophthalmodynia, corneal injury, and ocular necrosis (Grant, 1986). Figure 11.12 illustrates and summarizes the common toxic ophthalmological signs and symptoms associated with RCA aerosol exposure. It is important to note that eye findings tend to be more severe in RCA exposure victims if they are wearing contact lenses (Solomon et al., 2003).

Erythema and edema may last up to 48 h and vascularizing keratitis is not uncommon (Ballantyne et al., 1974), but symptoms generally subside after 30 min (Beswick, 1983), depending on the concentration and duration of exposure (Blain, 2003). Recovery is typically complete within 15–30 min after exposure, but a few signs such as erythema of the lid margins and photophobia may persist slightly longer. The conjunctivae may appear injected or even progress to fulminant conjunctivitis and blurred vision after some RCAs, including CS (Euripidou et al., 2004). Toxic signs in the conjunctivae from CN Mace exposure can include conjunctivitis, sloughing, limbal

ischemia, and symblepharon formation (adhesion of the eyelids to the eyeball) (Scott, 1995). Permanent eye injury is unlikely, except after exposure to high concentrations of CN Mace (Grant, 1986). Although permanent eye damage is uncommon, increased intraocular pressure from edema may precipitate acute angle closure glaucoma if left untreated. Long-term sequelae may include cataracts, vitreous hemorrhage, and traumatic optic neuropathy (Gray and Murray, 1995).

In studies involving human exposure (Rengstorff and Mershon, 1969a,b), CS (0.1% or 0.25% in water; 1.0% in triocyl phosphate) sprayed or administered as ophthalmic drops onto the eyes caused apraxia of eyelid opening with blepharospasm on eyelid closure for 10–135 s. It also caused a transient conjunctivitis but no corneal damage on further inspection with a slit lamp. Rabbit eyes contaminated with CS as a solution (0.5–10% in polyethylene glycol), as a solid, or thermally dispersed as a smoke (15 min at 6,000 mg/m^3) showed greater toxicity with solution. CS in solution caused profuse lacrimation, conjunctivitis, iritis, chemosis, keratitis, and corneal vascularization at concentrations of 1% or more. The lesions tended to be more severe and have a greater duration at higher doses. Histologically, the cornea appeared with patchy denudation of the epithelium and infiltration of neutrophils to the site of injury (Ballantyne et al., 1974). In general, more severe eye exposures have resulted from CN compared with CS agent.

CN causes a similar constellation of ocular signs and symptoms as CS, but CN toxicity is likely to be more severe in the eyes and skin. CN sprayed into the eyes from a distance causes lacrimation, edema of the corneal epithelium and conjunctivae, and reversible epithelial defects of the cornea (Leopold and Lieberman, 1971). At close range, CN can cause long-lasting and permanent damage to the eye. Because RCAs are solids, it is possible for a particle to clump or agglomerate, causing penetration into corneal or conjunctival tissues (Figure 11.12). Agglomerated CN particles can penetrate eye tissue as a result of tear gas cartridge discharge (Levine and Stahl, 1968). In addition to large powder CN agglomerates, traumatic effects from the propellant charge, wadding, or foreign pieces from the cartridge should also be suspected when evaluating eye damage from CN.

Although RCAs produce short-lived effects, rabbits exposed to 10% CN solution caused iritis and conjunctivitis for more than 7 days and caused corneal opacity (Grant, 1986) lasting longer than 2 months (Gaskins et al., 1972). In comparison, CS at the same concentration produced moderate conjunctivitis without iritis or corneal opacity, and eyes returned to normal by the end of 1 week. Another difference between the two agents is that CN produces a more severe reaction than CS when applied to the eye in powder form or as a spray at close range (McNamara et al., 1968).

In addition to opacification, additional corneal effects from particulate CN exposure include possible penetration of the corneal stroma, severe scarring and ulceration, and deficits in the corneal reflex (Scott, 1995; Blain, 2003). Penetration of the corneal stroma may lead to stromal edema and later vascularization, resulting in further ocular complications. These may include pseudopterygium, infective keratitis, symblepharon, trophic keratopathy, cataracts, hyphema, posterior synechia, secondary glaucoma, vitreous hemorrhage, and traumatic optic neuropathy (Hoffman, 1967). Furthermore, a 4% CN formulation produced permanent corneal injury but a 10% CS product did not (Gaskins et al., 1972). In animal studies, high concentrations of CN produce ocular necrosis (Grant, 1986).

The eyes are also affected by a CS agent without direct contact between the agent and the eye. In one report, seven patients were exposed to oral ingestion of a juice drink contaminated by CS pellets (Solomon et al., 2003). In addition to mild headache and gastrointestinal irritation, patients reported ocular irritation and lacrimation. The majority of symptoms resolved within 24 h of exposure.

CR

Higginbottom and Suschitzky (1962), the chemists who discovered CR, first noted the intense lacrimal response to this compound. A splash of CR (0.01–0.1% range solution) causes immediate ophthalmodynia, lacrimation, and blepharospasm, similar to CS and CN (Sidell, 1997). These effects can last 15–30 min before subsiding. Blepharitis (edema of the eyelids), periorbital edema, and injected conjunctivae can last for up to 6 h. In rabbits and monkeys, CR (0.1% solution) causes mild transient erythema, chemosis, and keratitis in the eye. Moderate conjunctivitis has been demonstrated with higher CR concentrations (5% solution) applied directly to the rabbit eye (Rengstorff et al., 1975). Ballantyne et al. (1975) showed that increasing CR concentrations as a solution caused dose-dependent corneal thickening but minor eye effects (mild conjunctivitis and lacrimation) as an aerosol. In animal studies, the effects of CR on the eye are very transient as they are cleared in 1 h, and it produces far less toxicity to the eye than CN (Salem et al., 2006).

Capsaicin

Capsaicin causes conjunctivitis, periorbital edema/erythema, ophthalmodynia, blepharospasm, blepharitis, corneal abrasions, and lacrimation. In a retrospective study of 81 patients who presented to the emergency department after aerosol exposure from law enforcement use of OC, 56% of individuals developed ophthalmodynia, 44% developed conjunctivitis, 40% developed conjunctival erythema, 13% developed lacrimation, and 9% developed corneal abrasions (Watson et al., 1996). Another study involved exposure of 47 human

volunteers to OC for evaluating effects on the cornea and conjunctivae (Zollman et al., 2000). All subjects reported significant eye pain, blurred vision, and lacrimation 10 min after exposure to OC pepper spray, but symptoms improved by 1 h later. Corneal abrasions were not apparent, but 21% of subjects showed evidence of punctate epithelial erosions and reduced corneal sensitivity. Corneal abnormalities were absent 1 week after exposure. Another human study identified 23% of subjects (7 of 30) with corneal abrasions after aerosol exposure to OC spray (Watson et al., 1996). In mice, a single subcutaneous injection of 12.5, 25, or 50 mg/kg capsaicin causes corneal changes characterized by neuronal axon degeneration in the corneal epithelium (Fujita et al., 1984).

Nasal/Pharyngeal Toxicity

RCAs produce oral and nasal symptoms immediately after exposure. Inhalation exposure to CN and CS causes rhinorrhea, sneezing, and burning pain within seconds (Beswick, 1983); a similar burning sensation with increased salivation occurs after oral contact with aerosolized powder or solution. The salivation, pharyngitis, and glossalgia occur within minutes after exposure (Thorburn, 1982; Beswick, 1983). A CR solution (0.01–0.1% range) splashed in the mouth causes salivation and burning of the tongue and palate for several minutes. Splashes of the solution can cause nasal irritation and rhinorrhea (Sidell, 1997). Fumes from burned *Capsicum* plants or capsaicin-containing pepper sprays are highly irritating to the nasal mucosa and cause immediate rhinorrhea (Geppetti et al., 1988).

Cardiovascular Toxicity

Although the evidence is not overwhelmingly impressive, RCAs have apparent effects on the cardiovascular system. Tachycardia and mild hypertension have been noted after exposure (Beswick, 1983). This response may result from anxiety or may be a reaction to the pain as opposed to any toxicological effect. The initial response to aerosolized CS is hypertension and irregular respiration, suggestive of the Sherrington pseudoeffective response. Bypassing the pain receptors of the nose and upper airway by endotracheal administration of CS leads to a decrease in blood pressure and bradypnea, effects also seen after intravenous injection. This suggests the initial pressor effect and irregular respiration are generalized responses to noxious stimuli rather than pharmacological effects of CS. Splash contamination of the face or whole-body drenching with dilute CR solution (0.0010% and 0.0025%) causes an immediate increase in blood pressure and bradycardia (Ballantyne et al., 1976). Intravenous administration of CR in cats causes transient but dose-dependent tachycardia. These pressor effects are postulated to be secondary to CR effects on sympathetic tone to the cardiovascular system or the result of stress and discomfort from the irritation (Ballantyne, 1977a,b).

RCAs have been shown to have a direct effect on the heart. One report linked exposure of high CS concentrations to the development of congestive heart failure (Hu et al., 1989). Furthermore, underlying cardiac disease has been shown to exacerbate toxicity from CS (Worthington and Nee, 1999).

Respiratory Toxicity

CS and CN are disseminated as an aerosol powder or solution. Therefore, the most common route of CN or CS absorption is by inhalation. Inhalation of RCAs causes burning and irritation of the airways, leading to cough, chest tightness, dyspnea (Beswick, 1983; Hu et al., 1989; Blain, 2003), shortness of breath (Euripidou et al., 2004), bronchospasm, and bronchorrhea (Folb and Talmud, 1989). Estimates of the minimal irritant exposure and ICt50 are 0.004 and 5 mg min/m^3, respectively, for CS (Olajos and Salem, 2001). Similar estimates have been made for CN (0.3–1 and 20–50 mg min/m^3) (Olajos and Salem, 2001). Other estimates report that 31 mg/m^3 CN vapor is intolerable to humans after 3 min (Punte et al., 1962).

Laryngospasm can occur immediately or can be delayed for 1–2 days after CN or CS exposure. Delayed-onset laryngotracheobronchitis 1–2 days after exposure, characterized by wheezing, dyspnea, tachypnea, hoarseness, fever, and purulent sputum, was reported in three of eight patients exposed to high concentrations of CN (Thorburn, 1982). Long-term bronchodilator therapy was required in one patient with preexisting pulmonary disease. Reactive airways are associated with high-level exposure to CS and CR (Blain, 2003). Paroxysmal cough, shortness of breath, and chest tightness, characteristic of reactive airway disease, have been demonstrated to last up to several weeks. Pulmonary effects typically resolve by 12 weeks after exposure.

Pulmonary edema may occur up to 24 h after exposure (Stein and Kirwan, 1964; Gonmori et al., 1987). Gonmori et al. (1987) reported a fatality from chloropicrin spray intoxication. The patient, an 18-year-old female, developed pulmonary edema 3 h after exposure. Furthermore, a 43-year-old man developed pulmonary edema complicated by pneumonia, heart failure, and hepatocellular damage after CS intoxication (Krapf and Thalmann, 1981). Delayed-onset bronchopneumonia may occur from prolonged exposure to some RCAs in enclosed spaces (Beswick, 1983).

There is no evidence that CS causes permanent lung damage after one or several exposures to field concentrations (Blain, 2003). Inhalation of an irritant might be expected to exacerbate underlying pulmonary disease such as asthma, emphysema, or bronchitis. Histories of

asthma and chronic obstructive pulmonary disease may exacerbate effects from CS (Worthington and Nee, 1999) or CN (Thorburn, 1982). CS may exacerbate chronic bronchitis or precipitate an attack in individuals with known asthma (Anonymous, 1971).

CN and CS Toxicity in Animals

In animal studies, the cause of death from CN inhalation is the result of toxicity in the pulmonary system. Postmortem examination from acute toxicity lethality studies in animals exposed to CN aerosols reveal pulmonary congestion, edema, emphysema, tracheitis, bronchitis, and bronchopneumonia in dogs, and pulmonary congestion, edema, and bronchopneumonia in mice, rats, and guinea pigs (Olajos and Salem, 2001). Sublethal CN aerosol exposure (62.6 mg/m^3, 0.1 LC50) for 60 min causes cellular degeneration in the bronchiole epithelium and alveolar septal wall thickening attributable to infiltration of mononucleocytes (Kumar et al., 1995).

Exposure to aerosol CS (unreported concentration) in male Wistar rats for 20 min can cause decreased minute ventilation and induce histological lesions of the trachea (cytoplasmic vacuoles in epithelial cells) and lung (emphysema) (Debarre et al., 1999). Lower respiratory tract injury, including fibrosing peribronchitis and peribronchiolitis, can be produced by chloropicrin (Buckley et al., 1984).

CR

CR does not produce any significant respiratory toxicity (Sidell, 1997). CR causes tachypnea and labored breathing in multiple animal species. In humans, aerosol exposure to CR causes respiratory irritation, choking, and dyspnea. One human study involving aerosol exposure to CR (0.25 mg/m^3) in volunteers for 60 min noted decreased expiratory flow rate minutes after exposure. CR was thought to stimulate irritant receptors in the conducting portion of the pulmonary system, causing bronchoconstriction (Ashton et al., 1978). Additionally, CR increased blood volume in the lungs by driving sympathetic tone. Two animal studies evaluated the effect of CR aerosol exposure on the physical and ultrastructural changes in rat lungs (Pattle et al., 1974; Colgrave et al., 1983). Even high CR aerosol doses did not produce significant pulmonary damage. Gross examination of the lungs was normal in both studies. Microscopic examination showed mild congestion, lobar hyperinflation characteristic of emphysema, and hemorrhage. Further pulmonary damage was evident on electron microscopy. CR-exposed lungs showed capillary damage of the endothelium and a thickened, swollen epithelial layer (Colgrave et al., 1983).

Capsaicin

In children, capsaicin spray was demonstrated to cause severe bronchospasm and pulmonary edema (Billmire et al., 1996). In the Billmire study, a 4-week-old infant was exposed to 5% pepper spray after discharge from a self-defense device. The infant suffered respiratory failure and hypoxemia requiring immediate extracorporeal membrane oxygenation. Inhaled capsaicin causes an immediate increase in airway resistance (Fuller, 1991). This dose-dependent bronchoconstriction after capsaicin inhalation in humans is the same as that demonstrated in asthmatics and smokers (Fuller et al., 1985). The capsaicin-induced bronchoconstriction and release of substance P is attributable to stimulation of nonmyelinated afferent C-fibers.

Neurologic Toxicity

RCAs are irritants to the peripheral nervous system (Anonymous, 1999). CN and CS interact with receptors on sensory nerves in the eyes, other mucous membranes, and skin, resulting in discomfort and burning pain. Their neurologic toxicity can range from paresthesias of the lips to burning pain of the eyes (ophthalmodynia), tongue (glossalgia), nose (rhinodynia), throat (pharyngodynia), and skin (dermatalgia). The reaction of CN with sulfhydryl (SH)-containing proteins and enzymes is the cause of denaturation associated with sensory nerve activity (Chung and Giles, 1972). Because RCAs affect the senses, the feeling can become disorienting after exposure, which may explain why some experience temporary loss of balance and orientation after exposure (Thorburn, 1982).

Agitation and panic may develop in those not previously exposed to CN (Stein and Kirwan, 1964; Beswick, 1983). Syncope has also been reported (Thorburn, 1982; Athanaselis et al., 1990), but this is likely attributed to panic. Headaches have been reported in 48% of symptomatic persons exposed to chloropicrin (Goldman et al., 1987). When CN was released into 44 prisoner cells, eight inmates experienced malaise and lethargy; among those hospitalized, one experienced syncope and a severe systemic illness (Thorburn, 1982).

A clinical case report of hand injuries caused by accidental discharges from tear gas pens (Adams et al., 1966) revealed specific neuronal toxicological findings. In each case, CN penetrated into the skin to cause a wound. Neurological examination indicated hyperesthesia of select digits in all cases. Biopsies of digital neurons performed for pathology showed thickened epineurium and tendon sheaths. Some of the patients reported paresthesias months after exposure. The study suggests a possible link between direct chemical injury and nerve damage. The same investigators exposed the sciatic nerves of rabbits to the agent by discharge of a CN pen or by dusting the exposed nerve with 0.2 g CN powder. These animal studies suggested CN can cause inflammation and necrosis in skeletal muscle,

loss of axon cylinders, and replacement of neural elements with granulation tissue and fibroblasts (Adams et al., 1966). Animals exposed to CR exhibit fasciculations, tremors, convulsions, and ataxia; intraperitoneal administration of CR can also cause muscle weakness (Salem et al., 2006).

Capsaicin activates receptors in trigeminal (cranial nerve V) and intestinal neurons. These include pain receptors located in the mouth, nose, stomach, and mucous membranes. Trigeminal neurons utilize substance P as their primary pain neurotransmitter. Capsaicin first induces the release of substance P from the neuron and then blocks the synthesis and transport of substance P to the effector side (Bernstein et al., 1981; Tominack and Spyker, 1987). Substance P depolarizes neurons to produce dilation of blood vessels, stimulation of smooth muscle, and activation of sensory nerve endings (Tominack and Spyker, 1987). Jancso characterized the effects of capsaicin as an initial intense excitation of sensory neurons followed by a lengthy period of insensitivity to physicochemical stimuli (Jancso et al., 1968, 1987). Substance P is associated with sensory (pain) or skin inflammation afferents. It is also a peripheral mediator of neurogenic inflammation and smooth muscle contraction (Lembeck and Holzer, 1979). It contributes to contraction of the esophagus, trachea, respiratory tract, and levator palpebrae muscles (blepharospasm and apraxia of eyelid opening). Capsaicin directly applied to the eye causes a neurogenic inflammation involving vasodilatation and extravasation of fluid and unresponsiveness to chemical stimuli. Capsaicin renders the skin of humans and animals insensitive to various types of painful chemical stimuli (Bernstein et al., 1981). In humans, OC exposure eventually causes loss of the corneal blink reflex (Olajos and Salem, 2001), which is mediated by sensory input from cranial nerve V and motor output via cranial nerve VII.

Gastrointestinal Toxicity

Many reviews state that gastrointestinal effects do not occur on inhalational exposure to RCAs, with the exception of DM; however, nausea, vomiting, and alterations in taste are commonplace in clinical case reports of exposure to CS (Athanaselis et al., 1990; Solomon et al., 2003) and CN (Thorburn, 1982; Blain, 2003). The involvement of retching and emesis tends to occur if the individual is sensitive, the concentration is sufficiently high, the exposure is prolonged, the range is close, or the event occurs in a confined space. Vomiting was reported in 25% of patients with severe reactions to CN in a confined area (Thorburn, 1982). Emesis did not resolve until the next week in one patient. Inhalation of RCAs often leads to parageusias or altered taste of the tongue. In particular, a metallic or burning sensation is often reported (Folb and Talmud, 1989).

Ingestion of CS can also produce episodes of nausea, vomiting, crampy abdominal pain (Blain, 2003), and diarrhea (Blain, 2003; Solomon, 2003). Seven patients in the Solomon study drank juice contaminated with CS pellets and primarily developed gastrointestinal symptoms. Two of the seven patients reported emesis and diarrhea; all patients reported abdominal pain, epigastric discomfort, and burning gastroesophageal reflux. Symptoms resolved 24 h later. Surprisingly, they did not develop parageusia or burning of the tongue after CS ingestion, which is often the case after inhalational CS exposure. Another study designed for patients to taste an admixture of sugar and CS (5–10 pellets, 500 mg each, dissolved in 10 L of water) indicated that patients experienced a 30 s delay in onset of altered taste (Kemp and Willder, 1972); this was most likely because of a masking effect from the sugar. In animal studies, rabbits and rats develop gastroenteritis on CN or CS exposure by ingestion (Gaskins et al., 1972).

Biting and ingesting *Capsicum* plants can cause nausea and vomiting (Tominack and Spyker, 1987). Nausea has also been reported in individuals exposed to pepperball tactical powder containing capsaicin (Hay et al., 2006). Capsaicin causes effects on gastric mucosa, including mild erythema, edema, epithelial cell damage, and gastric hemorrhage (Desai et al., 1977).

Dermatological Toxicity

CN and CS are primary irritants of the integumentary system able to cause first-degree and second-degree burns (Stein and Kirwan, 1964; Weigand, 1969; Hu et al., 1989). Low concentrations of either agent cause erythema, pruritis, subcutaneous edema, paresthesias, and/or burning sensations in exposed areas of the skin within minutes. Erythema is often the first sign of contact dermatitis, occurring minutes after exposure and subsiding approximately 1 h after exposure. These agents follow a time course of skin damage similar to that of mustard agent. Further, if the skin is wet or abraded, then the toxic effects on the skin are more prominent (Holland and White, 1972; Thorburn, 1982; Sidell, 1997). Exposure to higher doses leads to worsening erythema, edema, vesication with bullae (observed hours later), and fever. The extent of toxic effects also depends on thickness of the stratum corneum and time of exposure. Furthermore, contact with water up to 48 h after exposure can exacerbate the painful symptoms (Pinkus, 1978; Blain, 2003). High humidity, diaphoretic subjects, and warm temperatures can all exacerbate the contact dermatitis from RCAs (Hellreich et al., 1969). Areas of occlusive dress over the skin may also result in worse reactions.

Higher concentrations of CS or longer exposures will result in more than erythema, pruritis, and burning pain. Papulovesicular rashes are not uncommon with high

concentrations of RCAs. Typically, edema and vesiculation (bullae dermatitis) occur 24 h after CS or CN exposure (Sidell, 1997). Common sites of bullae are areas under the cuff of a shirt or glove and just under the collar. One study examined the effect of high CS concentrations (300 mg/m^3) tested on the arms of volunteer study patients for exposure times ranging between 15 and 60 min (Hellreich et al., 1967). All participants experienced burning pain approximately 5 min after exposure onset. A Ct range of 4,440–9,480 mg min/m^3 caused immediate patchy erythema, which subsided after 30 min. A Ct range of 14,040–17,700 mg min/m^3 led to greater dermal toxicity and required several hours to subside. Bullous dermatitis occurred in 50% of subjects as a delayed reaction. These bullous lesions resolved in 2 weeks, but an inflammatory hyperpigmentation of the skin remained by 6 weeks after exposure. Differences in individual sensitivities are attributable to skin pigmentation, complexion, and susceptibility to sunburns (Hellreich et al., 1969).

Exposure to other RCAs causes similar dermal effects. CN is a more potent irritant than CS. In a human study involving dermal application, CN (0.5 mg) powder caused irritation and erythema when on the skin for 60 min (Holland and White, 1972). It took 20 mg CS to cause similar effects for the same duration of exposure. Exposure to 5% capsaicin pepper spray causes immediate and severe erythema and edema in the skin (Herman et al., 1998). Similarly, pepperball pellets fired at individuals will cause erythema, pain, and edema at the site of impact. The initial point of contact may become infected, scar, or heal with hyperpigmentation (Hay et al., 2006).

Dermal exposure to CN or CS may lead to an allergic contact dermatitis (Madden, 1951; Penneys, 1971), a delayed hypersensitivity reaction that develops from a previous exposure to RCAs. CS and CN are both skin sensitizers, but CN is more potent (Chung and Giles, 1972). Initial exposure to either may not cause significant toxic signs or symptoms. Exposure to small amounts of the same agent years later, however, may produce a severe allergic erythematous, patchy rash with edema, bullae, purpura, and necrosis. Sensitization is likely to occur after dermal exposure to high concentrations of RCAs (Holland and White, 1972). Hypersensitivity reactions can persist for up to 4 weeks. This phenomenon has been demonstrated so far by CN (Ingram, 1942; Frazier, 1976) and CS (Ro and Lee, 1991), but not CR.

Dermal exposure to CR causes a burning sensation and erythema several minutes later. Burning pain goes away after 15–30 min, but the erythema lasts up to 2 h (Holland, 1974). CR does not induce inflammatory cell migration to the site of injury, bullous dermatitis, or contact sensitization (Ballantyne, 1977a). Repeated application of CR to the skin (applied 5 days/week for 12 weeks) has little effect (Marrs et al., 1982). Similar to the eye and lungs, CR does not demonstrate significant toxicity to the skin.

Hours after dissemination, CS, CN, or CR can pose a toxic danger because they are persistent in the environment. During the riots of the late 1960s, CS was frequently used to control crowds. Inadvertently, firefighters in those metropolitan areas sometimes were exposed as they entered buildings where CS had been disseminated. The force of water from fire hoses and movement within the buildings reaerosolized enough agent toxic enough to cause erythema and edema around the eyes and other areas of exposed skin (Rengstorff and Mershon, 1969a).

Although capsaicinoids may have a vesicant effect, depending on length of exposure, in most cases it produces a burning sensation and mild erythema. Capsaicins cause erythema and burning pain without vesiculation when applied topically to human skin (Watson et al., 1996; Herman et al., 1998). Skin blistering and rash may occur after chronic or prolonged capsaicin exposures.

Other Toxicity

One report noted renal tubular nephritis in a worker killed after an explosion inside a plant manufacturing CS agent (Cookson and Nottingham, 1969). Hepatocellular injury has been linked to serious CS inhalation (Krapf and Thalmann, 1981). To date, animal studies have not documented any relationship between RCA exposure and teratogenicity (Folb and Talmud, 1989). CS did not demonstrate mutagenic potential with the Ames assay (Rietveld et al., 1983). Similarly, CR did not have carcinogenic effects in mice or hamsters (Blain, 2003); CS lacks mutagenicity in several test systems (Wild et al., 1983).

Lethality

Human deaths have been reported from RCA exposure (Thorburn, 1982). Death is usually the result of excessive concentrations used, confined spaces, and prolonged exposures. Death occurs hours after initial exposure, and postmortem findings are consistent with severe airway damage seen in animals. Deichmann and Gerarde (1969) reported a fatality after exposure to high CN vapor concentrations (5.4 g in a 34 m^3 room) for less than 20 min, which equates to approximately 160 mg/m^3. Estimates of the human LCt50 range between 25,000 and 150,000 mg min/m^3 for CS and between 8,500 and 22,500 mg min/m^3 for CN (Olajos and Salem, 2001). High doses of CR aerosol do not produce lethality in animals; CR aerosols of 68,000 mg min/m^3 are not lethal in mice, guinea pigs, or rabbits. The large safety ratio for CR is clearly evident as compared with the other agents.

Although OC is widely regarded as a safe substance with low toxicity, more research should be conducted in light of recent deaths involving pepper spray use by law enforcement agencies. One case involving an inmate who died in custody implicated pepper spray as a direct

contributor to death (Steffe et al., 1995). Billmire et al. (1996) reported the life-threatening effects in a 4-week-old infant exposed to OC spray as a result of an accidental discharge.

RISK ASSESSMENT

The ideal process in RCA risk assessment is to characterize the effectiveness and risk from exposures to situations in which RCAs may be used (National Academy of Sciences/National Research Council, 1994; TERA, 2001; Patterson et al., 2004). To do that, one must identify all pertinent effects of the RCA in question, develop a dose–response assessment, consider an exposure assessment, and finally characterize the risk. When used as intended, RCAs are thought to be safe and of sufficiently low toxicity. They are designed with the purpose of disabling a targeted individual through sensory irritation of the eyes, respiratory tract, and skin. As discussed previously, they are not without additional unwanted effects, especially in circumstances in which high concentrations are used or exposure is prolonged. The previous sections have provided sufficient discussion regarding the potential toxicity to humans as a result of exposure to RCAs, including case reports.

Identification of Intended and Unintended Effects

By providing a minimal force alternative for controlling and managing individuals, RCAs are a desired public health and safety tool for military, domestic law enforcement, and civilian use. As with any chemical intended to benefit the public, it is important first to identify the compounds, their potential adverse impact (unintended effects), and their beneficial impact (intended effects). There are a number of chemicals designed and used as RCAs. In general, they are compounds with low vapor pressures and dispersed as fine particles or in solution from a variety of devices. These dispersal methods can include the gamut from aerial spray (Figure 11.6) to large spray tanks (see Figures 11.2 and 11.4) and small hand-held devices for self-protection. The modern RCAs used today include CN, CS, CR, OC, and PAVA. Their major adverse effects are summarized in Table 11.2. The intended effect for all RCAs is a change in behavioral response of the target. A better measure of this intended effect would be the actual physiological effects produced by RCAs on the eyes, skin, and respiratory tract (Patterson et al., 2004). These are the target organs designed for irritation by RCAs (see Figure 11.11 for review).

Each physiological effect can be evaluated and categorized on a broad spectral continuum from mild to severe. At lower aerosol dosages, the effects from RCAs will be reversible with no serious injury. For instance, typical mild ophthalmic effects include lacrimation (tearing) and transient burning pain (ophthalmodynia). When used at higher levels, in confined spaces, and/or for prolonged duration, there is a greater potential for the toxicity to escalate. Moderate effects would include conjunctivitis, keratitis, blepharitis, chemosis, and periorbital edema. Severe effects result from significantly prolonged duration or high concentrations leading to irreversible damage in the tissues (i.e., loss of vision). These include corneal abrasions, scarring, or opacification. Very serious effects on the eye include symblepharon, pseudopterygium, cataracts, hyphema, posterior synechia, secondary glaucoma, vitreous hemorrhage, and traumatic optic neuropathy. The same analysis can be applied to effects on the skin, respiratory tracts, and additional organ systems affected for each agent.

Dose Response

Dose–response assessment involves evaluating the dose required to produce a particular effect of interest. Ideally, quantitative data on specific doses and their corresponding responses are desired. In reality, threshold data for a particular target organ or effect in a target organ are often available as a substitute. The ophthalmic threshold levels and toxicity estimate for human responses to CN, CS, and CR are shown in Table 11.2. If empirical dose–response data are available, then a dose–response evaluation for a given RCA might include plotting the percent of individuals responding as a function of dose for each toxicological sign or symptom and target organ of interest. Dose–response curves can then be used in modeling studies to estimate the probabilities of intended and unintended effects for a particular risk assessment scenario (Patterson et al., 2004).

Exposure Assessment

The crux of exposure assessment is creating a scenario for human exposure to a given RCA and identifying the exposure factors. This would involve describing the intended targets, environmental conditions (windy, rainy weather, etc.), crowd size and characteristics, delivery device (tear gas canisters or grenades, powder or aerosol), hazards associated with the delivery system such as blunt trauma, the nature of the agent selected (physicochemical properties, solvents, concentration/dose), and duration of exposure. An exposure assessment might include estimation of the amount of systemic exposure through RCA inhalation, absorption through the skin from dermal contact, or intestinal uptake after ingestion. Availability of quality data for each of the aforementioned exposure factors will estimate exposure

with high confidence and a minimal uncertainty level. Unavailability of data is a major limitation if models are used to estimate exposure.

Characterization of the Risk and Risk Management

Estimating or developing probabilities of toxic effects within a population is at the heart of risk characterization. It integrates dose–response and exposure assessments. It is designed to provide the probability of occurrence for effects induced by a given RCA given a particular exposure scenario. For example, a decision-maker will use risk characterization to estimate the probability of a group of effects occurring as a result of clearing a confined space with CS. The probability can be derived as a function of the number of tear gas grenades used. Unfortunately, there is a dearth of specific federal risk assessment and risk management guidance or mandates on RCAs. Therefore, the potential for risk management or mitigation of concerns is not optimized for the health and benefit of the public good (Hauschild, 2004). This is partly attributable to the fact that the process for assessing risk of toxic chemicals has yet to be standardized among federal programs (Burke et al., 1993). Computer modeling to aid risk assessment without empirical data to feed the model can be an academic exercise. The two in combination can be a powerful predictor for risk assessment of any toxic chemical.

TREATMENT

Exposure to RCAs leads to a generalized stress reaction, causing leukocytosis (Thorburn, 1982), hypokalemia, elevated total protein, increased globulin, and high bicarbonate levels (Beswick et al., 1972). Treatment for RCA toxicity is not often required because the course of intoxication is self-limiting for the most part. Serum toxicological testing is not available to detect RCAs (Sidell, 1997). Clinical signs and symptoms from RCA exposure subside in less than an hour. Initial care involves removing the victim from a potentially crowded area of dispersal immediately to minimize exposure time. It is important to note that these victims may require additional assistance during evacuation because of their reduced vision and disorientation. In circumstances in which the concentration of the agent is substantially elevated or the area of release is confined, increased complications and risks of morbidity may arise in the eyes, skin, airways, and lungs.

Eyes

If the eyes are involved to any degree, then a protective mechanism to close the eyelids will be initiated as a result of conjunctivitis, iritis, or keratitis. Photophobia, blepharospasm, and apraxia of eyelid opening prevent the clinician from evaluating the damage. However, a local anesthetic applied to the eye will help with eye pain and allow for further evaluation of the eye by slit lamp. Contact lenses should be immediately removed and the eyes flushed of any dusting or agglomerated solid particles (see Figure 11.12). Eyes should be irrigated with copious volumes of water or saline for at least 15 min to adequately flush the irritant. Diphoterine has also been used to decontaminate eyes and skin after CS tear gas exposure (Viala et al., 2005). If symptoms or signs of eye toxicity persist, then consultation with an ophthalmologist is critical. Elderly patients should be monitored for evidence of possible acute glaucoma (Yih, 1995).

Skin

Early signs of skin toxicity at the time of clinical presentation will often be contact or allergic dermatitis because blisters form hours later. Removal of clothing should be the first step in decontamination. Placement of contaminated clothes in sealed plastic bags by first responders will prevent secondary contamination as a result of reaerosolized agent (Horton et al., 2005). Early studies of CS indicated that mixing CS with sodium hypochlorite (or household bleach) produced a greater reaction than CS alone in patch testing (Punte et al., 1963). Despite its usefulness as a decontaminant for many chemical agents, hypochlorite should never be used to decontaminate RCAs on skin. Use of water for decontamination of skin may result in an initial worsening of the burning sensation (described previously). A solution of 6% sodium bicarbonate, 3% sodium carbonate, and 1% benzalkonium chloride has been shown to provide immediate relief from CS dermatitis as the alkaline solution hydrolyzes the agent (Weigand, 1969; Sidell, 1997). Consultation with a burn unit should be considered when large areas of skin are involved or when children are affected. Medical treatment for dermatitis may include topical steroids such as triamcinolone acetonide (Hellreich et al., 1967; Sidell, 1997), oral antihistamines for pruritis, and topical antibiotics such as silver sulfadiazine (Hellreich et al., 1967). Systemic antibiotics can be administered for secondary infection. Oozing lesions from bullae dermatitis should be treated with wet dressings and changed daily. Deroofing closed vesicles is controversial (Carvajal and Stewart, 1987). Tetanus prophylaxis should be considered.

Respiratory

Removing an exposed patient from the source of intoxication to fresh air will provide immediate improvement.

Patients should be evaluated for hypoxia with pulse oximetry and arterial blood gases. Pulmonary function tests may be helpful in patients with prolonged pulmonary symptoms and followed-up until symptoms resolve. Chest radiography might be useful if concentration was sufficiently high, exposure was prolonged, or dispersal occurred in a confined space. Pulmonary edema may be delayed for 12–24 h after exposure, suggesting a need for follow-up radiographs (Stein and Kirwan, 1964; Solomon, 2003). Laryngospasm is a serious complication that may require tracheal intubation to secure a patent airway. Bronchospasm may be treated with inhaled beta-2 agonists, steroids (methylprednisolone), and aminophilline (Ballantyne and Swanston, 1978; Folb and Talmud, 1989). Arterial blood gas and pulse oximetry should be continued if patients are symptomatic hours after exposure.

CONCLUDING REMARKS AND FUTURE DIRECTION

The goal of RCAs is to irritate or produce temporary incapacitation. Use of irritants to harass enemies dates back several thousand years. Today, law enforcement agencies and military personnel use RCAs for quelling protestors, controlling crowds, subduing combatants, clearing buildings, training in chemical warfare, and area denial. Individuals use hand-held devices for self-protection against an assailant. RCAs are dispersed as aerosols or sprays, causing irritation of mucous membranes of the eyes, respiratory tract, and skin. Symptoms and signs of toxicity typically subside by 30–60 min.

Several lines of evidence suggest that RCAs are safe if used as they were originally intended. Even though RCAs are considered safe, nonlethal, temporary incapacitating agents, they are not without risk. Some of the adverse clinical effects from RCA exposure reported in the literature have involved indiscriminate use (excessive concentrations), prolonged exposure, and dissemination of compound in a confined space. In summary, these nonlethal agents can pose a serious health hazard in their intended targets. Some RCAs have such a poor safety profile that they have been abandoned long ago (DM and CA). CN and CS have a large body of literature from which to compare and contrast their safety, toxicity, and potency. As the data clearly suggest, CS is a safer compound compared with CN. The latest newcomers to the RCA scene are the inflammatory capsaicinoids. OC and PAVA are highly effective irritants that cause similar symptoms as CN and CS. Capsaicinoids gained considerable attention in the 1990s from police departments and the public at large for safe and effective chemical incapacitation of individuals. These compounds are primarily used as defensive sprays by law enforcement to subdue a combative suspect or by individuals for self-protection. Although OC, PAVA, and related capsaicinoids produce a similar constellation of toxic signs and symptoms, they are not currently used to control crowds at the level of a riot. If OC-containing pepper spray is preferred for riot control, then more research will be required to determine whether it is safe for humans. Finally, risk assessment is a process that can identify gaps in the literature and therefore serves to highlight research needs.

The toxicology of RCAs has been the focus of numerous reviews, publications, and textbooks. RCAs comprise a diverse array of chemical compounds with similar toxicities since their introduction on the battlefield in the early part of the past century. They are all designed with the purpose of disabling a targeted group or individual through sensory irritation of the eyes, respiratory tract, and/or skin. By providing a minimal force alternative for controlling and managing individuals, RCAs are a desired public health and safety tool for military, domestic law enforcement, and personal use.

Psychotomimetic Agent BZ (3-Quinuclidinyl Benzilate)

Josef Fusek, Jiri Bajgar, Jiri Kassa, Kamil Kuca and Daniel Jun

INTRODUCTION

The psychotomimetic effect of anticholinergic drugs has been known since ancient times. The first mentioning of deadly nightshade (*Atropa belladonna*) and its effect comes from a Greek philosopher and naturalist, Theophrastus (331–287 BC), known as the "father of botany." During ancient times into the Middle Ages, atropine and other natural alkaloids were commonly used for religious ceremonies, Sabbaths, or as a tool of poisoners. The beginnings of medical use for these substances date back to the seventeenth century. In the 1950s, a number of anticholinergic drugs, including glycolic acid, were investigated for potential military and industrial use. The origin of 3-quinuclidinyl benzilate (BZ; codenamed Agent BZ) can be attributed to the increasing interest of the US military in exploring chemical warfare agents (CWAs) which were nonlethal but incapacitating. Experience with the use of CWAs in World War II has led to an attempt to synthesize new chemicals for military use, but without lethal effects (Ketchum and Sidell, 1997). The research was focused on contemporary incapacitants influencing behavior but without substantial effects on important vital functions. Incapacitating agents include the esters of glycolic acid (i.e., atropine-like anticholinergic compounds). BZ (also known as *3-quinuclidinyl benzilate, QB, QNB, BZ agent, Buzz agent, Ro 2-3308*, or *EA 2277*) is a prototype of the central nervous system (CNS) depressants; and a prototype of CNS stimulants is LSD-25 (D-lysergic acid diethylamide) or cannabinol. LSD-25 was the first candidate for this group of CWAs. However, its physical and chemical properties, as well as unpredictable behavior after exposure, have led to its exclusion from military research. From many tested compounds, anticholinergic drugs were chosen for further research. The anticholinergics are generally "glycolates" (substituted glycolic and tropic acid esters) of which the representative and best-known member is atropine. Major symptoms of low-level atropinization include dry mouth, dilatation of pupils, and tachycardia. With toxic doses of atropine, central excitation becomes more prominent, leading to restlessness, irritability, disorientation, and hallucinations or delirium. With still larger doses of atropine, stimulation is followed by depression, coma, and medullary paralysis. A number of anticholinergic compounds influencing psychotic stage and higher nervous functions were tested (Table 12.1).

This group of compounds has both peripheral and central properties. It is known from ancient literature that atropine has psychotomimetic effects (extracts from *A. belladonna* were used to induce hallucinations in "wizards"). Central effects increase when the compounds are considered in the following rank: atropine, scopolamine, benactyzine, ditrane, and, finally, BZ and other esters of glycolic acid (Albanus, 1970). BZ was originally studied for the therapy of gastrointestinal diseases. But even in small doses, it produces side effects such as confusion and hallucinations. Therefore, BZ was withdrawn from commercial studies and turned over to the US army as a possible candidate for incapacitating agents (Sidell, 1982). BZ is known to neuropharmacologists as the standard drug for testing the central activity of muscarinic cholinergic receptors. Currently, BZ is used in the research of cholinergic neurons in the peripheral nervous system (PNS) and CNS, non-neuromuscular cells and tissues for identification of muscarinic receptors via several laboratory techniques, mainly radio-ligand binding assays (Soukup et al., 2011; Sherin et al., 2012; Arrighid et al., 2013). BZ has also been implicated in several experimental epilepsy models (Schneider and de Lores Arnaiz, 2013), animal models in Parkinson's disease (Knol et al., 2014), animal behavioral studies on the

impact on learning and memory (Misík, 2013), neurodegenerative disorders, such as Alzheimer's disease, and other types of dementia (Wyper et al., 1993; Parkasi et al., 2007; Schliebs and Arendt, 2011). In the 1960s, a number of similar compounds, including BZ, were studied in the framework of the military, through industrial liaison programs (Pearson, 2006). These compounds, by politico-military goals and requirements, must contain the following criteria:

- High potency for physiological action (acting in μg/kg or less)
- Rapid onset (min)
- Defined duration (optimally min–h) and reversible effect
- Stability at storage and delivery
- Significant and predictable effect
- Capability of rapid dissemination in defined conditions
- High safety ratio

BACKGROUND

BZ is a white crystalline powder with a bitter taste. It has good solubility in water and organic solvents and is stable at field conditions at a minimum of 1–2 days without loss of its incapacitating activity. BZ is effective by all routes of administration and is metabolized primarily in the liver and excreted by the kidneys. After exposure to an effective dose (ED), mild peripheral effects occur within 1 h and central effects occur after about 4 h. The central effects peak at 8–10 h and last 24–48 h. Physical and chemical properties of BZ are summarized in Table 12.2.

TOXICOKINETICS AND MECHANISM OF ACTION

BZ is absorbed by all the usual routes of administration (oral, parenteral, and inhalation). When administered

by inhalation, the absorption into the transport system (bloodstream) is more pronounced than with oral administration. Experimental studies were performed with parenteral administration and intravenous (i.v.) administration occur with no loss because of direct involvement of BZ in the transport system. In the bloodstream, the compound is bound to the plasma proteins (particularly albumin), and it is transported to the sites of toxic effect—namely, the CNS and PNS. BZ interferes with cholinergic nerve transmission at the muscarinic sites, both in the peripheral autonomic nervous system and in the brain and spinal cord. Because of the wide distribution of these sites, measurable effects upon almost each phase of neural regulation may be observed. BZ readily crosses the blood–brain barrier (BBB), is distributed to all areas of the brain and spinal cord, and interacts with cholinergic receptors as a competitor with the physiologically active transmitter acetylcholine (ACh). In the PNS, BZ binds to muscarinic ACh receptors in smooth muscles, and like atropine, it has a very high affinity but without intrinsic activity, as shown in Table 12.3 (Fusek et al., 1971).

At the CNS, BZ binds to all subtypes of muscarinic receptors, each of them with different functions in the brain (Lefkowitz, 2004). The particularly long duration of the central action of BZ may be related to its greater affinity for nervous tissue, especially the strong adsorption effect on mitochondria, the subcellular organelles concerned principally with the energy supply to the cell. BZ has been found to reduce the oxygen consumption of nerve cells stimulated in various ways (Jovic and Zupanc, 1973).

TOXICITY

The acute toxicity of BZ (expressed as LD_{50}) in different species following different routes of administration is shown in Table 12.4. It is clear that acute toxicity is relatively low. However, the dose that causes incapacitation is much lower. Therefore, the ratio between the lethal and incapacitant dose levels is in the range of the logarithmic scale.

The EDs of some psychotomimetic drugs for incapacitation in humans were assessed, as presented in Table 12.5. The dose required to produce incapacitation is roughly 40 times lower than the lethal dose. For humans, the ED_{50} for incapacitation by BZ under field conditions is about 60 mg min/m^3 with a body weight of 75 kg, volume of respiration of 15 L/min, and LD_{50} value about 200 μg/kg, p.o. administration.

Symptoms

BZ is active when it is given by the i.v., intramuscular, inhalation, or oral route. The fragmentary data available indicate that higher doses caused the greatest effects and longest durations. From 1960 to 1969, field tests were conducted with BZ by the US Army.

Sidell's (1982) description of the effects induced by BZ (4.5–17.1 μg/kg) is as follows.

At low doses, the effects include dry mouth, decreased gastric motility, inhibition of sweating, increase in heart rate, papillary dilatation and loss of accommodation, mild sedation, and mental slowing. At high doses these effects are severe. There are marked disturbances of function at all levels of the CNS, motor coordination, attentiveness, and control of thought and the learning process all decline. Confusion, restlessness, impairment of perception and interpretation, and memory span are observed. The first symptoms occur depending on the route of administration, judgment and deficient insight are all features of this syndrome. True hallucinations are present and if the dose is quite high the subject may become stuporous or even comatose for several hours.

After a single injection of BZ (5.0–6.4 μg/kg, i.m.), the following symptoms are observed at various time intervals:

- 10 min: lightheadedness and giggling
- 30 min: dry mouth, blurred vision, nausea, chilly sensations, and twitching
- 1 h: flushed skin, lack of coordination, fatigue, unsteadiness, sleepiness, and quivering legs
- 2 h: many of the above symptoms, plus poor concentration, restlessness or sleepiness, hallucinations, slurred speech, and muscle fasciculation
- 3 h: the above symptoms, plus tremors
- 4 h: the above symptoms, plus difficulty in handling the subject and an increased pulse rate to 130
- 8 h: the above symptoms, plus delirium and hallucinations
- 24 h: persistent delirium, hallucinations, restlessness, unsteadiness, and increased pulse rate in some (but not all) subjects
- 48 h: persistent impairment of functions

Mydriasis and disturbed accommodation remain unchanged (depending on the dose) after 2 or 3 days. BZ has a mean duration of incapacitation of about 70 h. In real-life situations, wide variations in dosage would occur, so the results will also vary over the large time interval.

RISK ASSESSMENT

BZ was stockpiled by US military forces in 1980. However, in 1992, a US delegation to the Conference on Disarmament in Geneva declared that their stocks of BZ were destroyed. It is not known if stocks of BZ are held by any other armed forces. The military use of BZ was limited to special operations, and at present, Agent BZ can be considered a potential agent dedicated for special military operations. There exist a group of other incapacitants (not anticholinergic hallucinogens) known as nonlethal chemicals with very strong effects

(e.g., fentanyl derivatives, as demonstrated in Moscow in 2002). Use of these incapacitants by terrorists and other small, nonstate groups cannot be excluded either. Today, BZ is considered one of a number of nonlethal incapacitating chemical weapons. These compounds are designed and primarily employed to incapacitate personnel or material while minimizing fatalities, permanent injury to personnel, and undesired damage to property and the environment (Pearson, 2006).

TREATMENT

Based on the knowledge of its mechanism of action (simply described as a lack of neurotransmitter ACh), the therapeutic principle of BZ intoxication is to increase the ACh level by inhibitors of cholinesterases. However, their use is limited to their ratio between therapeutic and toxic dose levels, and therefore, reversible inhibitors are preferred, although some experiments with interaction of highly toxic nerve agents (VX and sarin) and BZ on healthy volunteers were described (Sidell et al., 1973). Physostigmine was the first antidote proposed for BZ intoxication. Its antidotal effect against intoxication with extract from *A. belladonna* has been known for more than 150 years. It is known that physostigmine acts as a good antidote for scopolamine intoxication, as it is able to treat all kinds of symptoms, such as electrophysiological, psychiatric, and biochemical changes caused by this anticholinergic drug. Physostigmine was considered one of the potential antidotes against anticholinergics, including esters of glycolic acid. Physostigmine is an antidote against BZ intoxication. An injection of 2–3 mg i.m. is required to alleviate symptoms. Repeated injections at intervals of approximately 15 min to 1 h may be required to build sufficient levels. Once a desirable effect is achieved, it should be maintained by slow intravenous injection or infusion. Doses of 2–4 mg every 1–2 h may be required. Oral dosing (2–5 mg every 1–2 h) should replace i.v. therapy as soon as possible. Peripherally acting anticholinesterase drugs that do not cross the BBB (e.g., pyridostigmine, neostigmine, and pilocarpine) are ineffective antagonists of the central effect of BZ (Greaves, 2002). The side effects of physostigmine (such as bradycardia, arrhythmia, excessive secretion, and convulsion) and its short duration of action, led to use of new inhibitors having lower toxicity in comparison with physostigmine. Acridine derivatives are of great interest (Albert, 1966). From these compounds, 1,2,3,4-tetrahydro-9-aminoacridine (tacrine) was found to be very effective (Fusek et al., 1974). It was found to be an antagonist against morphine and curare overdoses. It is an inhibitor of cholinesterases comparable to neostigmine or physostigmine, and it also inhibits antihistaminic activity. Its effect is more prolonged than that of physostigmine. During the studies of antidotes against anticholinergic hallucinogens, it was recognized as the most promising antidote at the time (Gershon and Angrist, 1973). The antidotal effect of tacrine against ditrane intoxication, including improvement of the electroencephalogram (EEG) changes, was approved by Itil and Fink (1966) in 74 patients. Atropine, scopolamine, and ditrane intoxications were successfully treated using physostigmine and tacrine, as well as low amounts of sarin (Ketchum et al., 1973). However, the toxicity of tacrine was the reason for its limited use (Table 12.6). Moreover, it has other limitations, such as the fact that it caused temporary changes in hepatic function tests. Therefore, it was abandoned (Marx, 1987) (Figure 12.1).

TABLE 12.6 Lethal Doses of Tacrine, 7-Methoxytacrine and Physostigmine in Laboratory Animals

Compound	Animal	Route of Administration	LD_{50} (mg/kg)
Tacrine	Mouse	i.m.	28.9 (24.2–35.8)
	Rat	i.m.	33.8 (28.8–40.6)
	Rat	p.o.	103.7 (84.6–135.8)

	Rabbit	i.n.	13.3 (8.0–18.8)
	Dog	i.m.	12.6 (10.1–14.7)
7-Methoxytacrine	Mouse	i.m.	125 (110–143)
	Rat	i.m.	258 (224–313)
	Rat	p.o.	793 (662–950)
	Rat	i.p.	73.3 (61–90)
	Rat	i.v.	22.2 (19.9–25.2)
	Rabbit	i.m.	75.3 (60–89)
	Dog	i.m.	18.9 (15.2–22.1)
Physostigmine	Mouse	i.m.	0.86 (0.7–1.0)
	Rat	i.m.	2.2 (1.9–2.4)
	Dog	i.m.	0.83 (0.68–0.95)

The 7-methoxy derivative of tacrine (7-methoxytacrine, or 7-MEOTA) was synthesized and tested (Fusek et al., 1986). 7-MEOTA inhibited more butyrylcholinesterase (BuChE) ($I_{50} = 3.5.10^{-7}$ M) than acetylcholinesterase (AChE) ($I_{50} = 3.5.10^{-6}$ M) *in vitro*. The inhibition is a competitive–noncompetitive reversible type. The characteristics of AChE inhibition indicate that 7-MEOTA binds to the active surface of AChE in the gamma-anionic site, like galantamine or coumarine. Inhibition of blood AChE by *O*-ethyl-*S*-(2-dimethylaminoethyl) methylphosphonothioate (0.042 mg/kg = 1.5 × LD_{50}, i.m.) after premedication with 7-MEOTA (100 mg/kg, i.m.) was substantially smaller than in intoxicated animals pretreated with

FIGURE 12.1 Antidotes (7-MEOTA) for BZ intoxication; they can be administered by tablets (100 mg) or injections (50 mg/5 mL).

saline, which highlights its possible use for preventing intoxication by organophosphorus anticholinesterase agents. 7-MEOTA enhanced the contraction response of the guinea pig atria (ED_{50} positive inotropic effect = 1.7×10^{-6} M), reduced the frequency of contractions (by binding the compound to the effectors of the cholinergic system of the heart tissue), increased the contraction response of the isolated rat diaphragm, and antagonized the effect of d-tubocurarine. The dose of 3×10^{-6} M of 7-MEOTA entirely suppressed the effect of a dose of 2×10^{-6} M d-tubocurarine. 7-MEOTA elicited a contraction response (1×10^{-7} M) and intensified the response of the isolated rat jejunum to the applied concentration of cholinomimetics. The long-term increase of intestinal peristalsis after low concentrations of 7-MEOTA (1×10^{-7} M) bears witness to the inhibitory effect of the compound on tissue cholinesterases. In a dose-dependent manner, 7-MEOTA effectively antagonized symptoms of intoxication elicited by anticholinergics in dogs. A dose of 5 mg/kg, i.m. of 7-MEOTA shortened the time needed for a fall in the score of the intensity of symptoms elicited by BZ (0.05 mg/kg, i.m.) from 210 min in untreated intoxication to 54 min, respectively (Fusek et al., 1979).

The authors' results show that contributing to the effect of 7-MEOTA (besides the direct influence on effectors of the cholinergic system) can also be mediated through induced cholinesterase inhibition in the CNS and PNS. The more beneficial properties of 7-MEOTA in comparison with physostigmine suggests the possible therapeutic use of this compound in cases where physostigmine was applied previously. In contrast to physostigmine, the application of 7-MEOTA does not require repeated doses for maintaining the therapeutic effect at low dosages and has minimal side effects.

7-MEOTA is a potent, centrally active cholinesterase inhibitor. Therefore, this new drug has applications not only as an antidote against BZ intoxication, but also for the treatment of cholinergic deficit neurological disorders, such as Alzheimer's disease. In isolated rat jejunum, 7-MEOTA increased muscle contractility, and in isolated guinea pig ventricular myocytes, this compound was found to prolong transmembrane action potential and decrease the amplitude of the plateau. In isolated rat diaphragm, 7-MEOTA increased muscle contractility after electric stimulation of the phrenic nerve.

7-MEOTA was found to antagonize convulsive action of pentamethylenetetrazole and significantly decreased the number of surviving animals following administration of this drug. Results from behavioral studies indicated that 7-MEOTA antagonized the anticholinergic syndrome evoked by scopolamine, ditrane, and BZ.

The antidotal effect of 7-MEOTA on the anticholinergic syndrome was potentiated by nootropics, by diazepam, and especially by opioid peptides (Fusek, 1977). 7-MEOTA also antagonized the side effects of tricyclic antidepressants and protected AChE against inhibition by some organophosphate anticholinesterase compounds. Acute toxicity of 7-MEOTA was low: LD_{50} (i.m.) was 125 mg/kg in mice and 258 mg/kg in rats. The oral LD_{50} in rats was found to be 793 mg/kg. Analogous values for THA were 29, 34, and 104 mg/kg (Fusek, 1977). Also, 7-MEOTA was found to be markedly less toxic than THA in dogs and rabbits. A subacute toxicity study of 7-MEOTA (with 3 months of administration) demonstrated that the compound was well tolerated at doses of 25 mg/kg (i.m.) and 50 mg/kg (p.o.) in rats and 2.5 mg/kg (i.m. and i.v.) in beagles. No pathological changes were observed in biochemical, hematological, and morphological investigations.

ANALYTICAL METHODS

The fluorometric method for 7-MEOTA determination in biological material was developed, and blood concentration profiles of 7-MEOTA in rats and healthy volunteers were estimated (Filip et al., 1991). Maximal concentrations of 7-MEOTA in human blood were observed approximately 0.5–1 h after i.m. and 4 h after p.o. application of the drug. The half-life was 5 h, and an effective level was maintained for 12 h. Similar results in rats with radiolabeled [H3]7-MEOTA were obtained. The main part of 7-MEOTA was eliminated by both urine and feces within 6 h after administration. The majority of the compound was eliminated in an unchanged form, and the remaining portion was metabolized. Among the metabolites, 7-MEOTA and its conjugate with glucuronic acid were demonstrated; further metabolites were likely compounds with the OH group in position 1 or 2 (Patocka et al., 1996).

In healthy volunteers, 7-MEOTA was well tolerated at a single dose of 2 mg/kg (p.o.) or 1 mg/kg (i.m.) following

daily administration (for 7 days). The compound did not influence the cognitive functions of healthy persons. The blood concentration profiles of volunteers corresponded well with those in rats.

On the basis of the results obtained, it was decided that 7-MEOTA would be studied in more detail, including preclinical testing. The first and second phases of clinical testing on healthy volunteers were performed. It was found that 7-MEOTA is well tolerated after oral or intramuscular administration (2 mg/kg, p.o. and 1 mg/kg, i.m.) (Filip et al., 1991). Clinical testing of this drug was performed on patients with tardive dyskinesias occurring after lengthy administration of neuroleptics with good therapeutic efficacy (Zapletalek et al., 1989). As a result, it was introduced in the form of tablets (7-MEOTA, 100 mg) and injections (50 mg in 2 mL) to the Czech army as an antidote against psychotomimetic agents.

CONCLUDING REMARKS AND FUTURE DIRECTION

BZ was recognized as an incapacitant agent for military use. It was stockpiled and stored as a CWA by the US army, but their stocks were destroyed in 1992. The use of this agent is not excluded. Its mechanism of action is based on the interaction with cholinergic receptors. The symptomatology is characterized by peripheral action (vegetative symptoms) and influence on the CNS, including hallucinations. The antidotes and effective antidotal therapy are of vital interest and are possible using commonly available physostigmine or 7-MEOTA, respectively. The use of BZ in the research of the cholinergic nervous system cannot be neglected.

Neurological Effects and Mechanisms of Blast Overpressure Injury

Dorothy L. Dobbins and Xiaoping Pan

INTRODUCTION

Blast-induced neurotrauma is one of the most serious health concerns of soldiers returning from war. Blast-induced traumatic brain injuries (bTBIs) are considered the signature wound of the war in Iraq (Cernak and Noble-Haeusslein, 2010; Hicks et al., 2010; Balakathiresan et al., 2012; Tate et al., 2013). Approximately 20% of returning veterans sustain a traumatic brain injury (TBI) (Brenner et al., 2010; James et al., 2014) and 50% of all injuries involve explosive devices (Cernak et al., 2001). Generally, bTBIs are induced through exposure to oscillating overpressure airwaves generated by blasts from explosives. These pressured waves propagate and transfer kinetic energy to individuals, causing a variety of damages. Injuries sustained from blast exposures are graded based on the size and proximity to the blast (Cernak and Noble-Haeusslein, 2010; Hicks et al., 2010). Typically the initial neural tissue damage is short-lived and quickly overcome (McCrea et al., 2009; Balakathiresan et al., 2012). Unfortunately, in warfare, the possibility of repetitive exposure to blast overpressure is essentially certain. Repetitive bTBIs are problematic given their more complicated nature and the ability to cause extensive and prolonged damage in the brain (Comper et al., 2005; Hicks et al., 2010; Balakathiresan et al., 2012; Mouzon et al., 2014; Stein et al., 2014).

The bTBIs generally manifest through a sequence of events. Effects from the blast itself cause shearing of brain tissues, stretching and rupturing of axons, diffuse axonal injury, neuronal cell death, and neurodegeneration. Neuroinflammatory responses are generated soon after blast exposure (Saljo et al., 2000; Cernak et al., 2001, 2004; Comper et al., 2005; Hoge et al., 2008; Blyth and Bazarian, 2010; Brenner et al., 2010; Hicks et al., 2010; Balakathiresan et al., 2012; Cornelius et al., 2013). The cascade of biochemical changes, which occur after bTBIs, can serve as a mechanism for repairing tissue damage and neuron loss from inflammatory responses. These biochemical responses cause changes to neuronal circuitry and the density of neuronal populations through increased neurogenesis and axonal sprouting (Cernak et al., 2004; Blyth and Bazarian, 2010; Hu et al., 2012; Wang et al., 2012; Cornelius et al., 2013).

Cellular and molecular changes that result from bTBIs induce a sequela of behavioral and cognitive deficits as well. Individuals present with symptomology similar to that of posttraumatic stress disorder (PTSD) and exhibit changes in mood and sleep patterns (Cernak et al., 2001; Comper et al., 2005; Hoge et al., 2008; Blyth and Bazarian, 2010; Brenner et al., 2010; Hicks et al., 2010; Cornelius et al., 2013). These mental status changes may persist for a long time after the blast overpressure exposure. It is likely that the changes to the overall connectivity of the brain could account for the prolonged effects of bTBIs given the changes in neuronal populations after bTBI (Blyth and Bazarian, 2010; Hu et al., 2012; Cornelius et al., 2013).

Because of the transient nature of primary injuries, diagnosing bTBIs is difficult, especially in mild bTBIs, which lack visible characteristics for imaging. The damage to brain tissue is often short-lived and the delay in the generation of secondary effects allows many bTBI cases to remain undiagnosed (Comper et al., 2005; Ruff et al., 2009; Sivanandam and Thakur, 2012). Research focusing on advancing diagnostic approaches is active, especially in the fields of advanced imaging techniques and development of relevant clinical biomarkers. In addition to body fluid–based protein markers, further investigations have focused on identifying circulating

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00013-0

micro RNAs (miRNAs) as biomarkers and assessing its diagnostic value in clinical settings. Additionally, more research is needed to further investigate the mechanisms by which secondary injury occurs after bTBI. A greater understanding of bTBI pathological mechanism will enhance the development of intervention strategies to treat cognitive and behavioral deficits.

BLAST WAVES AND INJURY PHYSICS

The use of explosive devices in warfare has escalated within the past few decades. Physics of blast waves are well understood. Generally, a detonation from an explosive device transfers chemical energy to surrounding molecules. Medium receiving the transferred energy, generally air or water, will display a surge in density, temperature, and pressure. The changes lead to collisions of molecules and cause them to move at a speed that exceeds the speed of ambient pressure waves. The need to alleviate disturbances and compression cannot be achieved normally and the medium will form a transient blast wave to disperse molecules and restore the previous ambient state (Stuhmiller and Richmond, 1991). As a result, blast waves will spherically radiate outward at supersonic speeds from the detonation. Blast waves have a peak overpressure front that is followed by a negative pressure wave caused by the overexpansion of gases as ambient pressure is surpassed. Eventually, the energy dissipates and previous normal pressures are achieved. This description represents an ideal open field blast wave, which is highly predictable through the Friedlander equation. Unfortunately, contact with solid surfaces causes pressure waves to be reflected and rebounded with amplified force. When blast waves reflect off of solid surfaces, air molecules are compressed even further, allowing for incident wave fronts to propagate in different directions and move at various temperatures and pressures. This type of blast wave propagation is more typical to warfare explosions and is known as complex blast waves. Additionally, in warfare, crudely constructed explosive devices can issue multiple blast waves from a single device. These can impact initial waves, complicating blast wave propagation and its effects (Stuhmiller and Richmond, 1991; Cernak and Noble-Haeusslein, 2010; Hicks et al., 2010; Bass et al., 2012; Magnuson et al., 2012).

Exposure to blast overpressure waves can cause extensive damage to an individual. There are a variety of mechanisms through which injuries can be sustained. The transfer of kinetic energy from blast overpressure exposure typically generates primary injuries, such as the shearing of tissues. Shrapnel and other debris can impact an individual and cause secondary injury. Tertiary injuries are sustained from impact with surrounding objects and quaternary injuries are those sustained from intensive thermal changes caused by the primary explosion as well as any other injuries not previously described (Cernak and Noble-Haeusslein, 2010; Hicks et al., 2010; Balakathiresan et al., 2012; Bass et al., 2012; Magnuson et al., 2012; Nakagawa et al., 2011; Tate et al., 2013).

The primary effects of blast waves can often be overlooked and are under-represented when examining effects of overpressure exposure (Kocsis and Tessler, 2009). The means by which primary injuries impact the brain are summarized in Figure 13.1. The primary blast wave transfers kinetic energy to an individual. The transfer of energy primarily affects pressure-sensitive organs of the respiratory and circulatory systems, thorax, abdomen, and middle ear (Stuhmiller and Richmond, 1991; Kocsis and Tessler, 2009; Cernak and Noble-Haeusslein, 2010; Magnuson et al., 2012). This energy transfer causes substantial damage to the body, generally through shearing of tissues. Once kinetic energy has transferred to an individual, it can travel to the brain through vasculature and up through the foramen magnum via cerebrospinal fluid (Hicks et al., 2010). The transfer of kinetic energy can also be transcranial, impacting the brain with blunt force. Once inside an individual, blast waves can continue to rebound off of dense tissues such as bone. This makes the brain particularly vulnerable to impairment. The initial force from changes in pressure can cause a rotational movement of the brain on the brain stem, damaging medial temporal lobe structures, areas vital to learning and memory. Additionally, the pressure wave continues to rebound off the skull and further impacts the brain (Balakathiresan et al., 2012). It is important to note that, in a war situation, soldiers are often geared with heavy protective equipment, including helmets and body armor. Cernak and Noble-Haeusslein (2010) have stated that the protective equipment can provide an enhanced point of contact for the transfer of kinetic energy and can trap additional energy, allowing it to rebound further onto an individual.

DEFINING AND DIAGNOSING bTBI

Neurotrauma caused by overpressure exposure to the brain is described as bTBI. bTBIs vary in nature and are dependent on the force of the blast and proximity of the individual when exposed. Defining and diagnosing bTBIs present much difficulty. It is well-established that such injuries have both transient primary effects and secondary effects that can manifest some time after exposure. Generally, secondary effects of bTBIs occur approximately 3 months after injury and can persist for years (Busch and Alpern, 1998; Hoge et al., 2008; Blyth and Bazarian, 2010; Mouzon et al., 2014). Conventional imaging techniques such as computed tomography and

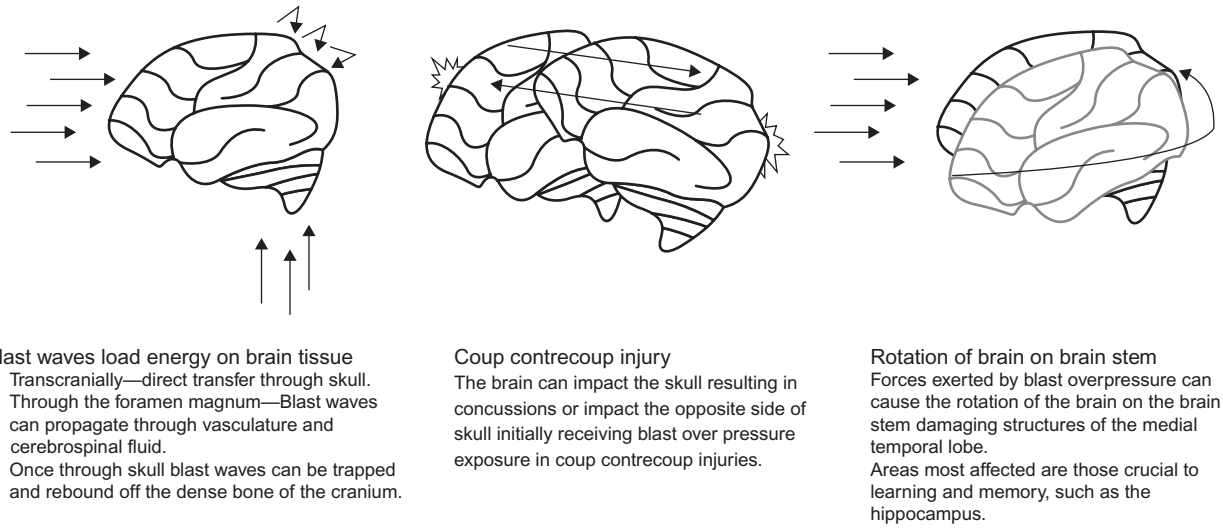

FIGURE 13.1 Loading and mechanical effects of blast over exposure on the brain. Blast overpressure waves issued from the detonation of explosive devices impact the brain in a variety of ways. Overpressure energy can load onto the brain transcranially or via the foramen magnum as it travels through cerebrospinal fluid or blood vessels. Once trapped within the skull, blast waves can further rebound off of the skull and impact the brain multiple times. Additionally, the sheer force of blast waves can cause the brain to impact the skull, resulting in a concussion. When such impacts occur on the opposite side from where the initial force was received, coup contrecoup injuries occur. Finally, torsional strain from blast waves can cause the rotational movement of the brain on the brain stem, damaging medial temporal lobe structures crucial to learning and memory.

magnetic resonance imaging are routinely used for TBI diagnostics; however, it is difficult to detect subtle or no observable pathological changes associated with mild TBI (Redell et al., 2010; Balakathiresan et al., 2012). Unfortunately, the majority of TBIs (approximately 70%) are classified as mild (mTBI) and it is estimated that three-quarters of mTBIs are undiagnosed (Busch and Alpern, 1998; Comper et al., 2005; Snell et al., 2009; Blyth and Bazarian, 2010). The World Health Organization identifies mTBIs as nonpenetrating damage to the brain caused by mechanical energy or physical force which results in at least one of the following: a loss of consciousness lasting less than 30 min; postconcussive amnesia lasting less than 24 h; confusion; disorientation and any other neurological abnormalities; or lesions that do not require surgery. This criterion is combined with a Glasgow Coma Scale score of 13–15 (Comper et al., 2005; Rao et al., 2009; Ruff et al., 2009). Mild TBIs often result in transient or little to no gross deformation to brain structures; therefore, they often go undiagnosed. In a war setting, soldiers without life-threatening injuries are often dismissed or are examined less. This is especially problematic with mTBIs, given that the focal injuries are transient and behavioral and cognitive symptomology does not occur until much later (Kobeissy et al., 2013). In a military setting, repeated exposure to blast overpressure waves is common as soldiers are quickly returned to duty because of the lack of obvious identifiable injury. The prognosis for an mTBI is generally good; symptomology and full recovery should occur within months after exposure (McCrea et al., 2009; Kobeissy et al., 2013; Wortzel et al., 2013). However, repeated exposure complicates bTBIs and causes long-lived and detrimental effects (McCrea et al., 2009; Balakathiresan et al., 2012; Wortzel et al., 2013; James et al., 2014; Mouzon et al., 2014).

Currently, mild bTBI diagnostics generally occur much later after blast exposure and are heavily reliant on recalled events from patients and those who witnessed the initial injury (Blyth and Bazarian, 2010). Individuals suspected of sustaining a bTBI will be interviewed about loss of consciousness and how the injury occurred. However, the postconcussive amnesia and loss of consciousness directly after injury make such diagnostic approaches unreliable (Ruff et al., 2009). Further, subsequent reports of headache, sleep disruptions, mental status changes, and other symptoms mimic other neurological disorders, which make diagnostics even more difficult. The cognitive and behavioral changes after bTBIs can manifest months after the initial injury, propagating this problem.

EXPERIMENTAL ANIMAL MODELS OF bTBI

A multitude of bTBI research has generated the current knowledge about such injuries. Generally, bTBI mechanisms are studied in animal models. There are many different methods for generating animal models

for investigating various aspects of bTBIs. Initially, open field exposure was used, which mimics the effects of a simple blast wave described. Animals were placed at various proximities to explosive devices to determine the lethality of blast exposure and generate dose–response curves. Some studies currently make use of this model when examining mild bTBIs (Rubovitch et al., 2011; Risling and Davidsson, 2012).

Cernak (2005) and Xiong et al. (2013) have examined the variety of TBI models currently used. Classic direct methods include fluid percussion injuries (FPIs) and the controlled cortical impact (CCI) in which craniotomies are performed, and a force is applied to the intact Dura. FPI uses a cylindrical reservoir containing saline. One end of the cylinder is attached to a cap adhered to the skull of the subject and the other end contains a pendulum. When the pendulum is released, a surge of pressure rushes down and impacts the skull. This model produces more severe injuries, such as swelling and intracranial hemorrhaging. The injury is also variable depending on the craniotomy. When pressure is applied between bregma and lambda, centrally, resulting injuries are more severe. For the majority of studies, a lateral approach is favored. Unfortunately, FPIs are sometimes difficult to replicate and the craniotomy methods vary and influence results. Recently, advances have been made to modify this model to increase reproducibility. Similar to FPI, CCI delivers force to the skull through the use of a piston, which is driven by the compressed air. This model is generally used in rodents and produces a more controlled and reproducible injury. Various mechanical factors such as the degree of impact and the depth of disturbance to the brain can be regulated. This model can be used to mimic a milder TBI and has been used in the examination of cognitive deficits as well as genetic and molecular mechanisms.

Other models have been developed to observe the brain injury and its progression *in vivo*. Roth et al. (2014) have demonstrated the benefits of skull thinning and compression injuries. The skull was shaved to a thickness of less than 50 μm and then compressed with surgical tools until it concaved slightly. This technique does not directly mimic blast injuries. However, it allows for a better understanding of the immediate response of brain tissue to damage because the brain can be observed through the thinned skull with a laser-scanning microscope.

There is a variety of weight-drop methods that are more popular. Feeney's model uses a craniotomy and allows for a metallic weight to be dropped on the exposed skull. This model does not directly mimic human injuries and causes focal damage, resulting in hemorrhaging and other tissue damages. Weight-drop models without the use of craniotomies are more common and are typically referred to as Marmarou's model or impact acceleration models. This method is much more controlled and better mimics blast injuries. Graded injuries result in response to the force impacting the brain, as is seen in bTBIs. This model uses a Plexiglas tube to drop the weight from a fixed height to the subject's head. The animal's head rests on a thick piece of foam, which cushions but does not impede the impact. Intense neuroinflammation and diffuse axonal injuries are observed with this model, making it a better representative of human bTBIs (Cernak, 2005; Xiong et al., 2013). Despites many advantages, animal models generated by direct impact methods are less preferable when studying complicated systemic responses as modeled by the open field exposure and the blast simulation techniques.

Finally, recent advancements have given rise to the development blast or shock tubes. These models place animals in a chamber some distance away from an explosive device. However, the explosion can be difficult to replicate and injuries may vary depending on the explosives used and impact angle at which blast waves hit the subject. A similar method uses compressed air instead of explosives. In this case, a diaphragm separates two sections, a compression chamber and a main section. The compression chamber is loaded with compressed air until the diaphragm ruptures, which projects an overpressure wave down the length of the main section. Subjects are usually placed at the end of the main section, where they can be impacted by the overpressure wave. This method produces a blast pressure profile that mimics the open field explosion. The injury in subjects is reproducible and directly mimics effects seen by primary blast injuries. Unfortunately, this method does not allow for the complex blast waves seen in warfare but does closely represent bTBIs exhibited by humans. Rodents are primarily used in these models (Cernak, 2005; Cernak et al., 2011; Risling and Davidsson, 2012; Xiong et al., 2013). The indirect methods of inducing bTBIs seem to be the most similar to human injuries and are the most preferable models currently available.

The selection of an appropriate model is crucial when studying bTBIs. There are many more models of TBIs that have been used. The ones detailed here are methods commonly used when investigating bTBIs. Although each of the methods has its benefits and limitations, all methods further the development of diagnostics, therapeutics, and mechanisms for understandings bTBIs.

NEUROLOGICAL EFFECTS

The sequence of neurological effects after blast exposure is outlined in Figure 13.2. Primary neurotruama after blast exposure presents as edema, embolisms, hematomas, and increased permeability of the blood–brain barrier (BBB). These are accompanied with shearing of

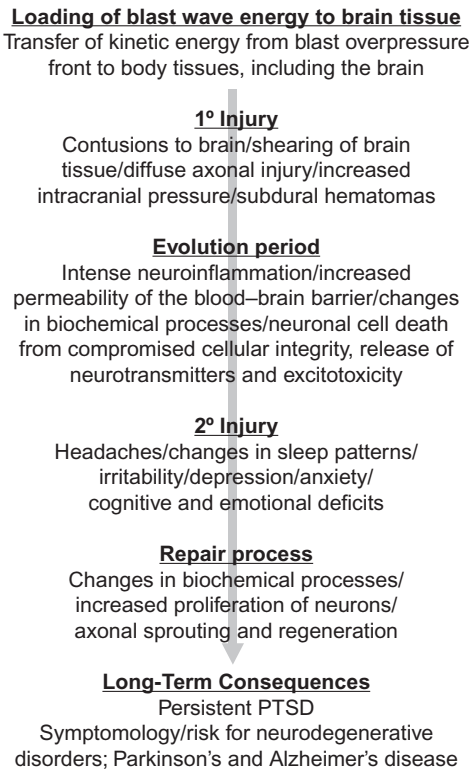

FIGURE 13.2 Progression of bTBI. The sequela of events after blast overpressure exposure. Blast-induced traumatic brain injuries follow a sequence of events. Initial tissue damage from the force of blast waves lead to an evolutionary period of changes in biochemical processes in the brain. These changes result in neurodegeneration and neurological dysfunction. Repair processes may lead to permanent changes to the neural networks through increased neuronal proliferation and regeneration. Long-term consequences can persist after bTBIs. Generally, permanent effects are increased risks for neurodegenerative disorders.

tissues, damage to axons (often seen as diffuse axonal injury), changes to the neuronal cytoskeleton, and other cellular damage and cell death through both apoptotic and necrotic pathways (Busch and Alpern, 1998; Saljo et al., 2000; Cernak et al., 2004; Kocsis and Tessler, 2009; McCrea et al., 2009; Blyth and Bazarian, 2010; Cernak and Noble-Haeusslein, 2010; Hicks et al., 2010; Balakathiresan et al., 2012; Wang et al., 2012). This damage will allow for an evolution period during which intense neuroinflammation occurs, further changes to the BBB will allow for the exchange of various molecules to and from the brain, and metabolic and energy dysregulation will manifest (Kocsis and Tessler, 2009; Cernak and Noble-Haeusslein, 2010; Cornelius et al., 2013). The tissue damage and compromised cellular integrity can cause excessive release of neurotransmitters and other molecules, contributing to excitability of neurons, neuronal death, and neurodegeneration (Cernak et al., 2001). This evolution period will lead to what is known as the secondary injury commonly called postconcussive syndrome (Busch and Alpern, 1998; Blyth and Bazarian, 2010; Hicks et al., 2010). These include a myriad of symptoms similar to PTSD and other neuropsychological effects, which include depression, anxiety, increased irritability and aggression, disruption to sleep patterns/ insomnia, and cognition and memory deficits. In addition, individuals suffering from mTBIs most often report headaches, dizziness, and fatigue (Comper et al., 2005; Hoge et al., 2008; Rao et al., 2009; Blyth and Bazarian, 2010; Brenner et al., 2010; Hicks et al., 2010; Sivanandam and Thakur, 2012; Bramoweth and Germain, 2013; Cornelius et al., 2013; Mouzon et al., 2014). There have even been reports linking mTBIs to increased substance abuse (Blyth and Bazarian, 2010; James et al., 2014) and suicidal ideations (Kang and Bullman, 2008; Bramoweth and Germain, 2013; James et al., 2014). Further, some long-term neurodegeneration risks are associated with the blast overpressure injury. Several recent studies have also suggested a relationship between bTBI and neurodegenerative disorders such as Parkinson's disease and Alzheimer's disease (Sivanandam and Thakur, 2012; Cornelius et al., 2013).

INJURY AND RECOVERY MECHANISMS

The mechanisms of bTBI-induced neurological effects have not been fully understood. Fortunately, this has been a rapidly growing area of research recently. Some studies focus on the initial injury, examining the role of oxidative stress in generating secondary effects. Cernak et al. (2001) suggested reactive oxygen species (ROS) would compromise the integrity of cell membranes, making them more susceptible to hyperexcitability. It was suggested that oxidative stress could play a role in the reduced hippocampal volume as seen in TBIs and contribute to cognitive deficits. The increased permeability of the BBB also plays a role in changes of metabolic functioning and decreases in neuronal density soon after blast exposure (Cernak et al., 2004). Cornelius et al. (2013) and Hicks et al. (2010) stated metabolic changes could lead to intense neuroinflammation after initial injuries. Several studies continue the idea that neuroinflammation mediates changes in neuronal populations, specifically within the hippocampus. Recently, a surge of interest regarding microRNAs has identified their role in the pathogenesis of bTBIs, given the ability of short noncoding RNAs, such as miRNAs, to regulate the destruction or downregulation of target genes. Several miRNAs are found to be upregulated soon after bTBI (Redell et al., 2010; Hu et al., 2012), and after bTBI several miRNAs have been found to mediate a decrease in neuroinflammation and an increase in cell survival in the hippocampus (Redell et al., 2010, 2011). Further studies

examining the functional outcomes of bTBIs have examined behavioral effects and found behavioral deficits to be persistent up to 1 year after bTBI in animal models (Mouzon et al., 2014; Snell et al., 2009).

It is plausible that the behavioral and cognitive deficits seen with PTSD symptomology could be mediated by changes in neuronal networks. After neuroinflammation, regeneration processes (neurogenesis, synaptogenesis, and cell proliferation) are prevalent, especially in the hippocampus (Blyth and Bazarian, 2010; Redell et al., 2010, 2011; Balakathiresan et al., 2012; Hu et al., 2012; Wang et al., 2012; Cornelius et al., 2013), and play a role in injury repair. This would also indicate behavioral and cognitive deficits may be attributed to the neurodegeneration and neuronal cell death after blast injury. It is important to note that the repair processes, changes in neuronal network, and an increased proliferation could contribute to further PTSD symptomology and its persistence. In addition, aberrant regulation of various proteins (Saljo et al., 2000; Blyth and Bazarian, 2010; Sivanandam and Thakur, 2012; Mouzon et al., 2014) can contribute to the pathogenesis of neurodegenerative disorders that may manifest much later after blast overpressure exposure.

Debates exist regarding whether bTBIs, PTSD, and other symptoms are comorbid or if bTBIs generate the symptomology. Many investigations have not found prolonged effects after mTBIs and, on the contrary, have seen complete reversal of mTBI symptomology (McCrea et al., 2009; Snell et al., 2009; Stein et al., 2014). Some studies agree with a comorbid stance between PTSD and bTBI but suggest the comorbidity amplifies and extends the effects of bTBI (Busch and Alpern, 1998; Brenner et al., 2010; Hicks et al., 2010). However, changes to neuronal tissue and therapeutic approaches would suggest against comorbidity of PTSD and bTBIs. There are conventional therapeutic techniques such as therapy sessions and exercise practices that have been shown to be beneficial for bTBI recovery (Comper et al., 2005; McCrea et al., 2009). However, pharmaceuticals targeting PTSD symptomology do not show the same improvement in individuals with PTSD or depression in the absence of bTBI when compared with individuals experiencing both (Comper et al., 2005).

Symptomology induced after bTBI is likely dependent on secondary effects of blast trauma. After exposure to blast overpressure, extensive tissue damage initiates neuroinflammation and neuronal cell loss. To combat such effects, biochemical processes are activated to mitigate neuroinflammation, promote cell survival, and enhance proliferation. Because of their anatomic locations, the medial temporal lobe structures are extremely vulnerable to impacts of blast overpressure. Therefore, studies of histological and biochemical changes in these areas will help to reveal mechanisms underlying the prolonged bTBI-induced behavioral and cognitive symptomology after such injuries.

BODY FLUID–BASED BIOMARKERS OF INJURY

Currently, there are studies investigating the use of protein and small RNA molecules in the brain and body fluids as biomarkers. Some promising protein markers are S100b, glial fibrillary acidic protein, and the ubiquitin carboxy-terminal hydrolase-1 (Svetlov et al., 2009). Tate et al. (2013) additionally described two proteins identified in TBIs that have the potential for biomarkers. The spectrin breakdown products are involved in the deterioration of the cytoskeleton in the central nervous system. Additionally, they identify the deregulation in ubiquitin carboxy-terminal hydroxylase–L1, a substance known to indicate axonal degeneration. One of the most significant recent findings has been with miRNAs circulating in the blood. These molecules represent a window to our status of health. Mitchell et al. (2008) reported that a set of miRNAs are measurable and highly stable in blood plasma of human subjects. They also demonstrated that although synthetic exogenous miRNA (naked) were rapidly degraded in the plasma, endogenous plasma miRNAs are resistant to RNase activity and remain stable. For neurological dysfunctions, blood miRNAs have been proposed as biomarkers for Alzheimer's disease (Maciotta et al., 2013) and predictor of brain aging (Li et al., 2011). Recent studies have suggested that TBI alters serum/plasma miRNA expressions, representing a rich source of molecular biomarkers. Several miRNAs markers (miR-16, miR-92a, and miR-765) have been identified as biomarkers for TBI diagnostics within the 24 h after injury, and the combined use of these miRNA markers has gained satisfactory diagnostic specificity and sensitivity for both severe and mild TBIs classified using the GCS score (Redell et al., 2010). Notably, the expression level of plasma miRNA can be used to indicate injury severity and discriminate mild and severe TBI (Redell et al., 2010), suggesting the value of miRNA markers as indicators for prognosis of TBI. Recently, Balakathiresan et al. (2012) have investigated the miRNA signature after repeated blast overpressure injury using a rat mode. Findings suggested that the miRNA let-7 is a promising biomarker for bTBI with high neurophysiological significance. However, more work needs to be performed to verify and assess the diagnostics value of body fluid–based biomarkers in human bTBI studies. The temporal and dynamic expressions of protein and small RNA markers are another area of importance requiring further investigation. It is clear that more reliable and effective means of diagnosis are essential for bTBIs, especially in a warfare setting.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

In warfare, blast-induced neurotrauma is common and many bTBIs are classified as mild and go undiagnosed. Repeated exposure amplifies effects of blast overpressure exposure that can result in long-lasting neurological deficits. The initial effects of bTBIs are gradient and dependent on exposure and proximity to the explosion. However, secondary biochemical responses alter neuronal networks and seem to be responsible for the sequela of behavioral and cognitive deficits that follow bTBI. The transient nature of initial injury and the delayed manifestation of secondary injury make diagnosis difficult when injuries are not immediately addressed, especially in warfare. Further advances in diagnostic techniques, especially for mild bTBI, are urgently needed. Emerging body fluid–based protein and small RNA biomarkers must be verified in human bTBI populations. More research is needed to examine bTBI and its relation to behavioral and cognitive deficits and to identify mechanisms of symptomology. Finally, the need for therapeutic interventions is high. Targeting the evolution of secondary injuries is of key importance and several research efforts are trending toward this method. Advances in understanding the biochemical nature of secondary injury of bTBIs have led to the identification of aberrantly regulated proteins and small RNAs that may serve as diagnostic markers and therapeutic targets that would halt the pathogenesis of bTBI. There have been several advancements made in recent years to further the understanding of bTBIs. However, the complex nature of blast waves in warfare makes exposure to overpressure waves a serious problem requiring continuous investigations for improved understanding and management of bTBIs.

CHAPTER

14

Thallium

Larry J. Thompson

INTRODUCTION

Thallium (Tl) is a soft, bluish-white metal that occurs naturally in the Earth's crust. It was discovered by Sir William Crookes in 1861 while making spectroscopic determinations of tellurium in residue material from a sulfuric acid plant. The name comes from the Greek word *thallos*, which means "green shoot" or "twig," which refers to the green spectral emission lines originally used to identify the element. It is a heavy metal (with density 11.83 g/cm^3 and atomic number 81) whose use is mainly in the electronics industry (e.g., infrared detectors and semiconductor materials), with smaller quantities of the substance used in glass manufacturing and the pharmaceutical industry (in which the radioactive isotope Tl-201 is utilized). Thallium can be released into the environment by cement manufacturing, the burning of certain coal deposits, and the production of nonferrous metals (Kazantzis, 2000; Peter and Viraraghavan, 2005). Normally, Tl is found in the environment in low concentrations, commonly in the Tl (+1) or Tl (+3) oxidation state. The maximum contaminant level (MCL) for Tl in drinking water is 0.002 mg/L (US EPA, 2009), a level at which no adverse human health effects are anticipated. Commercial Tl is usually obtained during the refining process for iron, cadmium, lead, or zinc (USGS, 2013). Thallium is a highly toxic element, and salts of Tl are colorless, odorless, and tasteless. Thallium has no known biological function and has been the least studied of the toxic metals; lead, mercury, and cadmium have attracted more attention. Thallium salts were introduced as pesticides in Germany in 1920. The sulfate salt is most common and has been widely used as a rodenticide and ant killer. Tl has been associated with intentional and accidental poisonings since that time, although problems decreased greatly after its use was banned in major parts of the world (Saddique and Peterson, 1983).

BACKGROUND

Thallium has two important oxidation states, Tl (+1) and Tl (+3). The trivalent form more closely resembles aluminum, and the monovalent form more closely resembles alkali metals such as potassium. The toxic nature of the monovalent Tl is due to its similarity to potassium in ionic radius and electrical charge. Thallium sulfate use as a pesticide was restricted in 1965 in the United States, and the World Health Organization (WHO) recommended in 1973 against its use as a rodenticide due to its toxicity (WHO, 1973). From 1912 to 1930, thallium compounds were used extensively for medicinal purposes; for example, in the treatment of ringworm (because of the depilatory effects), dysentery, and tuberculosis. The narrow margin between toxicity and therapeutic benefit, however, eventually eliminated the practical use of these compounds. Due to its highly toxic nature, delayed symptoms and lack of taste or odor, Tl salts have been used for suicide attempts and in the intentional poisoning of individuals or small groups of people. Although the reported symptoms of Tl poisoning are diverse, the classic syndrome involves gastroenteritis, polyneuropathy, and alopecia. Fictional accounts of Tl as the agent of an intentional poisoning include Agatha Christie's mystery novel *The Pale Horse.* More recent accounts or suspicions of Tl use include medical case reports and reports in the mainstream press. Chronic Tl exposure has been reported in the industrial setting and exposure limits have been established (Peter and Viraraghavan, 2005). However, there currently is insufficient epidemiological data concerning the chronic effects of Tl on humans, as well as a lack of data concerning the mutagenic effects and the effect of Tl on genetic material (Rodriguez-Mercado and Altamirano-Lozano, 2013). The radioactive isotope Tl-201 is a gamma emitter used in cardiac imaging, similar to technetium-99, and it

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00014-2

has a half-life of approximately 3 days. Tl-201 is the most common isotope in use. Tl-204 decays by beta particle emission and has a half-life of 3.8 years.

TOXICOKINETICS

Thallium is rapidly absorbed from the gastrointestinal tract and is well absorbed through the skin. There is little information concerning absorption from the respiratory tract. Once absorbed, Tl is rapidly distributed throughout the body to all organs, with the highest concentrations occurring in the kidney following an acute exposure. Both monovalent and trivalent Tl appear to distribute in a similar manner, and it is not known if metabolic processes can change the valence state. Thallium can pass the placental barrier and the blood–brain barrier (Sullivan, 1992; Leonard and Gerber, 1997).

Elimination of Tl is mainly through the gastrointestinal tract, but elimination also occurs through the kidneys, saliva, hair, skin, sweat, and breast milk. Relative amounts excreted by each route vary by species. Thallium is likely excreted through intestinal and gastric secretions associated with potassium loss or excretion. Likewise, reabsorption of Tl also occurs, mainly from the colon. The estimated biological half-life of Tl is 10 days, but values up to 1 month have been reported (WHO, 1996).

MECHANISM OF ACTION

Although the precise mechanism of action of Tl is unknown, its similarity to potassium has been shown to play a significant role. Thallium has an atomic radius similar to potassium and has shown a 10-fold affinity over potassium in Na/K-ATPase, resulting in lower activity of the enzyme. Tl will inhibit the influx and efflux of potassium in mitochondria without affecting the movement of sodium. In addition to disturbing mitochondrial function, Tl has been shown to increase the levels of hydrogen peroxide and increase lipid peroxidation and oxidative stress (Hanzel and Verstraeten, 2005). The metabolism of glutathione can be disrupted by Tl, increasing the susceptibility to reactive oxygen species (Cvjetko et al., 2010). Thallium can also inactivate sulfhydryl groups, including those that affect the permeability of the outer mitochondrial membrane. Thallium can act as a Lewis acid, with an affinity for organosulfur compounds, which may account for its causing hair loss. The binding of cysteine by Tl may inhibit the keratinization of hair by preventing the cross-linking of proteins (Mulkey and Oehme, 1993).

TOXICITY

The available human literature on Tl mainly consists of case reports from the results of acute poisoning, accidental ingestion, or suicide attempts (Hammouri et al., 2011). Although the acute classic syndrome of Tl poisoning involves gastroenteritis, polyneuropathy, and alopecia, not all these effects are observed in every case. The onset and sequence of symptoms will vary with the dose and duration of exposure. The lowest-known toxic dose in the human is 0.31 g, which was reported to cause symptoms but not death (Cavanagh et al., 1974). Oral doses of 6–40 mg/kg have been lethal within 10–12 days. Other toxic doses delivered by mouth to humans fall into the range of 10–15 mg/kg for adults (WHO, 1996; Moore et al., 1993). Children have been poisoned with Tl at dose levels of 4–8 mg/kg.

Several hours following an acute exposure, initial symptoms may include gastroenteritis, including nausea, vomiting, and diarrhea. With a relatively small dose, these symptoms may be relatively mild and diffuse, with little progression for 2–5 days. Gastrointestinal bleeding or constipation may then develop, along with central nervous system and peripheral nervous system effects. These include paresthesia, with reports of the feeling of "burning feet." Additional neurological symptoms can include lethargy, delirium, seizures, and coma (Tsai et al., 2006). An initial presentation resembling Guillain–Barré syndrome has been reported (Misra et al., 2003). Nonspecific kidney and liver damage can develop as well. In severe exposures, circulatory symptoms may result, including hypertension, tachycardia, and cardiac failure. Initial dermatological involvement may include anhydrosis (which can cause fever), and this can be followed some time later by diaphoresis. In the second week following exposure, additional dermatologic symptoms appear. These include an increased darkening of the hair papillae, followed in several days by a developing alopecia. By three weeks after exposure, almost complete alopecia may manifest. At this time in the syndrome, there may be ataxia, tremors, and a painful neuritis in the lower extremities that may be severe. Following a lethal dose, death by renal or cardiac failure commonly occurs within 10–12 days. Recovery from Tl poisoning can require several months and residual neurological problems may remain, including weakness, memory impairment, and psychological disturbances (Pau, 2000; Tsai et al., 2006).

RISK ASSESSMENT

Although reported as an agent of intentional poisoning for an individual or small group of people, the broad

use of Tl in chemical warfare or terrorism has not been reported (Salem et al., 2008). The most commonly available radioisotope of Tl-201 is a gamma emitter with a short half-life, making it a poor candidate for a radiological dispersion device (Burnham and Franco, 2005; Chin, 2007). The Tl-204 isotope is a beta emitter with a half-life of 3.8 years, and its commercial use is limited. It is really not used in any significant amount (and thus there is not enough raw material to make a decent radioactive device). The chelating agent used to treat Tl exposure, ferric-hexacyanoferrate (II), known as Prussian Blue, is also used to treat radiocesium exposure; therefore, it is included in many antidote stockpiles (Ansari, 2004).

TREATMENT

The diagnosis of Tl poisoning is based upon exposure history (if available), compatible clinical time course, and symptoms, as well as the finding of above-background levels of Tl in urine, serum, or other clinical specimens. The appropriate methodology for urine or blood Tl includes atomic absorption spectroscopy (flame or flameless) and evolving methodology such as inductively coupled plasma atomic emission spectroscopy (ICP-AES). Use of colorimetric analyses of these specimens can lead to false positives (CDC, 1987). Normal or background concentration of Tl in urine is given as up to a level of <10 μg/L, with concentrations elevating several hundred- to several thousand-fold following acute exposure. Treatment should be initiated when 24 h urinary Tl excretion exceeds 0.5 mg. Additionally, a toxic level of Tl in the urine of >300 μg/L has been suggested (Sullivan, 1992). Blood Tl levels in exposure situations are less well characterized, and values above 5 μg/L are considered evidence of excess Tl exposure (CDC, 1987). Prussian Blue is the treatment of choice for Tl exposure, in that it acts by binding Tl in the gastrointestinal tract, making it unavailable for reabsorption (Altagracia-Martínez et al., 2012; Sun et al., 2012; Riyaz et al., 2013). This will increase the fecal excretion of Tl and decrease the half-life. Prussian Blue is also used in the treatment of radiocesium and acts by the same mechanism (Yang et al., 2008). The suggested dosage regime for adults and adolescents is 3 g given orally three times a day. Children between the ages of 2 and 12 years can be given 1 g orally three times a day. The clinician should check for proper gut functioning before starting treatment because constipation is a common symptom of Tl intoxication. Fluid diuresis and other symptomatic and supportive care should also be provided. Recently, a workgroup composed of international experts assembled to review and provide recommendations on the use of extracorporeal treatment for poisonings. In the case of severe Tl poisoning, the workgroup strongly recommended extracorporeal removal for Tl, although it was acknowledged that limited evidence exists (Ghannoum et al., 2012).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Thallium remains a toxic metal of concern for both accidental and intentional exposure. Its historical use as an intentional poison against individuals or small groups is based on its delayed onset of symptoms and the fact that its salts are tasteless and odorless. Although the incidence of intoxication with Tl has decreased with its decreasing availability, clinicians should remain familiar with clinical features, diagnostic considerations, and treatment regimes. History has shown that Tl is not an agent of choice for chemical warfare or terrorism, and the use of radiological Tl for these purposes is also unlikely. However, preparations for such an unlikely event are relatively straightforward; major considerations include the stockpiling of Prussian Blue (which is handy to have because it is also needed for radiocesium treatment) and the retention of analytical capabilities for Tl in biological and other samples.

CHAPTER

15

Arsenicals: Toxicity, Their Use as Chemical Warfare Agents, and Possible Remedial Measures

Swaran J.S. Flora

INTRODUCTION

Arsenic is a metalloid (semi-metal) member of group V elements of the periodic table with oxidation states of +3 (As III) and +5 (As V), in which the former (As III) is more than the latter (As V) (Aposhian et al., 2003). Both species occur in organic as well as inorganic compounds. Arsenic combines chemically with most nonmetals to form a variety of both inorganic and organic compounds. Organoarsenic compounds with trivalent arsenic were produced as pesticides as well as chemical warfare (CW) agents in the first half of the twentieth century (Aposhian et al., 2003; Li et al., 2005). A number of organic arsenicals have been developed for use as CW agents. These arsenic-containing substances in chemical weapons programs are of human and ecotoxicologic relevance. The story of arsine and lewisite encapsulates the key elements of the history of chemical weapons and their continuing power (Sugden, 2008). Although, information about arsenic and its inorganic and organic derivatives are well-documented, there is little literature available about their role as CW agents. This chapter provides readers with updated information about the organic arsenicals as CW agents and also gives a comprehensive account of toxicity due to inorganic arsenicals. Arsenic poisoning has recently assumed an alarming proportion in approximately nine districts of West Bengal, India, so much so that it has been earmarked as "the biggest arsenic calamity in the world." In view of rapid spread of various diseases arising out of arsenic contamination (e.g., arsenical dermatosis, melanosis, keratosis, edema, gangrene) in different areas of West Bengal and also in adjoining areas of Bangladesh, there is a need to provide readers with information about the modes and sites of action after exposure to environmentally relevant levels of arsenicals and to determine the effects of arsenicals in susceptible populations. The most toxicologically potent arsenic compounds are in the trivalent oxidation state. This is because of their reactivity with sulfur-containing compounds and generation of reactive oxygen species (ROS). However, humans are exposed to both trivalent and pentavalent arsenicals.

BACKGROUND

Arsenic (As) occurs in a variety of different chemical forms, among them volatile (gaseous) species, usually referred to as arsine and methylarsines (Mestrot et al., 2011). It is also well-known as an insecticide in the form of lead arsenate and arsenic acid, and in pharmacy, especially in the forms of salvarsan and neosalvarsan. Arsenic derivatives are also of value from the point of view of a CW agent (Wexler, 2004).

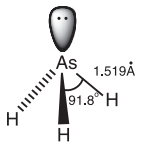
Arsine, the most toxic form of arsenic, exhibits some characteristics that may make it useful as a CW agent. Arsine is a colorless, odorless, nonirritating gas that is 2.5-times denser than air (Thomas and Young, 2001; James and Woods, 2006). At concentrations higher than 0.5 ppm, a garlic-like odor may be noted, but arsine is toxic at much lower concentrations. Acute arsine poisoning due to inhalation of arsine gas (AsH_3) is rare but has no known antidote. It is the most acutely toxic form of arsenic, causing rapid and severe hemolysis immediately on exposure. The mechanisms of hemolysis are not completely understood. Arsine has a short

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00015-4

half-life (27–96 h) and is converted to various arsenic derivatives. A number of other arsine-derived organoarsenic compounds have been developed and used as CW agents, including lewisite (L), methyldichloroarsine (MD), diphenylchloroarsine (DA), and ethyldichloroarsine (ED) (Ishizaki et al., 2005). Arsines family includes compounds with various toxicities; however, arsenic trihydride or arsine is the most toxic form. It is a powerful hemolytic gas but has never been used as a chemical weapon because it exerts nonimmediate and nonpersistent toxicity. However, cases of occupational exposure are still reported despite strict regulation. This agent, whose mechanism of action is still not well-defined, is poorly recognized because intoxication is rare. Fast detection means are available, but health professionals need to learn to recognize arsine intoxication to provide early, specific treatment and avoid damages (Plantamura et al., 2011).

Arsenicals are considered a threat, not so much from large nation states but from smaller, less developed nations and/or by terrorist organizations. The relative ease of production coupled with their effectiveness against an unprotected population make organic arsenicals a continued threat in the twenty-first century. This chapter describes the human health aspects of arsine, some of the important organic arsenicals including inorganic arsenic, and the current status of development of suitable therapeutic measures.

ARSINE



Arsine (AsH_3) is a colorless, extremely flammable gas with a garlic-like odor. The most common synonyms for arsine are arsenic hydride, arsenic trihydride, hydrogen arsenide, and arsenous hydride. The relative molecular mass of arsine is 77.95. Its boiling point is −62°C and vapor pressure at 20°C is 1,043 kPa. Arsine is a strong reducing agent, deposits arsenic on exposure to light and moisture, and is easily transformed into other oxidized arsenic forms (e.g., As (III) and As (V)). The arsine gas is colorless, odorless, and 2.5-times denser than air (Table 15.1). Arsine is a class of organoarsenic compounds of the formula $AsH_{3-x}R_x$, where R = aryl or alkyl (Franke 1967; Fowler and Weissber, 1974).

Possible sources of occupational exposure are many and include the semiconductor industry during microchip production and other industries in which workers are involved in galvanizing, soldering, etching, and lead plating. It also can be produced inadvertently by mixing arsenic-containing insecticides and acids (James and Woods, 2006). In humans and animals, arsine is metabolized to trivalent arsenic as well as pentavalent arsenic. Arsenic (III) is methylated to monomethylarsonate (MMA) and dimethylarsinate (DMA). Arsine metabolites are mainly excreted via urine (Apostoli et al., 1997; James and Woods, 2006).

TABLE 15.1 Table Showing Physical and Chemical Properties of Arsine

Properties of Arsine	
Molecular formula	AsH_3
Molar mass	77.95 g/mol
Appearance	Colorless gas
Density	4.93 g/L, gas; 1.640 g/mL (− 64°C)
Melting point	−117°C (157 K)
Boiling point	−62.5°C (210 K)
Solubility in water	0.07 g/100 mL (25°C)
Molecular weight	77.95

Arsine is supposed to be the most toxic form of arsenic. The acute toxicity of arsine in different species, including human, is high. The target organ of arsine is the hematopoietic system and, in particular, the erythrocytes. Inhaled arsine gas is distributed rapidly and causes massive red blood cell (RBC) hemolysis that can potentially lead to cellular hypoxia (Hatlelid et al., 1995; Hatlelid et al., 1996; Apostoli et al., 1997) The mechanisms involved in hemolysis are not elucidated fully, but studies reveal that arsine causes a nonspecific disruption of ion gradients, leading to cell membrane instability, that sulfhydryl group in cell membrane are probable targets of arsine toxicity, and that hemoglobin is an important subcellular target of arsine toxicity (Winski et al., 1997).

Arsine poisoning can lead to acute renal tubular necrosis and ultimately to oliguric/anuric renal failure (Rogge et al., 1983). Renal failure can be attributed to direct effect of arsine on renal tissue, heme-pigment nephropathy, or renal hypoxia secondary to massive hemolysis and decreased oxygen carrying capacity of the blood.

Exposure to other arsenic compounds to which arsine is metabolized can induce lung, bladder, kidney, and skin cancer in humans (Lenza, 2006).

Synthesis of Arsine

Arsine is formed whenever nascent hydrogen is released in the presence of arsenic or by action of water on a metallic arsenide. The formation of arsine

can be described with the help of the following reaction (Anthonis et al., 1968; Coles et al., 1969):

$$3H_2 + HAsO_2 \rightarrow AsH_3 + 2H_2O$$

AsH_3 is also prepared by the reaction of As^{3+} sources with H^- equivalents (Bellama and Macdiarm, 1968).

$$4AsCl_3 + 3NaBH_4 \rightarrow 4AsH_3 + 3NaCl + 3BCl_3$$

Alternatively, sources of As^{3-} react with protonic reagents to produce arsine:

$$Zn_3As_2 + 6H^+ \rightarrow 2AsH_3 + 3Zn^{2+}$$

Sources of Exposure

The main anthropogenic sources of arsine include its accidental formation, particularly in the chemical and nonferrous (zinc, copper, and cadmium) metallurgical industries, production or use of the gas itself during manufacture of semiconductors as a doping agent, and in battery production as an alloy with lead (Aposhian, 1997; Winski et al., 1997).

Arsine is extensively used in the semiconductor industry for epitaxial growth of GaAs and as a dopant for silicon-based electronic devices. Arsine is also used in organic synthesis and as an agent in the manufacture of light-emitting diodes, and for manufacturing certain glass dyes (HSDB, 1999).

Human Arsine Exposure

Arsine might be a potential CW agent (Lenza, 2006). Occupational sources where exposures to arsine at levels sufficient to cause acute arsine intoxication have occurred include copper smelting and refinery, bronzing process, chemical companies (cleaning a clogged drain), transistor industry, and burnishing of metals (Romeo et al., 1997). Many processes including electrolyte refining, galvanizing, soldering, etching, lead plating, metal smelting, and extraction may expose workers to toxic concentrations of arsine (Chein et al., 2006).

Metabolism of Arsine

Animal Studies

The main route of arsine excretion is via urine after metabolism. Levvy (1947) studied the elimination of arsenic in arsine-exposed mice and compared it with the animals exposed to sodium arsenite. Arsenic was excreted exponentially in mice intravenously administered arsenite; after 24h, less than 10% of the dose remained. However, arsenic arising from inhalation exposure to arsine 180mg/m^3 for 120min was excreted more slowly; after 24h, approximately 45% of arsenic remained in the exposed mice.

Human Studies

Apostoli et al. (1997) detected the presence of arsenic in tissues, blood, and urine of workers in the petroleum industry who were poisoned with arsine. In a fatal case of arsine poisoning, arsenic was found in the liver at a concentration of 11.8mg/g, in the spleen at 7.9mg/g, in kidneys at 3.2mg/g, in the brain at 0.6mg/g, and in the urine at 0.6mg/m. Trace amounts were also found in the blood (Apostoli et al., 1997). Inhaled arsine was rapidly dissolved in body fluids and oxidized to As(III) (Apostoli et al., 1997). Part of As(III) is further oxidized to As(V), as indicated by the appearance of As(V) in urine of humans exposed to arsine 1–2 days after exposure. Trivalent arsenic is methylated to MMA and DMA (Romeo et al., 1997).

Mechanism of Toxicity

The mechanism of arsine (AsH_3) toxicity is not completely understood, but hemoglobin (Hb) has long been recognized as a necessary component of the overall mechanism of AsH_3-induced hemolysis (Rael et al., 2006). After inhalation of arsine gas, it causes rapid destruction of RBCs, leading to hypoxia and renal failure. Two mechanisms have been proposed for arsine poisoning: reaction with sulfhydryl groups (Winski et al., 1997; Waters et al., 2004) and oxidative stress (Blair et al., 1990; Hatlelid et al., 1996; Hatlelid and Carter, 1997). Besides these two mechanisms, nonspecific disruption of ion gradient leading to cell membrane instability and lysis of RBCs has also been proposed as mechanism for the toxic effects of arsine (James and Woods, 2006). Hatlelid and Carter (1997) postulated that the hemolytic activity of arsine is related to oxidative stress through the formation of hydrogen peroxide and arsine adducts with hemoglobin.

Oxyhemoglobin (oxyHb) has been recognized as a necessary component for overall mechanism of AsH_3-induced hemolysis, as conversion of oxyHb to carboxyHb prevents hemolysis in erythrocytes exposed to AsH_3 (Rael et al., 2000).

Some studies have suggested that the sulfhydryl groups of glutathione (GSH) prevented hemoglobin oxidation and in this manner are essential for the maintenance of intact erythrocyte structure. In an *in vitro* study, a decrease in reduced GSH concentration in human RBCs was found to correlate with the hemolytic action of arsine (Rael et al., 2000). Blair et al. (1990) recorded a 60% decrease in reduced GSH level in erythrocytes exposed to arsine *in vitro*. However, Hatlelid et al. (1995) showed that the depletion of reduced GSH in RBCs in dogs neither preceded nor coincided with hemolysis.

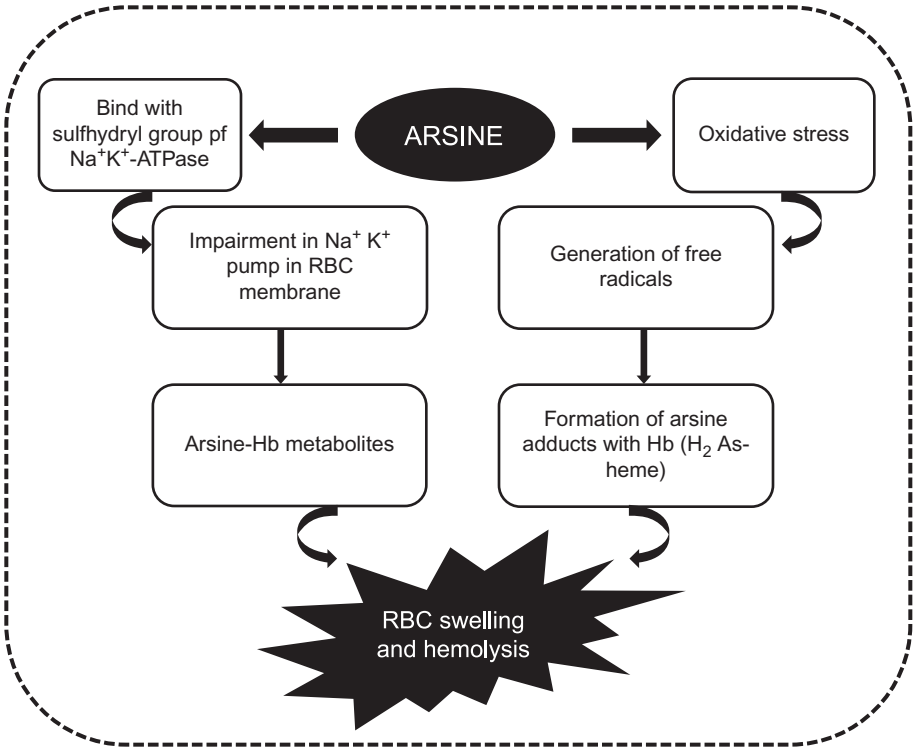


FIGURE 15.1 Schematic diagram showing hemolytic activity of arsine. Figure shows that arsine reacts with the sulfhydryl group of Na^+K^+-ATPase, leading to the impairment in the sodium-potassium pump which subsequently causes red cell swelling and hemolysis.

According to the hypothesis of the sulfhydryl-dependent mechanism of arsine toxicity, arsine reacts with the sulfhydryl group of Na^+K^+-ATPase, causing an impairment in the sodium-potassium pump that subsequently causes red cell swelling and hemolysis (Figure 15.1). The affinity of trivalent arsenic for the sulfhydryl group is well-known. Winski et al. (1997) reported profound abnormalities in membrane ultrastructure and in RBC volume, which were manifested by potassium leakage, sodium influx, and increases in hematocrit in arsine-exposed red cells. However, no change in ATP and ATPase was observed after exposure to arsine. Hemolysis in arsine-exposed RBCs depended on membrane disruption caused by arsine–hemoglobin metabolites, the ultimate toxic species (Winski et al., 1997).

Effects on Humans

Toxicity of arsine to humans was first demonstrated in 1815, when a German chemist accidentally inhaled arsine vapor during an experiment (Romeo et al., 1997).

Acute Arsine Poisoning

Persons exposed to arsine gas are often unaware because there are no symptoms at the time of exposure (James and Woods, 2006). The majority of arsine exposures are clinically acute; however, lower levels of chronic exposure have been reported in literature (Casarett and Doull, 2001). Most patients report little or no discomfort at the time of exposure. Although a garlic-like odor may be noted with higher ambient arsine concentrations, serious toxicity may result from clinically nondetectable exposures (Levvy, 1947; Apostoli et al., 1997; Thomas and Young, 2001; Young et al., 2003; Lenza, 2006; Song et al., 2006). Symptoms after sub-lethal arsine exposure may include abdominal pain, hematuria, and jaundice (Figure 15.2).

Physical Signs

Physical signs and their severity depend on the concentration of arsine gas and the duration of the exposure and have been mentioned in Figure 15.2 (Levvy, 1947; Apostoli et al., 1997; Thomas and Young, 2001; Young et al., 2003; Lenza, 2006; Song et al., 2006).

Immediate Effects

Clinical manifestation of arsine intoxication appears within 24 h of exposure (usually within a few hours). Renal failure due to tubular destruction is an important consequence of arsine exposure. The urine is frequently discolored (brown, red, or black), and hemoglobin in the urine is thought to be the major cause. Urinalysis

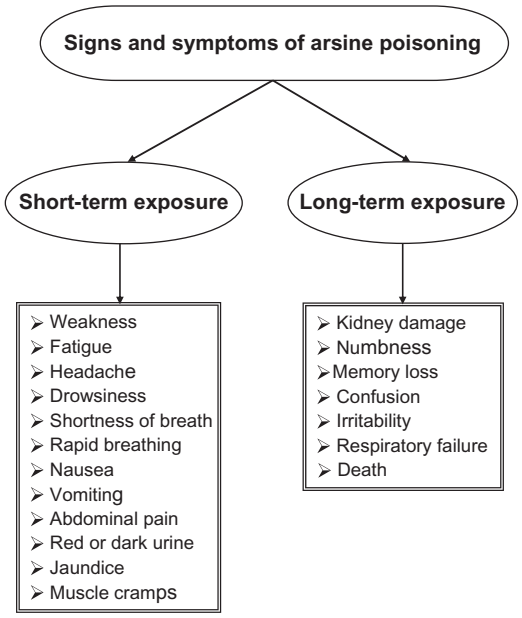

FIGURE 15.2 Figure showing signs and symptoms of arsine poisoning. Signs and symptoms following short-term and long-term sub-lethal exposure to arsine.

typically shows large amounts of protein and free hemoglobin with only a few RBCs. The characteristic red/bronze tint of the skin is induced by hemolysis and may be caused by hemoglobin deposits (James and Woods, 2006). In some cases, hepatomegaly and splenomegaly with tenderness of costovertebral angle, fever, tachycardia, and tachypnea occur. Hemolytic anemia is the most consistent clinical finding in humans. Massive hemoglobinuria may lead to anuria, which, if untreated, is often the cause of death (Hatlelid et al., 1996; Winski et al., 1997).

Late Effects

Late consequences of acute arsine poisoning include chronic renal damage, hematological changes, polyneuritis, and neuropsychological symptoms (e.g., irritation, confusion, memory losses, agitation, and disorientation). Peripheral neuropathy was still present 6 months after exposure (Gosselin et al., 1982). Extreme restlessness, loss of memory, agitation, and disorientation occurred several days after exposure and lasted approximately 10 days in two patients heavily exposed to arsine. An increase in total cell count and macrophages in bronchoalveolar lavage was observed in an arsine-exposed worker. Progressive improvement in diffusing capacity of lungs was observed only after 2 months of treatment. Hepatitis in an arsine-poisoned patient on day 20 after the acute hemolysis also has been reported (Mora et al., 1992).

Long-Term Exposure

Long-term exposure may cause symptoms similar to those observed in acutely poisoned individuals. The main differences from acute poisoning were in a delay in onset and development of peripheral neuritis, development of gastrointestinal track involvement, and development of hemolysis and renal impairment. Lowered hemoglobin levels were found in zinc ore smelting workers exposed to arsine for long periods and who had urinary arsenic concentration less than 0.2 mg/L (Watson and Griffin, 1992).

Diagnostic Tests

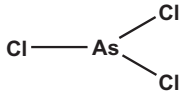
Laboratory Studies

Complete blood count, methemoglobinemia, urinalysis, arsenic levels, electrocardiogram, and imaging studies were performed.

Complications

Complications include hemolytic anemia, renal failure, hyperkalemia, and death. Overwhelming exposures cause rapid death from massive hemolysis. Most deaths occur from renal failure in patients who survive acute exposure. Patients surviving acute arsine exposure may develop chronic arsenic toxicity, including anemia and peripheral neuropathy.

ORGANIC ARSENICALS



Organic arsenicals are a series of blister agents based around a chloroarsine ($AsCl_3$) molecule in which one of the chlorine atoms is replaced by an organic radical. These chloroarsine are effective cytochrome oxidase destroyers, or blood agents. Many organic radicals penetrate human skin, carrying their compounds with them (Cohen et al., 2006).

Background

Interests in organic arsenicals date back to the mid nineteenth century. Chemists discovered that arsenic–chloride compounds (chloroarsines), in which one of the chlorine atoms is replaced by an organic radical, tends to be harmful both to insects and to human tissue (McManus and Huebner, 2005; Bartelt-Hunt et al., 2008). The trench warfare stalemate during World War I created a tactical need for a chemical weapon that was

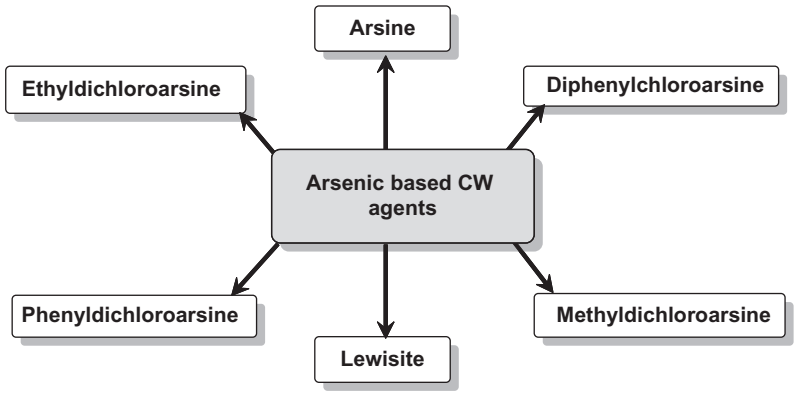


FIGURE 15.3 Figure showing arsenic based CW agents.

both short-acting (e.g., nonpersistent, volatile) and lethal (Stephenson, 2006). To fill this need, the first weaponized organic arsenical, MD, was delivered. Two additional organic arsenicals, DA and ED, soon augmented MD. A fourth organic arsenical named lewisite was discovered by US Army Medical Corps but was never deployed in World War I (Boronin et al. 1996; McManus and Huebner, 2005; Bartelt-Hunt et al.,2008) (Figure 15.3).

Mechanism of Toxicity

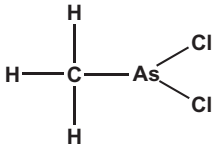
The exact mechanism for the toxic effects of organic arsenicals is unknown. DNA alkylation and/or inhibition of GSH-scavenging pathways are two postulated mechanisms (Nesnow et al., 2002). On contact with arsenicals, a blistering reaction occurs on skin, eye, or pulmonary tissues (Cohen et al., 2006; Devesa et al., 2006; Kojima et al., 2006). Animal data and limited human trials suggest that organic arsenicals readily penetrate the skin. Within seconds of contact, the chemical fixes itself to the epidermis and dermis. Pain is immediate, followed by destruction of subcutaneous tissue. The separation of dermis from epidermis and capillary leakage cause fluid-filled vesicles (McManus and Huebner, 2005; Naranmandura and Suzuki, 2008). Intravascular hemolysis of erythrocytes with subsequent hemolytic anemia may result (Wu et al., 2003).

Symptoms

Vapor contact with the conjunctiva may be the victim's first symptom. Severe conjunctival irritation and blepharospasm may lead to loosening of corneal epithelial cells and swelling and edema of the cornea. Mucosal damage starts in the nose and descends down the respiratory mucosa in a dose-dependent fashion. Immediate pain, lacrimation, and irritation accompany the damage. DA vapor causes vomiting that develops within 1–2 min after exposure to DA.

The immediate onset of symptoms after exposure makes severe or systemic toxicity to organic arsenical unlikely. However, prolonged contact may lead to involvement of multiple organs (Kojima et al., 2006; Kinoshita et al., 2007).

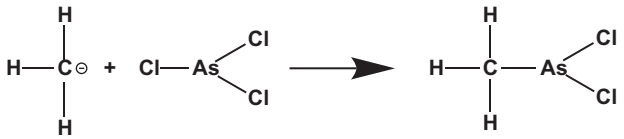
Methyldichloroarsine



MD was apparently used by Germans in 1917. MD is a colorless liquid with a powerful burning odor that boils at 132°C. It is somewhat soluble in water and is soluble in organic solvents. The specific gravity is 1.838 at 20°C. The vapor pressure at 25°C was found to be 10.83 mmHg. The material is not only toxic but also has remarkable vesicant properties, comparing favorably with mustard gas in this respect (Bennett and Dill, 1994).

Structure of MD

The structure of MD consists of a trichloroarsine ($AsCl_3$) molecule combined through catalysation with a methyl (CH_3) group.

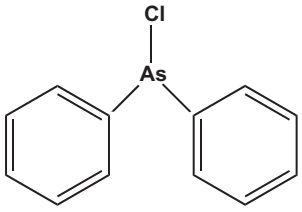


Pathology

Chlorine bonds in MD give it its blistering qualities. The methyl group simply aids in its assimilation into the

human body. Chlorine reactivity causes severe respiratory pain and damage to the membranes of the lungs. "Dry-land drowning" can occur as the lungs flood with water and mucous and the victim dies of a combination of blood poisoning and asphyxiation (Pitten et al., 1999).

Diphenylchloroarsine

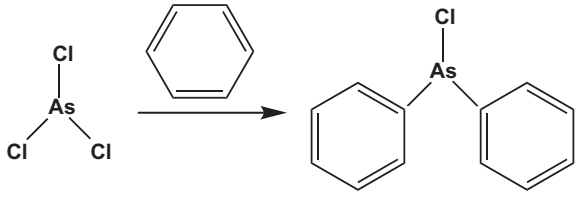


DA is an irritating substance that was developed in 1918 for use in a smoke generator known as the M-device. The researchers described DA as having "a very powerful irritant action on the mucous membranes of the eyes and nose, causes painful blistering of the skin, and is very dangerous for those working with it, since its vapor causes respiratory embarrassment, faintness, and long-lasting paralysis and anesthesia of the extremities" (Ishii et al., 2004; Kato et al., 2007).

Because DA and related compounds cause intense effects on the nasal and upper respiratory passages, they are referred to as "sneeze gas" (sternutators). Like other arsenicals, DA is a white solid and was originally produced as both a casualty gas and a mask breaker during World War I.

Structure

DA is prepared from trichloroarsine ($AsCl_3$):

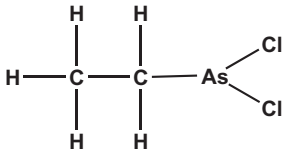


Two chlorine ions are replaced by benzene groups, forming a stable compound that may be safely stored under all field conditions.

Effects of DA

The immediate effects of DA are those associated with tear gas compounds: severe irritation to the eyes, nose, and throat. Severe headache and the feeling of tightness of the chest and of the bowels occur within 1 min of inhalation of this compound. Headache rapidly develops into a general nausea that results in vomiting within 3 min. In closed or confined spaces, DA can produce fatalities by first causing unconsciousness and then asphyxiation (Ochi et al., 2004).

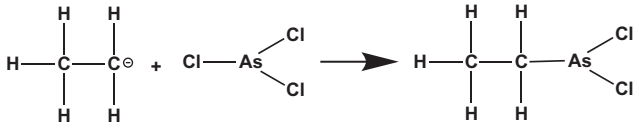
Ethyldichloroarsine



ED was the third, and last, of the three blistering arsenicals developed in late 1917–1918. Despite serious efforts made to weaponize this compound, few literature exists on the effectiveness and history of its use. Fast-acting compared with mustard or phosgene, ED is a colorless liquid that smells like rotting fruit and has multiple effects on the body.

Structure

The structure of ED consists of trichloroarsine ($AsCl_3$) molecule combined through catalysation with ethyl (C_2H_5) group.

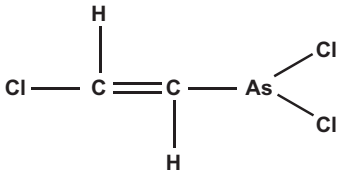


Production of ED is similar to that of MD, involving the ethylation of a chlorinated arsenite or arsenate salt, or in reductions of arsenious oxide, As_4O_6, a naturally occurring compound (Bartelt-Hunt et al., 2006).

Effects of ED

Chlorine bonds in ED cause its blistering, lachrymatory, and harsh respiratory effects. Fluid-filled blisters form only after prolonged exposure. Inhalation can cause pulmonary edema or "dry-land drowning." A lethal exposure, however, depends on the period of exposure. A dose of 3,000–5,000 mg min/m^3 is generally lethal. Dosages as low as 5 mg min/m^3 may cause severe discomfort to the eyes and throat. Sub-lethal dosages are detoxified by the body. The ethyl arsenic group of ED may cause systemic damage to bone marrow and to the digestive and endocrine systems. Blisters may appear within 2–4 h after skin redness or rash. However, like the mustards, ED actively attacks lung tissue. Damage to lung tissue is permanent in its survivors and presents a hazard area for future infections and tumors. ED is highly poisonous to the eyes. It may cause permanent corneal damage.

Lewisite



Lewisite (chlorovinyldichloroarsine), a war gas, is a colorless, oily liquid at room temperature with a faint "geranium-like" odor. Lewisite dissolves slowly in water and hydrolyzes rapidly to hydrochloric acid and lewisite oxide (Daniels et al., 1990). Lewisite produces irritation and blistering of the skin and injury to the eyes and lungs promptly after high exposure; at lower levels the effects resemble exposure to tear gas, with irritation of skin, eyes, and respiratory tract. Chronic exposure may lead to development of chronic bronchitis and predispose to Bowen squamous cell intraepithelial cancer of the skin.

History and Background Information

Lewisite (also known as Agent L), is no longer considered a state-of-the-art CW agent. Lewisite is a significant threat to unprotected personnel and causes prompt incapacitation from eye injuries and respiratory irritation, coupled with long-term incapacitation from skin burns, pulmonary injury, and systemic illness. Its decomposition products are toxic, making decontamination difficult. Munitions containing lewisite may contain toxic stabilizers. Lewisite is effective as vapor, aerosol, or liquid (Sidell et al., 1997).

Toxicity and Mechanism of Action

Trivalent arsenic is considered the component of lewisite that is primarily responsible for its vesicant and systemic toxicity (Aposhian et al., 2003). Trivalent arsenic exerts its toxic effect by binding to sulfhydryl-containing proteins, especially enzymes, thus inhibiting pyruvate oxidation (Black, 2008). Trivalent arsenic readily penetrates skin, exerting its toxic action systemically and causing painful localized blistering. Lewisite produces pulmonary edema, diarrhea, restlessness, weakness, subnormal temperature, and low blood pressure. Edema and hemorrhaging associated with lewisite exposure can lead to shock and death (Flora et al., 2007a).

A no-observed adverse-effect level of 0.016 mg/kg/day in rabbits and 1.5 mg/kg/day in rats was identified (Daniels et al., 1990). Lewisite is capable of producing DNA damage; however, direct tests of its mutagenic potential have been inconclusive (Datta et al., 2007).

Toxicokinetics

The cellular poisoning effects are attributed to the inhibition of cellular enzyme systems (Watson and Griffin, 1992), especially as a result of arsenic complexing with sulfhydryl groups of proteins and enzymes. This agent affects many sulfur-containing enzymes, including amylase, lipase, cholinesterase, some adenosine triphosphate (ATP) enzymes, creatine phosphokinase, and, of central importance, the pyruvate oxidase system. Two mechanisms have been proposed for the aforementioned effects (Sidell et al., 1997): reactions with GSH, leading to loss of protein thiol status, loss of calcium ion homeostasis, oxidative stress, lipid peroxidation (LPO), membrane damage, and cell death, and reactions with sulfhydryl groups on enzymes leading to inhibition of pyruvate dehydrogenase (PDH) complex, inhibition of glycolysis, loss of ATP, and cell death.

Clinical and Pathological Findings

Signs and symptoms of acute lewisite exposure include a rapid onset of irritation to the eyes and mucous membranes of the upper respiratory tract (lachrymation and rhinitis). In more serious cases of vapor intoxication, chest pain, nausea, vomiting, headache, weakness, convulsions, hypothermia, and hypotension occur (Sidell et al., 1997; Katos et al., 2007). Laboratory tests of the blood of persons exposed may show hemoconcentration; animal studies suggest elevated liver enzymes, including lactate dehydrogenase (LDH) (King et al., 1994; Sasser et al., 1999). The following sub-sections describe the effects on specific body sites.

Skin

Exposure of the skin to vapor causes immediate itching or stinging within 1 min, followed by erythema over 10–30 min. More intense exposures, including liquid contact, produce intense stinging and the formation of small vesicles over the next 24 h, with later enlargement of the vesicles with accumulation of a nontoxic fluid (McManus and Huebner, 2005; Kato et al., 2007).

Eye

Immediate eye pain and blepharospasm result from lewisite exposure, followed by conjunctival and lid edema. Severe exposures can produce necrotic injuries of the iris with depigmentation, hypopion, and synechia development (McManus and Huebner, 2005).

Respiratory System

Li et al. (2013) conducted an analysis of the damage of acute arsine poisoning on respiratory system. Mild respiratory exposures resemble upper respiratory infections, and more severe exposures cause lower respiratory effects, with continuous coughing, laryngitis, and aphonia (McManus and Huebner, 2005).

Nervous System

Neurological findings are inconsistent despite reports of convulsions and coma with severe exposures

(McManus and Huebner, 2005). Neurologic complications after mild exposures have not been described. Edema and hemorrhage in the brain are rare, but no reports of degeneration of peripheral nerves were found.

Cardiovascular System

Bradycardia, dyspnea, hypotension, and hemoconcentration have been reported in severe intoxication. These effects are mediated by vasodilatation and increased capillary permeability (Watson and Griffin, 1992). Dilation of the right side of the heart in severe poisoning in animals has been reported.

Other Systems

Human ingestion experience is not documented (NAS, 1997) but would be expected to produce severe abdominal pain and bloody diarrhea. Nausea and vomiting occur from respiratory or dermal exposure. In humans and animals, vomiting is associated with retching (Sidell et al., 1997). There is no documentation of liver effects from chronic lewisite exposure. There are no specific musculoskeletal findings, although weakness has been observed. There is little clinical information about effects on bone marrow and the immune and endocrine systems. Renal disorders, although theoretically possible, are not described. There is also no substantial evidence that lewisite is carcinogenic, teratogenic, or mutagenic (Sidell et al., 1997).

INORGANIC ARSENIC

Arsenic is a metalloid that belongs to group VA of the periodic table. It exists in three oxidation states: metalloid (0), trivalent (−3 or + 3), and pentavalent (+5). The most common inorganic trivalent arsenic compounds are arsenic trioxide, sodium arsenite, and sodium trichloride. Pentavalent inorganic arsenic compounds are arsenic pentaoxide, arsenic acid, and arsenate (e.g., lead arsenate and calcium arsenate). In general, the toxicity of arsenic compounds is in the following order: arsine > arsenites > arsenates > organic > elemental.

Sources and Uses

Uses

Arsenic is used as a bronzing and decolorizing agent in the manufacture of glass, as a desiccant and defoliant in agriculture and in the production of semiconductors, and as a byproduct of the smelting of nonferrous metals, particularly gold and copper, from coal residues (Tanaka, 2004).

Exposure

Arsenic exposure occurs from inhalation, absorption through the skin, and primarily by ingestion of arsenic-contaminated drinking water. The exposure to arsenic may come from natural sources, industrial processes (semiconductor manufacturing), commercial products, food, and medicines (Kosnett, 1990). Acute arsenic poisoning is only limited to homicidal or suicidal attempts.

Absorption, Distribution, and Excretion

Respiratory absorption of arsenic is a two-stage process involving deposition of the particles onto airway and lung surfaces, followed by absorption of arsenic from deposited particulates. Trivalent and pentavalent inorganic arsenic have been reported to cross the placenta in laboratory animals and humans (Bollinger et al., 1992). Recent studies indicate that the main form of arsenic bound to rat hemoglobin is dimethylarsinic acid (DMA), the primary metabolite of inorganic arsenic (Lu et al., 2004).

In humans as well as in most animal species, exposure to either arsenite or arsenate leads to an initial accumulation in the liver, kidneys, and lungs (Fujihara et al., 2004). Arsenic is a terribly poisonous material and there have been many reports of arsine poisoning in workers. Findings indicate induction of acute kidney injury by arsine. However, extensive investigations are required because reports describing ultrastructural findings are rare. Present evidence suggests incidents of acute arsine poisoning complicated by acute kidney injury as revealed by characteristics of the renal pathology (Lee et al., 2013). The clearance from these tissues is, however, rather rapid, and a long-term retention of arsenic is seen in hair, skin, squamous epithelium of the upper gastrointestinal tract, epidymis, thyroid, lens, and skeleton (Hughes et al., 2003). At 2–4 weeks after exposure ceases, most of the arsenic remaining in the body is found in keratin-rich tissues, such as skin, hair, and nails. Arsenic metabolism is characterized by two main types of reaction. First is reduction of the pentavalent arsenic to trivalent arsenic. This conversion of pentavalent arsenic species to trivalent arsenic species is catalyzed by arsenate reductase (Radabaugh and Aposhian, 2000; Radabaugh et al., 2002). Second is oxidative methylation reactions in which trivalent forms of arsenic are sequentially methylated to form monomethylated, dimethylated, and trimethylated products using *S*-adenosyl methionine as the methyl donor and GSH as an essential co-factor (Vahter, 2002). Pentavalent arsenic has been reported to be less toxic than inorganic trivalent arsenic. The metabolic methylation historically had been considered as a detoxification process. Recently, it has been established that trimethylated arsenicals, particularly monomethylarsinous acid (MMA(III)) and dimethylarsinous acid (DMA(III)), exist as intermediates in the metabolic methylation process of inorganic arsenic in humans (Mandal et al., 2001) and

are more active than the parent inorganic arsenic for enzymatic inhibition, cytotoxicity (Petrick et al., 2001), and genotoxicity (Nesnow et al., 2002). The major route of excretion after exposure to inorganic arsenic is via kidneys (Csanaky and Gregus, 2005).

Biochemical and Toxic Effects

Hematopoietic

The hematopoietic system is affected by both short-term and long-term arsenic exposure. Arsenic is known to cause a wide variety of hematological abnormalities like anemia, absolute neutropenia, leucopenia, thrombocytopenia, and relative eosinophilia, which is more common than absolute eosinophilia, basophilic stippling, increased bone marrow vascularity, and rouleaux formation (Rezuke et al., 1991). These effects may be due to a direct hemolytic or cytotoxic effect on the blood cells and a suppression of erythropoiesis. The mechanism of hemolysis involved depletion of intracellular GSH, resulting in the oxidation of hemoglobin (Saha et al., 1999). Arsenic exposure is also known to influence the activity of several enzymes of heme biosynthesis. Arsenic produces a decrease in ferrochelatase and a decrease in COPRO-OX, and an increase in hepatic 5-aminolevelinic acid synthetase activity (Woods and Southern, 1989). Sub-chronic exposure to arsenic has also been reported to inhibit δ-aminolevulinic acid synthetase and ferrochelatase activities, leading to increased uroporphyrin (URO) and coproporphyrin and COPRO urinary excretion. In chronically exposed humans, arsenic alters heme metabolism, as shown by an inversion of the urinary COPRO:URO ratio (Garcia-Vargas et al., 1996). Some recent studies also suggested a significant inhibition of blood δ-aminolevulinic acid dehydratase (ALAD) after sub-chronic and chronic arsenic exposure (Flora, 1999; Kannan et al., 2001; Flora et al., 2002). Anemia and leucopenia are common effects of poisoning and have been reported from acute, intermediate, and chronic exposure. These effects may be due to a direct effect of arsenic on the blood cells and a suppression of erythropoiesis. There was a proposal that the profile of urinary porphyrins could be used as early biomarkers for arsenic toxicity in humans chronically exposed to arsenic via drinking water.

Skin (Dermal)

Dermal changes most frequently reported in arsenic-exposed humans include hyperpigmentation, melanosis, hyperkeratosis, warts, and skin cancer. However, dermal effects appear to be highly dependent on time of exposure (Rossman, 2003). Arsenic-exposed skin cancer occurs mostly in unexposed areas such as trunk, palms, and soles. More than one type of skin cancer is reported, with the most common being Bowen disease, squamous cell carcinomas, basal cell carcinomas, and combined forms. It appears that skin cancer lesions related to arsenic exposure act as early warning signals of the subsequent development of cancers of internal organs many years later (Wong et al., 1998). Brittle nails, the surface of which are marked by transverse bands (leukonychia striata arsenicalis transverses), have been associated with arsenic poisoning; the characteristic bands are known as Reynolds Aldrich–Mees lines.

Hepatic

Arsenic is one of the first chemical agents that liver disease was attributed to in humans. Early symptoms in patients with arsenic-induced hepatic injury include bleeding esophageal varices, ascites, jaundice, or simply an enlarged tender liver (Rahman et al., 1999; Santra et al., 2000). Recent animal studies have shown that hepatic enzyme changes occur after arsenic exposure and these enzyme changes involved in the antioxidant defense system and membrane damage due to lipid per oxidation precede the pathomorphological lesions of arsenic-induced hepatic fibrosis in mice (Santra et al., 2000; Mishra et al., 2008).

Gastrointestinal

Gastrointestinal symptoms are common during acute poisoning. Gastrointestinal effects due to chronic arsenic poisoning are called arsenicosis. The patients report metallic taste and garlic odor. Clinical signs of gastrointestinal irritation due to acute arsenic poisoning include burning lips, painful swallowing, thirst, nausea, and abdominal colic (Goebel et al., 1990). The toxic effects of arsenic on the gastrointestinal mucosal vasculature are vasodilatation, transduction of fluid into the bowel lumen, mucosal vesicle formation, and sloughing of tissue fragments. Rupture of vesicle may cause bleeding, profuse watery stools (“rice-water stools”), and protein-losing enteropathy. The most likely mechanism of gastrointestinal toxicity is damage of the epithelial cells, with resulting irritations.

Respiratory

Studies from West Bengal, India, draw attention to both restrictive and obstructive lung disease. Respiratory disease is more common in patients with the characteristic skin lesions due to chronic arsenic toxicity (Mazumder et al., 2000). Humans exposed to inhalation of arsenic dust or fumes are more likely to be encountered in mining and milling ores and in industrial processing (such as smelting industry); this often produces irritation of mucous membranes, resulting in laryngitis, bronchitis, rhinitis, and tracheobronchitis, causing stuffy nose, sore throat, dyspnea, chest pain, and chronic cough (ATSDR, 2000). Pulmonary edema may occur, especially in cases of inhalation.

Cardiovascular

It has been suggested by several epidemiological studies that chronic inhalation of arsenic trioxide can increase the risk of death attributable to cardiovascular disease in humans (Saha et al., 1999). Both acute and chronic arsenic exposures cause altered myocardial depolarization and cardiac arrhythmias that may lead to heart failure. Arsenic causes direct myocardial injury, cardiac arrhythmias, and cardiomyopathy. Blackfoot disease, which causes gangrene of the foot and is unique to a limited area on the southwestern coast of Taiwan, is due to long-term exposure to high levels of inorganic arsenic in well water (range, 0.01–1.82 mg/L) (Tsai et al., 1999). Epidemiological studies also indicate that excess intake of arsenic leads to a variety of vascular diseases such as Blackfoot disease, Reynaud phenomenon, cardiovascular and cerebrovascular diseases, atherosclerosis, and hypertension (Simeonova and Luster, 2004).

Reproductive and Developmental

Reproductive and developmental effects of inorganic arsenic on humans and animal species have been reported. Limited animal studies suggest that arsenic can produce malformation, intrauterine death, and growth restriction (Gulob et al., 1998). Arsenic readily crosses the placenta. Sarkar et al. (2003) also suggested that spermatogenesis and/or sperm function might be impaired by organic arsenicals. Ahmad et al. (2001) observed pregnancy outcomes in women chronically exposed to arsenic through drinking water. The authors reported that arsenic contamination is a threat to healthy and safe pregnancy outcomes.

Neurological

After initial contradictory reports, it is now established that arsenic could cross the blood–brain barrier and produces alternations in whole rat brain biogenic amine levels in animals chronically exposed to arsenite (Tripathi et al., 1997). The neurological effects are many and varied. Usually, peripheral neuropathy, sensory neuropathy (Hafeman et al., 2005), and encephalopathy are the initial symptoms associated with acute arsenic poisoning. Acute exposure to arsenic in humans has been shown to result in problems of memory, difficulties in concentration, mental confusion, and anxiety (Rodriguez et al., 2003). Other neurological symptoms that arise because of arsenic are primarily those of a peripheral sensory neuritis, predominantly numbness, severe paresthesia of the distal portion of the extremities, diminished sense of touch, pain, heat, and cold, and symmetrically reduced muscle power (Menkes, 1997).

Diabetes Mellitus

Noninsulin-dependent (type 2) diabetes is the prevalent form of diabetes mellitus found in populations chronically exposed to inorganic arsenic from the environment (Rahman et al., 1998; Tseng, 2002). Type 2 diabetes is characterized by insulin resistance of internal organs and peripheral tissues, resulting in impaired glucose utilization and, consequently, in abnormally high blood glucose levels between meals and especially after meals. Insulin resistance and β-cell dysfunction can be induced by chronic arsenic exposure, and these defects may be responsible for arsenic-induced diabetes mellitus (Tseng, 2004).

Mechanisms of Toxicity

Arsenic in its free form generates free radicals, resulting in LPO, depletion of antioxidant enzymes, and DNA damage, thereby establishing oxidative stress as the major mechanism of As-induced toxicity and carcinogenicity (Ratnaike, 2003; Flora, 2011). Trivalent inorganic arsenicals, such as arsenite, readily react with sulfhydryl groups such as GSH and cysteine (Delnomdedieu et al., 1994). The complex between arsenic and vicinal sulfhydryl group is particularly strong. Arsenite inhibits PDH activity (Hu et al., 1998), perhaps by binding to the lipoic acid moiety. Inhibition of PDH ultimately leads to decreased production of ATP. Methylated trivalent arsenicals such as MMA^{III} are potent inhibitors of GSH reductase and thioredoxin reductase (Styblo et al., 1997). The inhibition may be due to the interaction of trivalent arsenic with critical thiol groups in these molecules. A mechanism of toxicity of pentavalent inorganic arsenic, such as arsenate, is its reduction to a trivalent form, such as arsenite. The reduction of arsenate to arsenite occurs *in vivo.* Another potential mechanism is the replacement of phosphate with arsenate. Oxidative injury causing damage to DNA molecules and various cell components, such as polyunsaturated fatty acid residues of phospholipids, amino acids, peptides, and proteins, has been reported as one of the foremost consequences of As exposure because these are susceptible targets of metal-induced ROS attack (Flora, 2011).

Oxidative Stress

Oxidative stress has now been established as one of the major mechanisms involved for arsenic-induced carcinogenesis. A number of recent reports provided direct evidence of inorganic arsenic-induced free radical formation or production of oxidative stress (Flora, 1999; Liu et al., 2000; Sun et al., 2005). ROS that damage DNA *in vitro* are generated from iron released from ferritin. The results suggest that some clastogenic effects of arsenic are mediated via free radicals (e.g., peroxynitrite, superoxide, hydrogen peroxide, and possibly free iron). Vega et al. (2001) suggested that arsenic exposure could increase the production of ROS, activation of transcription factors (e.g., AP-1, *c-fos* and NF-κB), and oversecretion of pro-inflammatory and growth-promoting

cytokines, resulting in increased cell proliferation and, finally, carcinogenesis. Increased ornithine decarboxylase activity is often interpreted as a biomarker for cell proliferation (Kitchin, 2001). Arsenite appears to have an effect on the cell cycle, which may alter cell proliferation. The amplification of the gene codes for the enzyme dihydrofolate reductase enhanced by arsenic.

Diagnosis

Clinical Features

Clinical features like skin lesions and neuropathy are crude and imprecise indicators of the severity of poisoning. White striae in the fingernails are also a useful clue in the diagnosis of arsenic toxicity. These white striae are also known as "Mee's line." Other symptoms are anemia, leucopenia or pancytopenia, gangrene of the feet (Blackfoot disease), hyperpigmentation, hypopigmentation, and hyperkeratosis. Keratosis and pigmentation are the characteristic skin lesions associated with arsenic toxicity. They are typically exhibited by diffuse thickening of palms and soles, alone or in combination with nodules and presence of raindrops in the form of numerous rounded hyperpigmented macules in the body (Tondel et al., 1999). Leucomelanosis is another common skin lesion, consisting of hypopigmented macules with a spotty white appearance. Elevated arsenic content in hair and nail segments, normally less than one part per million (ppm), may persist for months after urinary arsenic values have returned to baseline. They are preferable samples to detect and quantify exposure to arsenic, because absorbed arsenic accumulates in both hair and nails and elevated levels are noted within a few weeks after acute poisoning (Hinwood et al., 2003). The arsenic contents of the fingernails and toenails have also been used as bio-indicators of past arsenic exposure, and fingernail arsenic has been reported to be significantly correlated with hair arsenic content (Lin et al., 1998). The segmental growth of the hair shaft also provides valuable information about duration and type of arsenic poisoning (Kakkar and Jaffery, 2005).

Blood arsenic levels are highly variable. Blood arsenic, normally less than 1 μg/dL, may be elevated on acute intoxication. It is probably the most important diagnostic test for detecting arsenic exposure. Arsenic metabolites (inorganic arsenic + MMA + DMA) in urine have also been used as biomarkers of recent arsenic exposure (Yamauchi et al., 1989). A recent study by Yoshimura et al. (2011) showed that acute arsenic poisoning can also be confirmed by speciation analysis of arsenic compounds in the plasma and urine by HPLC-ICP-MS. Multiple blood purification methods can also be used as a combined treatment for acute arsine poisoning (Wu et al., 2010).

Clouded urine is frequently seen in most severely arsenic-intoxicated patients as absorbed arsenic if primarily excreted through urine (Hughes and Kitchin, 2006). Increased urinary protein content and aberrant excretion of trace elements also signify enhanced renal dysfunction (Xie et al., 2001). Although estimation of urinary arsenic is a consistent biomarker of exposure, it possesses few drawbacks, including accurate sample collection time and volume of urine to be voided.

Other Biomarkers

Essentially all organ systems must be evaluated. Thus, laboratory tests should include complete blood count, liver and renal functional tests, and blood, nail, and urine arsenic levels. Table 15.2 exhibits various biomarkers for effective diagnosis of arsenic intoxication. Other biomarkers of arsenic exposure include nonerythrocyte porphyrin enzyme activities and urine transforming growth factor TNF-α, accompanied by induction of heme oxygenase, mitogen-activated protein kinases, the ubiquitin-dependent proteolytic pathway, and protein kinase C in various tissues. These tests are still being investigated in laboratories and their clinical usefulness remains to be proven (Chapell et al., 2001). Cytogenetic markers such as chromosomal aberrations contribute significantly toward detection of this carcinogen. People with chronic arsenicosis have been shown to have increased chromosomal aberrations (Ghosh et al., 2006) and sister chromatic exchange (SCE). However, it is still not the most interesting biomarker to detect the précoce effects of arsenic and is difficult to use in large-scale epidemiological studies because of its cost and difficulty of implementation (Eslava, 2004). Micronuclei in isolated bladder and buccal cells have been considered possible target tissues from direct exposure to As in drinking water (Bonassi et al., 2007).

TREATMENT

Highly specific treatment is required for poisoning with arsenicals. There is no specific antidote for the treatment of arsine poisoning. Victims may be administered a high flow of oxygen. One of the first strategies for the treatment of arsine poisoning involves stopping the ongoing hemolysis, which may lead to renal dysfunction (Kilmecki and Carter, 1995). Exchange transfusion is currently the treatment of choice (James and Woods, 2006). Chelation therapy generally is not recommended to reduce hemolysis; however, chelating agents are shown to reduce arsenic in arsine-exposed subjects. Since World War II, dimercaprol has been the standard treatment for poisoning by arsenicals. DMPS (unithiol) and DMSA (succimer), dithiol water-soluble analogs of BAL, were developed in the Soviet Union and China in the late 1950s. These three agents were mainly used for the chelation treatment of arsenic and mercury intoxication for more than half a century. Studies indicate that dithiol chelators enhance arsenic excretion and support

TABLE 15.2 Routes of Exposure and Relevant Biomarkers for Various Arsenic Compounds

#	Compounds of Arsenic	Route of Exposure	Symptoms/Biomarkers	References
ARSINE				
		Inhalation	Vertical white lines on nails, discolored brown, red or black urine, free hemoglobin in urine, red/bronze tint in skin	James and Woods (2006)
ORGANIC ARSENICALS				
(a)	Methyldichloroarsine	Dermal exposure	Blistering in skin, "dry-land drowning"	Bennett and Dill (1994); Pitten et al. (1999)
(b)	Diphenylchloroarsine	Inhalation	Irritation in the mucous membranes of eyes and nose, painful blistering in skin	Ochi et al. (2004); Kato et al. (2007)
(c)	Ethyldichloro-arsine	Dermal, inhalation	Fluid-filled blisters form in skin, pulmonary edema or "dry-land drowning"	Bartelt-Hunt et al. (2006)
(d)	Lewisite	Dermal, inhalation,	Irritation and blistering of the skin, Immediate eye pain and blepharospasm	McManus and Huebner (2005)
INORGANIC ARSENIC				
		Inhalation, dermal, ingestion	Hyper pigmentation, melanosis, hyperkeratosis, warts, decrease in ferrochelatase, increase in hepatic 5-aminolevelinic acid synthetase activity, pulmonary edema, peripheral neuropathy, sensory neuropathy and encephalopathy, diabetes mellitus, clouded urine, SCE	Woods and Southern (1989); Mazumder et al. (2000); Rossman (2003); Hafeman et al. (2005); Ghosh et al. (2006); Hughes and Kitchin (2006)

a therapeutic role for these chelators in the prompt treatment of acute poisoning by arsenic (Kosnett, 2013). However, treatment should be initiated as rapidly as possible because delay may result in reduction of efficacy as the time interval between metal exposure and onset of chelation increases. DMPS and DMSA have a higher therapeutic index than BAL and do not redistribute arsenic or mercury to the brain. Although chelation may accelerate metal excretion, potential therapeutic efficacy in terms of decreased morbidity and mortality is largely unestablished in cases of chronic metal intoxication. In the next paragraphs, we discuss the efficacy of chelating agents for treating arsenicals, their drawbacks, and the current advancement in the area.

Chelating Agents and Chelation Therapy

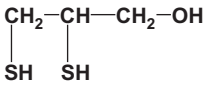
Chelating agents are organic compounds capable of linking together metal ions to form complex ring-like structures called chelates. Chelators act according to a general principle: the chelator forms a complex with the respective (toxic) ion, and these complexes reveal a lower toxicity and are more easily eliminated from the body. This mechanism could be represented as:

$$\text{Metal} - \textit{in vivo}\,\text{site} + \text{chelating agent} \rightarrow \textit{in vivo}\,\text{site} + \text{metal–chelating agent complex}$$

Chelation thus may be defined as the incorporation of a metal ion into a heterocyclic ring structure (Flora and Sekhar, 2004).

Some of the chelating agents listed here have been reported to be useful in the treatment of arsenic:

2,3-Dimercaprol (Dimercaprol; British Anti-Lewisite, BAL)



2,3-Dimercaprol (British anti-lewisite (BAL)) was originally developed to treat the effects of lewisite, namely systemic poisoning and local vesication. The empirical formula of BAL is $C_6H_8OS_2$ and its molecular weight is 124.21. It is an oily, clear, colorless liquid with a pungent, unpleasant smell typical of mercaptans and has a short half-life.

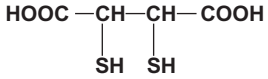
Drawbacks

BAL is unstable and easily oxidized; therefore, it is difficult to store and requires ready-to-use preparation. In addition to rapid mobilization of arsenic from the body, it causes a significant increase in brain arsenic (Hoover and Aposhian, 1983; Flora and Pachauri, 2010). Due to its oily

nature, administration of BAL requires deep intramuscular injection that is extremely painful and can cause an allergic reaction (Flora and Tripathi, 1998).

Two water-soluble analogs of dimercaprol have been studied as lewisite antidotes. They are meso 2,3-dimercaptosuccinic acid (DMSA) and 2,3-dimercapto-1-propane sulfonic acid (DMPS). These two drugs circumvent two major disadvantages associated with treatment with BAL: the need for intramuscular injection and limitation of dose by toxicity.

Meso 2,3-Dimercaptosuccinic Acid

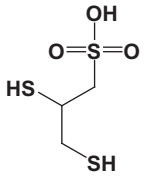


One of the chemical derivatives of dimercaprol (BAL) is DMSA. DMSA is an orally active chelating agent that is much less toxic than BAL and its therapeutic index is approximately 30-times higher. The empirical formula of DMSA is $C_4H_6O_4S_2$ and its molecular weight is 182.21. It is a weak acid that is soluble in water.

Drawbacks

DMSA distribution is predominantly extracellular because it is unable to cross the hepatic cell membrane. Hence, it is able to chelate arsenic from extracellular sites but not from intracellular sites. Adverse reactions of DMSA include gastrointestinal discomfort, skin reaction, mild neutropenia, and elevated liver enzymes. Some evidence of embryo toxicity/fetal toxicity due to DMSA administration was also reported (Domingo, 1998).

Sodium 2,3-Dimercaptopropane-1-Sulfonate



DMPS, first introduced as "Únithiol" as a BAL analogue, has the empirical formula $C_3H_7O_3S_3Na$ and molecular weight of 210.3. DMPS is more effective than BAL for arsenic therapy in mice (Hauser and Weger, 1989). DMPS, being hydrophilic, is distributed in the extracellular space but may enter cells by specific transport mechanisms. DMPS appears to be bio-transformed in humans to acyclic and cyclic disulfides, which are rapidly eliminated from the body through the kidneys. However, it is important to note that this drug does not redistribute arsenic, lead, or inorganic mercury to the brain (Flora and Pachauri, 2010).

There have been a number of published reports available for the treatment of chronic arsenic exposure in animals, but not for the treatment of subjects exposed to arsenic compounds.

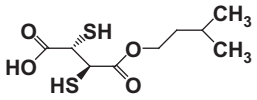
Drawbacks

No major adverse effects after DMPS administration in humans or animals have been reported (Hruby and Donner, 1987). Oral administration of DMPS did not adversely affect late gestation, parturition, or lactation in mature mice, and fetal and neonatal development does not appear to be adversely affected (Domingo, 1998).

Monoesters of DMSA

Recently, some monoesters and diesters of DMSA, especially the higher analogues, have been developed and tried against cases of experimental heavy metal poisoning to address the shortcomings of DMSA, particularly in depleting intracellular arsenic (Aposhian et al., 1992; Mehta et al., 2002; Kalia and Flora, 2005; Flora et al., 2007b,c). Due to its lipophilic nature, it can easily cross the cell membrane and chelate arsenic from intracellular and extracellular sites. This is the best advantage of treatment with DMSA monoesters. Among these monoesters are monoisoamyl DMSA (MiADMSA), mono *n*-amyl DMSA, mono *n*-butyl, and mono iso-butyl DMSA. MiADMSA was the most effective in increasing the survival of mice and in depleting arsenic tissue burden (Kreppel et al., 1995; Flora et al., 2004). Several recent published studies clearly point to the fact that the analogues of DMSA were capable of crossing the membranes and were more effective in reducing the toxic metal burden in acute and sub-chronic arsenic intoxication (Flora et al., 2004a,b, 2003; Flora and Sekhar, 2004; Saxena and Flora, 2004; Saxena et al., 2005). Most of these conclusions are based on experimentally induced metal intoxication, and no clinical data are available so far.

Monoisoamyl DMSA



Monoisoamyl DMSA (MiADMSA) is a C_5-branched chain alkyl monoester of DMSA. Kreppel et al. (1995) also reported the superior efficacy of MiADMSA and mono *n*-amyl DMSA in protecting mice from the lethal effects of arsenic and in reducing body burden from arsenic. These studies thus support that MiADMSA could be a potential drug to be used in the treatment of chronic arsenic poisoning. MiADMSA is new and is one of the most effective of the vicinal class of metal mobilizing agents (Xu et al., 1995; Saxena et al. 2005). Although, the compound is more

toxic than the parent diacid DMSA (Mehta et al., 2002; Flora and Mehta, 2003), its structure features and recent experimental evidence suggest that it might be effective in chelating arsenic (Flora and Kumar, 1993; Flora et al., 2002). More pronounced efficacy of MiADMSA could be attributed to its lipophilic characteristic (Flora et al., 2005). It appears plausible that MiADMSA could decrease the oxidative stress in tissues either by removing arsenic from the target organs or by directly scavenging ROS via its sulfhydryl group (Mishra et al., 2008).

No report is available regarding the therapeutic efficacy of MiADMSA against lewisite toxicity and other arsenicals. However, we reported the effect of MiADMSA on the reversal of gallium arsenide (GaAs)-induced changes in the hepatic tissue (Flora et al., 2002). MiADMSA was found to be better than DMSA in mobilizing arsenic and in the turnover of the GaAs-sensitive biochemical variables. A study was conducted to explore the optimum dose and route of administration for achieving maximum arsenic elimination with minimal side effects. Pharmacokinetic analysis of MiADMSA was conducted, including oxidative stress parameters, identification of arsenic levels in soft tissues, liver function test, and histopathological studies. Plasma kinetics involving MiADMSA (plasma-free drug and total drug) at 50 and 100 mg/kg orally was performed. MiADMSA at a 50 mg/kg dose administered orally provided approximately 45% and 75% protection against oxidative stress and in lowering body arsenic burden, respectively. Also, pharmacokinetic analysis supported prolonged availability of the drug through oral administration. Collectively, these findings led to the conclusion that oral administration of MiADMSA was more effective than intraperitoneal administration and that the minimum effective dose with the least side effects was 50 mg/kg (Flora et al., 2012). Generation of free radicals in case of arsenic toxicity is known to cause cellular apoptosis through a mitochondrial-driven pathway. A study was conducted to investigate the effect of arsenic interactions with various complexes of the electron transport chain and to evaluate if the complex could trigger apoptosis. Another aspect evaluated was chelation with MiADMSA and reversal of detrimental effects. Arsenic induced free radical generation in rat neuronal cells, leading to diminished mitochondrial potential and enzyme activities of all the complexes of the electron transport chain. MiADMSA, however, was able to reverse most of these arsenic-induced altered variables to various extents; still, DNA damage remained unaffected (Dwivedi et al., 2011). Ram Kumar et al. (2013) also reported that MiADMSA significantly reversed the As-induced alterations in behavior and biochemical variables suggestive of oxidative injury. As-exposed rats showed significant differences in behavioral functions and water maze learning. Further, biochemical studies performed also showed significant alteration, which was effectively restored on MiADMSA treatment. Not only in vivo studies but also in vitro studies have revealed the therapeutic efficacy of MiADMSA against arsenic-induced toxic manifestations. Arsenic toxicity leads to various skin manifestations and arsenic accumulation in keratinized tissue. Hence, a study was designed to investigate time-dependent and dose-dependent effects of arsenic using the HaCaT cell line along with evaluation of treatment with MiADMSA. Results interestingly depicted that pretreatment of cells with MiADMSA elicited significant protection against arsenic-induced oxidative stress and apoptotic cell death. The findings are of clinical relevance and suggest MiADMSA to be a promising candidate in protecting skin against arsenic-induced toxic effects (Pachauri et al., 2013).

Despite a few drawbacks/side effects associated with MiADMSA, these results suggest that MiADMSA may be a future drug of choice because of its lipophilic character and the absence of any metal redistribution. However, significant copper loss requires further studies (Mehta et al., 2002; Mehta et al., 2006). Moderate toxicity after repeated administration of MiADMSA may be reversible after the withdrawal of the chelating agent.

Drawbacks

It is reported that the toxicity of DMSA with LD_{50} of 16 mmol/kg is much lower than the toxicity of MiADMSA with LD_{50} of 3 mmol/kg but lesser than BAL (1.1 mmol/kg). Flora and Mehta (2003) reported that administration of MiADMSA led to no major alternations in the heme synthesis pathway except for a slight increase in the zinc protoporphyrin levels, suggesting mild anemia. MiADMSA was seen to be slightly more toxic in terms of copper and zinc loss and some biochemical alterations in the hepatic tissue in females as compared with male rats (Mehta et al., 2006).

Role of Antioxidants

Oxidative stress can be partially implicated in arsenic toxicity, and a therapeutic strategy to increase the antioxidant capacity of cells may fortify the long-term effective treatment of arsenic poisoning. This may be accomplished either by reducing the possibility of metal interacting with critical biomolecules and inducing oxidative damage or by bolstering the antioxidant defenses of the cells through endogenous supplementation of antioxidant molecules (Flora et al., 2007b; Flora et al., 2013). Although arsenic-induced oxidative stress has been well-documented, the usefulness of antioxidants in conjunction with chelation therapy has not yet been extensively investigated. *N*-acetylcysteine (NAC) is a thiol, a mucolytic agent, and a precursor of L-cysteine and reduced GSH. NAC is a source of sulfhydryl-containing antioxidant that has been used to mitigate various conditions

of oxidative stress. Combined administration of NAC and succimer after arsenic exposure led to a significant recovery in biochemical variables indicative of oxidative stress and arsenic depletion from soft organs (Flora, 1999; Kannan and Flora, 2006). Various vitamins have been found to reduce the toxic manifestation of heavy metals (Flora et al., 2002; Flora et al., 2013). Combined administration of vitamin C plus DMSA and vitamin E plus MiADMSA led to a more pronounced depletion of brain arsenic. Also, supplementation of vitamins led to significant restoration of inhibited blood δ-ALAD activity and other oxidative stress parameters in liver, kidneys, and brain. These results suggested that co-administration of vitamin E or vitamin C may be useful in arsenic poisoning, although it has only a limited role in depleting arsenic burden (Kannan and Flora, 2004). In another study, alpha-lipoic acid was shown to have substantial antioxidant properties when administered (70 mg/kg body weight) once daily for 60 days along with arsenic. Effects of alpha-lipoic acid over arsenic-induced oxidant production and LPO level in discrete brain regions of rats were also examined. Cortex, hippocampus, and striatum exhibited a greater increase of LPO levels than did the cerebellum and hypothalamus. Also, simultaneous lipoic acid treatment along with arsenic proved to be sufficient in reducing oxidant production and LPO levels in all rat brain regions. The study demonstrated that arsenic-induced deficits in brain regions can be overcome through simultaneous treatment with lipoic acid (Shila et al., 2005). Garlic is another well-known folk remedy for a variety of ailments; however, very few studies are available suggesting its beneficial role against arsenic toxicity. In a study by Flora et al. (2009), the protective efficacy of aqueous garlic extract on parameters suggestive of hepatic injury, tissue oxidative stress, and mobilization of arsenic was investigated using two different doses. Results suggested that garlic extracts contain strong antioxidant properties that could be beneficial in preventing arsenic-induced toxicity in cells. A study was conducted in rabbits to assess the oxidative injuries caused by arsenic toxicity and to evaluate the detoxifying effects of exogenous antioxidants, vitamins, zinc, selenium (VZS), or a plant polyphenol. Results in studies using rabbits indicated that arsenic induces toxicity associated with an increase in LPO and nitric oxide production in the body. Administration of exogenous antioxidants such as polyphenols and a recipe of vitamins, zinc, and selenium, however, was found to be useful for arsenic detoxification (Rabbani et al., 2003). Taurine (2-aminoethanesulfonic acid) has also been shown to exert a protective effect against arsenic-induced cytotoxicity in murine hepatocytes. The cytoprotective activity of taurine against arsenic poisoning was found to be comparable with that of a known antioxidant, vitamin C. This further suggests that taurine protects mouse hepatocytes against arsenic-induced cytotoxicity (Sinha et al., 2007). Among various herbal extracts, *Moringa oleifera* (*M. oleifera*) seed powder has also been shown to restore arsenic-induced oxidative stress and to reduce body arsenic burden. Hence, it was concluded that concomitant administration of *M. oleifera* seed powder with arsenic could significantly protect against arsenic-induced toxic manifestations and thus could also be beneficial during chelation therapy with a thiol chelator (Gupta et al., 2007). Concomitant oral supplementation of *Centella asiatica* (100, 200, or 300 mg/kg orally once daily) during arsenic exposure (20 ppm in drinking water for 4 weeks) has also been shown to be an effective strategy against arsenic toxicity. More extensive studies are recommended for determining the effect of co-administration of *C. asiatica* during chelation therapy with a thiol chelator (Gupta and Flora, 2006).

Not only altered biochemical variables but also supplementation of antioxidants has led to alleviation of arsenic-induced molecular alterations. Contamination of arsenic in drinking water is associated with several human diseases, including cancer. A significant increase in the levels of protein oxidation, DNA strand breaks, and DNA–protein cross-links was observed in blood, liver, and kidney of rats exposed to arsenic (100 ppm in drinking water) for 30 days. However, co-administration of ascorbic acid and alpha-tocopherol to arsenic-exposed rats showed a substantial reduction in the levels of arsenic-induced oxidative products of protein and DNA. The results support the fact that free radical generation is one of the major mechanisms of arsenic-induced toxic manifestations and suggest that ascorbic acid and alpha-tocopherol supplementation can improve the arsenic-induced molecular alterations (Kadirvel et al., 2007). Cardiac dysfunction has been shown to be associated with arsenic toxicity, which results in reduced cardiomyocyte viability, increased ROS production, and intracellular calcium overload, and has induced apoptotic cell death by mitochondrial-dependent caspase-3 activation and poly-ADP ribose polymerase (PARP) cleavage. All these changes were found to be associated with increased IKK and NF-kappaB (p65) phosphorylation. Arsenic also markedly increased the activity of p38 and JNK MAPKs. Taurine effectively suppressed these apoptotic actions, suggesting its protective role by attenuation of p38 and JNK MAPK signaling pathways. Results suggest that taurine effectively prevented arsenic-induced myocardial pathophysiology, attenuated NF-kappaB activation via IKK, p38, and JNK MAPK signaling pathways, and hence could be an effective therapy against As-induced cardiovascular burden (Ghosh et al., 2009).

Combination Treatment

As discussed, metal chelators are administered to increase the excretion of arsenic but, unfortunately, the

use of these chelators is comprised by a number of drawbacks (Mehta and Flora, 2001). These drawbacks mean that it is necessary to search for new treatments with no side effects. A number of strategies have been discussed (Kalia and Flora, 2005). Among these strategies, combination therapy is a new and a better approach to treat cases of metal poisoning (Flora et al., 2007c; Mishra et al., 2008). We investigated if co-administration of thiol chelators like meso 2,3-dimercaptosuccinic acid (DMSA) or sodium 2,3-dimercaptoprpane 1-sulfonate (DMPS) along with a newly developed thiol chelator, monoisoamyl DMSA, is more beneficial than monotherapy with these chelators in counteracting chronic arsenic toxicity (Flora et al., 2005; Bhadauria and Flora, 2007). It was concluded that concomitant administration of DMSA, a chelator known for its extracellular distribution with a lipophilic chelator, like MiADMSA, could play a significant and important role in abating a number of toxic effects of arsenic in animals compared with treatment with these chelators alone. We suggested that analogues with long carbon chain (MiADMSA and MchDMSA) are better chelators than a chelator with a shorter carbon chain (MmDMSA) or DMSA. It is assumed that analogues of DMSA eliminate arsenic simultaneously from the cell and provide assistance in bringing GSH homeostasis toward normalcy. Further combination therapy with DMSA and MiADMSA or MchDMSA was proven to be more beneficial than combined treatment with MmDMSA and DMSA (Mishra et al., 2008). Generation of ROS is one of the major mechanisms of arsenic-mediated oxidative stress; a study was conducted to explore the kinetic relationship of ROS with calcium and to dissect the calcium ion channels responsible for calcium imbalance after arsenic exposure. Another crucial aspect investigated was whether monotherapy or combinational chelation therapy prevents arsenic-induced neuronal apoptosis in guinea pigs. Results indicated that arsenic caused a significant increase in ROS, followed by NO and calcium influx, which was mainly dependent on L-type voltage-gated channels that disrupt mitochondrial membrane potential and increase bax/bcl2 levels and caspase 3 activity, leading to apoptosis. Another interesting and useful finding was that combination therapy of DMSA and MiADMSA was most effective in reversing arsenic-induced alterations. Results provide strong evidence for the role of L-type calcium channels in regulating arsenic-induced calcium influx and that DMSA plus MiADMSA combination therapy might be a better and much more effective strategy than monotherapy in mitigating chronic arsenicosis (Pachauri et al., 2013).

Not much experimental evidence is available and there is a need for in-depth investigation in this area. Investigating the effects of combination therapy, particularly in case of chronic arsenic poisoning, in which a strong chelating agent is administered along with another structurally different chelating agent, is necessary (Kalia and Flora, 2005) to evaluate if combination treatment is able to promote the elimination of arsenic and restore arsenic-induced biochemical and clinical alterations.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Arsenic is used in industries such as agricultural production and appears in the food chain. Although information about arsenic and its inorganic and organic derivatives is now widely reported, there is very little information about their use as CW agents. The use of arsenicals remains a potential threat because they are relatively easy to manufacture and may cause significant morbidity and mortality. Knowledge about these arsenicals is very important to plan a response in an emergency. Lewisite is one arsenical that has not been studied in detail. There is very little information available regarding the detailed toxic effects of organic arsenicals, particularly carcinogenicity, mutagenicity, and teratogenicity. Lewisite, an organic arsenical war gas that is a vesicant, has been reported for its ability to bind with the thiol group, leading to the possibility of its undesirable effects on a variety of enzymes. Thus, there is a very strong possibility that exposure to lewisite might also lead to carcinogenic effects, but this hypothesis requires experimental and epidemiological evidence. It is not known if lewisite is persistent. However, arsenic is an elemental poison and any residual hydrolysis, combustion, and decontamination product is likely to contain an arsenical compound. Some of the major areas for future research direction include the possibility of delayed or latent effects arising after organic arsenical (particularly lewisite) exposure. These effects have been studied in detail recently after inorganic arsenic exposure; however, there is very little information available after organic arsenical exposure. Development of antidotes is another area that requires immediate attention. Although one approved antidote, BAL, is available for lewisite. However, further investigations are required with other derivatives of BAL, like DMSA and DMPS, or monoesters of DMSA, like MiADMSA. Chelators are generally not of any immediate benefit as far as toxicity of arsine once hemolysis has begun. Some new chelating agents are in experimental stages like MiADMSA, but the effectiveness and safety of these chelating against arsine poisoning is unknown. Toxicodynamics of arsine is also one area that requires exploration because this information will be of immense help in developing a suitable antidote, particularly for impending hemolysis by removing or displacing arsine.

Inorganic arsenic, particularly arsenic (III), is a well-documented potent carcinogen causing cancer of bladder, lung, skin, and possibly liver and kidney. Because of failures in attempts to study the carcinogenic effects of arsenic in animal models, the mechanism of arsenic-induced carcinogenic effects remains unclear. The newly discovered potency of trivalent methylated arsenic metabolites opens new opportunities for mechanistic studies. No treatment of proven benefit is available to treat chronic exposure. Treatment options advocated are vitamins, mineral supplements, and antioxidant therapy. The benefits of these treatment measures need to be evidence-based to receive endorsement and wider application. Further research work is also recommended in the following areas: molecular mechanism of action of clinically important chelators; intracellular and extracellular chelation in relation to mobilization of aged arsenic deposits and the possible redistribution of arsenic to sensitive organs as the brain; effect of metal chelators on biokinetics during continued exposure to arsenicals; combined chelation with lipophilic and hydrophilic chelators; use of antioxidants, micronutrients, or vitamins as complimentary agents or antagonists; minimization of the mobilization of essential trace elements during long-term chelation; and fetotoxic and teratogenic effects of chelators.

Fluoroacetate

Nikolay Goncharov, Elena Savelieva, Valeriy Zinchenko, Sergey Kuznetsov, Igor Mindukshev, Maxim Vinokurov, Pavel Avdonin, Natalia Voitenko, Anton Ukolov, Tatiana Orlova, Richard Jenkins and Anatoliy Kuznetsov

INTRODUCTION

Fluororganic compounds attracted the attention of researchers more than 70 years ago, when a group of very toxic compounds was isolated from a large class of biologically inert chemicals, having the general formula CH_2FCOOR and the common name *fluoroacetate (FA)*. The toxicological effects of FA do not become apparent immediately, even after exposure to lethal doses, but only after a latent period of half an hour to several hours for animals and humans. The level of FA in some plants can reach up to 5 g/kg dry weight (Hall, 1972) and can cause death of livestock and domestic animals, sometimes with appreciable economic damage (McCosker, 1989; Minnaar et al., 2000a; Lee et al., 2012). FA can be found in fog and raindrops in some industrial regions (Rompp et al., 2001). The best-known representative of FA is its sodium salt (SFA, also known as *compound 1080*). This substance is used in several countries for controlling populations of some vertebrates, sometimes causing the death of farm animals (Giannitti et al., 2013). There are also series of fluorocompounds whose metabolism is connected with the formation of FA. These include the following:

- Antineoplastic drugs (5-fluorouracil and isomers of fluoronitrosourea)
- *N*-(2-fluoroethyl) derivatives of the narcotic analgesics normeperidin and normethazocin
- Pesticides, 1,3-difluoro-propanol and fluoroacetamide (FAA, compound 1081)
- 1-(di)halo-2-fluoroethans
- Fluoroethanol (Reifenrath et al., 1980; Tisdale and Brennan, 1985; Feldwick et al., 1998)

The urgency of the problems associated with FA toxicity and the need for an effective therapy for acute intoxication has greatly increased in connection with a more recent threat—international terrorism (Holstege et al., 2007). Physicochemical features of FA, the lack of taste and odor, delayed manifestation of toxicity, and similarity of clinical signs of intoxication to some natural indispositions—these characteristics necessitate comprehensive studies of mechanisms of action of FA and search for effective therapeutic means for treatment of acute intoxication.

BACKGROUND

FA was initially synthesized in 1896 and only decades after that was found in *Dichapetalum*, *Gastrolobium*, *Oxylobium*, *Acacia*, *Palicourea*, *Mascagnia*, *Tanaecium*, and *Amorimia* plants growing in Australia, South and Central Africa, and South America (Oerlichs and McEwan, 1961; de Oliveira, 1963; McEwan, 1964; Aplin, 1971; Vickery et al., 1973; Camboim et al., 2012a; Lee et al., 2012; Esters et al., 2013). Chemically pure FA is a very stable compound, and the energy of dissociation of the fluorocarbon bond in the molecule is considered one of the highest of the natural compounds (Ichiyama et al., 2004). However, FA is broken down in biological preparations from plants (Minnaar et al., 2000a). In soils, the major degradation pathway for SFA occurs through microbial degradation to the hydroxyl metabolite, hydroxyacetic acid, and microbial mineralization to CO_2; temperature, rather than soil type or moisture content, was the dominant factor affecting the rate of degradation (Northcott et al., 2014). Seven

DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00016-6

bacteria from soil and plant samples able to degrade SFA were identified by 16S ribosomal ribonucleic acid (rRNA) gene sequencing as *Paenibacillus* sp. (ECPB01), *Burkholderia* sp. (ECPB02), *Cupriavidus* sp. (ECPB03), *Staphylococcus* sp. (ECPB04), *Ancylobacter* sp. (ECPB05), *Ralstonia* sp. (ECPB06), and *Stenotrophomonas* sp. (ECPB07) (Camboim et al., 2012a). Also, two SFA-degrading bacteria from caprine rumen, *Pigmentiphaga kullae* (ECPB08) and *Ancylobacter dichloromethanicus* (ECPB09) (Camboim et al., 2012b), and one from bovine rumen belonging to the phylum Synergistetes (Davis et al., 2012) were identified, the latter functioning in anaerobic conditions.

After inhalation or ingestion, FA is easily absorbed by tissues, and its high toxicity is independent of its route of entry into organisms (Chenoweth, 1949). The mechanism of toxic action of FA is widely known as "lethal synthesis" (Peters, 1952; Peters and Wakelin, 1953), the essence of which is conversion of nontoxic FA to toxic fluorocitrate (FC) within the cells of an organism. The main reasons of death are considered to be imbalance of intracellular ions, osmotic imbalance, and deficit of adenosine triphosphate (ATP) as a consequence of aconitase blockade (Buffa et al., 1973). The latent period, from the moment of poisoning with FA to manifestation of clinical signs, is 0.5–3 h (in warm-blooded animals). This period reflects penetration of FA into blood and cells and conversion of FA to FC, with the consequent uncoupling of intracellular metabolism. Death usually occurs within 24–48 h, but can happen later. At autopsy, there are no specific signs of intoxication (Peters et al., 1981). For warm-blooded animals that are the least adapted to FA, the lethal dose is less than 2 mg/kg (Atzert, 1971). However, there is a considerable species-specific difference in clinical signs of intoxication and differences in sensitivity to the poison (Chenoweth, 1949). The mean lethal dose varies from 0.05 mg/kg for dogs to 150 mg/kg for possums. The most common criterion of tolerance or sensitivity of animals to FA is intensity of metabolism. Thus, in the lizard *Tiliqua rugosa*, the level of metabolism of FA is 10 times lower than that of the rat *Rattus norvegicus*, and the lethal dose for the lizard is 100 times higher than that of the rat (Twigg et al., 1986). Low intensity of metabolism means low conversion of FA to FC, which makes possible more effective excretion and detoxication. In the absence of specific clinical, physiological, and morphological signs of intoxication, determination of FA in tissues with citrate and fluoride ions can be a diagnostic confirmation of FA intoxication (Schultz et al., 1982; Koryagina et al., 2006).

TOXICOKINETICS

Detoxication

The main pathway of detoxication of FA is its defluorination via a GSH-dependent mechanism involving nucleophilic attack on the β-carbon atom and formation of fluoride and *S*-carboxymethylglutathion, with subsequent cleavage of the latter into amino acids and *S*-(carboxymethyl) excreted in the urine as a conjugate complex (Mead et al., 1979; Tecle and Casida, 1989). The highest defluorinating activity was found in liver, followed by kidney, lung, heart, and testicles in a descending line. No defluorinating activity was found in the brain. Activity of enzymes responsible for defluorination depends on glutathione (GSH) concentration with a maximum above 5 mmol/L, the apparent Km being 7 mmol/L at saturating concentrations of GSH (Soiefer and Kostyniak, 1983). Defluorination is mainly carried out by anionic proteins having GSH transferase activity, though the anionic fraction contains nearly 10% of proteins without this activity, but it is also capable of defluorination of FA. Moreover, cationic enzymes were shown to be responsible for about 20% of cytosolic defluorination of FA (Wang et al., 1986). The GSH-dependent enzyme defluorinating FA is not identical to GSH-dependent *S*-transferases; it is a FA-specific defluorinase having an acidic isoelectric point (pH = 6.4) and a molecular weight of 41 kD (27 kD for the main subunit; Soiefer and Kostyniak, 1984). Activity and specificity of defluorinase isoenzymes vary markedly and is a subject of research presently (Tu et al., 2006; Nakayama et al., 2012).

Analytical Procedure

Analysis of biological samples for FA is rather problematic because of the high polarity of the fluorine-carbon bond in the molecule. Liquid chromatography has been applied for analysis of FA in different media (Allender, 1990), and analysis of FA in plants and gastric content by high-pressure liquid chromatography with ultraviolet detection has also been described (Minnaar et al., 2000b). Being a nonvolatile substance, FA was commonly analyzed by gas chromatography (GC), as a methyl derivative (Stevens et al., 1976), ethyl or *n*-propyl derivatives (Peterson, 1975) and as pentafluorobenzyl esters (Vartiainen and Kauranen, 1984). Derivatization with 2,4-dichloroaniline in the presence of *N*,*N*-dicyclohexylcarbodiimide was used for GC analysis of SFA in water (Ozawa and Tsukioka, 1987) and blood serum (Demarchi et al., 2001). A modified procedure by Eason et al. (1994) achieved low detection limits for FA at the level of 0.01 µg/g in plasma and urine, and 0.002 µg/g in the tissue and feces of sheep and goats. However, this procedure is labor and time-consuming, and the GC-electron capture detection procedure applied is considered unreliable at this level of sensitivity.

The main problem for GC analysis of FA in biological samples is co-elution of the matrix components. This can be overcome by sampling of the analyte from an

equilibrium vapor phase. Static head-space analysis of SFA as ethyl fluoroacetate, with linear range for SFA in water of 5–200 µg/mL and a detection limit of 0.5 µg/mL has been reported (Mori et al., 1996). Solid-phase microextraction (SPME) from an equilibrium vapor phase has all the advantages of head-space analysis, whilst being a much more sensitive technique. We reported on a novel procedure for determination of FA in water and biological samples, involving ethylation of FA with ethanol in the presence of sulfuric acid, SPME of the ethyl fluoroacetate formed with subsequent analysis by GC-MS (Koryagina et al., 2006). To overcome the problem of the presence of the components co-eluting with FA derivatives, we made use of GC-MS in the Selective Ion Monitoring mode. To avoid a partial overlapping of the internal standard's peak with the sample matrices' components, quantification was performed with the use of two internal standards, carbon tetrachloride and toluene. The calibration plots for the determination of SFA in biological samples was linear in the SFA concentration range 0.01–5.0 µg/mL for both internal standards, and a linear relationship in blood plasma was observed in the range of 0.01–5.0 µg/mL ($r = 0.95$). With toluene as internal standard, the linear regression equation was $Y = 0.014X$ (Y was the ratio S(EthylFA)/S(toluene); X was the concentration of SFA, µg/mL). The relative standard deviation (RSD) for FA quantification at 0.1 µg/mL was 12% ($n = 5$). With carbon tetrachloride as internal standard, a linear relationship in plasma was observed in the range of 0.01–5.0 µg/mL ($r = 0.98$). The linear regression equation was $Y = 0.1656X$ (Y was the ratio S(EthylFA)/S(CCl4); X was the concentration of FA, µg/mL). The RSD for FA quantification at 0.1 µg/mL was 6% ($n = 5$), and the detection limit was 0.01 µg/mL ($S/N = 3$). The calibration characteristics of rat organ homogenates were identical to that of plasma.

Distribution in Tissues and Elimination

The data on toxicokinetics of FA are rather contradictory, apparently depending on analytical procedures and dose of the poison; also, there is evidence for animal species specificity. The first data on toxicokinetics of FA demonstrated its rather uniform distribution between organs, with some predominance in heart, brain, and kidneys (Gal et al., 1961). The half-life was calculated to be not less than 2 days, and this could cause secondary toxicity arising from ingestion of meat from the poisoned animals (Aulerich et al., 1987). The half-life of FA was shown to be 10.8 h for sheep and 5.4 h for goats that were administered 0.1 mg/kg; maximal concentration of FA 2.5 h after the poisoning was revealed in blood plasma (0.098 µg/mL), followed by kidneys (0.057 µg/g), skeletal muscles (0.042 µg/g), and liver (0.021 µg/g). Only traces of FA were found in all the tissues examined 96 h after the poisoning

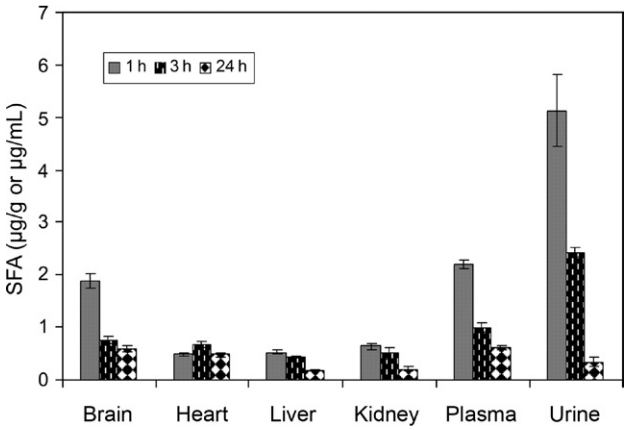

FIGURE 16.1 Data on the determination of FA (recounted as SFA) in rat organ homogenates and body fluids, at times following poisoning with SFA at a peroral dose of 2 mg/kg (1/2 LD_{50}). Standard deviations (shown) were based on 4–6 replicate analyses.

(Eason et al., 1994). At 1 and 12 h after introduction of SFA (0.25 mg/kg) to rats, a similar ratio of FA was found in rat plasma (0.26 and 0.076 µg/mL, correspondingly) (Eason and Turck, 2002), the half-life period being 2.9 h. On the other hand, for rabbits under subacute intoxication with FA, the half-life was found to be 1.1 h, and the level of FA in rabbit muscles, kidneys, and liver was much higher than in blood plasma (Gooneratne et al., 1995).

In our experimental work, the use of the above-mentioned SPME method in combination with GC-MS produced the following results (Figure 16.1): maximal concentrations were found in rats 1 h after the poisoning, 2.2 µg/mL in blood plasma and 1.89 µg/g in brain; there were 3–4 times less FA in rat kidneys, liver, and heart (from 0.64 to 0.50 µg/g). After a further 2 h, the distribution between the tissues was more equal, resulting from a prominent decrease of FA in plasma and brain and a small decrease (or even elevation) of FA in other organs. Further decrease of FA was found in all the tissues except for the heart 24 h after the poisoning. After 72 h, no FA was detected in plasma; we did not measure FA in rat organs at this point. The half-life was calculated to be 3.6 h.

MECHANISM OF ACTION

Molecular Mechanism of Aconitase Inhibition

The mechanism of the inhibitory effect of FA on aconitase (citrate (isocitrate) hydro-lyase, EC 4.2.1.3) is one of the most interesting in biochemistry. Upon entering an organism, nontoxic FA undergoes a series of metabolic conversions, the result of which is synthesis of highly toxic FC; this process was termed *lethal synthesis* (Peters, 1952). FC is formed by the enzymatic condensation of fluoroacetyl-CoA with oxaloacetate, catalyzed by citrate

(*si*)-synthase (EC 4.1.3.7) (Eanes and Kun, 1974). FC was initially considered to be a competitive aconitase inhibitor, but in the early 1990s, it was suggested that FC acts as a "suicide substrate" because it has a high affinity for aconitase at any concentration of the competitive citrate (Clarke, 1991). Aconitase affects the conversion of citrate to isocitrate through an intermediate, *cis*-aconitate, which binds with aconitase in two different ways, swung 180° to the $C^{\alpha} - C^{\beta}$ bond (Gawron and Mahajan, 1966). Aconitase includes a [4Fe–4S] cluster, and the catalytic conversion involves substrate coordination to a specific iron atom in this cluster, Fe_a (Lauble et al., 1992). The single inhibitory isomer was shown to be (−)-*erythro*-2-flurocitrate (2R, 3R) (Carrell et al., 1970), from which aconitase removes fluoride ion with a stoichiometry of 1 F^- per enzyme molecule (Tecle and Casida, 1989). The defluorination results in generation of an actual aconitase inhibitor, 4-hydroxy-*trans*-aconitate (HTA), which binds very tightly—though not covalently—with aconitase (Lauble et al., 1996). The natural aconitase substrate isocitrate should be at a 10^6-fold excess in order to slowly displace HTA from its complex with aconitase. The HTA–aconitase complex involves four hydrogen bonds, which hold together HTA, a water molecule, Asp165, and His167 (Lauble et al., 1994, 1996). In contrast, isocitrate has only one such bond.

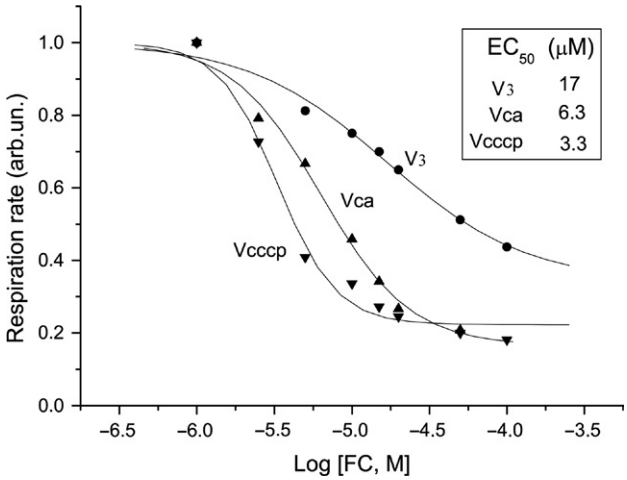

FIGURE 16.2 Effects of FC on respiration of rat liver MCh. Dependence of respiration rate activated by ADP (V_3), calcium transport (V_{Ca}), and protonophore CCCP (Vcccp) upon concentration of FC. Substrates: pyruvate + malate.

Physiological and Biochemical Effects of FA

Effects of FA and FC on Mitochondria and Other Intracellular Organelles

Functional disturbances of mitochondria (MCh) precede the appearance of structural anomalies (Buffa and Pasquali-Ronchetti, 1977) and consist of their decreased capacity to oxidize the substrates introduced. Within the mitochondrial matrix, FA induces changes that develop over several minutes, resulting in swelling and loss of electronic density. These changes are explained by the accumulation of citrate, rise of osmotic pressure, and decrease of energy production; change in the level of ATP is not caused by uncoupling of respiration and phosphorylation (Corsi and Granata, 1967). Mitochondrial volume changes are accompanied by their conformational reorganizations: they are displacement of granules, disintegration of cristae, and extension and rupture of their membranes. Axonal cylinders stretch in 3–4 h after small doses of the poison and 1–2 h after lethal doses. The cylinders are filled with MCh (most of which are swollen and degenerated), multilamellar lisosome-like bodies, vesicules, and neurofibrils. In the Golgi complex, a condensation of cisternae takes place (McDowell, 1972). Concurrently, a disruption of endoplasmic reticulum (ER), swelling of nucleus, and reduction of aggregated chromatin can be seen.

Having studied *in vitro* effects of FC on rat liver MCh, we revealed that maximal inhibition of respiration was registered when MCh were uncoupled (Figure 16.2). The level of alkalinization of the medium at the addition of adenosine diphosphate (ADP) was much lower in the presence of FC, thus evidencing an inhibition of ATP synthesis. The amplitude of alkalinization was also decreased, which could be caused by incomplete ATP synthesis, an additional transmembrane redistribution of protons, and/or change of the binding constant of ADP. FC induced a leak of Ca^{2+} from MCh, which was consistent with the observed inhibition of oxygen consumption in respiratory state 1. Addition of the substrates caused the reentry of Ca^{2+} into MCh. In the presence of FC, the MCh only partially took up the Ca^{2+} ions added to the medium, followed by their spontaneous efflux through an electroneutral $2H^+/Ca^{2+}$ exchanger with $K_{1/2} = 10\,\mu mol/L$ (Teplova et al., 1992).

The effects observed under exposure of MCh to SFA developed at much higher concentrations (from 4 mmol/L) than for FC and greatly depended on respiratory substrates. With pyruvate as substrate, the time period of oxidative phosphorylation (OP) and the level of nicotinamide adenine dinucleotide (NADH) oxidation increased linearly at increasing SFA concentration in the medium (Zinchenko et al., 2007). However, with utilization of succinate and especially glutamate, SFA had no effect on OP in concentrations as high as 8 mmol/L (Figure 16.3A) and even 16 mmol/L (not shown in the figure). Moreover, the effect of SFA with pyruvate as respiratory substrate can be prevented by incubation of MCh with cyclosporine A (CsA), a known inhibitor of the mitochondrial transition pore (Figure 16.3B). This means that under exposure to FA, development of mitoptosis and apoptosis is possible, but opening of the pore is reversible in nature, and preventing oxidation or

leak of NADH from MCh can return them to the normal functional state.

Effects of FA on Isolated Cells

The effects of FA on the physiological and biochemical status of cells and tissues are closely dependent upon the level of their oxidative metabolism. Thus, FA does not inhibit phagocytosis because of the low level of trichloroacetic acid (TCA) cycle activity within macrophages (Cifarelli et al., 1979). We investigated a series of cell types, transformed lines, and those obtained from animals under exposure to FA or FC. The level of NADPH in Ehrlich ascite tumor (EAT) cells slowly decreased and the level of Ca^{2+} increased when the cells were incubated with SFA (Zinchenko et al., 2007). SFA obviously induced depletion of intracellular calcium stores and activation of influx of extracellular Ca^{2+} ions through the store-operated calcium (SOC) channels. Discovery of other calcium channels, such as TRPV5 and TRPV6 (Hoenderop et al., 2003; van de Graaf et al., 2006), which remain inactivated when cytosolic $[Ca^{2+}]_i$ is increased and become activated when $[Ca^{2+}]_i$ is decreased, stimulated the investigation of the level of calcium ions in ER with chlortetracycline. FC does not affect the velocity of calcium efflux from ER, so the signal transmission from P2Y receptor via G-protein is not inhibited in EAT cells exposed to FC (Zinchenko et al., 2007). However, FC induced a growth in both amplitude of Ca^{2+} leakage and velocity of its influx into ER. A rather long period (8–10 min) of Ca^{2+} influx into ER was observed, which indicated efflux of intracellular Ca^{2+} from cells by plasma membrane Ca-ATPase immediately after mobilization and leaving ER. This greatly reduces $[Ca^{2+}]_i$ for transport back to ER. It has been demonstrated (Zinchenko et al., 2001) that the velocity of return transport of Ca^{2+} into ER depends upon the activity of SOC channels in plasma membrane. Therefore, we suggest that FA (or FC) can induce the entry of calcium ions into cells through SOC channels.

The toxic effects of FC on endothelial cells have been shown to be similar to its effects on other energy-dependent tissues: namely, reduction of ATP level and oxygen consumption but accumulation of lactate and considerable decrease of protein synthesis (Rist et al., 1996). We have demonstrated with rat aorta endothelial cells in culture a gradual decrease of the mitochondrial membrane potential and elevation of $[Ca^{2+}]_i$ under exposure to SFA, similar to that observed with EAT cells (not shown in this chapter). Conversely, in cardiomyocytes, SFA induced a slow enhancement of the mitochondrial membrane potential with a rise of basal $[Ca^{2+}]_i$; propagation of calcium waves along the surface of sarcoplasmic reticulum or visible elevation and velocity of spreading of the preexisting waves was also observed (Zinchenko et al., 2007). Probably the increased level of $[Ca^{2+}]_i$ is the reason for its transport into MCh with a subsequent inhibition of the proton ATPase and rise of membrane potential. Mechanistically, this phenomenon can be explained by the existence of a Ca^{2+}-dependent protein inhibiting H^+-ATPase (Hubbard and McHugh, 1996).

We have also studied kinetic parameters of platelet aggregation in experiments with rats *in vitro* and *ex vivo* (Mindukshev et al., 2006). Aggregation of platelets was induced with ADP over the concentration range 10–100 nmol/L. The median effective concentrations (EC_{50}) of ADP for the cells exposed to SFA (10 and 5 mmol/L) were calculated to be 25 and 35 nmol/L, respectively, and these platelets can be characterized as hypersensitive to ADP. Studying the kinetic parameters of platelet aggregation under intoxication of rats with SFA, we encountered a problem of spontaneous aggregation of the platelet-rich plasma, which agreed with the data on primary transition of the platelets to the hypersensitive state. However, the cells that avoided aggregation demonstrated an extremely high level of desensitization. In some experiments, ADP could not

induce platelet aggregation at very high (nonphysiological) concentrations near 10 µmol/L. Thrombocytopenia found in cats after poisoning agrees with our observations (Collicchio-Zuanaze et al., 2010).

Under intoxication with SFA, a significantly reduced thymus, as well as a prominent reduction of the quantity of freshly obtained thymocytes and elevation of apoptosis, were revealed (Figure 16.4A). SFA also caused an acceleration of apoptosis of intact and dexamethazone-treated human lymphocytes *in vitro* (Figure 16.4B), although spontaneous apoptosis of human neutrophils was inhibited (not shown in this chapter). Moreover, SFA either inhibited (high doses) or had little effect on reactive oxygen species (ROS) production by peritoneal macrophages of mice in our experiments *in vitro* (not shown here). In this regard, it should be noted that dexamethasone, in contrast to its effect on lymphocytes, also inhibits the apoptosis of neutrophils induced by ROS (Ruiz et al., 2002). One can suggest that the inhibitory effect of FA on neutrophil apoptosis is realized through ROS, whereas the enhanced apoptosis and depression of the cells responsible for adaptive immunity is a nonspecific reaction under SFA intoxication, reflecting a general decline and redistribution of energy resources of the organism. Leukopenia was again found in cats after poisoning (Collicchio-Zuanaze et al., 2010).

Biochemical Parameters Under Intoxication with FA

Among the biochemical effects caused by FA are accumulation of citrate and disturbance of its transport from MCh; elevation of lactate and disturbances in carbohydrate metabolism; decrease or increase of free fatty acid (FFA) concentration; elevation of adenosine and ammonia; disbalance of bivalent cations and acid-base equilibrium; hypokalemia; changes in gamma-aminobutyric acid (GABA) balance in brain; hyporphosphatemia or hyperphosphatemia; and rise of various enzymes in blood plasma, including creatine kinase enzyme and creatine kinase cardiac isoenzyme (Buffa and Peters, 1950; Engel et al., 1954; Maytnert and Kaji, 1962; Stewart et al., 1970; Buffa et al., 1973; Liang, 1977; Taitelman et al., 1983a; Bosakowski and Levin, 1986; Szerb and Redondo, 1993; Tsuji et al., 2009; Collicchio-Zuanaze et al., 2010). Recently, we specified changes in triglycerides and FFAs after acute intoxication with SFA (Table 16.1). As expected, the total level of triglycerides and FFAs changed in opposite directions within 3 h after poisoning; the former reduced down to 60% and the latter elevated up to 75%. Reduced level of triglycerides persisted in 24 h, whereas total concentration of FFA dropped below the normal level, though not significantly. GC-MS analysis of 36 fatty acids after extractive alkylation revealed reliable changes in concentration for 7 of them, in agreement with total FFA changes.

However, among this variety of biochemical changes, citrate seems to be the only parameter whose qualitative (but not quantitative) trends are not controversial. In rat hearts under acute intoxication with FA, the concentration of citrate can exceed control values 8–15 times (Bosakowski and Levin, 1986). Elevation of citrate concentration is in direct proportion to the respiratory activity of a tissue: metabolically active tissues, such as the heart, kidneys, and spleen, maximally accumulate citrate. Though in the liver, which is also characterized by high respiratory levels and metabolic activity, a small

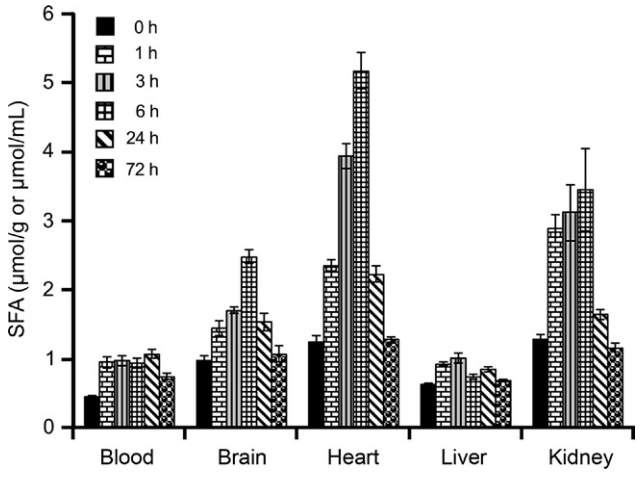

FIGURE 16.5 Concentration of citrate in blood and organs of rats after intoxication with SFA at 1/2 LD_{50}.

accumulation of citrate has been observed (Cole et al., 1955; Twigg et al., 1986). In our experiments with rats poisoned with SFA at a dose of 1/2 LD_{50}, the concentrations of citrate in blood plasma and organs increased within 1 h (Figure 16.5). The most prominent elevation of citrate was revealed 6 h after the poisoning in heart (5*x*), kidneys (3*x*), and brain (2.5*x*). There was doubling of the level of citrate in blood plasma after 1 h, though it was the only biochemical parameter of plasma that remained elevated for 3 days.

Transfer of citrate through the inner membrane of MCh is provided by a tricarboxylate transporter (m.w. 32.5 kD), which also catalyzes transport of *treo*-D_s-isocitrate, *cis*-aconitate, and other tricarboxylates (Kaplan et al., 1990). This is electroneutral exchange for either another tricarboxylate or dicarboxylate (e.g., malate or succinate), or for phosphoenolpyruvate. Formation of GSH-citryl thioester is irreversibly inhibited by (−)erythrofluorocitrate (IC_{50} = 25 pmol FC/mg protein), which makes a stable adduct with the synthase (Kun et al., 1977). However, the block of citrate transport is not absolute OR universal for all the organs and tissues. There are data on citrate transfer from MCh to cytosol with its subsequent utilization by cytoplasmic aconitase (c-aconitase), which is virtually unaffected under FA intoxication, and then by cytoplasmic NADP-dependent isocitrate dehydrogenase (cICDH) (Max and Purvis, 1965). Around 32% of citrate produced in MCh can be transported to cytosol (Buffa et al., 1972). These processes should be regarded as adaptive and positive; they lead to reduced oxygen consumption because the NADPH generated does not require further oxidation in the respiratory chain and can be utilized in other metabolic pathways.

Among the negative consequences of citrate accumulation is a change of electrolyte composition and acid-base imbalance in the organism. Moreover, elevation of citrate level in cells leads to disturbance of glucose metabolism due to inhibition of the key glycolytic enzyme phosphofructokinase (Bowman, 1964; Peters, 1972). Hyperglycemia during intoxication with FA can be very prominent, in spite of inactivation of gluconeogenesis (Godoy et al., 1968; Bobyleva-Guarriero et al., 1983). Nevertheless, we could not find significant changes in rat blood glucose throughout the periods of intoxication with FAA or SFA at a dose of 1/2 LD_{50}; at the same time, there was significant increase of glucose level in the liver, heart, and brain (not shown in this chapter). This may signify a utilization of glucose by other tissues (by skeletal muscles first of all). As a result, the local increase of glucose in organs is not reflected by the level of glucose in blood. Thus, glucose cannot serve as a reliable criterion of intoxication.

Some researchers considered the elevated glucose level to be a result of decreased insulin secretion by pancreatic β-cells due to their damage by FA (Cole et al., 1955; Karam and Grodsky, 1962). Along with hyperglycemia, there was hyperketonemia, observed characteristically for the diabetic state and caused by inhibition of the TCA cycle and depletion of oxaloacetate (Buffa et al., 1973; Taitelman et al., 1983a). Also consistent with diabetes is inhibition of hormone-induced lipolysis in adipose tissue (Taylor et al., 1977). Moreover, FA increased glucose conversion to fatty acids, and such a coincidence of antilipolytic and

lipogenetic effects of FA provides a basis for suggesting a relation between the effects of FA and insulin. However, injection of insulin does not alleviate FA intoxication in general and "FA diabetes" in particular (Reichelt, 1979). During FA intoxication, the initial hyperglycemia can even be reversed into hypoglycemia (Boquist et al., 1988), so this effect of FA was considered to be an insulin like phenomenon (Zieve et al., 1983). The principal distinction, however, should be the depletion of glycogen stores in different tissues under FA intoxication (Godoy et al., 1968; Boquist et al., 1988). After poisoning with FA, glycogen levels in animal tissues may decrease by 75% in 1 h and by 90% in 2 h (Buffa et al., 1973; Zhou et al., 1984). According to our data, during SFA intoxication (1/2 LD_{50}), glycogen levels are maximally decreased after 6 h in both liver (by 55%) and brain (by 40%), and the dynamics of the glycogen levels were similar in these organs. Such a decrease could result from the indirect action of adrenalin or sympathetic regulation (Buffa et al., 1973). In addition, inhibition of *de novo* glycogen synthesis has been reported (Zhou et al., 1984).

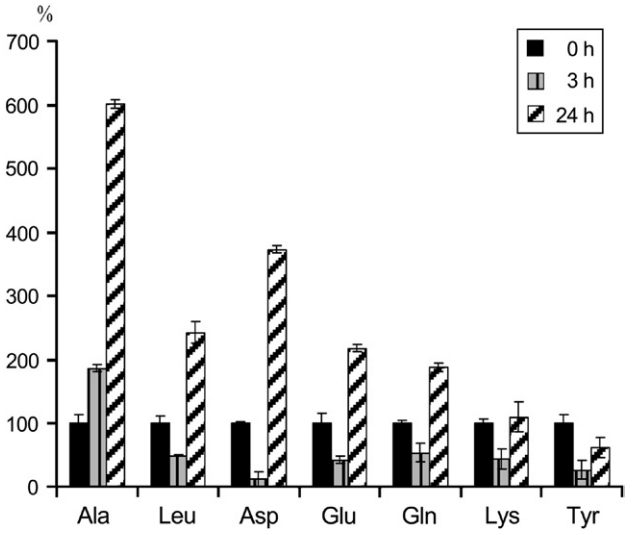

FIGURE 16.6 Changes of some amino acids in rat brain 3 and 24 h after administration of SFA at 1/2 LD_{50}.

Nevertheless, disturbances in hormonal regulation during the FA intoxication can also take place: reduction of calcium concentration in blood plasma could be caused by a poor reabsorption of calcium ions in kidneys due to a decrease of parathormone level; an excess of Ca^{2+} excretion of up to 0.173 mg/min (the control rate being 0.06 mg/mL) has been registered (Perez and Frindt, 1977). Decrease in calcium levels could be the reason of the so-called hypocalcemic tetanus (Roy et al., 1980), manifesting itself as typical convulsions, disturbances of blood clotting, and hypotension leading to vascular attacks. The level of decrease of calcium correlates with extension of the QT interval on electrocardiography (ECG), which is a consequence of broad spectrum cardiac arrhythmia (Buffa and Peters, 1950; Arena, 1970).

ATP level is usually reduced, and ADP and adenosine monophosphate levels can be elevated in the first hours of FA intoxication, with subsequent decreases (Bowman, 1964; Stewart et al., 1970). There are other reports of a constant level of ATP in some organs and tissues. For example, FA did not affect ATP and GTP, nor did it affect cyclic nucleotides levels in hepatocytes *in vitro* (Dohi and Murad, 1981). When dogs were intoxicated with sublethal doses of FA, there was no decrease in oxygen consumption and ATP level, which was explained by the utilization of glutamate and aspartate which can enter the TCA cycle distally of aconitase (Liang, 1977). The inversion of reactions at glutamate dehydrogenase (GDH) is a simple and effective compensative mechanism during blockade of the TCA cycle in kidney cells: instead of glutamine synthesis, glutamate is deaminated to form 2-oxoglutarate to support the flow of reducing equivalents in the TCA cycle and ATP synthesis, while the ammonia that is produced neutralizes local tissue acidosis (Yu et al., 1976). Such utilization of glutamate may account for the significant reduction of glutamate levels in rat organs, beginning from the first hour after intoxication with FA. The data obtained according to the GC method of Matsumura et al. (1996) have also shown decreases of glutamate, aspartate, and some other amino acids in rat brain (Figure 16.6), as well as decrease of glutamate and nearly complete absence of glutamine in blood plasma of rats and rabbits (not shown here) 3 h after poisoning with SFA. The levels of amino acids in the blood plasma of animals indicates the extent of protein breakdown in muscles on one hand, and the level of their utilization by other organs and tissues on the other. Under intoxication with FA, glutamate and its precursor glutamine are probably the main nutrients. Elevation of amino acid levels in blood plasma of rats within 3 h after poisoning signifies an elevation of protein breakdown. Furthermore, this indicates that other amino acids, because of their transport, catabolism, and other factors, are not nutrients of primary importance under energetic deficit conditions.

Elevation of lactate level in the blood of animals poisoned with FA has been reported (Engel et al., 1954; Taitelman et al., 1983a). In agreement with these results, we observed a prominent rise in lactate levels in blood just after convulsions (not shown here). In the rat heart and brain, lactate levels decreased under intoxication with SFA or FAA, regardless of convulsions. During SFA intoxication, the decrease in lactate level (and increase of glucose level) in rat heart takes place earlier and to a greater extent than for FAA intoxication: 38% decrease in 3 h for lactate, as compared with 25% in 6 h in the case of FAA; and 100% increase in 3 h for glucose, as compared with 67% in 6 h in the case of FAA. Also, the maximal

increase of citrate was registered at 24 h after poisoning with FAA, but at 6 h after poisoning with SFA. These and other biochemical data are consistent with clinical pictures of intoxication with equipotential doses of SFA and FAA: intoxication with SFA is generally more violent and takes a shorter period of time.

Effects of FA on the Cells of Nervous System: Interaction of Glia and Neurons

Acetate is metabolized in astrocytes nearly 18 times faster than in cortical synaptosomes, although the activity of acetyl-CoA synthase in synaptosomes is almost double that in astrocytes (5.0 and 2.9 nmol/min per mg of protein, respectively). The principal difference in the acetate metabolism rates is explained by differences in the kinetics of its transport, which is mediated by a monocarboxylate carrier (Hosoi et al., 2004); acetate uptake by astrocytes, unlike synaptosomes, rapidly increases and follows saturation kinetics (V_{max} = 498 nmol/mg protein/min, K_M = 9.3 mmol/L) (Waniewski and Martin, 1998). Having penetrated into astrocytes at one site, FA can diffuse into other cells through gap junctions (Ransom, 1995). Citrate accumulating in astrocytes is readily released from cells and effectively penetrates other astrocytes (Westergaard et al., 1994). The TCA cycle in nerve tissues is blocked by FA, but not completely—only by 35–55% (Patel and Koenig, 1968). This leads to decreased consumption of glucose and increased consumption of glutamine (if the latter is available); no reduction of ATP was observed (Hassel et al., 1994). The natural metabolic pathway is switched over to utilization of glutamine, glutamate, and 2-oxoglutarate in the TCA cycle. GDH of astroglia plays a big role in this switch, promoting the ATP-independent utilization of glutamate (Plaitakis and Zaganas, 2001). The absence of an aspartate/glutamate mitochondrial exchanger (the key component of the malate/aspartate cycle) in astrocytes also plays a role in supporting this (Xu et al., 2007). There is little GDH in neurons as compared to astrocytes, with activity of GDH depending not only upon proximity to glutamatergic fibers and terminals, but also upon activity of neighboring neurons regardless of their functional specialization; a deficiency of GDH activity in astroglia may be a cause of cytotoxic effects of glutamate and aspartate (Aoki et al., 1987).

The uptake of glutamate by astrocytes is an electrogenic process in which one molecule of glutamate is cotransported with three sodium ions (or 2 Na^+ and 1 H^+), being exchanged for 1 K^+ and 1 OH^- or 1 HCO_3^- (Bouvier et al., 1992). To reestablish the ionic balance, Na^+/K^+-ATPase would work with ATP provided by phosphoglycerate kinase binding to plasma membrane. This stimulates glycolysis and lactate production in astrocytes. Lactate is released from astrocytes and then is taken by neurons to be further oxidized. Pyruvate, which is also produced in astrocytes, can be utilized in the TCA cycle to form 2-oxoglutarate, or transaminated to form alanine; the latter can also enter neurons (Tsacopoulos and Magistretti, 1996; Tsacopoulos, 2002). However, the rate of alanine metabolism through alanine transaminase (ALT) in synaptosomes is much less than the rate of its uptake; moreover, neuronal ALT and aspartate aminotransferase work mainly to synthesize alanine and aspartate (Erecinska and Silver, 1990). Hence, we observed a stable elevation of alanine level in contrast to that of other amino acids in the brain of rats poisoned with SFA (Figure 16.6). The role of alanine as a source of glutamate increases during the restoration period after ischemia/hypoxia, when alanine concentration is elevated and glutamate concentration is reduced (Erecinska et al., 1994).

Inhibition of glutamate uptake by astroglial cells can be one of the causes of convulsions observed under intoxication with FA (Szerb and Issekutz, 1987). The toxic effect is governed mainly by citrate, which chelates calcium ions (Fonnum et al., 1997). Intrathecal injection of FC in mice caused convulsions in about 15 s, while in about 37 min by intracerebroventricular injection (Hornfeldt and Larson, 1990). Moreover, intrathecal injection of sodium citrate caused the same effect. This means that the main target of FC and citrate, and the area for generation of convulsions, should be the spinal cord. Convulsions could also be generated by other compounds having the common property of chelating calcium ions; these are ethylenediaminetetraacetic acid, ethylene glycol tetraacetic acid, glutamate, and lactate (Hornfeldt and Larson, 1990). Thus, along with elevation of citrate level, activation of anaerobic oxidation of glucose in neurons followed by accumulation of lactate in cerebrospinal fluid could also lead to coma and convulsions (Stewart et al., 1970). Chelation of zinc and other divalent cations by citrate enhances the signaling activity of *N*-methyl-D-aspartate (NMDA) receptors (Westergaard et al., 1995). In addition, disturbances of GABA metabolism were revealed as a result of the TCA cycle blockade: after injection of FA, there was initially an elevated level of GABA registered in different regions of the brain, followed by its reduction concurring with the start of clonicotonic convulsions (Maytnert and Kaji, 1962; Stewart et al., 1970).

The convulsive state is aggravated by increasing concentration of ammonia ions (Raable, 1981), an excess of which can lead to redistribution of K^+ and Cl^- ions, disturbances of neuronal depolarization and hyperpolarization, and impairment of postsynaptic inhibition. The neuron dysfunctions observed result in encephalopathy, ataxia, convulsions, and coma (Iles and Jack, 1980; Raable and Lin, 1983; Xiong and Stringer, 1999). Normally, ammonia specifically promotes GSH synthesis and export from astrocytes and increases its extracellular

degradation, which may improve the availability of precursors for GSH synthesis in neurons and their resistance to ammonia toxicity; FA abrogates this defense mechanism (Hilgier et al., 2010). Lymphocyte-mediated neuroprotection is also mediated by astrocytes, and it is no surprise that it is inhibited by FA (Shrestha et al., 2014). Moreover, FA impairs the enhancement of synaptic transmission and facilitation of long-term memory caused by nicotine, the effect being mediated by the gliotransmitter D-serine, an endogenous co-agonist of NMDA receptors (López-Hidalgo et al., 2012). On the other hand, FC affecting astroglia causes a drop in membrane potential and depolarization and a decrease of $[K^+]_i$ (Largo et al., 1997), which should lead to compensatory transport of bicarbonate ions into astrocytes and acidification of the extracellular medium. Together with the natural carbonate acidification of the medium close to chemoreceptors of the retrotrapezoid nucleus, this activates the diaphragmal nerve and increases the expired minute ventilation (Erlichman et al., 1998; Holleran et al., 2001): maximum ventilation is attained at 4% CO_2 against 8–10% in control hypercapnic trials. Control of extracellular pH in nervous tissue is coupled with functioning of the Na^+/HCO_3^- cotransporter, which exists in plasma membrane of astrocytes but is lacking in that of neurons (Deitmer, 1992; Romero and Boron, 1999). This transport has an electrogenic character because two (or even three) bicarbonate ions are transferred per sodium ion. Again, however, a continuous supply of glutamine to the glutamatergic nerve terminals is the necessary condition of respiratory rhythm generation; blockade of the TCA cycle in astroglial cells with FA can impair the respiratory activity (Hulsmann et al., 2000).

Physiology of Blood Vessels Under Intoxication with FA

FA does not affect circulation in resting organs, but significant increase of blood flow can be seen in working respiratory muscles (Johnson and Reid, 1988). Conversely, a reduction of blood was registered in the hepatic artery, and contractive activity of isolated portal veins was suppressed after introduction of FA into the medium (Liang, 1977). These data, along with data on the effects of FA on endothelial cells *in vitro*, suggested that the endothelium of blood vessels could be one of the primary targets for FA. If so, the endothelium-dependent relaxation of blood vessels would be affected. To test the hypothesis, we administered SFA to rats subcutaneously at a dose of 2–3 mg/kg (LD_{50}–LD_{84}), and investigated endothelium-dependent relaxation of rat aorta 3 and 24 h after the poisoning. Norepinephrine in saturating concentrations induced a rapid constriction of aorta followed by a smooth transition to plateau; in contrast, the vasoconstricting hormones angiotensin II, vasopressin, and 5-hydroxytryptamine induced a bell-shaped vasoconstricting response of aorta. To assess the functional state of endothelium, carbocholine was introduced at 10^{-5} mol/L. Acting on muscarinic receptors of endothelial cells, it induced the generation of nitric oxide and release of endothelium-derived hyperpolarizing factor (McCulloch et al., 1997). All the agonists applied had similar effects on the contraction of aortas obtained from control and poisoned animals (not shown in this chapter). The experiment clearly demonstrated that FA has no influence upon the contractile properties of isolated rat aorta at 3 and 24 h after poisoning. This endothelial function is not affected, at least directly, by intoxication with FA.

Body Temperature of Rats and Rabbits After Intoxication with FA

One of the main pathophysiological features of intoxication with FA is decrease of the body core temperature of endotherms, which indicates a disturbance of heat production, regulation, or both (Brockmann et al., 1955; Misustova et al., 1980; Taitelman et al., 1983b). It is interesting to note that the effects of FC are comparable with those of selective inhibitors of p38 MAP-kinases (activation of which precedes production of pyrogens) and antagonists of cytokines TNF, IL-1, and IL-6 (Milligan et al., 2001, 2003). In our experiments, following administration of lethal doses of SFA to male rats, a marked decrease of rectal temperature was registered beginning 1 h after the poisoning and gaining minimal levels in 6 or 24 h depending on doses. Then a gradual increase in temperature took place in the surviving rats, returning to normal in 2–7 days. For example, under intoxication with SFA at a dose of LD_{50}, a minimal rectal temperature of the surviving male rats (31.5°C, as compared to 38.5°C in control animals) was registered in 6 h, and 7 days after the poisoning, the temperature was 1°C below the control level. Under intoxication with FAA at equipotential doses, a minimal rectal temperature of the surviving male rats (32.6ºC, as compared to 38.9ºC in control animals) was registered in 2 days, and even 7 days after the poisoning, the temperature was 3°C below the control level. However, we observed a much smaller change of rectal temperature in rabbits after subcutaneous (s.c.) administration of SFA at a dose of LD_{50}: maximal decrease was only 1°C (38°C, as compared to 39.1°C) in 6 h. According to our observations, decrease of the temperature below 38°C in 3 h can serve as a reliable sign forecasting the lethal fate of the poisoned rabbits.

Electrophysiological Studies of FA Intoxication

Clinical analysis of ECG of rats poisoned with SFA or FAA (Kuznetsov et al., 2007) revealed a similar dynamic of the temporal parameters of ECG, with slowdown and delay of the repolarization processes being the most important (Table 16.2). A drop in amplitudes of the atrial and ventricular ECG complexes can be observed within 1 h after poisoning, followed by decrease of the systolic

index in 24 h. This indicated impairment of the contractile capacity of the myocardium. Registration of ECG of rats that died in 2 days of intoxication with SFA revealed a sharp drop in heart rate (down to 120–180/min, the normal rate being 420–500 beats/min) 24 h after the poisoning, together with complete absence of the P wave, which reflects atrial depolarization (Figure 16.7A). Simultaneous reduction of both amplitude and duration of the T wave can be seen. An upward shift of the ST segment, though not accompanied by growth of the T wave amplitude, was registered in 70% of rats (Figure 16.7B). The cumulative evidence of the shape and amplitude changes of the ECG waves indicates a development of acute myocardial ischemia, though it was transient and maximally expressed 24 h after the poisoning. Reduction of the S wave amplitude could be caused by disturbances of excitation processes in basal ventricular regions and in some areas of the right ventricle. Taking into account an increase in duration and shape distortions of the ventricular complex, one cannot exclude an incomplete right bundle-branch block. A significant extension of the T wave during the course of examination indicates deceleration of the fast repolarization of the myocardium, though the process of slow repolarization (the QT interval in ECG, corresponding to the systole of ventricles) is accelerated within 3–24 h after the poisoning.

Respiratory rhythm gradually increased in rats after intoxication with SFA, and there were additional respiratory components in 50% of animals 24 h after administration of the poison (Figure 16.8) that may indicate disturbances of innervation of respiratory muscles. Spectral analysis of the respiratory curve demonstrated that there was an enhanced synchronization of the respiratory rhythm observed within 3 h after the poisoning. Simultaneously, the amplitude of respiration increased, followed by a gradual decrease that took place by the third day. Over the same period, a certain reduction of lability of respiratory rhythm was noted, accompanied by the appearance of two distinct peaks corresponding with frequencies of 90 and 120 cycles of respiration per minute. By the seventh day, the respiratory spectrogram was similar to the initial one, though the frequency of respiration was not completely restored. Comparison of spectrograms of respiration and ECG demonstrates disturbances of control mechanisms underlying generation of the second order waves (respiratory arrhythmia visible at the spectrogram as a peak in the high frequency region 0.8–2.5 Hz). One day after administration of SFA, there was a marked frequency maximum at the respiratory spectrum, in contrast to that of the ECG spectrogram.

Analysis of the heart rate variability (HRV) demonstrates that 1 h after poisoning an enhancement of parasympathetic influence took place, and this was accompanied by insignificant and paradoxical enhancement of heart and respiratory rates (Table 16.3). Then, against a background of enhancement of humoral (metabolic) and sympathetic influences and simultaneous decline of parasympathetic influence, a stable decrease

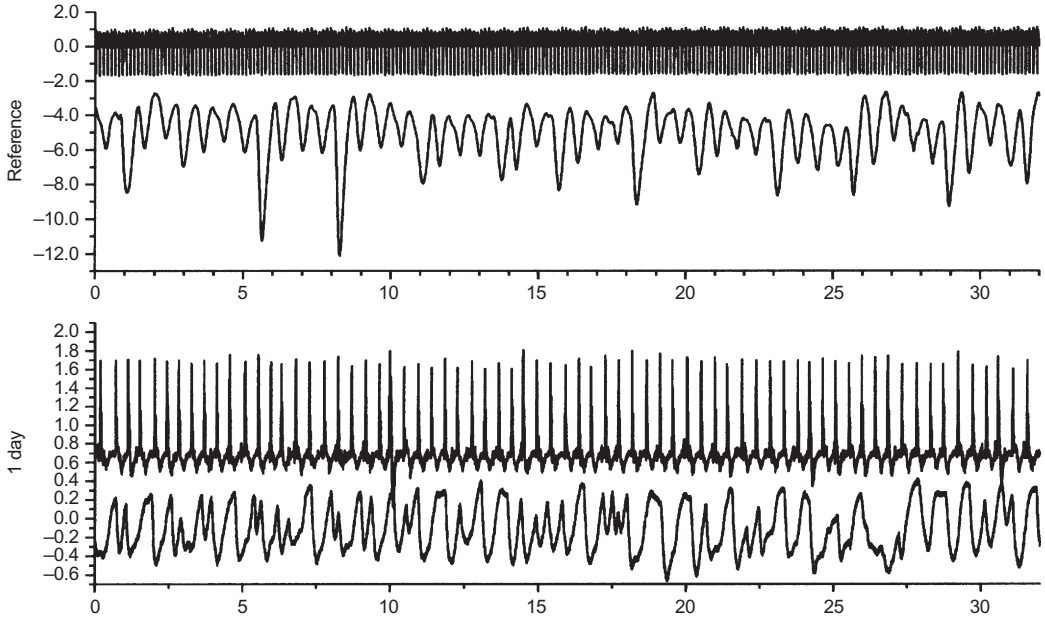

FIGURE 16.8 Records of ECG (upper) and respiratory rhythm (lower) from a narcotized rat before and 24 h after introduction of SFA.

of heart and respiratory rates took place, indicating a prominent divergence between vagosympathetic balance and resulting physiological parameters. Previously, it was shown in experiments with dogs that systemic, pulmonary, and coronary hemodynamic parameters during the first hours after introduction of FA were not mediated by the autonomic nervous system and adrenergic neuromediators (Liang, 1977). This is in partial agreement with our results obtained with rats, though this cannot be extrapolated to all the periods of intoxication and all animal species.

TOXICITY AND RISK ASSESSMENT

A characteristic feature of the clinical picture of intoxication with FA is a latent period of 0.5–6 h (Egekeze and Oehme, 1979). The duration of the latent period depends on animal species' metabolism and dose administered (Chenoweth, 1949; Goncharov et al., 2006). A broad variability of clinical manifestations of FA effects in different animal species is one of its characteristic features. There is a correlation between food specificity and toxic effect of FA; the cardiovascular system is mainly affected in herbivores, while the central nervous system (CNS) is mainly affected in carnivores. Accordingly, four groups were recognized in terms of clinical signs of intoxication (Chenoweth and Gilman, 1946). The first comprised herbivores (rabbits, goats, sheep, cattle, and horses), in which FA-induced ventricular fibrillation without notable CNS disorders (Marais, 1944; Chenoweth, 1949; Egekeze and Oehme, 1979). The second group comprised dogs and guinea pigs, in which the CNS was primarily affected. In dogs, a species highly sensitive to FA, symptoms of secondary intoxication appear after a latent period of 1–10 h (Chenoweth and Gilman, 1946; Egyed and Shupe, 1971). For animals in the third group (comprising rats and hamsters relatively tolerant of FA), the clinical pattern of intoxication is similar to that of the second group of animals, but slightly less pronounced. After a latent period lasting 1–2 h, tremor and elevated excitability were common symptoms. Death usually occurred within 4–6 h as a result of respiratory depression after exposure to high FA doses (Chenoweth and Gilman, 1946; Pattison, 1959). The surviving animals demonstrated depression, weakness, ataxia, and strongly pronounced bradycardia down to 30 heartbeats per minute. At sublethal doses of FA, full recovery can occur in 72 h after poisoning (Chenoweth and Gilman, 1946; Pattison, 1959). A mixed response to FA exposure was described in animals in the fourth group, which included cats, pigs, and rhesus monkeys; it included disturbances of both the CNS and cardiovascular system. On acute poisoning, adynamia, salivation, vomiting, frequent defecation, pupil dilatation, nystagmus, accelerated respiration, enhanced excitability, tremor, and clonicotonic convulsions were observed in these animals (Chenoweth and Gilman, 1946; Gammie, 1980). In cats, lesions were observed that were characteristic of degenerative and ischemic processes in the heart, kidneys, liver, brain, and lungs (Collicchio-Zuanaze et al., 2010).

Nevertheless, this classification was revised (Sherley, 2004). The division of animals into cardiac and neurological symptomatic groups is considered to be unnatural

because it ignores common neurological signs manifested in all the groups: these include tremor, ataxia, hypersensitivity, myotonic convulsions, weakness, and partial paralysis. The cardiac response in a pure form was not a common event and was described for a limited number of animals, though CNS involvement is obviously widespread.

As for humans, exposure to stock solution during formulation and dermal or respiratory exposure during application of bait, as well as accidental or intentional acute intoxication, are the main health concerns. Formulators and pest control workers are the largest occupational risk group (Norris, 2001; Beasley et al., 2009). Early monitoring indicated that exposures were highest in relation to cereal bait manufacturing and aerial carrot baiting procedures (Beasley et al., 2009).

The clinical picture of acute intoxication of humans is similar to that of rhesus monkeys; among the symptoms are nausea, vomiting, abdominal pains, salivation, irrational fear, weakness, tachypnea, cyanosis, and sometimes sweating and increased temperature (Brockmann et al., 1955; Pattison, 1959; Arena, 1970; Taitelman et al., 1983b). Psychomotor agitation and sometimes loss of spatiotemporal feeling can occur. In addition, tremor, nystagmus, involuntary dejection and urination, muscle spasms, hypertonus of the extremities, and even alalia, have been reported (Gajdusek and Lutheer, 1950; Robinson et al., 2002). The most characteristic signs of intoxication involve generalized recurrent convulsions alternating with deep depression. Sudden loss of consciousness and coma may occur. These symptoms were associated with metabolic acidosis and hypotension (Pattison, 1959; Chi et al., 1996, 1999), as well as cardiac rhythm disturbances, such as tachycardia, bradycardia, asystole, and sustained ventricular fibrillation (Gajdusek and Lutheer, 1950; Reigart et al., 1975; Trabes et al., 1983). Death usually occurs within 3 h to 5 days of heart block, arrhythmia, or respiratory failure (Reigart et al., 1975). Important diagnostic symptoms registered with ECG are arrhythmia, the QT and ST intervals, and the T wave (Pattison, 1959; Taitelman et al., 1983b, Chi et al., 1996). Kidneys are among the most sensitive organs: acute renal failure associated with uremia and increased level of creatinine in serum can be observed under acute FA poisoning (Chung, 1984; Chi et al., 1996). Pathomorphological abnormalities of humans poisoned with FA are also nonspecific and similar to those of animals. In the case of lethal outcome, petechial hemorrhages and excess blood filling of internal organs (Hayes, 1982), edema of lungs and brain, and sometimes mediastinal emphysema and acute inflammatory reaction with coagulating necrosis in esophagus were registered in humans (Brockmann et al., 1955). The morphological basis of cardiotoxic effects is acute myocardial dystrophy, a characteristic of which are diffuse lesions of cardiac muscle (Pattison, 1959; Taitelman et al., 1983b). Acute renal failure develops due to influence of FA on subcellular structures of kidneys. Metabolic acidosis aggravates the clinical course of renal failure. Diffuse degeneration of renal tubules was observed (Hayes, 1982). For cases that lack clinical and morphological specificity, biochemical data and primarily citrate and fluoride levels can be used for diagnostic purposes (Pattison, 1959; Schultz et al., 1982). Thus, under acute intoxication with FAA, citrate (108 µg/g in heart and 23.9 µg/g in kidney) and fluoride (6.3 mg/g dry weight of heart and kidney) were found in a human corpse; the dose of FAA was estimated to be near 23 mg/kg (Hayes, 1975). In addition, the indubitable diagnostic confirmation of the intoxication should be based on determination of the poison in tissues. Under acute SFA poisoning with lethal outcome, FA was found in urine (368 µg/mL), liver (58 µg/g), and brain (76 µg/g) (Harrison et al., 1952).

Among the aftereffects that develop following acute intoxication with FA or its derivatives are various neurological disturbances. These include impaired muscular tonus and reflex activity, transient spasmodic and meningeal syndromes, cerebellar dysfunction, such as ataxic gait, dysarthria, and intention tremor (Pridmore, 1978; Trabes et al., 1983; Kim and Jeon, 2009). Long after an acute poisoning (from 1.5 to 9 years), a tendency for epileptoid seizures, ataxia, extremity muscular hypertension, spastic tetraplegia, blindness of cortical origin, diffuse brain atrophy, and psychic disorders were observed. A case of chronic intoxication involving FA intoxication of a farm worker has been described (Parkin et al., 1977): the clinical signs included renal insufficiency and less pronounced injuries of other organs.

TREATMENT

Decades of studies on the toxicology of FA have led scientists to the conclusion that treatment of intoxications can be successful only if timely general and symptomatic therapy is applied, but not specific antidotes (Dorman, 1990; Norris, 2001). Much experimental work over an extensive period has been undertaken in an effort to find effective donors of acetate groups because of their property to inhibit conversion of FA to FC. Ethanol, monoacetin (glycerol monoacetate), acetamide, and cortisone acetate were tested for their ability to serve as antidotes (Chenoweth, 1949; Hutchens et al., 1949; Cole et al., 1955; Giller, 1956; Egyed, 1971; Egyed and Shlosberg, 1977). A therapeutic effect was revealed for the simultaneous introduction of ethanol and acetate (Hutchens et al., 1949; Tourtelotte and Coon, 1949). Negative effects of monoacetin and acetamide were the enhancement of hyperglycemia and metabolic acidosis, damage of capillaries and hemolysis of red blood

cells, and increase of citrate concentration in different organs (Engel et al., 1954; Egyed and Shlosberg, 1973). Administration of cortisone acetate inhibited FC synthesis and prevented the development of ketosis, though hyperglycemia increased (Cole et al., 1955).

Several antidotes were tested for their capacity to activate transport of the TCA cycle intermediates through mitochondrial membranes. For this purpose, fluoromalate was proposed, although positive results were negligible (Peters, 1972). Malate was also tested, but proved to be effective only in *in vitro* experiments (Buffa et al., 1972). GSH and a series of SH-containing compounds (cysteamine and *N*-acetylcysteine) were tested (Mead et al., 1985), also *in vitro.* However, they were incapable of replacing GSH in enzymatic defluorination of FA and have not found practical application. TCA cycle intermediates (succinate, malate, citrate, and glutamate) were tested, but they did not exhibit a protective effect (Hutchens et al., 1949). A positive result was observed in experiments with mice, which were administered calcium gluconate and succinate (Omara and Sisodia, 1990). This therapy was hardly more effective than ethanol, however. Some 16 years later, another research group tested the therapy with cats, which are known to be much more sensitive to FA. Again, differences in survival between treated and nontreated animals were insignificant ($P > 0.05$) (Collicchio-Zuanaze et al., 2006). Administration of calcium chloride to cats suffering acute intoxication with FA made it possible to postpone death up to 166 min; combination of calcium chloride with monoacetin gave a similar effect (Taitelman et al., 1983a). Nevertheless, calcium chloride reduced the QT interval and favored survival of humans after intoxication with FAA (Taitelman et al., 1983b).

Our strategy for developing therapeutic means of treating acute FA intoxication was based on a deep analysis of the biochemical literature, together with our own experimental data. Thus, a high sensitivity of aconitase to inhibition by superoxide anion and nitric oxide (Gardner et al., 1994; Andersson et al., 1998; Castro et al., 1998) means that ROS and NO could be competitive antagonists of FC to avert its effect on aconitase. Also, as considered earlier, glutamate could be utilized in the TCA cycle through GDH or transaminases during FA intoxication (Yu et al., 1976; Liang, 1977; Hassel et al., 1994). Moreover, the effects of FC could be prevented by prior introduction of isocitrate (bypass of inhibited aconitase) and fructose-1,6-bisphosphate (energy substrate for neurons; Lian and Stringer, 2004).

We have demonstrated that FA can adversely affect mitochondrial functions only if pyruvate was available as respiratory substrate, and that changes of redox state of pyridine nucleotides (PN) or their leakage from MCh could be critical factors that impair mitochondrial respiration and lead to cell death (Zinchenko et al., 2007). Opening of the mitochondrial pores is a reversible phenomenon: prevention of oxidation and leakage of NADPH from MCh can restore the normal functional state of MCh. For example, when succinate or glutamate was used as respiratory substrates, mitochondrial functions were not affected by FA (Figure 16.3A).

As for other alternative substrates, we suggest that the accumulating intracellular citrate could be among them. As discussed earlier, blockade of citrate transport from MCh under FA intoxication is not an obligatory event, and citrate can enter cytosol to be further utilized by cICDH (Max and Purvis, 1965; Buffa et al., 1972). The cICDH activity is almost equally distributed between cytosol and MCh of astroglia and microglia, whereas cICDH accounts for about 75% of activity in neurons and oligodendrocytes (Minich et al., 2003). We have not found data on the ratio of mitochondrial and cytoplasmic aconitases in the cells of the nervous system, but it is interesting to note that a similar ratio of mICDH and cICDH exists in hepatocytes (Rakhmanova and Popova, 2006), and that c-aconitase accounts for 65% of the aconitase in these cells (Konstantinova and Russanov, 1996). In rat heart, a similar ratio of m- and c-aconitases has been revealed: 35% and 65%, respectively (Medvedeva et al., 2002). Based on these data, one may suggest that an effective pathway for citrate utilization and NADPH synthesis exists in these (and other) cells in case of inhibition of m-aconitase. This alternative pathway could play a positive physiological role because NADPH might be used for anabolic reactions and heat generation, GSH reduction, and NO synthesis, and for regulation of blood vessel tone by ROS generation (Winkler et al., 1986; Bobyleva et al., 1993; Lee and Yu, 2002; Gupte and Wolin, 2006). As was pointed out earlier, studies focused on the pentose cycle as the main source of NADPH need to be reevaluated, taking into consideration the metabolic activity and substrate specificity of a tissue (Winkler et al., 1986). cICDH, along with malic enzyme and transhydrogenase, participate in NADPH regeneration to further reduce GSH in brain mitochondria (Vogel et al., 1999), but cICDH can provide a sevenfold increase in generation of NADPH compared to the malic enzyme (Winkler et al., 1986). The level of cytoplasmic NADPH can influence potassium channels and calcium balance (Wolin et al., 2005; Gupte and Wolin, 2006). In our *in vitro* studies, FA induced a slow elevation of $[Ca^{2+}]_i$ in different cells (Zinchenko et al., 2007). This could indicate activation of the SOC channels; the process is not affected by FA and does need ATP to be implemented, at least in glial cells (Lian and Stringer, 2004). We suppose that this mechanism is common for many types of cells, and this could explain a primary hypersensitivity of platelets exposed to FA (Mindukshev et al., 2006). In cardiomyocytes, elevated $[Ca^{2+}]_i$ can stimulate their functional activity observed in our experiments

in vitro and also supported *in vivo* by a primary increase of systolic index (Table 16.1). As for modulating effects of Ca^{2+} on the bioenergetics of MCh, it is pertinent to recall classic activation of the TCA cycle dehydrogenases, followed by increase of mitochondrial potential and NADH generation: 2-oxoglutarate dehydrogenase (OGDH) and mICDH can be activated by calcium ions through allosteric mechanisms, and pyruvate dehydrogenase is activated due to dephosphorylation by the Ca^{2+}-dependent phosphatase (McCormack et al., 1990; Hansford, 1994). The exact role of these dehydrogenases in the bioenergetic status of MCh affected by FA needs to be clarified, though one can suppose that OGDH could derive a special benefit from such an activation if it is provided with exogenic or endogenic 2-oxoglutarate.

In the above discussion, we have defined several directions for biochemical correction under acute intoxication with FA and suggested suitable preparations for therapeutic complexes: (i) competitive inhibition of FA and CoA interaction, (ii) competitive inhibition of FC and aconitase interaction, (iii) replenishment of the TCA cycle distally of aconitase, and (iv) utilization of accumulating citrate. In previous publications, we presented the first data on effectiveness of therapeutic complexes named METIS (Goncharov et al., 2006, 2009). These consisted of ethanol, methylene blue (MB), sodium glutamate (SG), and glycerol trinitrate (GT). Indices of therapeutic efficiency (ratio $LD_{50}^{treated}/LD_{50}^{non\text{-}treated}$) for different METIS complexes applied in different regimens are presented in Table 16.4. In addition to these data, a spectrum of physiological and biochemical data was also obtained. Animals treated with METIS complex experienced little change in body weight, temperature, and oxygen consumption. Dynamics of citrate in the brain, kidneys, and blood also improved, and the kinetic parameters of platelet aggregation were corrected. Comparative analysis of the FA level in the tissue homogenates, blood plasma, and urea of rats revealed that METIS complexes reduced the level of FA in the brain almost twofold, thus indicating inhibition of FA utilization (which first occurs in the cells of the nervous system).

TABLE 16.4 Assessment of Therapeutic Effectiveness of METIS Preparations Under Acute Intoxication of Rats with SFA

Therapy	Treatment Regimen After the Poisoning with SFA	Index of Therapeutic Efficiency Ratio LD_{50} Treated/LD_{50} Nontreated
Ethanol, $n = 42$	10 and 120 min	1.6
METIS-1, $n = 48$	10 and 120 min	2.5
METIS-2, $n = 92$	10, 60, and 120 min (ethanol and GT); 60 and 120 min (MB)	3.3
METIS-4, $n = 39$	10, 60, and 120 min, 24 and 48 h (ethanol, GT, and SG); 10 and 120 min, 24 and 48 h (MB)	4.3
Ethanol, $n = 43$	30 and 120 min	2.6
METIS-3, $n = 45$	30 and 120 min	3.2

n, number of animals used in experiment to calculate the index. *Experimental conditions and METIS components*. SFA was dissolved in distilled water and administered intragastrically at 0.2 mL per 100 g of rat body weight, after 7–8 h fasting. METIS-1 is a combination of two compounds: aqueous solution of MB administered subcutaneously (s.c.) at a dose of 5 mg/kg, and aqueous solution of SG administered intraperitoneally (i.p.) at a dose 250 mg/kg. METIS-2 is a combination of three compounds: MB (5 mg/kg, s.c.), ethanol and GT administered i.p. (corresponding doses for pure ethanol and GT were 1 g/kg and 10 mg/kg). METIS-4 is a combination of four compounds: MB (5 mg/kg, s.c.), and aqueous solution of ethanol (1 g/kg), GT (10 mg/kg), and SG (100 mg/kg) administered i.p. METIS-3 is a combination of three compounds: MB (5 mg/kg, s.c.), ethanol and SG administered i.p. (corresponding doses for pure ethanol and SG were 1 g/kg and 200 mg/kg).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The extreme toxicity of FA is determined by its similarity to acetate, which plays a central role in cell metabolism. FA enzymatically condenses with CoA-SH to produce fluoroacetyl-CoA, which replaces acetyl-CoA entering to the TCA cycle and produces FC. The latter reacts with aconitase and blocks TCA cycle. Energy production is reduced, as well as the concentration of metabolites generated distally to aconitase. Of these, 2-Oxoglutarate is the most important, being a precursor of glutamate, which is a neuromediator in the CNS and participates in neutralizing ammonia, either directly through glutamine synthase or indirectly through the urea cycle. Accumulation of citrate is one of the causes of metabolic acidosis. Chelating of Ca^{2+} is apparently one of the central events in pathogenesis of intoxication.

The first papers on the toxicology of FA were published in the 1940s. The long history of investigations was fruitful, with several important discoveries: biochemical mechanism of "lethal synthesis"; structure of aconitase; functional relations of glia and neurons; and switching of metabolic pathways. However, the main problem of toxicology (for any poison)—development of an effective therapy—was not solved. Analysis of the scientific literature has demonstrated that reciprocal relations of signaling and metabolic pathways under intoxication with FA are unclear. Inhibition of m-aconitase causes blockage of the TCA cycle, reduction of pyridine nucleotides, accumulation of citrate, disturbances of intracellular signaling, deenergization, and cell death. However, the dynamics and significance of these events are different depending of the type of cells and tissues, which is why it is very difficult to predict the primary reaction of different cells, let alone the whole organism.

Biochemical pathways underlie the basis of physiological rhythms; they should have a certain space-time structure and presuppose coordinated interactions of different cells. Thus, one of the causes of disturbances of normal respiration under FA intoxication could be disturbances in rhythmic activity of respiratory neurons; however, suppression of these neurons is a result of the inhibiting effects of FA on astrocytes, not neurons (Hulsmann et al., 2000). We have described the development of cardiac and respiratory tachyarrhythmia reflecting the reproduction of decasecond rhythms characteristic of immature or abnormal excitatory structures (Kuznetsov et al., 2007). Previously, it was suggested that such endogenic rhythmic activity could be determined by the level of pentose cycle activity (Kuznetsov, 2002). This cycle indeed plays an important role in neurons, protecting them from oxidative or traumatic stress (Ben-Yoseph et al., 1994; García-Nogales et al., 2003; Bartnik et al., 2005). However, it should be noted that although the activity of NADPH-generating enzymes of the pentose cycle in astrocytes (glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase) is two to three times higher than in the brain as a whole, the activity of cICDH is also very high in these cells (Rust et al., 1991). This metabolic pathway is interesting primarily because under FA intoxication, citrate accumulates, and the pathway may be regarded as a form of biochemical adaptation that facilitates the use of the central metabolite. It was suggested that spatial and temporal division of m- and c-aconitases not only provide regulation of iron balance in cells, but also actually provide regulation of balance between catabolic and anabolic processes (Tong and Rouault, 2007).

If the cells have utilized citrate entering the cytosol, another problem that results should be utilization of generating NADPH. One of the possible mechanisms of PN oxidation, which is very important, is heat generation through shivering and nonshivering thermogenesis. A rise in activity of NADPH-generating enzymes and pathways, including c-aconitase and cICDH, is accompanied by enhanced thermogenesis (Bobyleva et al., 1993). It was shown that NADPH could be used together with (or even instead of) NADH as a reducing cofactor for cytoplasmic glycerophosphate dehydrogenase (Bobyleva et al., 1993; Fahien et al., 1999). But if the role of this pathway for transferring electrons from cytoplasm to MCh in skeletal muscles is clear, then the level of activity and functional state of glycerophosphate shuttle in brain cells are contradictive. For example, its activity in brain is explained by the need for glycerol-3-phosphate as a substrate for phospholipids synthesis in oligodendroglia (Adler and Klucznik, 1982; Nguyen et al., 2003). In neurons and astrocytes, the activity of glycerophosphate dehydrogenases is much lower than in oligodendrocytes (Rust et al., 1991; Nguyen et al., 2003). There are data, however, that indicate an important role of this shuttle in astrocytes, taking into consideration: (i) the absence of malate-aspartate shuttle in these cells (Waagepetersen et al., 2001; McKenna et al., 2006), and (ii) the elevated level of mRNA of cICDH in astrocytes after convulsions, under exposure to morphine, indometacine and some other preparations (Link et al., 2000).

It is noted that FA can prevent the development of tolerance to morphine (Song and Zhao, 2001). Another positive aspect of FA in nontoxic concentrations is its radioprotective power due to its capacity to reduce body temperature and oxygen consumption (Misustova et al., 1980). Moreover, we have estimated that SFA significantly inhibits the growth of Ehrlich tumor carcinoma. In experiments with autochthonous-induced by benzo[a]pyrene subcutaneous tumors, SFA was not active in monotherapy regimes, though exhibited enhancement of antitumor effect of cyclophosphamide significantly increased the number of mice with stabilized or decreased tumor volume, as well as the duration of this effect (Anikin et al., 2013). These findings provide a basis for additional studies of mechanism of the antitumor effects of SFA. Thus, we suggest that future progress in toxicological (and perhaps pharmacological) studies of FA will depend on comprehensive consideration of these and more recent data, along with reevaluation of old and forgotten data.

Strychnine

Jiri Patocka

INTRODUCTION

Strychnine is a poisonous alkaloid of indole type found in the genus *Strychnos*. Its basic compound forms colorless or white rhombic crystals. These have a bitter taste and melt at approximately 290°C. Strychnine was the first alkaloid to be identified in plants of the genus *Strychnos*, family Loganiaceae. *Strychnos*, created by Linnaeus in 1753, is a genus of trees and climbing shrubs of the gentian order. The genus contains 196 various species and is distributed throughout the warm regions of Asia (58 species), America (64 species), and Africa (75 species). Plants of the genus *Strychnos* have opposite leaves and bear cymes of white or yellow flowers that have a four-lobed or five-lobed calyx, a four-part or five-part corolla, five stamens, and a solitary pistil, and bear fruit in the form of a berry. The seeds and bark of many plants in this genus contain the powerful poison strychnine. Strychnine is obtained commercially from the seeds of the Saint Ignatius bean (*Strychnos ignatii*) and from the nux vomica tree (*Strychnos nux vomica*) (Volfova and Patocka, 2003). *S. nux vomica*, also known as poison nut, semen strychnos, and quaker buttons, is a deciduous tree native to India and southeast Asia. It is a medium tree that grows in open habitats. The seeds contain approximately 1.5% strychnine, and the dried blossoms contain 1.0% (Harry, 1968). However, the tree's bark also contains other poisonous compounds. Strychnine was first discovered by French chemists Joseph-Bienaime Caenoiu and Pierre-Joseph Pelletier in 1818 in the Saint Ignatius bean. In some *Strychnos* plants, a 9,10-dimethoxy-derivative of strychnine, alkaloid brucine, is also present (Li et al., 2006). Brucine is not as poisonous as strychnine.

BACKGROUND

Chemistry and Physico-Chemical Properties

Strychnine has a chemical formula of $C_{21}H_{22}N_2O_2$, and its structural formula is shown in Figure 17.1 (CAS No: 57-24-9 [base], 60-41-3 [sulfate]). It occurs as white crystals or powder that is odorless, with a melting point of 286°C, boiling point of 270°C at 5 mmHg, density of 1.36 g/cm^3, vapor density of 11.0 (air = 1), and vapor pressure 0 torr at 20°C (Mackison et al., 1981). Strychnine is a stable compound and incompatible only with strong oxidizing agents.

Water solubility of strychnine is negligible, only 160 mg/L at 25°C, and pH of saturated solution is 9.5. Octanol/water partition coefficient ($\log K_{ow}$) is 1.93 (Hansch et al., 1995). Strychnine is very slightly soluble in ether, slightly soluble in benzene, ethanol (6.7 g/cm^3), and acetone, and soluble in chloroform and pyridine (Budavari, 1996).

History

The toxic and medicinal effects of strychnine have been well-known since the times of ancient China and India. The inhabitants of these countries had ancestral knowledge of the species *nux vomica* and Saint Ignatius bean. The species *S. nux vomica* is a tree of native Indonesia that attains a height of 12 m. The tree has a crooked, short, thick trunk and the wood is close-grained and very durable. The fruit has an orange color and is approximately the size of a large apple with a hard rind and contains five seeds that are covered with a soft wool-like substance. The ripe seed looks like flattened

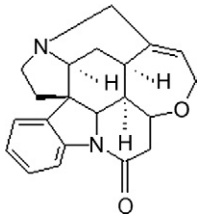

FIGURE 17.1 Structural formula of strychnine.

disks and are very hard. These seeds are the chief commercial source of strychnine and were first imported and marketed to Europe as a poison to kill rodents and small predators. *S. ignatii* is a woody climbing shrub of the Philippines. The fruit of the plant contains as many as 25 seeds embedded in the pulp. The seeds contain more strychnine than other commercial alkaloid plants. The properties of nux vomica and Saint Ignatius seeds are substantially those of the alkaloid strychnine.

Strychnine was discovered and identified as a main toxic principle of *Strychnos* in 1818, although *nux vomica*, the unpurified plant extract in which it is the active component, had been known and used for both medicinal and criminal purposes for some time. Historic records indicate that the strychnine alkaloid has been used to kill dogs, cats, and birds in Europe as far back as 1640. The structure of strychnine was first determined in 1946 by Sir Robert Robinson; in 1954, this alkaloid was synthesized in the laboratory by Robert W. Woodward (Woodward et al., 1954). This is one of the most famous syntheses in the history of organic chemistry. Both chemists won the Nobel prize, Robinson in 1947 and Woodward in 1965.

Therapeutic Purpose

Strychnine does have a history of use for therapeutic purposes, although in most cases this was entirely misguided and dangerous. It has a very bitter taste and so stimulates salivary and gastric secretion. This increases appetite and was used to counteract the loss of appetite associated with illness, giving the impression that strychnine had restorative properties. In fact, any constitutional improvement resulting from the increased appetite would probably be outweighed by the harmful effects of strychnine, and the underlying illness would be more or less unaffected. This is the same mechanism that gives tonic water its apparent "tonic activity," although in that case the bitter agent is quinine, which is much less dangerous.

Strychnine has an undeserved reputation as a useful therapeutic agent. There is no current justification for its presence in any medication. However, preliminary experimental reports suggest that judicious treatment with strychnine may modify the neurological deterioration in some infants with nonketonic hyperglycinemia, a rare metabolic disorder characterized by abnormally high concentrations of glycine in the brain and cerebrospinal fluid. Strychnine had been used as a tonic stimulant at one time for atonic constipation and as a stomachic and bitter. It produces no selective gastrointestinal effects and has no place in the therapy of any gastrointestinal disorder. At present, strychnine has no demonstrated therapeutic value in human medicine, despite a long history of unwarranted popularity. It was first used in medicine in 1540, but it did not gain wide usage until 200 years later (Gilman et al., 1985).

Although strychnine was previously used extensively in animals, it no longer has a rational place in the therapeutic armamentarium of the veterinarian. Its only interest is from a veterinary toxicology standpoint because animals are sometimes poisoned inadvertently or intentionally (Booth and McDonald, 1982; Gupta, 2012).

PHARMACOKINETICS AND TOXICOKINETICS

Absorptin, Distribution, Metabolism, and Excretion

Strychnine is rapidly absorbed from the gastrointestinal tract, mucous membranes, and parenteral sites of injection (Thienes and Haley, 1972), and also from the oral cavity (LaDu et al., 1971). A nonfatal case of strychnine poisoning through dermal exposure has been described (Greene and Meatherall, 2001). Strychnine is transported by plasma and erythrocytes, but protein binding is slight and distribution to the tissues rapidly occurs. Within a few minutes of ingestion strychnine can be detected in the urine, and excretion by that route accounts for approximately 15% of a sublethal (4 mg) dose over 6 h. Little difference was noted between oral and intramuscular administration of strychnine in a 4 mg dose. Blood levels in human poisoning were less than 0.5 μg/mL from 1 to 48 h after ingestion of a sublethal dose (700 mg), 2.7 μg/mL in a patient who survived the acute episode, and 40 μg/mL in a patient who died after massive ingestion (Haddad and Winchester, 1983). In persons killed by strychnine, the highest concentrations are found in the blood, liver, and kidney (Hayes and Laws, 1991).

The half-life of absorption is approximately 15 min and the half-life of metabolism is approximately 10 h. The apparent volume of distribution in one patient was 13 L/kg (Ellenhorn et al., 1997).

Strychnine is rapidly metabolized by the liver microsomal enzyme system and requires NADPH and O_2. Five metabolites formed *in vitro* by rabbit liver were isolated and identified as 2-hydroxystrychnine, 11,12-dehydrostrychnine, strychnine-21,22-epoxide, 21,22-dihydroxy-22-hydrostrychnine, and strychnine-*N*-oxide, which was

the major metabolite and accounted for approximately 15% of the metabolized strychnine. All other metabolites accounted for less than 1% (Mishima et al., 1985). Similar metabolites were identified in rat urine where the major metabolite was strychnine-21,22-epoxide (Oguri et al., 1989). Metabolic fate of strychnine in humans is unknown.

Toxicokinetics

Strychnine competes with the inhibitory neurotransmitter glycine, producing an excitatory state characterized clinically by hyperreflexia, severe muscle spasms, and convulsions. However, the toxicokinetics after overdose have not been well-described. In most severe cases of strychnine poisoning, the patient dies before reaching the hospital (Shadnia et al., 2004).

Palatnick et al. (1997) described a case of a 34-year-old man who presented to the emergency department 20 min after ingesting of 125 mL of 2% strychnine sulfate (2.25 g). He was alert and oriented and experiencing muscle spasms. His condition deteriorated, prompting sedation, muscle paralysis, and tracheal intubation. He was administered activated charcoal 100 g via nasogastric tube. He was admitted to intensive care, where he was managed with diazepam, pentobarbital, and pancuronium. Despite mild rhabdomyolysis, he recovered and was extubated on day 3. Although receiving prophylactic heparin therapy, a massive fatal pulmonary embolus ensued. Eighteen blood specimens for strychnine analysis were obtained from 20 min to 51 h after ingestion. Serum concentrations were determined with gas chromatography–mass spectroscopy. Disappearance followed a first-order process with a $t_{0.5}$ of 16 h. These results confirm the findings of a previous case report of 19 strychnine levels obtained between 4 and 19 h that described first-order kinetics with a $t_{½}$ of 10–16 h.

In a case report by Wood et al. (2002), a 42-year-old man ingested an unknown quantity of strychnine powder. Eight serum samples were taken over the first 5 days and analyzed subsequently for strychnine concentrations. The initial concentration at 1.5 h after ingestion was 4.73 mg/L, falling to 0.38 mg/L at 74 h postingestion. Serum concentrations followed a monoexponential elimination curve with a calculated elimination half-life of 12 h. The initial serum concentration of 4.73 mg/L is the highest reported concentration in a patient who has survived.

CLINICAL SYMPTOMATOLOGY

The symptomatology of human intoxication begins 15–30 min after ingestion of strychnine, usually without any warning, and the subject may experience violent convulsions. Convulsions lead to severe lactic acidosis that secondarily results in visceral (lung, heart, kidney, liver, and brain) collapse and death (Gordon and Richards, 1979). Prodromal symptoms are described such as apprehension, restlessness, heightened acuity of hearing, vision, and feeling, hyperreflexia, abrupt movement, and muscular stiffness of face and legs. Generalized convulsions last from 30 s to 2 min. At 10–20 min after exposure, the body's muscles begin to spasm, starting with the head and neck. At first convulsions are clonic, but a tetanic phase quickly intervenes. The body typically arches in hyperextension, the legs are adducted and extended, arms are flexed over the chest, and fists are tightly clenched. The jaw is rigidly clamped, face is fixed in grin, and eyes protrude in fixed stare (Philippe et al., 2004; Lages et al., 2013).

The convulsions progress, increasing in intensity and frequency until the backbone arches continually. Death comes from asphyxiation caused by paralysis of the neural pathways that control breathing or by exhaustion from the convulsions. The subject usually dies within 2–3 h after exposure. At the point of death, the body "freezes" immediately, even in the middle of a convulsion, resulting in instantaneous *rigor mortis*.

Initial symptoms of strychnine poisoning are tightness and twitching of the muscles agitation and hyperreflexia. Stiffness of the body, lockjaw, frothing of the mouth, cessation of respiration occur. Tetanus-like attacks appear every 10–15 min. During these attacks, the eyeballs protrude and the pupils enlarge. Severe cyanosis, which disappears after the attack subsides, also occurs. The attacks (each lasting approximately 3–4 min) appear to be spontaneous while other times they are the result of external stimuli, for example, noises, slight movements, or flashes of light. The patient never loses consciousness. When the poisoning is left untreated, each attack lasts longer than the previous and the interval between them grows shorter. Up to 10 attacks occur before death or recovery. This could happen from 10 min to 3 h and is a result of asphyxiation or inner tissue paralysis.

MECHANISM OF ACTION

Strychnine acts as a blocker or antagonist at the inhibitory or strychnine-sensitive glycine receptor, a ligand-gated chloride channel in the spinal cord and the brain (Song et al., 2006). The glycine receptor (GlyR) is the receptor for the amino acid neurotransmitter glycine (Rajendra et al., 1997). It is one of the most widely distributed inhibitory receptors in the central nervous system. Glycine receptors are found in most brain areas, including the hippocampus, amygdala, ventral tegmental area, and periaqueductal gray (Choi et al., 2013). Strychnine-sensitive glycine receptor is a member of

a family of ligand-gated ion channels. This ionotropic receptor can be activated by a range of simple amino acids, except glycine, β-alanine, and taurine, and can be selectively blocked by the high-affinity competitive antagonist strychnine. The receptor is arranged as five subunits surrounding a central pore, with each subunit composed of four α-helical transmembrane segments. There are presently four known isoforms of the α subunit (α_{1-4}) of GlyR that are essential to bind ligands and a single β-subunit. The adult form of the glycine receptor is the heteromeric $\alpha_1\beta$ receptor, which is believed to have a stoichiometry of three α_1 subunits and two β subunits or four α_1 subunits and one β subunit (Kuhse et al., 1993, 1995). The strychnine-binding subunit of the glycine receptor shows certain homology with nicotinic acetylcholine receptors (Grenningloh et al., 1987). The glycine receptor is highly enriched in microdomains of the postsynaptic neuronal surface apposed to glycinergic afferent endings. There is substantial evidence suggesting that the selective clustering of glycine receptor at these sites is mediated by the cytoplasmic protein gephyrin (Meier et al., 2000).

TOXICITY

Strychnine has been placed in toxicity category I, indicating a high degree of acute toxicity, for oral and ocular effects. Inhalation toxicity is also presumed to be high. Acute toxicity of strychnine to birds is very high. Mammalian studies indicate that strychnine is very highly toxic to small mammals on both an acute oral basis and a dietary basis. The extent of poisoning caused by strychnine depends on the amount and route of strychnine exposure at the time of the exposure; in humans, it depends on the person's condition of health. The signs of toxicity, including death, occur within 1 h.

Animal Toxicity

Reported toxic doses of strychnine at different routes of administration in some animals and humans are summarized in Table 17.1.

Strychnine toxicity in rats is dependent on sex. It is more toxic to females than to males when administered subcutaneously or intraperitoneally, and differences are attributable to higher rate of metabolism by male rat liver microsomes (Parke, 1968). Dogs and cats are more susceptible among the domestic animals, pigs are believed to be as susceptible as dogs, and horses are able to tolerate relatively larger amounts of strychnine (Humphreys, 1988). Birds affected by strychnine poisoning exhibit feathers fluffed or held tightly against the body, ataxia, wing droop, salivation, tremors, muscle tenseness, and convulsions. Death occurs as a result of respiratory arrest.

TABLE 17.1 Toxicity Values (LD_{50}) of Strychnine Found in Different Literature Sources

Organism	Route	LD_{50} (mg/kg)	Source
Bird—wild	Oral	16	Tucker and Haegele, 1971

[a]*RTECS, Registry of Toxic Effects of Chemical Substances.*

The clinical signs of strychnine poisoning relate to its effects on the central nervous system. After the ingestion (swallowing) of strychnine, symptoms of poisoning usually appear within 15–60 min. The first clinical signs of poisoning include nervousness, restlessness, twitching of the muscles, and stiffness of the neck. As the poisoning progresses, the muscular twitching becomes more pronounced and convulsions suddenly appear in all the skeletal muscles. The limbs are extended and the neck is curved to opisthotonus. The pupils are widely dilated. As death approaches, the convulsions follow one another

with increased rapidity, severity, and duration. Death results from asphyxia because of prolonged paralysis of the respiratory muscles (Humphreys, 1988; Gupta, 2012).

Human Toxicity

People exposed to low or moderate doses of strychnine by any route will have the following signs or symptoms: agitation; apprehension or fear; ability to be easily startled; restlessness; painful muscle spasms possibly leading to fever and to kidney and liver injury; uncontrollable arching of the neck and back; rigid arms and legs; jaw tightness; muscle pain and soreness; difficulty breathing; dark urine; and initial consciousness and awareness of symptoms. The reported medium lethal doses of strychnine in humans range from 5 to 120 mg/kg.

There are some cases of human poisoning. A 46-year-old man presented 2 h after ingestion of approximately 250 mg strychnine with severe, violent, generalized convulsions triggered by external stimuli. During the convulsion-free periods there were no abnormal signs in the physical examination (Scheffold et al., 2004). A 28-year-old man was admitted 2 h after ingestion of 1–1.5 g of strychnine. He was severely agitated and in mild respiratory distress; blood pressure was 90/60 mmHg, pulse was 110/min, and peripheral pulses were weak. He had generalized hyperactive reflexes and had several generalized tonic–clonic convulsions in the emergency department. Treatment consisted of gastric lavage with water, oral administration of activated charcoal and sorbitol solution, continuous intravenous administration of midazolam, and then sodium thiopental, furosemide, sodium bicarbonate, and hemodialysis for acute renal failure. His clinical course included respiratory distress, agitation, generalized tonic–clonic convulsions, hyperactivity, oliguria, and acute tubular necrosis before recovery in 23 days. This patient ingested what would normally be a fatal amount of strychnine. He had signs and symptoms of severe toxicity and recovered, suggesting that with aggressive supportive care patients may have favorable outcomes (Shadnia et al., 2004). In another case report described by Wood et al. (2002), a 42-year-old man presented soon after ingestion of an unknown but warranted lethal quantity of strychnine powder. After respiratory arrest with intensive supportive management requiring admission to an intensive care unit, he survived.

People exposed to high doses of strychnine may have respiratory failure (inability to breathe), possibly leading to death or brain death, within the first 15–30 min of exposure. No postmortem lesions are observed with the exception of small pinpoint hemorrhages in the lungs resulting from death attributable to asphyxia. Rigor mortis occurs soon after death and persists for days.

Toxicity of strychnine in humans, expressed as LD_{Lo} (lethal dose low), is approximately 30 mg/kg. Strychnine is less toxic in humans than in most animals. If the person survives the toxic effects of strychnine poisoning, then long-term health effects are unlikely. However, long-term effects may result from damage caused by the poisoning, for example, brain damage from low oxygen or kidney failure. People severely affected by strychnine poisoning are not likely to survive.

At the present time, fatal strychnine poisoning is uncommon. It is no longer used as a therapeutic drug and its availability to the public is controlled by legislations in various jurisdictions. Nevertheless, it is still in use as a rodenticide and an adulterant in street drugs. Homicide by strychnine is extremely rare. Because the autopsy findings are subtle, strychnine poisoning could easily be overlooked and a homicide may go undetected. This communication highlights an unusual case of homicide by strychnine. It is important in deaths in which there are no gross autopsy findings, sudden death in particular, that routine toxicology be performed because strychnine is likely to be detected (Kodikara, 2012).

Diagnosis

A tentative diagnosis can be made based on clinical signs and history. However, a positive diagnosis can only be made by identifying strychnine in the stomach contents, viscera, or blood. The drug can be identified by chemical tests and microscopic identification of typical strychnine crystals.

RISK ASSESSMENT

Human Health Hazard

The human health assessment for strychnine is based on the acute toxicity. Strychnine has been placed in toxicity category I, indicating the greatest degree of acute toxicity, for oral and ocular effects. It has been reported that the probable lethal oral dose is 1.5–2 mg/kg (Gosselin et al., 1984). Inhalation toxicity is also presumed to be high. An oral dose of 1.5–2 mg/kg is equivalent to 70–93 mg/m^3 for 30 min for a 70 kg human.

Strychnine was first registered as a pesticide in the United States in 1947; however, this natural toxin had been used in many counties to control vertebrate animals for many years before 1947. Currently, strychnine is registered for use only below ground as a bait application to control pocket gophers. The end-use products are formulated as grain-based bait or a paste. Baiting can be performed manually or with the use of application equipment.

The European Union (EU) withdrawal of strychnine marked its end as a method of mole control. The EU directive 91/414/EEC is midway through an ambitious

program to review all pesticides used within Member States. This requires manufacturers to provide health and safety data to support the continued registration of their products. Strychnine was to be reviewed in the fourth part of this program, but manufacturers have failed to provide such data. Despite last ditch appeals by users, from September 1, 2006, it was no longer legal to use.

However, strychnine in the form of a homeopathic preparation is still used and in exceptional cases may also cause poisoning. Gicquel et al. (2012) presented the case of a bulimic woman who was admitted to the emergency unit for painful muscle spasms and hypertonic crisis with respiratory blocking, after application of homeopathic nux vomica mother tincture, which contains indole alkaloids including strychnine. Toxicological screening revealed the presence of strychnine in the blood sample. This was corroborated by the patient, who explained that she had swallowed a whole bottle of nux vomica mother tincture as an emetic during a bulimic episode. This corresponded to 212 mg strychnine ingested. The therapeutic patient management consisted of symptomatic medication by diazepam and paracetamol and monitoring biological parameters and vital functions including breathing functions. Determination of strychnine concentrations in blood samples contributed to the control of poisoning. A blood concentration of 3 mg/L was first evaluated at admission of the patient, followed by a progressive decrease to 0.5 mg/L on the second day and the favorable clinical outcome of the patient.

Safety Data

Strychnine oral reference dose (RfD) of 0.0003 mg/kg/day or 0.02 mg/day for a 70 kg person is derived from the Seidl and Zbinden (1982) short-term to subchronic study by applying an uncertainty factor of 10,000. This factor accounts for extrapolation from a less-than-chronic to a chronic exposure study, extrapolation from animals to humans, and differences in sensitivity among the human population. An additional factor of 10 is used because a LOAEL/FEL (2.5 mg/kg/day) was utilized in the estimation of the RfD instead of a NOAEL. The immediately dangerous to life and health dose for strychnine by NIOSH REL is 0.15 mg/m^3, and the current OSHA PEL is 0.15 mg/m^3.

The work of Seidl and Zbinden (1982) is the only oral short-term or subchronic study reported in which rats received daily doses of 0–10 mg/kg of strychnine by gavage for 28 days. Data recorded for the surviving animals included blood cell counts, electrocardiograms, eye examinations, urine chemistry, weight gain, tissue histology, organ weights, behavioral tests, and food and water consumption. Mortality was observed in 5 of 12 male rats receiving 10 mg/kg and in 1 of 12 in each of the 5 mg and 2.5 mg/kg groups. All deaths occurred 0.5–6 h after oral doses.

Additional studies (Gitzelmann et al., 1978) reported that a 6-month-old human patient received strychnine doses of 0.3–1.1 mg/kg/day over an 18-month period without any adverse effects. However, the patient may have had a higher strychnine tolerance as a result of nonketotic hyperglycinemia. Risk phases of strychnine are R26, R27, and R28.

TREATMENT

There is no specific antidote for strychnine, but recovery from strychnine exposure is possible with early hospital treatment. Treatment consists of removing the drug from the body (decontamination) and getting supportive medical care in a hospital setting. Supportive care includes intravenous fluids, medications for convulsions and spasms, and cooling measures for high temperature.

Treatment of strychnine poisoning involves an oral application of an activated charcoal infusion that serves to absorb any poison within the digestive tract that has not yet been absorbed into the blood. Unabsorbed strychnine can be removed from the stomach by gastric lavage of tannic acid (strong tea) or potassium permanganate solutions used as chemical antidotes. Seizures are controlled and anticonvulsants such as phenobarbital or diazepam are administered to control convulsions, along with muscle relaxants such as dantrolene to combat muscle rigidity. Because diazepam is the anticonvulsant of choice but is not effective in all cases, a combination with midazolam, fentanyl, and pancuronium is recommended in controlling the convulsions (Scheffold et al., 2004). Fatal outcome of strychnine poisoning demands aggressive management with early intubation, control of muscle tremors, and prevention of rhabdomyolysis and renal failure. If the patient survives past 24 h, then recovery is probable.

Small doses of strychnine were once used in medications as a stimulant, a laxative, and as a treatment for other stomach ailments. Strychnine has stimulant effects at low doses but, because of its high toxicity and tendency to cause convulsions, the use of strychnine in medicine was eventually abandoned once safer alternatives became available.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Strychnine is a highly poisonous natural substance that is used in some countries for the control of wild animals. Today, strychnine is used primarily as a pesticide, particularly to kill rats. Its use is restricted by law.

Because strychnine is highly toxic and can be rapidly absorbed through the mucous membranes of the mouth, stomach, and small intestines, theoretically it may be used as a military toxic or terroristic agent. There are three main ways that strychnine can enter the body: inhalation, ingestion, and broken skin.

Goal-directed misuse of strychnine against humans is unlikely. Its misuse against domestic animals is realistic and more likely.

Uncommonly, strychnine is found mixed with "street" drugs such as LSD, heroin, and cocaine. It is very probable that seizures observed occasionally after cocaine application may be caused by admixed strychnine (Haddad and Winchester, 1983; Wijesekera et al., 1988). After analysis of heroin samples seized in the Florence area between 1975 and the first half of 1981, no dangerous substances were found in the samples and strychnine, if present, was found in very low concentrations (Mari et al., 1982).

CHAPTER

18

Superwarfarins

Michael J. Murphy and Andres M. Lugo

INTRODUCTION

Chemical warfare agents may be manufactured from a wide range of commercially manufactured household industrial products, such as bleach, antifreeze, fertilizers containing anhydrous ammonia, pesticides, or anticoagulant rodenticides, particularly superwarfarins (WHO, 2008). Some chemical warfare agents (e.g., nerve agents), when dispersed in air, are capable of harming or killing a large number of people. On the other hand, superwarfarins may be used to harm or terrorize people through the ingestion of contaminated food or water.

Superwarfarins, the second generation of anticoagulant rodenticides, are referred to as such in the modern medical literature (Pavlu et al., 2005; Sharma and Bentley, 2005; Dolin et al., 2006; POISINDEX, 2007). They are a group of commercially available, long-acting, anticoagulant rodenticides that are structurally similar to warfarin but are many times more potent. Many of them have the capacity to cause severe bleeding problems that may last for 2–8 months in humans (Ellenhorn et al., 1997; Goldfrank et al., 2002).

This group of long-acting anticoagulants may be used as chemical warfare agents because of their high potency and duration of action. The capability of terrorists to use these commercially available poisons depends upon the availability of large amounts of high-concentration product (whether obtained legally or illegally), the target population and its vulnerability, and the method of effective delivery and dissemination (EPA, 2005; WHO, 2008). Although these anticoagulants may be absorbed through the skin and lungs, the main route of exposure is ingesting food or water containing the product (Jones et al., 1984; Katona and Wason, 1989; Swigar et al., 1990; Wallace et al., 1990; Exner et al., 1992; Rauch et al., 1994; Gallo, 1998; Corke, 1997). Superwarfarin poisoning may result in a large number of casualties if these substances are ingested (Palmer et al., 1999; Baker et al., 2002; EPA, 2005; POISINDEX, 2007; HSDB, 2008).

Superwarfarin rodenticides are used to kill urban and agricultural rodent pests. They are readily available to the general public and pest controllers and are easy to obtain and conceal, so they may pose a risk of being used as chemical warfare agents (EPA, 2003, 2005; WHO, 2003, 2008). These rodenticides are available as meal bait packs, pellets, mini-pellets, blocks, mini-blocks, wax blocks, liquid bait formulations, tracking powder, and concentrate formulations (POISINDEX, 2007; WHO, 2008; Wilton, 1991).

BACKGROUND

Anticoagulants were discovered in the early twentieth century after livestock had eaten moldy sweet clover contaminated with bis-hydroxycoumarin and died of hemorrhagic disease. Newer long-acting warfarin derivatives such as brodifacoum, bromadiolone, diphenadione, and chlorophacinone can produce profound and prolonged anticoagulation and bleeding after a latency period that generally lasts 24–72 h (Gill and Redfern, 1980; FDA, 1985; Chong et al., 1986; Greeff et al., 1987; Smolinske et al., 1989; Swigar et al., 1990; Wallace et al., 1990; Routh et al., 1991; Wilton, 1991; Exner et al., 1992; Rauch et al., 1994; IPCS, 1995a–e; Hui et al., 1996; Tecimer and Yam, 1997; Chua and Friedenberg, 1998; Gallo, 1998; EPA, 2003, 2005) (Table 18.1).

In the 1940s, a small British pharmaceutical company suggested that dicoumarol might have rodenticidal properties. Trials carried out by Armour and Barnett (1950) confirmed the idea and started the era of anticoagulant rodenticides. Warfarin was the first anticoagulant rodenticide; it was introduced into the market shortly after World War II and became widely used in many countries. Other anticoagulant compounds with potency similar to that of warfarin were also synthesized. These early anticoagulant rodenticides have often been called

TABLE 18.1 Common Commercial Products Containing Superwarfarins

Name	Molecular Formula	Commercial Names
Brodifacoum CAS: 56073-10-0	C_{31}-H_{23}-Br-O_3	D-Con Mouse-Prufe I & II®, Havoc®, Klerat®, Ratak Plus®, Talon G®, Void® Finale, Folgorat, Matikus, Mouser, Rodend, Volak, Volid
Difenacoum CAS: 56073-07-5	C_{31}-H_{24}-O_3	Compo®, Diphenacoum®, Frunax DS®, Matrak®, Neosorexa®, Rastop®, Ratak®, Ratrick®, Silo®
Bromadiolone CAS: 28772-56-7	C_{30}-H_{23}-Br-O_4	Apobas®; Bromard®; Bromone®, Bromatrol®; Bromorat®; Contrac®; Deadline®; Hurex®; Lanirat®; Maki®; Morfaron®; Musal®; Maki®, Ramortal®; Ratimon®; Rodine-c®; Slaymore®; Super-caid®; Toidon®
Diphacinone CAS: 82-66-6	C_{23}-H_{16}-O_3	Diphacine®, Ditrac®, Gold Crest®, Kill-Ko®, P.C.Q.®, Promar®, Ramik®, Rat Killer®, Rodent Cake®, and Tomcat®
Chlorophacinone CAS: 3691-35-8	C_{23}-H_{15}-Cl-O_3	Caid®, Liphadione®, Microsul®, Ramucide®, Ratomet®, Raviac®, Rozol®, Topidox®
Difethialone[a] CAS: 104653-34-1	C_{31}-H_{23}-Br-O_2-S	None to report
Pindone[a] CAS: 83-26-1	C_{14}-H_{14}-O_3	Pestanal®, Pindone®, Pival®, Pivalyn®, Pivalyl Valone®, Tri-ban®
Coumatetralyl[a] CAS: 5836-29-3	C_{19}-H_{16}-O_3	Racumin®
Coumafuryl[a] CAS: 117-52-2	C_{17}-H_{14}-O_5	Fumarin®, Tomarin®
Valone CAS: 83-28-3	C_{14}-H_{14}-O_3	None to report
Flocoumafen[a] CAS: 90035-08-8	C_{33}-H_{25}-F_3-O_4	None to report

Available forms include: meal bait packs, pellets, mini-pellets, blocks, mini-blocks, wax blocks, liquid bait formulations, and tracking powder.
[a]*No longer produced or used in the United States.*

TABLE 18.2 The Oral LD_{50} Values (mg/kg body wt) of Some Anticoagulant Rodenticides

Animals	Bromadiolone	Brodifacoum	Difenacoum
Rat (acute)	0.65	0.27	1.8
Rat (chronic)	(0.06–0.14) × 5	(0.05–0.08)	0.15 × 5
Mouse	0.99	0.4	0.8
Rabbit	1.0	0.2	2.0
Pig	3.0	10.0	80.0
Dog	10.0	3.5	50.0
Cat	25.0	25.0	100.0
Chicken	5.0	10.0–20.0	50.0
Guinea pig	2.8	–	–
Opossum	–	0.17	–
Sheep	–	10.0	100.0

first-generation anticoagulant rodenticides. These compounds generally have moderate toxicity, with acute LD_{50} values ranging from 10 to 50 mg/kg body weight (Table 18.2).

The first-generation compounds often needed continuous bait exposure for rodent control. Many rodent species developed a resistance to warfarin (Jackson et al., 1975), presumably due to continued exposure and widespread use. Consequently, new chemical structures were synthesized and used as anticoagulant rodenticides. These newer compounds are generally more toxic than warfarin, with acute LD_{50}s of 0.2–3.9 mg/kg body weight. For example, a bait concentration of only 50 ppm of brodifacoum is adequate to control the population in a single feeding for most rodents and noncommensal species (Matolesy et al., 1988). These newer compounds were called *second-generation anticoagulant rodenticides* and are often now referred to as *superwarfarins* in the contemporary medical literature (e.g., Chong et al., 1986; Greeff et al., 1987; Swigar et al., 1990; Wallace et al., 1990; Routh et al., 1991; Wilton, 1991; Exner et al., 1992; Rauch et al., 1994; Hui et al., 1996; Tecimer and Yam, 1997; Gallo, 1998; Chua and Friedenberg, 1998; Pavlu et al., 2005; Sharma and Bentley, 2005; Dolin et al., 2006).

During the past 30 years, there have been more than 600 articles published in medical literature relating to the clinical assessment, laboratory testing, and treatment of patients exposed to superwarfarins. A great number of these articles are about children under 6 years old who accidentally ingested small amounts of these products and, in most cases, did not experience adverse effects (Brands et al., 1995; Ingels et al., 2002; AAP, 2003; Osterhoudt and Henretig, 2003). Also, there are a few cases describing severe bleeding or bleeding-related complications from patients who intentionally ingested large amounts of the substance, as well as a few fatal ingestion cases (Wallace et al., 1990; Casner, 1998; Walker and Beach, 2002; AAPCC, 2006). Most of the health hazards are associated with accidental ingestion of superwarfarins, and the risk of dermal and inhalation exposure is minimal (Bruno et al., 2000; POISINDEX, 2007). One-third of these publications concern domestic

animals and a few wild animals (Newton et al., 1990; Stone et al., 1999), with a small number of reported deaths. All animal exposures are due to accidental direct and indirect ingestion of these rodenticides. The great majority of animal exposures include dogs, which may need gastric decontamination and, in some cases, referral to a veterinarian for further clinical evaluation and treatment (DuVall et al., 1989; Hornfeldt and Phearman, 1996; McConnico et al., 1997; Robben et al., 1997; Borst and Counotte, 2002). In most cases, gastric decontamination will be recommended and treatment with vitamin K_1 may be needed. There are few data about the incidence or mortality rates from animal exposures to rodenticides.

Warfarin and dicoumarol found application as both oral anticoagulants and as rodenticides. Sweet clover requires the action of molds to form dicoumarol; giant fennel does not. Giant fennel (*Ferula communis*) grows in Mediterranean countries. It has a naturally occurring anticoagulant effect. An association between the plant and anticoagulation was first reported in the 1950s (Costa, 1950a,b; Carta, 1951). It was further investigated in Italy (Corticelli and Deiana, 1957; Corticelli et al., 1957; Mazzetti and Cappelletti, 1957; Cannava, 1958), and then in Israel (Shlosberg and Egyed, 1983). The anticoagulant activity of the plant in Morocco has also been reviewed (Lamnaouer, 1999).

Warfarin and its congeners are still used as therapeutic agents. Oral anticoagulants available therapeutically in Europe include warfarin, phenprocoumaron, and nicoumalone—also called acenocoumarol (Shetty et al., 1993). Oral anticoagulants are used therapeutically to reduce thromboembolic events. Warfarin examples include a reduction in catheter-related thrombosis (Guidry et al., 1991; Magagnoli et al., 2006); early venous thrombosis after operations (Calnan and Allenby, 1975; Pan et al., 2005), including hip surgery; atrial fibrillation (Middlekauff et al., 1995; Reiffel, 2000); and myocardial infarction (Asperger and Jursic, 1970). A number of adverse events have been recognized, most of which are related to drug interactions (Dayton and Perel, 1971).

An association between vitamin K_1 and coagulopathies was made in the mid-1930s (Dam, 1935; Fieser et al., 1939). Soon thereafter, Karl Paul Link reported the discovery of dicoumarol in moldy hay (Last, 2002). Naturally occurring coumarin in sweet-clover hay is converted by fungi to dicoumarol. Dicoumarol was found to be the causative agent of the disease, so the elements needed for the disease were coumarin-containing plant material plus mold growth. Subsequently, a range of molecules were synthesized, and one of these, warfarin, became the most popular (Duxbury and Poller, 2001). Warfarin takes its name in part from the Wisconsin Alumni Research Foundation and the rest from from coumarin.

AAPCC Data on Superwarfarins

Every year, tens of thousands of accidental ingestions of long-acting anticoagulant rodenticides are reported worldwide in medical literature. These include the annual report from the American Association of Poison Control Centers (AAPCC). During the past 23 years, the AAPCC reported 209,047 exposures to long-acting anticoagulant rodenticides (LAARs), which included 24 deaths due to LAAR ingestion. All fatalities were in adults who committed intentional suicide.

CLASSIFICATION OF SUPERWARFARINS

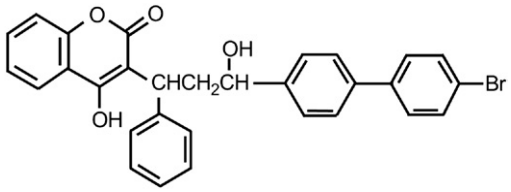
Anticoagulant rodenticides are also categorized by chemical structure. The chemical structure of the currently marketed products fits in one of two chemical classes: 4-hydroxycoumarins and indanediones.

4-Hydroxycoumarins

This group of compounds have a 4-hydroxycoumarin ring with different side-chain substituents at the 3-position. Commonly used superwarfarin anticoagulant rodenticides in this group are bromadiolone, brodifacoum, coumatetralyl, coumafuryl, and difenacoum. Brodifacoum, difenacoum, and bromadiolone are three of the most commonly used rodenticides around the world. Brodifacoum is the most frequently used rodenticide in the United States. These rodenticides share most of their physical and chemical characteristics, as well as their toxicokinetics, toxicodynamics, and mechanism of toxicity, and the medical toxicological management is the same for all superwarfarins.

Bromadiolone

Chemical formula: $C_{30}H_{23}BrO_4$

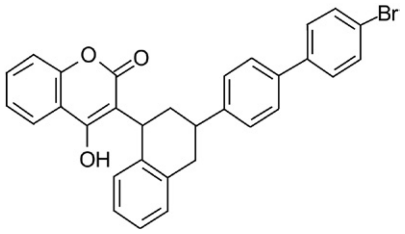


Bromadiolone [3-(3-(4′-bromobiphenyl-4-yl)-3-hydroxy-1-phenyl propyl)-4-hydroxycoumarin] was synthesized and marketed by the French company Lipha SA during the mid-1970s. It is used widely for control of commensal and field rodents in many countries. Technical-grade bromadiolone is 97% pure.

It is a yellowish powder and stable up to 200°C (Chalermchaikit et al., 1993). It is very soluble in dimethylformamide (730 g/L), but less soluble in ethyl acetate (25 g/L), and ethanol (8.2 g/L), and sparingly soluble in water (0.019 g/L). Bromadiolone is considered more palatable to rodents than most other anticoagulants. Its concentration in baits is usually 50 ppm (Chalermchaikit et al., 1993). Although bromadiolone is considered a second-generation anticoagulant rodenticide, some resistance problems have been reported with *Rattus norvegicus* and *Mus musculus* in the United Kingdom and Denmark (Rowe et al., 1981; Lund, 1984; IPCS, 1995d).

Brodifacoum

Chemical formula: $C_{31}H_{23}BrO_3$



Brodifacoum [3-(3-(4′-bromobiphenyl-4-yl)-1,2,3,4-tetrahydro naphth-1-yl)-4-hydroxycoumarin] is one of the newer and more potent second-generation anticoagulant rodenticides. It was first introduced in 1977 by Sorex Ltd. of London, and then developed by the Imperial Chemicals Incorporated (ICI) Plant Protection Division (Chalermchaikit et al., 1993).

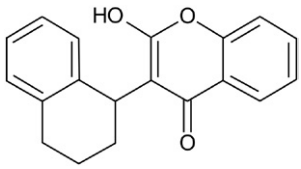
Pure brodifacoum is an off-white to fawn-colored powder with a solubility of 6–20 g/L in acetone, 3 g/L in chloroform, 0.6–6 g/L in benzene, and less than 10 mg/L water. It is very stable in the environment with no loss after 30 days of exposure to direct sunlight (Chalermchaikit et al., 1993).

Brodifacoum has been marketed in several countries for the control of a wide range of rodent pest species. It is available as a 0.005% pellet for rat and mouse control, a smaller 0.001% pellet for field rodent control, and as 29 g wax blocks for sewer rat control. It is the only anticoagulant rodenticide found to produce 100% mortality in most rodent species after only a 24 h dose (Chalermchaikit et al., 1993). Brodifacoum was effective against warfarin-resistant rats and mice in 1984, but the possibility of resistance has been raised (Lund, 1984).

There is variation in the susceptibility of species to brodifacoum. Dogs are susceptible and are commonly exposed to potentially toxic quantities of brodifacoum (Chalermchaikit et al., 1993).

Coumatetralyl

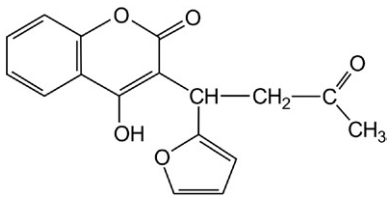
Chemical formula: $C_{19}H_{16}O_3$



Coumatetralyl [3-(alpha-tetralyl)-4-hydroxycoumarin] was introduced by Bayer AG with the trademark name of Racumin. It has been used for commensal rodent control in many countries. It is formulated as a dry bait (0.0375%), a liquid bait of its sodium salt, and a 0.75% tracking dust (Chalermchaikit et al., 1993). Pure coumatetralyl is a colorless powder that is stable at temperatures below 150°C. Its solubility is 20–50 g/L in propan-2-ol, 50–100 g/L in methylene dichloride, and 4 mg/L in water. The acute and chronic LD_{50}s of *R. norvegicus* are 16.5 and 0.3 mg/kg for five consecutive doses, respectively. Chickens are somewhat resistant to coumatetralyl, with a chronic LD_{50} of 50 mg/kg for eight consecutive doses. Signs did not appear in fish until the concentration of coumatetralyl reached 1,000 mg/L in water (Chalermchaikit et al., 1993). In spite of its low toxicity, it is reported to be a little more effective than warfarin against *R. norvegicus*, apparently due to a higher palatability. Coumatetralyl was introduced after the detection of warfarin-resistant rat populations and showed considerable success for a number of years, but resistant pests have been reported in the United Kingdom and Denmark (Rowe and Redfern, 1968; Lund, 1984).

Coumafuryl

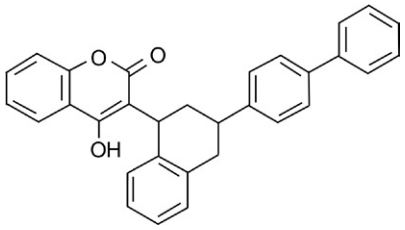
Chemical formula: $C_{17}H_{14}O_5$



Coumafuryl [3-(alpha-acetonylfurfuryl)-4-hydroxycoumarin] is a German anticoagulant, introduced in 1952, and is used at 0.025–0.05% in baits. Its toxicity is considered equal to warfarin for *R. norvegicus*, but slightly less efficient against *M. musculus*. The chronic LD_{50} in *R. norvegicus* is 1.4 mg/kg for five repeated doses. Cats and dogs seem to be almost as susceptible as rats, with dogs being killed by 2 mg/kg for five repeated doses and cats by 10 mg/kg for four repeated doses (Chalermchaikit et al., 1993).

Difenacoum

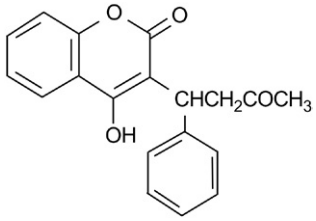
Chemical formula: $C_{31}H_{24}O_3$



Difenacoum [3-(3-*p*-diphenyl-1,2,3,4-hydronaphth-1-yl)-4-hydroxycoumarin] was synthesized in the United Kingdom and marketed in 1975 by Sorex Ltd under the trademark Neosorexa, and by ICI Plant Protection Division under the trademark Ratak as a 0.005% pelleted bait, and as a wax block. Pure difenacoum is an off-white powder with a solubility of greater than 50 g/L in acetone, 600 mg/L in benzene, and less than 10 mg/L in water. It is more toxic than warfarin but less palatable (IPCS, 1995c). Difenacoum is still effective against many populations of warfarin-resistant rats (Desideri et al., 1979), but resistance may be developing in the United Kingdom (Greaves et al., 1982).

Warfarin

Chemical formula: $C_{19}H_{16}O_4$



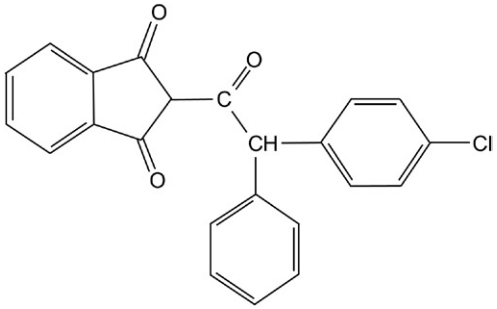
Warfarin [3-(a-acetonylbenzyl)-4-hydroxycoumarin] was the first anticoagulant rodenticide. It was introduced shortly after World War II after being developed by the Wisconsin Alumni Research Foundation. Warfarin is still used widely, especially for the control of *R. norvegicus* in areas where resistance has not yet developed. In its racemic form, warfarin is colorless and crystalline, insoluble in water but readily soluble in acetone, dioxane, and moderately soluble in alcohols. Warfarin is formulated as dry bait (0.005–0.05%), as well as a liquid bait, based on the sodium salt, and a tracking dust (0.5–1.0%). It is generally applied as the S-isomer, which has a toxicity ten times greater than the R-isomer. The acute and chronic LD_{50}s for *R. norvegicus* are around 10–12 and 0.75 mg/kg for five repeated doses, respectively (Colvin and Wang, 1974). Warfarin is sometimes combined with an antibacterial agent, sulfaquinoxaline, in order to reduce the bacterial production of vitamin K in the rat intestine, but the effectiveness of this combination has not been proven. Warfarin is considered one of the safest anticoagulants, as far as domestic and other nontarget animals are concerned. Serious resistance problems have been reported in Europe. It has recently been evaluated against sewer rats in London (Channon et al., 2000).

Indanediones

This group of compounds has a 1,3 indanedione structure with different side-chain substituents at the 2-position. The most common superwarfarins in this group are chlorophacinone and diphacinone.

Chlorophacinone

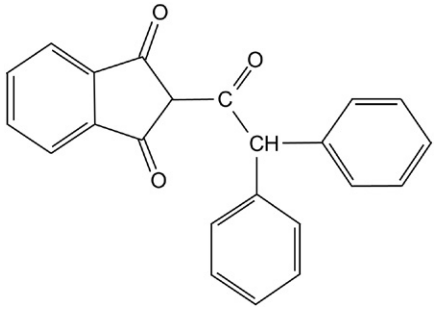
Molecular formula: $C_{23}H_{15}ClO_3$



Chlorophacinone [2-(alpha-4-chlorophenyl-a-phenylacetyl)-1,3-indandione] was introduced in the mid-1960s by Lipha SA at concentrations of 0.05% in baits and 0.2% in tracking dust. Pure chlorophacinone is a yellow crystalline solid that is very soluble in acetone, ethanol, ethyl acetate, but is only somewhat soluble in water. It is quite stable and resistant to weathering. Chlorophacinone does not induce bait-shyness and is compatible with cereals, fruits, roots, and other potential bait substances. Its acute LD_{50} in *R. norvegicus* is about 20.5 mg/kg, which is less toxic than warfarin, but it has a stronger initial effect on rats and mice. For control of house mice populations, a prolonged feeding period is needed. Chlorophacinone may not be effective against warfarin-resistant rodents (Chalermchaikit et al., 1993).

Diphacinone

Molecular formula: $C_{23}H_{16}O_3$



Diphacinone (2-diphenylacetyl-1,3-indandione) is an old anticoagulant rodenticide introduced by Vesicol Chemical Corp. and the Upjohn Co. It has been produced and used primarily in the United States as a 0.005% dry or liquid bait. Pure diphacinone is a yellow powder that is very soluble in chloroform (204 g/kg), toluene (73 g/kg), xylene (50 g/kg), and acetone (29 g/kg), but only somewhat soluble in water (0.30 g/L). It will decompose in water due to sunlight. The acute LD_{50}s in *R. norvegicus* are 22.7 mg/kg in females and 43.3 mg/kg in males. It is more toxic than warfarin to rats, mice, and dogs, but its palatability is somewhat lower. Diphacinone may not be effective against some warfarin-resistant rodents (Chalermchaikit et al., 1993). The anticoagulant rodenticides are marketed to have efficacy against a number of target pest species.

TOXICOKINETICS

Absorption, Metabolism, and Excretion in Laboratory Animals and Humans

Superwarfarins are primarily well absorbed from the gastrointestinal tract. Almost 90% is absorbed, with peak plasma concentrations often occurring within 12 h of ingestion. Binding to plasma proteins may prolong distribution and half-life. Toxicity after dermal or respiratory exposure is rare (Boermans et al., 1991; Berry et al., 2000), but not unreported (Spiller et al., 2003).

The metabolism and elimination of the trans-isomer was more rapid than those of the *cis*-isomer. The elimination from the liver is biphasic, with an initial rapid phase of 3 days and a slower phase with a half-life of 120–130 days. The liver is the major organ for accumulation and storage, which has been found mainly as the unchanged parent compounds. The major route of elimination in different species after oral administration is via the feces. The urine is a very minor route of elimination (Watt et al., 2005).

MECHANISM OF ACTION

The mechanism of action of all anticoagulant rodenticides is similar to that of warfarin, specifically inhibition of vitamin K_1 epoxide reductase (Park et al., 1979; Leck and Park, 1981; Breckenridge et al., 1985). In the coagulation cascade, the clotting factors II, VII, IX, and X must bind calcium ions to be active in clot formation. The Ca^{2+}-binding ability requires converting glutamyl residues on these clotting factors to carboxyl glutamyl residues by the process of carboxylation. This carboxylation uses vitamin K_1 hydroquinone as a cofactor. This vitamin K–dependent carboxylase reaction converts vitamin K_1 hydroquinone to its epoxide form, vitamin K_1 2,3-epoxide. In the normal cycle, vitamin K_1 2,3-epoxide is reduced to the original vitamin K_1 (phylloquinone) by epoxide reductase, and thus it gets recycled. The anticoagulant rodenticides produce their effect by interfering with vitamin K_1 epoxide reductase, resulting in the depletion of vitamin K_1 and subsequently impairing the synthesis of normal clotting factors II, VII, IX, and X (Craciun et al., 1997, 1998). Clinical coagulopathy soon follows the depletion of vitamin K_1 in the liver. In the dog, these clotting factors have plasma half-lives of 41, 6.2, 13.9, and 16.5 h, respectively. The coagulation system continues to function well until about 3–5 days after ingestion, when the natural decay of clotting factors occurs. It has been suggested that they bind more strongly to the liver than warfarin, resulting in more persistent effects (Jackson and Suttie, 1977; Suttie, 1986; Murphy and Gerken, 1989; Barnett et al., 1992; Babcock et al., 1993; James et al., 1998). The interrelationship of vitamin K, prothrombin, and gamma-carboxyglutamic acid is reviewed in Stenflo (1978). The interaction of warfarin and vitamin K is reviewed in Suttie (1990).

TOXICITY

Clinical Effects: Signs and Symptoms

Clinical signs and symptoms of acute intoxication by superwarfarins range from a mild tendency to bleed (in less severe poisoning cases) to severe coagulopathy. Mild bleeding tendencies often show themselves clinically as nose or gum bleeding, hemoptysis, ecchymosis, bloody or melenotic stools, hematuria, abdominal or flank pain, enhanced bruising, and ventral hematomas. Severe bleeding may lead to shock and death. Internal and external bleeding are the most frequent clinical signs, followed by tachycardia and hypotension, and then multiple organ failure due to substantial blood loss. The onset of the signs of poisoning may not be evident until a few days after absorption (Vogel et al., 1988; Nighoghossian et al., 1990; Swigar et al., 1990; Weitzel et al., 1990; Wilton, 1991; Ross et al., 1992; Corke, 1997; Casner, 1998; Chua and Friedenberg, 1998; Baker et al., 2002; Tsutaoka et al., 2003).

Animal Toxicology

Clinical signs are usually delayed until 24–36 h after ingestion. The most common signs include vomiting, diarrhea, dyspnea, weakness, depression, anorexia, hematuria, and melena. Other signs, such as pale mucous membranes, bleeding from nose and gums, and generalized bruising, may be noticeable as well. Internal bleeding also causes generalized pain; fever;

lameness from bleeding into a joint; bleeding into the thorax or abdomen, brain, or pericardium; or sudden death (Braithwaite, 1982; Berny et al., 1995; Munday and Thompson, 2003).

Pediatric Exposures

The great majority of human exposures are children under the age of 6 due to accidental or unintentional ingestion. They usually do not require any medical intervention or routine follow-up laboratory studies and can be adequately managed by poison control centers with home observation and parent education (Mullins et al., 2000; Ingels et al., 2002; Kanabar and Volans, 2002; Shepherd et al., 2002). Children with acute, unintentional superwarfarin ingestions may often be managed without gastric decontamination or prophylactic vitamin K. Laboratory testing for coagulopathy should be reserved for cases involving clinically evident bleeding abnormalities (Ingels et al., 2002).

A small number of reported cases of children have presented with mild to moderate hematological effects, requiring minimal to nonmedical intervention (Smolinske et al., 1989; Watts et al., 1990; Babcock et al., 1993; Travis et al., 1993; Golej et al., 2001; Osterhoudt and Henretig, 2003).

Intentional suicidal ingestion of large amounts of product conveys a greater risk for severe toxicity and increased mortality and should be referred to a healthcare facility for examination and treatment if needed (Ingels et al., 2002).

Adult Exposures

The great majority of adult exposures to rodenticides are due to deliberate acute and chronic surreptitious ingestion. Bleeding disorders may persist for 6 weeks to many months. Serious poisoning has been reported in adults with massive overdoses. These long-acting anticoagulants have produced rapid and persistent bleeding due to hypoprothrombinemia (Chong et al., 1986; Hoffman et al., 1988; Katona and Wason, 1989; Wallace et al., 1990; Routh et al., 1991; Barnett et al., 1992; Exner et al., 1992; Mack, 1994; Morgan et al., 1996; McCarthy et al., 1997; Gallo, 1998; Berry et al., 2000). There is a risk of spontaneous abortion with long-acting anticoagulants (Lipton and Klass, 1984; Zurawski and Kelly, 1997; Nelson et al., 2006).

The severity of the intoxication depends on the amount of rodenticide ingested, preexisting comorbidity, and coingestion of other toxic substances (Seidelmann et al., 1995; Palmer et al., 1999; Stanziale et al., 1997; Tecimer and Yam, 1997; Walker and Beach, 2002). Fatalities are usually due to intentional suicidal ingestion of large amounts. Bleeding disorders and organ failure have been described in adults due to deliberate acute and chronic surreptitious ingestion. A total of 24 deaths have been reported by the AAPCC in the past 20 years (Table 18.3; AAPCC-TESS annual reports from 1983–2006).

Household Pets and Farm Animal Exposures

Household pets and farm animals may be accidentally exposed to rodenticides. The possible effects on nontarget organisms can be considered in two types: direct poisoning and secondary poisoning. Secondary poisoning is generally considered to occur after an animal has consumed anticoagulant rodenticide–poisoned rodents. The most common type of exposure is direct poisoning by eating a cereal-based bait containing the rodenticide. The most commonly affected household pets are dogs, followed by cats, hamsters, rabbits, and pet birds (Redfern and Gill, 1980; Park and Leck, 1982; Boermans et al., 1991; Woody et al., 1992; Hornfeldt and Phearman, 1996; Peterson and Streeter 1996; McConnico et al., 1997; Robben et al., 1997, 1998; Munday and Thompson, 2003; Radi and Thompson, 2004) (Table 18.4).

Cats may be more resistant to the toxic effects of brodifacoum and difenacoum than dogs. Cases of abortion and hemorrhage in sheep and goats after misuse of brodifacoum have been reported (Jones, 1996; Watt et al., 2005).

Nontarget Wildlife Exposures

Nontarget wildlife may be exposed to rodenticides as well. The possible effects on nontarget organisms can also be considered in two types: direct poisoning and secondary poisoning. The potential for secondary poisoning is more likely in carnivorous wildlife (Mathur and Prakash, 1980; Mahmoud and Redfern, 1981; Greaves et al., 1982; DuVall et al., 1989; Newton et al., 1990; James et al., 1998; Borst and Counotte, 2002; Eason et al., 2002). The most commonly affected species are birds such as great horned owls, barn owls, eastern screech owls, golden eagles, red-tailed hawks, Cooper's hawks, and crows. Bird species varied in their susceptibility. Other wild animals also may be exposed, such as polecats, wildcats, and foxes. Brodifacoum was highly toxic for fish when tested as a technical material.

Laboratory/Monitoring and General Recommendations

Superwarfarins lower the blood concentrations of the vitamin K–dependent clotting factors II, VII, IX and X; this results in prolongation of prothrombin time (PT) and partial thromboplastin time (PTT). PT and PTT should be repeated at least twice daily until normal PT and PTT levels are established. Also, the blood clotting time and the bleeding time should be measured. Blood is often demonstrable in the excreta. Secondary hypochromic or microcytic anemia may be marked (Goldfrank et al., 2002; Nelson et al., 2006).

A PT 24–48 h after exposure in asymptomatic children with accidental ingestions of large or unknown amounts

TABLE 18.3 Number of Exposures to Long-Acting Anticoagulant Rodenticides and Deaths Reported by the American Association of Poison Control Centers—Toxic Exposure Surveillance System (AAPCC-TESS) Annual Reports: 24-Year Data

Year	No. of Participating Centers	Population Served (Millions)	No. of Human Exposures Reported (All Substances)	No. of Exposures/ Thousand Population	No. of Exposures to Long-Acting Anticoagulant Rodenticides (LAAR)	No. of Deaths Due to Anticoagulants (Alone and Combined with Other Substances)	Reason: Intentional Suicidal (IS)	% of Deaths from Exposure to (LAAR)

Total			43,482,940		222,165	24	IS	0.01%

should be obtained. In adults with deliberate ingestions and children with clinical evidence of bleeding, an initial PT and PTT should be obtained and then repeated at 24 and 48 h after ingestion (Manoguerra and Cobaugh, 2005).

Analytical Methods

A number of analytical methods have been reported for detecting anticoagulant rodenticides in various matrices. Early fluorimetric methods were used to detect warfarin in serum (O'Reilly et al., 1962; Corn and Berberich, 1967; Lewis et al., 1970; Welling et al., 1970; Keiser and Martin, 1974; Vesell and Shivley, 1974; Fasco et al., 1977; Hanna et al., 1978; Lee et al., 1981) and GLC for warfarin (Mildha et al., 1974).

Warfarin-specific methods were generally inadequate for anticoagulant rodenticides, so a number of other methods were developed. These include thin-layer chromatography (TLC), high-pressure liquid chromatography (HPLC), mass spectroscopy (MS), and antibody-mediated tests. Coumarin anticoagulant rodenticides were initially detected using TLC (Lau-Cam

TABLE 18.4 Dosing of Ipecac

Adult[a]	15–30 mL
Adolescent[a]	15–30 mL
Child 1–12 years old	15 mL
Child 6–12 months	Dose: 5–10 mL (Position child in left lateral decubitus position to reduce risk of aspiration)
Child under 6 months of age	NOT recommended for pre-hospital use

[a]*Katona and Wason (1989).*

and Chu-Fong, 1972; Mallet et al., 1973). A high-performance TLC method with an estimated detection limit of 200 ppb and 87% recovery from liver has been reported (Berny et al., 1995).

Early HPLC methods focused on an individual chemical. For example, methods to detect chlorophacinone in formulations (Grant and Pike, 1979; Vigh et al., 1981), brodifacoum in serum (Murphy and Gerken, 1989), brodifacoum (Koubek et al., 1979; Keiboom and Rammel, 1981; Hoogenboom and Rammell, 1983; Ray et al., 1989), bromadiolone (Hunter, 1983; Subbiah et al., 2005), chlorophacionone (Hunter, 1985), difethiolone (Goldade et al., 1998), and difenacoum (Mundy and Machin, 1977) in tissue have been reported.

Then a method was developed to look for all the anticoagulant rodenticides on the market at the time. It succeeded in extracting and detecting eight anticoagulant rodenticides in serum and liver using fluorescence and ultraviolet (UV) detection. Samples were extracted with acetonitrile then cleaned up on solid phase columns. Four hydroxycoumarins were detected by fluorescence with excitation at 318 nm and emission at 390 nm. The indandiones were detected at 285 nm. An extraction recovery of 75% from serum and 69% from liver was reported. Hydroxycoumarins may be detected down to about 1 ng/mL of serum and 1 ng/g of liver, and indandiones down to 10 ng/mL of serum and 10 ng/g of liver (Felice and Murphy, 1989; Felice et al., 1991; Chalermchaikit et al., 1993). Another HPLC method for detecting brodifacoum in serum and liver using difenacoum as the internal standard has been reported (O'Bryan and Constable, 1991). There is also a method for the simultaneous detection of five superwarfarin rodenticides in human serum (Kuijpers et al., 1995).

Other serum methods have been reported; for example, detection limits of 3–12 ng/mL for fluorescence and 20–75 ng/mL for UV detection (Mura et al., 1992; Kuijpers et al., 1995; McCarthy et al., 1997; Feng et al., 1999). Tissue methods include a solid phase cartridge extraction from liver, with recoveries ranging from 52% for difenacoum to 78% for warfarin. The limit of detection is 10 ppb for warfarin and difenacoum and 110 ppb for chlorophacinone (Addison, 1982; Jones, 1996; Fauconnet et al., 1997).

HPLC methods have also been published to distinguish *cis*- and *trans*-isomers of difenacoum with detection limits of 5 ng/mL (Kelly et al., 1993). An early, interesting approach was to use a post-column pH shift to enhance fluorescence detection (Hunter, 1983, 1985). Several earlier HPLC methods have also been reported (AOAC, 1976a,b; Mundy and Machin, 1982; Hunter, 1983): diphacinone (Bullard et al., 1975, 1976), fluorescence for bromadiolone (Deepa and Mishra, 2005), brodifacoum (Fu et al., 2006), brodifacoum in tissues (Hoogenboom and Rammell, 1983), difenacoum (Hadler and Shadbolt, 1975), determination of Rozol in parafinized formulations (Kawano and Chang, 1980), and bromadiolone in tissues (Nahas, 1986).

A recent method uses diode-array detection (DAD) (Yang et al., 2001). An interesting new method uses HPLC to detect anticoagulant rodenticides in soft drinks (Dimuccio et al., 1991). An ion pair liquid chromatography method has been reported to detect chlorophacionone and diphacinone in oats (Primus et al., 1998).

Contemporary confirmatory methods use MS. Most recently, liquid chromatography-electrospray ionization-mass spectroscopy (LC-EIS-MS) has been reported for the analysis of 10 anticoagulant rodenticides with a quantity limit of about 5 µg/L (Grobosch et al., 2006). Other recent methods use LC-MS-MS for unknown drugs, including warfarin (Marquet et al., 2003), and LC-ESI-MS and HPLC UV to detect anticoagulant rodenticides as low as 20 ng on a column (Mesmer and Flurer, 2000). One of the earlier MS methods used a direct-probe technique to detect indandione residues in food animals (Braselton et al., 1992).

A cell culture/enzyme-linked immunosorbent assay (ELISA) has been developed to detect anticoagulant rodenticides in treated grain (Lawley et al., 2006). A prior immunoassay was used to detect diphacinone and chlorophacionone (Mount et al., 1988). Enantiomers of warfarin, coumachlor, and coumafuryl can be separated chromatographically (Armstrong et al., 1993).

Serum concentration of dogs with anticoagulant rodenticide poisoning ranged from less than 10–851 ng/L for brodifacoum, difethialone, and difenacoum (Robben et al., 1998).

Animal samples are routinely analyzed in veterinary diagnostic laboratories. For example, the Texas Veterinary Medical Diagnostic Laboratory, in College Station, TX (http://tvmdl.tamu.edu/), performs such analyses. A list of other laboratories performing anticoagulant rodenticide analyses on animal samples can be obtained from the American Association of Veterinary Laboratory Diagnosticians (www.aavld.org). Human samples are generally analyzed at either the National Medical Services Laboratory in Willow Grove, PA, or the Medtox Scientific Laboratories in St Paul, MN (Table 18.5).

TABLE 18.5 Dosing of Activated Charcoal

Charcoal dose Recommended to Dilute 240 mL of Water per 30 g Charcoal (FDA, 1985)	
Adults and adolescents	50–100 g
Children aged 1–12 years	25–50 g
Infants up to 1 year old	1 g/kg of body weight

Chyka and Seger (1997).

GENERAL TREATMENT RECOMMENDATIONS

Referral to Healthcare Facilities

In case of a suspected terrorist act, misuse, intentional criminal, or any deliberate intentional suicidal ingestion, or when the amount ingested is either large or indeterminate, the patient should be referred to a healthcare facility for clinical and laboratory assessment, as well as treatment if necessary (Manoguerra and Cobaugh, 2005; POISINDEX, 2007).

Home Observation Criteria

Accidental ingestion of a small amount (less than a few pellets) can be adequately managed at home by either poison control centers or a healthcare professional with home observation and parent education. Usually, these types of exposures do not require any medical intervention or routine follow-up laboratory studies. Gastric decontamination has no effect on the clinical outcome after "taste" (one fifth of a spoonful) amounts are ingested by children (Mullins et al., 2000; Kanabar and Volans, 2002; Shepherd et al., 2002).

If the amount ingested by a child is a "moderate amount" (defined as more than a handful, or a mouthful), or is questionably high, then it is recommended that the parent contact a physician or call a local poison control center for instructions on how to induce emesis with syrup of ipecac (Tenenbein et al., 1987; AAP, 2003).

There is no risk of poisoning for animals ingesting taste amounts, but if the amount ingested is unknown, or cannot be estimated, then a local poison control center or veterinarian should be contacted for instructions on how to induce emesis and to obtain a 24- to 48-h blood test (PT) to determine the need for treatment with vitamin K_1 (Murphy and Gerken, 1989; Munday and Thompson, 2003).

Treatment at Healthcare Facilities

A PT should be obtained 48 h after exposure in asymptomatic children with accidental ingestion of a suspected large amount of rodenticide (Babcock et al., 1993; Berry et al., 2000). Adults with intentional ingestion and children with clinical evidence of bleeding should obtain an initial PT and PTT, repeated at 24 and 48 h after ingestion (Greeff et al., 1987; Hoffman et al., 1988; Goldfrank et al., 2002). If any significant prolongation or evidence of bleeding is observed, PT should be repeated every 6–12 h. Determination of factors II, VII, IX, and X may be abnormal in patients with a normal PT and PTT, which may provide evidence of earlier significant ingestion (Brands et al., 1995; Corke, 1997; Pavlu et al., 2005; Spahr et al., 2007). Hemoglobin and hematocrit should be monitored in patients with clinical evidence of bleeding or significant coagulopathy. Determination of the ABO blood type may be necessary in cases of toxic ingestions and bleeding. Patients may require red blood cell transfusions or the administration of fresh frozen plasma (Ellenhorn et al., 1997; Bruno et al., 2000; Laposata et al., 2007; Olmos and Lopez, 2007).

Emesis

Currently, there is controversy regarding the use of syrup of ipecac; the American Academy of Pediatrics reversed its policy position about using syrup of ipecac to help with poisoning emergencies in children (AAP, 2003). Simultaneously, the AAPCC is still indicating that syrup of ipecac does have a place in therapy, and "concluded that individual practitioners and poison control centers are best able to determine the particular patient population, geographic and other variables that might influence the decision to recommend having ipecac on hand" (Manoguerra and Cobaugh, 2005). We recommend that the first action for a caregiver of a child who may have ingested one of these rodenticides is to consult with their local poison control center (AAP, 2003).

Emesis with syrup of ipecac has been recommended for children with a history of accidental ingestion of small amounts (defined as more than a "grain or two,") if it can be administered within 1 h from the time of ingestion (Katona and Wason, 1989).

Emesis is contraindicated in patients with a prolonged PT or a bleeding disorder due to the risk of bleeding following ipecac-induced increased intracranial pressure (POISINDEX, 2007). Taste amounts (a few pellets or a bite of one block of bait) do not require emesis. If the amount is more than two mouthfuls or one block of bait, or if an unknown amount is ingested, then emesis is most effective if initiated within 30 min to 1 h from the time of ingestion. The decision to induce emesis or not is often controversial; it must be carefully considered. It could be most appropriate in pre-hospital settings and is not recommended once the patient is in the emergency room (Chyka and Seger, 1997; Krenzelok et al., 1997).

Contraindications: Patients with a bleeding disorder, particularly those under treatment with anticoagulants

or with histories of chronic, long-acting anticoagulant ingestion, are at risk from gastrointestinal and central nervous system (CNS) bleeding from ipecac-induced emesis. The administration of activated charcoal is preferred when large amounts have been ingested or chronic ingestion has occurred. Also, it is contraindicated if there is a risk for choking or aspiration, CNS excitation or depression, coma, seizures, or signs of oral, pharyngeal, or esophageal irritation (Chyka and Seger, 1997; Golej et al., 2001; Goldfrank et al., 2002).

Before or after ipecac is administered, patients should be encouraged to drink water. Adults are given approximately 8 oz (240 mL), and children 4–8 oz (120–240 mL) (Goldfrank et al., 2002; POISINDEX, 2007).

Activated Charcoal

For patients with a potentially toxic ingestion who are awake and able to protect their airway, activated charcoal diluted in water may be administered before going to the hospital. It is more effective when administered within 1 h after ingestion. It is recommended to dilute the mixture with 240 mL of water per 30 g charcoal (Chyka and Seger, 1997).

In patients who are at risk from the abrupt onset of seizures or depression, activated charcoal should be administered by medical or paramedical personnel capable of airway management to prevent aspiration in the event of spontaneous emesis (POISINDEX, 2007).

Use of a cathartic with activated charcoal is not routinely recommended, as there is no evidence that cathartics reduce drug absorption, and cathartics can cause adverse effects such as nausea, vomiting, abdominal cramps, electrolyte imbalances, and occasionally hypotension. Complications include emesis and aspiration (Chyka and Seger, 1997; Golej et al., 2001).

Gastric Lavage

Gastric lavage is recommended within 1–2 h after ingestion. For chronic ingestion, it is not recommended, as it may induce bleeding in adults with significant coagulopathy. In addition, it is not necessary in children after accidental ingestion (Brands et al., 1995).

Laboratory Monitoring

PT and PTT values should be obtained 24 and 48 h post-ingestion in asymptomatic children with nonintentional ingestion of a "large amount." Adults with intentional ingestions and children with clinical confirmation of bleeding should obtain initial PT and PTT readings, repeated at 24 and 48 h post-ingestion, followed by blood type verification (Barnett et al., 1992; Ellenhorn et al., 1997; Robben et al., 1998). If any significant prolongation or evidence of bleeding is observed, PT should be repeated every 6–12 h. Determination of factors II, VII, IX, and X may be abnormal in patients with a normal PT and PTT, which may provide proof of earlier significant ingestion. Serial hemoglobin and hematocrit in patients should be followed with clinical evidence of bleeding or significant coagulopathy (Babcock et al., 1993; Robben et al., 1998). Hematocrit should be monitored closely at least every 4 h until the patient is stable (Brands et al., 1995).

Hematest should be performed in stools and vomit for occult blood, and PT and PTT monitored routinely. PT and PTT readings obtained within 48 h post-ingestion may not be predictive of subsequent coagulopathy (Greeff et al., 1987). A 24 h and 48 h PT and PTT, therefore, are recommended every 6–12 h to assess efficacy of therapy. If prolongation is observed, then PT or international normalized ratio (INR) measurements should be repeated (Hoffman et al., 1988; Smolinske et al., 1989).

Antidote: Vitamin K_1 (Phytonadione: AquaMephyton®, Mephyton®) is the specific antidote and should be administered to any patient with a prolonged PT (Braithwaite, 1982; Bruno et al., 2000; Tsutaoka et al., 2003). Blood and fresh or frozen plasma are recommended if the anticoagulation is severe.

Administration of vitamin K_1 is recommended if anticoagulation is excessive. A small intravenous dose of 1–5 mg, titrated to return PT to the therapeutic range, has been recommended. In anemic patients, the hematocrit should be monitored about every 4 h until it is stable. Stools and vomit may also be tested using Hematest (Hornfeldt and Phearman, 1996).

Oral vitamin K_1 may be administered in small doses after the patient has been stabilized. Recommended doses are 15–25 mg p.o. in adults, 5–10 mg in children (Greeff et al., 1987), and 2.5–5 mg/kg body weight in animals. A large daily maintenance dose of vitamin K_1 may be required for prolonged therapy in severe overdoses, particularly in patients in whom vitamin K_1 absorption is variable (Lipton and Klass, 1984; Hoffman et al., 1988; Ross et al., 1992; Murphy, 2012).

Intravenous phytonadione may be instituted in severe cases where rapid correction is needed. The adult dose is a minimum of 10 mg diluted in saline or glucose, injected intravenously (i.v.) at a rate not exceeding 5% of the total dose per minute. Doses should be repeated at intervals of 6–8 h. Initial i.v. doses of 25, 100, 150, 160, and 400 mg have been required in patients actively bleeding (Hoffman et al., 1988; Vogel et al., 1988). Anaphylaxis may occur if vitamin K_1 is injected too rapidly.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Today, there is a greater risk than ever that extremist or terrorist groups may use industrial or household chemical substances to harm, kill, or terrorize our society

because these substances are very easy to obtain and conceal. Also, numerous highly toxic chemicals can be stolen and released or detonated from storage tanks or from transportation and manufacturing facilities. These commercial and industrial chemicals stored in large quantities are considered agents of opportunity because they are readily and commercially available. A large number of industrial and household chemicals, including the superwarfarins, have the potential to be used as chemical warfare or terrorist agents. However, the Federal Insecticide, Fungicide, and Rodenticide Act classifies these rodenticides in the "low toxicity group." Nevertheless, they may be used to harm and terrorize people through the ingestion of contaminated food or water. Superwarfarins are available to consumers as meal bait packs, pellets, mini-pellets, blocks, mini-blocks, wax blocks, liquid bait formulations, and tracking powder in diluted to concentrated formulations. The ingestion of small amounts may not cause any bleeding problems. Ingestion of greater amounts provides increased risk of severe bleeding in 36–48 h. The coagulopathy may last several weeks to months despite vitamin K_1 treatment. Inhibition of synthesis of vitamin K_1–dependent clotting factors may also occur following repeated ingestion of small amounts, making these agents insidious.

The use of chemical weapons by terrorists remains a major threat. Until recently, UN resolutions required complete disclosure of chemical warfare agents and their destruction. More action is needed to prevent radical groups from accessing or accumulating these agents. Participation of the entire community, particularly the civilian population, is needed. Participation may increase due to educational programs that boost awareness, improved surveillance, and reporting to the authorities of any suspicious activity, as well as the purchasing and stockpiling of large quantities of these commercial products.

What should be done at this time? Be wary if people from a community that attended the same event, meal, party, or restaurant show similar signs of bleeding disorders. Ingestion of superwarfarins may go unnoticed when they are mixed with food, and signs or symptoms are delayed 36–48 h. Consequently, the victims may not associate the ingestion with the coagulopathy.

Identification of superwarfarins is easy today. Analytical methods for the detection of these products in serum and tissues are readily available. Routine laboratory tests for coagulopathy may help support the need for such analytical chemistry testing. It may be useful to create stockpiles of vitamin K_1, particularly in places where large stocks of superwarfarin rodenticides are used, such as livestock areas.

Although viral infections manifest with different signs and symptoms, it is possible that members from a community who are victims of superwarfarins may begin to panic, thinking that they were victims of a virus such as Ebola, but the signs and symptoms of superwarfarin ingestion differ from viral infection. Superwarfarin intoxication may have no signs or symptoms other than the appearance of bleeding in the stools, urine, mucous membranes, or the thoracic or abdominal cavities. The Ebola virus causes sudden hemorrhagic fever, weakness, muscle pain, headache, and sore throat, followed by vomiting, diarrhea, rash, limited kidney and liver functions, and both internal and external bleeding.

Consequently, good differential diagnostic and laboratory work-up algorithms are needed for both humans and animals. Teams of subject matter experts for both humans and animals may be useful in this regard. Also, community education programs should be developed to inform residents about superwarfarin rodenticides and other household commercial chemicals that could be used as chemical warfare or terror agents. Fact sheets may be one method of disseminating such information to the public. Identifying those at risk, as well as deciding when they should be informed, may be a useful part of this education campaign. Such a program may also improve security in industrial plants and limit access from outsiders to all industrial and storage facilities where flammable or highly toxic chemicals are stored, particularly livestock facilities.

Finally, surveillance of food sources, particularly those derived from livestock, should be assessed to determine whether these agents are available to consumers in low concentrations, which may lead to long-term accumulation and eventual coagulopathies.

PCBs, Dioxins and Furans: Human Exposure and Health Effects

Bommanna G. Loganathan and Shigeki Masunaga

INTRODUCTION

Polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), polybrominated dibenzo-*p*-dioxins (PBDDs), and polybrominated dibenzofurans (PBDFs) are members of the group of halogenated aromatic hydrocarbons. This group of chemicals has been identified by the national and international agencies as priority environmental pollutants posing significant effects on aquatic and terrestrial animals, including humans (Loganathan and Kannan, 1994; Jacobson, 1994; International Programme on Chemical Safety, 1998; Van den Berg et al., 1998; Kodavanti et al., 2008). PCBs do not occur in nature except for forest fires and were synthesized by humans. PCBs were produced in large quantities (millions of pounds) for a variety of industrial uses during 1940 to the late 1970s, especially by developed nations. However, PCDDs and PBDDs (dioxins) and PCDFs and PBDFs (furans) were never produced commercially but are formed in small quantities as by-products of combustion of various industrial as well as natural processes. Because of their persistent, bioaccumulative, and toxic properties, residues of these compounds are found in every component of the global ecosystem (Lipnick et al., 2001; Kodavanti et al., 2008). Some PCBs (coplanar PCBs), dioxins, and furans are three structurally and toxicologically related families of compounds that are classified as the most toxic synthetic chemical substances to a variety of animal species, including humans (Tucker et al., 1983; Loganathan et al., 1995; ATSDR, 1998). Production of PCBs was banned during the 1970s; however, already produced PCBs are still causing environmental and health problems (Loganathan et al., 2008; Sajwan et al., 2008; Loganathan, 2012). Fortunately, these compounds were never used as chemical warfare agents, weapons of mass destruction, or agents of threat or terror by contamination of air, water, or food/feed. However, inadvertent poisonings by these chemicals have caused significant environmental and health problems (Yusho Support Center, 2007; Loganathan, 2012; Kodavanti and Loganathan, 2012). In this chapter, historical background, chemical characteristics, analysis, pathways of human exposure to these compounds, and toxic effects associated with the exposures are presented.

HISTORICAL BACKGROUND

PCBs were first synthesized in the early 1880s (Schmidt and Schultz, 1881) and commercial production began in 1929. Biphenyls were reacted with Cl_2 in the presence of ferric chloride catalyst, where some of the hydrogen atoms are replaced by chlorine atoms. PCBs were produced as complex mixtures potentially containing 209 congeners formed by chlorinating biphenyl with from 1 to 10 chlorines (Figure 19.1). The amount of chlorination of biphenyls corresponded to the duration of chlorination process. For example, Aroclor 1221, 1242, 1248, 1254, 1260, and 1268 are commercial preparations that were formerly produced by the Monsanto Chemical Company in the United States (St. Louis, MO) that contain 21%, 42%, 48%, 54%, 60%, and 68% chlorine by weight, respectively, as indicated by the last two digits in the numerical designation (Giesy and Kannan, 1998). The PCB mixture formulations were different depending on the country of origin and were produced in Germany (Clofen), France (Phenoclor and Pyralene), Japan (Kanechlor), Italy (Fenclor), Russia (Sovol), and Czechoslavakia (Delor). PCB mixtures were produced

for a variety of uses such as fluids in electrical transformers, capacitors, heat transfer fluids, hydraulic fluids, lubricating and cutting oils, and as additives in plastics, paints, copying paper, printing inks, adhesives, and sealants (Loganathan et al., 1989; Safe, 1990).

Dioxins and furans are not produced deliberately but are produced unintentionally as by-products of combustions of organic matter in the presence of chlorine. Dioxins and furans consist of 135 possible chlorinated (or brominated) dibenzofuran and 75 chlorinated (or brominated) dibenzo-*p*-dioxins with from one to eight chlorine (bromine) substituents (Figure 19.2). PCDDs/DFs are found as by-products during the manufacture of some industrial chemicals such as PCBs, polychlorinated naphthalenes, chlorinated phenols, chlorinated phenoxyacids, polychlorinated diphenyl ethers, polyvinyl chlorides, and chlorinated phenoxy-2-phenols (Hutzinger et al., 1985; Hryhorczuk et al., 1986; ATSDR, 2001; Masunaga et al., 2001a). Similarly, PBDDs/DFs are found as by-products in brominated organic chemicals, such as brominated flame retardants (polybrominated diphenyl ethers (PBDEs), decabromobiphenyl, 1,2-bis(tribromophenoxy) ethane, tetrabromobisphenol A (TBBPA)) (International Programme on Chemical Safety, 1998). These compounds are also formed during incineration of industrial and municipal waste, forest fires, fireplaces, and combustion engines (Loganathan et al., 1997; Feil and Larsen, 2001). Because of anthropogenic as well as natural processes, PCBs, dioxins, and furans are widely dispersed in the global environment and their presence was reported in air, water, soil, sediment, aquatic organisms, and terrestrial organisms, including human tissues (Safe, 1990;

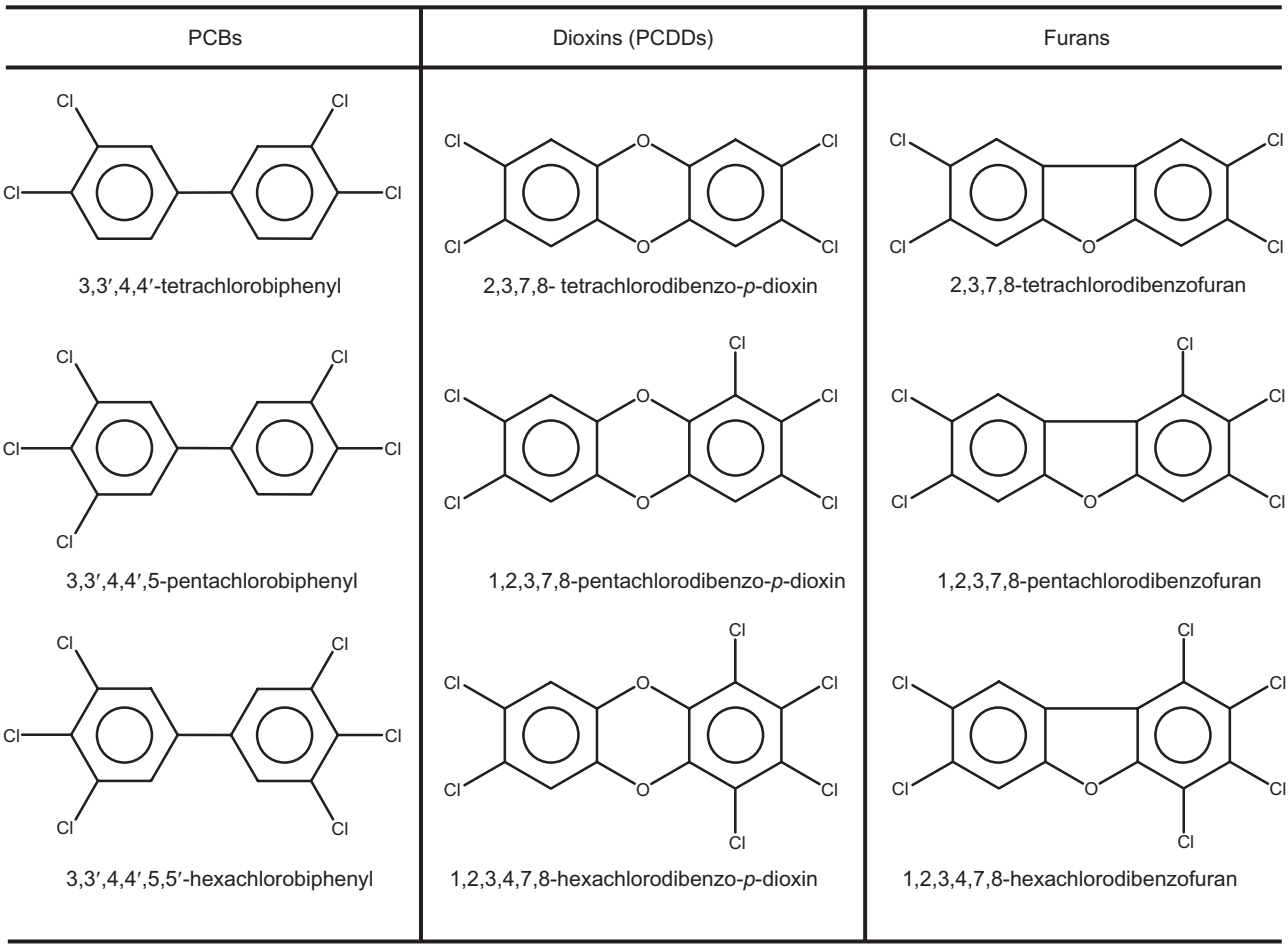

FIGURE 19.2 Structures of highly toxic PCBs, dioxins, and furans.

Loganathan and Kannan, 1994; Giesy and Kannan, 1998; Masunaga et al., 2001b; Ogura et al., 2001).

HUMAN EXPOSURE TO PCBS, PCDDS, AND PCDFS

Direct human exposure to PCBs/PCDF occurred because of inadvertent poisoning due to consumption of PCB contaminated food, resulting in Yusho and Yucheng poisoning (oil disease) in Japan and Taiwan during 1968 and 1979, respectively. The Yusho Support Center Report (2007) states that "39 years have passed since the outbreak of YUSHO, the PCB/dioxin tragedy—the most unprecedented incident in the history of mankind whereby people ingested toxic chemicals unknowingly, directly through food." The outbreak of a strange disease "Yusho" (Kanemi Oil Poisoning) occurred in the western part of Japan in 1968. The major symptoms and signs of the disease consisted of acne-like eruptions, pigmentation of the skin, nails, and conjunctivas, increased discharge from eyes, and numbness in the limbs (Yao et al., 2002; Yusho Support Center Report, 2007). The epidemic was identified later (1969) to be an unprecedented mass food poisoning caused by the ingestion of commercial brand rice oil that had been contaminated by PCB and their related compounds. The number of people who reported to have ingested the rice oil was approximately 14,000 and 1,867 persons were designated as Yusho victims. A similar outbreak of "oil disease" occurred in Taiwan in 1979. Toxicological studies revealed that PCDF congeners, including 2,3,4,7,8-pentachlorodibenzofuran, played an important role in the manifestation of these diseases. Research conducted with Yusho victims revealed harmful effects of the exposure continued two generations (Yusho Support Center Report, 2007).

Direct human exposure to dioxin occurred in southern Vietnam and also in Seveso, Italy. It was estimated that southern Vietnam has been contaminated by 160–600 kg of dioxin as a result of 80 million liters of defoliant herbicides (Agent Orange, a 50:50 mixture of 2,4,5-T and 2,4-D) being sprayed by the US military over a large area of forests and crops of southern Vietnam from 1962 to 1971 (Westing, 1984; Schecter et al., 2006;

FIGURE 19.3 Dioxin poisoning. Ukrainian former Prime Minister and presidential candidate Viktor Yushchenko, with his face disfigured by illness due to dioxin poisoning. *Source: Photo: www.mindfully.org; November 19, 2004 (accessed on July 13, 2008).*

Le Hong Thorn et al., 2007). The defoliant was contaminated with a very toxic form of dioxin (TCDD) known to have caused adverse effects on human health. Dioxin may cause harmful effects on the whole body and can affect separately the functioning of the systems such as the nervous system, immune responses, carcinogenicity, hepatotoxicity, and metabolic and enzyme toxicity (Le Hong Thorn et al., 2007). Another example of direct human poisoning of dioxin was food poisoning of Viktor Yushchenko (Figure 19.3), Ukrainian Presidential candidate, in 2004. The dioxin poisoning caused a mysterious illness that resulted in his face becoming pockmarked and ashen (www.mindfully.org). Manahan (1992) classified dioxin (2,3,7,8-TCDD) as super toxic in comparison with other known toxic substances (Table 19.1).

TABLE 19.1 Toxicity Level of Various Chemical Compounds (Prepared from Manahan, 1992)

Toxicity Level	Compounds	LD_{50} Estimated from Laboratory Animals[a] (mg/kg)
Slightly toxic	Ethyl alcohol	10,000
	Sodium chloride	5,000
Moderately toxic	Malathion (organophosphorus pesticide)	1,000
	Chlordane (termite exterminator)	500
Very toxic	Heptachlor (pesticide)	100
Extremely toxic	Parathion (pesticide)	10
	Dioxin (2,3,7,8-TCDD)	5 (hamster)
	Tetraethyl pyrophosphate (pesticide, raticide)	1
Super toxic	Tetrodotoxin (toxin of blowfish)	0.1
	Dioxin (2,3,7,8-TCDD)	0.0006 (guinea pig)
	Botulin (toxin of botulinum)	0.00001

[a]*LD_{50} are rough values estimated from oral-dose experiment on laboratory animals (usually rats). Unit: mg/kg body weight.*

PHYSICO-CHEMICAL PROPERTIES AND GLOBAL DISTRIBUTION

The unusual industrial versatility of PCBs was directly related to physical and chemical properties that include resistance to acids and bases, compatibility with organic materials, resistance to oxidation and reduction, excellent insulating properties, nonflammability, and thermal stability (Hutzinger et al., 1985). Physical and chemical stability of PCBs are vital to the industrial applications and the same properties have been responsible for global environment contamination. In addition, multi-media releases and volatility lead to long-range environmental transport, both via water and atmosphere, resulting in widespread environmental contamination of humans and wildlife at sites distant from their use (Lipnick and Muir, 2001; Loganathan et al., 2008). In PCBs, dioxins, and furans, the properties vary widely and depend on the number and position of chlorine (or bromine) atoms attached to the molecule. In general, vapor pressure, water solubility, and biodegradability decrease with increasing number of chlorine atoms. Lipophilicity adsorption capacity shows a reverse trend (Loganathan and Kannan, 1994). Because of these unique properties, PCBs, dioxins, and furans have been detected in air and water (rivers, lake ecosystems) (Pearson et al., 1997; Loganathan et al., 1998a,b, 2001). Apart from this, these compounds were recorded in fish, birds, and marine mammals of several other ecosystems such as the Atlantic, Baltic, and Pacific Oceans and Swedish environments (Kawano et al., 1988; Loganathan et al., 1999). They have been identified in processed fish and other food products (Kannan et al., 1997; Patandin et al., 1999). Further, the residues of these contaminants were found in human adipose tissue, blood, and milk, and also in numerous other matrices (Loganathan et al., 1993, 1998a,b, 1999; Petreas et al., 2001; Czaja et al., 2001). The comparison of PCDD/DFs and PBDD/DFs in terms of toxic equivalents (TEQs) calculated based on WHO-TEF (World Health Organization's toxic equivalent factors) in pooled human milk samples of 17 countries showed that PBDD/DF levels are significantly lower than the PCDD/DF (mean PBDD/DF:PCDD/DF-TEQ ratio was 0.13 and its range was 0.06–0.25), indicating that exposure

of PCDDs/DFs is much greater than PBDD/DFs and more important to human health (Kotz et al., 2005). Because of the large production and indiscriminate use of PCBs in industries, these contaminants extended their boundaries of distribution over the global environment, and this was evidenced by their detection even in pristine environmental media and biota such as the Arctic and Antarctic atmosphere, hydrosphere, and biosphere (Muir et al., 1988; Corsolini et al., 2002; Kumar et al., 2002). The discovery of the widespread environmental occurrences, the increased general environmental concern, and the apparent link to carcinogenesis and other health disorders prompted public outcry that resulted in prohibition of PCBs as well as chlorinated pesticides in several developed nations during the early 1970s. The following section deals with the chemical analysis of PCBs, dioxins, and furans in environmental and biological samples.

ANALYTICAL METHODS

PCBs and PCDDs/DFs consist of a total of 419 individual congeners and PBDDs/DFs have 210 congeners. In addition, dioxins and furans with mixed chlorine and bromine substitution can occur. These congeners have quite a variety of toxicity and some of these congeners, especially planar dioxins, furans, and dioxin-like PCBs (non-*ortho* chlorine substituted coplanar PCBs), are extremely toxic even at very low concentrations (Table 19.1). Therefore, determination of some toxic congeners to a very low concentration (parts per trillion) has become important.

Congener-specific determination was required for those congeners that have toxic equivalency factors (TEFs), namely 2,3,7,8-chlorine substituted dioxins and dioxin-like PCBs (Table 19.2). Thus, they are analyzed using high-resolution gas chromatography–high-resolution mass spectrometry (HRGC-HRMS). A schematic flow chart of a representative analysis procedure for environmental and biological samples is shown in Figure 19.3 based on standard analytical methods such as US EPA Methods 1613, 1668, 1668a, and JIS K0312 (US EPA, 1994, 1997, 1999; JISC, 2008).

Biological samples are either freeze-dried or dewatered (homogenized) with anhydrous sodium sulfate salt and spiked with internal standards (clean-up spike) and then extracted using Soxhlet apparatus. Obtained extracts are concentrated and their solvents are changed to an appropriate solvent such as hexane, followed by a series of clean-up procedures to remove lipids and other interfering chemicals. Then, the eluates are concentrated again and spiked with internal standards. The prepared samples were injected into HRGC-HRMS and monitored by multiple ion monitoring mode. Concentrations are calculated by isotope dilution method. Stable isotope-labeled target compounds are used as internal standards and spiked into samples. Calibration with internal standards and determination by isotope dilution are necessary to obtain reliable data under very low concentrations and after repeated pretreatment and clean-up procedures.

Solid samples such as soil and sediment are air-dried and extracted using the Soxhlet/Dean-Stark apparatus. Aqueous samples are separated into solids and filtrates by filters. Solids are Soxhlet extracted similar to biological samples and filtrates are liquid–liquid extracted. Then, these extracts are cleaned and injected into HRGC-HRMS, similar to biological samples.

In cases when congener-specific information is not necessary, other simpler methods can be used. EPA Methods 608 and 8082a use GC/ECD to determine concentrations of PCBs in terms of Aroclor (Federal Register, 1984; US EPA, 2007). EPA Method 680 (US EPA, 1985) uses GC/MS (low-resolution mass spectrometry) to determine the homolog concentration of PCBs (Figure 19.4).

MECHANISM OF ACTION AND TOXICITY

The toxicity of PCBs, PCDDs/DFs, and PBDDs/DFs is complicated by the presence of a large number of congeners, each with its own toxicity. Commercial PCB mixtures elicit a broad spectrum of toxic responses that are dependent on several factors, including chlorine content, purity, dose, species, age, sex, and duration of exposure. Immunotoxicity, carcinogenicity, and developmental toxicity as well as biochemical effects of commercial PCB mixtures have been studied extensively in various laboratory animals, fish, and wildlife (Giesy and Kannan, 1998). Several studies have confirmed the common receptor-mediated mechanism of action of toxic halogenated aromatics and have resulted in the development of a structure–activity relationship for this class of chemicals (Safe, 1990). The most toxic halogenated aromatics is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), which is assigned the maximum toxicity factor of 1; the relative toxicities of individual halogenated aromatics have been determined relative to TCDD (i.e., toxic equivalents). The 17 congeners of PCDD/DFs and the 12 congeners of dioxin-like PCBs are assigned TEFs lower than TCDD (Table 19.2). In June 1997, the World Health Organization established the levels of toxicity factors (WHO-TEFs) to be applied to evaluating the risks for humans and animals (Van den Berg et al., 2006). The WHO consultation set the tolerable daily intake (TDI) between 1 and 4 pg TEQ/kg body weight, emphasizing that the aim was to lower the TDI to a level less than 1 pg TEQ/kg body weight (Guerzoni and Raccanelli, 2004).

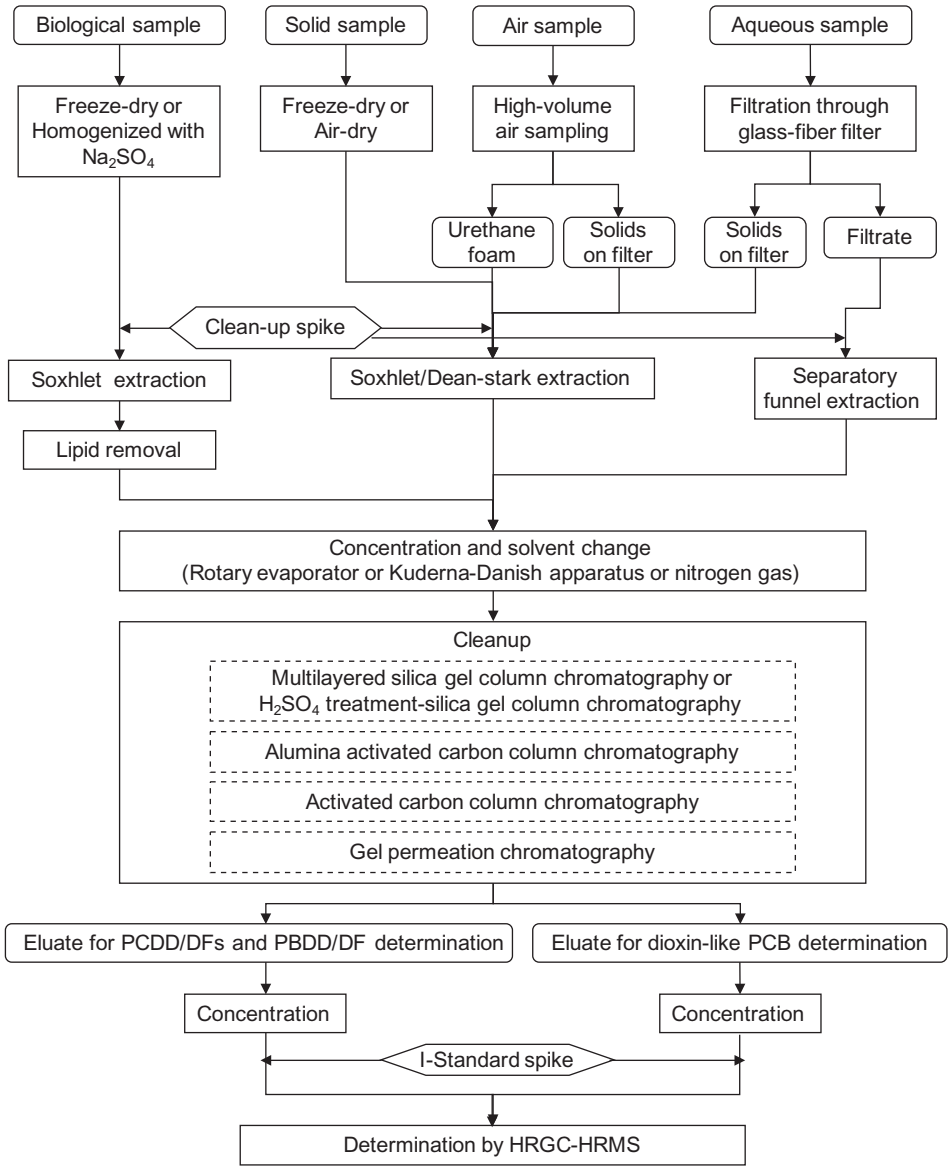

FIGURE 19.4 Analytical procedure of dioxins, furans, and dioxin-like PCBs.

The most toxic PCB congeners are those that have chlorine substitution in most of the non-*ortho* positions, such as 3, 4, and 5 in each ring. These coplanar PCB congeners (Figure 19.2) are structurally similar to highly toxic 2,3,7,8-TCDD and exhibit similar toxic responses (Ah receptor–mediated toxicity) (Figure 19.5). There are no TEFs for 2,3,7,8-substituted PBDDs/DFs that have international agreement; however, use of the same TEF values for the corresponding PBDD/DF congeners as described for the chlorinated analogues appears to be justified (International Programme on Chemical Safety, 1998). 2,3,7,8-TCDD and structurally related halogenated aromatic compounds induce a variety of microsomal enzymes primarily in the liver. 2,3,7,8-TCDD evokes dose-related induction of cytochrome-P-450–associated aryl hydrocarbon hydroxylase (AHH) activity. The most widely studied of these responses are induction of AHH and EROD (markers of CYP1A activity) in mammalian cell cultures and in laboratory rodents (Goldstein and Safe, 1989).

Ah receptor–mediated toxicity resulted in a wide range of biological responses, including alterations in metabolic pathways, body weight loss, thymic atrophy, impaired immune responses, hepatotoxicity, chloracne and related skin lesions, developmental and reproductive effects, and neoplasia.

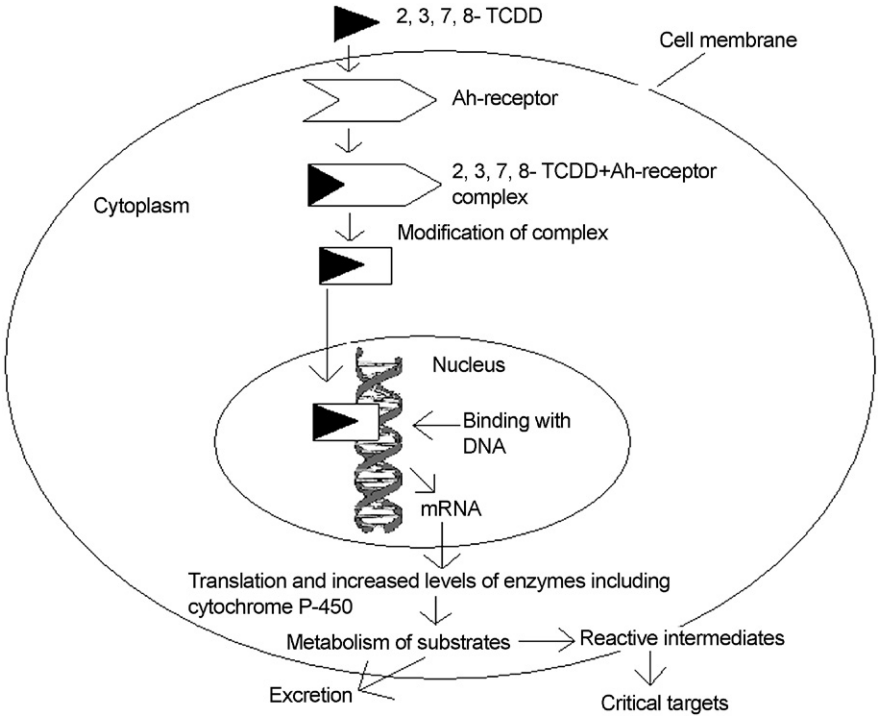

FIGURE 19.5 Possible mechanism of toxic action of 2,3,7,8-TCDD.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

PCBs, dioxins, and furans are persistent organic pollutants that have negative effects on the environment and health of humans, including skin toxicity, immunotoxicity, neurotoxicity, negative effects on reproduction, teratogenicity, endocrine disruption, and a predisposition to cancer. A major pathway of exposure to these chemicals is through consumption of food contaminated by PCBs and dioxins. The Committee of Experts on Food of the European Commission proposed a dose called "tolerable weekly intake" given by the total of dioxins and PCBs of 14 pg TEQ/kg of body weight, which is an average of 2 pg TEQ/day/kg of body weight (Guerzoni and Raccanelli, 2004). By reducing the environmental contamination, we can diminish the food chain accumulation and, ultimately, we can reduce the intake levels of PCBs and dioxins and their toxic effects.

Polycyclic Aromatic Hydrocarbons: Implications for Developmental, Molecular, and Behavioral Neurotoxicity

Claire E. Bollinger, Monique McCallister, Ryan Clark, Raina Rhoades, Mark Maguire, Russell E. Savage, Yuqin Jiao, Aramandla Ramesh and Darryl B. Hood

INTRODUCTION

Airborne polycyclic aromatic hydrocarbons (PAHs) arise from incomplete combustion of carbon-based fuels. They are common in the environment, arising from multiple sources including industrial emissions from coal-fired power plants, motor vehicle emissions (especially diesel exhaust), tobacco smoke, and dietary sources such as charbroiled foods (Banks et al., 2014). Exposure to PAHs is rapidly being recognized as a global problem, particularly in major urban centers in the United States and developing nations such as China, where urban environmental protections tend to be weaker and where biomass is used as a source of indoor fuel (Zhang and Tao, 2009). In these situations, these contaminants accumulate to toxic levels in the body within a short period of time and enter the environment rapidly (ATSDR, 1995; WHO, 2010). Chronic exposure to even low concentrations of PAHs cause long-lasting damage, such as cancer, infertility, and neurotoxicity to humans and wildlife (Banks et al., 2014).

The goal of this chapter is to encourage research activity into both novel intervention strategies and therapeutic approaches to mitigate the neurotoxicity associated with *in utero* exposure to PAHs as combustion-derived agents of urban industrialization. The focus of this chapter is to highlight current epidemiological data pertaining to the known neurobehavioral outcomes from PAH exposures, as well as supporting data in animals. An attempt is made to suggest potential operative pathways contributing to PAH exposure–induced neurodevelopmental deficits.

A critical review of the post–September 11, 2001, literature has resulted in a specific focus on studies that have revealed critical neural signaling/activity pathways and the identification of primary targets of PAH toxicity, as well as toxicity modifiers. It is hoped that this chapter stimulates multidisciplinary efforts to look at the conduct of temporal integrative analyses of developmental processes affected by exposure to PAHs.

BACKGROUND

Epidemiological Evidence for the Negative Effects of PAHs on Pregnant Women

A number of cohort studies have been undertaken to assess pregnancy outcomes and early life impacts associated with the September 11, 2001, attack and other airborne PAH exposures. To study the acute exposure of pregnant women either working in the World Trade Center (WTC) or residing in the communities of lower Manhattan on September 11, 2001, a Mount Sinai Hospital cohort was assembled (Berkowitz et al., 2003). Of the 187 recruited pregnant women, 12 (about 6%) were inside the WTC towers at the time of attack, and an additional 121 (65%) were within eight blocks (Wolff et al., 2005). A comparison group (n = 2,367) consisted of all private patients not known to have been near the

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00020-8

WTC who delivered at Mount Sinai Hospital during the same time period.

Another cohort of 300 women who lived, worked, or delivered their infants in lower Manhattan in the weeks and months after September 11 were recruited to examine chronic exposure after the attacks (Lederman et al., 2004). These women were followed by the Columbia Center for Children's Environmental Health. The New York City Department of Health and Mental Hygiene and the Agency for Toxic Substances and Disease Registry (ATSDR) established the World Trade Center Health Registry, a voluntary registry to prospectively monitor physical and mental health in the aftermath of the attacks among those with a high probability of direct exposure, including pregnant women (Lipkind et al., 2010).

In recognition of the impact of environmental toxicants encountered *in utero* and the disparities in adverse birth outcomes among inner-city, minority populations, the Columbia Center for Children's Environmental Health established a prospective cohort to follow pregnant women and their children longitudinally (Perera et al., 2003). Nonsmoking Dominican and African-American women residing in three NYC neighborhoods were monitored for exposure to environmental tobacco smoke (ETS), airborne PAHs, and pesticides. A parallel prospective cohort was assembled in Krakow, Poland, with the same eligibility criteria, study design, and air-monitoring methods (Jedrychowski et al., 2009). In Tongliang, China, the effects from PAH exposure secondary to coal combustion was studied prior to and after the shutdown of a coal-fired power plant (Perera et al., 2005a; Tang et al., 2006).

Conclusions from Prospective Epidemiology Cohort Studies

Table 20.1 outlines the main findings from follow-up studies of the cohorts described earlier in this chapter. Analysis of the 187 exposed women in the Mount Sinai WTC cohort revealed nearly a twofold increase in the odds of intrauterine growth retardation in their babies (IUGR; adjusted odds ratio (AOR) 1.90; 95% CI, 1.05–3.46) (Berkowitz et al., 2003). Biologically plausible causes of IUGR in these babies include exposures to fine particulate matter (PM) and PAHs. Previous studies have found associations between particulate air pollution and IUGR (Dejmek et al., 1999; Bobak et al., 2001). Other investigations have linked air pollution to preterm births (Ritz et al., 2000). Additionally, high levels of PAH-DNA adducts in umbilical cord leukocytes are associated with reduced birth size (Perera et al., 1998).

Among the cohort of 300 nonsmoking women who were pregnant on September 11, 2001, and lived within a 2-mile radius of the WTC during the following month, a number of decrements were found in their babies compared to the babies of other pregnant women studied. Infants born to exposed women showed a decrease of 122 g in birth weight and 0.74 cm in birth length after adjusting for gestational duration, sociodemographic, and biomedical risk factors (Lederman et al., 2004). Infants born to women who were in their first trimester at the time of the attacks had significantly shorter gestation (−3.6 days) and smaller head circumference (−0.48 cm) compared to infants born to mothers exposed during their second or third trimester. The 446 births recorded in the World Trade Center Registry also showed a variation in mean gestational age by trimester on September 11, in addition to differences in birth weight (Lipkind et al., 2010). Analysis of births from previous years, however, revealed that the effect of trimester observed may have been due to a seasonal effect unrelated to exposure. It is important to note that the odds of low birth weight and preterm delivery were higher in registry-linked births to mothers that probably had posttraumatic stress disorder (PTSD; Lipkind et al., 2010).

Effects of Maternal Stress

In addition to PAH exposure during pregnancy, maternal stress associated with a terrorist attack or disaster has been shown to affect birth outcomes and later neurocognitive development. Among the 187 women in the Mount Sinai cohort who were pregnant and living or working within close proximity to the WTC on September 11, 52 women completed at least one psychological assessment prior to the delivery of their child. In this analysis, Engel et al. (2005) found that posttraumatic stress symptomatology (PTSS) was associated with decrements in infant head circumference at birth. These decrements could later influence neurocognitive development, although follow-up on this cohort has not yet been reported.

Analysis of live singleton births to women enrolled in the World Trade Center Health Registry between September 11, 2001, and October 31, 2002, also found an apparent effect of maternal stress. When comparing women enrolled in the registry (who were exposed) to those not in the registry and who lived in a NYC census tract more than 5 miles from the WTC site, adjusted analyses found no differences in birth weight, gestational age of delivery, the odds of low birth weight, or the odds of preterm delivery. However, when comparing women with a high PTSD score to those with a lower score, increased odds of preterm delivery (AOR 2.48, 95% CI 1.05–5.84) and low birth weight (AOR 2.49, 95% CI 1.02–6.08) were detected (Lipkind et al., 2010).

In analysis of birth certificate data obtained from the Office of Vital Statistics in New York State and NYC, excluding lower Manhattan, Eskenazi et al. (2007) found

TABLE 20.1 Summary of Findings from Studies Examining Cognitive and Developmental Outcomes Resulting from *In Utero* Exposure to PAHs

Cohort and Authors	Age	Development Measure	Findings
Tongaliang, coal-fired power plant pre- and post-shutdown (Perera et al., 2008)	2 years of age	GDS	Significant association between elevated cord blood adducts and decreased motor development quotient and average development quotient in 2002 cohort (pre-shutdown), but not 2005 (post-shutdown)
Tongaliang, coal-fired power plant pre- and post-shutdown (Tang et al., 2013)	Summary of birth—2 years	GDS	Children born after the power plant shutdown had greater head circumference ($P = 0.001$), reduced levels of cord blood adducts ($P < 0.001$) and were exposed to lower levels of ambient PAHs compared to the cohort born prior to shutdown ($P = 0.01$)
Tongaliang, coal-fired power plant pre- and post-shutdown (Tang et al., 2014)	Summary of birth—2 years	GDS	An inverse association was found between BDNF and PAH-DNA adducts in cord blood. Developmental quotient scores were positively associated with BDNF levels
A subset of the CCCEH cohort pregnant on 9/11 or became pregnant in following month ($n = 300$) (Perera et al., 2007)	3 years	BSID-II	A significant interaction between cord blood DNA adducts and *in utero* exposure to ETS on MDI score ($P = 0.02$), but cord blood adducts or ETS alone were not significant predictors of cognitive development
The 182 of the WTC cohort versus Mt. Sinai births (Mt. Sinai Pregnancy Outcome Study) (Berkowitz et al., 2003)	Birth outcomes		No differences in mean gestational age, mean birth wt, frequency of preterm birth Twofold increase in IUGR among WTC exposed women No association found between probable PTSD and RR of preterm birth, LBW, or IUGR
The **52** of the 182 of the WTC cohort versus Mt. Sinai births (Mt. Sinai Pregnancy Outcome Study) (Engel et al., 2005)	Birth outcomes		PTSS and depression were associated with longer gestational duration PTSS was associated with decrements in head circumference
Dominican and African American (Washington Heights, Central Harlem, and South Bronx) (Perera et al., 2003)	Birth outcomes		Among African Americans, high PAH exposure was associated with lower birth weight ($P = 0.003$) and smaller head circumference ($P = 0.01$)
Dominican and African American (Washington Heights, Central Harlem, and South Bronx) (Perera et al., 2006)	3 years	BSID-II	Prenatal exposure to PAHs significantly associated with lower MDI at age 3, but not at 1 or 2 years. Prenatal PAH exposure was also unrelated to PDI
Dominican and African American (Washington Heights, Central Harlem, and South Bronx) (Perera et al., 2009)	5 years	WPPSI-R	High PAH levels, above the median of 2.26 ng/m^3, were associated with full-scale IQ (4.31 lower, $P = 0.009$) and verbal IQ (4.67 lower, $P = 0.002$) reductions compared to less exposed children
Dominican and African American (Washington Heights, Central Harlem, and South Bronx) (Perera et al., 2012)	6–7 years	CBCL	High PAH exposure, defined as greater than the median exposure from personal air monitoring, or detectable and higher maternal and cord adducts, was associated with symptoms of Anxious/Depressed and Attention Problems ($P \leq 0.05$)
Krakow, Poland cohort (2001–2006 enrollment) (Edwards et al., 2010)	5 years	RCPM	Children with higher than the median (17.96 ng/m^3) prenatal exposure to airborne PAHs had decreased RCPM scores at age 5. These reduced scores correspond to an estimated average decrease of 3.8 IQ points

GDS, Gesell Development Schedules; CBCL, Child Behavior Checklist; WPPSI-R, Wechsler Preschool and Primary Scale of Intelligence-Revised; BSID-II, Bayley-II Scales of Child Development; ETS, Environmental Tobacco Smoke; MDI, Mental Development Index; PDI, Physical Development Index; RCPM, Raven Coloured Progressive Matrices.Included are studies related to the events of September, 11, 2001, as well as international studies of PAH exposures.

an increased chance of very low birth weight (<1,500 g) around the start of 2002 (i.e., among infants that would have been in their first or second trimester of gestation at the time of the September 11 attacks). This same finding was noted in births 33–36 weeks after the disaster (i.e., those conceived around or shortly after September 11). The authors suggest that these effects could be the result of the increased stress associated with a terrorist attack (Eskenazi et al., 2007). A study of maternal stress resulting from the 1998 ice storm in Quebec, Canada, found that more severe prenatal maternal stress was associated with decrements in Bayley Scales of Infant Development (BSID)–Mental Development Index (MDI) scores and parent-reported language abilities at 2 years of age (Laplante et al., 2004).

An interaction between exposure to PAHs and maternal stress has been suggested. Among children who experienced high prenatal exposure to PAH, maternal demoralization during pregnancy has a greater negative effect on children's neurobehavioral development. In the longitudinal study of 248 children from the Krakow cohort, maternal demoralization had an effect on syndromes of depression (anxious and withdrawn), rule-breaking and aggressive behaviors, and composite internalizing and externalizing scores at age 9 (Perera et al., 2003). These effects were seen only in those with high prenatal exposure. Both prenatal PAH exposure (Tang et al., 2014) and prenatal stress (Neeley et al., 2011) have been found to decrease hippocampal mature brain-derived neurotrophic factor (mBDNF) expression and signaling cascades for long-term potentiation (LTP), providing a potential mechanism for the observed interaction.

PAH-DNA Adducts

PAH-DNA adducts provide a reflection of individual variation in exposure and toxicokinetics and have been associated with risk of cancer and reproductive and developmental effects (Tang et al., 2006; Perera et al., 2007). In the cohorts followed by researchers from the Columbia Center for Children's Environmental Health, mean DNA adduct concentrations in both maternal and fetal cord blood, as well as the proportion of samples with detectable adducts, increased across the populations studied in a manner consistent with the trend in estimated ambient exposure to PAHs ($P < 0.001$, northern Manhattan < WTC < Krakow < Tongliang). Data from these four populations indicate that the developing fetus may have a 10-fold greater susceptibility to DNA damage than mothers (Perera et al., 2005a).

Higher adduct levels have been associated with a number of adverse birth and neurocognitive developmental outcomes. In a cohort of 150 mother-infant dyads in Tongliang County, China, that received exposure from a seasonally operated, coal-fired power plant, those with higher than median PAH-DNA cord blood adducts weighed less than their low-exposure counterparts at 18, 24, and 30 months of age (Tang et al., 2006). Exposure for a longer duration was associated with shorter length at birth and height at 18, 24, and 30 months. In children who were *in utero* during power plant operation, there was a 91% increase in the odds of being developmentally delayed in the motor area for each 0.1-unit increase in cord blood adducts (0.1 adducts/10^8 nucleotides). The mean cord adduct levels in this cohort were 0.32 adducts/10^8 nucleotides (Perera et al., 2008). After the shutdown of the power plant, the head circumference of the children was greater than that of those born prior to the shutdown (33.766 cm versus 34.130 cm; $P < 0.05$), and consistent with the reduced levels of ambient PAHs and reduced levels of cord blood adducts (Tang et al., 2013).

In comparisons of these pre- and post-shutdown cohorts, it was also found that the mean level of mBDNF was significantly higher in the 2005 post-shutdown cohort (1266.56 versus 752.87 pg/mL; $P < 0.05$) (Tang et al., 2014). The brain-derived neurotrophic factor (BDNF) levels were inversely correlated with PAH-DNA adducts in cord blood in both cohorts ($P < 0.01$) and positively associated with average, motor area, and social area development quotients. Based on their analyses, Tang et al. (2014) deemed BDNF to be a potential mediator between PAH-DNA adducts measured in cord blood and later cognitive outcomes. This is consistent with findings that prenatal exposure to ETS, of which PAHs are a component, was linked to down-regulation of BDNF through increased methylation of the BDNF exon (Toledo-Rodriguez et al., 2010).

Among women in the WTC cohort who were also exposed to ETS during pregnancy, increased PAH-DNA adducts were associated with reduced birth weight (276 g; 8% for a doubling of adducts) and head circumference (1.3 cm; 3% for a doubling of adducts) (Perera et al., 2005b). At age 3, children born to these mothers had an average reduction in MDI of 6% for a doubling of adducts (Perera et al., 2007). Lower MDI at age 3 was also found in the cohort of African-American and Dominican mothers and children (Perera et al., 2006).

Assessment of gene and environment interactions has found that both maternal and newborn haplotypes of CYP1A1 and CYP1B1 appear to be important effect modifiers of MDI at 12, 24, and 36 months of age (Wang et al., 2008, 2010). Subsequent analysis has identified a potential relationship between maternal haplotypes of XRCC1 and GSTM3, in addition to a maternal haplotype of CYP1B1, maternal PAH exposure, and newborn cord blood adducts in African Americans (Iyer et al., 2014). This study also found interactions with maternal PAH exposure and newborn cord blood adducts with newborn CYP1A2 and XRCC1 in African Americans,

maternal XRCC1 among Dominican women, and newborn NQO1 in Dominican infants (Iyer et al., 2014).

Refinement of Our Susceptibility-Exposure Paradigm to Access the Effects of *In Utero* Exposure to PAH Aerosols on Neurodevelopmental Processes

The determination of the embryonic "critical period of development" for the brain structures involved in learning and memory processes in mice is based on the original work by Rodier (1976). This study identified the embryonic time frames for peak neurogenesis and neuroepithelial proliferation for cerebral cortex, hippocampus, septum, amygdala, corpus striatum, thalamus, hypothalamus, cerebellum, and olfactory bulb as the period from embryonic day E14 through E17. Rodier documented almost 40 years ago that the specific time of the central nervous system (CNS) insult is an important factor in subsequent effects on both anatomy and behavior. Therefore, this early work established what we refer to as the embryonic "critical period of development." The report suggested that the behavioral effects of toxicants such as benzo(a)pyrene (B(a)P) are similar in both rats and mice. This study was one of the first to demonstrate that mice could be used successfully as subjects in a variety of behavioral evaluation experiments.

Novel object discrimination testing has been used for over two decades because it is perfectly suited to test the effects of pharmacological and genetic interventions on learning and memory processes (Dere et al., 2007). When comparisons are made among experimental model systems of learning and memory, the object discrimination test is more closely related with the conditions under which human recognition memory is measured. This is primarily due to a shortened training period coupled with the fact that novel object discrimination does not induce high levels of arousal and stress in animals (Ennaceur and Delacour, 1988). The component of memory likely affected by PAH is the medial prefrontal cortex (mPFC) and is referred to as *relative recency memory* (Fuster, 2001). In support of this argument concerning relative recency memory, it is known that lesions to the mPFC impair relative recency discrimination in humans, nonhuman primates, and rodents across a wide range of stimulus modalities (Fuster, 2001). This is true despite the fact that in some instances, recognition of novel and familiar stimuli is preserved.

Conversely, studies have reported that after bilateral mPFC lesions, an impairment or deficit is observed with respect to the ability to differentiate between previously presented and recently presented familiar objects (Mitchell and Laiacona, 1998). Results from our laboratory testing *in utero* of B(a)P aerosol–exposed $Cpr^{lox/lox}$ offspring in object discrimination paradigms were consistent with results from the aforementioned bilateral mPFC lesion studies. They support the suggestion that the mPFC is involved (at least in part) in making judgments regarding the sequence and order of object presentations. Additionally, the involvement of cortical glutamate receptors in performance of the novel object discrimination task in rodents is well established, as deficits and impairments have been reported following the application of AMPA (CNQX) or NMDA (AP-5) antagonists. By characterizing the effects of *in utero* exposure to PAH on $Cpr^{lox/lox}$ and brain-*Cpr*-null offspring, we further validate novel object discrimination phenotying as a measure of prefrontal and limbic circuit integrity by demonstrating that this behavior is negatively affected subsequent to *in utero* B(a)P exposure.

Refinement of our Susceptibility-Exposure Paradigm to Access the Effects of *In Utero* Exposure to PAH Aerosols on Behavioral Phenotypes

Cytochrome-P_{450} is an important modifier of mental development at an early age. Recently, significant interactions were reported among a maternal haplotype in the cytochrome P_{450}1B1 (CYP1B1) gene (ACCGGC), PAH exposure, and reductions in the MDI in a cohort of children (Wang et al., 2010). These studies have important implications for our society; they are valuable from a translational standpoint because they can inform the design of molecular neurotoxicology studies using experimental model systems.

Recently, Xia et al. (2011) evaluated the effects of subchronic exposure to B(a)P (intraperitoneal injections of 6.25 mg/kg B(a)P/day for 14 weeks) versus diluent on both neurotransmitter receptor gene expression and performance in a Morris water maze. Mircoarray results revealed that 1,016 genes were differentially expressed in B(a)P-treated specimens versus diluent controls. The Database for Annotation, Visualization, and Integrated Discovery was used to analyze those genes differentially expressed in the gene ontology and Kyoto Encyclopedia of Genes and Genomes pathways. Their analysis showed that the most significantly affected category was behavior, and the fourth-highest was learning and memory. They ranked 22 genes involved in learning and memory and 25 genes associated with neuroactive ligand–receptor interactions. Both lists included up-regulation of the ionotropic glutamate receptor *N*-methyl D-asparate 2A (GRIN2A). A conclusion was that "neuroactive ligand–receptor interactions" were among the most negatively affected by B(a)P exposure at ($P < 7.7$ E−6). In the Morris water maze test, B(a)P-treated rats had spatial learning deficits and had a decreased number of platform crossings and time spent in the target area, suggesting that B(a)P caused a deleterious effect on long-term

memory. Several other studies have also suggested that neurotransmitter and neurotransmitter receptor gene expression play important roles in modulating neurobehavioral effects, especially within the context of learning and memory.

These results confirmed the notion that the PAH component can have a direct negative impact on the developmental expression of (i) key glutamatergic regulators of NMDA-mediated processes (receptor tyrosine kinase-MET) and (ii) behavioral deficit phenotypes.

PAH EXPERIMENTAL MODEL SYSTEMS

Toxicological Observations from Modeling B(a)P Aerosols

In our experimental model system, *Cpr*$^{lox/lox}$ and brain-*Cpr*-null timed-pregnant dams were exposed to a B(a)P aerosol on E14–E17 exhibiting a trimodal distribution with a 93% cumulative mass less than 5.85 μm, 91% cumulative mass less than 10 μm, 57.6% cumulative mass less than 2.5 μm, and 43% less than 1 μm (Figure 20.1 and Table 20.2). The characterization of the aerosol atmospheres generated in these studies was comparable to those generated previously for rat studies (Hood et al., 2000). The B(a)P aerosol used in our earlier rat studies comprised a mass median aerodynamic diameter with a geometric standard deviation of 0.9 ± 0.09 μm, compared to 1.0 ± 0.07 in the present *Cpr* mouse experiments. Analysis of live birth indices revealed no significant differences in the number of mouse pups born per litter between control *Cpr*$^{lox/lox}$ dams and B(a)P-exposed *Cpr*$^{lox/lox}$ dams. The analysis of the live birth index for control *Cpr*$^{lox/lox}$ dams was 6.12 ± 0.42, compared to 5.9 ± 0.9 for B(a)P-exposed *Cpr*$^{lox/lox}$ dams, and 5.7 ± 0.31, compared to 5.99 ± 0.41 for the control and B(a)P-exposed brain-*Cpr*-null dams, respectively. Statistical analysis (P = 0.241) indicated no significant difference in this index between these groups. This finding is consistent with our previous reports using rat and mouse models (Hood et al., 2000, 2006; Wormley et al., 2004a,b; Brown et al., 2007; Sheng et al., 2010). During the prenatal exposure period, as well as the subsequent preweaning period, there were no identifiable B(a)P-related effects on conventional reproductive indices of toxicity, and there were no convulsions, tremors, or abnormal movements noted in any of the control or B(a)P-exposed *Cpr* litters.

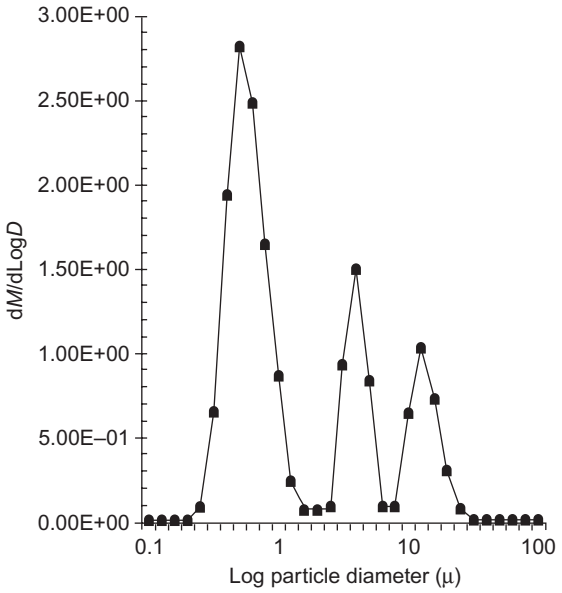

FIGURE 20.1 Differential particle-size distribution representative of B(a)P:carbon black aerosol delivered to timed pregnant *Cpr*$^{lox/lox}$ and brain-*Cpr*-null dams (100 μg/m^3). During a typical exposure, aerosol was collected on substrates every 30 min during a 4 h exposure period from E14 to E17. Subsequent to the exposure period each day, substrate post-weights were uploaded into a custom impactor data reduction program to generate average particle-size distributions as previously described (Wu et al., 2003).

In Situ Generation of "Oxidative Metabolites" in Neocortical Tissue from *In Utero* Exposure to B(a)P Aerosol

The quantitation of B(a)P metabolites from *Cpr*$^{lox/lox}$ and brain-*Cpr*-null offspring is shown in Figure 20.2A and B. In neocortical tissue from *in utero* B(a)P aerosol–exposed *Cpr*$^{lox/lox}$ offspring, we found 4.5-, 7.8-, 9-, and 10-diols, 3.6- and 6.12-diones, and 3-OH and 9-OH B(a)P metabolites, indicating the presence of an active phase 1 biotransformation pathway (Figure 20.2A). In contrast, in brain-*Cpr*-null offspring, all metabolites were essentially below the level of detection (note the change in the *y*-axis values in Figure 20.2B). The important point in Figure 20.2A is the identification of the developmental period over which there is formation/accumulation of the reactive 3-OH and 9-OH metabolites. These metabolites can further oxidize to form B(a)P quinones that can undergo redox cycling and generate reactive oxygen species (Li et al., 2012).

F_2-isoprostane measures assessed the *in vivo* prefrontal cortex (PFC) oxidative milieu occurring primarily in neuronal membranes. Figure 20.3 shows the quantitation of F_2-isoprostanes derived from neocortical homogenates from control and B(a)P-exposed *Cpr*$^{lox/lox}$ offspring (Figure 20.3A), and control and B(a)P-exposed brain-*Cpr*-null offspring (Figure 20.3B). (Note: There are no control *brain-Cpr-null* mouse isoprostane data for P3 to P15 due to the lack of available tissue.) The data document a sustained high neocortical tissue burden of F_2-isoprostanes in B(a)P-exposed *Cpr*$^{lox/lox}$, including the period from P7–P14, the extent of which was not observed in null mice (Figure 20.3B).

TC_p and T_{premix} were generally high enough for top side of orifice plate > T_{sat}, rows 1–3 of each group of four rows. For each group, values greater than the second row are given in the fourth row for the purposes of evaluating overheating of the humidified B(a)P stream. Bold values in row 2 indicate the experimental conditions under which the studies were conducted. Assume T_{Wright} = 70°F; m = 0.565; b = 37.432 (for details, see Li et al., 2012).

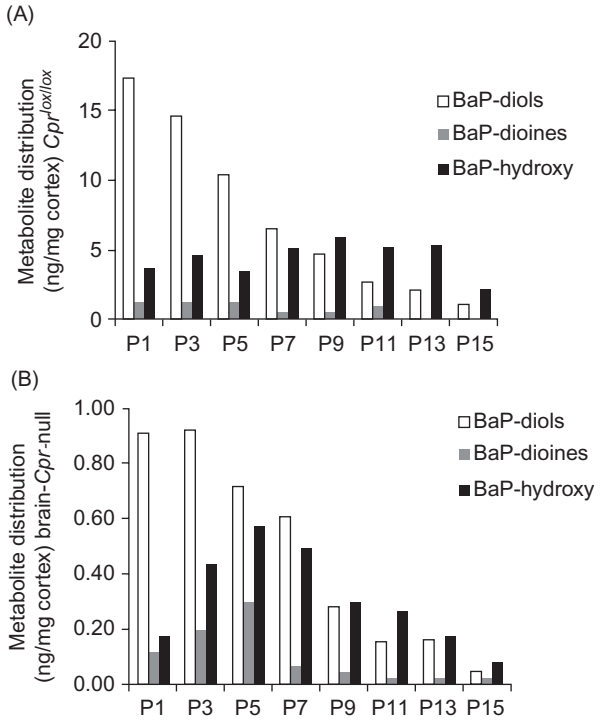

FIGURE 20.2 Metabolite distribution of cortical B(a)P metabolites during the critical postnatal period when synapses are forming for the first time in B(a)P-exposed *Cpr* offspring. Timed-pregnant $Cpr^{lox/lox}$ or brain-*Cpr*-null dams received either carbon black only or 100 μg/m³ B(a)P via nose-only inhalation on E14–E17 for 4 h/day. Offspring were sacrificed on P1, 3, 5, 7, 9, 11, 13, and P15. Shown are the distribution of metabolites detected in B(a)P-exposed (A) $Cpr^{lox/lox}$ offspring or (B) brain-*Cpr*-null offspring.

Temporal Modulation of NMDA-Mediated Developmental Processes as a Result of *In Utero* Exposure to B(a)P Aerosol

Evidence supporting the hypothesis that an early insult to an NMDA-mediated signaling system leads to phenotypical changes that manifest later in life as elevated glutamate concentrations in mPFC is provided in Figure 20.4A. Figure 20.4A shows a time course plot indicating basal levels of glutamate in C57BL background controls, $Cpr^{lox/lox}$, B(a)P-exposed $Cpr^{lox/lox}$, and B(a)P-exposed brain-*Cpr*-null offspring obtained by microdialysis. Studies were carried out in a control group of mice performing the same task and B(a)P aerosol–exposed *Cpr* offspring over a 120 min sampling period. Quantitation of the results in Figure 20.4 shows a statistically significant increase in the basal concentration of glutamate in the mPFC of B(a)P-exposed $Cpr^{lox/lox}$ offspring compared to WT C57BL, WT $Cpr^{lox/lox}$, or B(a)P aerosol–exposed brain-*Cpr*-null offspring. The basal glutamate concentrations obtained in our *Cpr* mouse model are identical to recent reports in the literature for dorsal hippocampus in a 129/SvEv mice KATII KO model (*45*) and for the PFC in a Wistar rat ethanol model (Chefer et al., 2011). These findings are consistent with the idea that increases in glutamate concentration promote altered inward currents via the NMDA receptor.

As a means of assessing the impact of *in utero* exposure to B(a)P aerosol on developmental NMDA-mediated processes, we evaluated developmental expression profiles for NMDA receptor subunits compared to those of Sp4 and Sp1 proteins with and without *in utero* B(a)P exposure. Inspection of the expression profile (P1–P15) in control $Cpr^{lox/lox}$ offspring (Figure 20.5A, left panel) revealed that Sp4 expression is constitutively low on P1, reaches peak expression levels on P7, and subsides to constitutive levels by P15, which is consistent with earlier reports (Li and Pleasure, 2005). Conversely, the Sp4 developmental expression profile in B(a)P-exposed $Cpr^{lox/lox}$ offspring (Figure 20.5B, right panel) indicates that as early as P1, Sp4 reaches near maximal levels and by P3, it reaches peak expression levels and remains at maximal levels through P7. The interpretation of this finding is that the leftward shift in peak Sp4 expression is in response to *in utero* B(a)P aerosol exposure occurring during the E14–E17 period. The consequence of this exposure is the mistiming of peak Sp4 expression in B(a)P-exposed $Cpr^{lox/lox}$ offspring, which could significantly affect downstream signaling processes, perhaps in a way similar to those reported for Sp4 null mice (Zhou et al., 2007).

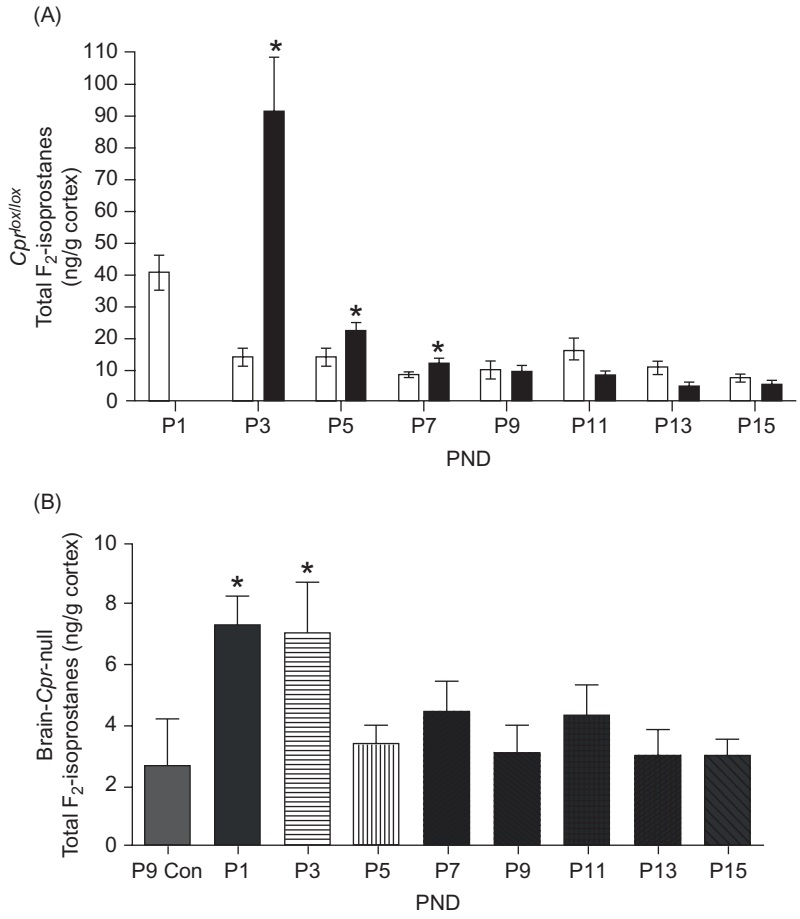

FIGURE 20.3 *In utero* **exposure to B(a)P aerosol (100 μg/m^3) produces an approximate 10× higher concentration of F_2-isoprostanes on P3 in B(a)P-exposed *Cpr*$^{lox/lox}$ offspring as compared to B(a)P-exposed brain-*Cpr*-null offspring.** (A) F_2-isoprostanes levels derived from control (white bars) and B(a)P-exposed *Cpr*$^{lox/lox}$ (black bars) offspring neocortex. (B) F_2-isoprostane levels for derived from control PND9 (white bar) and B(a)P-exposed (black bars) brain-*Cpr*-null offspring neocortex. Due to the limited number of control offspring, only PND9 was used for time points in favor of reserving pups for behavioral determinations in later-life. *P = <0.05 versus Control.

Having demonstrated that B(a)P exposure shifts the Sp4 expression profile to the left and given that NR2A is a Sp4 target gene, it is not surprising that B(a)P exposure also modulated the temporal expression of NR2A. The Sp4 nontarget NR2B developmental expression profile, on the other hand, for control *Cpr*$^{lox/lox}$ offspring (Figure 20.5A, left panel) revealed that expression was low from P1–P3 and gradually increased until peak NR2B levels were present on P15. The NR2B developmental expression profile in B(a)P-exposed *Cpr*$^{lox/lox}$ offspring (Figure 20.5B, right panel) is strikingly similar to that of controls. What is apparent is the significant change in the NMDA subunit ratio of NR2B:NR2A on P7 in control *Cpr*$^{lox/lox}$ offspring (NR2B:NR2A = 1/0.4, as seen in Figure 20.5A, lower-left panel) as compared to B(a)P-exposed *Cpr*$^{lox/lox}$ offspring (NR2B:NR2A = 1/0.78, seen in Figure 20.5B, lower-right panel). Reminiscent of Sp4 expression, the NR2A developmental expression profile in B(a)P-exposed *Cpr*$^{lox/lox}$ offspring (right panel) is constitutively "on," beginning from P1–P5, and by P13, it reaches maximal expression levels compared to P15 in B(a)P-exposed offspring.

The developmental expression profiles for brain-*Cpr*-null offspring are shown in Figure 20.6. Inspection of the expression profiles from these *null* mice (P1–P15) in control brain-*Cpr*-null offspring (Figure 20.6A, left panel) revealed that Sp4 expression is constitutively low on P1 and reaches peak expression levels on P13. Conversely, the Sp4 developmental expression profile for B(a)P-exposed brain-*Cpr*-null offspring (Figure 20.6B, right panel) indicates that as early as P1, Sp4 expression is evident, reaches maximal levels by P3, and then drops to constitutive expression levels by P7. What is apparent from the brain-*Cpr*-null offspring data is that the NMDA subunit ratio of NR2B:NR2A on early postnatal days (P1, P3, P5, and P7) in B(a)P-exposed brain-*Cpr*-null offspring (NR2B:NR2A = 1/0.5, seen in Figure 20.6B, lower-right panel) is approximately the same as for P7 in control *Cpr*$^{lox/lox}$ offspring (NR2B:NR2A = 1/0.5, as seen in Figure 20.6A, lower-left panel). Based on the results of

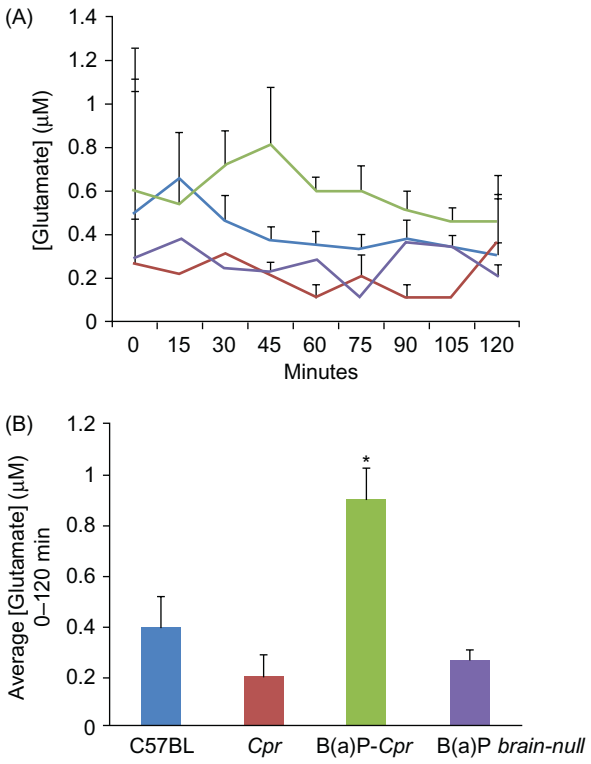

FIGURE 20.4 ***In utero*** **exposure to B(a)P aerosol (100 μg/m^3) results in a robust increase in prefrontal cortical glutamate concentrations as assessed in awake behaving *Cpr$^{lox/lox}$* offspring but not in brain-*Cpr*-null offspring (PND100).** (A) Glutamate concentrations assessed from medial PFC as a function of time. (B) Quantitation of average glutamate concentrations over this time period (μM) assessed in control C57BL, control *Cpr$^{lox/lox}$* offspring versus B(a)P-exposed *Cpr$^{lox/lox}$* and brain-*Cpr*-null offspring. See text for details (C57BL, blue; *Cpr*, red; and B(a)P-*Cpr*, green; B(a)P brain-*Cpr*-null, purple). *P = <0.05 versus *Cpr*.

a recent NR2A subunit knockout study in mice (Brigman et al., 2008), it would be reasonable to predict that in our null model, the absence of modulation in NMDA subunit ratios would mean that these mice would not exhibit a behavioral deficit phenotype. Such a finding would support our hypothesis that a significant deficit in behavioral learning results from the loss of proper temporal functioning of the NR2A subunit.

Rescue of Spatial Discrimination Deficit Phenotypes in Brain-*Cpr*-Null Offspring Subsequent to *In Utero* Exposure to B(a)P Aerosol

Novel object discrimination testing was used to measure B(a)P-induced behavioral effects as described in our recent report (Sheng et al., 2010). Data in Figure 20.7 show that control *Cpr$^{lox/lox}$* offspring mice were better able to discriminate between novel and familiar objects (8.1 ± 0.31), as compared to B(a)P-exposed *Cpr$^{lox/lox}$* offspring (2.0 ± 0.17). An analysis of variance revealed significant differences between the control *Cpr$^{lox/lox}$* offspring (observational, small zone, and large zone) with regard to entries into the novel zone compared to the B(a)P-exposed *Cpr$^{lox/lox}$* offspring. The exposed group exhibited a diminished ability to discriminate novel from familiar objects as indicated by a significantly reduced time as compared to controls ($P < 0.05$ for the 100 μg/m^3 group). Post hoc analysis using the Bonferroni's test revealed the significance at $P < 0.01$. Testing of control brain-*Cpr*-null offspring versus B(a)P-exposed brain-*Cpr*-null offspring in the 100 μg/m^3 group revealed no significant differences in object discrimination at 9.1 ± 1.4 versus 9.0 ± 0.8. Given that brain-*Cpr*-null offspring are incapable of producing significant levels B(a)P metabolites via CYP1B1, these data strongly implicate a sustained-oxidative neocortical tissue metabolite burden during the critical period from P0-P5 that contributes to the discrimination deficit phenotype observed in B(a)P aerosol–exposed *Cpr$^{lox/lox}$* offspring.

Figure 20.8 shows coronal sections of adult neocortical sections from *Cpr$^{lox/lox}$* offspring that were analyzed for cytoarchitecture by immunoshistochemical staining for NeuN. Neocortical neurons were counted in *Cpr$^{lox/lox}$* offspring that had not been exposed to B(a)P *in utero* (A, low magnification; B, higher magnification) and compared to *Cpr$^{lox/lox}$* offspring that were exposed to the B(a)P *in utero* (C, low magnification; D, higher magnification). Figure 20.8E shows the plot resulting from stereological analysis of neocortical neurons subsequent to application of a two-tailed *t*-test. As can be seen, no significant differences were seen in the density of neocortical neurons as a result of *in utero* exposure to B(a)P aerosol.

Negative modulation of cortical inward currents in neurons derived from B(a)P-exposed *Cpr$^{lox/lox}$* offspring. Finally, electrophysiology experiments were performed on *ex vivo* primary cortical neurons as a means of ascertaining potential B(a)P exposure–induced effects on cortical currents. On the seventh day in culture, *ex vivo* primary cortical neurons derived from control and B(a)P-exposed Cpr$^{lox/lox}$ offspring were voltage-clamped using the whole cell configuration and held at −60 mV, in a Mg^{2+} free external solution. The current–voltage (I–V) relationship of cortical neurons derived from control and B(a)P-exposed (100 μg/m^3) Cpr$^{lox/lox}$ offspring was nearly linear between −100 and −20 mV (Figure 20.9A). Figure 20.9B shows a representative current trace obtained from carbon black control and cortical neurons derived from 100 μg/m^3 B(a)P aerosol–exposed offspring at −80 mV using the same experimental configuration as in Figure 20.8A. Although there were no apparent differences between the current recorded results in control and B(a)P-exposed cortical neurons at positive membrane

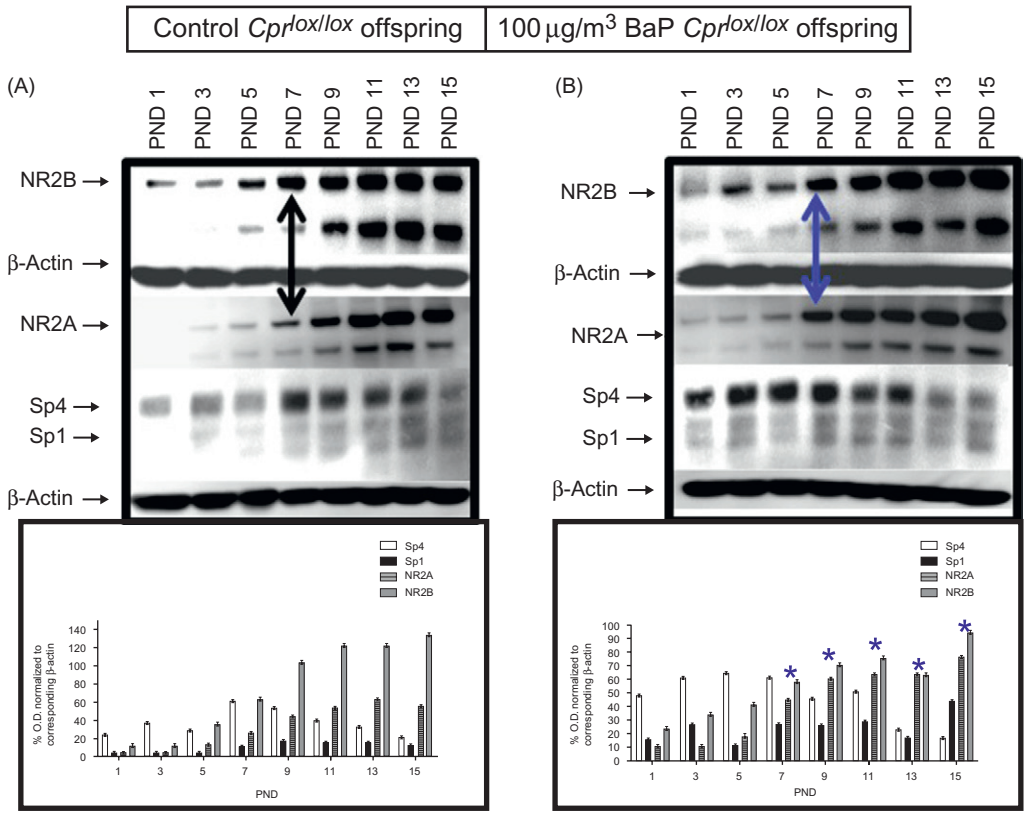

FIGURE 20.5 *In utero* **B(a)P aerosol exposure (100µg/m^3) induces a leftward shift in the peak temporal developmental expression of Sp4 and alters NMDA subunit ratios in B(a)P-exposed *Cpr*$^{lox/lox}$ offspring (B, right panel) as compared to control *Cpr*$^{lox/lox}$ offspring (A, left panel).** Representative results from a typical experiment. The panels show developmental expression profiles from PND1 to PND15 for NR2B-Sp4 nontarget gene, NR2A-Sp4 target gene and Sp4-Sp1 proteins following SDS-PAGE of neocortical tissue from offspring gauged relative to internal β-actin controls. Lower panels represent quantitation of left and right upper panels. *Post hoc* analysis with the Bonferroni test with significance shown at $P < 0.05$.

potentials, there was a statistically significant, voltage-dependent decrease in the inward currents recorded at negative membrane potentials, as shown in Figure 20.8C ($t = -2.92789$, $P < 0.0429$).

IMPLICATIONS

We have presented complementary biophysical, molecular, neurochemical, and neurobehavioral approaches examining how the PAH component of combustion processes negatively affects gestational and developmental processes in our experimental model systems.

Our central findings are that *in utero* exposure to the PAH component of *c* (as B(a)P aerosol; Figure 20.1) in the *Cpr* mouse results in a substantial neocortical oxidative tissue burden of B(a)P metabolites (Figure 20.2) and F_2-isoprostanes (Figure 20.3) during a period when synapses are developing for the first time. Such a sustained neocortical tissue burden might be expected to contribute to an increased cortical oxidative load. The presence of three distinct categories of metabolites (diols, diones, and hydroxy-derivatives) indicate an active phase 1 biotransformation pathway in our control *Cpr* mouse model. Present in B(a)P-exposed *Cpr*$^{lox/lox}$ offspring were the 4.5-, 7.8-, 9-, and 10-diols, the 3.6- and 6.12-diones and the 3-OH and 9-OH B(a)P metabolites. The important point in interpretation of this data is the identification of the developmental period over which there is formation and accumulation of 3-OH and 9-OH metabolites. These metabolites further oxidize to form B(a)P quinines that could undergo redox cycling and generate reactive oxygen species (Li et al., 2012). While the data from the brain-*Cpr*-null support the suggestion that accumulation of hydroxy-metabolites and their conversion into reactive intermediates in the *Cpr*$^{lox/lox}$ mouse likely contribute to the observed neurotoxicity, the levels may be below the threshold required to cause gross alterations in neuropathology (Figure 20.8). Additional experiments will be needed to gain a better mechanistic understanding on why there were no observable pathologies in the neocortical cytoarchitecture in B(a)P-exposed animals. While speculative, one possibility may be that the plastic state of these young brains allows for certain compensations—for example, these mice may have an

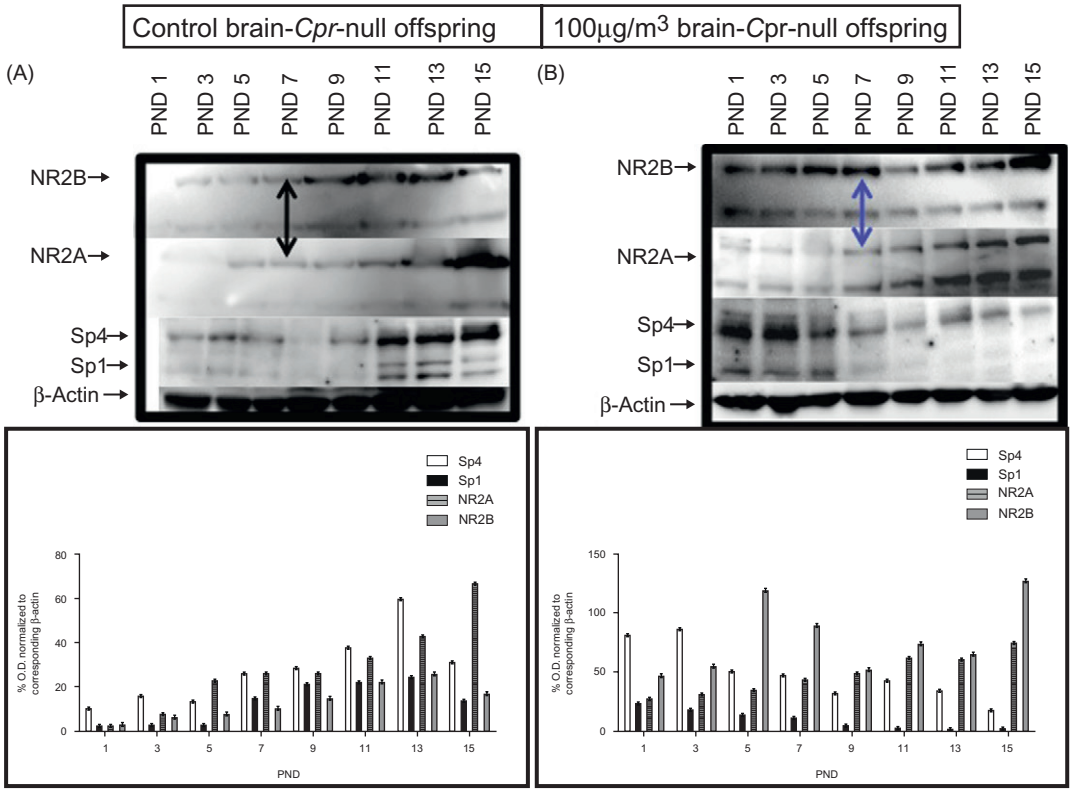

FIGURE 20.6 ***In utero*** **B(a)P aerosol exposure (100 μg/m^3) upregulates developmental expression of Sp4 in brain-*Cpr*-null offspring (right panel) with accompanying dysregulation of NMDA subunit ratios as compared to control *Cpr*$^{lox/lox}$ offspring (left panel).** Representative results from a typical experiment. The panels show developmental expression profiles from PND1 to PND15 for NR2B-Sp4 nontarget gene, NR2A-Sp4 target gene and Sp4-Sp1 proteins following SDS-PAGE of neocortical tissue from offspring gauged relative to internal β-actin controls. Lower panels represent quantitation of left and right upper panels. *Post hoc* analysis with the Bonferroni test with significance shown at $P < 0.05$.

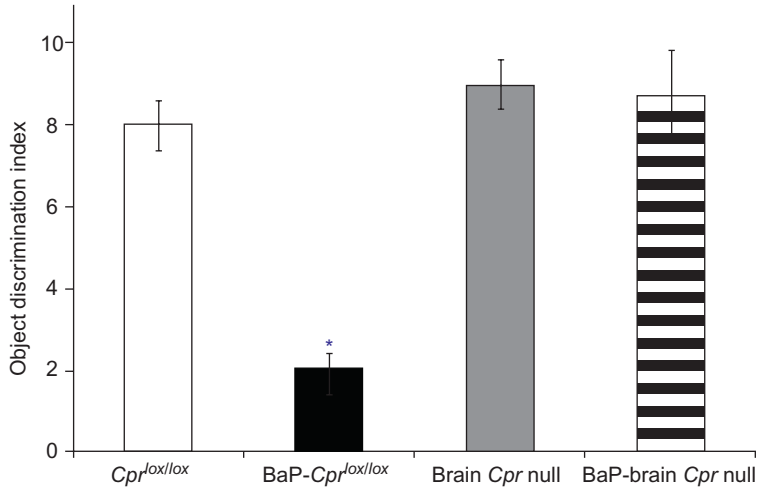

FIGURE 20.7 ***In utero*** **B(a)P aerosol exposure induces a significant deficit in object discrimination in B(a)P-exposed *Cpr*$^{lox/lox}$ offspring as compared to control *Cpr*$^{lox/lox}$, WT brain-*Cpr*-null or B(a)P-exposed brain-*Cpr*-null offspring.** Object discrimination index for control *Cpr*$^{lox/lox}$ offspring mice was 8.1 ± 0.31 and 2.0 ± 0.17 for B(a)P-exposed *Cpr*$^{lox/lox}$ offspring. An analysis of variance revealed a significant difference ($P < 0.05$ for the 100 μg/m^3 group). Testing of control brain-*Cpr*-null offspring revealed an index of 9.1 ± 1.4 versus 9.0 ± 0.8 for the B(a)P-exposed brain-*Cpr*-null offspring. *Post hoc* analysis with the Bonferroni test failed to reveal a statistically significance difference at $P < 0.05$.

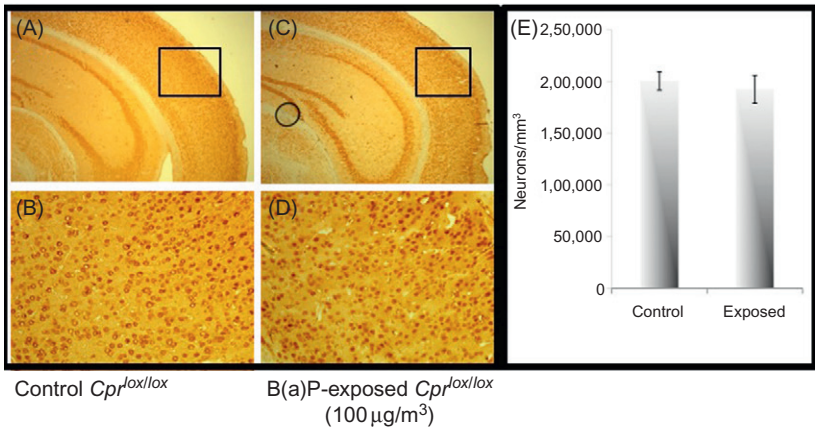

FIGURE 20.8 **Post-behavior characterization of neocortical cytoarchitecture.** Coronal sections of adult neocortical sections from *Cpr*$^{lox/lox}$ offspring were analyzed for cytoarchitecture by immunoshistochemical staining for NeuN. Neocortical neurons were counted in *Cpr*$^{lox/lox}$ offspring that had not been exposed to B(a)P *in utero* (A, low magnification; B, higher magnification) and compared to *Cpr*$^{lox/lox}$ offspring that were exposed to the B(a)P *in utero* (C, 4 × -low magnification; D, 20 × -high magnification). (E) It shows the plot resulting from stereological analysis of neocortical neurons subsequent to application of a two-tailed *t*-test. As can be seen, no significant differences in the density of neocortical neurons is observed as a result of *in utero* exposure to B(a)P aerosol.

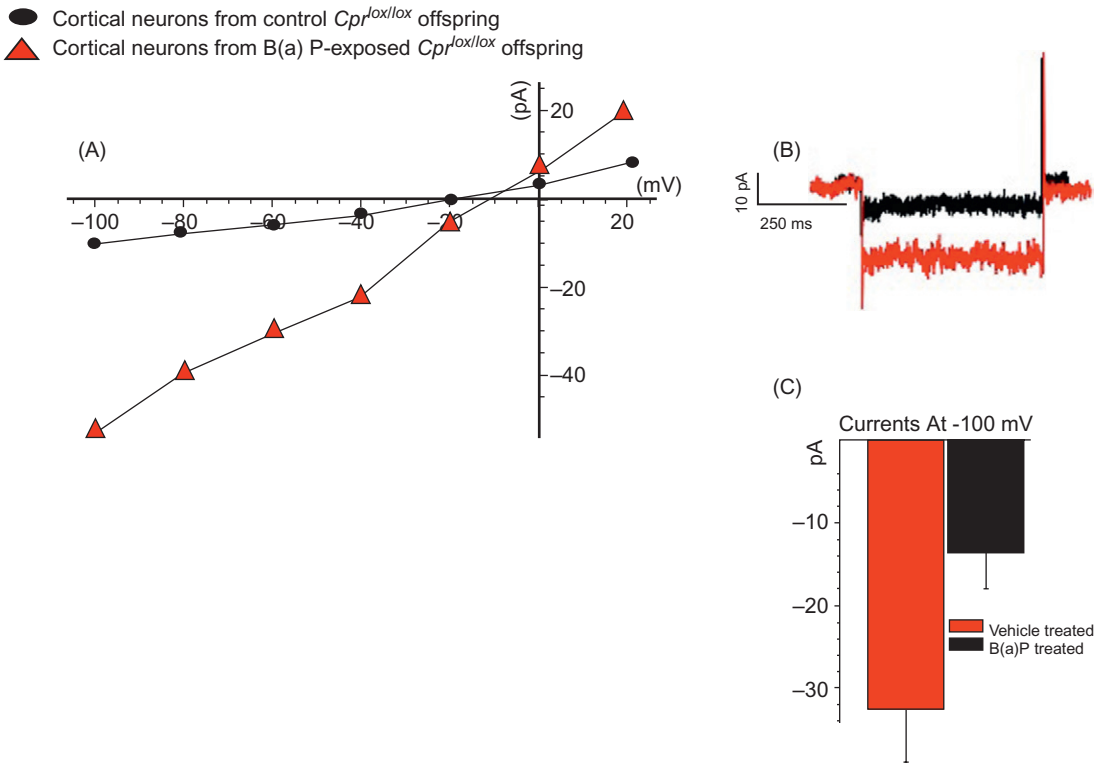

FIGURE 20.9 **B(a)P aerosol exposure (100 µg/m^3) induces a voltage-dependent decrease in the inward currents of cortical neurons derived from B(a)P-exposed *Cpr*$^{lox/lox}$ offspring.** Cortical neurons were voltage clamped using whole-cell configuration in a Mg^{2+} free external solution. Current–voltage relations were generated using a voltage step (1 s) protocol ranging from −80 to 20 mV separated by 20 mV from a holding potential of −60 mV. The experimenter was blind to the type of treatment. (A) Representative *I–V* currents for cortical neurons derived from carbon black and 100 µg/m^3 B(a)P aerosol–exposed *Cpr*$^{lox/lox}$ offspring. There is a voltage-dependent decrease in the magnitude of inward currents at negative membrane potentials in the cortical neurons derived from 100 µg/m^3 B(a)P-exposed *Cpr*$^{lox/lox}$ offspring. (B) Representative current traces obtained from carbon black control and cortical neurons derived from 100 µg/m^3 B(a)P aerosol–exposed offspring at −80 mV using the same experimental configuration as in (A). (C) Bar graph shows pA inward current recorded at −100 mV in control and B(a)P-exposed cortical neurons ($t = -2.92789$, $P < 0.0429$, $n = 3–5$).

improved mitochondrial capacity. Such an effect has already been noted in response to severe hyperglycemia and hyperinsulinemia. Also, no studies are available on the effect of B(a)P on the NRF2 transcription factor, a master switch that regulates an antioxidant pathway. We may find that the susceptibility-exposure paradigm inherent to the present study causes up-regulation of several or all antioxidant genes in response to Nrf2. Thus, despite dysregulation of glutamate homeostasis and ROS production, gross morphological alterations may be absent. Furthermore, it should be considered that the lack of change in total cell numbers would not take into consideration a more subtle change in cellular migration patterns and synaptogenesis in $Cpr^{lox/lox}$ offspring exposed *in utero* to a beno(a)pyrene aerosol.

The present study demonstrates that *in utero* exposure to a B(a)P aerosol in a *Cpr* experimental model system results in a temporal modification of upstream Sp4 transcription factor protein expression (Figure 20.5) during a time when synapses are forming for the first time. It is likely that this response has negative effects downstream as follows: (i) Sp4 target gene–subunit ratio protein expression (NR2A, Figure 20.5); (ii) homeostatic glutamate neurotransmitter concentrations (Figure 20.4); (iii) novel object discrimination phenotype (Figure 20.6); and (iv) the magnitude of inward currents in cortical neurons (Figure 20.9). The latter finding presents the potential for pharmacological augmentation of NR2A-mediated currents at cortical synapses as a means of modulating evoked activity in a structure-specific manner. The basal glutamate concentrations obtained in our *Cpr* experimental model system are identical to recent reports in the literature for dorsal hippocampus in a 129/SvEv mice KATII KO model and for the PFC in a Wistar rat ethanol model. These findings are consistent with the concept that increases in glutamate concentration promote alteration of inward currents via NMDA receptor expression. Whether these elevated concentrations of glutamate result from modulation in the activities of vesicular, glial, or astrocyte transporters (VGluT, GLT, or GLAST) remains to be seen.

That the mPFC integrity is, in part, important for the expression of object discrimination memory is supported by several studies where hippocampal lesions per se were found not to impair object discrimination (i.e., the ability to recognize a familiar object and discriminate it from a novel object). These studies would suggest that the hippocampus is not totally required for the type of discrimination utilized in the present study. We agree that there are examples in the literature demonstrating that hippocampal lesions can impair object discrimination when the memory for the sample object includes spatial information. This is to say that when an object is presented in a complex environment with many visual and tactile cues, it appears less salient to the animal and therefore can be encoded by the hippocampus as part of this "complex" environment. Conversely, when an object is placed in an impoverished environment, it might appear highly salient and therefore can be encoded by the perirhinal cortex (for example), separate from the environment. The data from these studies may facilitate a discussion regarding the currently accepted hypotheses as to why rodents with hippocampal lesions may or may not be impaired in the object discrimination paradigm under complex but not impoverished environment conditions.

Other pharmacological studies have investigated the role of the parahippocampal glutamate receptor within the context of performance on the object discrimination task, and those results support our findings. The parahippocampal region is located dorsal to the hippocampal formation, and the evidence argues against a role of hippocampal NMDA receptors in object discrimination. In one study, intraseptal infusions of a low (0.4 mg) dose of the NMDA receptor antagonist AP-5 (D,L-2-amino-5-phosphono-pentanoic acid) improved object discrimination at a delay of 24 h, but not 45 min in rats when the dose was given either prior to or after the sample, or prior to the test trial. Another study reported that a subcutaneous (s.c.) injection of kynurenic or 5,7-dichlorokynurenic acid (antagonists at the glycine-site of the NMDA receptor) given before the sample trial in doses of 0.6 or 30 mg/kg also improved one-trial object recognition in rats at a 1 h delay. These studies argue against a crucial role for the hippocampal NMDA receptor, thereby diminishing the necessity of performing of *in vivo* microdialysis to delineate a role for glutamate in hippocampal formations within the context of performance of the object discrimination task.

It has been previously demonstrated that subacute exposure to B(a)P (0–200 mg/kg) (1 intraperitoneal injection per day for 10 days) in adult mice modulated gene expression of NMDA-NR1 subunits in brain regions highly involved in cognitive function (Grova et al., 2007). Subacute exposure to B(a)P seemed to differentially affect NMDA-R1 expression in different parts of the brain. Cerebral regions, including the temporal cortex, showed no change in expression regardless of the B(a)P dose administered. In the hippocampus, exposure to B(a)P led to a 17-fold increase in a dose-dependent manner. In the frontal cortex, mRNA expression decreased 4–35 times with increasing doses of B(a)P. The results from these subacute studies in adult mice at relatively high doses in comparison to the present study suggest a link between *in utero* exposure to B(a)P aerosol, expression of functional obligatory NMDA-R1 mRNA, and impairments in short-term and spatial memory.

We know that postnatal brain development requires experience-dependent input that can induce the release of glutamate and thereby promote critical aspects of synaptic

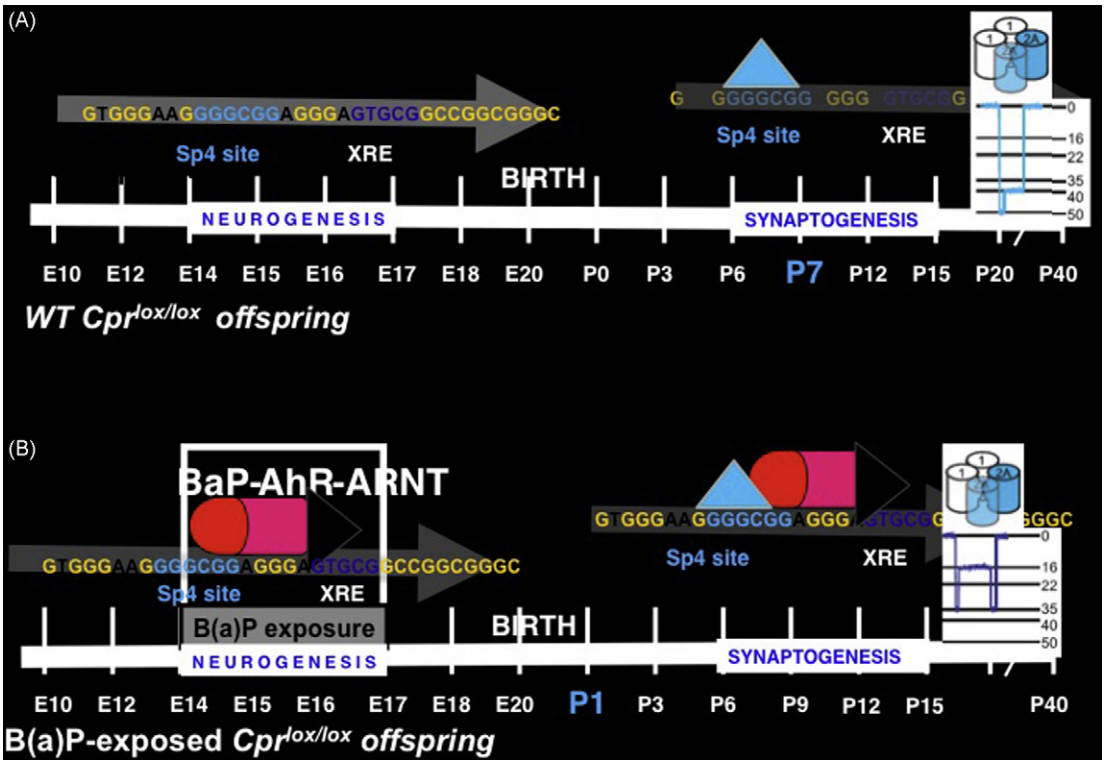

FIGURE 20.10 (A) Normal glutamate and NMDA-NR2A homeostasis. (B) Dysregulated (elevated) cortical glutamate and NMDA-NR2A homeostasis. (A) Normal temporal activation of Sp4 expression and of its target genes during embryonic development in timed-pregnant control $Cpr^{lox/lox}$ dams is depicted from E10-E20 (birth). During the early postnatal period, the Sp4 target gene-NR2A facilitates in establishing constitutive NMDA-NR2A-driven cortical currents. This occurs during the *critical period of synapse formation* (P7-P15) and contributes to a normal object recognition/discrimination phenotype in $Cpr^{lox/lox}$ offspring. (B) Premature activation of Sp4 expression and of its target gene, NR2A occurs subsequent to *in utero* exposure of timed-pregnant $Cpr^{lox/lox}$ dams to B(a)P in aerosol. During the early postnatal period in exposed $Cpr^{lox/lox}$ offspring, dysregulated Sp4 and target gene expression results in upregulated NMDA-NR2A-driven cortical currents. This occurs during the *critical period of synapse formation* when NR2A-NR2B subunit ratios are altered (P7-P15) thus contributing to an impaired object recognition/discrimination phenotype in exposed $Cpr^{lox/lox}$ offspring.

maturation. It is during this process of postnatal synaptogenesis that the effects of *in utero* B(a)P exposure on neural activity are most likely to alter the expression of genes, each with its unique temporal expression profile. In neurons of the neonatal brain, NR2A mRNA progressively increases during development and is dependent upon synaptic activity (Cull-Candy et al., 2001). In sensory pathways, Philpot et al. (2001) showed that the developmental shift from NR2B to NR2A can be postponed by sensory deprivation (Philpot et al., 2001). Studies such as these have predicted whether an alteration in the biophysical or molecular properties of NMDA receptors (NMDARs) from insertion of NR2A, loss of the NR2B, or both, places upper-limit constraints on the length of the critical period with respect to neural activity and experience-dependent fine-tuning of certain circuits.

A recent study by Zhou et al. (2007) reported on postnatal development of the hippocampus in the complete absence of the Sp4 gene. Notable observations were that the dentate granule cell precursors appeared to divide less during postnatal development in Sp4 *null* mice. Dentate granule cells from Sp4 *null* mice displayed less dendritic growth and arborization than those from wild-type mice placed into primary neuronal cultures. Additionally, Sp4 *null* mutant adult mice displayed both decreased neuronal cell density in the dentate granule layer and presented with a smaller dentate gyrus. The dentate gyrus is the primary gateway for hippocampal trisynaptic circuits to process the information received from the entorhinal cortex. The overall conclusion from this Sp4 *null* report is that abnormalities in circuitry exist in the *null* mouse characterized by a reduced hippocampal volume, representing a significant risk factor for some neurobehavioral deficit disorders. Collectively, results from genome-wide analyses predict an overlap of Sp protein transcription factor family members with the AhR network, and the Grin family of ionotropic glutamate receptor subunits (e.g., NR2A). Earlier studies have reported that knockdown of the transcription factor Sp4 in mice leads to increased numbers of highly branched dendrites during the maturation of cortical neurons in primary neuronal cultures (Ramos et al.,

2007). The results from this report suggest that the Sp4 transcription factor likely controls dendritic patterning during development by limiting branch formation and by promoting activity-dependent pruning during a time when synapses are forming for the first time.

The signaling events that regulate deactivation kinetics for the establishment of fast synapses are preceded by changes in the subunit composition of the NMDA receptor at the synapse. This occurs during the postnatal critical switch period and is represented by the preweaning, postnatal period from P1–P14. Results from a study by Brigman et al. (2008) illustrate the principle that NMDA receptor subunit proteins mediate certain forms of synaptic plasticity and learning. A touch-screen system was used to assess spatial discrimination learning in an NR2A subunit protein knockout (KO) mouse (Brigman et al., 2008). The study found that NR2A KO mice exhibited a significantly retarded discrimination learning pattern, supporting the currently accepted hypothesis that relative increases in the NR2A subunit protein during development ultimately serve to stabilize memories by constraining excessive synaptic plasticity.

Alternatively, NR2B-containing NMDARs appear to be the dominant form found during development, and their activity can initiate anatomical and functional plasticity, including LTP (Feldman and Knudsen, 1998). Paradoxically, NR2B does not contain GC-box elements within the 5′ promoter region, suggesting a potential mechanism for regulation of NR2A by the Sp4 transcription factor during the time when synapses are developing (Figure 20.10). The rationale for the Sp4 transcription factor and its target genes as viable targets for B(a)P exposure–induced modulation during critical periods of development, is based on the identification of canonical xenobiotic responsive element consensus sequences and GC-box elements within the 5′ promoter region (Figure 20.11A). This is thought to render this gene and its target genes susceptible to modulation by B(a)P during critical phases of development. Figure 20.11B shows the 5′ promoter region of the GRIN2B (NR2B) gene, which contains a single Sp4 binding site (GC box) and no xenobiotic response element (XRE) sequence in its 5′ promoter. The NR2B gene, however, does have seven XRE sequences in its 5′UTR (Figure 20.11B). Due to the absence of canonical XRE sequences and multiple GC-box elements in the 5′ promoter region, NR2B would not be classified as an Sp4 target gene. Conversely, the GRIN2A gene (NR2A) contains two Sp4 binding sites (GC-boxes) and six XRE sequences in its 5′ promoter (three in a forward orientation and three in a reverse orientation) (Figure 20.11C). There are two additional XRE sequences in the ORF of GRIN2A (one forward and one reverse), as is shown in Figure 20.11C. The NR2A receptor subunit thus qualifies as a Sp4 target gene and has been reported as such (Liu et al., 2003).

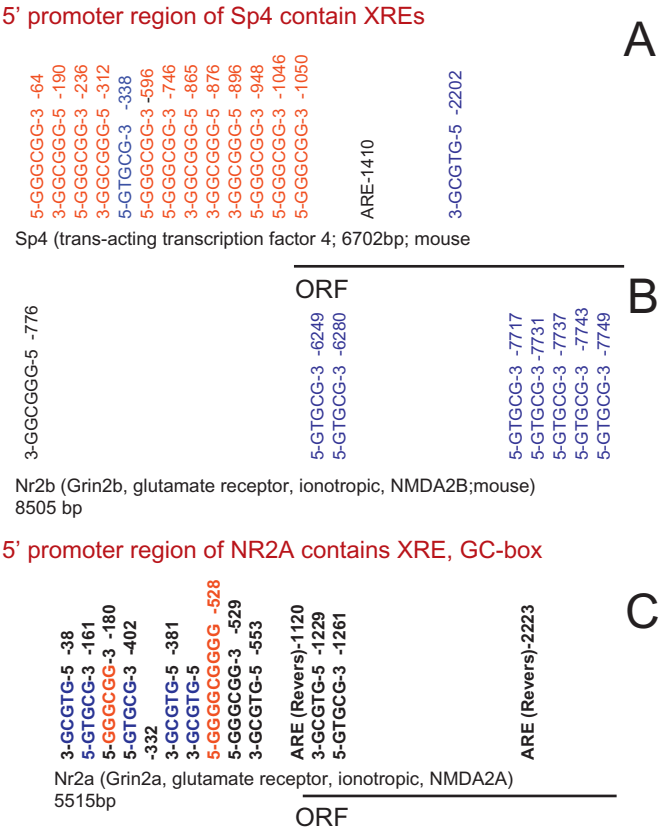

FIGURE 20.11 Promoter analyses for canonical XRE and GC-box consensus sequence requirements in Sp4 target gene versus nontarget genes. (A) Core Sp4 promoter; (B) Core GRIN2B (NR2B) promoter; (C) Core GRIN2A (NR2A) promoter. *Blue*—XRE, xenobiotic response element; *Red*—GC box/Sp4-binding site; *Black*—ARE, antioxidant response element.

Clearly, the novel object discrimination task is sensitive enough to detect deficits in response to object discrimination that are reflective of learning and memory impairments. PAH aerosol–induced negative modulation in the temporal developmental expression of Sp4 demonstrates a particular sensitivity to environmental exposure during a critical period of development. Studies in the immediate future will seek to elucidate the functional changes and mechanisms undergirding alterations in Sp4 target gene-driven neural activity (NMDA NR2A-mediated) and plasticity using our *Cpr*-null model. Translating these new concepts into animal studies offers the promise of advancing our ability to establish the presently absent mechanistic connections between exposure-induced diseased phenotypes, due to disturbances in temporal expression patterns during critical windows of development. In order for significant advances in the field to come to fruition, molecular-level hypotheses of *in utero* air pollution exposure effects on later-life phenotypes must continue to be investigated by multidisciplinary teams.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The research described in this chapter represents the contribution toward leading the development of novel methodology to systematically discover and develop therapeutic glutamate receptor/aryl hydrocarbon receptor antagonists that will mitigate the neurotoxicity associated with *in utero* exposure to B(a)P aerosol. A fundamental premise of future research takes into account the need for simultaneous temporal measurements, and integrative physiological analysis of critical signaling processes, to better understand the mechanisms of PAH exposure–induced neurotoxicity. Future experiments should also define the signatures of PAH exposure–induced neurotoxicity and novel therapeutics/protectants in experimental model systems.

CHAPTER

21

Carbon Monoxide: From Public Health Risk to Painless Killer

Daya R. Varma, Shree Mulay and Sylvain Chemtob

Carbon monoxide causes more health problems and death every year than any other poison or many together.

Lewin (1920) Translation from German, Pankow (2000)

INTRODUCTION

Colorless carbon monoxide (CO) is everywhere. Wherever there is combustion there is CO; it is the predominant product above 800°C. The concentration of CO might vary from 0.1 ppm in clean atmosphere to 5,000 ppm in the proximity of domestic wood fire chimneys (Fawcett et al., 1992) and is present in significant quantities in cigarette smoke (Hartridge, 1920; Hoffmann et al., 2001). The atmospheric lifetime of CO is 1–2 months, which allows its intercontinental transport (Akimoto, 2003).

The universal presence and unsuspecting inhalation of CO make it the most common source of poisoning in the modern world and the leading cause of unnatural death in the United States. However, CO is not on the list of chemicals used as chemical weapons in wars (Elsayed and Salem, 2006), although there are reports that the Nazis used CO gas against Jewish people during 1941 because CO was cheaper than bullets.

Mysterious illnesses, strange visions, and inexplicable deaths of entire households, generally attributed to haunted houses, are most likely due to malfunctioning chimneys, resulting in carbon monoxide poisoning. Even nonlethal concentrations of CO can exert dramatic effects in the presence of preexisting cardiac diseases. Continued exposure to relatively high, yet nonlethal, concentrations of CO can adversely affect a pregnant woman and her fetus. CO is a contributory factor in the adverse effects of smoking (United Nations Environment Program and WHO, 1979; Akrawi and Benumof, 1997); moreover, smokers occasionally set the entire home on fire, producing excessive quantities of CO (Sacks and Nelson, 1994).

CO is also endogenously generated. CO is a bit like other endogenous gases of great physiological and pathological significance such as O_2, NO, and hydrogen sulfide (H_2S). CO also shares some properties with hydrogen cyanide (HCN) in that both produce hypoxia.

Given the toxicological and epidemiological importance of CO, it has been the subject of several books and monographs since 1920 (Lewin, 1920; Hamilton, 1921; Nicloux, 1925; Drinker, 1938; Flandin and Guillemin, 1942; Von Oettingen, 1944; Grut, 1949; Raymond and Vallaud, 1950; Cooper, 1966; Bour and Ledingham, 1967; Gras, 1967; Bouletreau, 1970; Putz et al., 1976; Coburn et al., 1977; Buchwald et al., 1979; Tiunov and Kustov, 1980; Pankow, 1981; Shephard, 1983; Jain, 1990; Penny, 1996; IPCS, 1999; Mannaioni et al., 2006). CO has also been a subject of numerous reviews, some of which are referred to here (Beck, 1927; Killick, 1940; Lilienthal, 1950; Pugh, 1959; Root, 1965; Goldsmith and Landow, 1968; Fenn, 1970; Lawther, 1975; Winter and Miller, 1976; Morandi and Eisenbud, 1980; Thom and Keim, 1989; Penny, 1990; Ernst and Zibrak, 1998; Von Berg, 1999; Weaver, 1999; Blumenthal, 2001; Piantadosi, 2002; Gorman et al., 2003; Ryter and Otterbein, 2004; Kao and Nanagas, 2006; McGrath, 2006; Raub et al., 2006; Prockop and Chichkova, 2007).

During the past 20 years, however, the attention of researchers has shifted from the toxicity of CO to its physiological role (Snyder and Ferris, 2000; Wu and Wang, 2005). As a result, the toxicity of CO is sometimes not mentioned as much as it should be. For example, the

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00021-X

first edition of the textbook *The Pharmacological Basis of Therapeutics* by Louis Goodman and Alfred Gilman published in 1941 (MacMillan, New York) devoted five and one-quarter pages to carbon monoxide; the 11th edition of the same book edited by L.L. Brunton, J.H. Lazo, and K.L. Parker and published in 2006 (McGraw-Hill) mentions nothing under the heading of carbon monoxide; the term "carbon monoxide" appears only in relation to the therapeutic uses of oxygen. Similarly, the *Pharmacological Reviews* had the subject reviewed twice—first in 1950 (Lilienthal, 1950), when CO was known for its toxicity, and then 55 years later (Wu and Wang, 2005), but only dealing with its physiological role.

The pharmacology of CO spans a broad spectrum, from public health risk to endogenous modulator of important biochemical events to lethal poison. Given the theme of this book, this chapter mainly focuses on the toxicology of CO. However, for the sake of completeness, physiological roles of endogenous CO are also presented. CO relates to all forms of life; however, its roles in microorganisms (Frankland, 1927) and plants (Wilks, 1959; IPCS, 1999; Muramoto et al., 2002; K. Liu et al., 2007; Han et al., 2008) are not covered in this chapter.

HISTORICAL BACKGROUND

An adequate amount was known about carbon monoxide at the beginning of the twentieth century. Haldane (1922) devoted 14 pages to the history of carbon monoxide in his book titled *Respiration*; it occupied almost the same number of pages in the second edition 13 years later (Haldane and Priestley, 1935). An excellent description of the history of CO is contained in an article by Pankow (2000). Because most of the pioneering work regarding CO was performed in Germany, and because Pankow is based in Halle, Germany, he has been able to do justice to the celebrated first book about CO by Lewin (1920) and other related literature. There is another book called *Carbon Monoxide: The Silent Killer* by the University of Toronto Professor Roy J. Shephard. The title contains every ingredient of the history and toxicology of this mysterious poison—not invented by humans but made by nature itself, like arsenic or cobra venom.

CO has always been a part of the universe. However, atmospheric CO has increased over time. When volcanoes erupted, continents collided, and winds embraced the trees sparking fires millions of years ago, all this contributed to the stock of CO. However, when CO first made a significant presence in the air we breathe, humans lived in the open. A very long time must have passed by before humans inhabited caves or built enclosures for protection from the effects of the weather or the tyranny of predators. In the process, however, humankind invited the unwanted guest—carbon monoxide, the silent killer. So where there is smoke, there is not only fire but also CO; in terms of human cost, the latter is more dangerous than the former. However, it must have taken several thousands of years to tame the fire, and over those years CO has claimed many innocent victims who went to sleep after a hearty meal, never to wake up. The knowledge of these mysterious events has been unraveled over time.

Just as concoctions of cinchona, bark of willow, and leaves of the common foxglove plant were used during ancient times without knowing that they contained, respectively, quinine, aspirin, or digoxin, so is the story of CO. The toxicity of CO was recorded by Aristotle (384–322 BC) in the third century BC; by the first century BC, charcoal fumes were used for suicide and executions without any knowledge of the exact nature of the killer (Lewin, 1920; Shephard, 1983). Byzantine emperor Julian the Apostate and his successor, Jovian, were poisoned in AD 363 and 364, respectively, because coal was used to heat their braziers (Lascaratos and Marketos, 1998).

The industrial revolution in Britain and Europe and the discovery of the New World introduced coal for domestic heating and cooking. In 1700, Bernardino Ramazzini (1633–1714), a physician and professor at the University of Modena, published the book *De Morbis Arteficium Diatriba* (*Diseases of Workers*), which was translated from the original Latin text into Italian, French, German, English, and Dutch. Ramazzini recognized that fumes from burning coal by confectioners caused headache and dyspnea, and miners encountered "noxious vapors;" burning coals, unless vented out, could "kill a man on the instant" (Shephard, 1983; Pankow, 2000).

In their review, Prockop and Chichkova (2007) wrote "CO was first prepared by the French chemist de Lassone in 1716. Because it burned with a blue flame, de Lassone thought it to be hydrogen." In his book *Carbon Monoxide: The Silent Killer* (page 7), Shephard (1983) attributes this episode to the illustrious British chemist Joseph Priestley (1733–1804) who mistook this "noxious vapor" for hydrogen for the same reason—it burned with a bright blue flame. However, both Prockop and Chichkova (2007) and Shephard (1983) agree that the identity of this noxious vapor was evaded until Cruikshank demonstrated that the gas that burned with the blue flame was an oxide of carbon (CO) that could be converted into a dioxide of carbon (CO_2) by exploding it with oxygen.

Because the cause of CO poisoning that often resulted in death was unknown, myths emerged. Friedrich Hoffmann (1660–1742) of Halle, Germany, recounts that two farmers and a student used charcoal fire on a Christmas night. The farmers died and the student was found very sick; theologians, who claim to possess great knowledge, opined that it was a divine curse (Pankow, 2000).

French physiologist Claude Bernard (1857) was perhaps the first to describe the toxicity of carbon monoxide. In 1846, he forced a dog to inhale CO; of course, the dog

died and on autopsy he noted that the blood was crimson in color in all the heart chambers as well as in the veins (Bernard, 1865). Claude Bernard correctly assumed that the crimson color was due to excess of oxygen in the blood. It was left to the celebrated British physiologist J.S. Haldane (1860–1936), to whom this chapter is dedicated, to identify carboxyhemoglobin (COHb) and determine its chemical nature (Haldane, 1895a).

By the end of the nineteenth century, Haldane had not only described the effects of exposure to various concentrations of CO on himself and mice but also discovered that the symptoms of CO poisoning could be alleviated by oxygen (Haldane, 1895a; Haldane and Priestley, 1935), which remains the most effective antidote against CO toxicity to date (Sluijter, 1967; Tibbles and Edelsberg, 1996). Haldane (1895a) also noted that "symptoms of poisoning occur far more rapidly in mice than in man [himself]" because the relationship of the body mass to surface area is such that the mouse "produces [CO] in an hour 10 grams per kilo body weight, while man produces only about half a gramme." Haldane was the first to use mice for the detection of CO in mines until canaries took over this service in 1921. By 1987, chemical methods for the detection of CO replaced the fate of the canaries.

Haldane worked out the physical chemistry of the CO–hemoglobin interaction. His first law states: "When a solution containing hemoglobin is saturated with a gas mixture containing O_2 and CO the relative proportions of the haemoglobin which enters into combination with the two gases are proportional to the relative partial pressures of the two gases, allowing for the fact that the affinity of CO for hemoglobin is about 3 times greater than that of O_2." This law is valid today; however, Haldane underestimated the affinity of CO for hemoglobin.

EPIDEMIOLOGICAL CONSIDERATIONS

Morbidity and mortality from CO poisoning vary from country to country because of the different standards of surveillance, extent of urbanization, housing conditions, source of energy, and so on. The major source of CO in the modern era is from the burning of petrol gas. Naturally, megacities with a population of more than 10 million have a much higher level of atmospheric CO than smaller cities and rural areas.

Demography is changing rapidly in many countries, especially in the two countries with populations of more than one billion each—China and India. With surging economies in both countries, the number of automobiles is fast increasing. In China, for example, the number of automobiles has been increasing at a rate of 13% per year since the 1980s; there were 18–21 million automobiles in China in 2000 compared with 11 million barely 3 years earlier in 1997. It is estimated that 3,000 kg of CO is discharged from every 1,000 automobiles each day (Chen and Wang, 2000).

In most countries, CO accounts for the maximum number of unintentional deaths in peace time. The estimated annual number of emergency admissions due to unintentional CO poisoning is approximately 40,000 in the United States (Weaver, 1999), 5,000–8,000 in France (Annane et al., 2001), 6,000 in Italy (Gandini et al., 2005), and 523 in Poland (Sokal and Pach, 2000). Annual unintentional deaths from CO poisoning are approximately 600 in the United States (Cobb and Etzel, 1991) and 1,500 in the United Kingdom (Hamilton-Farrel and Henry, 2000).

Atmospheric CO is related to human civilization; consequently, its concentration varies markedly from east to west and from south to north. Also, CO in the atmosphere varies greatly within different regions of the same country, denoting uneven industrialization. To highlight these variables, we deal with this subject under two separate headings—the external source and the endogenous source of CO. Details can be found in an excellent article by Vreman et al. (2000).

It is common knowledge that death due to CO poisoning is painless. The generation of CO in an enclosed space is also well-known. Consequently, CO poisoning has emerged as the method of choice for suicides in favor of hanging and firearms.

TOXICOKINETICS AND TOXICODYNAMICS

Sources of CO

There are two main sources of CO, exogenous and endogenous. Although the atmospheric CO is the principal cause of CO toxicity, the endogenous source is physiologically very important (Marks et al., 1991; Maines, 1997; Wu and Wang, 2005) and, under certain conditions, may even become pathological (Nezhat et al., 1996).

External Sources of CO

Carbon monoxide is a product of incomplete combustion as encountered in the operation of vehicles, heating, coal power generation, and biomass burning (Godish, 2003). Natural geographical events such as volcanic eruptions, emission of natural gases, degradation of vegetation and animals, and forest fires all contribute to atmospheric CO. Approximately 40% of global CO comes from these natural sources. Human intervention such as fossil fuel consumption, garbage disposal, tobacco smoke, and charcoal fires contribute to the remaining 60% of global CO (Jain, 1990; Vreman

et al., 2000). Because human activity and density differ from place to place because of socioeconomic factors, atmospheric CO varies greatly from place to place. CO emission in the United States in 2001 was 120.8 million short tons, of which 74.8 million came from on-road vehicles (McGrath, 2006).

Apart from various other changes, the developing countries are characterized by increasing migration of rural population to slums and shanty towns on the outskirts of cities like São Paulo, Mexico, Johannesburg, Mumbai, Shanghai, and others; this is associated with, among other things, an increase in atmospheric CO. Fortunately, atmospheric CO has not exceeded safety levels globally or in any specific areas, including, for example, Mexico City and Los Angeles, but it can. It is reassuring that many efforts are being made by government agencies to reduce CO emissions.

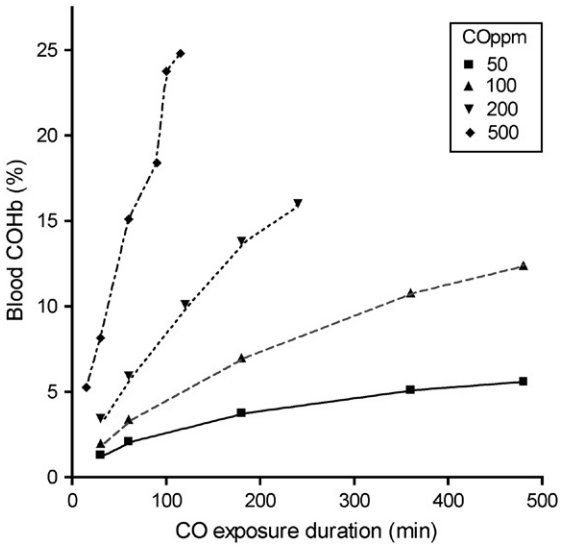

FIGURE 21.1 Relationship between the duration of exposure to different concentrations of carbon monoxide and blood carboxyhemoglobin (COHb) in healthy volunteers. The plot is based on the data of Stewart and Peterson (1970).

Endogenous Sources of CO

The knowledge that CO is normally present in the body dates back to 1894, when Grehant (1894) detected a combustible gas in blood. By 1898, this combustible gas was suspected to be carbon monoxide (De Saint-Martin, 1898; Nicloux, 1898). At the time, methods did not exist to ascertain if the CO in the blood was generated inside the body or if it was derived from the air. It was not until 1949 that the evidence for endogenous production of CO was firmly established (Sjorstrand, 1949). Tenhunen et al. (1968, 1969, 1970) elaborated on the role of heme oxygenase in the generation of CO.

The major source of endogenous CO in a healthy individual is from the degradation of heme by heme oxygenase (HO)—HO-1 and HO-2. The enzyme HO-1 is inducible and HO-2 is constitutive; heme oxygenase degrades heme into CO and biliverdin, and the latter is rapidly converted into bilirubin (Coburn et al., 1963, 1967; Coburn, 1979; Mores and Sethi, 2002). Current literature emphasizes only a physiological role for endogenously generated CO (Choi and Otterbein, 2002; Boehning and Snyder, 2003; Ryter and Otterben, 2004; Wu and Wang, 2005; Mannaioni et al., 2006), although it is quite likely that it could add to the toxicity of inhaled CO.

Heme oxygenase is the rate-limiting step in the production of CO and its activities account for 86% of endogenous CO production. The remaining 14% is derived from nonheme sources. The lifespan of red blood cells is approximately 120 days. The older the erythrocyte, the greater is its CO output. In neonates, red blood cells have a shorter lifespan and, relative to erythrocytes of adults, they produce two- to three-times more CO (Fallstrom, 1968). HO-2 is activated during neuronal stimulation by phosphorylation by the enzyme CK2 (Boehning et al., 2003).

The rate of COHb formation is a function of inhaled CO concentration and duration (Figure 21.1). The rate of CO production and excretion parallels the rate of bilirubin production; hence, a measurement of COHb serves as a measure of heme degradation and bilirubin production. A measurement of end-tidal CO in breath corrected for inhaled CO is used as a measure of assessing infants at risk for severe hyperbilirubinemia because CO and bilirubin are produced in equimolar amounts (Bartoletti et al., 1979).

A small fraction (20%) of endogenous CO is derived from other hemoproteins such as myoglobin and many other iron-containing enzymes (Coburn, 1970; Vreman et al., 2000). This serves as an example of the use of endogenous CO monitoring for diagnostic purposes.

In addition to the major exogenous and endogenous sources of CO described, certain medical procedures within the body can also generate CO. For example, laser and bipolar electrocautery during laparoscopy can generate more than 200 ppm CO in the body cavity, which finds its way into the circulation, increasing COHb levels (Wu et al., 1998) sufficient to induce toxicity (Nezhat et al., 1996). Anesthetic machines equipped with drying material like soda lime or barium hydroxide were found to generate CO (Moon et al., 1992; Baum et al., 1995) from several anesthetic agents (Fang et al., 1995). Likewise pulmonary function tests based on determining the CO diffusion capacity as a means of determining the alveolar-capillary diffusion capacity for gases can also elevate CO and, in turn, COHb (Vreman et al., 2000).

TABLE 21.1 Physicochemical Properties of Carbon Monoxide

Property	Description
Chemical structure	
Molecular weight	28.01
Critical point	−140°C at 3,495 kPa
Melting point	−199°C
Boiling point	−191.5°C
Fundamental vibration transition	2143.3 cm^{-1} (4.67 μm)
Density at 25°C, 101.3 kPa	1.145 g/L
Specific gravity relative to air	0.967
Solubility in water at 0°C	35.4 mL/L
Solubility in water at 25°C	21.4 mL/L
Explosive limit in air	12.5–74.2%

Physicochemical Properties of CO

CO is a colorless, odorless, tasteless, noncorrosive, stable diatomic molecule in the atmosphere. Unlike hydrogen peroxide (H_2O_2) or superoxide ($O^{\bullet}$), CO is not a radical. CO has low water solubility and negligible quantities dissolve in blood at normally encountered pressure (Shephard, 1983). CO has a shorter inter-atomic distance (~1.13 Å) than would be anticipated for a single bond. It has high-heat formation from the constituent atoms (bond strength 2.07 MJ/mol) and the electric charge is distributed rather uniformly between the carbon and oxygen atoms. Pauling (1960) postulated that under normal circumstances CO existed as a hybrid containing approximately equal proportions of three structures. According to the modern atomic theory, carbon atoms have the first shell filled with two electrons in S orbitals, whereas the second shell contains two electrons in the S orbital and two in the P orbital (Shephard, 1983). The general properties of CO are presented in Table 21.1.

Methods for CO Measurement

Appropriate techniques exist for the quantitation of CO in gaseous samples and tissue samples. In either case, caution needs to be exercised to ensure that CO concentration is not altered by interaction with the sample vessel during storage and transport. For example, Vacutainer tubes were found to greatly alter CO levels when used for storage of blood samples (Vreman et al., 1984). Furthermore, routine monitoring of air for public health requires a simple and yet reliable sample collecting system. Ambient CO levels at the workplace can be very low, requiring sensitive analytical techniques. With the recognition of the hazardous nature of CO and its almost universal presence, several sophisticated methods for quantifying CO have been developed (IPCS, 1999; Vreman et al., 2000).

Measurement of Blood CO

Haldane (1895b) wrote: "In view of the very poisonous nature of carbonic oxide, and the comparative frequency with which cases of poisoning by this gas occur, much attention has been given to its detection and estimation…The method now to be described is very simple, and depends on the fact that when a hemoglobin solution is well shaken with air containing carbonic oxide and the proportion of hemoglobin, which finally combines with carbonic oxide, varies with the percentage of carbonic oxide in the air. By determining colorimetrically the proportion of the hemoglobin which has combined with the carbonic oxide it is thus possible to infer the percentage of carbonic acid in the air."

"The bottle containing the blood solution and sample air must be covered with a cloth during the process of shaking, and (although this is by no means so important) very bright light should be avoided during the process of titration with the carmine solution" (Haldane, 1896).

The currently used method of quantifying blood CO and the precaution that is needed for accuracy are simply refinements of the method described by Haldane (1895b, 1896) more than a century ago; colorimetric detection was soon replaced by the spectroscopic detection method (Hartridge, 1912) and has undergone further sophistication since then. Both gas chromatography and spectrophotometry are considered appropriate, although the former is favored (Coburn et al., 1964; Collison et al., 1968; Vreman et al., 1984, 1998; Kane, 1985; Constantino et al., 1986). However, blood CO is still measured by determining COHb levels, which are normally undetectable but might be involved in the transfer of CO between cells. The measurement of COHb is useful not only in the quantification of CO but also to detect neonatal hemolysis (Necheles et al., 1976; Ostrander et al., 1982).

COHb is quite stable and its concentration does not change over a long period (up to 6 months) if the blood sample is stored in the dark and under sterile conditions. Blood levels of COHb are not expected to exceed 5% at ambient levels of CO. IPCS (1999) focuses on methods that can accurately measure COHb less than 10%. A method that simply requires finger-prick blood is convenient for mass screening and is described in detail by Commins and Lawther (1965). In this method, the sample is diluted in ammonia solution, which is divided into two parts; from one of these, CO is displaced by oxygen and the COHb-containing part is placed in the sample beam of a spectrophotometer, so that the instrument records the difference between the absorbance of COHb and oxyhemoglobin.

Several techniques for measuring COHb exist (IPCS, 1999). The sensitive techniques require the release of CO from hemoglobin into a gas phase. CO can then be detected directly by a number of methods such as infrared absorption, difference in thermal conductivity between CO and the carrier gas, amount of ionization after conversion of CO to methane, or the release of mercury vapor resulting from interaction of CO with mercuric oxide.

The conventional method of expressing CO in blood samples is as percent COHb, and it is determined by a formula where CO content is the CO concentration in mL/100 mL blood, Hb is hemoglobin in g/100 mL blood, and 1.389 is the combining capacity of CO for Hb in mL of CO per gram Hb.

The blood level of COHb as a percent of total hemoglobin is directly related to the exposure duration at any concentration of CO (Figure 21.1).

Blood COHb measurements have been used to monitor exposure of populations to atmospheric CO, which also functions as a measure of air pollution. Using this approach, New Hampshire, Vermont, and the city of St Louis (Missouri) were found to have blood COHb levels in the range 1–1.5% in the early 1970s (Davis and Ganter, 1974; Kahn et al., 1974).

Ambient Air CO

Because CO concentrations in ambient air and at workplaces are usually quite low, reliable methods for sample collection and transport as well as highly sensitive methods for measurement are needed (Smith and Nelson, 1973; IPCS, 1999). The sampling method recommended by WHO (IPCS, 1999) comprises a sample introduction system consisting of a sampling probe, an intake manifold, tubing, and air remover. Known gas concentration is periodically collected to verify the method.

According to IPCS (1999), the analyzer system consists of an analyzer as well as sample preconditioning components fitted with a moisture-control system such as the nondispersive infrared (NDIR) analyzer. The infrared absorption near 4.6 μm, characteristic of CO, is used to measure its concentration. The most sensitive analyzers can detect CO concentrations as low as 0.05 mg/m^3 (0.044 ppm). The NDIR analyzer designed by Luft (1962) is considered appropriate because it is little affected by flow rate, requires no wet chemicals, has a short response time, and is sensitive over wide concentration ranges.

Other analyzers include gas chromatography, which is a sensitive, automated, and semi-continuous technique in which CO is separated from water, CO_2, and hydrocarbons (other than methane) by a stripper column and CO is passed through a catalytic reduction tube where it is converted to methane. The converted CO is passed through a flame ionization detector; its sensitivity range is 0.026–43.7 ppm (IPCS, 1999). Other methods such as small personal exposure monitors can measure CO concentrations on a continuous basis and store data on internal digital memories (Ott et al., 1986).

Home Detectors

Residential CO detectors are designed like smoke detectors and provide protection from excessive CO concentrations inside homes by sounding alarms. They are based on an interactive-type sensor, such as tin oxide, artificial Hb that relies on an interaction between CO, and the sensitive element to generate an alarm. The alternate current–powered home detectors have a metallic sensor that reacts with CO. The battery-powered ones have a chemically treated gel that darkens on exposure to CO. They are designed to sound the alarm within 90 min at CO concentrations of 100 ppm, within 35 min at 200 ppm, or within 15 min at 400 ppm (IPCS, 1999). CO concentration of 400 ppm can increase COHb to 10%, and CO toxicity is observed at levels higher than 10%.

CO in Expired Breath

Measurement of CO in the expired breath is based on the assumption that CO in alveolar air is in equilibrium with the partial pressure of CO in blood, which, in turn, is in equilibrium with CO bound to Hb, that is COHb (Douglas et al., 1912).

Absorption, Distribution, and Elimination of CO

Atmospheric carbon monoxide can travel thousands of kilometers from its source and has a half-life of 1–2 months (Akimoto, 2003). Although the biological effects of CO differ depending on whether it is inhaled or endogenously produced, the ultimate fate of CO is the same regardless of its source.

Exogenous CO reaches the body solely by pulmonary absorption. Once inhaled, CO combines reversibly with hemoglobin and, to a smaller extent, with myoglobin and other iron-containing macromolecules. Because most of the CO in the body is bound to hemoglobin, the relative affinities of CO and oxygen for hemoglobin are of critical significance in terms of both its toxicity and excretion. This relationship was first described by Haldane (1922) in what is known as Haldane's first law, represented by an equation where M is the affinity constant, thought to be between 208 and 245 at 37°C, and PCO and PO_2 are the partial pressures of CO and oxygen, respectively.

Haldane had conducted the experiments on himself and found that he needed to inhale 0.07% CO in the air containing 20.9% oxygen for Hb to achieve 50% oxygen and 50% CO saturation. On this basis, he calculated the relative affinities of CO and oxygen for Hb as 1.299. Although more refined techniques have estimated the affinity of CO for Hb to be much higher (Sendroy

and Liu, 1930; Roughton and Darling, 1944; Ernst and Zibrak, 1998), the fundamental relationship proposed by Haldane (1922) remains valid and has been discussed in detail by others (Forster, 1970; Roughton, 1970). This relationship between CO, oxygen, and hemoglobin explains both the high toxic potential of CO and the need of hyperbaric oxygen to treat CO overdose (Pace et al., 1950; Peterson and Stewart, 1970; Jay and McKindley, 1997).

Under normal physiological states there is almost always a certain amount of COHb even when breathing CO-free air, because the breakdown of Hb results in endogenous production of CO, which can result in 0.5–0.8% COHb in normal blood (Lawther, 1975). At any CO concentration in the air, COHb will attain an equilibrium (16% at 100 ppm ambient CO and 1.7% at 10 ppm CO). It follows that if CO in the air is lower than that required for a given COHb % at equilibrium, then CO will leave COHb and be exhaled until a new equilibrium is established. This has practical implications. For example, a smoker with a relatively high COHb at equilibrium may exhale CO. Also, if the basal COHb is high, then an equilibrium at a high CO concentration in the air will be achieved more quickly than it would be at an initial low COHb.

The reaction of CO with ferrous iron is relevant to its pharmacology. Shephard (1983) provides the following description of this reaction. When reacting with ferrous iron, carbon atoms of CO form a sigma bond, also involving a D-orbital electron from the third shell of Fe^{2+}. In the body, Fe^{2+} also has four nitrogen linkages that contribute a substantial electron density. The effective valency is less than Fe^{2+}, enabling a more readily reversible reaction with both oxygen and carbon monoxide. The solubility of CO in water is approximately 20% less than that of O_2, such that it is practically absent from the solution in blood.

Reaction of CO with hydroxyl radicals ($OH^{\bullet}$) is the major method of removing CO from the atmosphere (IPCS, 1999). The cycle of hydroxyl radicals is coupled to cycles of CO, methane, water, and ozone. They are produced by the photolysis of ozone followed by the reaction of the excited oxygen atoms with water vapor to produce two hydroxyl radicals: ($O(^1D) + H_2O \rightarrow OH^{\bullet} + OH^{\bullet}$). A small proportion of atmospheric CO is removed by the soil.

Carbon monoxide is eliminated from the body almost exclusively via the lungs. When respiring room air, the elimination half-life of CO in a healthy adult is approximately 4 h, which can be reduced to 1 h when breathing oxygen at normal atmospheric pressure (Roughton and Root, 1945; Pace et al., 1950; Bartlett, 1968). High concentration of COHb can shorten the elimination half-life of CO (Haldane, 1895a; Henderson and Haggard, 1921) and low concentration can increase it (Peterson and Stewart, 1970). However, half-life for a drug is a meaningful feature only if it is not dose-independent, which is not the case with CO (Jay and McKindley, 1997).

MECHANISM OF TOXICITY

Wu and Wang (2005) chose to name endogenous CO as "Dr. Jekyll" and not "Mr. Hyde" because it is good rather than bad. If they are correct, then this mysterious gas proves more than any other agent the correctness of the dictum of Paracelsus (1493–1541) that: "All substances are poisonous. Only the dose differentiates a poison from a remedy." If Paracelsus had known about the views of Wu and Wang (2005) regarding CO, he might well have added not only the "dose" of the substance but also its source.

There are very few agents like the anticoagulant warfarin whose toxicity and therapeutic effects are produced by the same mechanism. In most cases, beneficial and harmful effects recruit different mechanisms of action. As far as CO is concerned, its mechanisms of toxic and physiological actions differ and the source from where it is derived matters, too. So, the mechanisms of action of inhaled-generated and heme-generated CO also seem to differ. Because the focus of this chapter is CO toxicity, we attempt to elaborate the mechanism of its toxicity more than the mechanism of its physiologic actions.

The French physiologist Claude Bernard (1857) and the British physiologist Haldane (1895a) inferred that the toxicity of CO was caused by its interaction with hemoglobin. In his review of carbon monoxide, Lilienthal (1950) wrote: "It has been said many times that the effect of CO on man may be attributed to two actions and, in essence, to these two actions alone: (a) occupation of the Hb molecule by CO, with a resultant decrease in the O_2 transport capacity of the blood; and (b) alteration of O_2Hb dissociation characteristic produced by COHb, with a resultant impaired unloading of O_2 at the tissues." The O_2Hb dissociation curve is shown in Figure 21.2.

Both features described by Lilienthal (1950) boil down to hypoxia as the principal mechanism of CO toxicity, thereby confirming the basic observations of Claude Bernard and J.S. Haldane made 150 years earlier, and working out details of CO–hemoglobin interaction. Haldane (1894a, 1896) knew that the affinity of CO for hemoglobin was greater than that of oxygen, even if he underestimated it. The color of COHb is red, which explains the cherry-like discoloration of CO victims. This is generally but erroneously believed to be a specific characteristic of cyanide poisoning. Obviously, any time oxygen is not fully extracted from the arterial side, the venous blood will become cherry red.

More sophisticated techniques than the ones used by Haldane have established that CO binds to hemoglobin with an affinity 200-times greater than that of oxygen

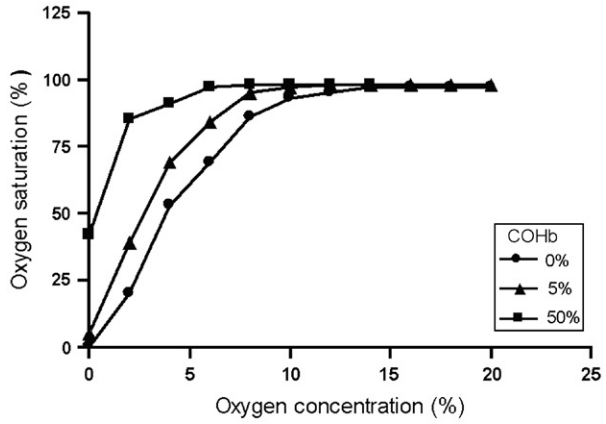

FIGURE 21.2 Effect of carboxyhemoglobin (COHb) on the shape of the oxyhemoglobin dissociation curve in healthy males. Based on the data of Haldane and Priestley (1935) as presented by Shephard (1983).

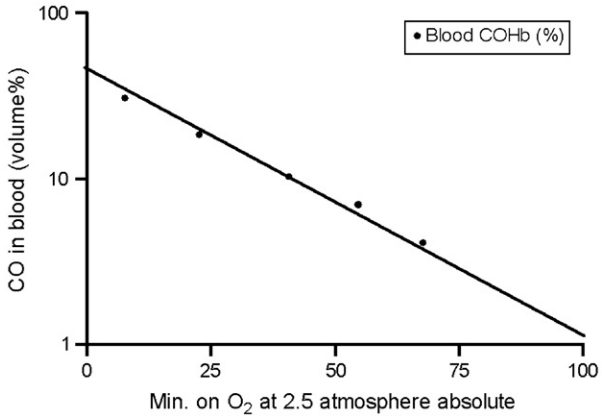

FIGURE 21.3 Data are from a healthy male volunteer who breathed a low concentration of carbon monoxide and then oxygen at 2.5 atmospheric pressure, absolute. Blood was collected at different times after starting oxygen. Data points are taken from Pace et al. (1950) and may not be exactly the same as in their figure. Each point is the mean of triplicate determination and intercept indicates CO level at time zero before oxygen therapy.

(Sendroy et al., 1930; Roughton and Darling, 1944; Ernst and Zibrak, 1998). Carbon monoxide diffuses from the alveoli to the blood in pulmonary capillaries across the alveoli–capillary membrane, which is composed of pulmonary epithelium, the capillary epithelium, and the fused basement membranes of the two. The uptake of CO by Hb is very rapid and the transfer of CO is diffusion-limited (Prockop and Chichkova, 2007).

The greater the duration of the exposure to CO, the concentration of CO in the inhaled air, and the alveolar ventilation, the greater the total amount of COHb. Although the uptake of CO by Hb is very rapid, the release of CO from COHb complex is extremely slow. Because the concentration of COHb increases, the formation of oxyhemoglobin at any concentration of oxygen in the inhaled air decreases. There is a strong case for using COHb concentration as a predictor of CO toxicity (Renwick and Walton, 2001).

There is yet another mechanism by which CO produces hypoxia. COHb shifts the dissociation curve of the remaining oxyhemoglobin to the left, which further decreases the release of oxygen (Douglas et al., 1912; Roughton and Darling, 1944), which causes headaches when it is mild and death when it is extreme. Douglas et al. (1912) also observed that "the presence of a small proportion of oxygen may greatly increase the formation of CO–haemoglobin, and *vice versa*" and this "paradoxical effect explains the favorable physiological effect sometimes produced by carbon monoxide in conditions of great anoxhaemia." The studies of Pace et al. (1950) of human volunteers demonstrated that the release of CO bound to hemoglobin and its expiration can be increased by inhalation of hyperbaric oxygen (Figure 21.3).

However, the data of Goldbaum et al. (1975, 1976) imply that formation of excess of COHb might not account for the lethal effects of CO. These researchers found that dogs breathing 13% CO died within 1 h after achieving COHb levels between 54% and 90%, but transfusion of blood containing 80% COHb, which resulted in 57–64% COHb in the recipient dog, did not cause marked toxicity. It would thus appear that the toxicity of CO results from a combination of tissue hypoxia due to COHb plus other effects of CO, which would explain why COHb levels do not always correlate with the severity of clinical effects (Myers, 1984; Norkool and Kirkpatrick, 1985; Rottman, 1991; Brown and Piantadosi, 1992).

Besides hemoglobin, CO binds to many heme-containing proteins such as myoglobin, guanylyl cyclase, and cytochrome oxidase (Chance et al., 1970; Hill, 1994; Omaye, 2002; Kao and Nanagas, 2006). However, the affinity of CO for cytochrome oxidase is very low and this interaction would require a dose far exceeding the lethal dose of CO (Prockop and Chichkova, 2007). However, even at sublethal concentrations, binding of CO to cytochrome may lead to the generation of superoxides (Zhang and Piantadosi, 1992; Hardy and Thom, 1994) and interfere with cellular respiration. Cellular metabolism remains inhibited even after COHb levels decline to normal range (Olson, 1984; Brown and Piantadosi, 1992; Piantadosi et al., 1995).

The interaction of CO with myoglobin can explain some of its toxic effects. It might impair oxygen supply to the mitochondria, which can result in myocardial ischemia. Patients with underlying cardiac conditions are therefore at high risk for cardiac arrhythmias after exposure to CO (DeBias et al., 1976; Olson, 1984; Sangalli and Bidanset, 1990) as well as chest pain and even death. A study of Swiss soldiers accidentally exposed to CO

noted a substantial number had development of chest pain some time after exposure to CO (Henz and Maeder, 2005). The interaction of CO with skeletal muscle myoglobin can cause muscle weakness (Herman et al., 1988; Wolf, 1994; Richardson et al., 2002).

Nitric oxide (NO) and NO donors as well as phosphodiesterase inhibitors increase gyanylyl cyclase and, hence, cGMP, causing marked vasodilatation. Patients using nitrates for angina are well aware that the drug may cause dizziness and loss of consciousness. CO also activates guanylyl cyclase, and there is always a possibility that the resulting hypotension and cerebral vasodilatation may lead to a loss of consciousness. It is therefore prudent to also treat an increase in cGMP as a potential toxic effect, and not only as a physiological activity of CO or proof of a neurotransmitter role for CO, as suggested by many (Verma et al., 1993; Snyder and Ferris, 2000; Wu and Wang, 2005).

Any event that leads to hypoxia can lead to reperfusion and secondary hyperoxia, especially if vascular autoregulation is not fully developed such as in premature births and certain animal models (Chemtob et al., 1991; Hardy et al., 1997, 2000). Hyperoxia leads to generation of superoxides and other radicals, which are involved in a number of pathologies (Kowluru et al., 2001; Pryor et al., 2006; Brault et al., 2007). Recent studies suggest that hypoxia caused by the formation of COHb may also be followed by reperfusion injury in addition to that produced by the initial hypoxia. The oxidants generated during reperfusion can oxidize essential proteins and nucleic acid and can cause lipid peroxidation, leading to demyelination of CNS lipids and other effects (Ernst and Zibrak, 1998; Prockop and Chichkova, 2007).

In addition, CO can promote neutrophil adhesion to the microvasculature, resulting in the activation of xanthine oxidase and generation of oxidative radicals, which ultimately culminate in brain lipid peroxidation, which is the likely cause of delayed neurological sequelae (Thom, 1990, 1993; Hardy and Thom, 1994; Thom et al., 1994, 1997, 2001; Ischiropoulos et al., 1996; Gilmer et al., 2002). The observed brain lipid peroxidation in CO poisoning is likely to be caused by changes in cerebral blood flow plus oxidative damage (Thom, 1990, 1992; Zhang and Piantadosi, 1992; Hardy and Thom, 1994; Ischiropoulos et al., 1996; Thom et al., 1997).

CO might also alter myelin basic protein, which may react with lipid peroxidation products to produce immunologic cascade (Thom et al., 2004). Other events that could contribute to CO toxicity include glutamate-induced neuronal injury (Ishimaru et al., 1992; Penny and Chen, 1996; Piantadosi et al., 1997), atherogenesis (Lightfoot, 1972; Thom et al., 1999), and apoptosis (Piantadosi et al., 1997).

The model of carbon monoxide toxicity proposed by Kao and Nanagas (2006) combines the cascade of changes resulting from three primary events—binding to HB, direct cellular injury, and increased NO activity. CO is not a radical but many of the injuries produced by it are those that are caused by oxidative stress, which is secondary to hypoxia. In the model of Kao and Nanagas (2006), the oxidant is NO, which contributes to oxidative damage to the brain and produces the clinical syndrome of delayed neurologic sequelae (Thom et al., 1997).

TOXICITY OF CARBON MONOXIDE

Acute Toxicity

All chemicals produce toxicity. However, only a few of them cause death every time if taken in overdose; carbon monoxide is one of them. The toxicity of CO has been extensively reviewed (Hamilton, 1921; Drinker, 1938; Lilienthal, 1950; Putz et al., 1976; Thom and Keim, 1989; Robkin, 1997; Gorman et al., 2003; Ryter and Otterbein, 2004; Kao and Nanagas, 2006; Mannaioni et al., 2006; McGrath, 2006; Prockop and Chichkova, 2007; Samoli et al., 2007) or contained in monographs (Shephard, 1983; IPCS, 1999; Penny, 2000).

The acute toxicity of CO spans from dizziness to death. Symptoms of CO poisoning begin at approximately 20% COHb and death occurs between 50% and 80% COHb (Ryter and Otterbein, 2004). The relationship between blood COHb and toxic signs and symptoms is presented in Table 21.2.

Haldane (1895a) provided the first description of the relationship of CO in inhaled air to its toxic effect on humans. In the first experiment on himself and a

TABLE 21.2 Relationship of Carboxyhemoglobin (COHb) to Toxicity in Humans following Exposure to Carbon Monoxide

COHb %	Signs and Symptoms
<10	No effects in healthy individuals[a]
10–20	Mild headache, exertional dyspnea, cutaneous vasodilation
20–30	Throbbing headaches, nausea
30–40	Severe headaches, dizziness, visual disturbance, fatigue
40–50	Tachypnea, tachycardia, collapse, syncope
50–60	Coma, convulsions, Cheyne–Stoke's respiration
60–70	Cardiorespiratory depression, possible death
>70	Respiratory failure and death

Source: Based on data from Goodman and Gilman (1941); Renwick and Walton (2001).

[a]*Symptoms may appear in subjects with cardiovascular disease. Concentration of COHb depends upon the duration of exposure to any concentration of CO in the air and therefore not included in the table. Exposure to approximately 200 ppm for 2 h results in 10% COHb; ~12,000 ppm CO would produce lethal concentrations of COHb within 2–3 breaths.*

mouse, Haldane inhaled 0.5% CO for 11.5 min with no obvious symptoms except "hyperapnea after running upstairs." In the second experiment, Haldane and his mouse inhaled 0.39% CO. At 15 min his COHb was 23%, but he had no symptoms; however, the mouse started panting after 1.5 min and lay helplessly on its side by 15 min. At 29 min his pulse was 120 beats/min and he felt distinctly "abnormal," while the mouse lay on its back with hyperapnea. At 30.5 min the COHb was 39% and he stopped inhaling CO but felt giddy and had palpitations after running up 24 steps and could not see well. On resting for 2–3 min, Haldane felt better and hyperapnea disappeared; 45 min after stopping the inhalation of CO, COHb was 23%, at 105 min it was 18%, and at 186 min it was 5%.

Not satisfied with the data Haldane had so far collected, he performed nine more experiments (total of 11) with his companion mouse. Aside from all other facts, Haldane came to the conclusion that mice are more sensitive than humans to CO toxicity and COHb remains elevated for a long time.

The higher sensitivity of mice than of humans led to the introduction of canaries in the coal mines. To our knowledge, CO toxicity on humans was again experimentally determined 75 years after Haldane's experiments (Hosko, 1970; Peterson and Stewart, 1970; Stewart et al., 1970). Stewart et al. (1970) exposed 25 human volunteers to CO concentrations from less than 1 to 1,000 ppm for variable time periods and determined COHb as well as subjective symptoms and objective signs (EEG recording, EECG, hand and foot reaction). The main conclusions of these researchers was that even exposure up to 100 ppm CO for up to 24 h did not produce detectable subjective or objective changes; exposure to 200 ppm CO caused mild frontal headache in 4 h and headache was experienced within 1 h at 500 ppm. Full recovery occurred in all cases when subjects were transferred to a hyperbaric oxygen chamber. COHb strongly correlated with inhaled CO concentration reaching approximately 20% at 100 ppm and 30% at 200 ppm CO (Peterson, 1970; Peterson and Stewart, 1970). Hosko (1970) found that at COHb more than 20%, visually evoked responses were altered in human volunteers; at high altitudes, even a much smaller increase in COHb (5–10%) can exert similar effects (Lilienthal and Fugitt, 1945).

The data cited and the relationship of COHb to CO toxicity presented in Table 21.2 clearly show that the acute toxicity of CO is concentration-dependent. This is of great relevance in setting permissible or desirable atmospheric CO concentration standards. However, the binding affinity of CO for Hb is 200- to 300-times greater than that of oxygen to Hb; therefore, the effects of CO must be considered cumulative. Prolonged exposure to CO would increase COHb more than can be accounted for by its ambient concentration; likewise, a long period of CO-free atmosphere would be needed for COHb to return to normal levels, as also revealed by the data of Haldane (1895a). As a caution, it should be noted that toxic symptoms of CO poisoning do not necessarily correlate with COHb levels; for example, seizures in a 4-year-old child were noted at COHb levels of approximately 25%, but 40% is the usual level for such symptoms (Herman, 1998). Putz et al. (1976) exposed 30 volunteers for 4 h to 5–70 ppm CO and found that 5% COHb (achieved after exposure to 70 ppm CO) impaired coordination, response time to light, and auditory acuity. However, exposure to CO during sleep, which increased COHb to 12.5, did not impair performance after awakening, although it had some effect on sleep pattern (O'Donnell et al., 1971).

Air pollution, which consists of particulate matter, CO, sulfur oxide, nitrogen oxide, hydrogen sulfide, acid gases like HF and HCl, volatile organic solvents, and radiation, is estimated to be responsible for 800,000 annual deaths worldwide (Cohen et al., 2005). A review of the health effects of these pollutants found that respiratory and cardiovascular mortality was consistently associated with particulate matter and CO (Curtis et al., 2006). A large study of the effect of air pollution on mortality was investigated in 19 European cities under the APHEA (Air Pollution and Health: A European Project) project. Samoli et al. (2007) found a significant association of CO both with total and cardiovascular mortality. However, because CO is not the only noxious air pollutant, such epidemiological studies fail to categorically establish a role of CO because it is also possible that CO toxicity is aided by the presence of other pollutants. Purser (1996) analyzed scenarios in the event of fire in aircrafts that release a host of toxic gases including CO, and concluded potentially serious consequences in terms of performance of the crew and the survival of passengers.

It is of interest that big cities like Mexico City and Los Angeles harbor not only high concentrations of CO in the air but also an excess of noise, and there are both clinical and experimental data (Cary et al., 1997; Fechter et al., 1988) to show that noise increases the toxicity of CO as well as of other noxious chemicals.

Edmund Hillary and Sherpa Tenzing conquered Mount Everest on May 29, 1953. This sparked great enthusiasm about mountain climbing. However, at high altitudes the partial pressure of oxygen is low and even a small amount of CO can be fatal. For example, two healthy men died at a height of approximately 6,000 m in Alaska from exposure to CO generated just by a cooking stove in their tent (Foutch and Henrichs, 1988). Even a 5–10% increase in COHb can cause appreciable deterioration in flicker fusion frequency at high altitudes (Lilienthal and Fugitt, 1945). Also, altitude exaggerates CO toxicity in subjects with coronary artery disease (McGrath, 2006).

Atmospheric CO is the main source of exposure to the population. For this reason, WHO has set the

following limits for CO exposure (IPCS, 1999): 100 mg/m^3 (87 ppm) for 15 min; 60 mg/m^3 (52 ppm) for 30 min; 60 mg/m^3 (26 ppm) for 60 min; and 10 mg/m^3 (9 ppm) for 8 h (the usual working period per day).

Delayed Toxicity

Delayed CO toxicity is also referred to as the interval form of toxicity (Mannaioni et al., 2006) with significant effects on the central nervous system (Raub and Benignus, 2002). The interval form refers to neuropsychiatric symptoms within several days or even weeks after asymptomatic existence after recovery from unconsciousness caused by exposure to CO. The most common symptoms of the "interval form" of delayed CO toxicity are lethargy, behavior changes, forgetfulness, memory loss, and Parkinsonian symptoms (Yoshii et al., 1998). These symptoms are attributed to diffuse demyelinization of cerebral white matter in specific regions of the brain (Okeda et al., 1981; Yoshii, et al., 1998; Hsiao et al., 2004; Mannaioni et al., 2006). Neurological symptoms were found to accompany lesions in the brain as detected by magnetic resonance imaging in several other studies (Parkinson et al., 2002; Hsiao et al., 2004).

Daily exposure of dogs for 11 weeks to 100 ppm CO resulted in persistent ECG changes as early as 2 weeks and cardiac muscle degeneration at the end of the study. Observed disturbances in gait and posture were attributed to lesions in the cerebral cortex (Hamilton and Hardy, 1974). Visual disturbances after recovery from a period of CO-induced unconsciousness have also been reported (Kelly and Sophocleus, 1978). Moderate to severe CO poisoning can shorten lifespan because of myocardial injury (Henry et al., 2006).

A lack of close correlation between COHb levels and the severity of CO toxicity is well-recognized (Mannaioni et al., 2006); this clearly suggests the involvement of other factors. These other factors most probably include xanthine oxidase–derived reactive oxygen species, which are produced due to hyperperfusion after the initial hypoxia. This inference is supported by several animal studies (Sokal and Kralkowska, 1985; Thom, 1992; Zhang and Piantadosi, 1992).

CO and cyanide have certain similar toxicities that are a consequence of hypoxia such as disruption of cochlear functions (Tawackoli et al., 2001). CO has been found to cause hearing loss in humans (Sato, 1966; Morris, 1969; Goto et al., 1972; Makishima et al., 1977) and in animal models (Douglas et al., 1912; Fechter et al., 1988; Liu and Fechter, 1995).

Cardiovascular Toxicity

CO can cause and exacerbate underlying cardiovascular diseases (Atkins and Baker, 1985; Thom and Keim, 1989). CO seems to affect each step in the course of ischemic heart disease (Goldsmith and Aronow, 1975; Turino, 1981). CO has been found to exacerbate the atherogenic potential of cholesterol in monkeys (Webster et al., 1970). Inhalation of CO during treadmill exercise in patients with coronary artery disease hastens the onset of anginal symptoms and causes a prolongation of ECG changes (Anderson et al., 1973; Aronow and Cassidy, 1975). A number of deaths from myocardial infarction have been recorded at COHb levels much lower than the levels required to produce neurological effects (Scharf et al., 1974; Atkins and Baker, 1985). The potential of CO to aggravate myocardial pathology is understandable because the disease is associated with relative decrease in oxygen supply to the myocardium. At any concentration, CO can only further increase hypoxia as well as interfere with any compensatory mechanism. Given that cardiac disease is common in the developed world, which also has more than the usual level of CO in the atmosphere, important public health measures would be required to deal with this issue.

Anemia will exert a profound effect on CO saturation and its toxicity because most, if not all, of the CO in the blood is bound to hemoglobin. This subject assumes special importance because anemia is quite common in the general population, particularly in slum dwellings in developing countries. Anemic subjects approach equilibrium levels of COHb more rapidly than those with normal hemoglobin at any level of exposure to CO. For example, a 4 h exposure of subjects with hemoglobin levels of 7 g/100 mL could attain COHb concentrations of 4–5% compared with an anticipated level of 2.5% for normal individuals. This fact coupled with greater production of endogenous CO would pose a greater threat of toxicity in subjects with anemia than in normal subjects (United Nations Environmental Program and WHO, 1979).

Maternal, Fetal, and Infant Toxicity of CO

Carbon monoxide crosses the placenta freely. Blockage of maternal and fetal hemoglobin by CO places the fetus at serious risk, especially in the final weeks of gestation (Shephard, 1983). Maternal and fetal hemoglobin are not identical. Fetal hemoglobin has a higher affinity for CO than maternal hemoglobin. Almost 2 days are needed to achieve equilibrium in maternal and fetal hemoglobin, and at equilibrium fetal COHb is slightly higher than maternal COHb (Longo, 1970; Hill et al., 1977).

Smoking is a well-recognized risk factor during pregnancy (Rogers, 2008). Norman and Halton (1990) analyzed 60 cases of exposure of pregnant women to CO and concluded that severe acute exposure to CO can lead to fetal deaths as well as anatomical malformation and functional alterations. Cigarette smoke has also been

found to decrease fetal weight in rats (Carmines and Rajendran, 2008). Cigarette smoke contains 4,800 identified chemicals, including CO, HCN, and, of course, nicotine; there is no difference in the toxicities of different brands of cigarettes (Hoffmann et al., 2001). The well-established adverse effects of smoking on the fetus may be contributed by CO. Although effects of chronic exposure to CO at levels that can be delivered by smoking CO have not been clearly documented, several animal studies and studies with embryos reviewed by Robkin (1997) suggest that the adverse effects of smoking on fetal development are due to factors other than CO.

CO poisoning of pregnant women can cause fetal death and malformation (Norman and Halton, 1990; Rogers, 2008). Several reports document that exposure to CO from ambient air pollution during pregnancy can decrease fetal weight and lead to preterm births (Ritz et al., 2002; Gilboa et al., 2005; Mannes et al., 2005; Wilhelm and Ritz, 2005; Ziaei et al., 2005; Leem et al., 2006; S. Liu et al., 2007). However, a large study conducted in 96 counties in the United States between 1999 and 2002 examined the effect of air pollution on pregnancy outcome. The study analyzed 3,538,495 births, including 6,639 infant deaths, and air composition of particulate pollutants more than 2.5 μm as well as CO, SO_2, and O_3. The study concluded that infant mortality was contributed to by particulate matters and not by CO (Woodruff et al., 2008).

In animal models, exposure to low levels of CO during pregnancy, which does not reveal obvious signs of fetal toxicity at birth, results in neurological and other abnormalities in later life (Annau and Fetcher, 1994; Carratu et al., 1997; Giustino et al., 1999; Benagiano et al., 2005). The commonly encountered behavioral abnormalities in children could be due to prenatal exposure to low concentrations of CO. This possibility is very much real and, if so, then prophylaxis is a monumental task and a major public health challenge because people have no choice but to breathe the air around them.

Tolerance to CO Toxicity

Hypoxia is the principal mechanism of CO toxicity. Hypoxia can also be produced by the low partial pressure of oxygen at high altitudes. The fact that people living at high altitudes do not exhibit signs of hypoxia implies adaptation to low oxygen pressure. It is thus no surprise that continuous exposure to CO also leads to adaptation (Killick, 1948). In one of the earliest studies on adaptation to CO, mice were exposed to successively higher concentrations of CO for 6–15 weeks; by the end, CO concentration was nearly 3,000 ppm and COHb 60–70%. Symptoms of this very high COHb were far less in the adapted than in the nonadapted mice (Killick, 1937). The underlying mechanism of this adaptation seems to be increased synthesis of hemoglobin (IPCS, 1999). These data have been confirmed by other researchers (Clark and Otis, 1952; Wilks et al., 1959).

Adaptation to CO toxicity also seems to occur in humans. Performing experiments on herself, Killick (1940) found diminished symptoms and lower COHb on chronic exposure to CO than in the beginning, which is in accord with the data of Haldane and Priestley (1935). Adaptation to hypoxia is the reason why people living at high altitudes feel perfectly normal while a visitor from the plains may feel quite unwell. Indian and Pakistani soldiers are facing one another in Siachen of Kashmir, the highest place for any military confrontation in the world. Unless the soldiers are acclimatized before they go to Siachen, many develop fatal pulmonary edema. If they are acclimatized, then the incidence of pulmonary toxicity is considerably reduced.

PHYSIOLOGICAL ROLES OF CARBON MONOXIDE

The primitive earth atmosphere was composed of CO_2, CO, nitrogen, and water, and somehow radiation, heat, and sparks contributed to the generation of amino acid from these basic materials (Kobayashi et al., 2002; Miyakawa et al., 2002). If this is true, then it should be possible to experimentally prove this. We are not aware whether this has been done. However, if it is true, then nothing could be physiologically more important than CO, nitrogen, and H_2O.

Furchgott and Zawadzki (1980) made the seminal observation that vascular endothelium was essential for the vasorelaxant effect of acetylcholine. Soon after, this vasorelaxant substance was identified as nitric oxide (Palmer et al., 1987). It was subsequently found that NO increases guanylyl cyclase activity and cGMP and performs numerous physiological functions (Moncada et al., 1991; Culotta and Koshland, 1992). The study of the physiological role of CO is relatively recent, but it would not be surprising that in years to come CO may be on a par with NO. The excellent and extensive review of the physiological role of CO by Wu and Wang (2005) most certainly paints a rosy picture of CO. One can interpret the review to imply that the infamous CO is about to become a cure for many maladies.

NO and CO have several common properties. Both are gases, both are putative neurotransmitters, both cause vasorelaxation, both increase cGMP, both inhibit platelet aggregation, both increase cGMP, albeit from different pools, and both are synthesized endogenously, although CO also had an exogenous source (Snyder and Ferris, 2000; Hartsfield, 2002). Being gases, neither CO nor NO directly depends on plasma membrane transporters or channels for its entry into cells. Also, certain

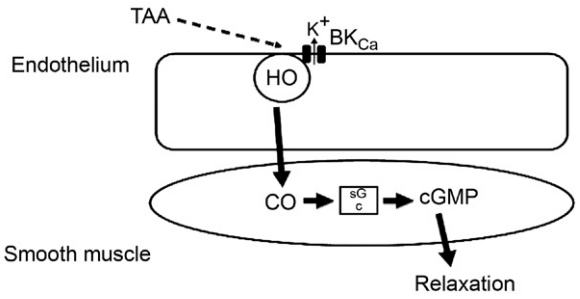

FIGURE 21.4 A model depicting the involvement of CO in mediating relaxation of brain pial microvessels of rats by trans-arachidonic acid (TAA). In this model, TAA acts on calcium-dependent potassium cannels (BKca), leading to activation of hemeoxygenase-2 (HO-2), which releases carbon monoxide (CO). CO activates guanylyl cyclase (sGC) activity. The resulting increase in cGMP causes dilation of rat brain pial microvessels. *Source: Reproduced from Kooli et al. (2008) with permission from* Free Radical Biology & Medicine.

interdependence exists between CO and NO. NO augments HO-1 gene expression and, consequently, CO formation (Hartsfield et al., 1997). Heme oxygenase can decrease NO synthesis (Maines, 1997). On the basis of data from our laboratory, we have proposed that *trans*-arachidonic acid increases the activity of heme oxygenase-2, leading to the generation of CO, which increases cGMP and thereby causes relaxation of cerebral microvasculature of rats, as depicted in Figure 21.4 (Kooli et al., 2008).

At the same time there are differences between CO and NO. For example, NO is an unstable gas and a radical, whereas CO is a stable gas and not a radical. CO binds only ferrous heme but NO binds to both ferrous and ferric hemoprotein (Hartsfield, 2002). The combination rate of NO with hemoglobin is faster and dissociation is slower than that of CO (Sharma and Ranney, 1978), so that the affinity of NO for hemoglobin is ~1,500-times that of CO (Foresti and Motterlini, 1999). Formation of endogenous CO in a variety of tissues has been demonstrated (Marks et al., 2002). Given the complexity of colocalization and activities of heme oxygenase and nitric oxide synthase, it has been speculated that "CO and NO could function in a synergistic, compensatory, and/or counterregulatory way" (Hartsfield, 2002).

The source of endogenous CO and NO and the enzymatic mechanisms in their synthesis differ (Hibbs et al., 1987; Marletta et al., 1988; Moncada et al., 1991; Wu and Wang, 2005). There is no common mechanism of coordinating the release and activities of these two molecules; therefore, it is difficult to conceptualize what would be the ultimate physiological effect of any interaction between the two molecules. Usually, if a substance has physiological effects, its excess or deficiency manifests in some physical disorder. Although there is strong evidence that decreased formation of NO can affect blood pressure homeostasis, no condition has yet been identified that can be attributed to an excess or deficiency of endogenous CO. In contrast, the toxic effects of exogenous CO are well-characterized and there is no reason to assume that the source of this molecule makes a fundamental difference in its pharmacology. In any case, this chapter focuses on CO toxicity. Putative physiological functions of endogenous CO have been extensively reviewed (Marks et al., 1991; Baringa, 1993; Snyder and Ferris, 2000; Choi and Otterbein, 2002; Wu and Wang, 2005; Mannaioni et al., 2006). A brief account of the postulated physiological roles of CO is presented.

CO as a Putative Neurotransmitter

The colocalization of heme oxygenase-2 (HO-2), the enzyme responsible for the release of CO from COHb, and guanylyl cyclase in discrete brain areas lacking NOS, coupled with changes in cGMP by agents and procedures that alter CO, has been advanced as evidence for a putative neurotransmitter role for CO (Verma et al., 1993). However, these workers (Verma et al., 1993) did not test whether changes in cGMP were associated with any changes in neuronal activity, nor did Baringa (1993) feel any need for such details in a commentary in the same issue of *Science*. In further support for a neurotransmitter role for CO, Boehning et al. (2003) demonstrated that HO-2 is activated by phosphorylation of CK2 (casein kinase 2) during neuronal depolarization, and that CK2 activation is essential during CO-mediated nonadrenergic noncholinergic relaxation of the smooth muscle. Also, a role of heme oxygenase and CO has been demonstrated in olfactory neurons in culture (Ingi and Ronnett, 1995; Ingi et al., 1996), myenteric plexus (Zakhary et al., 1996), and vas deferens (Burnett et al., 1998).

The researchers cited have provided strong evidence that CO is released during heme breakdown and that liberated CO can increase cGMP. However, according to the established criteria, a neurotransmitter, among other things, must transmit a message across a synapse. Unless clear evidence is presented for an effect of CO on neuronal transmission, CO should be treated only as a putative, but not a proven, neurotransmitter.

Other Physiologic Effects of CO

Brune and Ullrich (1987) demonstrated that CO increases the activity of guanylyl cyclase–like NO and inhibits platelet aggregation triggered by a variety of agents. CO was found to dilate coronary arteries and increase coronary blood flow in rats (McGrath and Smith, 1984; McFaul and McGrath, 1987). These researchers did not examine if this was associated with an increase in cGMP, but they excluded involvement of an adrenergic system. Similar vasodilator effects of CO have been

found on porcine coronary artery (Graser et al., 1990), rabbit cerebral arteries (Brian et al., 1994), rabbit aorta (Furchgott and Jothianandin, 1991), and rat aorta (Lin and McGrath, 1988). CO produces similar effects on cerebral blood flow. This subject has been reviewed by Koehler and Traystman (2002). CO has been shown to relax cerebral microvasculature (Leffler et al., 1999) and pulmonary as well as systemic vessels (Villammor et al., 2007) of newborn pigs. The vasorelaxant effect of CO is endothelium-independent (Vedernikov et al., 1989; Wang et al., 1997) and exerted via K^+ channels (Graser et al., 1990; Wang and Wu, 1997) in a manner similar to the oxidant OCl^- (Varma et al., 2006), which is also endogenously produced (Weiss et al., 1985, 1986). Also, CO can increase cerebral blood flow in rats (Macmillan, 1975), rabbits (Meyer-Witting et al., 1991), and fetal sheep (Rosenberg et al., 1986).

Heme oxygenase activation as well as CO induce the synthesis of vascular endothelial growth factor (Dulak et al., 2002) but suppress its induction by hypoxia (Liu et al., 1998). Heme oxygenase-1 plays a protective role against vasoconstriction and proliferation (Lee et al., 1996; Sammut et al., 1998; Duckers et al., 2001), regulates vascular cGMP (Morita et al., 1995), suppresses endothelial cell apoptosis (Brouard et al., 2000), and activates mitogen-dependent protein kinase pathway (Otterbein et al., 2000). Paradoxically, CO can prevent ischemic lung injury by suppressing fibrinolysis (Fujita et al., 2001).

A number of studies have examined the anti-inflammatory activities of CO (Abraham et al., 1988; Mannaioni et al., 2006). An activation of the heme oxygenase system and exposure to CO *in vitro* (Otterbein et al., 1999, 2000; Sethi et al., 2002; Gibbons and Farrugia, 2004; Pae et al., 2004; Chauveau et al., 2005) and *in vivo* (Otterbein et al., 1999; Nakao et al., 2003; Dolinay et al., 2004; Neto et al., 2004) revealed anti-inflammatory activity in animal models but not in humans (Mayr et al., 2005). CO can inhibit apoptosis of endothelial cells (Soares et al., 2002). There is some evidence that upregulation of HO-1 might be beneficial in inflammatory diseases (Willis et al., 1996). In any case, the ability of CO to inhibit platelet aggregation and inflammation has important therapeutic implications and needs to be explored.

Liver is a site for cytochrome P450 synthesis as well as degradation of senescent erythrocytes and, consequently, catabolism of hemoglobin and heme oxygenase, which mediates the generation of endogenous CO. Because oxyhemoglobin can capture CO, it would reduce available CO, which could and has been shown to increase hepatic vascular resistance (Suematsu et al., 2000). There is some evidence that endogenous CO formation in the hypothalamus might modify hypothalmo-pituitary-adrenal axis (Mancuso et al., 1997).

In conclusion, there is definite evidence that endogenously produced CO exerts biological effects. If these are important physiological effects, then one can assume that a deficiency in endogenous CO generation might manifest as a disease state or worsen existing diseases. Vascular NO is thought to be of relevance in maintaining vascular tone and its deficiency can cause hypertension or platelet aggregation. Diseases caused by a deficiency of hormones or neurotransmitters are ameliorated by substitution therapy. There is no reason to think that exogenous CO cannot substitute for a deficiency of endogenous CO. For example, endogenous CO deficiency increases acid-dependent bile flow; this can be corrected by exogenous CO (Shinoda et al., 1998; Suematsu et al., 2000). A lower incidence of Parkinson's disease among smokers than in nonsmokers is attributed to nicotine in cigarettes (Quick, 2004). Fortunately, the beneficial effects of nicotine in cigarettes have not led to promoting smoking. Hopefully, any useful role for CO would also not lead to promoting the therapeutic value of cigarettes, which is a rich source of CO.

TREATMENT OF CARBON MONOXIDE OVERDOSE

Oxygen

When Humphrey Bogart rescued Audrey Hepburn from a garage where she had turned on the ignition keys of several cars in the film *Sabrina*, she knew that exhaust fumes could kill and he knew that fresh air could save life. The treatment of CO intoxication by oxygen was elaborated by Haldane (Haldane, 1895a, 1922; Haldane and Priestley, 1935). Perhaps the general public is aware of this therapy.

It was implicit in Haldane's studies that oxygen at high pressure would be more effective than at atmospheric pressure. However, there was a reluctance to resort to this practice because of the fear of oxygen toxicity. End and Long (1942) successfully demonstrated the value of oxygen at high pressure to treat CO overdose in laboratory animals. To our knowledge, the first controlled study of the value of hyperbaric oxygen against CO poisoning was performed by Pace et al. (1950) on 10 human volunteers (five men and five women). Data of these workers show that changing ambient pO_2 from 0.2 to 2.5 atmospheric pressure, absolute, increased the rate constant (k) of elimination of CO from 0.0028 to 0.0315 min, which would alter the half-life of CO elimination from 246 to 21 min.

Other Therapeutic Measures

CO poisoning leads to several abnormalities such as generation of oxidants, lipid peroxidation, disturbance in glucose metabolism, and so on, which compound the toxic

effect of CO caused by hypoxia. Measures other than oxygen are intended to deal with these secondary changes.

Allopurinol and N-Acetylcysteine

There is strong evidence that some of the toxic effects of CO poisoning are produced by release of reactive oxygen metabolites and xanthine oxidase plays a major role in these processes (Sokal and Kralkowska, 1985; Thom, 1992; Zhang and Piantadosi, 1992). Xanthine oxidase is a nicotinamide adenine dinucleotide (NAD)-dependent dehydrogenase, which is converted to oxidase under ischemic conditions utilizing molecular oxygen in place of NAD and, in the process, generates superoxide radicals and hydrogen peroxide. Allopurinol is a xanthine oxidase inhibitor and *N*-acetylcysteine is a sulfhydryl donor. The efficacy of these agents against neuronal injury caused by CO has been documented (Howard et al., 1987; Thom, 1992).

Insulin

Hyperglycemia, which follows stroke or myocardial infarction, worsens the resulting neurological insult. Acute CO poisoning is also characterized by hyperglycemia, which has been found to worsen brain dysfunction in rats (Penny et al., 1990). Similar observations have also been made in CO-poisoned patients (Pulsinelli et al., 1980). Moreover, neurological complications of CO poisoning in diabetic patients seem worse than in healthy individuals. There is evidence that insulin treatment is effective in reducing neuronal damage caused by stroke or cardiac arrest, and similar encouraging results have been found after CO poisoning in humans (White and Penny, 1994).

Other Measures

Because of the role of excitatory amino acids in ischemic neurodegeneration, Ishimaru et al. (1992) studied the effect of several agents including NMDA receptor antagonists against CO poisoning in mice with encouraging results. We are not aware of any clinical studies of the efficacy of NMDA receptor antagonists in reducing neurological toxicity in humans after CO poisoning. Cerebrolysin, produced by enzymatic breakdown of lipid-free proteins of porcine brain, have been found to offer protection against certain neurological changes after CO poisoning in animal models. Hypothermia has also been found to be of benefit in CO poisoning (Peirce et al., 1972).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

We have attempted to deal with most, though not all, aspects of the pharmacology, toxicology, and physiology of carbon monoxide. The literature on CO is immense and dates back to 1857 or even earlier. The omnipresence of this colorless, odorless, tasteless, and nonirritating gas, generated by incomplete combustion and ever present in megacities, has traveled a long way from being a leading cause of unintentional death and an agent of choice for suicide to finding a physiological role as big as a neurotransmitter like nitric oxide.

Many currently used drugs like acetyl salicylic acid, digitalis, nitrates, and quinine have existed for a long time, and so have many poisons like cyanide and neurotoxins. However, their mechanism of action was not known until the middle of twentieth century or even later. CO is unique. The details of its mechanism of toxicity were published by Haldane as early as 1895, and subsequent work has only elaborated these details while affirming their correctness. The generation of COHb is the principal cause of CO toxicity; however, it is not the only one. Much research has been performed to elaborate these additional mechanisms of CO toxicity, but we have not discussed them in detail, just as we have not gone into detail about the physiological role of endogenous CO as one of the many warfare chemicals.

If detected in time, CO poisoning can be treated with hyperbaric oxygen plus other supplementary measures. However, safeguarding against chronic toxicity, if it results from chronic exposure to low levels of CO, is a difficult challenge. Many megacities are highly polluted with CO. Burning petroleum in automobiles as the chief source of CO in the modern world would, in most probability, increase rather than decrease atmospheric CO, ozone, nitrogen, and hydrogen sulfide. This poses one of the great challenges of modern times to public health care. It is the responsibility of the environmental toxicologists, other scientists, and a socially conscious population to do whatever they can to ensure that measures are taken to protect the citizenry from hazardous chemicals in the air we breathe.

Acknowledgments

We thank Ms. Emily Gibson for compiling and checking references. This article is dedicated to the memory of Professor John Sanderson Haldane, FRS (1861–1936), who conducted experiments on himself with poisonous carbon monoxide to save the lives of miners, and whose laws on the exchange of gases remain valid even today.

CHAPTER

22

Methyl Isocyanate: The Bhopal Gas

Daya R. Varma and Shree Mulay

INTRODUCTION

Methyl isocyanate (MIC), the smallest, most reactive, and most toxic member of the isocyanate family, was unheard of until December 2–3, 1984, when nearly 40 metric tons of this deadly chemical leaked out of the Union Carbide India Limited (UCIL) pesticide plant at Bhopal within a period of 45–60 min. Bhopal became a "city of death," in the words of *India Today* (December 30, 1984). The journal *Nature* (Opinion, 1984) wrote: "…. the anguish vividly carried round the world by the television cameras seems not to have matured into the anger, even hysteria, there would have been had the accident occurred on the edge of a European city—or in Connecticut [site of Union Carbide's U.S. headquarters]."

Prior to the Bhopal disaster, there had been only one scientific report on MIC toxicity (Kimmerle and Eben, 1964); this led *Lancet* (Editorial, 1984) to comment: "In a year's time we will have learnt a lot more about methyl isocyanate—at an appalling price."

The Bhopal disaster evoked immense interest amongst journalists, scientists, the corporate world, lawyers, social activists, and the Indian government (Chemical and Engineering News, 1985; Varma, 1986). This chapter mainly focuses on how the disaster took place in Bhopal, as well as the physicochemical characteristics of MIC and its toxicity; how such disasters can be prevented in developing countries like India, which lack rigorous safety protocol against hazardous chemicals. Legal implications are not elaborated in this chapter.

The population of Bhopal in 1984 was 800,000. The Union Carbide plant was within 1 kilometer of the Bhopal railway station and not too far from the city's two large hospitals; densely populated slums lay across the road just a few hundred meters from the factory. The toxicity of a chemical, barely tested in animal models, was now suddenly being observed as it acted on 200,000 people, as well as on animals and plants living in Bhopal. There is no precise information on how many people died in the immediate aftermath of the disaster; usually a figure of 2,500 is quoted, but our estimate based on projecting deaths in a sample survey (Varma, 1987) is that about 8,000 people died. Most of the deaths happened between 24 and 48 h after the discharge of MIC, which would not have been the case if the culprit had actually been hydrogen cyanide (HCN), as was thought initially (HCN acts within minutes). A British medical student on her elective at a Bhopal hospital wrote: "The dead and dying arrived by the truckload, others came by rickshaw or were carried by relatives. For some, the effort of the journey itself proved too much, and they died soon after arrival." (Sutcliffe, 1985).

Soon after the Bhopal accident, the government of India promised to conduct a comprehensive study on the acute and long-term effects of exposure to MIC. The Indian Council of Medical Research (ICMR) released approximately $2 million for research; a cohort of 80,021 gas-exposed people and 15,931 controls were registered, but only 16,860 exposed subjects and 5,741 controls could be contacted in 2010 (Sharma, 2013). Researchers were not recruited to study all aspects of toxicity. No definite criteria were set to make a quantitative assessment of the exposure to MIC; the best estimate has remained the distance from the Union Carbide factory (Dhara et al., 2002). A number of laboratories in the United States and United Kingdom initiated research on MIC (Environmental Health Perspective, 1987), but their interest faded quickly. The twentieth anniversary of the disaster drew the attention of the media, but not of researchers.

THE MAKING OF A DISASTER

For days after the disaster, no one was sure how the accident had happened. A detailed account of how MIC escaped from Tank E-610 of UCIL was ultimately

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00022-1

provided by Stewart Diamond in *The New York Times* on January 28, and this report was corroborated by others as well (Varadarajan et al., 1985; Varma, 1986). Although it is highly unlikely that an accident would occur exactly in the way it happened in Bhopal, the accidental escape of hazardous chemicals is not uncommon. The US Environmental Protection Agency (EPA) had recorded 28 instances of minor leaks of MIC from the Union Carbide plant in Institute, West Virginia, between 1980 and 1984, and a leak of aldicarb oxime from the same plant on August 11, 1985, sent 200 people to hospitals.

According to Diamond's article, water entered the pipes on the floor of the factory during routine cleaning, which took place without placing safety slips at the joints. It would seem that the floor of a chemical factory was cleaned with no more precautions than are taken when cleaning the platform of an Indian railway station. The water reached Tank E-610. The exothermic reaction between the water and MIC increased the temperature of the tank, converting liquid MIC into gas. The increase in pressure forced open the vent valve, letting most of the MIC escape as gas. Various safety measures to neutralize MIC, such as caustic soda scrubbers, were either inadequate or completely nonfunctional. Even if safety measures had been in perfect working order, they were not designed to handle such a big leak. MIC gas, being almost twice as heavy as air, settled on the ground, which affected all living beings in the area. Undoubtedly, the lack of rigorous safety procedures in the maintenance was the cause of the accident.

Fortunately, MIC stored in the other two tanks (E-611 and E-619) was not affected. The Indian Council of Scientific and Industrial Research (CSIR) decided that the safest way to dispose the remainder of MIC was to convert it into carbaryl, the pesticide for which the factory had been set up to produce. This exercise was termed "Operation Faith," and it was extensively covered by Indian and international media. Operation Faith ended safely on December 22, 1984, without any further mishap. Nonetheless, the disaster frightened the people of Bhopal so much that despite all assurances by the Indian government, almost half of the population left the town; some never returned to Bhopal.

An examination of the causes of the Bhopal disaster clearly indicates that the accident would not have occurred if all necessary precautions had been taken in the maintenance and operations of UCIL. Union Carbide had sent a team of American experts in May 1982, and they pointed out many lapses in the operation of the plant. However, the company failed to act on their suggestions. In addition, after making a number of visits to the plant, the local journalist Rajkumar Keswani warned of the impending disaster 4 months before the accident.

MIC was used in the United States, Germany, and Japan, but it was stored in Bhopal in much greater quantities than in any of these other places. The question of whether the operation of hazardous industries (like the chemical industry) can be both safe and profitable is debatable. What is not debatable, however, is that safety must remain the top priority. Following a cyclohexane explosion in Flixborough in 1974, an Advisory Committee on Major Hazards was set up in the United Kingdom, and the European Economic Council Directive of 1982 was triggered by the Sevesco accident of 1976 in Italy. However, the Bhopal disaster of 1984, which was far worse than the Flixborough and Sevesco accidents (in fact, it was the worst in history), has not led to additional regulations outlining corporate and state responsibilities, despite the strong case for global monitoring of potentially toxic materials (Sriramachari and Chandra, 1997).

TOXICOKINETICS OF ISOCYANATES

As stated previously, MIC is a member of the isocyanate family of chemicals. The high chemical reactivity of isocyanates is central to their commercial use, but it is also a key element of their toxicity. No clinical use of isocyanates has so far been demonstrated.

Chemistry of Isocyanates

Organic isocyanates were first synthesized in 1849. Isocyanates (Table 22.1) are highly reactive heterocumulene chemicals. The general structure of isocyanates is R—N═C═O, which is distinct from that of cyanate (N═C—O—H). The reactivity of organic isocyanates is due to the strain in the cumulative double bonds (—N═C═O) of isocyanates (Varadarajan et al., 1985).

TABLE 22.1 Commonly Used Isocyanates

Isocyanates	MW	LC_{50} (ppm)[a]	Ceiling (ppm)[b]
Methyl isocyanate (MIC)	57	5.1	0.02
Hexamethylene diisocyanate (HDI)	168	55.9	0.02
Toluene diisocyanate (TDI)	174	49.0	0.02
Isophorone diisocyanate (IPDI)	222	28.5	0.02
Diphenylmethane diisocyanate (MDI)	250	36.0	0.02
Dicyclohexylmethane diisocyanate (SMDI)	262	–	0.01
1,5 Naphthalene diisocyanate (NDI)	210	–	0.02

[a] *LC_{50} (lethal concentration killing 50 of experimental animals) values are after 4 h exposure.*
[b] *To convert ppm to mg/m^3, divide it by (24.4/MW); see, review by Varma (1986).*

Most of the commercially used isocyanates are diisocyanates, and R is an aromatic ring. MIC is an exception; its structure is $H_3C{-}N{=}C{=}O$. The physicochemical properties of MIC differ from those of other isocyanates (Lowe, 1970). Because of the high chemical reactivity of MIC with alcohols, it serves as an intermediate in the production of carbaryl, a pesticide. Diisocyanates are primarily used for the manufacture of polyurethanes.

Synthesis of MIC

MIC ($CH_3N{=}C{=}O$) can be synthesized using different reactions. The commercial synthesis of MIC by Union Carbide, Bayer, and Dupont is described next:

At Union Carbide Corporation, Bhopal, India:

$$CH_3NH_2\,(\text{monomethyl amine}) + COCl_2\,(\text{phosgene}) \rightarrow CH_3N{=}C{=}O + 2HCl$$

At Bayer, Germany:

$$CH_3NH{-}CO{-}NHCH_3\,(\text{dimethyl urea}) + (C_6H_5O)_2CO\,(\text{diphenyl carbamate}) \rightarrow CH_3\,N{=}C{=}O + \text{by products}$$

At Dupont, the United States:

$$CH_3{-}NH{-}CHO\,(\text{methyl formamide}) + O_2 \rightarrow CH_3\,N{=}C{=}O + H_2O$$

MIC was produced and stored in Bhopal, whereas CO and phosgene, which also are required for the production of carbaryl, were not stored; rather, it was produced and utilized right away. In the United States and Germany, MIC is produced as needed; it is not stored.

Various steps in the production of carbamate pesticide at Bhopal were as follows (Varadarajan et al., 1985):

1. Petroleum coke (2C) was reacted with oxygen to produce 2CO.
2. CO and chlorine were reacted to produce phosgene ($COCl_2$).
3. Phosgene and methylamine (CH_3NH_2) were reacted to form methylcarbamoyl chloride ($CH_3NHCOCI$) plus HCl.
4. Methylcarbamoyl was then pyrolyzed to yield MIC ($CH_3N{=}C{=}O$) and HCl.
5. Finally, MIC was reacted with a slight excess of α-naphthol in the presence of a catalyst in carbon tetrachloride solvent to produce the desired pesticide carbaryl.

In the system used in Bhopal, the stored liquid MIC was transferred through pipes to charged pots weighing 1 metric ton and under 16 psi of pressure of nitrogen. These charged pots were connected to two reactors, where MIC and α-naphthol reacted to produce carbaryl. The charging of α-naphthol was done by dissolving it in carbon tetrachloride at approximately 50°C in the presence of a trimethylamine catalyst. The reaction between MIC and α-naphthol is exothermic. The temperature was maintained at 70°C for efficient production of carbaryl.

$$CH_3N{=}C{=}O + \alpha\text{-naphthol} \rightarrow \text{1-naphthyl-}N\text{-methyl carbamate (carbaryl)}$$

The alternative way to make carbaryl involves reacting α-naphthol with phosgene to generate α-naphthol chloroformate. Then, α-naphthol chloroformate reacts with methylamine to produce carbaryl.

Physicochemical Reactions with MIC

MIC can interact with a large number of molecules, as well as with itself. Indeed, 21 products were identified (Varadarajan et al., 1985) and almost 10 unidentified chemicals (Sriramachari, 2004) were detected leaking from Tank E-610. An MIC trimer, as well as other metabolites of MIC such as dimethyl isocyanurate and 2, 4-dione of MIC, were identified in autopsies of Bhopal victims. Reaction of MIC with water is important because it will occur whenever MIC comes into contact with the body or the environment, as happened in Bhopal. It is important to note that while excess of water can neutralize MIC, only small quantities of water are enough to generate heat during the reaction, which leads to the vaporization of MIC, and this actually happened in Bhopal. Some important interactions of MIC are enumerated next.

1. Polymerization (self-addition of many MIC molecules).
2. Trimerization: 3 ($CH_3N{=}C{=}O$)→trimethyl isocyanurate.
3. Dimerization is common with aromatic isocyanates, but is rare with aliphatic isocyanates like MIC.
4. Additive reactions with molecules containing reactive hydrogen species, which migrate to the nitrogen of MIC.
5. General reaction of MIC with molecules containing hydroxylic groups:

   $CH_3N{=}C{=}O + ROH \rightarrow CH_3NHCOOR$ (urethane)

6. Reactions with water:

   $CH_3NCO + H_2O \rightarrow CH_3NH_2$ (MMA) + CO_2
   $2(CH_3NCO) + H_2O$ (excess)→$CH_3NHCONHCH_3$ $(DMU)_+CO_2$
   $3(CH_3NCO)$ in excess + $H_2O \rightarrow CH_3NHCON\,(CH_3)$ $CONHCH_3$ (TMB) + CO_2
   $4(CH_3NCO) + H_2O \rightarrow DMI + (CH_3)2NH$ (DMA) + CO_2

7. Reaction with DMA:

   $CH_3NCO + DMA \rightarrow (CH_3)2N\text{-}CO\text{-}NH\text{-}CH_3$ (TMU)

8. Reaction with alcohols and phenols (used by UCIL to produce carbaryl pesticide):

   CH_3NCO + α-naphthol→1-naphthyl-*N*-methyl carbamate (carbaryl)

9. Reaction with primary and secondary amines:

   $CH_3NCO + R\text{-}NH_2 \rightarrow CH_3\text{-}NH\text{-}CO\text{-}NH\text{-}R$

10. Reaction with nitrates and nitrites:
    The reaction of MIC with nitrates and nitrites, which are normally present in water, can yield carcinogenic nitrosamines.
11. Decomposition into HCN at temperatures in the range of 427–548°C at 55–300 torr (Blake and Ijadi-Maghsoodi, 1982).
12. Reaction with HCN at normal temperatures, leading to the formation of other cyanides (Slotta and Tschesche, 1927).
13. Reactions with body constituents:
    In general, interactions between isocyanates and endogenous molecules are reversible (Tse and Pesce, 1978). MIC has been shown to cause greater interaction with macromolecules than aryl isocyanates (Brown et al., 1987). Reversible conjugation of isocyanates with glutathione (Slatter et al., 1991), which occurs both spontaneously and enzymatically, may have been the mechanism of distributing MIC molecules to different parts of the body and the reason behind its diffuse toxicity profile (Baillie and Slatter, 1991; Pearson et al., 1991). MIC can act as a hapten, which leads to the generation of antibodies in both animals and humans (Karol et al., 1987). MIC can carbamylate macromolecules (Segal et al., 1989). MIC has been shown to be an effective anti-sickling agent *in vitro*; it combines with α-amino groups of hemoglobin and thus increases its oxygen binding affinity (Lee, 1976).

Quantification of MIC

Measurement of MIC in the workplace requires the collection of samples with special tubes and then reacting it with an amino-based reagent such as 1-(2-methoxyphenyl) piperazine (2MP) or other similar substances (von Zweigbergk et al., 2002). Sampling under controlled experimental conditions can be done using gas-tight syringes. Several techniques have been used for the quantitative analysis of MIC. Methods used by Ferguson et al. (1986) and by ourselves (Varma et al., 1987) used a Perkin-Elmer Model 3920 gas chromatograph equipped with a nitrogen-phosphorus detector. The absolute retention time for MIC under these conditions was approximately 1 min and sensitivity of the method was 0.8 ng MIC.

MECHANISM OF DEATH FOLLOWING EXPOSURE TO MIC

MIC exerts a wide spectrum of toxic effects. The immediate effect of exposure to MIC in Bhopal was lacrimation, choking sensations, and difficulty in breathing, followed in many cases by death. An important element of the fatalities in Bhopal was a lag period of several hours between the exposure to MIC and death (Paintal, 1986; Varma, 1986). Most deaths occurred more than 24 h after the exposure. Delayed death was also observed in experimental animals exposed to MIC (Alarie et al., 1987; Bucher et al., 1987; Varma et al., 1988). It would thus appear that the lethal effects of MIC were caused by pulmonary complications. It was also found that a single exposure to MIC can produce long-lasting pulmonary complications (Ferguson and Alarie, 1991; Kamat et al., 1992; ICMR, 2004).

The pattern of death in experimental animals (i.e., rats, mice, and guinea pigs) following exposure to MIC was biphasic and similar to that observed in Bhopal. Even excessive concentrations (3506 ppm for 15 min) of MIC were not lethal to rats in a 10 min period. Exposure to MIC caused a significant decrease in body weight within 24–48 h (Varma et al., 1988), suggesting substantial loss of body fluid. In the only controlled experiments on humans, Kimmerle and Eben (1964) noted that subjects could not tolerate 21 ppm MIC even for a few seconds.

THE CYANIDE CONTROVERSY

In the chaos that prevailed in Bhopal following the disaster, a number of journalists, social activists, and even some scientists contended that the culprit was HCN, not MIC. HCN poisoning leads to cherry-red venous blood (which showed up in the autopsies of the victims) because oxygen is not being used by the tissues. Sodium thiosulfate is a known antidote for HCN, and because there were reports that the victims benefited from this type of treatment, that further supported the theory of HCN involvement. Also MIC can get converted into HCN at high temperatures and pressure (Sriramachari, 2004). But this was not borne out by the sum total of evidence that emerged. The physicochemical properties and toxicity profiles of MIC and HCN are shown in Table 22.2.

Cyanide is an instant killer at a certain dose level. However, deaths by pulmonary edema after a lag period (Paintal, 1986) and other toxicities observed in Bhopal victims (Varma, 1987) are not known to be caused by cyanide. Some cyanide is present in most individuals, and more so if there is smoke and fire. Any beneficial effect of sodium thiosulfate could be explained by environmental exposure to cyanide, especially because a

TABLE 22.2 Properties of MIC and HCN

Property	MIC	HCN
Molecular weight	57	27
Appearance	Liquid	Liquid/gas
Boiling point (°C)	39.1	25.7
Vapor density (air = 1)	1.97	0.95
Threshold limit value (ppm)	0.02	10.0
Lethal level 1 h exposure (ppm)	3.0	100
Concentration immediately fatal (ppm)	Undetermined	>270
Antidote	None	Sodium thiosulfate
Long-term effects	Many	None identified

majority of the victims were slum dwellers who may have been using fire to keep their homes warm, and many were chronic smokers. Cherry-red blood could have resulted from the formation of carboxyhemoglobin from exposure to atmospheric carbon monoxide.

Under controlled experimental conditions, sodium thiosulfate did not reduce the toxicity of MIC (Alarie et al., 1987; Bucher et al., 1987; Varma et al., 1988). Finally, HCN is a fast killer at concentrations >100 ppm (Goldstein et al., 1968), and the concentrations of MIC that were achieved in Bhopal would not have killed anyone if the gas actually were HCN. Moreover, HCN could not descend to the ground because, unlike MIC, it is lighter than air. Moreover, there is definite evidence of long-term effects in survivors of the Bhopal disaster (Bucher, 1987; Dhara and Dhara, 2002; Dhara et al., 2002; Sriramachari, 2004), whereas a single dose of cyanide is not known to produce such effects (Goldstein et al., 1968). Sodium thiosulfate is well known to be an effective antidote against cyanide poisoning, and it should be administered almost immediately for that purpose, rather than several days or even months later (Chen and Rose, 1956; Goldstein et al., 1968).

TOXICITY OF ISOCYANATES

Commonly used isocyanates include toluene diisocyanate (TDI), methylenediphenyl diisocyanate (MDI), naphthalene diisocyanate (NDI), and hexamethylene diisocyanate (HDI). All isocyanates are toxic (Rye, 1973) to varying degrees; TDI seems to be the most toxic.

The National Institute of Occupational Safety and Health in the United States projected as early as 1978 that approximately 50,000 to 100,000 workers would be exposed to these chemicals within 2 years (NIOSH, 1978). The routine method of exposure of workers to isocyanates is by inhalation, and their toxicity is greater following inhalation than following oral ingestion; isocyanates that produce both pulmonary and sensory irritation are more toxic than those that cause only sensory irritation (Weyel et al., 1982).

Toxicity of MIC

Experimental research on the toxicity of MIC vapor on rats, mice, rabbits, and guinea pigs, as well as on human volunteers, was first reported in 1964 (Kimmerle and Eben, 1964). For the next 20 years, though, no follow-up studies were done. It is to the credit of Kimmerle and Eben (1964) that their stringent observations were confirmed by all the studies that followed the Bhopal disaster of 1984.

It is tragic that the toxicity of poisons is tested on humans during wars, more often than not by the most developed countries. It is equally unfortunate that one finds out about human toxicity of chemicals during industrial accidents or as a consequence of environmental neglect. In this sense, Bhopal offered the most expansive opportunity to observe and investigate the toxicity of MIC on such a large scale on humans, as well as livestock and vegetation. Surprisingly, however, most of the obvious questions raised in the aftermath of the Bhopal disaster have not been answered.

Although human toxicity to MIC has only been observed following inhalation, animal experiments reveal that it is also toxic following injection; this contradicts the prediction by the visiting American team soon after the disaster that MIC is so reactive that it will be destroyed upon contact with the body. Metabolites of MIC are also toxic (Varma and Guest, 1993).

For the sake of simplicity, data on the toxicity of MIC on humans and animals are presented separately in the rest of this chapter. It is worth mentioning, however, that almost all the data derived from animal studies seem to confirm what has been observed in humans in Bhopal.

Toxicity of MIC in Animal Models

Mortality

Barely 4 h after the disaster on December 3, 1984, the streets of Bhopal were littered with dead animals—790 buffalo, 18 bullocks, 84 calves, 270 cows, 483 goats, 90 dogs, and 23 horses (Varma, 1986). According to autopsy reports, the dead animals showed swollen livers and lymph nodes, bloated digestive tracts, engorged blood vessels, edema, necrosis in lungs with blood clots, and congested hearts and kidneys (Varma, 1986). House flies survived, however, but it is not known why.

Kimmerle and Eben (1964) estimated an LC_{50} value of 5 ppm in rats following a 4 h exposure, and 21 ppm following a 2 h exposure. Unlike with cyanide, death

followed several hours after MIC exposure and continued for up to 18 days. In later studies, it was found that 10 min exposure to as much as 3506 ppm was not immediately lethal (Dodd et al., 1986), although guinea pigs died during exposure to high concentrations (i.e., greater than 500 ppm). In general, deaths following exposure to MIC occur 1–2 days later, and a second phase of mortality follows after a week or more (Alarie et al., 1987; Bucher et al., 1987; Varma et al., 1988). Guinea pigs are more sensitive to MIC toxicity than rats (Dodd et al., 1986).

Pulmonary Toxicity

Kimmerle and Eben (1964) reported that MIC caused lacrimation, mucosal irritation, and pulmonary edema in rats, mice, rabbits, and guinea pigs. Other studies also found that MIC causes both sensory and pulmonary irritation; if death did not ensue, the recovery from these pulmonary effects was very slow to occur (Ferguson et al., 1986; Alarie et al., 1987). Exposure to MIC caused concentration-dependent degenerative changes in bronchiolar and alveolar epithelium in rats and guinea pigs, resulting in the plugging of major airways and atelectasis (Nemery et al., 1985; Fowler et al., 1987), increase in lung weight (Bucher et al., 1987; Stevens et al., 1987), pulmonary (Bucher et al., 1987) and olfactory epithelial necrosis, airway obstruction, and compromised cardiopulmonary function (Tepper et al., 1987) in surviving animals.

In a retrospective study of 4,782 Bhopal gas victims and 1,190 control subjects, De (2012) found a much higher risk of developing obstructive pulmonary complications in younger subjects (age 10–29 years) exposed to MIC than older ones (age 30–60 years).

Ocular Toxicity

As was the case in humans, lacrimation has also been found to be one of the earliest effects of MIC vapor in experimental animals (Bucher et al., 1987; Varma et al., 1988). However, exposure of rats to 3, 10, or 30 ppm MIC for 2 h (which approximates the situation in Bhopal) was not found to cause any damage to the cornea, although copious lacrimation was observed up to 3 months. Similar findings have been reported in mice (Boorman et al., 1987). On the other hand, exposure of lens explants to MIC *in vitro* has been shown to cause opacity (Harding and Rixon, 1985). It is very likely that profuse lacrimation acted as a protective mechanism, by chemically inactivating MIC.

Reproductive Toxicity

Exposure of mice on day 8 of gestation (gestation period 19 days) to 2, 6, 9, and 15 ppm MIC for 3 h or 1–3 ppm for 6 h on days 14–17 of gestation caused concentration-dependent fetal loss and maternal mortality (Varma, 1987; Varma et al., 1987); lengths of different fetal bones were significantly reduced in mice following exposure to 9 and 15 ppm MIC (Varma, 1987). MIC also caused maternal and fetal toxicity in rats; pregnancy loss accompanied a sudden decrease in progesterone, although it could not be determined which of the two events occurred first (Varma et al., 1990). Given the extensive nature of MIC toxicity, it is difficult (if not impossible) to determine if MIC-induced reproductive toxicity is a direct effect on the conceptus or a consequence of general toxicity; however, several observations indicate the possibility of a direct effect.

Radio-labeled MIC rapidly reaches the fetus (Ferguson et al., 1988). Intraperitoneal injection of MIC also caused reproductive toxicity of a similar magnitude as with inhalation (Varma et al., 1990). Moreover, MIC metabolite methylamines also produced reproductive toxicity without other obvious effects on pregnant mice. Of the three amines tested, monomethylamine, dimethylamine, and trimethylamine, the last was most toxic *in vivo*, as well as in mouse embryos in culture (Varma and Guest, 1993). Interestingly, administration of trimethylamine during mouse pregnancy resulted in stunting of male but not female progeny (Guest and Varma, 1993), similar to the effect reported years later in Bhopal victims (Ranjan et al., 2003). Another metabolite of MIC, *S*-(*N*-methylcarbamoyl) glutathione (GSH) and MIC metabolite trimethylamine exerted marked toxicity on cultured mouse embryos, as well as yolk sac and limb bud (Guest et al., 1992).

Immunotoxicity, Genotoxicity, and Carcinogenic Effects

MIC has been found to generate specific antibodies in guinea pigs following both inhalation and subcutaneous injections (Karol et al., 1987). MIC was found to be genotoxic in rats (Dutta et al., 1988) and caused dose-dependent increases in sister chromatid exchange, as well as chromosomal aberrations in hamster ovary cells in addition to cell cycle delay in mice (Shelby et al., 1987). MIC has also been reported to be mutagenic in mammalian and bacterial cell cultures (Caspary and Myhr, 1986; Meshram and Rao, 1988); MIC has been estimated to have a 76.6% probability of being a genotoxic carcinogen, but only in tests with low specificity (Ennever and Rosenkranz, 1987).

Mishra et al. (2009) examined the carcinogenic potential of MIC using cultured human lung fibroblasts and found that MIC induced inflammatory response, resulting in extensive DNA damage and genomic instability.

Other Toxic Effects

MIC caused dose-dependent necrosis of rat brain cells in culture (Anderson et al., 1990); these findings show that MIC can exert its effects even in liquid media.

Exposure of mice to 1–3 ppm MIC was found to inhibit erythroid precursors, pluripotent stem cells, and granulocyte-macrophage progenitor; recovery from this inhibitory effect was found within 3 weeks after 1 ppm but not after 3 ppm (Hong et al., 1987). At higher concentrations of 6–15 ppm, MIC inhibited cell cycling in bone marrow, alveolar cells, and T lymphocytes (Shelby et al., 1987); similar data were reported by others (Tice et al., 1987). MIC can inhibit bone marrow cell proliferation in mice (Meshram and Rao, 1988).

Exposure of rats, mice, and guinea pigs to MIC vapor caused dramatic body weight decrease in the first 2 days, which was followed by incomplete to complete recovery (Dodd et al., 1986; Bucher et al., 1987; Varma, 1987). The most likely cause of the rapid decrease in body weight is fluid loss, which may also explain the increase in hematocrit.

MIC also caused an increase in creatinine kinase, hemoglobin, hematocrit, reticulocytes, neutrophils, and blood PCO_2 in rats and guinea pigs (Dodd et al., 1986), as well as a decrease in blood pH and PO_2. MIC can cause hyperglycemia, lactic acidosis, and hypothermia in rats (Jeevaratnam and Vaidyanathan, 1992). Mishra et al. (1991) exposed rats to different concentrations of MIC vapor for 8 min and measured drug metabolizing enzymes in lungs and found that aminopyrene demethylase and aniline hydroxylase activities were inhibited, but glutathione-*S*-transferase activity was increased.

Toxicity in Humans

The human toxicity of MIC has been reviewed by several investigators (Mehta et al., 1990; Dhara and Dhara, 2002; Sriramachari, 2004). Toxicity in Bhopal consisted of minor eye ailments; throat irritation and cough; severe conjunctivitis, keratitis, acute bronchitis, and drowsiness; severe pulmonary edema; convulsions followed by cardiorespiratory arrest (Kamat et al., 1985; Misra et al., 1987).

Acute Toxicity

Nonlethal Effects Eye irritation, lacrimation, choking sensations, and difficulty in breathing were first reported by Kimmerle and Eben (1964), who exposed human volunteers to MIC vapor; the observation of these workers was confirmed by thousands of the victims of the Bhopal disaster. In addition, many of the victims lost consciousness; some, but not all, regained it (Varma, 1986).

Fatal Effects Although the precise number of people who died after being exposed to MIC is still not known; our estimate, based on fatalities in 3,270 households surveyed to determine effects on pregnancy (Varma, 1987), would suggest 6,000–8,000 deaths within 24–72 h after the gas leak in Bhopal. Deaths can be attributed to pulmonary edema. As mentioned earlier, deaths did not occur as quickly as is characteristic of cyanide poisoning; rather, it happened after a delay of several hours.

Subacute and Chronic Toxicity

Mortality. Anecdotal reports suggest that the Bhopal disaster resulted in approximately 20,000 deaths over approximately 2 years. Since late deaths have been observed by several workers in animal models (various articles in EHP, 1987), it is reasonable to assume that there will be reports of late deaths in humans as well. It is very likely that severe lung damage accounted for most of these late deaths, although a contributory role of dehydration, internal hemorrhage, and other complications cannot be ruled out.

Pulmonary Complications

Examination of 500 exposed people within 3 days of the Bhopal disaster (Sharma and Gaur, 1987) identified alveolar edema and destructive lesions in 8%. A retrospective study of 978 patients found mortality in 7.14%, breathlessness and cough in 95%, irritation and choking in the throat in 46%, and chest pain in 25% (Misra et al., 1987). Evidence of necrotizing lesions in respiratory tract, as well as radiological changes and compromise in lung function, has been documented (Gupta et al., 1988; Misra and Nag, 1988). Since the prevalence of compromise in lung function was higher in the population closer to the Union Carbide plant than in the population farther away, it is very likely that this occurred as a result of exposure to the toxic gases rather than preexisting bronchitis, tuberculosis, or emphysema. A follow-up of 113 exposed patients revealed worsening of pulmonary symptoms 2 years later, forced expiratory flow (FEF) between $FEF_{25\%}$ and $FEF_{75\%}$ of forced vital declined progressively over a 2-year period (Kamat et al., 1985, 1992; Patel et al., 1987), a 1- to 7-year period (Vijayan et al., 1989; Vijayan and Kuppurao, 1993; Vijayan and Sankaran, 1996) and a 10-year period (Acquilla et al., 1996; Dhara et al., 2002). Likewise, other researchers have found a direct relationship between pulmonary function compromise and inflammatory alveolitis and the severity of exposure (Vijayan et al., 1989). A causative relationship between the intensity of exposure to toxic gases and a decrease in $FEF_{25–75\%}$ is also suggested by another follow-up study of 454 adults conducted 10 years after the disaster (Cullinan et al., 1997).

Persistent airway hyperreactivity after a single exposure to chemical irritant has been termed *reactive airways dysfunction syndrome (RADS)* (Brooks et al., 1985). There is a strong likelihood of RADS among the victims of the gas exposure in Bhopal (Nemery, 1996); however, the question of whether the exposed Bhopal population suffers from RADS has not been carefully studied.

Ocular Toxicity

There are reports that eye irritation and some level of lacrimation was a common experience of workers at the UCIL pesticide plant. Indeed, because of these frequent episodes of eye irritation, workers initially did not suspect that something unusual was happening in the early morning of December 3, 1984. It would seem that the eyes are most sensitive to MIC toxicity since eye irritation was experienced even by people who lived quite far from the plant and seem not to have experienced pulmonary and other symptoms (Varma, 1986). Exposure to MIC produced ocular burning, watering, pain, and photophobia (Dwivedi et al., 1985), as well as conjunctivitis and corneal opacity (Maskati, 1986). Within the first 2 weeks of the disaster, Andersson et al. (1988) found no case of blindness in a community-based survey; surprisingly, the incidence of photophobia and interpalpebral erosion were highest in areas where the death rates were lowest.

Follow-up studies up to 2 years after the incident revealed persistent eye watering, itching, redness, photophobia, burning, Bitot's spots, and even corneal opacity (Khurrum and Ahmad, 1987; Andersson et al., 1988). It is noteworthy that in a gas-exposed cohort of 232 children admitted to the Pediatric and Eye Ward of the Hamidia Hospital, respiratory and cardiac complications were not accompanied by equally serious eye injuries (Dwivedi et al., 1985). It is very likely that poor living conditions, which favor infection (especially in children), further worsened ocular toxicity (Dhara and Dhara, 2002). On the other hand, it was feared at the time of the accident that a large number of survivors might be left with severe visual impairment; fortunately, this does not seem to be the case, which does indicate that profuse watering, a toxic effect of MIUC, also had the effect of minimizing ocular toxicity.

Reproductive Toxicity

A follow-up study of 865 pregnant women living close to the UCIL pesticide plant at the time of the Bhopal disaster found that 379 (43.8%) did not give birth to live babies (Varma, 1987). Another follow-up of 2566 pregnant women from 18,978 households also found that 23.6% of the exposed women suffered miscarriages, as compared to 5.6% of 1218 control cohorts (Bhandari et al., 1990). Kanhere et al. (1987) found that exposure to toxic gases resulted in decreased placental and fetal weights. In addition, approximately 14% of the subjects experienced increased loss of pregnancy and infant deaths within 1 month, 2 years, and 5 years after birth, compared with 2.6–3% within the pre-accident period (Varma et al., 1990). Other effects of exposure to MIC in women include leucorrhea, suppression of lactation, pelvic inflammatory disease, and irregular menstruation (Varma, 1986). No effect on spermatogenesis was detected within 6 months after the Bhopal disaster (Daniel et al., 1987).

Genotoxicity

In a study involving 43 gas-exposed women and 40 gas-exposed men 3 years after the disaster, a significant increase in chromosomal aberration was reported; these aberrations included breaks, gaps, and dicentric rings, which were more marked in females than in males (Ghosh et al., 1990). Chromosomal aberrations (Goswami, 1986; Ghosh et al., 1990) and cell cycle abnormalities have been identified in Bhopal victims (Deo et al., 1987).

Carcinogenicity

The possibility of cancer in the Bhopal population exposed to MIC was raised by journalists. Usually, multiple contacts with a carcinogen are needed to produce cancer, but a single dose of a chemical can have the same effect (Calabrese and Blain, 1999). A cancer registry was initiated by the ICMR. However, no conclusive evidence of increase in cancer in the exposed population has been documented. Senthikumar et al. (2011) have reported a total of 1,261 cancer patients in the long-term Bhopal survivors, but they do not provide information about the size of the population examined; it is, therefore, difficult to infer whether exposure to MIC increased cancer.

Immunotoxicity

Saxena et al. (1988) studied 31 exposed adults and found a significant increase in abnormal lymphocytes; however, they saw no compromise in humoral and cellular immunity in exposed populations in Bhopal. Anti-MIC antibodies were detected in blood samples from gas-exposed subjects, but the clinical implications of this discovery are not clear (Karol et al., 1987).

Neurotoxicity and Psychological Effects

Soon after the Bhopal disaster, there were displays of bizarre drawings by the surviving children, almost all of whom depicted gusts of flames going upward—starkly different from the usual pictures painted by children. Many of these drawings reflected their loss of parents or other family members or friends. While these drawings are unlikely to be specific to MIC, they probably reflected the children's response to unanticipated horror. Psychological trauma was experienced by adults, which shared many similarities with that experienced by soldiers returning from combat missions. One study categorized post-disaster psychological impact into four categories: (i) posttraumatic stress disorder characterized by anxiety, restlessness, and sleep disorder; (ii) pathological grief reactions expressed as suicidal tendencies and helplessness at not being able to save family members; (iii) emotional reaction to physical problems imposed upon them; and (iv) exacerbation of preexisting

problems (Murthy and Isaac, 1987). A survey of 164 gas-exposed children 105 days after the disaster found them apprehensive and jittery (Irani and Mahashur, 1986).

The authors of this chapter encountered a volunteer at Sambhavana Trust Clinic, which is located near the now-decommissioned pesticide plant. This young man, whose parents died during the disaster, was perfectly normal on the many occasions we saw him, but other workers at the clinic told us that from time to time, he would become very depressed. One day in 2007, we received a message from Bhopal that he had committed suicide. There are reports of other such cases, although it is never possible to causally link such tragic events with exposure to MIC.

Sethi et al. (1987) reported that a large number of survivors suffered from organic neurological problems, including neuroses, anxiety states, and accentuation of previous psychological problems. Bharucha and Bharucha (1987) also observed neurological and neuromuscular abnormalities in both adults and children and concluded that the incidence was lower than expected following a disaster of such magnitude as occurred in Bhopal; 24 of the 47 children examined by these authors experienced coma lasting for a maximum duration of 24 h. Neurological problems have also been reported by others (e.g., Kamat et al., 1985; Gupta et al., 1988; Misra and Kalita, 1997). Raphael and Middleton (1988) have suggested that 30–59% of those exposed to a disaster may suffer from traumatic neuroses.

Other Toxic Effects

Soon after the disaster, Bhopal was flooded with people hoping for a cure, as well as vendors selling all kinds of medicines that they claimed would provide one. Some did not know what to expect in days following the accident and hoped that pills would safeguard against existing ailments like loss of appetite, weakness, and breathlessness and prevent complications. This scenario is typical of developing countries.

At present, 25 years later, victims of the disaster still occupy hospital beds and clinics and go to private practitioners of all branches of medicine, with complaints ranging from vague to very specific. In general, however, it is difficult to relate many of these symptoms, such as weakness, loss of appetite, anxiety attacks and menstrual problems, to exposure to MIC. But many subjects continue to suffer from pulmonary dysfunctions and some compromise in visual functions.

As mentioned before, most of the victims of the disaster belonged to economically disadvantaged groups and lived in poor housing with nonexistent sanitary facilities. Therefore, they already probably suffered from many chronic diseases, including bronchitis, tuberculosis, and malaria. Even so, the Bhopal disaster certainly worsened their maladies.

TREATMENT

By their very nature, disasters involving chemicals pose special problems because they concern a large number of people in a state of panic, all at the same time. Most places are not equipped to deal with such situations, especially if there is confusion about the nature of the chemical. If the chemical is a pulmonary irritant, as was the case with MIC, there is a good likelihood of suspecting cyanide poisoning, as happened in Bhopal. The other reason for mass confusion is the erroneous belief that antidotes exist for every poison.

Laypeople are not expected to know that supportive therapy is the cornerstone of managing drug overdose or poisoning, rather than antidotes; a few exceptions include cyanide, narcotic analgesics, acetaminophen, methanol, organophosphates, digitalis, and carbon monoxide. It was legitimate for the media and people in Bhopal to demand an antidote. Therefore, conveying accurate information to the panicked population was vital. In the case of Bhopal, nondisclosure of the nature of the chemical for some period of time, inaccurate information on the cause (like the mistaken belief that it was cyanide), and lack of proper treatment proved as harmful as the poison itself. For example, if people had been warned not to run away, but instead encouraged to stay still and cover their faces with wet cloth, the benefits would have been significant.

In the midst of all the confusion, the doctors in Bhopal worked out as rational a treatment as possible, which comprised of atropine, antibiotic eyedrops, and antispasmodics. Treatment of pulmonary edema requires hospitalization and positive pressure respiration; Bhopal neither had enough beds nor equipment to provide this.

Long-term treatment is also supportive and is unrelated to the initiating factors. For example, the treatment of pulmonary, ophthalmic, or neurological complications has nothing to do with whether these occur due to MIC or phosgene poisoning or due to some other cause. Cyanide, unless ingested on a regular basis from the environment or food, does not produce long-term disability if it fails to cause death.

A redeeming feature of the Bhopal tragedy was the overwhelming response of the Indian people. Hundreds flocked into Bhopal on the morning of December 3 from nearby villages, and some came from far away. In addition, doctors did a commendable job working for long hours without a break. In contrast, the medical team dispatched by Union Carbide arrived 10 days later and tried to assure the public that MIC would be destroyed rapidly and that no long-term effects were to be expected. The government of India could not summon a high-level medical team to deal with the disaster and failed miserably in following up as well. Voluntary groups and nongovernmental organizations shared a major burden

of reassuring people and helping with both treatment and rehabilitation.

TOXIC POTENTIAL OF MIC BEYOND THE BHOPAL DISASTER

The Bhopal incident was the first case of mass exposure of humans, animals, and vegetation to MIC. Several factors influenced the toxicity of MIC, such as the living conditions of the victims. Under identical conditions in a developed country, the consequences most likely would have been different. At the same time, the exposure of the Bhopal population was to a specific concentration of MIC and for a specific duration.

The accidental release of MIC can happen wherever the chemical is stored. A minor leak occurred from the Union Carbide plant in West Virginia only a few months after the Bhopal disaster, and a school in the area had to be evacuated. Exposures to MIC at higher concentrations and for longer durations than in Bhopal can also occur, and these can be fatal to a substantially greater percentage of population regardless of where they happen. The fact that MIC is heavier than air makes it a potentially highly hazardous chemical, both in enclosed and open spaces.

If animal experiments were solely directed to answer questions relating to the Bhopal disaster, the use of excessively high concentrations of MIC (Dodd et al., 1986; Fowler et al., 1987) and repeated exposures would not have been very relevant. However, workers are likely to encounter repeated exposure to MIC; indeed, anecdotal reports suggest that the impending disaster was not suspected because workers were used to minor leaks (and consequently, eye irritation) in the Union Carbide plant.

No workers died inside the plant in Bhopal because MIC spewed outside the factory; however, an accident worse than Bhopal cannot be ruled out, especially if the space is enclosed.

The confusion caused by the lack of transparency about the identity of the poison by the concerned authorities at the Union Carbide headquarters and conflicting instructions only worsened the tragedy. It can be assumed that whenever a disaster of this kind of magnitude occurs, rumors are likely to come out. To counter this, it is vital that the facts about such incidents be made public by management as soon as possible.

BENZYL CHLORINES AND OTHER CHEMICALS AT BHOPAL

MIC and many other chemicals were stored in Bhopal. The disaster in 1984 led to the closure of the UCIL factory. While the remaining MIC was disposed of during Operation Faith, Union Carbide closed its Bhopal location, and several hundred metric tons of hazardous waste stored in open areas and sheds were not destroyed. The first study on this topic, by Dikshith et al. (1990), demonstrated the presence of 1-napathol in the soil and water in Bhopal. In all, 15 other studies were conducted between 1990 and 2010 by groups like Greenpeace International, Centre for Science and Environment (CSE), and National Environmental Engineering Research Institute (NEERI), to address the issues of whether the stored pesticides and chemicals on the factory grounds, solar evaporation ponds, and soil surrounding the factory contaminated the drinking water, and if so, which chemicals were present in levels that exceeded permissible levels. There is close agreement about the extent and type of contamination among several studies. In studies by CSE (Johnson et al., 2009; CSE, 2013), the maximum concentration found in soil samples from specific locations like the storage, processing, and dump areas recorded contamination with carbaryl (51,003 ppm), aldicarb (7,876 ppm), dichlorobenzene (2,049 ppm), HCH isomers (99,700 ppm), and α-naphthol (9,914 ppm), as well as heavy metals like mercury (128,000 ppm), lead (406 ppm), and chromium (1,065 ppm). The NEERI report downplayed contamination of groundwater, stating that it most likely occurred due to runoff from the material dumped in the pesticide plant; but the CSE report (2013), along with several other studies, concluded that the groundwater was contaminated significantly with chemicals. All the reports acknowledged that there was very little information on the contaminants in the solar evaporation ponds where factory waste was discharged during the entire operation of the UCIL plant (CSE, 2013). Both the CSE and the NEERI reports documented the type and amount of chemicals dumped within the factory premises from 1969 to 1984. What is most surprising is that none of these reports were published in mainstream journals.

Why remediation of the site has not occurred is no secret. The cost of incineration of over 1 million metric tons of contaminated soil would be well over 10,000 million rupees, and no one—neither the Indian government nor Dow Chemical, which bought Union Carbide in 2001—was prepared to pay the bill. So to date, very little has been done to get rid of the contaminated soil, let alone treat the contaminated water. In addition, the area surrounding the old UCIL plant has gained in population (now over 40,000 people), and these people have been drinking the chemical-laced water for 5–10 years, or even longer (up to 2 decades). There is concern that these chemicals (some known to be teratogens) might increase the incidence of birth defects. Indeed, a systematic study by the authors is underway to document the effect on people of exposure to contaminated water, gas, or both, as compared to people who were not exposed to any toxic substances. We anticipate the completion of this study by the end of 2014.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

We have described the chemistry, pharmacology, and toxicology of MIC in the context of more commonly used diisocyanates. Combatants and civilians have been subjected to lethal and debilitating chemical agents during war. However, no poisonous chemical other than MIC has the dubious distinction of killing nearly 8,000 people within 72 h, and many more in the subsequent years and maiming civil society on a scale as large as what happened in Bhopal in peacetime. Unlike the September 11, 2001 terrorist attack in the United States, where the total number of casualties is accurately known, no one is still certain about the exact death toll from the Bhopal incident, whether immediately afterward and in the subsequent months and years; unfortunately, the same can be said about most disasters in the developing part of the world. While acute deaths were most likely caused by pulmonary edema, only a well-planned epidemiological study coordinated by official agencies could have determined the nature and the magnitude of long-term effects. Unfortunately, such a study was not done, and many of the long-term effects cannot be identified retroactively. Carcinogenicity and genotoxicity requires long-term follow-up of a large population. So far, the results have been disappointing.

MIC toxicity amply demonstrates that the full dimension of the pharmacology of a chemical cannot be predicted from its chemical structure, but it can be approximated by careful and painstaking research. Such an inquiry into MIC would be advisable.

India may be the 12th-largest economy in the world; however, the victims of Bhopal do not benefit from that fact. Just in the period of February to May 2008, hundreds of women, men, and children marched a distance of 800 km to the Indian capital of Delhi to demand clean water, appropriate therapy, and rehabilitation. The last time such a march happened in 2006, some promises were made, but they were not fulfilled. What will happen this time? Only time will tell.

Acknowledgments

We thank Sambhavana Trust Clinic, Bhopal, for their help with our epidemiologic research. This article is dedicated to the victims of the 1984 Bhopal Disaster.

CHAPTER

23

Cyanide Toxicity and its Treatment

Rahul Bhattacharya and Swaran J.S. Flora

INTRODUCTION

Cyanide refers to a highly toxic chemical compound containing one atom of carbon and nitrogen each. Deaths caused by cyanide poisoning are relatively rare, largely because of its limited availability (Musshoff et al., 2002). However, the name cyanide and its toxic characteristic have long been a source of dread for humans. The first reported isolation of hydrocyanic acid from Prussian blue was by the Swedish chemist C.W. Scheele in 1782, and he was reported to be the first victim of this poison in 1786 when he accidentally broke a vial of the chemical in the laboratory and died from vapor poisoning (Ballantyne, 1987).

Since the days of ancient Rome, cyanide and its derivatives were used in weapons (Sykes, 1981). Nero used cherry laurel water, which contained cyanide as its main toxic component, to poison members of his family and others who displeased him. Napoleon III proposed the lacing of soldiers' bayonets with cyanides during the Franco-Prussian War. Hydrogen cyanide (HCN) was not very successful as a chemical warfare agent during World War I because it was not persistent. During the same period, the French army used artillery shells under the name Vincennite (50% HCN, 30% arsenic trichloride, 15% stannic chloride, and 5% chloroform) but because of high volatility of HCN, these munitions could not be used effectively. Also, German soldiers were adequately equipped to protect themselves from HCN exposure. In 1916, the French experimented with cyanogen chloride, which was heavier and less volatile than HCN. The effect of cyanogen chloride was similar to HCN. Additionally, it caused marked lacrimation, rhinorrhea, and bronchial secretions similar to phosgene. However, these effects were considered to be of little military importance compared with its tissue effects. During World War II, the Nazis used Zyklon B (briquettes of calcium sulfate impregnated with 40% HCN) made by IG Farben, Germany, to exterminate millions of civilians and enemy soldiers in the death camps (Robinson, 1971; Baskin, 1998). It is also reported that in the late 1980s, there was the possible use of cyanide against the inhabitants of the Syrian city of Hama, the inhabitants of the Kurdish city of Halabja, Iraq, and in Shahabad, Iran, during the Iran–Iraq war (Baskin and Rockwood, 2002). Cyanide gas precursor compounds were found in several subway restrooms in Tokyo after the release of sarin in Tokyo in 1995 (Sidell, 1996). Allegedly, cyanide was added to the explosives used in the first attack on the World Trade Center in New York (Brennan et al., 1999).

The use of cyanides for murder and suicide and accidentally use have been passably reviewed by Gee (1987). One hundred nine passengers in 1973 and 303 pilgrims in 1980 were feared killed in Paris and Riyadh, respectively, because of inhalation of HCN from smoldering plastic inside aircrafts that accidentally caught fire (Mohler, 1975; Weger, 1983). In 1985, the explosion of a Boeing 737 during take-off at Manchester, England, revealed that 20% of the 137 victims who escaped had dangerously high levels of carbon monoxide, whereas 90% had significantly elevated levels of cyanide. Similarly, short circuits in electrical wires also caused fire on ships that led to the combustion of plastic materials releasing HCN, which resulted in severe poisoning (Levine et al., 1978). The murders of two Ukrainians, Rebet (1957) and Bandera (1959), were committed by a Soviet agent in Munich using a gas pistol containing cyanide (Anders, 1963). In September 1982, seven people in Chicago died when cyanide was illicitly placed in bottles of Tylenol (acetaminophen manufactured by McNeill Consumer Products Co., Fort Washington, PA) (Wolnick et al., 1984). In 1978, 912 members of a religious sect in Port Kaituma, Guyana, committed mass suicide after consuming a grape-flavored drink laced with cyanide (Thompson et al., 1987; Sidell et al., 1997). Some other incidents of illicit cyanide use include cyanide

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00023-3

gas–producing devices in Tokyo subway and railway station restrooms in 1995 (Okumura et al., 2003), ingestion of cyanide tablets by Michael Martin on receipt of a guilty verdict for arson in June 2012 (Davenport, 2012), and the death of Urooj Khan, a lottery winner, in Chicago in July 2012 (Keyser, 2013). The first case of illegal euthanasia in Spain was reported when a tetraplegic patient whose repeated legal requests for euthanasia were refused consumed potassium cyanide (KCN) (Blanco and Garcia, 2004).

The toxicology of cyanide and its treatment modalities have been extensively discussed by many authors (Vennesland et al., 1981; Way, 1984; Ballantyne and Marrs, 1987; Gonzales and Sabatini, 1989; Borowitz et al., 1992; Salkowski and Penney, 1994; Marrs et al., 1996; Baskin and Brewer, 1997). Additionally, over the years thousands of research articles on cyanide have appeared. Cyanide, being such an old poison, and its effects seem to be known universally. But most of the crucial molecular mechanisms underlying cyanide toxicity have been elucidated only in the recent past (Gunasekar et al., 1996; Sun et al., 1997; Borowitz et al., 2001). Cyanide is a very interesting molecule; it has always fascinated researchers and is the reason for further study. This chapter attempts to enlighten the reader with the known facts about cyanide and some of the recent advances made in its toxicology and antagonism.

SOURCES OF EXPOSURE

The use of cyanide for military purposes has been very insignificant and most of the cases of poisoning have involved civilians, for example, in the case of fires and industrial accidents. The human–cyanide interaction is very common because of its wide industrial applications. Worldwide industrial consumption of cyanide is estimated to be 1.5 million tons per year, and occupational exposures account for a significant number of cyanide poisonings (Cummings, 2004; Logue et al., 2010; Coentrão and Moura, 2011). Cyanide poisoning may occur from a broad range of exposures and is summarized in Table 23.1. Some of the major sources of poisoning are as follows.

TABLE 23.1 Various Possible Sources of Cyanide Poisoning

Fire smoke	Smoke generated after combustion of silk, polyurethanes, polyacrylonitriles, nylon, melamine resins, plastics, etc., in accidents including industrial, residential, car, aircraft, ship fire
Industrial exposure	Plastics production, dyeing, printing and photography, fumigation of pesticides/rodenticides, synthetic rubber production, fertilizer production, metal polish, tanning in leather industry, electroplating, metallurgy, paper and textile manufacture
Drugs	Sodium nitroprusside, Laetrile, Succinonitrile
Dietary	Cassava, lima beans, linseed, bamboo sprout, macadamia nuts, hydrangea, Rosaceae family (plum, peach, pear, apple, bitter almond, cherry), *Sorghum* species (Johnson grass, sorghum, Sudan grass, arrow grass), *Linum* species (flax, yellow pine flax)
Others	Cigarette smoking, phencyclidine synthesis, ingestion of nail polish remover, suicide, homicide, terrorist attack, chemical warfare, capital punishment

Fire Smoke

Residential fires may result in life-threatening poisoning (Alarie, 2002; Megarbane et al., 2003). In a closed space, fire induces a combination of oxygen deprivation directly related to combustion and simultaneous intoxication by asphyxiant and irritant gases (Baud, 2007). Cyanide can be liberated during combustion of products containing carbon and nitrogen. These products include wool, silk, polyurethane, polyacrylonitriles, melamine resins, and synthetic rubber (Vogel et al., 1981; Bismuth et al., 1987; Homan, 1987). It is estimated that significant levels of cyanide are present in almost 35% of all fire victims (Clark et al., 1981; Barillo et al., 1994; Sauer and Keim, 2001). Carbon monoxide is also an important component of fire smoke and its concomitant exposure with HCN is known to exacerbate the toxicity because both cause tissue hypoxia by different mechanisms (Barillo et al., 1994).

Industrial Exposure

Occupational exposures to cyanide in industry have caused serious problems (Blanc et al., 1985; Peden et al., 1986). Cyanide is used in many chemical syntheses, plastics and rubber processing, gold and silver extraction, tanning, metallurgy, photography, and fumigation of pesticides/rodenticides (ATSDR, 1997). Cyanide poisoning can also occur after contamination of the skin with cyanide solution or inhalation of released HCN during electroplating in jewelry polishing (Sullivan and Krieger, 2001; Megarbane et al., 2003). Exposure to silver brightener, which contains cyanide, has also caused death. Subsequent to initial lethal inhalation of cyanide, an extensive postmortem transcutaneous diffusion of cyanide was also shown to occur (Seidl et al., 2003). Cyanogens are complex nitrile-containing materials that can generate free cyanide of toxicological significance. Many of the cyanogens occur naturally or are produced synthetically. The synthetic cyanogens have a variety of industrial, domestic, and therapeutic uses (Ballantyne, 1987). Some of the synthetic cyanogens include acetonitrile, acrylonitrile, adiponitrile, malononitrile, propionitrile, succinonitrile, sodium nitroprusside, and

tetremethyl succinonitrile. Fires involving nitrogen-containing polymers, often found in fibers used in fabrics, upholstery covers, and padding, produce HCN (Tsuchiya and Sumi, 1977).

Drugs

Cyanide is a metabolic product of amygdalin (Laetrile®) that was introduced as an anti-neoplastic agent in the 1950s and was responsible for several cyanide poisoning cases (Hall et al., 1986; Bromley et al., 2005). Intestinal beta-D-glucosidase digests the amygdalin, releasing HCN. Also, iatrogenic exposure to cyanide may result after the use of sodium nitroprusside, an anti-hypertensive agent (Vesey and Cole, 1985), and succinonitrile, an anti-depressant (Ryan, 1998). Sodium nitroprusside is used medicinally as Nipride®, and its intravenous infusion is used to lower blood pressure in hypertensive emergencies. This application of sodium nitroprusside occasionally causes classical cyanide toxicity (Kurt, 1983). Death caused by mercuric cyanide or mercuric oxycyanide poisoning was reported because of possible ingestion of an antiseptic or a hair lotion commercialized in France (Labat et al., 2004).

Dietary

Cyanide occurs naturally in cassava (*Manihot esculenta* Crantz) as linimarin, a cyanogenic glycoside. Cassava roots are a major source of energy for millions of people in the tropics. However, chronic ingestion of cassava-based foods accounts for several toxicological effects, including various neuropathies and amblyopia (Rosling, 1989; Kamalu, 1995). Several common plants also contain cyanogenic glycosides and their ingestion can result in death attributable to improper processing (Conn, 1988). The family Rosaceae, which includes plum, peach, pear, apple, bitter almond, and cherry, is responsible for many cases of cyanide poisoning (Ryan, 1998).

Other Sources

There are numerous other instances of cyanide poisoning that include illicit synthesis of phencyclidine, ingestion of nail polish remover (acetonitrile), use in terrorist attacks, use as suicidal, homicidal, and chemical warfare agents, and use in capital punishment. HCN was considered to be a notorious chemical warfare agent because of its rapid lethal actions. It was used as a war gas in World War I (Gee, 1987), in World War II (Williams and Wallace, 1989), and in the Iran–Iraq War (Lang et al., 1986; Heylin, 1988). Because of poor persistence of HCN in the environment and lack of delivery system, cyanides were not optimistically considered for future use in wars. However, its possible use in local terrorist actions cannot be overlooked. Because cyanide can be released from both synthetic and natural materials, terrorist acts with explosives or incendiaries, which could cause fire in enclosed spaces, make cyanide and cyanogenic compounds potential threats for terrorism (Rotenberg, 2003). During the past decade, Japan has experienced the largest burden of chemical terrorism-related events in the world, which included the Nagano cyanide incident in 1998 and two intentional cyanide releases in Tokyo subway and railway station restrooms, which were thwarted in 1995 (Okumura et al., 2003). Because of the natural cyanide found in tobacco, cigarette smokers show a significant increase in blood cyanide levels as compared with nonsmokers. Visual abnormalities of tobacco amblyopia are usually associated with heavy smoking and vitamin B_{12} deficiency (Wilson, 1983; Homan, 1987).

TABLE 23.2 Toxicity of Hydrogen Cyanide by Inhalation

Concentration		
mg/m^3	ppm	Effects
20–40	18–36	Slight symptoms after several hours
50–60	45–54	Endurable for 20–60 min without effect
120–150	110–135	Very dangerous (fatal) after 30–60 min
150	135	Lethal after 30 min
200	181	Lethal after 10 min
300	270	Immediately lethal

TOXIC LEVELS OF CYANIDE

It is not easy to determine the lethal doses of cyanide in humans. Morbidity or mortality depends on the magnitude of poisoning, which varies with the dose and form of cyanide and the route of poisoning. The maximum permissible concentration for HCN in human is 11 mg/m^3 (Ballantyne, 1974). Taken orally, the fatal dose of HCN to adults is estimated at 50–100 mg, and for KCN it is approximately 150–250 mg (DuBois and Geiling, 1959). Figures estimated in terms of body weight for HCN vary from 0.7 to 3.5 mg/kg (Hallstrom and Moller, 1945). However, victims ingesting as much as 3.0 g of KCN have been saved with immediate therapy (Van Heijst et al., 1987). Table 23.2 shows that inhalation of HCN at a concentration of 300 mg/m^3 (approximately 270 ppm) will be immediately fatal, whereas at 20–40 mg/m^3 mild symptoms will appear after several hours of exposure (Rumack, 1983; FOA, 1992). Victims with a blood cyanide level of 2.5–3.0 µg/mL frequently succumb to respiratory cessation within 20–30 min of exposure or may survive up to 3 h (Ballantyne, 1974;

TABLE 23.3 Acute Lethal Toxicity of KCN by Oral Route for Different Species of Animals

Species	Sex	LD_{50} (mg/kg)	Reference
Mouse	Male	8.50	Sheehy and Way (1968)
	Male	12.5	Bhattacharya et al. (2002)
Rat	Male	10.0	Hayes (1967)
	Female	7.49	Ballantyne (1984)
	Female	14.1	Bhattacharya and Vijayaraghavan (2002)
Rabbit	Female	5.82	Ballantyne (1984)

Van Heijst et al., 1987). Oral ingestion of cyanide may also produce rapid onset of symptoms because many human doses far exceed the minimal lethal dose. Studies of experimental animals have shown that absorption of cyanide decreases with a more alkaline stomach and that normally most cyanide is absorbed within 2–3 h of ingestion (Ryan, 1998). However, substances such as nitrile compounds and amygdalin from plants require enough time for conversion to cyanide before they can produce symptoms of toxicity (Ryan, 1998). Laetrile is synthesized from amygdalin. One gram of laetrile contains the equivalent of 60 mg of cyanide, and each laetrile tablet may contain up to 100 mg of laetrile. A 12-table to 18-tablet laetrile overdose is sufficient to produce severe metabolic acidosis and convulsions (Ellenhorn et al., 1997). The lethal toxicity of HCN and its alkali salts by different routes for different species of animals and sexes has been largely discussed elsewhere (Ballantyne, 1984, 1987). A study performed using rabbits revealed the following order of decreasing toxicity of KCN administered by different routes: intravenous > intramuscular > intraperitoneal > per oral > instillation into conjunctival sac > percutaneous (Ballantyne, 1984). The comparative per oral LD_{50} values of KCN for different species of animals are given in Table 23.3. Rabbits were found to be more susceptible than rats and mice.

DETECTION AND ESTIMATION OF CYANIDE

Determination of cyanide or its metabolites in biological fluids is necessary for forensic, clinical, military, research, and veterinary purposes. The choice of analytical methods depends on a variety of factors like sensitivity, specificity, rapidity, convenience, facilities, and expertise. The selection of biological sample, time of sampling, time to analyze and storage conditions, and interfering substances are other factors that influence the choice of analytical methods (Troup and Ballantyne, 1987; Jackson et al., 2014). There are several convenient and sensitive methods for measuring cyanide in biological fluids, but many of them have limitations. Some of the methods are summarized here.

One of the most common procedures includes diffusion and trapping of cyanide in the alkaline media before colorimetric analysis in pyridine–pyrazolone mixture (Epstein, 1947). This method was subsequently modified for microdiffusion analysis of cyanide (Feldstein and Klendshoj, 1954). This procedure is widely used during the treatment of cyanide intoxication and thiosulfate is known to interfere in the colorimetric estimation, which was subsequently resolved (Morgan et al., 1979). A rapid (approximately 20 min), specific, and sensitive spectrophotometric method for whole blood cyanide assay has also been developed (LaForge et al., 1994). All these procedures are based on the König reaction, which starts with the production of cyanogen chloride. A spectrofluorometric determination of cyanide and thiocyanate based on modified König reaction in a flow-injection system was also reported with detection limits of 30 nM for both anions (Tanaka et al., 1992). Spectrophotofluorometry is also a convenient, sensitive method provided that previous microdiffusion has been performed to isolate and concentrate the cyanide. The fluorometric methods using pyridoxal are more sensitive and require fewer and more stable reagents than the colorimetric method (Takanashi and Tamura, 1970). However, sodium thiosulfate is known to interfere with the chemical conversion of the fluorophore and it is possible to circumvent the interference by using acetate buffer (pH 5.2) as the acidifying agent. Another fluorescent method with an advantage over pyridoxal uses parabenzoquinone, and this method is not known to have any extraneous interference (Guilbault, 1976).

The potentiometric determination of cyanide using ion-selective electrodes has become yet another very popular technique because it is a convenient, rapid, and sensitive method of analysis (Frant et al., 1972). Microdiffusion of biological samples containing cyanide is recommended before potentiometric determination. The use of a cyanide ion–selective electrode in combination with the Conway microdiffusion method for the measurement of cyanide concentrations in human red blood cells (RBCs) and plasma was reported with remarkable recovery of cyanide (Yagi et al., 1990). Ion chromatographic determination of sulfide and cyanide in real matrices by using pulsed amperometric detection on a silver electrode was reported by Giuriati et al. (2004).

The measurement of HCN directly by gas chromatography has also been reported, but this method lacks sensitivity with most detectors (Valentour et al., 1974). Gas chromatographic techniques are not widely used for measuring cyanide because other methods are more convenient. A simple and sensitive method was devised for determining cyanide and its major metabolite,

thiocyanate, in blood using an extractive alkylating agent (pentafluorobenzyl bromide). The detection limits of cyanide and thiocyanate were 0.01 and 0.003 µmol/mL, respectively (Kage et al., 1996). Rapid quantitation of cyanide in whole blood by automated headspace gas chromatography was performed on clinical samples from fire victims. This method could detect a wide concentration of blood cyanide (30–6,000 µg/L) in approximately 17 min (Calafat and Stanfill, 2002).

A direct and sensitive isotope dilution–mass spectrometry determination of blood cyanide by headspace gas chromatography was developed with the detection limit of 0.3 µmol/L (Dumas et al., 2005). This method was also compared with other techniques in a round-robin exercise. Cyanide can also be measured by indirect atomic absorption spectrometry where a metal–cyanide complex is formed and is then extracted in organic solvent to determine the metal content (Manahan and Kunkel, 1973). An original high-performance liquid chromatographic–mass spectrometric (HPLC-MS) procedure was developed for the determination of cyanide in whole blood. The limits of detection and quantitation were 5 and 15 ng/mL, respectively (Tracqui et al., 2002). Also, several other methods including HPLC, using post-column derivatization with *o*-phthalaldehyde (Sumiyoshi et al., 1995), capillary electrophoresis with fluorescence detection (Chinaka et al., 2001), polyphenol oxidase/clay biosensors (Shan et al., 2004), capillary electrophoresis microchip (Lu et al., 2004), ICT-based probes (Badugu et al., 2005), and microchemiluminiscence (Lv et al., 2005) have been reported for different environmental or biological samples. However, their utility to detect cyanide in blood samples is yet to be ascertained. A technique to detect cyanide currently utilized by water treatment facilities was used to rapidly detect concentrations of cyanide in the clinically important range (Rella et al., 2004). The CYANTESMO test strips accurately and rapidly detect cyanide more than 1 µg/mL. A paper test for cyanide (CYANTOSNO) in whole blood is now commercially available in the United States (Ellenhorn et al., 1997).

TOXICOKINETICS OF CYANIDE

Absorption

Oral absorption of cyanide is rapid, and toxic effects can occur within minutes. When salts of cyanide are ingested, hydrochloric acid in the stomach causes the release of HCN, which is readily absorbed as cyanide ion (CN^-). Cyanide (hydrocyanic acid [HCN]) is a small molecule with good lipid and water solubility. It is rapidly absorbed irrespective of route of exposure because of its low molecular weight (Borowitz et al., 2001). It is mainly absorbed by the respiratory and gastrointestinal mucosa and through skin and eyes on prolonged contact (Ballantyne, 1974; Ellenhorn et al., 1997; Ryan, 1998). In experimental rabbits, cyanide introduced into the conjunctival sacs was quickly absorbed in significant quantities to produce systemic toxicity (Ballantyne, 1983). Dermal exposure is rare, but the large surface area of the skin facilitates absorption of toxic consequences. Nitriles are more readily absorbed through the skin but the onset of toxicity is delayed.

Distribution

After absorption, cyanide distributes to a volume of approximately 40% total body weight. The distribution is rapid and is completed within 5 min after a single intravenous dose (Sylvester et al., 1983). Cyanide is rapidly transported in the body by blood and approximately 60% is bound to plasma proteins, a small amount is present in the RBCs, and the remainder presents as free cyanide (Ryan, 1998). The concentration of cyanide in RBC is estimated to be at a RBC:plasma ratio of 100:1 (Ellenhorn et al., 1997). After acute exposures, the plasma elimination half-life of cyanide was observed to be 14.1 min (Egekeze and Oehme, 1979). After oral poisoning, a significant amount of cyanide was traced in the brain, blood, kidney, stomach wall, liver, and urine (Ansell and Lewis, 1970). This indicates that after absorption, cyanide is widely distributed in all the tissues.

Elimination

Cyanide is rapidly detoxified in mammals. The detoxification rates of cyanide after intravenous administration in humans, dogs, guinea pigs, and rabbits are 0.017, 0.020, 0.04, and 0.008 mg/kg body weight per minute, respectively (Hinwich and Saunders, 1948; NIOSH, 1975). The major pathway of cyanide detoxification (approximately 80%) is through enzymatic transulfuration to thiocyanate (SCN^-), which is nontoxic and excreted in the urine (Lang, 1933). This reaction is catalyzed by an enzyme, rhodanese (thiosulfate cyanide sulfur transferase; EC.2.8.1.1). Rhodanese uses a precursor like thiosulfate, which is a source of sulfane sulfur (divalent ionized sulfur bound to another sulfur atom). The endogenous supply of this substance is very limited. Therefore, detoxification of cyanide largely depends on an exogenous supply of thiosulfate (Westley et al., 1983). However, cyanide detoxification by this pathway is often debated because rhodanese is located principally in the mitochondria and penetration of the cell wall and mitochondrial membrane by thiosulfates is very slow (Bhat and Linnell, 1983). It is presumed that the sulfane sulfur binds first to the serum albumin to yield a sulfane sulfur albumin complex that eventually reacts with cyanide to form thiocyanate (Westley et al., 1983; Way, 1984).

In normal metabolism of cyanide, the serum albumin–sulfane complex may be the primary detoxification mechanism (Sylvester et al., 1983). Unlike other chemical warfare agents, cyanide appears biologically in blood, urine, and expired breath (Lundquist et al., 1988). Cyanide is eliminated from the body by several mechanisms. After 3h, approximately 90% of injected cyanide has been shown to be eliminated in the dog model (Sylvester et al., 1983). A small amount of cyanide is excreted in the urine and via the lungs after being incorporated into cyanocobalamin (vitamin B_{12}), oxidated to formate and carbon dioxide, and incorporated with cystine (Ballantyne, 1987). Other minor pathways of detoxification include enzymes like mercaptopyruvate sulfur transferase, thiosulfate reductase, and cystathionase γ-lyase or disulfide cystine, and 2-iminothiazolidine-4-carboxylic acid (2-ICA) or its tautomer, 2-aminothiazolidine-4-carboxylic acid (2-ACA) (Wood and Cooley, 1956; Baskin et al., 2004). Cyanide reacts with cystine to produce β-thiocyanoalanine, which spontaneously undergoes ring closure to form 2-ICA and 2-ACA, depending on the pH in the cells (Borowitz et al., 2001). To determine the effect of species on cyanide metabolism, toxicokinetics of cyanide was studied in rats, pigs, and goats after oral dosing of KCN (Sousa et al., 2003). The study showed that metabolism of cyanide and its main metabolite, thiocyanate, is species-linked, with goats being the most sensitive to the toxic effects of cyanide.

MECHANISM OF ACTION

The toxic effect of cyanide is attributed predominantly to the production of anoxia after inhibition of the metal-containing enzymes. The critical interaction appears to be the inhibition of the terminal respiratory chain enzyme, cytochrome oxidase a_3 (containing iron), within the mitochondria. The enzyme is essential for the production of adenosine triphosphate (ATP). As a result, aerobic oxidative metabolism and phosphorylation are impaired, leading to cellular hypoxia. The pyruvate that is produced can no longer be used and is now reduced to lactate. The shunt from aerobic to anaerobic metabolism leads to profound lactic acidosis (Solomonson, 1981). Cyanide toxicity may not be ascribed solely to a single biochemical lesion but rather to a complex phenomenon. Cyanide reacts with several metalloenzymes, carbonyl groups of different enzymes, coenzymes, and substrates, resulting in inhibition of normal activity. Cyanide also interacts with sulfhydryl compounds like cystine, mercaptopyruvate, reduced glutathione, and oxidized glutathione to form different complexes (Way, 1984; Borowitz et al., 1992). Cyanide also strongly interacts with iron in protein molecules, inhibiting enzymes including carbonic anhydrase and succinic dehydrogenase (Ballantyne, 1987). Formation of cyanhemoglobin by interaction of cyanide with ferric iron abolishes the ability of hemoglobin to carry oxygen (Way, 1984). The mechanism of cyanide toxicity is summarized in Figure 23.1.

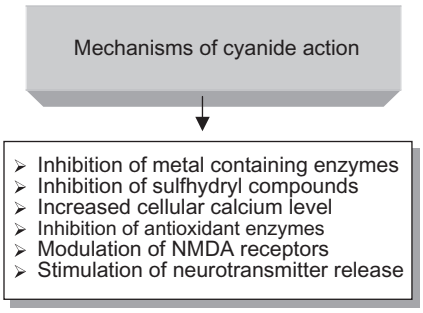

FIGURE 23.1 Mechanisms for the toxic manifestations of cyanide exposure.

Cyanide is regarded as a selective neurotoxin and its toxicity has frequently been associated with elevated levels of cellular calcium (Johnson et al., 1986), inhibition of antioxidant defense enzymes in the brain (Ardelt et al., 1989), and generation of reactive oxygen species (ROS), leading to lipid peroxidation (Ardelt et al., 1994; Kanthasamy et al., 1997). Cyanide increases intracellular calcium through activation of voltage-sensitive calcium channels (Johnson et al., 1987), direct redox modulation and enhancement of *N*-methyl-D-aspartate (NMDA) receptor function (Patel et al., 1992; Sun et al., 1997), and mobilization of intracellular calcium stores (Yang et al., 1997). It was proposed that elevated cytosolic calcium activates proteases, which in turn converts xanthine dehydrogenase to xanthine oxidase. In the presence of oxygen, xanthine oxidase can catalyze the formation of superoxide radicals that initiate lipid peroxidation (Figure 23.2) (Chan and Fishman, 1985). Modulation of NMDA receptor has been widely implicated in cyanide-induced neurotoxicity. Nitric oxide and ROS generation after NMDA receptor activation was found to mediate cyanide-induced neurotoxicity (Gunasekar et al., 1996). Several other studies also showed activation of NMDA receptors during cyanide toxicity (Patel et al., 1992; Sun et al., 1997). Cyanide can stimulate release of glutamate from intracellular stores, resulting in elevation of cytosolic Ca^{2+} through NMDA receptor activation. There is also evidence that cyanide may interact directly with NMDA receptor to enhance NMDA receptor–mediated Ca^{2+} influx (Patel et al., 1994; Sun et al., 1995). It was further shown that cyanide selectively interacted with NMDA subunits, possibly by formation of thiocyanate adduct with a cysteine residue located in NR1 receptor subtype (Arden et al., 1998). Cyanide is also known to interact with cystine to produce 2-ICA and 2-ACA, and the former is responsible for memory loss, convulsions, and loss of consciousness (Bitner et al., 1991). Cyanide

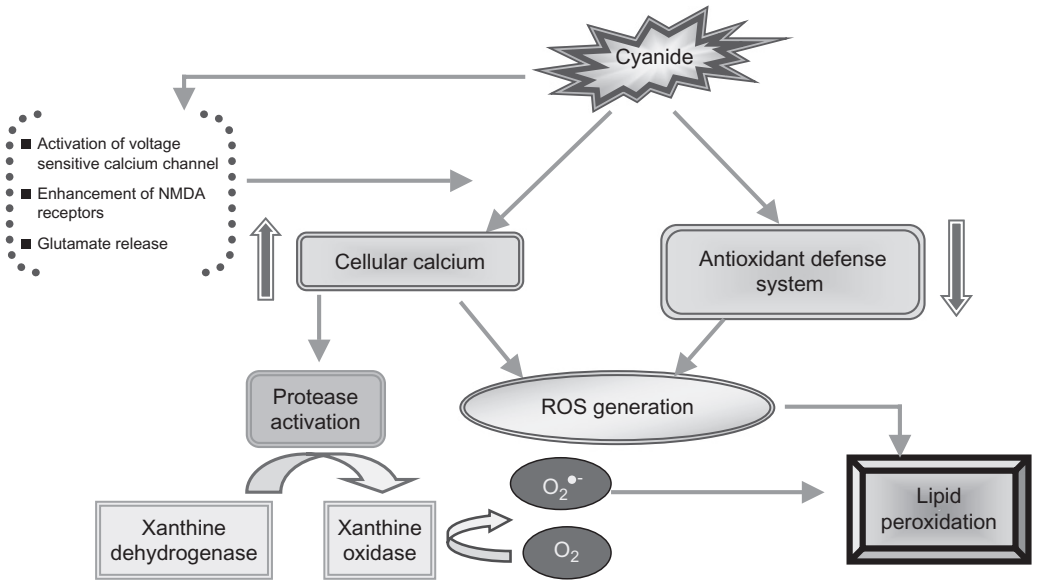

FIGURE 23.2 Pathway of cyanide-induced oxidative stress. Abbreviations used: ROS, reactive oxygen species; O_2, oxygen; $O_2^{\bullet-}$, superoxide anion.

can produce dopaminergic toxicity characterized by loss of dopaminergic neurons in the basal ganglia that is accompanied by impaired motor function (Kanthasamy et al., 1994). Cyanide is also known to stimulate neurotransmitter release in both the central and peripheral nervous systems (Kanthasamy et al., 1991). It is suggested that the convulsive effects of cyanide are due to changes in the levels of dopamine (Cassel, 1995). It has also been opined that protein kinase C, calmodulin, and nitric oxide (NO)-dependent cyclic guanosine monophosphate-dependent enzymes may contribute to the induction of convulsions. ATP depletion may also contribute, in part, to the development of cyanide-induced convulsions (Yamamoto, 1995). Other biochemical processes that may mediate or at least influence cyanide toxicity include lactic acidosis, mitochondrial ADP ribosylation, and hyperammonemia (Borowitz et al., 1992). It is possible that some of these mechanisms are independent of cellular energy deficit but produce severe effects on the cells. Overall, it appears that oxidative stress plays a crucial role in cyanide-induced neurotoxicity (Ardelt et al., 1989; Kanthasamy et al., 1994). Another important aspect of cyanide toxicity is its cardiotoxic manifestations. However, it has been excluded from the present chapter because it has been adequately discussed by others (Baskin, 1991; Borowitz et al., 1992).

DIAGNOSIS AND CLINICAL FEATURES OF CYANIDE POISONING

Signs and symptoms of acute cyanide poisoning are often nonspecific and vary in both time and intensity depending on the scale of exposure (Ballantyne, 1987; Ellenhorn et al., 1997; Nicholson, 2012). Low concentrations may produce delayed and various nonspecific symptoms like headache, dizziness, nausea, vomiting, confusion, coma, and incontinence of feces and urine, but exposure to high concentrations may lead to a series of events like dyspnea, incoordination of movements, convulsive seizures, coma, and cardiac and/or respiratory failure, culminating in death (Ballantyne, 1974; Way, 1984). Pathologically, no particular lesions can define cyanide toxicity, although animal experiments indicate that the lesions are principally in the central nervous system (CNS), particularly necrosis in the white matter (Ballantyne, 1974). Probably the most widespread pathologic condition attributed to chronic cyanide poisoning is tropic ataxic neuropathy after cassava consumption (Rosling, 1989; Kamalu, 1995). Other effects associated with cassava consumption include tropical pancreatitis (Gee Varghese, 1985), tropical neuropathies (Banea et al., 1997), and endemic goiter (Abuye et al., 1998). Repeated or prolonged skin contact to low concentrations of KCN dust may lead to dermatitic effects (cyanide rash) characterized by itching and skin eruptions (NOHSC, 1993).

Although the signs and symptoms of cyanide poisoning are well-documented, more than 55 signs and six biochemical idiosyncrasies are known to possibly occur during cyanide poisoning (Hall et al., 1987). Signs and symptoms of acute cyanide poisoning reflect cellular hypoxia and are often nonspecific. Onset of symptoms depends on dose, route, and duration of exposure. In general, the signs and symptoms correlate with the whole blood cyanide level and are usually tachycardia, flushing, headache, hyperpnea, and dizziness (Table 23.4). Laboratory tests suggestive of cyanide intoxication include arterial blood gases (metabolic acidosis with normal PO_2), serum

TABLE 23.4 Whole Blood Cyanide Levels and Clinical Signs and Symptoms

Whole Blood Cyanide		
μg/mL	**μmol/L**	**Signs and Symptoms**
0–0.5	8–20	No symptoms
0.5–1.0	20–38	Tachycardia, flushing, headache, hyperpnea, dizziness
1.0–2.5	48–95	CNS depression including giddiness, tachypnea, nausea, vomiting feeling, suffocation, confusion
2.5–3.0	95–114	Respiratory depression, convulsion, coma, cyanosis, apnea, circulatory collapse, fixed dilated pupils
≥3.0	114	Death

electrolytes (elevated anion gap), central venous percent O_2 saturation (elevated), calculated arterial percent O_2 saturation (normal), and measured arterial percent O_2 saturation (decreased). Quantitative determination of cyanide in whole blood, urine, gastric contents and tissues, and plasma thiocyanate levels are also important (Ballantyne, 1983). Unfortunately, these tests take several hours and the results may not be available to the clinician during the acute phase of poison management. Usually, the "Lee-Jones test" is a quick bedside test that can qualitatively detect cyanide in gastric aspirate but may give false-positive results with many drugs (Hall et al., 1987).

TREATMENT OF CYANIDE POISONING

The onset of toxicity after cyanide poisoning is very fast. The prognosis of the victim depends on termination of further exposure, supportive care, and institution of immediate and aggressive specific treatment. Early diagnosis and clinical information would enhance the chances of recovery. The first principle of therapy is termination of further exposure, which can be facilitated by the following: (i) remove the victim from the contaminated atmosphere; (ii) apply a protective mask to the patient as soon as possible to prevent further inhalation; (iii) remove any liquid on skin or clothing as soon as possible; (iv) remove all contaminated clothing, rinse skin with soap and copious amounts of water or water alone if there is liquid on the skin; and (v) gavage and administer activated charcoal if cyanide was ingested (Baskin and Brewer, 1997).

Supportive Therapy

The details of supportive therapy are presented in Table 23.5. Briefly, before specific therapy, the patient is administered supportive aid. This includes mechanical airway support, artificial ventilation with 100% oxygen possibly delivered via an Ambu bag containing the contents of two ampoules of amyl nitrite (0.6 mL), and cardiac monitoring (Van Heijst et al., 1987). Anecdotal evidence suggests that hyperbaric oxygen augments the protective efficacy of nitrite–thiosulfate therapy (Goodhart, 1994). Lactic acidosis resulting from anaerobic metabolism and convulsions should be treated with intravenous administration of sodium bicarbonate and diazepam, respectively (Van Heijst and Meredith, 1990; Baskin and Brewer, 1997). The use of antidotes should be restricted to patients in deep coma with respiratory insufficiency.

TABLE 23.5 Supportive Therapy and Specific Antidotal Therapy for Acute Cyanide Poisoning

	Agents	**Drug Category and Action**
Supportive therapy	100% oxygen or hyperbaric oxygen	Oxygen: Potentiates the efficacy of nitrite–thiosulfate therapy
	Sodium bicarbonate	Alkalizing agent: Corrects lactic acidosis
	Diazepam	Anticonvulsant: Depresses CNS activities
	Epinephrine	Sympathomimetic: Improves coronary and cerebral blood flow, corrects anaphylactoid reactions
Specific antidotal therapy	Amyl nitrite	Methemoglobin inducers: Converts hemoglobin to methemoglobin which binds with cyanide to form cyanmethemoglobin. In the presence of sodium thiosulfate cyanide is excreted as thiocyanate
	Sodium nitrite	
	4-Dimethylaminophenol	
	Sodium thiosulfate	Sulfur donors: Facilitates enzymatic conversion of cyanide to thiocyanate
	Dicobalt edentate	Cobalt compounds: Forms stable metal complexes with cyanide
	Hydroxocobalamin	

Specific Antidotal Therapy

Patients who are in critical condition and do not satisfactorily respond to supportive therapy should be administered specific cyanide antidotes as outlined in Table 23.5. Cyanide antidotes have been classified into

three main groups based on their mechanism of action: methemoglobin inducers; sulfur donors; and cobalt compounds. The definitive treatment of cyanide poisoning differs in various countries because of different medical practices and guidelines. The safety and efficacy of all the antidotes are still being debated. There is no worldwide consensus for treatment of cyanide intoxication.

Methemoglobin Inducers

The basic aim of rapid detoxification of cyanide is prevention or reversal of inhibition of cytochrome oxidase by cyanide. This is usually facilitated by providing a large pool of ferric iron in the form of methemoglobin to complex cyanide. Cyanide preferentially competes with the Fe^{3+} of methemoglobin as compared with that of cytochrome oxidase and eventually binds with the former to form cyanmethemoglobin. Thereby, the activity of inhibited cytochrome oxidase is restored (Baskin et al., 1992). The various methemoglobin inducers used as cyanide antidotes are discussed.

Amyl Nitrite

Although inhalation of amyl nitrite as a first aid measure for cyanide poisoning has been known for many years (Pedigo, 1888), its efficacy as a methemoglobin inducer is often disputed because of its inability to generate methemoglobin more than 6% (Jandorf and Bodansky, 1946). Approximately 15% of methemoglobin is required to challenge one LD_{50} of cyanide (Van Heijst et al., 1987). The protective effect of amyl nitrite is attributed to its vasodilatory effect, which can reverse the early cyanide-induced vasoconstriction (Van Heijst and Meredith, 1990). Artificial ventilation with amyl nitrite broken into Ambu bags has been reported as a life-saving therapy in cyanide-poisoned dogs before induction of significant levels of methemoglobinemia (Vick and Froehlich, 1985).

Sodium Nitrite

Sodium nitrite is the most prevalent drug for cyanide poisoning. It takes approximately 12 min to generate approximately 40% of methemoglobin after intravenous administration of the recommended dose (Van Heijst et al., 1987). Despite this delay in inducing a significant level of methemoglobinemia, reasonable protection offered by sodium nitrite can be attributed to its vasodilatory effects (Van Heijst and Meredith, 1990). A major drawback with sodium nitrite is that it causes serious cardiovascular embarrassment, particularly in children (Berlin, 1970). Because methemoglobinemia impairs oxygen transport, sodium nitrite cannot be recommended for fire victims when concomitant exposure of HCN and carbon monoxide usually occurs. Because carbon monoxide also reduces the oxygen-carrying capacity of blood, administration of sodium nitrite would further aggravate the underlying hypoxic condition. Sodium nitrite is also contraindicated for individuals with glucose-6-phosphate dehydrogenase-deficient red cells because of the possibility of serious hemolytic reactions (Way, 1984). Excessive levels of methemoglobin are known to be reverted by intravenous administration of 30 mL of 1% methylene blue solution (Van Heijst et al., 1987). In the United States, the Lilly Cyanide Antidote Kit (manufactured by Eli Lilly and Company, Indianapolis, IN) includes 10 mL ampoules of 3% sodium nitrite solution and 50 mL of 25% sodium thiosulfate solution. The kit also contains amyl nitrite encased in glass "pearls," which are meant to be broken so the drug could be inhaled. In India, a similar kit is manufactured by Troikaa Pharmaceuticals Ltd (Thiol).

4-Dimethylaminophenol

The relatively slow rate of methemoglobin formation by sodium nitrite prompted the development of rapid methemoglobin formers like aminophenols. 4-Dimethylaminophenol (DMAP) is the treatment of choice for cyanide poisoning in Germany. Administered intravenously, a dose of 3.25 mg/kg DMAP was reported to produce methemoglobin levels of 30% within 10 min and 15% methemoglobinemia was attained within 1 min without any immediate effect on the cardiovascular system (Kiese and Weger, 1969). However, there are differences in individual susceptibility to DMAP that may result in undesirable levels of methemoglobin even after normal therapeutic doses (Van Dijk et al., 1987). Intramuscular injection of DMAP results in local abscess and fever. Its clinical utility remains limited because of its other toxicological implications like nephrotoxicity (Weger, 1983).

Sulfur Donors

After the initial therapy of methemoglobin inducers, cyanide has to be converted to thiocyanate, which is eliminated in urine. This enzymatic detoxification of cyanide is facilitated by a sulfur donor like sodium thiosulfate. The mechanism of this reaction was discussed previously under elimination of cyanide. High tissue oxygen markedly potentiates the effects of this reaction. In cases in which methemoglobin formation is not desirable, sodium thiosulfate together with oxygen alone is sufficient. The utility of thiosulfate alone is limited because of its short biological half-life and its small volume of distribution (Sylvester et al., 1983). Also, thiosulfate is contraindicated in patients with renal insufficiency because the thiocyanate formed may cause toxicity (Van Heijst and Meredith, 1990).

Cobalt Compounds

The cobalt ion, which forms a stable metal complex with cyanide, is an effective therapeutic agent against

cyanide poisoning (Evans, 1964; Hillman et al., 1974; Linnell, 1987). Various cobalt-containing compounds known to antagonize cyanide poisoning are discussed.

Dicobalt Edetate (Kelocyanor)

Dicobalt edetate chelates cyanide as cobalticyanide. This drug is known to antagonize cyanide more quickly than the nitrites, but its clear superiority has not been established. Intravenous administration of 300 mg of dicobalt edetate in glucose solution is the current treatment of choice in France and the United Kingdom. Serious side effects like vomiting, urticaria, anaphylactoid shock, hypotension, and ventricular arrythmias have been reported in patients receiving Kelocyanor (Van Heijst and Meredith, 1990).

Hydroxocobalamin (Cyanokit)

With the exchange of the hydroxy group of hydroxocobalamin (vitamin B_{12a}) for cyanide, nontoxic cyanocobalamin (vitamin B_{12}) is formed (Hall and Rumack, 1987). An injectable solution of hydroxocobalamin (5 g in water) has been used in France and Germany. In France, a 4 g hydroxocobalamin solution in 80 mL of sodium thiosulfate has also been used (Van Heijst and Meredith, 1990). EMD Pharmaceutical Company has produced a lyophilized packaging of 2.5 g of hydroxocobalamin that can be readily reconstituted in a 100 mL sodium chloride solution. This product is pending FDA approval. It has been in use in Europe since 1996 as the Cyanokit™. Hydroxocobalamin is also used in other countries, including Sweden, Denmark, Spain, Japan, and Hong Kong. Now, sodium thiosulfate or hydroxocobalamin has also been recommended for empiric treatment of cyanide poisoning (Hall et al., 2007). There are several disadvantages in the clinical use of this drug. It has a relatively short half-life because it decomposes in light, and the dose required to counter cyanide poisoning is quite large. Also, recorded side effects include anaphylactoid reactions and acne (Van Heijst and Meredith, 1990). However, in a case study, clinical laboratory data did not show any evidence of toxicity (Borron et al., 2007).

Investigational Drugs

Numerous agents analogous to the specific antidotes or compounds belonging to different pharmacological classes have also been evaluated against experimental cyanide poisoning. The cardiovascular implications and poor pharmacokinetics of nitrite led to evaluation of yet another group of methemoglobin formers like aminophenones and derivatives. Out of all these compounds, *p*-aminopropiophenone was considered to be the most suitable agent for prophylaxis (Marrs and Bright, 1986; Bright, 1987). Hydroxylamine was examined as a rapid methemoglobin former with anticonvulsive properties, which conferred significant protection against acute cyanide poisoning (Kruszyna, et al., 1982). Combinations of sodium nitrite with DMAP or hydroxylamine were found to provide sustained prophylaxis against acute cyanide poisoning in rats by virtue of rapid, protracted, and desired levels of methemoglobinemia (Bhattacharya et al., 1991, 1993). However, toxicity of these regimens prevented their further use (Bhattacharya et al., 1995). A number of 8-aminoqunoline analogs of primaquine (e.g., WR242511) were also studied as potential prophylactic drugs because they induced elevated levels of methemoglobin for a longer duration (Steinhaus et al., 1990). Stroma-free methemoglobin solution (SFMS) was yet another alternative treatment proposed for cyanide poisoning (Ten Eyck et al., 1985). SFMS was formed by oxidizing outdated human blood and intravenous administration of this solution did not impair the oxygen-carrying capacity of blood as caused by most other methemoglobin formers. It was shown to directly sequester cyanide to protect against a 4x LD_{90} dose of sodium cyanide in rats. Among sulfur donors, several compounds containing sulfane sulfur, like polythionates, thiosulfonates, and persulfides, were examined as cyanide antidotes (Isom and Johnson, 1987). Compounds containing more lipophilic sulfane sulfur (e.g., ICD1021) or those that can be actively transported into the cells to mediate enzymatic detoxification of cyanide were synthesized as new anti-cyanide drugs (Baskin et al., 1999). Antagonism of cyanide intoxication with murine carrier erythrocytes containing bovine rhodanese and sodium thiosulfate has been demonstrated (Cannon et al., 1994; Petrikovics et al., 1995). Exogenous supplementation of the enzyme has been reported to accelerate the transulfuration of cyanide to thiocyanate. However, stability and sensitivity of the enzyme remain to be addressed. Several cobalt compounds were also evaluated against experimental cyanide poisoning, but none of them except cobalt edetate and hydroxocobalamin could be put to human use (Way, 1984; Linnell, 1987; McGuinn et al., 1994).

Cyanide is a nucleophile known to react with various carbonyl moieties like ketones and aldehydes to yield cyanohydrin derivatives (Morrison and Boyd, 1976). Sodium pyruvate (Schwartz et al., 1979), α-ketoglutarate (Moore et al., 1986), pyridoxal-5′-phosphate (Keniston et al., 1987), and many other carbonyl compounds and their metabolites or nutrients that interact with cyanide to form cyanohydrin complexes (Way, 1984; Niknahad et al., 1994; Bhattacharya and Tulsawani, 2008) have been reported to afford significant protection against acute cyanide poisoning *in vitro* or *in vivo*. Out of all these agents, α-ketoglutarate, either alone or with sodium thiosulfate, has been considered to be a promising antidote for cyanide (Borowitz et al., 1992). In a recent study, α-ketoglutarate and *N*-acetyl cysteine were found to protect rat pheochromocytoma (PC12) cells from cyanide-induced cytotoxicity and altered energy metabolism (Satpute et al., 2008). *N*-acetyl cysteine, a free

radical scavenger, was previously found to attenuate cyanide-induced cytotoxicity and DNA damage in isolated rat thymocytes (Bhattacharya and Lakshmana Rao, 1997). Also, in several other acute (Tulsawani and Bhattacharya, 2007) and subacute studies (Tulsawani et al., 2005), α-ketoglutarate was found to antagonize cyanide poisoning in experimental animals. This agent is being actively pursued as an oral treatment for cyanide poisoning, particularly in instances when nitrites are not recommended (Bhattacharya, 2004). At present, phase I clinical trials with α-ketoglutarate are being conducted in India.

There are several other compounds that are regarded as nonspecific cyanide antidotes, and their mechanisms have been only tentatively explained. These compounds are usually not very effective *per se* but as adjuncts significantly augment the efficacy of conventional antidotes. Chlorpromazine (phenothiazine), phenoxybenzamine (α-adrenergic blocker), centrophenoxine (neuroregulator), etomidate (nonbarbiturate hypnotic and anticonvulsant), naloxone (morphine antagonist), and flunarizine, verapamil, and diltiazem (calcium-channel blockers) are some of the compounds (Way, 1984; Marrs, 1988; Bhattacharya, 2000). Additionally, a few more compounds have been found to antagonize cyanide poisoning in the recent past. They include protein kinase C inhibitor (Maduh et al., 1995), nitric oxide generator (Sun et al., 1995), endothelium-derived relaxing factor/nitric oxide releasers or calcium ionophore A23187 (Baskin et al., 1996), local anesthetic, procaine hydrochloride (Jiang et al., 1998), and antioxidants like melatonin, a pineal hormone (Yamamoto and Tang, 1996), and its metabolite, 6-hydroxymelatonin (Maharaj et al., 2003). In general, antioxidants are found to be good adjuncts to nitrite–thiosulfate therapy. Another study has shown that ATP, encapsulated in unilamellar fusogenic lipid vesicle when injected intraperitoneally in mice before cyanide, significantly increased the survival time and the fatal dose of cyanide (Chiang et al., 2004). Most importantly, extracorporeal filtering or hemodialysis has also been found to supplement specific cyanide antidotes. This would hasten the elimination of cyanide and its metabolites. Hemodialysis achieved dramatic response in patients with severe acidosis (Wesson et al., 1985). This is only an anecdotal case report and has not been substantiated further.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Currently, cyanide is considered to be neither an important CW agent nor an agent of choice for suicidal or homicidal purposes. However, the threat of its possible use in local terrorism cannot be overlooked. Also, the occupational hazard of cyanide is likely to increase with its escalating industrial use. Serious epidemiological studies and reporting in poison control centers can be observed in many developed nations. However, many cases of fatal cyanide poisoning from fire smoke, drug side effects, dietary sources, and industrial exposures may go undetected because of poor surveillance in many countries. Cyanide toxicity is mainly ascribed to its ability to inhibit cytochrome oxidase, an end-chain enzyme of cellular respiration. Numerous new mechanisms of action of cyanide unfold the complex toxic phenomena occurring at cellular and molecular levels. Many of these mechanisms have been the target for pharmacological interventions. Although very primitive, the combination of sodium nitrite and sodium thiosulfate still continues to be the most favored treatment for cyanide poisoning. Hydroxocobalamin has also been used as a cyanide antidote with considerable success in the recent past. If we could circumvent the side effects of this drug, then it would possibly be the most successful second-generation antidote for cyanide. Cyanide antagonism by scavengers like carbonyl compounds, particularly α-ketoglutarate, has also been very encouraging in animal models. Further clinical trials would determine its safety for human use. Also, the stability of this molecule needs to be addressed. Perhaps these kinds of molecules could be of use for occupational exposures, chronic dietary cyanide poisoning, or as prophylaxis for fire-fighters/personnel engaged in evacuation operations in cyanide-contaminated areas. Another area of interest would be the development of field-based detection systems for rapid diagnosis of cyanide poisoning or for retrospective detection of cyanide in biological samples. This is a prerequisite for effective therapeutic measures.

Acknowledgment

The authors thank Dr. R. Vijayaraghavan, Director, Defense Research and Development Establishment, Gwalior, India, for his keen interest and critical suggestions in the preparation of this chapter.

CHAPTER

24

Chlorine

Sylvia Milanez

INTRODUCTION

Diatomic chlorine (Cl_2) is a gas under ambient conditions, with a pungent, suffocating odor. Because its vapor density is twice that of air, chlorine forms a greenish-yellow cloud near the ground upon release into the environment (Haynes et al., 2013; O'Neil et al., 2013). The Cl_2 odor detection threshold is approximately 0.2–0.4 ppm, with considerable variation among humans, although odor perception tends to decrease over time (NIOSH, 1976; ATSDR, 2010). Chlorine gas is slightly water-soluble (~4.4 g/L; O'Neil et al., 2013), but it reacts quickly with water to form hydrochloric acid (HCl) and hypochlorous acid (HOCl). Selected chemical and physical properties of Cl_2 are listed in Table 24.1.

Very little chlorine gas is found naturally in the environment due to its high reactivity with other compounds and its degradation by sunlight; it has a half-life of <10 min (Hov, 1985). Chlorine and sodium hydroxide are co-produced by the electrolysis of brines (the chlor-alkali process) using mercury, membrane, or diaphragm cells; the ion exchange membrane cell has become the predominant process, for economic and environmental reasons (Burridge, 2005). The major uses of Cl_2 are in the manufacture of polyvinyl chloride and other plastics, chlorinated solvents, and pharmaceuticals; as a bleaching agent and biocide in pulp and paper production; and in water purification and waste treatment systems (Evans, 2005; CEH, 2011). Worldwide, there are over 500 chlor-alkali producers at over 650 sites, with an annual chlorine production capacity of 58 million tons (World Chlorine Council, 2012). Chlorine is one of the top 10 production volume chemicals in the United States, with over 10 million tons produced in 2010 (US Census Bureau, 2011).

Chlorine is a contact irritant in both humans and animals, and the respiratory tract is the primary, and most sensitive, target organ. Toxicity resulting from short- and long-term chlorine inhalation has been studied in humans and laboratory animals, and exposures associated with various endpoints have been defined.

HISTORY OF USE

Chlorine's utility as a bleaching agent was discovered in the late 1700s, and its use as a water disinfectant in the United States began in the early 1900s, dramatically cutting the death rate from typhoid fever (Toren and Blanc, 1997; Evans, 2005). Chlorine gas was used as a chemical warfare agent during World War I, most notably when the German army buried 5,730 chlorine-containing cylinders in trenches along a 6-mile front near Ypres, Belgium. On April 22, 1915, over 150 tons of chlorine gas was released from the cylinders in 5 min and was blown by wind toward the Allied forces. It was estimated that 800 soldiers were killed and 2,500–3,000 more were incapacitated from lack of adequate protective gear (Joy, 1997). Because chlorine gas has significant warning properties (i.e., color and odor) and its toxicity is relatively easy to avoid, it is less than ideal as a warfare agent, and its use declined after World War I. Recently, however, chlorine has been used by terrorists in the Iraq war, with bombs being rigged to chlorine tanker trucks or cylinders intended for use in water treatment or for other industrial purposes (Wetz et al., 2007).

A number of accidents have occurred during chlorine production and transport, which occurs primarily by rail. In a recent fatal accident in January 2005, 9 people died and nearly 600 required medical attention when a chlorine tank ruptured from a train collision in Graniteville, South Carolina (Van Sickle et al., 2009; Jones et al., 2010). However, due to its great utility as a water disinfectant, bleaching agent, and industrial chemical, chlorine continues to be produced, transported, and used in great quantities worldwide, making it a persistently hazardous material (HAZMAT) threat (Jones et al., 2010).

TABLE 24.1 Chemical and Physical Data for Chlorine

Parameter	Value	Reference
Molecular formula	Cl_2	Haynes et al. (2013)
Molecular weight	70.90	Haynes et al. (2013)
CAS registry number	7782-50-5	Haynes et al. (2013)
Synonyms	Bertholite, molecular chlorine, chlorine mol, dichlorine	ATSDR (2010)
Physical state	Greenish-yellow gas	Haynes et al. (2013)
Odor threshold	0.2–0.4 ppm	ATSDR (2010)
Conversion factors in air	1 ppm = 2.90 mg/m^3; 1 mg/m^3 = 0.34 ppm	NIOSH (2010)
Boiling point	−34.04°C	Haynes et al. (2013)
Melting point	−101.5°C	Haynes et al. (2013)
Vapor pressure (mmHg)	5,830 mmHg at 25°C	ATSDR (2010)
Vapor density (air = 1)	2.48 at 20°C	O'Neil et al. (2013)
Liquid density (water = 1)	2.898 g/L at 25°C	Haynes et al. (2013)
Flash point/flammability	Not flammable	O'Neil et al. (2013)
Water solubility (g/L)	4.4 g/L at 25°C	O'Neil et al. (2013)

ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

Almost all inhaled chlorine (>90%) is absorbed via the respiratory tract, in both humans and animals (Abdel-Rahman et al., 1983; Nodelman and Ultman, 1999a,b; Morris et al., 2005). Humans absorbed >95% of an inhaled bolus of 0.5–3 ppm chlorine in the upper airway and <5% in the lower airway, regardless of the mode of breathing or respiratory flow rate (Nodelman and Ultman, 1999a,b). Chlorine that is absorbed is not subject to metabolic biotransformation and is distributed widely throughout the body and joins the pool of chloride ions. Rats that were orally administered HO^{36}Cl in distilled water excreted the majority of ^{36}Cl in the urine (36.43%) and feces (14.80%) over a 96 h post-exposure period (Abdel-Rahman et al., 1983).

MECHANISM OF TOXICITY

Chlorine is a strong oxidizing agent that hydrolyzes in water, and in the fluid lining of the respiratory tract surface (pH ~7), where it exists predominantly as HOCl and the hypochlorite ion (OCl^-) (ATSDR, 2010; Squadrito et al., 2010; O'Neil et al., 2013). In both humans and animals, the respiratory tract is the primary target organ for inhaled chlorine, which reacts with the epithelial lining of the airways and lungs. Depending on the chlorine exposure concentration and duration, respiratory toxicity can be manifested as sensory irritation, increased airway resistance, and respiratory tract lesions, and can lead to death (Withers and Lees, 1985; Bitron and Aharonson, 1978). In rats and mice, chlorine sensory irritation decreases the respiratory rate by stimulating the trigeminal nerve endings in the respiratory mucosa (Alarie, 1981).

The precise mechanism by which chlorine or its reaction products cause cellular toxicity is unknown, but it is widely believed that chlorine toxicity is due to its oxidant properties, and is mediated largely by the hypochlorite ion (Morris et al., 2005; ATSDR, 2010). An alternative model has proposed that Cl_2 itself can react with biomolecules in the epithelial lining fluid in the respiratory tract, and may be able to penetrate the lung surface (Squadrito et al., 2010). This hypothesis was based on a kinetic analysis that found that the reaction rate of chlorine with water was several orders of magnitude lower than its reaction rate with low molecular weight antioxidants and N-terminal functions of peptides and proteins in lung epithelial fluid (Squadrito et al., 2010). In addition to causing epithelial injury, the presence of HCl and HOCl in the airway causes an inflammatory response. The recruited neutrophils and macrophages increase the local concentration of nitric oxide (NO) and H_2O_2, which can react with HOCl and HCl to produce hydroxyl radicals and reactive intermediates able to nitrate, chlorinate, and dimerize aromatic amino acids (Olin et al., 1999; Evans, 2005; Jones et al., 2010).

In vitro mechanistic studies with bacteria and mammalian cells have led to various theories for the chlorine mechanism of action, including direct interaction of

chlorine or hypochlorite with enzymes, other proteins, and nucleotide bases, and disruption or degradation of cell membrane structure and function (US EPA, 1994). Chlorine was proposed to cause systemic endothelial dysfunction by inhibiting endothelial nitric oxide synthase (eNOS)–dependent signaling, based on its inhibition of eNOS-dependent vasodilation in isolated rat aortas (Honavar et al., 2011).

TOXICITY

Chlorine is a direct-contact irritant, of which the primary and most serious target is the respiratory tract, although it can also damage the skin, eyes, and internal organs at high exposure levels (Evans, 2005). The acute, repeat-exposure, and chronic inhalation toxicity of chlorine has been studied in humans and in laboratory animals, which showed many similarities in their response.

Human Studies

The effects on humans of a single chlorine gas exposure lasting up to 8 h have been described anecdotally, as well as in controlled experiments with volunteers. In a summary of various anecdotal reports, Winder (2001) noted that exposures of up to 3 ppm caused mild irritation; 5–15 ppm caused moderate irritation; >15 ppm caused severe irritation with pulmonary involvement, and death occurred from exposure to ≥430 ppm after 30 min or less.

Controlled human studies (Table 24.2) generally found that exposure to 0.5–2 ppm Cl_2 for a period of a few minutes to 8 h caused slight to moderate irritation of the eyes, nose, and throat, and small decrements in pulmonary function (such as the forced expiratory volume in 1 s (FEV_1) and airway resistance (R_{aw})) (Anglen, 1981; Rotman et al., 1983; D'Alessandro et al., 1996; Shusterman et al., 1998; Schins et al., 2000). The severity of irritation increased with exposure duration and concentration, and effects were greater in subjects with preexisting respiratory conditions (such as asthma and airway hyperreactivity) and in smokers. A number of cases of reactive airways dysfunction syndrome have been reported, and all were seen in individuals with preexisting respiratory conditions and current or former smokers (Evans, 2005). Withers and Lees (1985) applied probit analysis to human and animal lethality data to estimate that chlorine concentrations of 250 and 100 ppm were lethal to 50% of a regular and vulnerable population (LC_{50}), respectively, that was exposed for 30 min with an inhalation rate of 12 L/min.

Few repeat-exposure human studies have been conducted with chlorine gas (Table 24.3). Subjects exposed to 0.1, 0.3, or 0.5 ppm for 6 h/day for 3 days had no pulmonary function decrements, but did report eye and respiratory tract irritation (Schins et al., 2000). Workers exposed chronically to <0.1 ppm experienced no chlorine-related toxicity; exposure to ~0.2–0.3 ppm had little or no effect on pulmonary function but did result in fatigue, anxiety, wheezing, and chest tightness; and exposure to 1.7 ppm was associated with numerous respiratory symptoms (including sore throat, shortness of breath, chest tightness, wheezing, and rhinitis), chest X-ray abnormalities, and pulmonary function decrements (Capodaglio et al., 1970; Patil et al., 1970; Chan-Yeung et al., 1980; Enarson et al., 1984; Shi, 1990). The severity of effects increased with the number of working years and was greater in smokers.

Laboratory Animal Studies

Animal studies with chlorine gas have been conducted using monkeys, dogs, rabbits, guinea pigs, rats, and mice, with the majority of the data being for rats and mice. Single-exposure durations ranged from 2 min to 24 h (Table 24.4), and repeat-exposure durations were 3 days to 2 years (1–8 h/day) (Table 24.5). Early studies tested concentrations causing severe toxicity, often extending into the lethal range (Weedon et al., 1940; Schlagbauer and Henschler, 1967; Faure et al., 1970; MacEwen and Vernot, 1972; Barrow and Smith, 1975; Barrow et al., 1979; Jiang et al., 1983; Klonne et al., 1987; Zwart and Woutersen, 1988). Early studies also examined the sensory irritation of chlorine gas in rodents, determining the concentration that caused a 50% decrease in the inhalation rate (i.e., the RD_{50}) (Barrow et al., 1977; Barrow and Steinhagen, 1982; Buckley et al., 1984; Chang and Barrow, 1984; Gagnaire et al., 1994). Several more recent studies, as well as a few earlier studies, were designed to explore aspects of the mechanism of chlorine toxicity, including its progression over time and post-exposure tissue repair (Dodd et al., 1980; Demnati et al., 1995; Wolf et al., 1995; Martin et al., 2003; Yildirim et al., 2004; Morris et al., 2005; Hoyle et al., 2010; Jarabek et al., 2010; Leikauf et al., 2010, 2012; Peay et al., 2010; Song et al., 2010; Musah et al., 2012; Mo et al., 2013). Some of the more recent mechanistic studies evaluated the ability of various classes of compounds to mitigate chlorine toxicity (see the next section of this chapter, "Risk Assessment").

The respiratory tract was consistently the primary target of toxicity, and similar effects were seen following single and repeated inhalation exposures. The upper respiratory tract was primarily affected at lower chlorine concentrations, with symptoms such as sensory irritation and nasal lesions. Sensory irritation was manifested as a decreased respiration rate, sneezing, flared nostrils, reddened eyes, lacrimation, salivation, and foamy nasal secretions. Nasal symptoms included inflammation, epithelial necrosis, deciliation,

TABLE 24.2 Human Single-Exposure Chlorine Inhalation Studies

Exposure Time	Concentration (ppm)	Effects	Reference
15 min	0.5	At 0 and 15 min post-exposure, NAR was ↑ in rhinitics but not normal subjects; rhinitics had greater nasal irritation and congestion; no effect on pulmonary peak flow, rhinorrhea, or headache in either group.	Shusterman et al. (1998)
15 min	1.0	At 0 and 15 min post-exposure, NAR was ↑ in rhinitics but not normal subjects; effect ↑ with age; very slight nasal irritation and odor perception.	Shusterman et al. (2003b)
15 min	1.0	At 0 and 15 min post-exposure, NAR ↑ in rhinitics but not normal subjects; no effect on nasal lavage fluid levels of mast cell tryptase, or plasma neuropeptides, albumin, urea, lysozyme, or 7F10-mucin.	Shusterman et al. (2003a, 2004)
1 h	0.4	No pulmonary function changes in those with airway hyperreactivity or asthma.	D'Alessandro et al. (1996)
1 h	1.0	Modest changes in pulmonary function measurements, greater in hyperreactive subjects (± asthma), of which 2/7 had "respiratory symptoms."	
15 min – 2 h (left room every 15′)	0.5, 1.0	Barely perceptible irritation of eyes, nose, and/or throat.	Joosting and Verberk (1974)
	2.0	Distinctly perceptible irritation of eyes, nose, and throat; some coughing.	
	4.0	Nuisance level irritation of eyes, nose, and throat; some coughing.	
4 h + exercise 15 min/h	0.5	Moderate or mild itching or burning of throat and nose; severity generally ↑ with exposure time.	Anglen (1981)
	1.0	Moderate or mild irritation of throat, eyes, and nose; runny nose; severity ↑ over time; few had pharynx injection, ↑ mucous secretion, and inspiratory rales.	
	2.0	Moderate or mild irritation of throat, eyes, and nose; runny nose; severity ↑ over time; few had pharynx injection or palpebral fissures, ↑ mucous secretion, inspiratory rales, altered pulmonary function.	
8 h + exercise 15 min/h; had 30 or 60 min break after 4 h	0.5	Moderate or mild itching or burning of throat and nose; severity generally ↑ with exposure time.	Anglen (1981)
	1.0	Moderate or mild itching or burning of throat, eyes, and nose; runny nose; urge to cough; severity ↑ with exposure time; few had pharynx injection or palpebral fissures, ↑ mucous secretion, and inspiratory rales after 4 and 8 h; after 8 h had slight changes in pulmonary function.	
8 h + exercise 15 min/h	0.5	Slight changes in pulmonary function measurements after 4 and 8 h; changes were greater in an atopic subject.	Rotman et al. (1983)
	1	Itchy eyes, runny nose, mild burning in throat, and slight changes in pulmonary function after 4 and 8 h; changes were sufficient in an atopic subject to terminate exposure after 4 h due to dyspnea and wheezing.	

↑, increase(d); ↓, decrease(d); NAR, nasal airway resistance.

hyperplasia, and metaplasia. At higher chlorine concentrations, the lower respiratory tract was also affected. Lower respiratory tract effects included dyspnea, emphysema, bronchopneumonia, pulmonary edema, and hemorrhage, and increased protein content and IgM in the bronchoalveolar (BAL) fluid. In many cases, the irritation and pulmonary toxicity were reversible, but at sufficiently high doses, lung toxicity led to death. Exposure to near-lethal concentrations caused lesions in organs outside the respiratory tract, including the

TABLE 24.3 Human Repeat-Exposure Chlorine Inhalation Studies

Exposure Time	Concentration (ppm)	Effects	Reference
6 h/day for 3 day	0.1, 0.3, and 0.5	At unspecified concentration(s) had eye, nose and throat irritation, wheeze, nasal congestion and mucous production; pulmonary function normal.	Schins et al. (2000)
10.9 ± 2.8 years	0.146 ± 0.287	Male workers had fatigue, anxiety, dizziness, and white blood cell count; ↓ hematocrit. No effect on chest X-ray or pulmonary function.	Patil et al. (1970)
>10 years	0.298 ± 0.181	Workers had ↓CO lung diffusing capacity but no effects on pulmonary function measurements or ↑ in pulmonary emphysema.	Capodaglio et al. (1970)
13.9 ± 9.3 years	<0.05 (mean)	Male workers had no ↑ in respiratory symptoms or abnormalities in pulmonary function or chest radiographs. Possible co-exposure to low levels of H_2S, methyl mercaptan, SO_2 and particulates.	Chan-Yeung et al. (1980)
8.9 ± 8.6 years	0.18 (mean)	Male workers had ↑ frequency of wheeze, chest tightness, chest illness, and decrements in pulmonary function. No ↑ in cough, phlegm, or dyspnea. Possible co-exposure to low levels of SO_2, CH_3SH, and particulates.	Enarson et al. (1984)
<10–25 years	1.7 ± 0.12	Workers had sore or dry throat, shortness of breath, chest tightness or pain, headache, wheezing, chronic rhinitis and tonsillitis, olfactory deficiency, chest X-ray abnormalities, and impaired pulmonary function.	Shi (1990)

↑, increase(d); ↓, decrease(d).

TABLE 24.4 Animal Single-Exposure Chlorine Inhalation Studies

Species	Exposure Time	Concentration (ppm)	Effect	Reference
Rabbit	30 min	50	Temporary ↓ in lung compliance.	Barrow and Smith (1975)
		100–250	Lung edema, hemorrhage, emphysema, inflammation, impaired function.	
		500–1,000	LC_{100}	
Guinea pig	15–30 min	200	Severe lesions of upper respiratory tract mucous membranes, emphysema, inflammation and exudate in bronchioles.	Faure et al. (1970)
Rat	2, 10 min	1,500	Lung edema with bronchial epithelial sloughing and airway wall leucocyte infiltration; some epithelial regeneration after 72 h.	Demnati et al. (1995)
	15 min	1,330	Lung eosinophilic accumulation, edema, and bleeding, which became interstitial fibrosis and thickening of alveolar septa after 45 days.	Yildirim et al. (2004)
	30 min	184, 400	Labored breathing, expiratory grunting; 1 h after exposure, had ↓ arterial oxygen pressure and↑CO_2 levels, and respiratory acidosis. Had lung necrosis and epithelial sloughing, neutrophil accumulation, and mild alveolitis; BAL fluid had ↑ albumin, IgG, IgM, and phospholipid levels (400 ppm), and ↓ levels of ascorbate and reduced glutathione.	Leustik et al. (2008)
	30 min	400	Transient hypoxemia, severe epithelial pathology in airways; increased BAL protein, neutrophils, epithelia; lung edema; effects lessened by sodium nitrite given (i.p.) 2–6 h post-exposure.	Yadav et al. (2011)
	10 min	579–2,248	LC_{50} = 1,931, 690, 448 ppm for 10, 30, 60 min; majority died in 1 week; were restless, had eye and nasal irritation, dyspnea, and lesions in nose, larynx, trachea, and lung; some were reversible.	Zwart and Woutersen (1988)
	30 min	547–645		
	60 min	322–595		
	60 min	213, 268, 338, 427	LC_{50} = 293 (260–329) ppm; had eye and nose irritation, and after 60 min had lacrimation, rhinorrhea, and gasping; survivors had lower weight gain. Liver tissue mottling was most common finding at necropsy.	MacEwen and Vernot (1972)

(*Continued*)

TABLE 24.4 (Continued)

Species	Exposure Time	Concentration (ppm)	Effect	Reference
	60 min	6, 30, 60	Nasal lesions (necrosis, inflammation, hyperplasia, degeneration), severity increasing with concentration and greatest in more anterior regions.	Peay et al. (2010)
	6 h	0.1, 1.0, 5.0, 10	Nasal epithelial inflammation and hyperplasia, olfactory necrosis and degeneration; severity increased with concentration and was greatest in anterior regions; lesions seen at ≥1.0 ppm persisted at least 5 days.	Peay et al. (2010) and Jarabek et al. (2010)
	6 h	9.1 ± 1.02	Nasal cavity lesions (epithelial degeneration, ulceration, and necrosis); most severe in olfactory mucosa.	Jiang et al. (1983)
	16 h	63	All survived 5 months post-exposure; had gross changes in brain, lungs, heart, stomach, intestines, liver, kidneys, and lung adhesions.	Weedon et al. (1940)
		250, 1,000	Lacrimation, dyspnea; all died by 16 h at 250 ppm and 1.7 h at 1,000 ppm; had lesions in brain, lungs, heart, liver, stomach, intestine, and kidneys.	
	24 h	0.25, 1.25, 2.5	Nasal necrosis/degeneration followed by inflammation and hyperplasia; severity increased with concentration and greatest in anterior regions.	Peay et al. (2010)
Mouse	5 min	100	Airway hyperresponsiveness, increased cells and glutathione in BAL, dimethylurea given (i.p.) 1 h before/after exposure decreased BAL protein and glutathione levels and prevented lung lipid peroxidation.	McGovern et al. (2010)
		200, 400	As at 100 but more severe; had microscopic pathological changes in airway epithelium (BAL fluid and effect of dimethylurea not evaluated).	
	5 min	100, 200, 400, 800	Dose-related increases in airway responsiveness, airway epithelial loss, alveolar damage and inflammation, leukocytes and nitrate in BAL fluid, nitric oxide synthase expression and oxidation of lung proteins.	Martin et al. (2003)
	10 min	0.7–38.4	RD_{50} = 9.3 ppm; respiratory rate ↓ was dose-related and was attained at each concentration within 5–7 min.	Barrow et al. (1977)
	10 min	1.0–760	RD_{50} = 25 ppm; appearance of animals was not addressed.	Barrow and Steinhagen (1982)
	10 min	~2.5–1,000	RD_{50} = 10.9 ppm; animal appearance was not addressed.	Chang and Barrow (1984)
	10 min 30 min	579–1,654 458–645	LC_{50} = 1,034 and 517 ppm for 10 and 30 min, respectively. Animals had signs of restlessness, eye and nasal irritation, dyspnea, and ↑ lung weight.	Zwart and Woutersen (1988)
	15 min	0.8, 2.0, 3.1, 3.8	RD_{50} = 2.3 ppm; dose-related ↓ in respiratory rate (30–80% of baseline) and ↑ in airway resistance (64–186%) and length of the expiratory pause (20–522 ms).	Morris et al. (2005)
	15 min	200	Anorexia, lethargy, hypothermia; acute lung edema, collagen deposition (fibrosis), and inflammation; dexamethasone (i.p.) reduced severity if given within 1–6 h after exposure.	Jonasson et al. (2013)
	7.5 min 15 min 30 min 60 min	800 400 200 100	After 6 h: mortality was 8/8; 6/41; 0/40, 0/40; had increased lung weights (pulmonary edema), BAL protein and IgM levels, neutrophil infiltration, and airway epithelial denudation – more severe for the shorter exposures. After 24 h: only lung weight returned to sham control levels.	Hoyle et al. (2010)
	30 min	400	Lung deciliation, epithelial sloughing, alveolar inflammation, ↑ airway resistance, ↑ protein and inflammatory cells in BAL; arformoterol (β_2-agonist) given nasally starting 10 min post-exposure reduced airway resistance and improved alveolar clearance.	Song et al. (2010, 2011)

(*Continued*)

TABLE 24.4 (Continued)

Species	Exposure Time	Concentration (ppm)	Effect	Reference
	30 min	55–179	The 30 min LC_{50} = 127 (106–152) ppm; ↑ lung weight; tracheal, bronchiolar, and alveolar lesions; regenerative changes seen after 9–10 days.	Schlagbauer and Henschler (1967)
	3 h	10, 22	Pathology as 30 min exposure; 8/10 died at 10 ppm and 10/10 at 22 ppm.	
	6 h	10	Similar pathology as after 30 min exposures, 9/10 died.	
	45 min	600	Most (14/18) died within 72 h of exposure; had labored breathing, lung inflammation, epithelial sloughing; lipid peroxidation; had less mortality (4/18) and toxicity if given ascorbate and deferoxamine (i.m., inhalation) starting 1 h post-exposure.	Zarogiannis et al. (2011)
	60 min	122–193	LC_{50} = 137 (119–159) ppm; had eye and nose irritation, and gasping; survivors had weight loss; liver tissue mottling was seen at necropsy.	MacEwen and Vernot (1972)
	60 min	228–270	Lung edema and ↑ protein and IgM in BAL; airway hyperreactivity and impaired pulmonary function; rolipram given post-exposure (i.p. or intranasally) inhibited pulmonary edema and airway hyperreactivity.	Chang et al. (2012)
	60 min	240	Sloughing of Clara and ciliated cells from tracheal epithelium, after 2–4 days had cell proliferation in K5- and K14-expressing basal cells; at d 7–10 fibrosis was seen primarily in distal trachea.	Musah et al. (2012)
	60 min	240	Airway epithelial damage and hyperreactivity, neutrophil inflammation, lung edema and dysfunction; mometasone and budesonide (i.p., given 1 h post-exposure) decreased lung neutrophil levels and lung edema.	Chen et al. (2013)
	60 min	240	FVB/NJ mice and A/J mice had fibroproliferative lesions in large airways 4 days post-exposure, which by day 7 was repaired in A/J mice but fibrosis in FVB/NJ mice, latter had less keratin 5 in basal cells of large airways.	Mo et al. (2013)
	60 min	1.7–8.8	RD_{50} = 3.5 ppm; appearance of animals was not addressed.	Gagnaire et al. (1994)
	120 min	2.2–6.6	Respiratory rate ↓ 31–65% after 60 min, and ~38–72% after 120 min.	
	67 min	179–263	Several mice died within 24 h after exposure; had edema, airway epithelial sloughing, and ↑ protein and neutrophils in BAL.	Tian et al. (2008)
	6 h	9.1 ± 1.02	Marked nasal cavity epithelial degeneration, ulceration, and necrosis, most severe in olfactory mucosa of anterior dorsal meatus.	Jiang et al. (1983)
	16 h	63	All survived; showed less distress than at higher concentrations.	Weedon et al. (1940)
		250, 1,000	Lacrimation, dyspnea, convulsions; all died after 8.4 h (250 ppm) and 50 min (1,000 ppm); had lesions in lungs and numerous internal organs.	
	24 h	45	Most died; mean survival time was 7.6–38.1 h for 40 different strains; had lung hemorrhage, alveolar wall thickening, ↑ BAL total protein and altered metabolite content.	Leikauf et al. (2010, 2012)

↑, increase(d); ↓, decrease(d); BAL, bronchoalveolar lavage (fluid); BW, body weight(s); LC_{50}, the concentration that results in 50% mortality; OE, olfactory epithelium (nasal); RD_{50}, concentration causing a 50% decrease in the respiration rate.

spleen, thymus, brain, lungs, heart, stomach, intestines, liver, and kidneys. In the single-exposure studies, toxicity was generally influenced more by exposure concentration than exposure duration; this relationship was less clear in the repeat-exposure studies, which were complicated by intermittent periods of nontreatment (e.g., 5 days/week), allowing partial recovery of the chlorine-induced lesions.

No animal studies have linked chlorine exposure with developmental or reproductive toxicity or cancer; genotoxicity studies with chlorine gas yielded negative results, but mixed results were obtained with the chlorine hydrolysis product hypochlorite (US EPA, 1999; ATSDR, 2010).

RISK ASSESSMENT

There are a number of factors to consider in defining the risk of chlorine inhalation on a diverse human population and in defining levels that are safe for short- and long-term exposures. For example, how do age, gender, and preexisting respiratory conditions such as asthma and airway hyperreactivity affect susceptibility

TABLE 24.5 Animal Repeat-Exposure Chlorine Inhalation Studies

Species	Exposure Scenario	Concentration (ppm)	Effect	Reference
Monkey	6 h/day, 5 days/week × 12 months	0.10 ± 0.03, 0.50 ± 0.10, 2.3 ± 0.4	Eye tearing and reddening during exposure to 2.3 ppm seen after ~6 week; after 1 year had conjunctival irritation but no gross eye lesions. Had trace or mild nasal epithelial hyperplasia, loss of cilia and goblet cells (dose-related), with tracheal involvement at 2.3 ppm.	Klonne et al. (1987)
Rat	6 h/day × 3 days 6 h/day × 5 days	9.1 ± 1.02 (TWA)	BW ↓; marked nasal epithelial degeneration, cell exfoliation, ulceration, and necrosis; neutrophil infiltration of epithelium and squamous metaplasia after 5 days; milder lesions in pharynx, trachea, and lungs.	Jiang et al. (1983)
	6 h/day × 5 days	0.1, 0.5, 1.0 2.5	Nasal inflammation and hyperplasia in squamous and respiratory epithelium (concentration-dependent) but not OE; extended to the nasopharyngeal duct at 2.5 ppm.	George et al. (2010); Jarabek et al. (2010)
	With 7 days recovery	1.0, 2.5	Hyperplasia (concentration-dependent) in squamous and respiratory epithelium of anterior nasal sections.	
	6 h/day, 5 days/week × 2 weeks	12	Looked unkempt, wheezed, had swelling around eyes and nares, ↓ BW, and reversible ↑ in lung sulfhydryl level after 3–6 days.	Dodd et al. (1980)
	6 h/day, 5 days/week × 6 weeks	1	Signs of irritation, mild nasal, tracheal, bronchial, alveolar inflammation.	Barrow et al. (1979)
		3	As at 1 ppm; also, lacrimation, conjunctivitis, nasal discharge, liver lesions.	
		9	As at 3 ppm; also, gasping, lung rales, emaciation; 3/20 died by 30th exposure; lesions in lungs, liver, kidney, stomach, spleen, and thymus.	
	6 h/day × 104 weeks; 5 days/week (M) or 3 days/week (F)	0.4, 1.0, 2.5	BW ↓ in all M and at 1.0 and 2.5 ppm in F after > 3 months; closed eyes at 2.5 ppm in F. All had nasal lesions, most severe in anterior and generally concentration-related (inflammation; OE degeneration; squamous metaplasia; goblet cell epithelial hypertrophy and hyperplasia).	Wolf et al. (1995)
Mouse	8 h/day × 3 days	2.5	BW was 93.2% of initial weight.	Schlagbauer and Henschler (1967)
		5	BW was 87.5% of initial weight; lesions in tracheal epithelium and mucosa, bronchioles, and alveoli.	
	6 h/day × 3 days 6 h/day × 5 days	9.1 ± 1.02	BW ↓; marked nasal lesions (epithelial degeneration, ulceration, necrosis); neutrophil infiltration of epithelium and squamous metaplasia after 5 days; milder lesions in pharynx, larynx, trachea, lungs.	Jiang et al. (1983)
	6 h/day × 5 days	9.7	Nasal, tracheal, and lung lesions, with anterior to posterior severity gradient (exfoliation, necrosis, inflammation, squamous metaplasia, hyperplasia, bronchiolitis).	Buckley et al. (1984)
	6 h/day, 5 days/week × 104 weeks	0.4, 1.0, 2.5	BW ↓ for M at 1.0 and 2.5 ppm and F at 2.5 ppm after >3 months. All had nasal lesions, most severe in anterior and generally concentration-dependent (septal fenestration; proteinaceous accumulation; epithelial hyperplasia; squamous metaplasia; OE atrophy).	Wolf et al. (1995)

↑, increase(d); ↓, decrease(d); BW, body weight(s); F, female; M, male; OE, olfactory epithelium (nasal).

to chlorine toxicity? How do chlorine exposure concentration and duration contribute to chlorine toxicity?

A review of human chlorine inhalation studies led White and Martin (2010) to conclude that there was no basis for considering young subjects more susceptible than adults to chlorine toxicity. Although it was speculated that children might be more susceptible than adults to chlorine toxicity, based on reports of illness following several accidental chlorine releases, the actual air chlorine levels and exposure durations of the subjects were unknown (ATSDR, 2010).

Among healthy non-asthmatic adults aged 18–69 years who were exposed to 1.0 ppm chlorine for 15 min, nasal airway resistance, congestion, and irritation increased with age and preexisting allergic rhinitis, independent of gender (Shusterman et al., 2003a,b, 2004). Adults with nonspecific airway hyperreactivity or asthma, or those who smoke, were more susceptible to chlorine respiratory symptoms and pulmonary dysfunction and recovered more slowly after chlorine exposure (Rotman et al., 1983; D'Alessandro et al., 1996; ATSDR, 2010).

The degree to which endpoints such as respiratory tract irritation and mortality are influenced by chlorine exposure concentration or duration have been evaluated using studies that varied both parameters. The concentration-time relationship for many irritants and systemically acting vapors and gases can be described by the equation $C^n \times t = k$ (ten Berge et al., 1986), which is equivalent to Haber's rule ($C \times t = k$) when $n = 1$. A value of $n = 1.9$ was determined for chlorine gas nuisance irritation by ten Berge and Vis van Heemst (1986) using the Anglen (1981) human data. This value of n indicates that exposure concentration was a greater determinant of toxicity than duration; a similar conclusion was drawn by Shusterman et al. (2004) in their analysis of chlorine sensory irritation in a number of controlled human studies. Haber's rule did not adequately capture the type, incidence, and severity of nasal lesions in female rats exposed once to 0.1–10 ppm chlorine for 1–24 h, such that the product of the test concentration and duration ($C \times t$) was constant (Peay et al., 2010). Mice exposed to 100–800 ppm chlorine at a constant $C \times t$ of 100 ppm h had much greater mortality and lung injury at 800 ppm (0.125 h exposure) than at 100 ppm (1 h exposure) (Hoyle et al., 2010).

Current US workplace standards limit chlorine air concentrations to 0.5 ppm (NIOSH REL-TWA Ceiling (NIOSH, 2010); ACGIH TLV-TWA (ACGIH, 2010)) or 1 ppm (OSHA Ceiling (OSHA, 2006); ACGIH TLV-STEL (ACGIH, 2010)). These standards reflect human data showing that inhalation of 0.5–1 ppm chlorine, whether once or repeatedly, causes mild upper respiratory tract irritation, which is more severe in individuals with preexisting conditions such as asthma, rhinitis, and airway hyperreactivity (Joosting and Verberk, 1974; Anglen, 1981; Rotman et al., 1983; D'Alessandro et al., 1996; Shusterman et al., 1998, 2003a,b, 2004). The human studies also served as the basis for guidelines to prevent adverse but nondisabling effects from a single 10 min to 24 h inhalation exposure. The Acute Exposure Guideline Levels (AEGLs) limit chlorine air concentration to 0.5 ppm for a 10–480 min exposure (Talmage, 2004). The provisional advisory levels (PALs) limit chlorine levels to 0.096 ppm for a 24 h exposure (Milanez et al., 2014). Additional AEGL and PAL values were developed for chlorine that are associated with serious irreversible effects or lethality (Talmage, 2004; Milanez et al., 2014).

TREATMENT

Currently, treatment for chlorine inhalation is largely nonspecific and geared to alleviating the patient's symptoms, and a chlorine-specific antidote is unavailable (Jones et al., 2010). All persons exposed to Cl_2 should be given humidified oxygen, and inhaled beta-adrenergic agents should be administered if there is evidence of airway obstruction (White and Martin, 2010). If ocular irritation is present, the eyes should be copiously irrigated. Respiratory peak flow should be measured in patients with mild or greater symptoms, and patients with moderate or severe effects should have a chest X-ray (IPCS, 2008). All symptomatic patients should be observed for 8–24 h for delayed pulmonary edema, which can be treated with positive airway pressure (Traub, 2006; IPCS, 2008). Endotracheal intubation and mechanical ventilation may be used in the most extreme cases (IPCS, 2008). However, the majority of individuals exposed to mild to moderate chlorine levels see resolution of their symptoms in 3–5 days and recover normal pulmonary function within several months (Jones et al., 2010).

The most commonly prescribed medications for over 60 people who were hospitalized following the release of chlorine gas in the 2005 train accident in Graniteville, SC, were inhaled β-agonists, ipratropium bromide (an anticholinergic drug used to treat chronic obstructive pulmonary disease), and inhaled and oral corticosteroids (Van Sickle et al., 2009). Less common treatments included antibiotics and intravenous or nebulized sodium bicarbonate. Sodium bicarbonate can theoretically neutralize the HCl and HOCl formed in the respiratory tract from Cl_2 hydrolysis, although its efficacy and optimal treatment have not been clearly established (Jones et al., 2010). Corticosteroids are used to reduce the inflammatory response and lung scarring resulting from acute exposure to respiratory irritants, although the ideal steroid and treatment regimen for Cl_2 exposure is undefined (Jones et al., 2010; Chen et al., 2013).

Various compounds have been tested in animal studies in the quest to develop an effective chlorine-specific treatment based on its mechanism of action (Table 24.4). The evaluated compounds include the antioxidants dimethylthiourea, ascorbic acid, *N*-acetyl-L-cysteine, and deferoxamine mesylate (Leustik et al., 2008; McGovern et al., 2010; Zarogiannis et al., 2011); sodium nitrite (Yadav et al., 2011); the corticosteroids mometasone, budesonide, and dexamethasone (Chen et al., 2013; Jonasson et al., 2013), the type 4 phosphodiesterase inhibitor rolipram (Chang et al., 2012), and the β2-agonist arformoterol (Song et al., 2011).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Chlorine studies have been conducted with humans and laboratory animals since before its use as a chemical weapon in World War I. Chlorine gas is a direct-acting irritant that primarily affects the respiratory tract, causing irritation and tissue damage that can lead to death at sufficiently high doses. Chlorine toxicity is believed to be due to its oxidant properties and to be mediated by the hypochlorite ion, although the precise mechanism of cellular damage is unknown. An alternative hypothesis suggests that chlorine itself may play a substantial role in toxicity. The chlorine exposure concentrations and durations associated with various degrees of toxicity in humans have been defined, taking into consideration the impact of human variability such as preexisting respiratory conditions, age, and gender.

Despite its toxicity and potential for nefarious use, chlorine continues to be widely used in manufacturing and as a disinfectant. Currently, treatment for chlorine inhalation is largely supportive and nonspecific. Research continues into elucidating chlorine's mechanism of action and into finding methods to mitigate its toxic effects.

CHAPTER

25

Phosgene

Cheryl B. Bast and Dana F. Glass-Mattie

INTRODUCTION

Phosgene is a colorless gas at ambient temperature and pressure. Its odor has been described as similar to newly mown hay (Leonardos et al., 1968). This mild odor and the weak acute irritant properties, however, provide little warning of its presence (Lipsett et al., 1994).

Phosgene is manufactured from a reaction of carbon monoxide and chlorine gas in the presence of activated charcoal. Phosgene is used in the manufacture of isocyanates, polycarbonates, pesticides, dyes, and pharmaceuticals. Manufacture of phosgene in the United States is almost entirely captive in that more than 99% is used in the manufacture of other chemicals within a plant boundary (US EPA, 2003). The odor threshold is between 0.5 and 1.5 ppm (NIOSH, 1976); unfortunately, the odor threshold is inadequate to protect against toxic inhalant exposure because damage to the deep respiratory tract can take place at lower concentrations (Sidell et al., 1997). Phosgene has an odor safety classification rating of "E," which indicates that fewer than 10% of attentive persons can detect the Threshold Limit Value (TLV) (Amoore and Hautala, 1983).

Inhalation is the most important route of exposure for phosgene. Because of its mild upper respiratory, eye, and skin irritancy, and a mildly pleasant odor, an exposed victim may not actively seek an avenue of escape before lower respiratory damage has occurred (Currie et al., 1987a; Lipsett et al., 1994). Small amounts of phosgene can be irritating to the eyes (lacrimation) and throat (coughing) as phosgene undergoes hydrolysis to create hydrochloric acid, which acts as an irritant. Far more dangerous, however, is the pulmonary edema that can develop after a latent period of 1–24 h after exposure. Exercise can increase the extent of pulmonary edema (Marrs et al., 1996). If severe clinical signs are not present after 48 h, then chances for full recovery are great. Physical and chemical properties of phosgene are summarized in Table 25.1.

BACKGROUND

Phosgene was first made in 1812 and was eventually used as a chemical warfare agent in WWI. Because of its higher density compared with air, phosgene gas can accumulate in low-lying areas; thus, concentrated pockets within war trenches caused significant exposure during WWI. German troops in WWI used phosgene gas as a chemical warfare agent against the British troops. Possibly up to 85% of the deaths in WWI were a result of phosgene gas exposure (Ministry of Defense, 1987). Sandall (1922) examined 83 British soldiers 3 years after phosgene exposure. Shortness of breath on exertion (70%), cough with expectoration (54%), tight feeling in the chest (25%), sporadic giddiness (14%), and nausea (12%) were the most frequently reported symptoms. No physical lung abnormalities were noted in 53% of the men.

The concept of a "death product" was introduced by Haber to explain the relationship between the extent of exposure to phosgene and death (Haber, 1924). According to "Haber's law," the biological effect of phosgene is directly proportional to the exposure expressed as the product of the atmospheric concentration (C) and the time of exposure (T) or $CT = k$, where k can be death, pulmonary edema, or other biological effects of phosgene exposure (US EPA, 1986). Haber's law has subsequently been shown by other investigators to be valid for both nonlethal and lethal effects within certain limits. There appears to be little species variability with regard to lethality between rats, mice, and guinea pigs, and the $CT = k$ relationship appears to be generally

TABLE 25.1 Physical and Chemical Data

Parameter	Data	Reference
Synonyms	Carbonyl chloride, carbon oxychloride, carbonic dichloride, chloroformyl chloride	US EPA (1986) and Lipsett et al. (1994)
Chemical formula	$COCL_2$	Lipsett et al. (1994)
Molecular weight	98.92	Lipsett et al. (1994)
CAS registry No.	75-44-5	Lipsett et al. (1994)
Physical state	Colorless gas at room temperature	Budavari et al. (1989)
Odor threshold	0.5–1.5 ppm	NIOSH (1976)
Odor description	Pleasant, like newly mown hay	Dunlap (2001)
Vapor pressure	1215 mmHg at 20°C	Budavari et al. (1989)
Vapor density	3.5 (air = 1)	NIOSH (2010)
Specific gravity	1.92 (water = 1)	CRC Handbook (1988)
Melting/boiling/flash point	−118°C/8.2°C/non-flammable	NIOSH (2010)
Water solubility	Slightly soluble in water, decomposes rapidly ($t_{½}$ = 0.26 s)	US EPA (2003); NIOSH (2010)
Reactivity	Reacts with alcohols, alkalis, ammonia, and copper	NIOSH (2010)
Conversion factors in air	1 ppm = 4.1 mg/m^3 1 mg/m^3 = 0.25 ppm	NIOSH (2010)

valid (although at very high or very low concentrations or exposure times so short that the animal can hold its breath, the $CT = k$ relationship may not be relevant).

TOXICOKINETICS

After inhalation exposure, a small portion of phosgene hydrolyzes to hydrochloric acid (HCl) and carbon dioxide (CO_2) in the mucous coating of the upper respiratory tract (Diller, 1985), but in the moist atmosphere of the terminal spaces of the lungs more extensive hydrolysis is thought to occur (Beard, 1982). Although phosgene is only slightly soluble in water, once in solution it rapidly hydrolyzes to HCl and CO_2. However, phosgene reacts even faster with other functional groups such as amino, hydroxyl, and sulfhydryl groups (Diller, 1985; Jaskot et al., 1991). Because of the affinity for lung tissue and the hydrolysis and acylation that take place in the pulmonary system, very little, if any, phosgene is dispersed to other locations in the body.

MECHANISM OF ACTION

The toxicity of phosgene is attributable to both hydrolysis and acylation, with the latter being most important.

Diller (1985) accumulated data and described the clinical signs associated with phosgene exposure. Phosgene inhaled at concentrations of more than 1 ppm triggers a transient vagal reflex and causes shallow, rapid respiration with a decrease in respiratory volume and capacity, a decrease in arterial oxygen partial pressure, and bradycardia. The intensity varies greatly between individuals. Phosgene at more than 3 ppm becomes moderately irritating to the eyes and upper airways (cough) as some of the phosgene undergoes hydrolysis, producing HCl.

The acylation reaction of phosgene with nucleophiles, such as amino, hydroxyl, and sulfhydryl groups, also occurs rapidly, causing lipid and protein denaturation, irreversible membrane changes, and disruption of enzymatic function. These acylation effects observed at exposures more than 30 ppm·min produce pulmonary edema as the blood–air barrier becomes more permeable to blood plasma after a clinical latent period (1–24 h). This is called the clinical edema phase, which is characterized by increasing inefficiency of gas exchange as more defects in the blood–air barrier occur, allowing more accumulation of a protein-rich fluid. Clinical signs in this phase are labored breathing and a frothy expectorant. Progression usually results in death from paralysis of the respiratory center due to anoxemia with secondary cessation of heart function. If anoxemia is controlled, then circulatory shock may still occur. At very high concentrations (>200 ppm), phosgene may cause death within a few minutes from "acute cor pulmonale" (acute overdistention of the right heart), often before pulmonary edema can develop.

Phosgene depletes lung glutathione, whereas glutathione reductase and superoxide dismutase increase as a result of the lung's response to injury. On exposure to

TABLE 25.2 Summary of Major Signs and Symptoms of Phosgene Inhalation Exposure in Humans

Exposure					
Concentration	**Duration**	**$C \times T$ product (ppm min)**	**Acute Effect**	**Time to Onset of Pulmonary Edema**	**Time to Death**
3 ppm	"Acute"	–	Throat irritation	–	–
4 ppm	"Acute"	–	Ocular irritation	–	–
4.8 ppm	"Acute"	–	Cough	–	–
1 ppm	20 min	20	–	–	–
5 ppm	5 min	25	–	–	–
1 ppm	150 min	150	–	10 h	–
50 ppm	5 min	250	–	5 h	–
100 ppm	5 min	500	–	3 h	24 h
1.3 ppm	400 min	520	–	7 h	30 h
300 ppm	2 min	600	–	–	Minutes

Source: Diller and Zante (1982) and Borak and Diller (2001).

phosgene, cellular glycolysis, oxygen uptake, intracellular ATP, and cyclic AMP are decreased and associated with increased permeability of pulmonary vessels, leading to pulmonary edema. Phosgene exposure also causes increased lipid peroxidation and leukotriene synthesis, with no change in cyclooxygenase metabolism (Borak and Diller, 2001).

TOXICITY

Human

Noncancer

Reports of human phosgene poisoning present a relatively consistent set of clinical effects and sequelae (Delephine, 1922; Hegler, 1928; Galdston et al., 1947a,b; Herzog and Pletscher, 1955; Everett and Overholt, 1968; Henschler, 1971; Stavrakis, 1971; Diller et al., 1979; Bradley and Unger, 1982; Misra et al., 1985; Regan, 1985; Wells, 1985; Cordasco et al., 1986; Kaerkes, 1992; Hardison et al., 2014). After acute phosgene exposure, brief (20 min) ocular and throat irritation, cough, nausea and vomiting, and dizziness are experienced, followed by a period (24 h) of apparent well-being. After this clinical latent phase, cough accompanied by expectoration, a sensation of pain or tightness of the chest, shortness of breath, and a choking sensation are experienced. Clinical findings may include hemoconcentration, leukocytosis, rales, and pulmonary edema. After recovery, rapid and shallow breathing, shortness of breath on exertion, and a sense of decreased physical fitness may persist for months. Pulmonary emphysema may occur with repeated exposure to phosgene.

Diller and Zante (1982) identified ocular irritation, throat irritation, and cough as acute irritating effects of phosgene. In a follow-up analysis, Borak and Diller (2001) also performed an extensive literature review concerning human phosgene exposure and concluded the following: the smell has no warning property; immediate irritation is not prognostic; and pulmonary edema can appear several hours after exposure and the length of clinical latency can be used as a prognostic indicator (i.e., the shorter the time to effects, the worse the prognosis). The data also show that although concentration is the primary driver for the onset and severity of symptoms, duration of exposure also plays a role. Information synthesized from these reviews is presented in Table 25.2.

Cancer

Epidemiology studies have shown no increase in cancer in workers exposed to phosgene compared with controls. Polednak (1980) and Polednak and Hollis (1985) examined a cohort of chemical workers exposed to chronic low levels of phosgene as well as daily exposures more than 1 ppm. Approximately 35 years after exposure to phosgene, no increase in overall mortality or mortality from cancer or respiratory disease was noted.

Animal

Noncancer

Animal studies with phosgene show a steep concentration–response curve for pulmonary edema and mortality. Acute animal studies also indicate little species variability because rats, mice, sheep, pigs, and dogs

exposed had development of similar clinical signs (dyspnea, labored breathing, and pulmonary edema after a latent period) and histopathological lesions in the lungs. Although there are no chronic animal data, subchronic studies indicate little accumulation of phosgene or increased severity of lesions with continuous exposure.

Bronchoalveolar lavage (BAL) fluid analysis may be used to assess pulmonary edema/lung injury after acute inhalation exposure to phosgene (Pauluhn et al., 2007). Maximum protein concentrations in BAL fluid typically occur within 1 day after exposure, followed by a latency period up to 15 h. For acute exposures, the *CT* relationship is constant over a wide range of concentrations. However, after noncontinuous and repeated exposure, increased tolerance to subsequent exposures is observed. Although limited, the longer-term data indicate that effects do not increase in severity over time but do increase with increased concentration, suggesting that chronic toxicity is dependent on an acute pulmonary threshold dose. A comparison of BAL fluid constituents from acute inhalation studies in rats and dogs suggests that dogs are three- to four-times less sensitive to phosgene than rats (Pauluhn et al., 2007).

A summary of selected lethal and nonlethal animal toxicity studies is presented in Tables 25.3 and 25.4, respectively.

Animal Cancer

A study by Selgrade et al. (1989) showed that exposure to very low levels of phosgene enhances the susceptibility of mice to lung tumor formation. Female C57BL/6 mice were exposed for 4 h to 0.01 ($N = 13$), 0.025 ($N = 28$), or 0.05 ppm phosgene ($N = 35$) and injected intravenously with syngeneic B16 melanoma cells the next day. Controls were injected with tumor cells and exposed to air. The

TABLE 25.4 (Continued)

Concentration (ppm)	Time	Species	Effect	Reference
0, 0.1, 0.2, 0.5, or 1.0	0.1 ppm for 5 days/week; 0.2 ppm for 5 days/week; 0.5 ppm for 2 days/week; 1.0 ppm for 1 day/weekAll exposed 6 h/day for up to 12 weeks	Rat	LOAEL = 0.1 ppm based on reversible lung histopathology; ↑lung displacement volume NOAEL = none	Kodavanti et al. (1997)
0, 0.1, 0.2, or 0.5	0.1 and 0.2 ppm for 5 days/week; 0.5 ppm for 2 days/week All exposed 6 h/day for up to 12 weeks	Rat	LOAEL = 0.1 ppm based on decreased bacterial clearance after infection with *Streptococcus zooepidemicus* NOAEL = none	Selgrade et al. (1995)

[a]*LFP, lavage fluid protein; BAL, bronchiolar lavage.*

lungs were removed 2–3 weeks after tumor cell injection and the tumors were counted. Compared with controls, there was a statistically significant ($P < 0.05$) increase in the number of B16 melanoma tumors in the lungs of mice treated with 0.025 or 0.05 ppm phosgene. Exposure to 0.025 ppm was considered the lowest observed effect level. Extending the exposure time from 4 to 8 h did not alter the susceptibility to B16 tumors at 0.01 ppm.

RISK ASSESSMENT

Many inhalation regulatory and guideline levels have been derived for phosgene. These values are summarized in Table 25.5, and the definitions and basis for the values are described in the footnotes to Table 25.5.

TREATMENT

Treatments that have been proposed to prevent pulmonary edema in exposed persons include sedation, steroids, ibuprofen, *N*-acetylcysteine, B2-andregenic agonists, aminophylline/theophylline, leukotriene agonists, and positive pressure airway ventilation. However, there is no known antidote for phosgene poisoning, and although animal studies suggest that these treatments may be effective, no clinical data are available to verify efficacy in humans (Borak and Diller, 2001; Grainge and Rice, 2010; ACC, 2013). Asymptomatic individuals exposed to phosgene should be observed and evaluated to determine if symptoms develop. Vital signs and lung auscultation should be evaluated every 30 min and serial chest X-rays should be performed starting 2 h after exposure. If no clinical signs occur and no signs of pulmonary abnormalities are detected on the X-ray after 8 h, then patients may be discharged. If no X-ray is available, then patients should be observed for 24 h after exposure. If signs develop, then patients should be treated. Therapy for the cardiogenic pulmonary edema may include positive airway pressure and monitoring (endotracheal intubation and mechanical ventilation with high oxygen concentrations), steroids, theophylline, diuretics, and antibiotics (in patients who develop bacterial pulmonary infections) (Borak and Diller, 2001).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Phosgene is a colorless gas at ambient temperature and pressure, and inhalation is the most important route of exposure for phosgene. The odor of phosgene has been described as similar to newly mown hay. Because of its mild upper respiratory, eye, and skin irritancy, and a mildly pleasant odor, an exposed victim may not actively seek escape before lower respiratory damage has occurred (Currie et al., 1987a; Lipsett et al., 1994). Pulmonary edema is the cause of death after a clinical latent period of 24 h (Franch and Hatch, 1986). Phosgene exhibits a steep concentration–response curve and little species variability with regard to lethality. Data (Pauluhn, 2006a–c; Pauluhn et al., 2007) suggest that with regard to physiology of the respiratory tract and acinar structure of the lung, dogs are more similar to humans than rodents. Thus, it may be most appropriate to base future phosgene risk assessments on data extrapolation from dogs to humans when dog data are available. Recent studies appear to focus on acquiring an additional in-depth understanding of the mechanism of action of phosgene through use of animal models (Chen et al., 2009; Li et al., 2013; Wang et al., 2013).

TABLE 25.5 Inhalation Standards and Guidelines for Phosgene

	Exposure Duration				
Guideline	**10 min**	**30 min**	**1 h**	**4 h**	**8 h**
AEGL-1[a]	NA	NA	NA	NA	NA
AEGL-2[a]	0.60 ppm	0.60 ppm	0.30 ppm	0.08 ppm	0.04 ppm
AEGL-3[a]	3.6 ppm	1.5 ppm	0.75 ppm	0.20 ppm	0.09 ppm
ERPG-1[b]			NA		
ERPG-2[b]			0.5 ppm		
ERPG-3[b]			1.5 ppm		
EEGL (NRC)[c]			0.2 ppm		0.02 ppm (24 h)
NIOSH IDLH[d]	2 ppm				
NIOSH STEL[e]	0.2 ppm (15 min ceiling)				
NIOSH REL[e]					0.1 ppm (10 h)
OSHA PEL-TWA[f]					0.1 ppm
ACGIH TLV[g]					0.1 ppm
MAK (Germany)[h]					0.1 ppm
MAC (Netherlands)[i]					0.1 ppm
RfC[j]					7.33×10^{-5} ppm

	Exposure Duration			
	24 h	**30 days**	**90 days**	**2 years**
PAL 1[k]	0.0017 ppm	0.0006 ppm	0.0006 ppm	0.0006 ppm
PAL 2[k]	0.0033	0.0012 ppm	0.0012 ppm	0.0012 ppm
PAL 3[k]	0.022	NA	NA	NA

[a]*AEGL (Acute Exposure Guideline Levels) (NRC, 2002) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels (AEGL-1, AEGL-2, and AEGL-3) are developed for each of five exposure periods (10 and 30 min, 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects. The three AEGLs tiers are defined as follows.*

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, non-sensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure. The AEGL-1 is not recommended for phosgene because the odor threshold is at the concentration approaching AEGL-2 values, and odor cannot be used as a warning.

AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. The AEGL-2 for phosgene is based on chemical pneumonia in rats (Gross et al., 1965).

AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death. The AEGL-3 is based on concentrations causing no death in rats or mice (Zwart et al., 1990).

[b]*ERPG (Emergency Response Planning Guidelines, American Industrial Hygiene Association (AIHA, 2013). The ERPG-1 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing other than mild, transient adverse health effects or without perceiving a clearly defined objectionable odor. The ERPG-1 for phosgene is not derived. The ERPG-2 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing or developing irreversible or other serious health effects or symptoms that could impair an individual's ability to take protection action. The ERPG-3 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing or developing life-threatening health effects.*

[c]*EEGL (Emergency Exposure Guidance Levels, National Research Council (NRC, 1985). The EEGL is the concentration of contaminants that can cause discomfort or other evidence of irritation or intoxication in or around the workplace, but avoids death, other severe acute effects and long-term or chronic injury. The EEGL for Phosgene is based on the "most relevant animal exposure studies (Rinehart and Hatch, 1964; Gross et al., 1965)" and studies suggesting that animals do not tolerate phosgene at 0.2 ppm administered 5 h/day for 5 days (Cameron and Foss, 1941; Cameron et al., 1942).*

[d]*IDLH (Immediately Dangerous to Life and Health, National Institute of Occupational Safety and Health) (NIOSH, 2010) represents the maximum concentration from which one could escape within 30 min without any escape-impairing symptoms, or any irreversible health effects. The IDLH for phosgene is based on acute inhalation toxicity data in humans (Diller, 1978).*

[e]*NIOSH REL-STEL (Recommended Exposure Limits—Short Term Exposure Limit) (NIOSH, 2010) is defined analogous to the ACGIH TLV-TWA.*

[f]*OSHA PEL-TWA (Occupational Health and Safety Administration, Permissible Exposure Limits—Time Weighted Average) (NIOSH, 2010) is defined analogous to the ACGIH-TLV-TWA, but is for exposures of no more than 10 h/day, 40 h/week.*

[g]*ACGIH TLV-TWA (American Conference of Governmental Industrial Hygienists, Threshold Limit Value—Time Weighted Average) (ACGIH, 2013) is the time-weighted average concentration for a normal 8 h workday and a 40 h workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effect. The ACGIH TLV-TWA was derived from the marked potential for pulmonary irritation after exposure to phosgene at concentrations greater than 0.1 ppm; this conclusion was based on two studies. Gross et al. (1965) found that phosgene at 0.5 ppm for 2 h caused some pathologic changes in the lungs of rats and Cameron et al. (1942) found that 0.2 ppm, 5 days/week for 5 consecutive days caused pulmonary edema in 41% of animals exposed (goats, cats, rabbits, guinea pigs, rats, and mice).*

[h]*MAK (Maximale Argeitsplatzkonzentration (Maximum Workplace Concentration)) Deutsche Forschungsgemeinschaft (German Research Association) 2012 is defined analogous to the ACGIH-TLV-TWA.*

[i]*MAC (Maximaal Aanvaaarde Concentratie (Maximal Accepted Concentration)). SDU Uitgevers (under the auspices of the Ministry of Social Affairs and Employment), The Hague, The Netherlands 2012 is defined analogous to the ACGIH-TLV-TWA.*

[j]*US EPA (US Environmental Protection Agency Reference Concentration). (US EPA, 2005). The RfC is an estimate of a continuous inhalation exposure concentration to people (including sensitive subgroups) that is likely to be without risk of deleterious effects during a lifetime. The RfC was developed by using incidence of the lung histopathological findings from Kodavanti et al. (1997) in a bench-mark dose analysis.*

[k]*PAL (Provisional Advisory Levels). (Glass et al., 2008). Provisional Advisory Levels represent exposure limits for the general public applicable to emergency situations. Three levels (PAL 1, PAL 2, and PAL 3), distinguished by the degree of severity of toxic effects, are developed for up to 24 h, 30-day, 90-day, and 2-year durations of potential drinking water and inhalation exposures. The PALs have not been promulgated nor have they been formally issued as regulatory guidance. They are intended to be used at the discretion of risk managers in emergency situations when site specific risk assessments are not available.PAL 1 represents the assumed continuous exposure concentration of a chemical in air or drinking water above which changes from baseline of specific biomarkers or physiological responses could have adverse health effects in the general population. Concentrations at or below PAL 1 are not expected to be associated with adverse health effects. Increasingly greater concentrations above the PAL 1 value could cause progressively harmful effects in the general population, including all ages and sensitive subpopulations.PAL 2 represents the assumed continuous exposure concentration of a chemical in air or drinking water above which serious, irreversible, or escape-impairing effects could result. Increasingly greater concentrations above the PAL 2 value could cause progressively harmful effects in the general population, including all ages and sensitive subpopulations.PAL 3 represents the assumed continuous exposure concentration of a chemical in air or drinking water above which lethality in the general population, including all ages and sensitive subpopulations could occur.*

CHAPTER

26

Other Toxic Chemicals as Potential Chemical Warfare Agents

Jiri Bajgar, Jiri Kassa, Josef Fusek, Kamil Kuca and Daniel Jun

INTRODUCTION

For the development of new chemical weapons (CWs), a number of criteria are necessary: a research base including scientists and equipment, access to information, chemical and arms industries, and, of course, financial support. It is noteworthy that the development of CWs is possible not only for states, but also for terrorists. It is necessary to stress that the intention of this chapter is not to describe new CWs or chemical warfare agents (CWAs), but to comment on a number of trends in toxicology with the aim that these chemicals may be proposed for inclusion in the Chemical Weapons Convention (CWC) verification mechanisms. However, the text of the CWC is comprehensive and covers practically all chemicals that may be misused as CWs.

The objective of this chapter is to briefly describe a number of chemicals that could be used as toxic compounds or CWAs against humans.

GENERAL

Chemical Weapons Convention: Article II, Definitions and Criteria

1. "CWs" means the following, together or separately:

- **a.** Toxic chemicals and their precursors, except where intended for purposes not prohibited under this Convention, as long as the types and quantities are consistent with such purposes.
- **b.** Munitions and devices, specifically designed to cause death or other harm through the toxic properties of those toxic chemicals specified in subparagraph (a), which would be released as a result of the employment of such munitions and devices.
- **c.** Any equipment specifically designed for use directly in connection with the employment of munitions and devices specified in subparagraph (b).

2. "Toxic chemical" means:

Any chemical which, through its chemical action on life processes, can cause death, temporary incapacitation or permanent harm to humans or animals. This includes all such chemicals, regardless of their origin or their method of production, and regardless of whether they are produced in facilities, in munitions, or elsewhere.

Therefore, CWAs can be characterized as toxic chemicals. Initially, it is difficult to differentiate between the research aimed at protection against CWAs (defense) and development of new CWAs (offense). Both actions deal with the synthesis of chemicals, based on either information or ideas, or incidentally synthesized toxic compounds. A typical example is the synthesis of organophosphates (OPs) by G. Schrader, originally dedicated to the development of new pesticides. Another example of the development of a new CW would be the synthesis of OP compounds of the V series. After synthesis, the compound in question will be characterized chemically and biologically, and sometimes modified to increase its military properties (toxicity and physicochemical properties, such as stability and volatility). Then the compound can be studied in detail for its pharmacological and toxicological characteristics by using more convenient species and routes of administration. At this stage, it is practically impossible to decide if the research is offensive or defensive though some indications would lead to the opinion that the direction is offensive; for example, when attention is given to its efficacy following percutaneous

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00026-9

or inhalation administration. Studied methods of dispersion under field conditions are an indication of an offensive approach; testing for protective qualities under real conditions can be regarded as a defensive approach. However, further steps, like production of large quantities and weaponization, are clearly offensive. It is useful to compare the time from synthesis to production or use of certain CWs. After the synthesis of phosgene and diphosgene (1812 and 1887), their use in 1916 was observed; a similar situation was observed for mustard (1866–1917); for CS, this period was shortened (synthesis in 1928 and use in 1950); and VX was synthesized in the early 1960s and weaponized in 1968. The big question is: What is meant by large quantities? This can be addressed using the approach contained in the CWC. Quantities would also be compared with the contamination density prescribed for different CWAs. For instance, for yperite, it is 19 tons/km^2 for percutaneous administration and 4 tons/km^2; for *O*-ethyl *S*-[2-(diisopropylamino) ethyl] methylphosphonothioate (VX) (percutaneous) it is 2 tons/km^2; for sarin and 3-quinuclidinyl benzilate (BZ) (by inhalation), this value is about 0.5–0.6 tons/km^2 (Robinson, 1985). Of course, it does not apply to the synthesis or production of these substances for terroristic purposes.

Apart from this "classic" approach, it would be possible to "improve" the properties of known CWs (e.g., microencapsulation so that less stable or highly volatile substances) can be used. Nanotechnology offers new possibilities, as described recently by Price and Peterson (2008). The other option is to improve penetration using known enhancers like dimethyl sulfoxide (DMSO). While the percutaneous toxicity (expressed as LD_{50} in rats) of one of the toxic OPs (namely, *O*-isopropyl *S*-2-diisopropylaminoethyl methyl phosphnothiolate) is 59.1 μg/kg, when it is mixed with DMSO, this value decreases to 10.1 μg/kg (Bajgar, 1989).

Binary technologies are also acknowledged; however, the development of other methods of synthesis is not excluded (the more steps involved in synthesis, the more difficult it is to control the process). An alternative is to search for compounds either used or synthesized already. From the groups of highly toxic chemicals, these could be fluorophosphorylcholines (unstable) or toxic silatrans. In the group of medications, there are also highly toxic chemicals like cardiac glycosides (digoxin), sympathomimetics (noradrenalin), and myorelaxans (succinylcholine, curare derivatives). The other compounds to be included are insulin, cantharidin, aconitin, galantamine, pancuronium, pipecuronium, some derivatives of vitamin D (cholecalcipherol), some antibiotics, cytostatics, etc. It is necessary to point out that their use is limited (e.g., parenteral administration of insulin or delayed acute effect of cytostatics). A possible candidate would be centrally acting alpha 2-adrenergics with antihypertensive and sedative properties. All bioregulators are of great interest, especially in connection with the increased possibility of obtaining significantly sufficient quantities for military and terroristic purposes. All these examples are more or less hypothetical and require further testing. There exist some groups of compounds whose misuse is more probable and some of these chemicals are under suspicion (not proved) of being introduced into military arsenals. An illustrative but not exhaustive list of warfare agents is given next.

SPECIFIC AGENTS

Carbamates

Compounds in the carbamate group have a broad spectrum of toxicities—from relatively slightly toxic (carbaryl) to highly toxic compounds comparable with nerve agents (T-1123) (Figure 26.1). As described by Robinson (1971), carbamates including T-1123 had been studied by British and Canadians as CW agents since 1940. Other carbamates were described in detail by Badawi and Hassan (1995). They are well absorbed by the lungs, gastrointestinal tract, and the skin. The clinical representation of

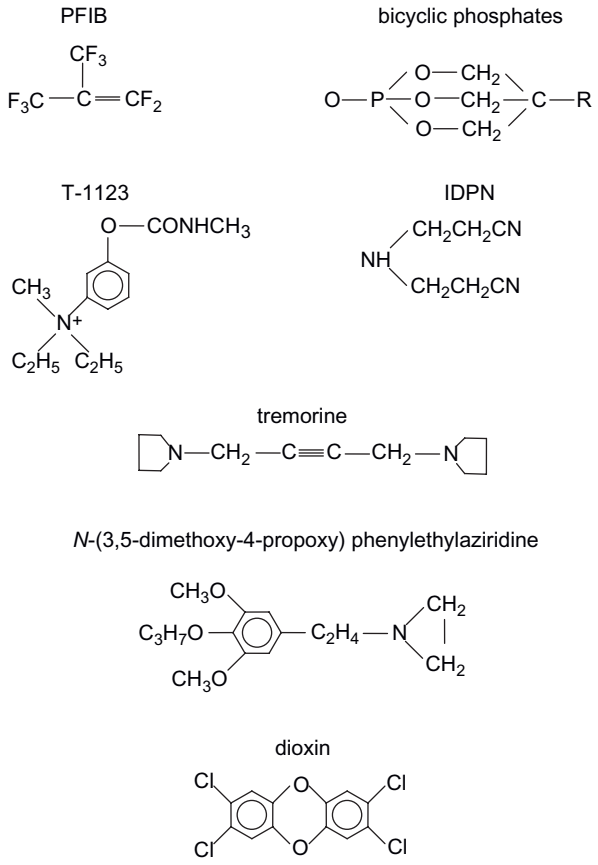

FIGURE 26.1 Chemical formulas of some toxic chemicals.

poisoning is similar to that for nerve agents, though perhaps with more expressed peripheral signs because of quaternary nitrogen in the molecule (T-1123); therefore, penetration through the blood–brain barrier is difficult (Bajgar and Patocka, 1976; Fusek et al., 1996a). The basic mechanism of action is reversible inhibition of cholinesterases. However, the inhibition of carbamates is based on carbamylation of the active center of the acetylcholinesterase (AChE). Spontaneous decarbamylation is a relatively quick process (taking approximately 24 h) and carbamylated cholinesterases are resistant to the effect of reactivators. Therefore, the treatment is symptomatic, preferably using only atropine. These difficulties would be reasons for military use (Patocka, 1990).

Dioxin

Dioxin is one of the most toxic low-molecular-weight compounds (Figure 26.1). Its oral LD_{50} for guinea pigs is 2–20 μg/kg; for monkeys, it is 2 μg/kg; for rats, it is 18–60 μg/kg; and for humans (subcutaneous administration), it is about 107 μg/kg (Bajgar, 2006; Patocka and Fusek, 2004). Dioxin interferes with the metabolism of porphyrins (and the main symptom of poisoning is derived from an increase of porphyrins in the organism—i.e., porphyria cutanea tarda) by induction of delta aminolevulate synthetase. Dioxin also has carcinogenic, hepatotoxic, nephrotoxic, teratogenic, and embryotoxic effects and causes dermal changes (except porphyria cutanea tarda), including chloracne, followed by development of cachexia. There is no specific antidote, making treatment very difficult and symptomatic. Effects of dioxin following acute administration are relatively delayed. This is a limiting factor for its use as a CW. Dioxin in the organism is bound to lipids and concentration of dioxin in plasma fat in persons exposed to dioxin was 100–1,000× higher than that of normal population (Neuberger et al., 1999; Pelclová et al., 2011; Klement et al., 2013). It should be mentioned that dioxin is one of the polychlorinated biphenyls and dibezofurans that appears to be problematic for the environment (Sofronov et al., 2001; Bajgar, 2006). Dioxin was used to poison Ukraine's President Viktor A. Yushchenko (Sorg et al., 2009).

Bicyclic Phosphates

Bicyclic phosphates have been used as flame retardants, antioxidants, stabilizers, and for spectroscopic studies. At present, however, they are being replaced by other compounds that are not so highly toxic. In a chemical structure (Figure 26.1), when R is substituted by isopropyl, the toxicity is very close to that of sarin (LD_{50} = 0.18 mg/kg, i.m. in rats). Bicyclic phosphates act rapidly—within minutes following parenteral administration. Clinical symptoms include behavioral perturbation, muscle weakness, hyperactivity, muscle tremors, and convulsions leading to paralysis. Intoxication is slightly similar to poisoning with nerve agents, but with a different mechanism of action; i.e., probably connected with gamma-aminobutyric acid receptors. Specific antidotal therapy does not exist, but a relatively good effect was observed following administration of benzodiazepines (Patocka and Fusek, 2004; Bajgar, 2006).

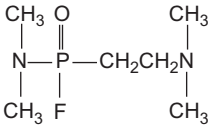
Perfluoroisobutene

Perfluoroisobutene (PFIB) is designated a chemical 2 by the CWC and therefore is contained in Schedule 2A. Its chemical structure is shown in Figure 26.1. PFIB is produced by thermal decomposition of Teflon and has high inhalation toxicity characterized by pulmonary edema. PFIB has been characterized in more detail in an *ASA Newsletter* (Patocka and Bajgar, 1998). Therapy is symptomatic.

Organophosphates

There are other known OPs having relatively high toxicity, like amiton (Tetram®), Armin®, dimefox (Hanane, Terrasytam®), paraoxon (E 600®), and TEPP (Tetron®). These compounds could be used for military and terrorist purposes; however, it would be uneconomic for the military to replace these substances. However, a new group of OP compounds has been described and characterized. This class of OPs can be described in general as 2-dialkylaminoalkyl-(dialkylamido)-fluorophosphates. In their chemical formulas, structural similarities with the group of so-called G-compounds (i.e., sarin, soman, and tabun) and V-compounds (i.e., VX and others) are found. These chemicals were designated as *GP* or *GV compounds* (Bajgar, 1992; Bajgar et al., 1992; Halámek et al., 1995; Fusek et al., 1996b). The toxicities of the most toxic derivatives are shown in Table 26.1. Intoxication

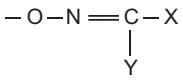
TABLE 26.1 LD_{50} Values of GV in Mice and Rats Following Various Routes of Administration



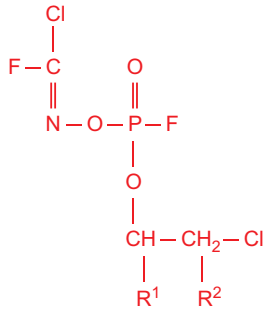
LD_{50} (μg/kg) with their 95 % Confidence Limits		
Route of Administration	**Mice**	**Rats**
i.v.	27.6 (25.6–29.4)	11 (8.5–17.6)
i.m.	30.5 (28–55)	17 (15.5–23.6)
s.c.	32 (29–53)	21 (18–26)
p.o.	222 (194–255)	190 (881–272)
p.c.	Not tested	1366 (881–3138)

with this compound has practically the same syndromes as observed with nerve agents. Treatment with atropine and reactivators is difficult because of the absence of the ability to reactivate inhibited cholinesterases by common oximes (Kassa, 1995; Fusek et al., 1996b; Kassa et al., 2006; Kuca et al., 2006). The lack of reactivation is different from that observed for soman (i.e., aging and dealkylation) and it is probably caused by steric hindrance in the cavity of cholinesterase. The volatility of GV compounds is between VX and sarin and therefore these agents are effective when penetrating through uniforms. This is an example of an intermediate volatility agent.

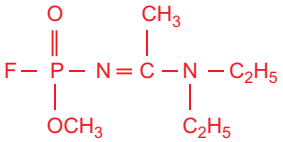
There are sources of information that suggest a new nerve agent known as Novichok or Novichok 5. In 1982, the Soviets began a secret CW development program that was code-named Foliant. The program had the apparent goal of developing new binary nerve agent weapons. Novichok has been described as a new toxic agent, and it is very difficult to treat poisoning by it (practically impossible; the toxicity was about 10 times greater than VX agents). Its exact chemical structure is unknown. The Novichok class of chemicals almost certainly belongs to the organophosphorus compounds containing the dihaloformamide group (Bajgar, 2006):



where X and Y are Cl, F, Br, or even a stable pseudohalogen like–CN. An example of Novichok (Kuca et al., 2013) could be as follows:



Another possibility could be compound A232:



There are other analogs of A232, including A230 and A234. Because these chemicals are relatively unstable, binary recepture was probably developed (Halamek and Kobliha, 2011).

Toxins

Toxins are prohibited by the Convention on the Prohibition of the Development, Production, and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on their Destruction (known for short as the Biological Weapons Convention), signed in London, Moscow, and Washington on April 10, 1972. Their isolation from natural sources is sometimes difficult, but some toxins are possible to synthesize using biotechnology. Their toxicity is very high (e.g., the inhalation LD_{50} of botulinum toxin and tetanotoxin is measured in tens of $mg/kg/m^3$). Some other known toxins are saxitoxin, tetrodotoxin, and batrachotoxin. They are highly effective by other routes of administration as well. Effects are observed within 10–20 min, beginning with muscle weakness, insensitivity of tongue, fingers, and mouth, followed by muscle paralysis, including respiratory muscles. Specific therapy is unknown, so it is necessary to save basic life functions (using artificial ventilation, etc.). When death is not observed within the first 24 h after exposure, the prognosis is relatively good.

Other types of toxins are mycotoxins, mostly trichothecenes. Their production is straightforward by fermentation, and they are highly stable and therefore may be stored for a long time. They are effective by all routes of administration, including inhalation and percutaneous absorption. Their toxicity is not very high, and the effect is prolonged. Symptoms of intoxication vary greatly, including fever, hemorrhagic eruption, bleeding, necrotic angina, decrease of leukocytes, and sepsis. Some toxins are carcinogenic, teratogenic, mutagenic, and hepatotoxic, while some of them also have a neurotoxic effect. There is no specific therapy; treatment is focused only on relieving symptoms (Patocka, 2004). They caused an epidemic (alimentary toxic aleukia) in the former Soviet Union and were the subject of discussion for possible use in Asia (yellow rain).

In August 1981, based on limited physical evidence, the United States announced that trichothecene mycotoxins had been used—but the findings were less than convincing to the scientific community and the issue became extremely contentious. This controversy was never totally resolved, and no definitive evidence was found (Bajgar, 2006).

The question of neurotoxins and neurotoxicity mechanisms was extensively described by Segura-Aguilar and Kostrzewa (2006). Some of them are described next.

Aziridines

Aziridines are 2-(trisubstituted phenyl) ethyl aziridines that induce changes in behavior and motor influencing neurotransmission. Their toxicity is not very high, and they play a role in modeling a number of diseases. The effect is long-lasting, and mostly irreversible without

specific antidotal treatment. Some aziridines, e.g., *N*-(3,5-dimethoxy-4-propoxy) phenylethylaziridinium (Figure 26.1), have convulsive properties. Convulsions are treatable with benzodiazepines (Herink, 1977, 1995).

Tremorine

A relatively simple compound (Figure 26.1), tremorine is known to induce symptoms similar to Parkinson's disease in mice and monkeys. The onset of symptoms, such as salivation, miosis, lacrimation, muscle weakness, and bradycardia, was evident within 15–30 min after administration. Typical symptoms are muscle twitch or fine tremor of the head and extremities, decrease in body temperature, and analgesia. This stage usually lasts for a few hours. Therapy is symptomatic only and not very effective (Bajgar, 2006; Patocka, 2004).

Imino-β,β-Dipropionitrile

Imino-β,β-dipropionitrile (IDPN) is one of the compounds (Figure 26.1) isolated from *Lathyrus sativus*, also called *lathyrogenic substances.* The toxicity of IDPN (and also of aziridines and tremorine) expressed as LD_{50}, is not very high, falling in the range of tens of mg/kg. Following administration of lower doses of IDPN, a condition called *waltzing syndrome* is characterized by a circling movement in both directions, and sometimes movement of the head similar to chorea (and hyperkinetic syndrome). High doses of IDPN are known to produce conjunctivitis and edema of the eyelids. In severe cases, it causes hemorrhages in the retina with the possibility of blindness. Hyperkinetic syndrome is irreversible and does not react to therapy (Bajgar, 2006).

Bioregulators

A variety of agents have the potential to be used as weapons of bioterrorism. These weapons have been used in wars from the start of recorded history (Metcalfe, 2002). The development of technologies on a modern militarily significant scale was initiated in several countries during the period between the two world wars (Roffey et al., 2002). However, as a result of modern technology, the risks are greater now, and the outcomes more serious (Henderson, 1999). Today, agents include not only toxins, but also a new group of compounds and bioregulators. Bioregulators are naturally occurring organic compounds that regulate diverse cellular processes in all organisms. There are substances normally found in the body that regulate normal and critical biological processes, such as blood pressure, heart rate, breathing, muscle contraction, temperature, mood control, consciousness, sleep, emotions, and immune responses. Their characteristics include activity in extremely low doses and they frequently have rapid effects. Unlike traditional disease-causing biowarfare agents that take hours and days to act, bioregulators can act within minutes after administration. There is comprehensive knowledge available on these compounds because all these compounds work as regulators and modulators of all vital biochemical pathways, linked with physiological functions of living organisms. If bioregulators were exploited for the purpose of terrorism, they could potentially cause profound pathophysiological effects. The main group of bioregulators under discussion includes different biochemicals such as neurotransmitters, hormones, and proteolytic enzymes. The common property of all bioregulators is their ability to induce biological effects and a consequential rapid fall in their concentrations in tissues. The problem is their route of administration (Patocka and Merka, 2004; Patocka et al., 2013).

A brief description of some bioregulators from a military viewpoint is given next. These peptides have been chosen based on the criteria of bioregulators intended for terrorism and warfare agents (Bokan et al., 2002).

Angiotensins

Angiotensins regulate blood pressure and contribute to sustaining hypertension (Mazzolai et al., 1998). The principal effect of angiotensin is to stimulate the synthesis of aldosterone and elevate blood pressure via vasoconstriction of the smooth muscle in arterioles.

Bombesin

Bombesin is a tetradecapeptide isolated from the skin of the amphibian frog *Bombina bombina* (Anastasi et al., 1971). It has been proposed that bombesin-related peptides may be released from the gastrointestinal tract in response to ingested food, and that they bridge the gut and brain via neurocrine means to inhibit further food intake (Merali et al., 1999).

Bradykinin

Bradykinin is a vasoactive nonapeptide, which is the most important mediator generated by the kinin system and it is involved in inflammation processes (Calixto et al., 2000). Kinins identified thus far include bradykinin and kallidin. They cause local increases in the permeability of small blood vessels. Bradykinin is a potent stimulator of pain receptors in the skin and has a powerful influence on stimulating smooth muscle contraction, inducing hypotension, and increasing blood flow and permeability of capillaries (Cyr et al., 2001).

Endorphins

Endorphins are peptides that bind to the neuroreceptors in the brain to give relief from pain (Terenius, 1992). Beta-endorphin is the most active, and it is about 20 times more potent than morphine.

Endothelins

Endothelins constitute a family of peptides (Hart and Hart, 1992). They are very potent endogenous vasoconstrictors and vasopressors and are secreted by various cells and tissues in the human body. Of the three isoforms, endothelin-1 (ET-1) is one of the most potent contractors of vascular smooth muscles (Miller et al., 1993). Endothelins have very similar structure and biological properties to sarafotoxins (Kloog and Sokolovsky, 1989), and the toxic peptides are obtained from the venom of mole vipers (Atractaspidae).

Enkephalins

Enkephalins are endogenous pentapeptides. Two enkephalins have been identified: Met-enkephalin and Leu-enkephalin. Both enkephalins are relatively weak analgesics, which activate all opioid receptors but appear to have the highest affinity for the delta-receptors. In the central nervous system, enkephalins have been found in many areas, but predominantly those associated with nociception (Przewlocki and Przewlocka, 2001).

Histamine Releasing Factor

Histamine releasing factor (HRF) is one of the many immune system protein molecules called *cytokines*, which trigger allergic reactions. Unlike other cytokines, HRF stimulates basophils to release histamine (MacDonald, 1996).

Neuropeptide Y

Neuropeptide Y (NPY) is the most abundant neuropeptide in the brain. Its concentration is many times higher than other neuropeptides. It is a member of a family of proteins that include pancreatic polypeptide, peptide YY, and seminalplasmin. In addition to its function of stimulating feeding behavior, several other physiologic roles have been assigned to NPY, including involvement in circadian rhythms, sexual function, anxiety responses, and vascular resistance (DiBona, 2002; Halford and Blundell, 2000).

Neurotensin

Neurotensin is an endogenous peptide neurotransmitter inducing a variety of effects, including analgesia, hypothermia, and increased locomotor activity. It is also involved in regulation of dopamine pathways. Neurotensin is found in endocrine cells of the small intestine, where it leads to secretion and smooth muscle contraction (Moore and Black, 1991).

Oxytocin

Oxytocin is a nine amino acid peptide that is synthesized in hypothalamic neurons and transported down through axons of the posterior pituitary for secretion into blood. Oxytocin has three major physiological effects: stimulation of milk ejection, stimulation of uterine smooth muscle contraction at birth, and establishment of maternal behavior.

Somatostatin

Somatostatin is a cyclic tetradecapeptide hormone, characterized as the major physiological inhibitor of growth hormone released from the pituitary, but inhibits the release of many other physiologically important compounds, including insulin, glucagon, gastrin, and secretin (Wolkowitz, 1994).

Substance P

Substance P is an 11–amino acid polypeptide, and a physiologically significant (and the best-known) member of a family of three related peptides known as *neurokinins.* The specific receptor subtypes corresponding to these three neurokinins are known (Sandberg and Iversen, 1982). These neurotransmitters appear to play a key role in the regulation of emotions, and antagonists of their receptors may be the novel psychotropic drugs of the future. Koch et al. (1999) demonstrated that substance P, in combination with thiorphan, administered as an aerosol, is highly potent and extremely toxic. Exposure to the substance at extremely low air concentrations may result in incapacitation of humans.

Vasopressin

Vasopressin, also called *antidiuretic hormone (ADH)*, is a cyclic nonapeptide hormone released from the posterior pituitary. Its primary function in the body is to regulate extracellular fluid volume by affecting renal handling of water. Specific actions include inhibition of diuresis, contraction of smooth muscles, stimulation of liver glycogenesis, and modulation of adrenocorticotropic hormone release from the pituitary gland. ADH belongs to the family of vasoactive peptides involved in normal and pathological cell growth and differentiation.

Thyroid-Stimulating Hormone

Thyrotropin (also known as *thyroliberin* and *thyroid-stimulating hormone (TSH)*) is a peptide released by the anterior pituitary gland that stimulates the thyroid gland to release thyroxine (Ladram et al., 1994). The release of TSH is triggered by the action of thyrotropin-releasing factor, a peptidic substance found in the hypothalamus of the brain and influencing the secretion of glandula thyroidea.

Not long ago, most bioregulators had been unavailable in the amount needed for terroristic attacks or military operations. However, by the end of the twentieth century and beginning of the twenty-first century, there had been intensive developments in biomedical sciences,

biotechnology, and chemical engineering in the pharmaceutical industry, and because of the revolution in the science and technology of drug discovery, the control of bioregulators will be significantly complicated.

In the near future, genomic and proteomic methods will stimulate increasing use of computer modeling techniques to identify new biologically active compounds and then determine their mode of action. Currently, new compounds are being generated in large numbers by combinatorial methods and assayed for potential activity, and it seems likely that genomic and proteomic methods will make these compounds accessible in amounts necessary for terroristic use. This is a very disagreeable situation and a new problem for the control of chemical and biological weapons.

NONLETHAL WEAPONS

Nonlethal weapons can be of a chemical, physical, or pharmacological character (Hess et al., 2005). Such weapons are designed and primarily employed for the purpose of incapacitating personnel or material while minimizing fatalities, permanent injury to personnel, and undesired damage to property and the environment (Pearson, 2006). Weapons used for physically immobilizing personnel include lasers, microwave impulses, ultrasound, electric current, nets, solidifying foams, and sliding gels. For CWs, immobilizing gases and irritants and smelly bombs can be considered. For pharmacological immobilization, ketamine, benzodiazepines, and onset accelerators are the compounds of real interest. Basic requirements for the use of immobilizing drugs are necessary, such as minimal cardiovascular and respiratory side effects; easy administration, primarily by inhalation; rapid onset; high biological accessibility and well-controlled effects; and specific antagonists that can be used within a large therapeutic range. These drugs are used for animal immobilization, using narcotizing blowpipes, darts, or guns. This group is also called *calmatives.* The compounds considered include ketamine and phencyclidine, alpha-2-agonist, opioids (including etorphine, fentanyl, and carfentanyl) and muscle relaxants (Patočka and Cabal, 2001; Dejmek, 2004; Patočka and Fusek, 2004; Streda and Patočka, 2004; Hess et al., 2005; Halamek and Kobliha, 2011; Klement et al., 2013).

As for fentanyl derivatives, there are more effective drugs than fentanyl. These include carfentanil (probably used in Moscow in 2002 against terrorists), whose effectiveness in 500–3,000 times greater than morphine, and remifentanil, which is 5,500–11,000 times more effective (Halamek and Kobliha, 2011). Methods of determination of fentanyl derivatives were described, too (Jelinkova et al., 2013).

Genetic and Ethnic Weapons

Another possible threat is modification of the effects of commonly used chemicals or biological agents. The first administration produces no toxic effect, but the second administration of the same or another compound causes damage.

The present genetic material of a human population could be misused. Recent advances in biological research could eventually lead to the creation of new types of CWs targeting a specific group of human beings with common genetic characteristics, as is perhaps the case with certain ethnic groups. Biologically, there are more similarities than differences between human beings. However, differences do exist, and if the data on ethnic differences are known, the selective effect of different chemicals to the groups cannot be excluded. Glucose-6-phosphate dehydrogenase, the enzyme that catalyzes the dehydrogenation of glucose-6-phosphate to 6-phosphogluconate, has been genetically determined and found to be low or nonexistent in some groups (though it appears more frequently in Africans and Scandinavians). It is connected with the male chromosome, and in men where it appears, hyperbilirubinemia is observed. Following administration of some normal medications, like acetylsalicylic acid, sulfadimidine, chinine, and chloramphenicol, a hemolytic syndrome is induced. Individuals with other pathologic states (e.g., chronic methemoglobinemia) will be more sensitive to drugs that are able to increase the level of methemoglobin, including analgesics, antipyretics, and nitrates. Deficiency of alpha-1-antitrypsine can cause increased sensitivity to asphyxiation agents. Plasma cholinesterase activity is also genetically determined, and individuals with decreased cholinesterase activity are more sensitive to myorelaxants. It is very probable that these people will be more sensitive to nerve agents (Bajgar, 2006).

Comparison of some criterias of the use of new chemicals for military or terroristic purposes is shown in Table 26.2.

For military purposes, using new nerve agents is the most likely possibility; however, their use is generally prohibited by the CWC. For terroristic purposes, there is a wide range of toxic chemicals and their choice is very dependent on the capabilities of potential users and their aims—namely, to achieve immediate effects or the liquidation or incapacitation of people over longer periods.

In the end, let us consider (very hypothetically!) terroristic use of one of the most obvious drugs: insulin. It is known that some other routes (e.g., inhalation) of administration for medical purposes have been developed (Mastrandrea, 2010). Therefore, this does not rule out the development of effective administration by inhalation. If suitable stability and aerosolization is achieved, could we realistically conclude that this drug would *not*

TABLE 26.2 Different Criteria for the Suitability of Different Chemicals to be CW

Criterium	Carbamates	New OP	Dioxin	Bicyclic Phosphates	Toxins	Incapacitants
Occurrence of first symptoms	Minutes	Minutes	Hours–days	Minutes	Different	Minutes
Death observed within	Hours	Hours	Weeks–months	Hours	Hours–weeks	Not in incapacitant doses
Availability of antidotes	Symptomatic	Yes	no	Symptomatic	Symptomatic	Yes
Easy to synthesize	+	+	+	++	+++	++
Toxicity	High	High	Very high	High	Varied	Low
Stability	+	+	+++	+	Different	++
Cost	+	+	+	++	+++	+++

be misused by terrorists? The effects are quick and antidotes to protect potential users would not be a problem. Military use of this drug for states or groups that are not CWC members is not ruled out either.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

This chapter explains that the misuse of knowledge of pharmacology and toxicology is possible and can be applied to all human activities. The task is to be well informed in cases where it is important to know the best protection and therapeutic means, and to control all activities connected with the synthesis and the possible availability of CWs/CWAs to both nonqualified and qualified people.

Ricin

Russell Dorsey, George Emmett and Harry Salem

INTRODUCTION

Biological toxins are metabolic products from living organisms. They are produced by a vast number of different life forms ranging from the simplest to the most complex, and each has a distinctive mode of action in conjunction with a characteristic molecular structure and biochemistry. A common feature to all toxins is that minute quantities will exert a pronounced effect on their intended targets. Algal toxins constitute a very diverse group of compounds ranging from simple ammonia to complex polypeptides and polysaccharides. Dinoflagellates are a source of some potent, nonprotein toxins, such as saxitoxin and tetrodotoxin; one such toxin causes the deleterious effects during a red tide. A red tide is the common name for an estuarial algal bloom when the photosynthetic pigments of certain species of phytoplankton can alter the hue of water; colors vary from purple to almost pink, but normally they are red or green. The mycotoxins are secondary metabolites, which are nonprotein substances produced by molds and fungi. Many molds produce more than one toxin and, in several cases, combinations of mycotoxins synergize to enhance toxicity (Weber et al., 2005). Leaves, roots, or seeds from some plants can be poisonous. Examples include the protein toxins ricin, derived from castor beans, and abrin, from the jequirity pea. Finally, there are a number of toxins produced by animals, including the nonprotein batrachotoxin found in certain species of frogs (poison dart frog), Melyridae beetles, and birds (*Pitohui*, *Ifrita kowaldi*), and a wide variety of peptide and proteins from marine snails, scorpion venoms, and snake venoms.

In the wake of recent terrorist-related incidents across the globe, biological agents have become well-known for the threat they pose to the US and Allied militaries and the civilian populations they guard. The agents are attractive to both foreign states and terrorists because they are relatively inexpensive to produce and require minimal technical infrastructure.

Ricin is defined as a biological category B agent that has the potential to pose a severe threat to public health and safety. There are currently 41 agents and toxins, including ricin, listed in the Center for Disease Control and Prevention (CDC) regulation found in Part 73 of Title 42, Code of Federal Regulations (Possession, Use, and Transfer of Select Agents and Toxins).

Both the ricin toxin and castor bean plant have a long history of human use. The earliest human records contain references to the castor bean plant, which was known and cultivated by the ancient Egyptians. Oil pressed from the beans was used as a lubricant, and the beans were sometimes ingested to treat constipation. Even today, castor oil is still commercially produced globally. Castor oil is presently used in bath oil products, detergents, lubricants, dying agents, and most recently in the production of biodiesel fuel. The ricin toxin is easily produced from the castor bean mash, remaining after the beans are pressed to extract castor oil (Wannemacher et al., 1992). Peter Hermann Stillmark first isolated and named the toxin ricin in 1888. Initially, the ricin protein was not known for its toxicity, but rather for causing the agglutination of erythrocytes. Later, the field of immunology was founded based on Paul Ehrlich's research with ricin. By introducing small amounts of the toxin to mice, Ehrlich was able to induce immunity specifically to ricin. This seminal work proved that in response to a challenge, certain serum proteins (antibodies) are produced that afford the host protection.

During the era of the biological weapons offensive program in the United States, ricin, by virtue of its toxicity, availability, and ease of production, was one of the first agents to be weaponized (Cookson and Nottingham, 1969). Today, ricin is one of the few biological agents utilized with known success. The most prominent of these was the attack leading to the death of the Bulgarian exile,

Handbook of Toxicology of Chemical Warfare Agents.

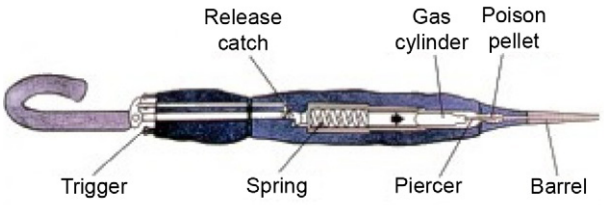

FIGURE 27.1 An artist's conception of the "umbrella gun." *Source: Figure from James (2014).*

Georgi Markov. On September 7, 1978, Markov was jabbed in the leg with an umbrella while waiting at a bus stop. A man holding the umbrella apologized to Markov before casually walking away from the scene (Crompton and Gall, 1980). Markov would later tell doctors that the man had spoken with a foreign accent. He recalled feeling a stinging pain from the site where he had been jabbed with the umbrella tip and noticed that a small, red, raised wound had formed at the site. That evening, he developed a high fever and was admitted to a hospital, where he died 3 days later. An autopsy revealed a 1.52-mm-wide metal pellet in the wound, speculated to be a watch bearing. Two 0.34-mm-diameter holes had been drilled at right angles to form a well inside the bearing. The pellet contained no trace of the poison that killed Markov, and investigators relied on standard differential diagnosis techniques and intel (military discipline that exploits a number of information collection and analysis approaches to provide guidance and direction to commanders in support of their decisions) to identify the causative agent. A host of toxins were considered, including tetanus, diphtheria, dioxin, and several nerve agents. Ricin seemed most likely because intelligence agents knew that it had been under research for decades in the Soviet Union. Working together, scientists and investigators surmised that an "umbrella gun" shot a ricin-laced pellet. The modified umbrella may have contained a cylinder of compressed air that propelled the pellet after pulling a trigger mounted in the umbrella's handle. An artist's conception of the "umbrella gun" is shown in Figure 27.1.

Two years later, another assassination attempt with ricin occurred at a shopping mall parking lot in Tyson's Corner, Virginia. Boris Korczak, a Soviet citizen who had been a CIA double agent, felt a slight sting, "something like a mosquito bite" he reported, while walking across the parking lot. He developed a fever of 106°F a few hours later, followed by a sharp decline in body temperature. Internal bleeding and an irregular heartbeat ensued. After his recovery, he extracted a tiny metal ball from his "mosquito bite" (Figure 27.2) (Douglas and Livingston, 1987).

More recently, ricin was discovered in a Las Vegas motel room. Roger Von Bergendorff awoke from a

FIGURE 27.2 Ricin-laced pellet extracted from Boris Korzak.

comatose condition on March 14, 2008, at which time he was questioned by police as to why he had such a large quantity of ricin. Subsequently, he was arrested on April 16, 2008, and charged with possession of a biological toxin and two weapons offenses. Several other related cases involving ricin on US soil occurred in November 2003. Ricin was found in the mailroom that served Senate Majority Leader Bill Frist's office. No injuries were reported. The White House mail-processing facility and a mail-sorting facility in Greenville, South Carolina discovered ricin. The envelope discovered in Greenville was addressed to the US Department of Transportation and labeled "Caution Ricin Poison." The enclosed letter threatened to "turn DC into a ghost town." There are more than a dozen other events that have occurred in the past (CNS, 2008).

HISTORY OF BIOLOGICAL WEAPONS

The known use of biological weapons dates back to the beginning of written record, with many examples of use on the battlefield. In 190 BC, Hannibal hurled venomous snakes onto enemy ships on Pergamus at Eurymedon. Scythian archers used arrows dipped in the blood of decomposing bodies in 400 BC. Biological weapons have also seen use in more recent times on the North American continent. In 1763, during the Pontiacs Rebellion in New England, the British officer Colonel Henry Bouquet gave blankets infected with smallpox to Native Americans at Fort Pitt, Pennsylvania, an act that devastated the Native American population. In 1863, Confederate soldiers retreating through Mississippi left dead animals in

wells and ponds to deny drinking water to Union troops. Another US Civil War use of biological weapons was executed by Dr. Luke Blackburn, who attempted to infect clothing with smallpox and yellow fever for sale to unsuspecting Union troops (Diamond, 1997).

Biological weapons research and development in the United States was very active during World War I, with the impetus provided by the American Anton Dilger. After joining the German Army in 1914, Dilger experienced a nervous breakdown and returned home to the United States, which was neutral at that point. At the request of the German Government, Dilger brought strains of anthrax and glanders with him for inoculating horses awaiting shipment to Europe (Erhard, 1999). After becoming aware of Germany's involvement with biological weapons, the US Government initiated its own biological weapons program, using ricin for retaliatory use in 1918 (DA, 1977; Carter, 2000). Two methods of dispersal were examined: the adherence of ricin to pellets contained in an artillery shell and the production of a ricin dust cloud. Because of limited amounts of purified ricin on hand and its less efficient delivery via the respiratory tract, the latter approach was considered less promising. Although both approaches were laboratory-tested to some degree, neither was perfected for battlefield use before the end of the war. During the early 1920s, the US military leadership determined that conducting further research into the use of biological weapons was not an efficient use of resources. Germany, France, Great Britain, Canada, and Japan, however, aggressively pursued the development of offensive biological weapons (Carter, 2000). The reported use of cholera, dysentery, typhoid, plague, and anthrax by the Japanese against the Chinese motivated the United States to reinitiate a biological offensive development program. The US Army's biological warfare program began at the Edgewood Arsenal (now the Edgewood Area of the Aberdeen Proving Ground, MD) and was later moved to Camp Detrick (now Fort Detrick, Frederick, MD). The first agents produced at Camp Detrick were botulinum toxin, anthrax, and brucella, but none was weaponized before the conclusion of World War II. After the war, research continued into the weaponization of biological agents until President Nixon's decision in 1969 to redirect the research toward a defensive posture, where the United States stands today. Because biological warfare agents are typically etiological agents of naturally occurring disease, the majority of military defensive efforts are focused on vaccine development and diagnostic testing. Although research continued, the program was only a skeleton of the former offensive effort. Despite a 1979 anthrax outbreak in Sverdlovsk, Russia, which exposed Russia's ongoing biological weapons research, the United States did not place much weight on the possibility of its forces facing biological weapons. This position, however, changed after the invasion of Kuwait by Iraqi troops and the deployment of US troops to the Persian Gulf. Iraq had a large biological agent production facility and a history of using biological and chemical agents during military offensives (Warrick, 2006). To counter this, intensive research focused on measures for protection, detection and destruction; these efforts are still ongoing today. In addition to state-sponsored entities, the revelation that terrorist organizations, such as the Aum Shinrikyo in Japan, were actively developing biological agents has brought attention to domestic defense against biological weapons. Defending against these agents requires not only an understanding of the agent but also an understanding of how an adversary might utilize it.

THE WEAPONIZATION OF BIOLOGICAL AGENTS

Although many pathogens and toxins cause disease or toxicity, relatively few of the naturally occurring agents can be adapted for use as a biological weapon. Paramount is its ability to survive the mechanical rigors of large-scale aerosol dissemination. Other important characteristics include an agent's availability, ease of production and storage, and its lethality, or its ability to incapacitate through morbidity (NATO, 1992). While some pursue agents of death, the philosophy of others is that the most attractive agents are those that incapacitate an adversary. During the era of the US biological offensive program, agents such as *Staphylococcus aureus* enterotoxin B (SEB) and Venezuelan equine encephalitis were selected for their ability to incapacitate rather than kill. It was estimated that an afflicted soldier would require the care from a minimum of three personnel, whereas a dead soldier placed no burden on personnel. Providing care to sickened forces can quickly render entire military units mission-ineffective by overloading field-forward medical facilities intended to treat the wounded. In addition, these same agents could also be turned on civilians, concentrating the population at care centers, which in turn would facilitate attack and invasion by our forces. A final mark of an ideal agent is one that renders the adversary defenseless while the disseminating force is unaffected.

Terrorist organizations have historically lacked technical expertise; this often leaves insurmountable challenges for large-scale production and agent delivery. Thus, these organizations require an agent that can be easily disseminated in open air using common items such as crop dusters or liquid spray devices. Agents that can survive drying have high inhalational efficiency and can effectively cause infection or toxicity, which makes them ideal biological threat agents. The options

for indoor dissemination or individual targets are much broader and essentially only limited to the creativity of the perpetrator. Use of the postal service, for instance, before the anthrax attacks on the United States, was believed to be impossible. During decontamination efforts after the anthrax attack, it was also discovered that reaerosolization was a threat. The optimal agent particle size is dependent on the delivery mode. For aerosol dissemination, the smaller the particle size, the longer it will stay airborne and the more likely it can be reaerosolized after settling. Bacterial agents have a minimum size that is limited by their cellular dimensions; this is typically 1–5 μm. Alternatively, viral agents can be as small as 0.1 μm, and toxins are limited only by their molecular weight. It has been shown that particles of less than 10 μm can stay airborne for extended periods of time (Winters and Chenoweth, 2002). Particle size is inconsequential for attack via injection, ingestion, or transdermal transmission.

Agent stability after production is another important factor to consider when selecting an agent for weaponization. Environmental factors, including temperature, relative humidity, atmospheric pollution, and sunlight, can all have an effect on agent viability. Feasible options for storage of agents are as liquid samples at room temperature, as liquid samples under refrigeration, as dry samples at room temperature, and as dry samples under refrigeration. The most desirable option is dry sample storage at room temperature, because this eliminates the need for refrigeration, allows for particle sizing before dissemination, and minimizes the environmental effects on dissemination.

Considering all factors, toxins are probably the most suitable biological agents for use in any attack. In contrast to replicating agents, using toxins as biological agents requires that a lethal amount must be injected, ingested, or inhaled. Given this caveat, a sizeable amount of toxin must be available for dispersion in large-scale attacks, severely limiting the effective toxins to those that are the most lethal and easily produced. Ricin is one of only a few toxins that meet these requirements, along with botulinum toxin, SEB and the trichothecene mycotoxins. Principally because of its suitability as a biological warfare agent, the ricin toxin has been one of the biological weapons of choice for state-sponsored organizations (Kortepeter and Parker, 1999).

THE FAMILY OF RIBOSOME-INACTIVATING PROTEINS

Ribosome-inactivating proteins (RIPs) are toxins that act intracellularly. They consist of two different subunits: a subunit A that is responsible for the enzymatic activity of the toxin and a subunit B that binds to a specific receptor on the host cell membrane, thus allowing the A subunit, the enzyme, to cross the cell membrane. The enzymatic component is not active until it is released from the native (A + B) toxin. Isolated A subunits are enzymatically active but lack binding and cell entry capability. Isolated B subunits may bind to target cells (and even block the binding of the native toxin), but they are nontoxic.

There are a variety of ways that toxin subunits may be synthesized and arranged: A + B indicates that the toxin is synthesized and secreted as two separate protein subunits that interact at the target cell surface; A-B or A-5B indicates that the A and B subunits are synthesized separately, but associated by noncovalent bonds during secretion and binding to their target; 5B indicates that the binding domain of the protein is composed of five identical subunits. A/B denotes a toxin synthesized as a single polypeptide, divided into A and B domains that may be separated by proteolytic cleavage (Todar, 2014).

Ricin is a ribosome inactivating lectin isolated from the beans of *Ricinus*. Ricin and other plant lectins, e.g., abrin and modeccin, consist of two peptide chains, A, the toxin, and B, a lectin, linked together by a disulfide bond. Lectins are a class of carbohydrate-binding proteins that interact specifically with glycoconjugates present in other organisms. Specific carbohydrate-binding activity distinguishes lectins from other plant proteins (Zhu-Salzman et al., 1998). This interaction is as specific as enzyme–substrate or antigen–antibody interactions.

Another characteristic property of lectins is that they agglutinate cells and precipitate polysaccharides and glycoproteins. That is because lectins are, as a rule, divalent or oligovalent, i.e., each lectin molecule has at least two carbohydrate binding sites that allow cross-linking between cells (by combining with sugars on their surfaces) or between sugar-containing macromolecules. Lectins have accordingly been defined as sugar-binding proteins of nonimmune origin that agglutinate cells and precipitate polysaccharides or glycoproteins (Goldstein et al., 1980).

Lectins are present in numerous edible plants. For many years it has been known that they occur in major food sources for humans and animals such as soybeans, kidney beans, lima beans, mung beans, lentils, garden peas, and peanuts. One family is composed of proteins that contain one or more 30- to 43-amino acid cysteine-rich chitin-binding domains. Another family, mainly legume lectins, binds carbohydrate substrates by way of interactions involving specific amino acid residues that are located spatially throughout the peptide. The exact role of lectins in plants is unclear, although they can serve as potent insecticides. Castor beans contain so much lectin that they are toxic to most organisms.

The binding ability and specificity of the lectin is preserved when bound to the toxic A chain. It is the lectin that directs the toxin to its target within the cell. There are a number of toxins that are bound to lectins. These

are all classified as type III toxins. This classification is based on the mode of entry into the cell. There are two categories of type III toxins: those that are bound to a single lectin, referred to as an AB toxin, and those that are bound to four lectins, known as AB5 toxins. The most commonly known type III toxins are:

AB toxins (usually plant toxins):

1. Ricin
2. Abrin
3. Mistletoe (viscumin)
4. Modeccin (Gasperi-Campani et al., 1978)
5. Diphtheria

AB5 toxins (usually bacterial toxins):

1. Campylobacter jejuni enterotoxin (from *Campylobacter jejuni*)
2. Cholera toxin (*Vibrio cholerae*)
3. Heat-labile enterotoxins (LT and LT-II) (*Escherichia coli*)
4. Pertussis toxin (*Bordetella pertussis*)
5. Shiga toxin (*Shigella dysenteriae*)
6. Shiga-like toxin (or verotoxin) (enterohemorrhagic varieties of *E. coli* including O157:H7)

Cholera toxin, Shiga toxin, ricin, and abrin are protein toxins that damage mammalian cells by a mechanism that includes four essential events: receptor-mediated endocytosis; retrograde transport into the lumen of the endoplasmic reticulum (ER); passage through the ER membrane into the cytoplasm; and catalytic inactivation of a target substrate in the cytoplasm. The receptor-binding site of a protein toxin is usually within a subunit or domain that is distinct from the subunit or domain that bears the catalytic activity of the toxin. Both cholera toxin and Shiga toxin belong to the AB5 protein toxin family in which the A chain is the enzymatic subunit, and each of the five identical B chains bind cell surface receptors.

Some peptide and protein toxins have been classified into families containing a number of different toxins with the same biological activity. Within any one family, the toxins can differ in amino acid sequence and number, but their molecular architectures and active site conformations are conserved. One of the most intensely studied toxin families is that of the RIPs, which includes ricin. The term "ribosome-inactivating protein" was introduced to designate plant proteins that inactivate animal ribosomes. The toxins were later found in certain bacteria and fungi (Endo et al., 1988). These are cytotoxins that catalytically and specifically inactivate the large subunit of eukaryotic or prokaryotic ribosomes (Stirpe and Barbieri, 1986). Historically, RIPs have been classified into two types based on their quaternary structure.

The type I RIPs are the most numerous and are all synthesized as a single chain enzyme of approximately 30 kD. Type II RIPs are synthesized as larger precursors that accumulate in protein bodies and contain an approximately 30-kD A-chain linked by a disulfide bond to a lectin B-chain of similar size (Stirpe and Barbieri, 1986). Plant RIPs, including all type I toxins and the A-chains of type II toxins, are RNA *N*-glycosidases capable of hydrolyzing the nitrogen–carbon glycosidic bond of a specific adenosine located in the sarcin/ricin domain of the largest ribosomal RNA (Barbieri et al., 2006). The B-chain is able to bind the D-galactose-terminated receptors on the membranes of animal cells and facilitates the internalization of the enzymatic A-chain. To date, more than 50 type I RIPs and approximately 15 type II RIPs have been identified (Stirpe and Barbieri, 1986). Although there is some variation at the N- and C-termini of their respective polypeptide chains, the active sites of the type I RIPs and the A-chains of type II RIPs are well-conserved, as are their three-dimensional conformations (Gasperi-Campani et al., 1985).

Originally, type I and type II RIPs were identified based on biological activities. Type II RIPs were discovered more than a century ago, when Stillmark isolated the toxic protein ricin from castor beans. As mentioned, the toxicity of ricin was initially attributed to its agglutination activity for red blood cells and not by ribosome inactivation. Type II RIPs attribute their carbohydrate binding activity to their B-chain, which contains two or possibly three binding sites (Robertus, 1991). The multiple binding sites allow B-chains to aggregate with red blood cells and platelets.

Evidence for type I RIPs was not uncovered until 1925. Duggar and Armstrong observed that the so-called *Phytolacca Americana* antiviral protein (PAP) inhibited the transmission of tobacco mosaic virus in plants. In 1978, PAP was recognized as an inhibitor of protein synthesis. Not all type I RIPs, however, are believed to be antiviral proteins (Lam and Ng, 2001). Unlike their type II counterparts, type I RIPs exhibit low toxicity because they are not able to bind and cross the cell membrane efficiently. Type I RIPs, however, are cytotoxic to certain cells such as macrophages. The cells can absorb type I RIPs by pinocytosis and subsequently succumb to RIP activity. Recently, a type III RIP has been isolated from *Hordeum vulgare*, the common barley plant. The RIP consists of an amino-terminal domain resembling type I RIP and is linked to an unrelated carboxyl-terminal domain with unknown function (Bolognesi et al., 2002). The type III RIP accumulates in the barley kernel as an inactive precursor that, on germination, is processed into a two-chain RIP by removal of an internal peptide from the catalytic domain (Peumans et al., 2001).

RIPs have been identified in more than 50 different plant species and have also been found in fungi, bacteria, and at least one algal species. The highest quantity of RIPs has been isolated from the carnation family Caryophyllaceae, the elder family Sambucaceae, the family of gourd-producing

plants Cucurbitaceae, the Euphorbiaceae family of flowering plants, the pokeweed family Phytolaccaceae, and the family of flowering grasses Poaceae (Reinbothe et al., 1994). Presently, the role of RIPs in plant physiology is not entirely clear. Based on their variable activity toward heterologous and autologous plant ribosomes, several possible roles have been proposed: anti-viral activity, anti-fungal activity, herbivore defense, a role in the arrest of cellular metabolism during periods of senescence, and, finally, a role as storage proteins (Bolognesi et al., 2002). Conclusive evidence has been obtained that RIPs not only deadenylate ribosomal RNA but are also capable of removing adenine residues from DNA and several other polynucleotide substrates. Thus, it has been proposed to rename RIPs as polynucleotide: adenosine: glycosidases (PAGs) (Shakirova and Bezrukova, 2007).

THE RICIN TOXIN STRUCTURE AND BIOSYNTHESIS

Ricin is a toxin originating from *Ricinus communis*, the castor bean plant. A photograph of the plant is shown in Figure 27.3A; a photograph of the beans it produces is presented in Figure 27.3B. As for all type II RIPs, ricin is a protein consisting of two folded peptide chains, designated the A-chain and B-chains. The two are linked by a single disulfide bridge. Ricin has a molecular weight of approximately 64–65 kDa; ricin A-chain (RTA) is a 267-amino acid globular protein domain containing eight α-helices and eight β-sheets (Wright and Robertus, 1987). The catalytically active site occurs as a long cleft on the A-chain surface. Within the active site, Glutamic acid 177 is a key catalytic residue, and conversion to Glutimate reduces activity 180-fold.

Ricin B-chain (RTB) is a 262-amino acid protein domain that conforms to a barbell-shaped architecture. The folded domain has a sugar-binding site at each end, allowing hydrogen bonding to galactose and *N*-acetyl galactosamine typically found on cell surfaces. The B-chain is not toxic and the A-chain alone is not toxic. In fact, many edible plants such as barley synthesize A chain. The B-chain has been expressed in monkey COS-M6 cells with no adverse effects (Weston et al., 1994). A representation of the ricin protein based on X-ray crystallographic data is presented in Figure 27.4.

FIGURE 27.4 Representation of the ricin protein derived from X-ray crystallographic data. The A-chain and B-chain are blue and orange, respectively. Random coil regions are strings, β-sheets are flat ribbons, and α-helices are coiled ribbons.

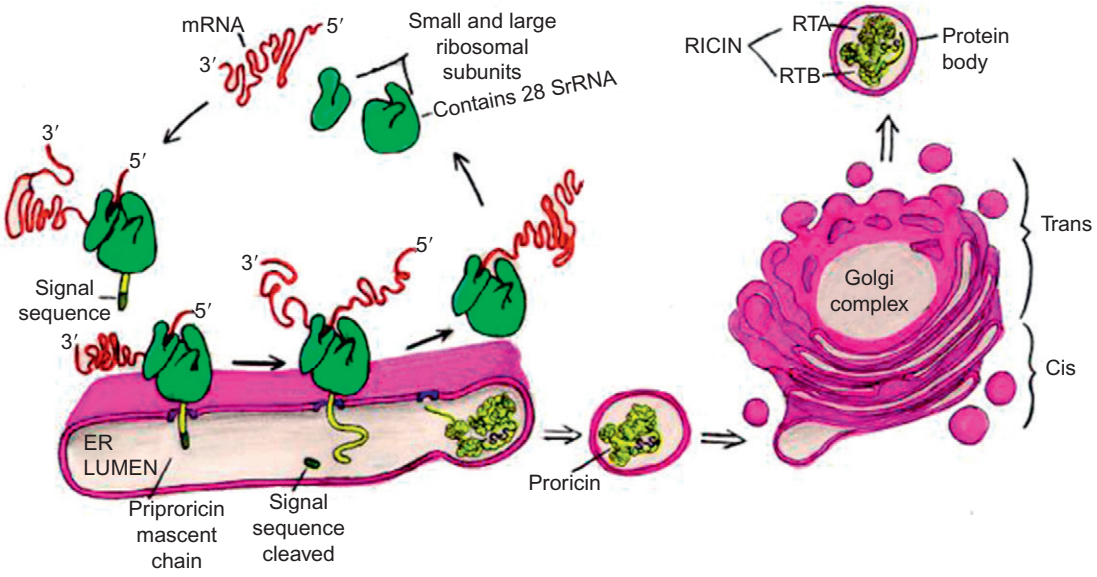

FIGURE 27.5 Biosynthesis of the ricin toxin. *Source: Illustration taken from EHSO (2014).*

The biosynthesis of ricin and RCA occurs in the endosperm cells of maturing *R. communis* seeds for storage in subcellular vacuolar compartments referred to as protein bodies. This entire process is illustrated schematically in Figure 27.5. Biosynthesis begins with the translation of a propolypeptide encompassing both the A-chain and B-chain as well as an amino-terminal signal sequence (Butterworth and Lord, 1983; Lord, 1985). The signal sequence directs the nascent chain to the ER lumen, where it is cleaved and removed from the rest of the long polypeptide chain. The resulting proricin is N-glycosylated in the lumen, and protein disulfide isomerases catalyze disulfide bond formation as the proricin chain folds into two globular protein domains. Proricin undergoes further oligosaccharide modifications within the Golgi complex before it is transported within vesicles to the protein bodies (Hiraiwa et al., 1997). The toxins are stored in the protein bodies until their ultimate destruction by hydrolysis, typically only a few days after germination of the mature (Lord, 1985).

THE CELLULAR INTERNALIZATION OF RICIN

The entry of ricin into a living cell begins with the reversible binding of its B-chain to cell-surface glycolipids and glycoproteins bearing β(1→4)-linked galactose residues (Moya et al., 1985). The toxin has two galactose binding sites for cell surface binding, but ricin may also be bound to certain cells by an entirely different mechanism. Ricin, a glycoprotein, contains mannose-rich N-linked oligosaccharides in both of its constituent subunits. On the surface of cells in the reticuloendothelial system, mannose receptors are present that have been shown to bind these carbohydrates (Simmons et al., 1986). Further, the binding by these mannose receptors results in subsequent cell death (Simmons et al., 1986), and deglycosylation of the toxin abolishes both binding and intoxication by the mannose receptor pathway (Foxwell et al., 1987). It is estimated that 10^6–10^8 toxin molecules may bind to a single cell at one time. The toxin molecules are internalized into cells via endocytosis in coated pits and vesicles, or smooth pits and vesicles (Moya et al., 1985). Once in the cytosol, these vesicles fuse with endosomes that can return some of the toxin molecules to the cell surface by exocytosis or, as shown in Figure 27.5, endosomes can fuse with lysosomes that will destroy the ricin molecules (Sandvig and Olsnes, 1979; Sandvig et al., 2004). Alternatively, the endosomes can carry ricin molecules to the Golgi complex and ER by retrograde transport (Sandvig et al., 2004) (Figure 27.6). Ricin molecules reaching the trans Golgi network can penetrate its membrane and reach the cytosol or, in some cases, return to the cell surface (Sandvig et al., 2004). For ricin molecules reaching the ER lumen, the disulfide bond connecting their A-chain and B-chain will be reduced, facilitating a partial unfolding of the A-chain (Kornfeld et al., 1991). The unraveling toxin protein will be translocated across the ER membrane via the Sec61p translocon, following the same pathway as that for incorrectly folded ER proteins targeted to the ER-associated degradation machinery (Simpson et al., 1999; Lord et al., 2003). Ricin molecules escaping the degradation machinery may find their way into the cytosol. These ricin molecules, and those crossing the trans

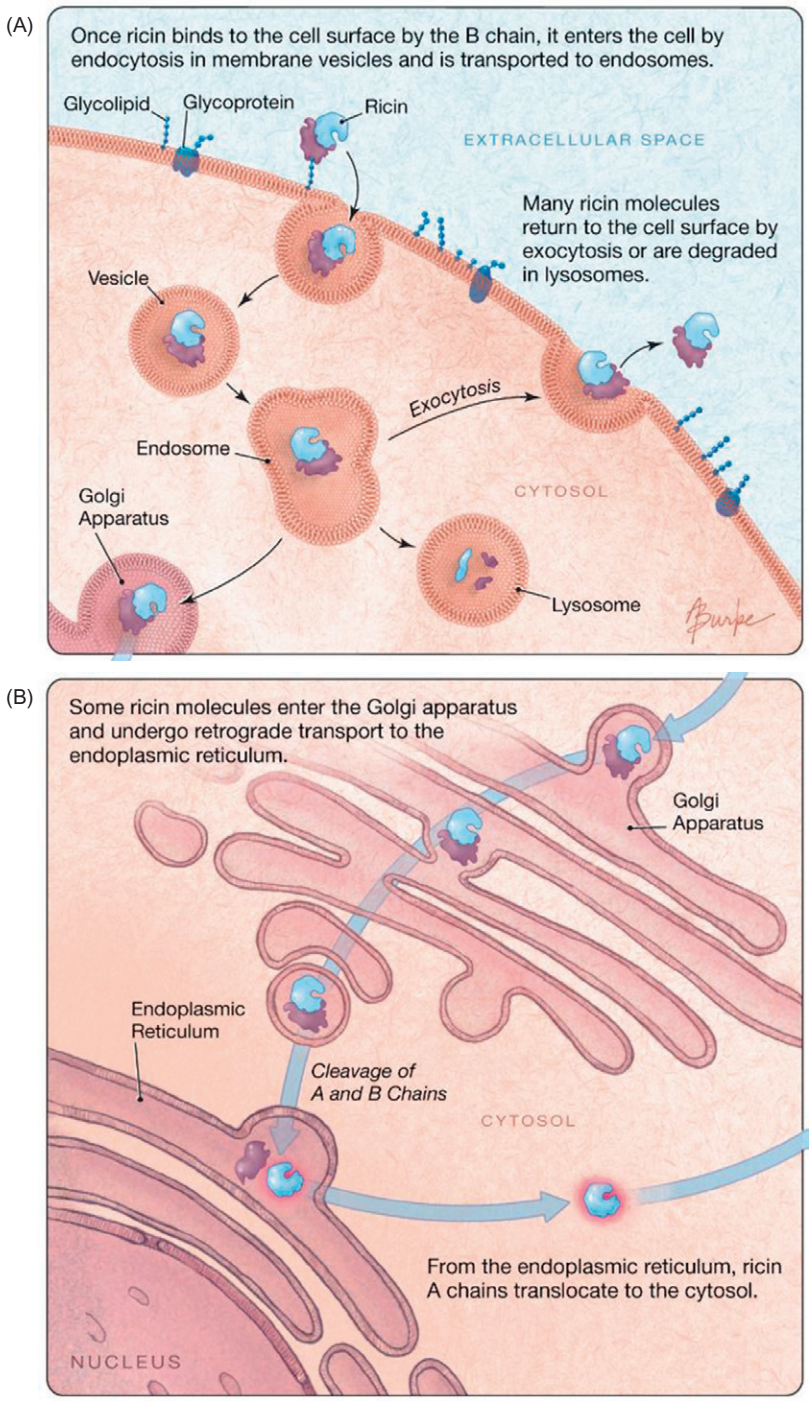

FIGURE 27.6 Example of the cellular internalization of ricin. The process involves endocytosis by coated pits and vesicles (A) or smooth pits and vesicles, followed by vesicle–endosome fusion (B). Ricin molecules can then return to the cell surface by exocytosis, or the vesicles may fuse to lysosomes for toxin destruction. *Source: Illustrations taken from Audi et al. (2005).*

Golgi network membrane into the cytosol, can refold into a protease-resistant, enzymatically active structure (Lord et al., 2003). Just a single ricin molecule entering the cytosol of a living cell with a K_{cat} of 1,500/min can inactivate enough ribosomes to ultimately result in cell death (Endo et al., 1987).

N-GLYCOSIDASE ACTIVITY OF RICIN

The ricin A-chain contains an enzymatically active site that recognizes and binds a highly conserved region in the large 28S rRNA of the intoxicated cell, referred to as the sarcin/ricin loop (Rajamohan et al.,

2001). This loop is a very short stem-loop structure of the overall ribosome and the loop is located in domain VII, approximately 400 nucleotides from the 3′-end of the rRNA. Within the stem-loop, the ring of a single adenine (A_{4324}) becomes sandwiched between two tyrosine rings in the catalytic cleft of the ricin A-chain and is hydrolyzed at the carbon–nitrogen glycosidic bond by the N-glycosidase action of ricin (Endo et al., 1987). This particular site-specific RNA N-glycosidase activity is a common property of all identified type I and type II RIPs (Barbieri et al., 2006). The activity prevents the binding of elongation factors EF-1 and EF-2, resulting in the cessation of mRNA translation.

Although all RIPs exhibit N-glycosidase activity toward ribosomes, they display marked differences in substrate specificity. Most type I toxins exhibit very broad specificities, whereas type II toxins display a preference for animal ribosomes. Ricin, for example, is highly active against mammalian and yeast ribosomes but poorly active, or even inactive, against plant and bacterial ribosomes (Yoshinari et al., 1997). In contrast, pokeweed antiviral protein depurinates ribosomes from plants, bacteria, yeast, and various evolutionally diverse animals (Rajamohan et al., 1999). Both the RIP and ribosome in a RIP–ribosome interaction contribute to the apparent substrate specificity (Kurinov et al., 1999). Because the rRNA sarcin/ricin loop structure is universally conserved, differences in sensitivity to different RIPs may possibly reside within the associated ribosomal proteins that confer tertiary structure to the ribosome (Kurinov et al., 1999). These differences may either allow or prevent access of the RIPs to the sarcin/ricin loop. Vater et al. (1995) identified the rat liver ribosomal proteins L9 and L10e as the binding target of the ricin A-chain, whereas yeast ribosomal protein L3 has been identified as the binding factor for pokeweed antiviral protein. The specific interaction between pokeweed antiviral protein and L3 is probably explained by the broad-spectrum activity of pokeweed antiviral protein toward ribosomes from species of different taxonomic groups, because L3 is highly conserved in ribosomes (Rajamohan et al., 1999). Differences in activity and ribosome substrate specificity are also due to differences in the structure of different RIPs. This was demonstrated by an approach in which pokeweed antiviral protein–ricin A-chain protein hybrids were created and examined for activity on rabbit reticulocyte and *E. coli* ribosomes (Vater et al., 1995). Experimental results demonstrated that the amino-terminal half of the hybrid proteins determine the substrate specificity. Structurally dissimilar surface polypeptide loops apparently do not play a role. In addition to the highly specific action on ribosomes, ricin and related RIPs have a less specific action *in vitro* on super-coiled double-stranded DNA (dsDNA), dsDNA, single-stranded DNA (ssDNA), and RNA substrates releasing multiple adenine residues and, in some instances, guanine residues (Wang and Tumer, 1999). RTA also catalyzes the hydrolysis of synthetic oligonucleotides as short as 6 base pairs, provided a GAGA tetra loop is present (Amukele and Schramm, 2004). Other reported RIP activities are lipase, chitinase, and superoxide dismutase (Xu et al., 2008). To date, activity against synthetic DNA or RNA oligonucleotides for the various RIPs has not been compared.

SIGNS AND SYMPTOMS OF RICIN EXPOSURE

As with most biological warfare agents, ricin remains biologically active through several different modes of entry into a living animal, including ingestion, injection, and inhalation. Symptoms and toxicity, however, can vary dramatically with mode of entry (Olsnes, 2004). Response to cutaneous contact with ricin, however, is not particularly noteworthy. An urticarial, IgE-mediated allergic reaction may occur after handling the intact castor bean plant or exposure to castor bean dust or pomace. Irritation and the development of pseudomembranous conjunctivitis after ocular exposure to very low ricin concentrations are commonly reported. In humans, general signs and symptoms of ricin exposure include fever, fatigue, weakness, muscle pain, and dehydration.

Most of what is known about the effects of ingested ricin derives from animal studies, which reflect a 100-fold variation in lethal toxicity between the various animals studied. Of all tested animals, the chicken is the least sensitive and the horse is the most sensitive. In mice, the lethal dose for 50% of an animal test group (LD_{50}) is 20 mg/kg when ingested (Ishiguro et al., 1992). Absorption occurs within 2 h with uptake by both gastrointestinal lymphatic and blood vessels, and approximately 20–45% of the ingested ricin is excreted unchanged in the feces (Ishiguro et al., 1992). The toxin accumulates mainly in the liver and spleen, with the onset of symptoms usually occurring within 4–6 h (Challoner and McCarron, 1990; Ishiguro et al., 1992). Initial symptoms are nonspecific and may include abdominal pain, vomiting, diarrhea, heartburn, and oropharyngeal pain (Klaim and Jaeger, 1990). Without treatment, fluid losses may lead to electrolyte imbalances, dehydration, hypotension, and circulatory collapse. Blood chemistry changes can lead to leukocytosis, elevated transaminases and creatinine kinase activities, hyperbilirubinemia, renal insufficiency, and anemia. Postmortem findings of diffuse intestinal hemorrhagic lesions are common (Fodstad et al., 1976; Klaim and Jaeger, 1990).

Many of the results for ricin injection derive from rodent studies. The highest concentration of ricin was found to localize to the spleen after either intravenous or intraperitoneal administration of ^{125}I-ricin, whereas

the urine was found to be the major route of elimination. The ricin LD_{50} in mice is approximately 5 μg/kg by injection (Fodstad et al., 1976). In general, for rodents, the majority of ricin excretion occurs in the urine over the course of the first 24 h (Blakey et al., 1988). The onset of nonspecific signs and symptoms, which may be similar to sepsis (fever, headache, dizziness, nausea, anorexia, hypotension, abdominal pain), occurs within 12 h after dosing. Abnormalities include elevated liver transaminases, amylase, and creatinine kinase activities, hyperbilirubinemia, myoglobinuria, and renal insufficiency, and these can progress to multisystem organ failure (Ishiguro et al., 1992; Bradberry et al., 2003). Postmortem findings are consistent in forensic case investigations as well as animal studies and include focal hemorrhage in the intestines, brain, myocardium, and pleura (Fodstad et al., 1976). The lymph nodes, kidneys, and intestines may also show signs of necrosis, hemorrhage, and edema (Flexner, 1897).

In cases of ricin inhalation, particle size can significantly influence lung deposition and lethality. Smaller particles typically deposit deeper into the respiratory tract, resulting in higher mortality. Larger particles deposit higher in the airways and can be swept up into the mouth by the mucociliary system and subsequently swallowed (Roy et al., 2003). The LD_{50} in mice exposed to ricin particles smaller than 5 μm is between 3 and 5 μg/kg (Wilhelmsen and Pitt, 1996). For monkeys, inhalation of 1- to 2-μm particles at 21–42 μg/kg results in progressive dyspnea 20–24 h after dosing (Wilhelmsen and Pitt, 1996). Postmortem findings typically include diffuse pulmonary edema with multifocal areas of necrosis and inflammation, and injury tends to be significantly worse in the distal airways and alveoli (Soler-Rodríguez et al., 1993; Griffiths et al., 1995; Wilhelmsen and Pitt, 1996; Brown and White, 1997). Toxicity results directly from the inhibition of protein synthesis, release of cytokine mediators, and direct injury to the epithelial membrane, with the primary targets of toxicity as the type I and type II pneumocytes (Soler-Rodríguez et al., 1993; Griffiths et al., 1995; Wilhelmsen and Pitt, 1996; Brown and White, 1997; Roy et al., 2003). Significant systemic absorption is usually not observed after inhalation, and toxicity is primarily limited to the respiratory tract (Soler-Rodríguez et al., 1993; Wilhelmsen and Pitt, 1996). Respiratory failure is likely to be the primary cause of morbidity and mortality in humans after ricin inhalation, and symptoms include severe lung inflammation with progressive cough, dyspnea, cyanosis, and pulmonary edema (USAMRIID, 2011).

The CDC recommends taking the following precautions when handling ricin in the laboratory (CDC, 2014):

- Avoid any activity that places persons at risk for exposure, especially activities that might create aerosols or droplet dispersal.
- Follow laboratory safety practices to prevent exposure.
- Decontaminate laboratory benches after each use and dispose of supplies and equipment in proper receptacles.
- Avoid touching mucosal surfaces with gloved or ungloved hands and never eat or drink in the laboratory.
- Remove gloves before leaving the laboratory, dispose of gloves in a biohazard container, wash hands, and remove laboratory coat.

FIELD-FORWARD BIOLOGICAL AGENT DETECTION

Immunoassays

Conventional assays used to detect biological toxins involve traditional biochemical techniques such as immunoassays based on antibodies raised against the toxin target. Immunoassays were first developed in the 1950s; 30 years later, the assays were in common use due to the development of standard reagents and automated assay readers (Ngundi et al., 2006). The immunoassay is a rapid and reliable technique for identifying a molecule that contains at least one antigenic moiety. Immunoassays rely on the inherent ability of an antibody to bind specific chemical groups on conformationally flexible antigens, such as carbohydrates, or specific molecular conformations in the case of large, conformationally rigid molecules, such as proteins. These chemical groups and conformations are referred to as antigenic determinants and epitopes, respectively. Because antibodies are produced against a specific determinant or epitope, they are highly specific and selective and, therefore, are ideal for use in the detection of biological molecules. Today, the gold standard of immunoassays for toxin detection is the enzyme-linked immunosorbent assay (ELISA) (Hammond et al., 2006; Guglielmo-Viret and Thullier, 2007; Garber and O'Brien, 2008). In its simplest terms, the ELISA is a technique used to detect the presence of an antigen in a sample by affixing the sample contents to a solid support and visualizing the immobilized antigens with specific antibodies. Performing an ELISA involves at least one antibody with specificity for the target antigen. The sample is first immobilized to a solid support such as the surface of a polystyrene microtiter plate, either nonspecifically via direct adsorption or specifically via capture by another antibody specific for the target antigen that is affixed to the solid support. After antigen immobilization, a second mixture of antibodies sometimes referred to as detector antibodies are added to the complex with target antigens. Detector antibodies can be covalently linked to an enzyme or a chromophoric

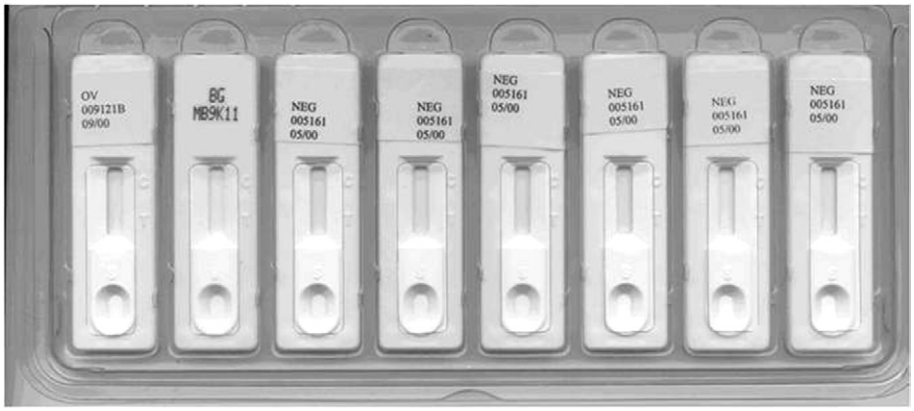

FIGURE 27.7 Photograph of an HHA packet.

reporter group, or itself can be detected by a secondary antibody linked to an enzyme or chromophoric reporter group. The labeling of the detector antibody allows for visualization of the antibody/antigen complex. Washing with a mild detergent solution typically is used between each step to remove nonspecific antibodies or other proteins. After a final wash, the assay is developed to visualize the results, either by addition of an enzymatic substrate to produce a color change or precipitate, or by irradiation of a specific wavelength of light in the case of chromophoric reporter groups. Older ELISAs typically used chromogenic substrates, whereas newer assays use fluorogenic or electrochemiluminescence-based technology to significantly enhance assay specificity.

The most recently developed technique aimed at enhancing immunoassay sensitivity is immune-polymerase chain reaction (I-PCR). The technique is markedly more sensitive than ELISA, primarily because it combines the detection specificity of an antibody with the amplification power of real-time PCR for a nucleic acid. The technique was first described by Sano et al. (1992). Realized limits of detection have surpassed ELISA by 10-fold to 10,000-fold. Typically, lateral flow immunochromatographic assays are used in field-forward situations due to lenient storage and equipment requirements (Pastoor et al., 2008). The problem with PCR-based assays is that they do not detect toxin protein, but they do detect co-purifying DNA, which is not always present. Cell-based bioassays are sometimes used to confirm intact toxin-killing activity of the ricin in environmental samples (Brzezinski and Craft, 2007). Field-forward analysis for biothreat agents is limited to antibody-based tests and PCR. The most commonly used tests are the ELISA and immunochromatographic tests typically referred to as hand-held assays (HHAs), as shown in Figure 27.7.

The ricin toxin has been detected in tissue sections, some tissue specimens, nasal swabs, and fluids by using immunologically based methods to study animals and animal tissues (DOD, 1999; Brzezinski and Craft, 2007). Immunologically based methods applied to human and animal fluid specimens have the potential to measure ricin concentrations as low as 0.1 ng/mL (1.54 pmol/L) (Shyu et al., 2002a,b). However, such applications have not been clinically validated, and concentrations after toxic exposures are unknown. Reference laboratories such as the US Army Medical Research Institute of Infectious Diseases (Aberdeen Proving Ground, MD) and the CDC are currently adapting these and other analytic methods for application to human specimens. At the Edgewood Chemical Biological Center (ECBC, Aberdeen Proving Ground, MD), matrix-assisted laser desorption-ionization mass spectrometry (MALDI-MS) is used as a definitive method for identification in biological specimens, but this technique is not currently able to provide quantitative results. Technologies used for assessing enzymatic activity are the cell-free luciferase-based assay, the cell-based apoptosis assay, and a recently developed liquid chromatography tandem mass spectrometry (LC-MS) technique (Zamboni et al., 1989). Another technique that has been described measures the liberation of radio-labeled adenosine from RIP substrates resulting from their enzymatic activity. This technique has similar sensitivity to the LC-MS method with a range of 0.01–10 pmol, but it involves the hazards of radio-labeled nucleotides and is not readily transferable to field-forward use (Brigotti et al., 1998).

DNA-Based Assays: The PCR

The PCR is a technique for logarithmically amplifying a DNA sequence to the extent that a sufficient quantity of material may be available to detect through either fluorescence or gel electrophoresis. The technique was developed in 1993 by Kary Mullis, who was awarded the Noble Prize in Chemistry that year for his pioneering work (Bartlett and Stirling, 2003). Because of its simplicity, PCR is a highly popular technique with a

wide range of applications, including direct nucleic acid sequencing, genomic cloning, DNA typing, the detection of infectious organisms, site-directed mutagenesis, parental genetic disease research, and the analysis of allelic sequence variations (Sambrook and Russell, 2001). Typically, when PCR is used as an identification technique, the target sequence to be amplified is a sequence of DNA known to be specific to one particular organism; this is referred to as template DNA. The complementary strands of the double-stranded template are separated at 95°C, and the temperature is lowered slightly to allow two 10- to 30-base pair (bp) ssDNA primers to anneal to their complementary strands of the template. DNA polymerase binds the primer–template hybrid and initiates synthesis of DNA complementary to the template from the primer in a 5′–3′ direction. This cycle of heating to denature the double-stranded template DNA, followed by annealing and extension of the primers by DNA polymerase, is typically repeated approximately 30 times to yield literally billions of copies of the original template (Antwerpen et al., 2008).

In the original PCR process described by Mullis, *E. coli* DNA polymerase was used for DNA synthesis. The challenge presented by using the enzyme was that the 95°C melting step destroyed its polymerase activity, and the enzyme had to be replenished after the heating stage cycle. As a result, the original Mullis PCR process was very laborious and required vast amounts of DNA polymerase. The problem was resolved in 1986 by utilizing DNA polymerase from *Thermophilus aquaticus* bacterium that was discovered in Colorado hot springs. The bacterium was well-adapted to the extremely high water temperatures of the springs, and its DNA polymerase was found to endure the high temperatures required for PCR (Munster et al., 1986). Gelfand et al. successfully purified and cloned this DNA polymerase, now commonly referred to as Taq polymerase. The enzyme allows a series of 30–40 cycles of PCR amplification without the need of replenishing the polymerase and also reduces the associated potential for introducing contamination into the PCR assay. Moreover, because of its thermophilic origins, Taq polymerase functions optimally at approximately 72°C, allowing DNA synthesis to be performed at much higher temperatures than was possible with the *E. coli* enzyme. Because of the higher stringency of PCR primer annealing at the higher temperatures, the DNA template is copied with much higher fidelity, and the nonspecific products that had affected many previous PCR reactions are reduced (Saiki et al., 1988). One of the major disadvantages of Taq polymerase, however, is its low replication fidelity. Taq polymerase does not have a 3′–5′ exonuclease proofreading mechanism to replace base-pairing mismatches in the newly synthesized DNA strand; however, it does have a 5′–3′ exonuclease activity that allows real-time PCR (Luthra et al., 1998). The intensity of fluorescence emitted during the PCR reaction is monitored in real-time PCR, acting as an indicator of the degree of PCR amplification occurring during each PCR cycle. Thus, with newer real-time PCR instruments, reaction progress can be observed visually in real time.

The CDC and Department of Homeland Security Laboratory Response Network centers conduct polymerase chain reaction tests and time-resolved immunofluorescence assays to detect the ricin toxin in environmental specimens. Immunofluorescence is the immunoassay technique that uses a detector antibody or an antigen labeled with florescent dyes (Lim et al., 2005). Time-resolved florescence simply delays the time between excitation of the florescent dyes and quantifying resulting emission. The long-lived emissions of the florescent dyes are exploited to reject background signals such as sample autofluorescence as well as Rayleigh and Raman scatter (Marriott et al., 1991). Detection of the delayed emission leads to an increase in the signal-to-noise ratio of the dye, thereby lowering the detection limit of the assay. Time-resolved fluorescence also enhances separation of emission spectra from multiple dyes, thus improving assays that are multiplexed (Yan and Marriott, 2003).

Because PCR-based assays cannot directly detect the toxin protein, cell-based bioassays are sometimes used to confirm the intact toxin-killing activity of ricin in environmental samples (Brzezinski and Craft, 2007).

Many of these technologies have the potential to quickly and conveniently determine whether an unknown sample possesses ricin activity and could greatly aid in triage of victims after suspected exposure of ricin. Furthermore, it would enable determination of the effective decontamination for a site. Technology of this nature may also greatly aid in an initial forensic investigation by immediately determining potency, and field-forward personnel could estimate the purity, grade, and the age of the weapon. Finally, a rapid screening assay for RIP activity would also prove beneficial for the pharmaceutical industry as a screening tool for genetically engineered ricin developed for cancer chemotherapeutics, and for basic researchers attempting to identify and characterize new and novel RIPs.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The assays for ricin described in this chapter are based on either ELISA detection of the toxin or DNA-based detection. Largely ignored is the fact that the lectin portion (B-chain) of the intact toxin could also serve as an analytical target. Carbohydrate-binding lectins bind to carbohydrate ligands with weak binding affinities, ranging in molar to sub-millimolar concentrations, even when

preserving high specificities of the interaction. Lectins have the ability to distinguish a wide range of carbohydrate structures on the surface of cells. Their importance in cell recognition as related to mitogenesis, agglutination, and direction of cell cytotoxicity has been established (Sharon and Lis, 1989). This specificity has been exploited to differentiate various cancer cells (Welty et al., 2006). Our understanding of the adsorption and distribution of the ricin toxin within the target organism could be greatly enhanced through the use of such techniques.

CHAPTER

28

Botulinum Toxin*

Jaime Anderson and Corey J. Hilmas

INTRODUCTION

Botulism is a disease caused by anaerobic, spore-forming bacteria found in soil. Disease results from the actions of chemical toxins produced by these bacteria. The most common forms of human botulism include foodborne, infant, and wound. The main etiology of botulism in humans is foodborne; this form is caused by eating foods contaminated with botulinum spores, which germinate and multiply into bacteria to produce neurotoxins in the food. Commonly contaminated foods include improperly preserved home-processed foods such as honey, corn, green beans, and beets. Less frequent sources are fish products and commercially processed foods. Infant botulism is often associated with eating honey contaminated with spores, but new evidence suggests that soil and dust brought into the house from the outside may be a significant source of botulinum spores. Wound botulism occurs when spores contaminate a wound, germinate, and produce toxins that are absorbed into the bloodstream. Regardless of the form of botulism, disease results from the intoxicating effects of potent neurotoxins.

Botulinum neurotoxins (BoNTs) comprise a family of seven distinct neurotoxic proteins produced by immunologically discrete strains of the anaerobic bacteria. These spore-forming, Gram-positive bacteria secrete deadly toxins with an estimated human LD_{50} of 1–3 ng/kg (Simpson, 2004; Sobel et al., 2004). In fact, BoNTs are the most potent substances known to humankind. Due to their extremely high potency, ease of production, and previous history of weaponization, the BoNTs have been designated as category A threat agents by the US Centers for Disease Control and Prevention (CDC). Category A agents are defined by the CDC as those that "result in high mortality rates and have the potential for major public health impact; might cause public panic and social disruption and require special action for public health preparedness."

While there are currently seven known antigenic serotypes of BoNT, only serotypes A, B, and E are predominantly associated with human intoxication. Intoxication by BoNTs leads to bilateral flaccid paralysis, involving skeletal muscle and structures innervated by autonomic fibers (Simpson, 1986; Shapiro et al., 1998). Death is inevitable if the intoxication is left untreated. The toxicity of BoNTs leading to flaccid paralysis of skeletal muscle is due to their ability to block acetylcholine (ACh) release from peripheral cholinergic nerve endings. Paralysis could persist for weeks to months (depending on the serotype), and the available treatment consists of supportive care including fluids, total parenteral nutrition (TPN), and mechanical ventilation. Death occurs when the diaphragm and intercostal muscles become sufficiently compromised to impair ventilation or when patients succumb to secondary infections following long periods of intensive care (Hatheway et al., 1984; Shapiro et al., 1998).

BoNTs pose a serious concern to our national security. The toxins are highly lethal, easy to isolate, and easy to deliver by terrorists. Activities of hostile nations, international terrorists, and antigovernment groups make the threat of BoNTs a serious problem for both our military and civilian populations. Development of BoNTs as weapons of mass destruction began over 50 years ago. Nonstate-sponsored terrorists have an interest in BoNTs; members from the Aum Shinrikyo cult attempted to disperse BoNT in Tokyo and at US military installations throughout Japan on at least three occasions in the 1990s (Brackett, 1996). Furthermore, in the years following Operation Desert Storm in the first Gulf War (1990–1991), it was discovered that Iraq produced thousands of liters of concentrated BoNT in their weapons program.

* Opinions, interpretations, conclusions, and recommendations are those of the authors and are not necessarily endorsed by the US Army or the US Food and Drug Administration.

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00028-2

Moreover, approximately half that volume was already loaded into military weapons. The BoNT generated by Iraq has yet to be fully accounted for. An act by terrorists to release BoNT into a civilian population through contamination of products of consumption or inhalation would pose a serious threat to national security and public safety. Wein and Liu (2005) modeled the threat of deliberate BoNT release into a milk-processing facility. The actions by such a terrorist group could lead to massive casualties. Another study estimated that dispersal of BoNT via inhalation could kill 10% of an exposed population within 0.5 km downwind of the incident.

BACKGROUND

Toxin Structure and Molecular Function

Background

The highly potent neurotoxins synthesized by the *Clostridium botulinum* microorganism and several related clostridial species (*C. baratii*, *C. butyricum*, and *C. argentinense*) are the causative agents of botulism, a potentially lethal disease historically associated with the ingestion of contaminated food products. Seven different BoNTs, designated A through G, are currently known to be produced by various strains of clostridial bacteria; these neurotoxins are antigenically distinct but comparable in basic structure. The BoNTs are members of a superfamily of homologous proteins that also include tetanus neurotoxin. BoNTs are generated as single-chain polypeptides that are then posttranslationally modified (i.e., proteolytically nicked) to yield a disulfide bond-linked dichain structure composed of a heavy chain (H-chain or HC) and a light chain (L-chain or LC). Enzymes synthesized by these microorganisms themselves often mediate this cleavage, although the gastrointestinal enzymes of the host can also generate the dichain structure from the ingested toxin. The three-dimensional dichain protein structure of the purified toxin is provided (Figure 28.1).

Function of Heavy and Light Chains

The HC and LC of BoNTs each play critical roles in toxicity. HC is thought to mediate binding and internalization of the toxin at peripheral nerve synapses. LC, the toxic moiety, inhibits neurotransmitter exocytosis

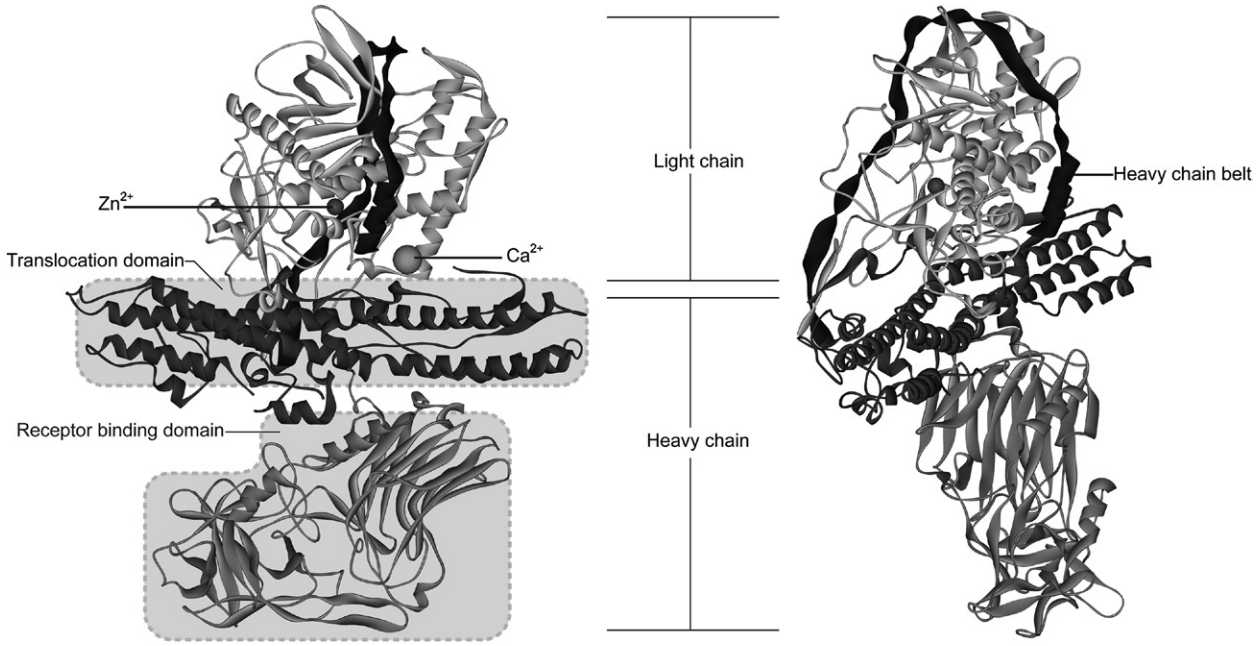

FIGURE 28.1 Three-dimensional structure of botulinum toxin serotype A (BoNT/A). BoNT/A (1296 amino acids), rendered as a ribbon structure, is depicted in two views. BoNTs are synthesized as a single polypeptide and nicked by bacterial proteases to form a dichain molecule. The 50-kDa LC, with 448 residues, and the 100-kDa HC, with 848 residues, are linked by a dilsulfide bond. All BoNTs comprise three major domains: a receptor-binding domain (C-terminal end of HC), a translocation domain (N-terminal end of HC), and a zinc-binding metalloprotease domain on LC. All seven BoNTs exhibit conserved sequences, but they are also antigenically distinct at the same time. The LC seems to be held in place by the translocation belt of HC (Brunger et al., 2007). The belt spans residues 492–545 in BoNT/A and 481–532 for BoNT/B and wraps around the catalytic domain of the LC. Brunger et al. (2007) suggest that the belt acts as a surrogate pseudosubstrate inhibitor of the LC protease and acts as a chaperone during translocation across the endosome membrane into the cytosol. The belt occludes access to the active site of LC, thereby holding the unreduced holotoxin in its catalytically inactive state. The sphere represents the bound Zn^{2+} at the LC active site. The structure of BoNT/A holotoxin was provided free of copyright restrictions from the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank (PDB) (Berman et al., 2000; PDB ID: 2nz9; Garcia-Rodriguez et al., 2007) and rendered using Accelrys DS Visualizer 2.0 software.

through its zinc-dependent endoproteolytic activity. The LCs of the various BoNT serotypes differ in their distinct molecular targets within the peripheral cholinergic nerve terminals (Schiavo et al., 1992, 1993a,b; Blasi et al., 1993). The endoproteolytic activities of the different toxin LCs produce similar flaccid paralytic effects, despite their distinct targets.

BoNT serotype A is the most well characterized of the different serotypes in terms of both structure and function. Early biochemical efforts led to its crystallization, and this crystalline form was used in numerous animal studies on the pathogenesis of botulism. Crystalline type A toxin has a sedimentation constant of 19S (around 900 kDa), which is far larger than the combined size of the HC and LC components (Simpson, 1981). This large progenitor toxin form was shown to dissociate under moderately alkaline conditions, releasing the derivative (7S) or neurotoxin component (Heckly et al., 1960; Sugii et al., 1977a,b; Chen et al., 1998). The derivative neurotoxin has a molecular weight of 150–160 kDa, representing the combined size of the H- and L-chains. Additional work led to the finding that the dichain molecules comprising the various neurotoxins are often released as higher-order polypeptide complexes. The crystalline type A progenitor toxin consists of the 7S neurotoxin and one or more non-covalently linked accessory proteins. These nontoxic components of the progenitor toxin complex were later identified as three different hemagglutinins (HAs) and a nontoxic nonhemagglutinin (NTNH) protein.

Accessory Proteins of the Progenitor Toxin Complex

The accessory proteins of the progenitor toxin serve to enhance the stability of the toxin to ensure uptake from the gut. The NTNH component of the multimeric type A toxin complex is encoded by a single gene upstream of the neurotoxin locus, while three different HA proteins have been characterized in association with BoNTs. All *C. botulinum* serotypes have been shown to produce neurotoxin complexes with the NTNH and HA proteins.

Overview of BoNT Action

After gaining entry to the lymphatics and circulation via the gastrointestinal tract, BoNTs function as potent neuromuscular blockers. The cellular and molecular mechanisms involved in toxin absorption, transit to specific target tissues, escape from the vasculature, and uptake within peripheral cholinergic nerve terminals have yet to be fully characterized. However, each of the neurotoxins has been shown to block vesicular neurotransmitter release at peripheral cholinergic synapses through the endoproteolytic cleavage of proteins associated with the exocytosis machinery (Schiavo et al., 1993a,b, 1995,; Blasi et al., 1993). At peripheral cholinergic nerve endings, BoNT binding to high-affinity receptors leads to acceptor-mediated endocytosis and low pH-induced translocation across the endosomal membrane into the cytosol. The carboxy-terminal region of the toxin HC appears to mediate binding at the nerve synapse, while the amino-terminal domain controls translocation. The LC is held in close association with the HC by an amino acid belt. The LC of each toxin functions as a zinc-dependent endoprotease, cleaving at least one of three soluble *N*-ethylmaleimide-sensitive fusion (NSF) protein attachment receptor (SNARE) proteins involved in neurotransmitter release.

Stimulus-evoked, calcium-dependent release of ACh from the cholinergic synapse normally occurs through the formation of a fusion complex between ACh-containing vesicles and the intracellular leaflet of the nerve terminal membrane (Arnon et al., 2001). This synaptic vesicle (SV) fusion complex consists of several proteins of the SNARE family, including a 25-kDa synaptosomal associated protein (SNAP-25), vesicle-associated membrane protein (VAMP, or synaptobrevin), and the synaptic membrane protein syntaxin. Other SNARE proteins have been identified as components of membrane transport systems in yeast and mammals but have not been implicated as targets for BoNTs. Meanwhile, type A and E neurotoxins cleave SNAP-25, while types B, D, F, and G act on VAMP and type C1 toxin cleaves both syntaxin and SNAP-25. Neurotoxin-mediated cleavage of any of these substrates disrupts the processes involved in the exocytotic release of ACh and leads to flaccid paralysis of the affected skeletal muscles.

Clinical Forms of Botulism in Humans and Animals

Exposure to BoNTs can produce lethal disease in humans and other animal species. Six different clinical forms of human botulism have been described in the literature (see Table 28.1), including (i) foodborne botulism, (ii) infant botulism, (iii) wound botulism, (iv) an adult form of infant botulism, (v) inadvertent systemic botulism, and (vi) inhalation botulism (reviewed by Cherington, 1998; Middlebrook and Franz, 2000; Arnon et al., 2001). Botulism is the result of either an infectious process involving elaboration of toxin from the colonizing clostridial organism, or a noninfectious process. Infant and wound botulism are the most prevalent infectious forms of botulism. Although rare, an adult form of infant botulism has been documented; gastrointestinal colonization in adults may be enabled by alterations in normal gastrointestinal flora resulting from antibiotic treatment (Cherington, 1998). Foodborne and inhalational have noninfectious etiologies and are the result of ingesting or inhaling preformed toxin. Although only one inhalational botulism incident has been reported

TABLE 28.1 Clinical Forms of Botulism

	Infectious			Noninfectious		
	Infant	**Wound**	**Adult Colonization**	**Foodborne**	**Inhalational**	**Inadvertent Systemic**
Cause	Colonization of immature intestinal tract	Wound colonization resulting from contact with contaminated material	Intestinal colonization secondary to disruption of normal intestinal flora	Ingestion of preformed toxin in contaminated food products	Respiratory exposure to toxin aerosols or droplets	Systemic toxin uptake after therapeutic toxin administration
Susceptibility	Young infants (2–4 months of age) prior to establishment of normal intestinal flora	Self-administering users of IV drugs (often black tar heroin)	Antibiotic-treated patients	All exposed individuals	All exposed individuals	Patients treated with local toxin injections

in humans, this incident demonstrates that humans are susceptible to respiratory intoxication similar to that which has been experimentally produced in many laboratory species (reviewed by Middlebrook and Franz, 2000). Finally, the emergence of a multitude of therapeutic applications for BoNTs has led to infrequent cases of inadvertent systemic botulism resulting from local toxin injection (reviewed by Arnon et al., 2001).

Infectious Forms of Botulism

Infant Botulism

Infectious botulism is a consequence of ingesting or inhaling clostridial spores that colonize the large intestines, germinate, and elaborate toxin into the bloodstream. Infant and wound botulism are the most prevalent infectious forms of botulism. Infant botulism comprises the majority (72%) of reported human botulism cases in the United States, while most of the remaining cases involve foodborne and wound botulism (Mackle et al., 2001). Infants are especially susceptible to infant botulism. Infants were found to be uniquely susceptible to gastrointestinal colonization due to a lack of well-established competing gut flora (Arnon, 1995). While infant botulism can be acquired by inhaling spores, this differs markedly from inhalational botulism, which results from inhaling preformed aerosolized toxin and not spores. Clostridial spores do not pose a threat in older infants or most adults (Arnon, 1995, 1998; Cox and Hinkle, 2002).

Wound Botulism

Wound botulism involves growth of *C. botulinum* spores in a contaminated wound with *in vivo* toxin production (Weber et al., 1993). It accounts for less than 25% of all botulism cases. The majority of wound botulism cases are caused by serotype A and the remainder by serotype B (Shapiro et al., 1998). The neurological symptoms of wound botulism differ little from those of foodborne botulism except for the general absence of gastrointestinal symptoms. From its discovery in 1943 until 1996, only 111 incidents of wound botulism were documented (Merson and Dowell, 1973; CDC, 1998; Shapiro et al., 1998); among the 100 laboratory confirmed cases, 83 cases were type A, 16 cases type B, and one a mixture of type A- and B-producing organisms (CDC, 1998). Risk factors for wound botulism include deep wounds, avascular areas, compound fractures, and crush injuries of the hand. Although a rare form of naturally occurring BoNT intoxication, it most recently occurred in Maryland as a result of a construction worker receiving a contaminated, compound fracture of the femur after falling into an excavated pit (Hilmas, personal observation). Wound botulism also occurs in intravenous (IV) drug users as a result of bacterial colonization at needle puncture sites or nasal/sinus lesions secondary to cocaine snorting (MacDonald et al., 1985). From 1986 through 1996, 78 cases of wound botulism were reported, and the majority of cases were linked to black tar heroin, introduced intravenously.

Child or Adult Botulism from Intestinal Colonization

Gastrointestinal colonization in adults or children by *Clostridia* bacteria does not typically take place except in circumstances where the normal flora has been altered by antibiotic treatment (Cherington, 1998). Botulism results from *in vivo* production of toxin, analogous to the pathogenesis of infant botulism (Chia et al., 1986). Support for this form of botulism is provided by the demonstration of prolonged excretion of toxin and *C. botulinum* in stool, by the demonstration of *C. botulinum* spores but not preformed toxin in suspected foods, or both.

Noninfectious Forms of Botulism

Foodborne Botulism

Worldwide, BoNT intoxication is most commonly associated with food poisoning. In the early nineteenth century, the effects of botulism were observed

to be associated with the consumption and handling of meat products. Thus, German physician Justinus Kerner described what he termed "sausage poisoning" (Erbguth, 2004). It was later in the nineteenth century that the term *botulism* was used, from the Latin *botulus*, meaning "sausage." Foodborne botulism results from ingesting preformed toxin in food contaminated with toxin spores. Inadvertent and inhalational botulism, two other noninfectious forms of botulism, also involve exposure to preformed toxin. Outbreaks of foodborne botulism in the United States result from eating improperly preserved home-canned foods (CDC, 1995). The majority of cases of foodborne botulism are due to serotypes A, B, and E. From 1990 through 1996, type A accounted for 44.6% of foodborne outbreaks in the United States, followed by type E (35.7%) and type B (12.5%) (CDC, 1998). The prompt recognition of such outbreaks in the United States and early treatment with serotype-specific botulinum antitoxin has limited the number of casualties, severity of the disease, and the case-to-fatality ratio. Mortality from foodborne botulism has declined from 60% (CDC, 1998) in 1950 to less than 10% of clinical cases (Shapiro et al., 1998).

Inhalational

Because humans are relatively resistant to gut colonization by the *C. botulinum* microorganism, oral and inhalational exposures to preformed neurotoxin are likely to present the greatest threats with respect to intentional dissemination. The ability for inhaled BoNTs to produce illness has been documented in humans and in several experimental species. Only one incident involving inhalational intoxication in humans has been reported. Three laboratory workers presented with physical and neurological symptoms after accidental respiratory exposure to aerosolized type A toxin (Middlebrook and Franz, 2000; Arnon et al., 2001). These patients were all successfully treated with antiserum, gradually recovering from their weakness and visual disturbances over the next several days. After inhalational exposure, the neurotoxins are absorbed from the respiratory tract into the lymphatics and circulation for transport to peripheral cholinergic synapses (reviewed by Simpson, 2004). The pathogenesis following neurotoxin absorption is thought to be similar for both the respiratory and gastrointestinal exposure routes. Thus, the primary neurophysiological signs and symptoms associated with respiratory exposure parallel those observed in cases of foodborne botulism.

Inadvertent Systemic Botulism

The therapeutic indications for BoNTs are numerous. They are used in the treatment of ophthalmological disorders (strabismus, Duane's syndrome, esotropia/exotropia), movement disorders (focal dystonias, blepharospasm), spasticity, neuromuscular disorders, pain (headache, myofacial pain), disorders of the pelvic floor (anal fissures), ear/nose/throat disorders, cosmetic applications (wrinkles), and hyperhidrosis. The recent explosion in new indications for BoNTs in the treatment of a wide range of medical conditions also brings the possibility of medical errors in BoNT dosing. Systemic botulism may result from injection of excessive doses of the potent neurotoxin. The most infamous case of systemic botulism involved the paralysis of four Florida patients, including a doctor, who were treated with BoNTs for wrinkles. The physician used formulations of type A from Toxin Research International, Inc., which were approved by the US Food and Drug Administration (FDA). The research grade type A neurotoxin was apparently sold to the doctor and reconstituted to be thousands of times more potent than the typical dose used in BOTOX® for paralyzing facial muscles. Later testing estimated that the raw bulk toxin that was used contained between 20,000 and 10 million units of botulinum toxin. In comparison, a typical vial of BOTOX from Allergan, Inc. contains only 100 units (CIDRAP, 2004). All three patients and the physician were injected with the toxin preparation; they developed severe systemic botulism requiring mechanical ventilation. While all four survived the superlethal dose of type A toxin, several of the patients experienced a syndrome involving chronic gastrointestinal symptoms and discomfort months after exposure.

Human Intoxication

The basic syndrome of BoNT intoxication is similar for all naturally occurring forms, as well as for inhalation exposure, and does not vary appreciably among serotypes (Hatheway et al., 1984; Simpson, 1986; Jankovic and Brin, 1997). Based upon documented laboratory evidence, human BoNT intoxication is caused by exposure primarily to serotypes A, B, E, and (to a much lesser extent) to serotype F; disease manifests mostly as a result of foodborne, infant, and wound botulism (Simpson, 1986). BoNTs are also lethal when inhaled in aerosolized form, although this is not generally observed in nature.

The various toxin serotypes are usually associated with analogous clinical presentations. Paralysis proceeds in a descending fashion after an initial bulbar involvement. The earliest symptoms of botulism typically include visual disturbances, followed by dysphagia, dysphonia, and dysarthria, reflecting an especially high susceptibility of cranial efferent terminals to BoNT action (Jankovic and Brin, 1997). A descending generalized skeletal muscle weakness may then develop, progressing from the upper to the lower extremities. Involvement of the diaphragm and intercostal muscles can lead to ventilatory failure and death unless appropriate supportive care is provided (Shapiro et al., 1998).

EPIDEMIOLOGY

Foodborne Botulism

Human foodborne botulism outbreaks have typically been linked to the consumption of toxin-contaminated home-prepared or home-preserved foods (Maselli, 1998). The vast majority of foodborne botulism cases are attributed to toxin types A, B, or E. Maselli (1998) reports that type B is the most prevalent (52%) in the United States, followed by type A (34%) and type E (12%), while the CDC (1998) suggests 37.6% of all foodborne botulism outbreaks since 1950 were caused by type A, 13.7% by type B, 15.1% by type E, 0.7% by type F, and 32.9% were unidentified with respect to toxin type. Outbreaks of type F and G botulism are rare (Sonnabend et al., 1981; Maselli, 1998; Richardson et al., 2004), and only anecdotal reports of isolated type C1 and D botulism cases can be found in the published literature (e.g., Lamanna, 1959).

The natural epidemiology of foodborne botulism provides additional insight into the similarities and discrepancies between the human disease and that represented in various animal models. In the United States, around 25% of reported human botulism cases are classified as foodborne and 72% are infant (Mackle et al., 2001). Human type A and B foodborne botulism cases occur worldwide and constitute the vast majority of reported human intoxications (Maselli, 1998). The majority of other botulism cases are attributed to serotype E and are typically associated with the consumption of contaminated seafood. Generalizations have been made regarding the geographic distribution of the most common *C. botulinum* strains within the United States. Most human foodborne botulism outbreaks occurring west of the Mississippi are due to type A toxin; type B strains are more prevalent east of the Mississippi, while type E strains are typically isolated to Alaska and the Pacific Northwest (Arnon et al., 2001; Richardson et al., 2004).

Several clinical and epidemiological reports have evaluated the worldwide geographic distributions of human foodborne botulism cases. A review of 13 outbreaks between 1970 and 1984 identified geographic differences in the toxin serotypes associated with human foodborne botulism cases. Type B botulism was predominant in Portugal, Spain, France, and several other European countries (Lecour et al., 1988). Interestingly, the low mortality rate associated with human type B foodborne botulism (8.8%, versus 24.3% for type A and 30.8% for type E in the United States from 1950 to 1979) did not correlate with the high oral toxicity for type B toxin in mice (Ohishi et al., 1977; Sugii et al., 1977a–c). Serotype E was linked to botulism outbreaks in select regions such as the Baltic countries (Lecour et al., 1988) and typically resulted from the consumption of contaminated fish (Maselli, 1998).

Type F toxin was associated with only two reported outbreaks of human foodborne botulism prior to 1998 (Maselli, 1998). The first of these outbreaks occurred in Denmark (on the island of Langeland) and was attributed to a contaminated liver paste product (Richardson et al., 2004). The second outbreak, in 1966, affected three individuals in California and was associated with homemade venison jerky (Richardson et al., 2004). While a few other type F botulism cases have been reported, they are generally thought to have resulted from intestinal colonization and type F toxin production by another related species, *C. baratii* (Richardson et al., 2004). A recent report of a type F botulism case in California provided some additional insight into this uncommon toxin serotype and the associated clinical disease (Richardson et al., 2004). The patient described in this report presented with typical signs and symptoms, including ptosis, dysphagia, and weak extremities. Although the source of the ingested toxin was not conclusively determined, the exposure was tentatively linked to shellfish consumption, and type F toxin was subsequently detected in the patient's stool (Richardson et al., 2004). Human type F botulism cases may have been underreported in the past since some laboratories did not test culture isolates for the presence of *C. baratii*, which also produces type F toxin.

Type G toxin-producing clostridial organisms (*C. argentinense*) have been detected in several soil samples from a South American cornfield (Maselli, 1998), but only one reported outbreak of type G botulism (in Switzerland) has been identified in the published literature (Sonnabend et al., 1981). Certain aspects of this outbreak draw questions as to whether it was truly associated with type G intoxication. Type G organisms were isolated from all four affected adults and an 18-week-old infant, suggesting that the intoxications were due to ingestion and subsequent colonization by type G spores (Sonnabend et al., 1981). Type G toxin was detected at low levels of 2–7 mouse intraperitoneal lethal dose 50 ($MIPLD_{50}$)/mL in the serum of three out of the four lethally intoxicated adults, all of whom died suddenly sometime after the presumed foodborne intoxication. Type A toxin was also detected in two of these individuals, suggesting that the intoxications may have involved colonization either by a mixed set of clostridia or by a unique strain producing multiple toxins (Sonnabend et al., 1981). Alternatively, detection of dual serotypes could have been an artifact of the culture or testing methods. Soil samples taken from the area indicated the presence of only type A clostridial organisms (Sonnabend et al., 1981). Regardless, the occurrence of human type G botulism is rare, and the relative susceptibility of humans to colonization and intoxication from this serotype is not clear.

Species-specific patterns of susceptibility to different toxin types are common in both naturally occurring and

experimental foodborne botulism. These differences do not necessarily facilitate identification of the most appropriate animal models from the human condition, but they may help to eliminate highly variant species. For example, mink were reported to be relatively resistant to toxin types A, B, and E (Yndestad and Loftsgard, 1970), which are responsible for the vast majority of human botulism outbreaks (Maselli, 1998; Arnon et al., 2001). Weanling pigs, on the other hand, were shown to be moderately resistant to types A, C1, E, and F and highly resistant to type D toxin (Smith et al., 1971). Experimental and epidemiological studies have identified one persistent difference in the epidemiology of botulism in humans compared to many other animal species. Few reports citing human outbreaks of type C and D are available. One of these reports mentions two type C outbreaks and one type D outbreak in humans but provides no source for these cases (Lamanna, 1959). More recent reports of human type C or D botulism have not been found in the literature, and it is widely assumed that human foodborne intoxications are rarely, if ever, associated with these toxin types. In contrast, naturally occurring botulism of both types is quite common among domestic and wild animal species, and several studies have established the susceptibility of various laboratory species to experimental type C and D botulism.

The authors of this chapter have studied the effect of C and D toxin serotypes, as well as A, B, and E, on human intercostal muscle (Hilmas, unpublished data). All serotypes showed a similar ability to produce complete muscular paralysis in *ex vivo* human intercostal muscle. Intercostal muscle was excised from patients receiving a thoracotomy and intercostal muscle flap procedure. The muscle was removed tendon to tendon by surgical excision without electrocautery and dissected into multiple bundles with their associated intercostal nerves. The nerve–muscle units were placed in a vertical twitch bath and stimulated at 0.03 Hz (0.2-ms pulses of supramaximal strength) using a novel nerve clamp electrode to illicit an indirect muscle twitch. Potent toxins (1 nM) from various serotypes were added to the bath after confirming the stability of control muscle responses. In each case, twitch tensions declined to negligible amplitudes by 1 h after direct toxin application to the tissue bath.

Several nonhuman primate species are known to be susceptible to type C1 and D toxins both in nature and as experimental models. A large natural outbreak of type C botulism was reported in a troop of captive *hamadryas* baboons in 1989 (Lewis et al., 1990). The outbreak resulted in the deaths of 36 animals, including 3 adult males, 6 subadult males, 17 adult females, and 10 subadult females. Additional animals displayed mild to moderate symptoms that resolved themselves over a period of several days (Lewis et al., 1990). As with human foodborne botulism, various age groups and both sexes were affected, and no macroscopic lesions were apparent. Serum samples and gastric contents taken from ill animals contained type C1 toxin, although the source of the toxin was not identified (Lewis et al., 1990). The authors speculated that humans are probably also susceptible to type C1 toxin. The reason for the relative lack of human type C botulism cases remains unknown. It has been suggested that serotype C is often associated with carrion, providing a possible explanation for the absence of reported human cases. At least two other outbreaks of naturally occurring type C botulism in nonhuman primates were previously reported, one in squirrel monkeys (*Saimiri sciureus*) and capuchin monkeys (*Cebus capucinus* and *Cebus olivaceus*) (Smart et al., 1980) and the other in gibbons (*Hylobates lar*) (Smith et al., 1985).

In addition to nonhuman primates, most other animal species that show some sensitivity to botulinum intoxication are in fact susceptible to toxin serotypes C1 and D. Several rodent species are susceptible to oral intoxication with most botulinum toxins, including types C1 and D (Jemski, 1961a,b; Cardella et al., 1963; Sergeyeva, 1966; Sugiyama et al., 1974; Smith, 1986; Gelzleichter et al., 1999; Middlebrook and Franz, 2000). The majority of botulism outbreaks in cattle have also been attributed to toxins C1 and D. Cattle intoxication is typically associated with the ingestion of contaminated bones and other carcass remains; their apparent susceptibility to type C and D botulism might simply be due to frequent ingestion of decaying material that is primarily contaminated with these toxin types. A recent study indicated that cows are also uniquely sensitive to IV injection of type C1 toxin (Moeller et al., 2003). The high susceptibility of cattle to type C botulism is not dependent on exposure route, although the specific factors contributing to their sensitivity are not known.

A recent outbreak of type C botulism among farmed mink and foxes in Finland underscores the need to consider not only the quantitative susceptibility of various species to the toxins but also the potential epidemiological significance of interspecies differences in dietary patterns. Lindstrom et al. (2004) reviewed the Finland incident, which was the largest documented type C botulism outbreak in fur production animals. Over 52,000 animals developed illness after consumption of feed product that was contaminated with over 600 MLD of type C1 toxin per gram. This feed consisted of acidified slaughter by-products from poultry, beef, and fish (Lindstrom et al., 2004). According to national regulations, these by-products were acidified with an organic acid to yield a final pH of 4.0 or lower. Such processing would inhibit the growth of many microorganisms but would not necessarily result in significant toxin inactivation. Over 44,000 of the 52,000 affected animals died, and the death rate among all potentially exposed animals was almost 22% (Lindstrom et al., 2004).

The large number of animals affected and the high lethality associated with the outbreak could be considered indicative of the high susceptibility of the affected species to foodborne type C botulism. This high susceptibility might appear to be in stark contrast to that of humans due to the scarcity of type C cases in humans. However, the Finland outbreak provides a clear indication that dietary differences between species may play a significant role in these epidemiological patterns. Humans would be far less likely to consume slaughter by-products (including intestinal tissues), as opposed to higher-quality beef, poultry, and fish products. Moreover, the preparation of such products for human consumption would generally involve cooking rather than acidification. Thus, the influence of dietary habits must be taken into consideration when evaluating interspecies differences in epidemiological patterns for the various toxin serotypes.

It remains possible that humans generally do not consume the types of foods that are typically subject to contamination with type C1 and D toxins. Some researchers continue to speculate that humans are likely to be susceptible to both serotypes because they lead to botulism in monkeys, both in nature and after experimental oral exposure. Alternatively, humans might display a unique pattern of physiological susceptibility to the different toxin types. Lack of human susceptibility to type C1 and D intoxication could be attributed either to poor absorption of these specific toxins from the human gastrointestinal tract or to resistance of human cholinergic nerve terminals to the activity of these toxins. One cell culture study provided some support for the latter explanation. Type C1 neurotoxin was shown to bind with high efficiency to mouse neuroblastoma cells and to hybridomas of mouse neuroblastomas and rat gliomas, but not to human neuroblastoma cell lines (Yokosawa et al., 1989). Yokosawa et al. (1989) suggested that reduced binding of type C1 toxin to human versus mouse neuroblastoma cells could provide one explanation for the lack of type C botulism cases in humans.

Another potential explanation for the unique epidemiology of human botulism was provided in a study of botulinum toxin binding and transcytosis across polarized monolayers of two human colon carcinoma cell lines (T-84 and Caco-2). Substantial binding of iodinated BoNT/A and BoNT/B to human colon carcinoma cells was observed, while minimal binding of type C1 neurotoxin was detected (Maksymowych and Simpson, 1998). Both type A and B neurotoxins were also efficiently taken up, transcytosed, and released, by the polarized human carcinoma cells, whereas minimal transcytosis of type C1 neurotoxin was observed. The patterns of neurotoxin transcytosis (A and B, but not C1) observed in these human gut epithelial cell lines correlate with human susceptibility to foodborne botulism (Maksymowych and Simpson, 1998). The authors speculated that since human tissues are fully sensitive to the neuromuscular blocking properties of C1 neurotoxin (Coffield et al., 1997; Eleopra et al., 2004), the relative absence of human foodborne type C botulism could be due to the inability of this toxin to penetrate from the gut to the general circulation. Human susceptibility to type C1 and D neurotoxins remains unclear; however, clarification of this issue will be important in interpreting data derived both from *in vitro* studies on toxin transcytosis and from animal models for oral intoxication.

PATHOGENESIS

Overview of Pathogenesis

BoNTs are a group of immunologically distinct but closely related bacterial proteins that act as potent inhibitors of synaptic transmission in skeletal muscle. Inhibition of ACh release from the presynaptic terminal of the neuromuscular junction (NMJ) is thought to be the sole mechanism involved in the toxins' lethal action (Simpson, 1986) and therefore the cause of botulism. The pathogenesis of intoxication is not completely understood but is generally thought to involve a multistep process to interrupt the normal vesicular release of ACh from the presynaptic motor nerve terminal. In a process of transcytosis, ingested or inhaled BoNT must first cross a barrier (either intestinal or pulmonary epithelial cells) to gain access to the circulation (see intestinal absorption of BoNT; Figure 28.2). Once in the circulation, BoNT travels to its major target, the presynaptic membranes of alpha motor neurons at NMJs and neuroeffector junctions. Toxin binding through its HC to a cell surface receptor on the presynaptic motor nerve ending is followed by internalization via an endocytotic vesicle, acidification of the endosome, conformational change allowing cleavage of the enzymatically active LC from a bound HC, and release of LC toxin into the cytoplasm. Here, the LC cleaves one of the integral members of the SNARE complex (SNAP-25, VAMP, or syntaxin), proteins involved in exocytosis of ACh (Simpson, 1986, 2004; Black and Dolly, 1986; Blasi et al., 1993; Montecucco et al., 1994; Schiavo et al., 1995). BoNT thereby prevents docking of SVs with presynaptic plasma membrane by selective proteolysis of synaptic proteins. Each stage in BoNT action provides a potential point for pharmacological intervention.

Toxin Stability

Biological Stability of the Toxins in the Gastrointestinal Tract

A major factor to consider in botulism is the stability of both the organism and the toxin. A variety of

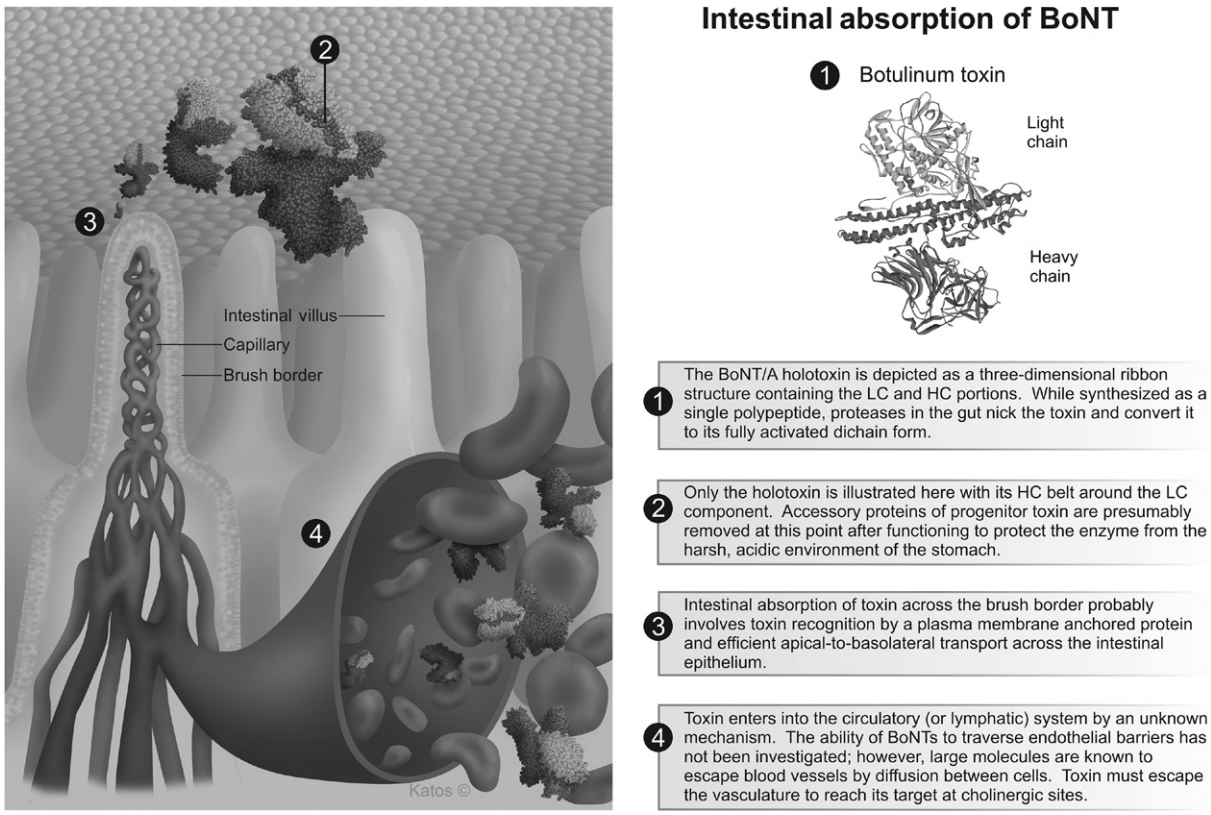

FIGURE 28.2 Intestinal absorption of BoNT. Neurotoxin present in the gut lumen as a result of foodborne (ingested toxin) or infant botulism (toxin synthesized by clostridial spores) must cross the epithelial membrane to reach the circulatory and lymphatic systems. The toxin presumably binds to an as-yet-unidentified receptor on the intestinal villus epithelium that is linked to an efficient transport process. Progenitor toxin contains nontoxic HA and NTNH accessory proteins, which are probably shed from the protein prior to entry across the intestine brush border. Progenitor toxin is thought to be too large for any significant rate of paracellular diffusion (Simpson, 2004). The ability of botulinum holotoxins without accessory proteins to traverse endothelial barriers has not been investigated; however, large molecules are known to escape blood vessels by diffusion between cells. Toxin escapes the circulatory system and reaches peripheral (and possibly central) cholinergic sites. These include NMJs, ganglia of the sympathetic and parasympathetic nervous system, postganglionic parasympathetic sites, and postganglionic sympathetic sites that release ACh. *Source: Illustrations are copyright-protected and printed with permission by Alexandre M. Katos.*

factors can affect the stability of ingested BoNTs within the gastrointestinal tract. The oral potency of the toxins is closely related to their ability to withstand the conditions found in these biological compartments prior to absorption into the lymphatics and general circulation. The stability of BoNT preparations, therefore, has been examined in the gastrointestinal compartments of intoxicated animals, as well as under different enzymatic and acidic conditions *in vitro*. Some of the earliest work on BoNT intoxication indicated that the stability and resulting potency of type A toxin vary both qualitatively and quantitatively in different rodent species (Minervin and Morgunov, 1941).

Several groups have evaluated the influence of ingested foods on the gastrointestinal stability and potency of BoNTs. Lamanna and Meyers (1959) reported that the ingestion of protein- or fat-containing foods prior to oral type A exposure in mice resulted in moderate increase in toxicity. The mechanisms by which food intake enhanced toxin potency were not clarified; however, the relatively small observed increases (twofold) could have been due to normal experimental variation in determining oral toxicity values. The same study demonstrated that fluorescein-labeled type A toxin was quickly destroyed in the stomachs of mice. Crystalline and purified toxins form stable complexes with albumin and other proteins found in food and serum (Lamanna and Meyers, 1959). Albumin was later shown to prevent loss of potency when type A toxin was exposed to a wide range of pH values (Zacks and Sheff, 1967). This observation was consistent with the more recent finding that the enzymatic activity of BoNT/A was enhanced in the presence of albumin (Schmidt and Bostian, 1997).

Subsequent studies expanded upon this early work by investigating the stability of other toxin types and preparations in solutions having different pH values and other conditions similar to those encountered in the gastrointestinal tract. Type C1 toxin was stable in most acidic and basic environments, as significant inactivation (as indicated by loss of toxicity in a mouse lethality assay)

was observed only following exposure to extreme pH values (i.e., pH 1.8 and pH 12) (Halouzka and Hubalek, 1992). Progenitor type E toxin was more stable than its derivative (purified) form, which was subject to rapid inactivation when exposed to pH values less than 4.0 (Sakaguchi and Sakaguchi, 1974). This study demonstrated that type E progenitor toxin dissociated either during or after gastrointestinal absorption in mice, as only the derivative component could be detected in the blood and lymph following oral administration of the progenitor form.

Similar findings on the relatively high stability of progenitor versus derivative forms of the other toxin serotypes have been reported in other studies. Types A, B, and F progenitor toxins were more stable under conditions of low pH, as well as more resistant to digestion by pepsin and papain, than their corresponding derivative toxins (Sugii et al., 1977a,b).

The derivative forms of toxins A and B were almost completely inactivated after 10 min of peptic digestion at pH 2.0, while the progenitor forms retained over 60% toxicity after an 80-min treatment (Sugii et al., 1977a). Crystalline type A toxin was shown to be partially resistant to proteolysis by trypsin, retaining 25% of the potency of control-treated toxin even after a 72-h trypsin digestion at 37°C (Coleman, 1954). The crystalline toxin was more readily inactivated by digestion with pepsin at pH 1.4 and chymotrypsin at pH 6.5. Interestingly, another group reported that the potency of type A toxin was weakened by 80% after a 5-h incubation in phosphate buffer (pH 7.5), while toxins C1 and D maintained 100% toxicity under the same conditions (Miyazaki and Sakaguchi, 1978). These findings demonstrate both serotype- and enzyme-dependent effects on the *in vitro* stability of the BoNTs that are also likely to affect their persistence in the gastrointestinal tract. A similar pattern of stability among the various BoNT forms in gastrointestinal juices isolated from different animal species has been demonstrated (Sugii et al., 1977a). The progenitor forms for all toxin serotypes retained significant toxicity in comparison to their derived holotoxin counterparts.

Epitope mapping experiments suggested that the nontoxic component of the intact progenitor toxin complex covers a large portion of the binding domain of the neurotoxin (Chen et al., 1998). Toxin interaction studies also revealed that the purified neurotoxin adheres to lipid monolayers while the progenitor complex is not subject to significant adsorption to the same monolayers. This observation led to speculation that the protective nontoxic components (HA and NTNH) may also facilitate progenitor toxin transit through the gastrointestinal tract by minimizing neurotoxin adherence to lipid membranes (Chen et al., 1998). On the other hand, toxicity studies suggest that adherence to lipid membranes is not critical for neurotoxin absorption since the intact progenitor complex is generally much more potent by the oral route than the purified neurotoxin. Moreover, the neurotoxin has been shown to protect the agglutination capacity of the associated nontoxic HA components within the progenitor toxin complex (Chen et al., 1998).

Importantly, the nontoxic HA components of the progenitor complex appear to protect the neurotoxin from proteolysis and degradation under pH extremes while the agglutinating activity of the nontoxic component is maintained by the presence of the neurotoxin. The type A progenitor toxin complex contains several HA components that might contribute to protecting the neurotoxin from degradation. One of these HA components, referred to here as *HA-33* (or *HA1* in some studies), was shown to interact directly with type A neurotoxin and to significantly increase its resistance to enzymatic proteolysis *in vitro* (Sharma and Singh, 2004). The authors of this work hypothesized that HA-33 provides protection against enzymatic degradation either by blocking the accessibility of protease-sensitive sites on BoNTs or by inducing structural changes within the neurotoxin itself.

Collectively, these studies offer important insight into the relative stability of the BoNTs within the gastrointestinal tract based upon their resistance to inactivation under various enzymatic conditions. In general, toxin stability directly correlates with the presence of the accessory HA and NTNH components of the multimeric progenitor toxin complex. These proteins appear to function in protecting the neurotoxin from degradation or inactivation. The various toxin serotypes also display unique resistances to enzymatic digestion although the basis for these differences is not known.

Oral Intoxication: Toxin Absorption from the Gastrointestinal Tract

Role of Progenitor Toxin Accessory Proteins

The role of the nontoxic accessory proteins within the progenitor toxin complexes is not fully understood. They appear to function in protecting the ingested toxins from degradation and in facilitating absorption from the gastrointestinal tract. Functional characterization of the HA and NTNH proteins has been advanced by biochemical techniques for generating toxin preparations containing only select components of the progenitor complex. These 7S toxins are relatively sensitive to proteolytic degradation and denaturation in the stomach (Schiavo et al., 1992). The auxiliary HA and NTNH proteins within the multimeric complex have been shown to dramatically increase the stability of the associated neurotoxin during transit through the gastrointestinal tract (Ohishi et al., 1977; Sugii et al., 1977a–c). The multimeric complex is then thought to readily dissociate either in the intestine or after absorption into the circulation.

Most studies suggest that the accessory proteins do not appear to have any involvement in the activity of the toxins at peripheral nerve terminals. Thus, the HA and NTNH components are likely to be dispensable in disease pathogenesis after parenteral or respiratory exposure, where the toxins bypass the harsh conditions of the gastrointestinal tract.

Role of Enterocytes

Both absorptive enterocytes and Peyer's patch-associated M cells have been implicated in toxin transcytosis from the gastrointestinal tract after oral exposure. Peyer's patches are collections of lymphoid tissue that are part of the gut-associated lymphoid tissue. M cells are found not only in the intestinal tract, but also in the respiratory epithelium overlying bronchus-associated lymphoid tissue. Park and Simpson (2003) indicate that knockout mice deficient in Peyer's patch-associated M cell complexes are still susceptible to both oral and respiratory botulinum intoxication and the development of HC-specific antibody responses. Based upon these results, the authors suggest that M cells are not likely to be involved in toxin uptake and processing from the respiratory tract. In addition, both cell types have comparable transcytosis rates (M cells are five times as efficient in transcytosis than intestinal enterocytes), but enterocytes greatly outnumber M cells; therefore, gastrointestinal enterocytes are the predominant cell types involved in toxin uptake and processing from the gastrointestinal tract.

Maksymowych and Simpson (1998) used transwell culture systems with various transformed epithelial cell lines to evaluate the fate of the HA components of type A progenitor toxin complex. Radiolabeled preparations of both BoNT/A and HA were taken up by cultured T-84 human colon carcinoma cells by bulk endocytosis. However, efficient delivery across the T-84 cells was observed only for the neurotoxin.

Respiratory Intoxication

The potential threat posed by aerosolized botulinum toxins is emphasized by their ease of production, their extremely high potency relative to other biological toxins, and their use in various weaponization programs over the past several decades (Arnon et al., 2001). This threat, along with the relative lack of information on respiratory toxicity and pathogenesis in humans, has fueled research on inhalational botulism in several animal models, including mice, rabbits, guinea pigs, mongrel dogs, and rhesus monkeys.

Toxin Absorption from Respiratory Tract

The relative persistence and absorption of the toxins following experimental respiratory exposure have been investigated in a few animal species. An early literature review suggests that type A toxin is more potent in mice by the respiratory route than by subcutaneous (s.c.) administration but less potent by the intraperitoneal (i.p.) route (Morton, 1961).

Guinea pigs were shown to be highly sensitive to inhaled botulinum toxins when compared to other rodent species. Respiratory penetration and retention of inhaled toxin are higher in guinea pigs than mice (Lamanna, 1961). Toxin could be detected in the lungs of guinea pigs after intranasal (i.n.) administration of only two mouse lethal doses of type E toxin, although detection in the blood or liver required higher doses (Sergeyeva, 1962, 1966). Guinea pigs were also reportedly more susceptible than mice to type A toxin by inhalation because shorter incubation periods were observed in guinea pigs prior to the onset of acute disease (Iakovlev, 1958).

Although inhalational botulinum intoxication was investigated in other animal species, these studies have not provided specific data on toxin absorption. The behavior of BoNTs in the respiratory tract was only recently investigated. Park and Simpson (2003) studied the properties of pure BoNT/A neurotoxin both *in vivo* and *in vitro* using mice and pulmonary cell culture models, respectively. Mean survival times were compared in mice receiving various doses of pure BoNT/A either i.n. or i.p. Pure BoNT/A was found to be a potent i.n. poison, although the toxicity (as determined by mean survival time) associated with i.p. administration was somewhat higher. Mean survival times in mice were less than 100 (i.p.) or 600 min (i.n.) after administration of 0.1 μg pure toxin; 75 (i.p.) or 400 min (i.n.) for 1 μg toxin; and 120 min (i.n.) for 10 μg toxin (Park and Simpson, 2003). As seen with oral and parenteral routes, a linear relationship existed between the log of the intranasal dose administered and the geometric mean survival time. The HA and NTNH component of the progenitor toxin did not enhance toxicity, establishing different requirements for the stability and absorption of inhaled versus ingested toxin (Park and Simpson, 2003).

Transwell experiments were also performed to investigate BoNT/A transcytosis across a human pulmonary adenocarcinoma cell line (Calu-3), the MDCK cell line, and a primary rat alveolar epithelial cell line (Park and Simpson, 2003). Efficient BoNT/A transcytosis in both directions across polarized Calu-3 monolayers was observed, while toxin transcytosis occurred at a much lower rate across MDCK cells. These findings were in agreement with previous work demonstrating that the efficiency of BoNT/A transcytosis across MDCK monolayers was much lower than that observed across gut epithelial cells (Maksymowych and Simpson, 1998). BoNT/A transcytosis was also observed across primary rat alveolar cells, although at a slightly slower rate than that seen for the human adenocarcinoma cells (Park

and Simpson, 2003). While the LC of BoNT/A was not essential for transcytosis, HC apical–basolateral (A–B) and basolateral–apical (B–A) transcytosis rates were somewhat lower than those of intact BoNT/A for both Calu-3 cells (HC 53% lower than BoNT/A for A→B; 45% lower for B→A) and rat alveolar cells (HC 62% lower for A→B; 17% lower for B→A). The transcytosis process was shown to involve an active-energy-dependent mechanism and was significantly inhibited by toxin preincubation with immune serum (Park and Simpson, 2003).

An important caveat to consider when evaluating the relevance of these *in vitro* studies is the use of pulmonary adenocarcinoma and alveolar epithelial cell lines in modeling respiratory absorption. It is generally believed that systemic absorption of inhaled particles is more likely to occur within the distal regions of the respiratory tract; therefore, particles must pass through thinner membranes in the deep lung and are less susceptible to nonabsorptive particle clearance (Lamanna, 1961). Some potential also exists for significant particle absorption from the nasopharyngeal and tracheobronchial regions of the respiratory tract; the cell lines utilized in these *in vitro* studies clearly do not account for this absorption potential. Importantly, investigators in the field have recently sought to characterize the specific cell types involved in toxin absorption from the respiratory tract.

M cells are found not only in the intestinal tract, but also in the respiratory epithelium overlying bronchus-associated lymphoid tissue. The studies of Park and Simpson (2003) indicate that M cells are not the major players in transepithelial transport of toxin across the respiratory epithelium. Additional studies directly investigating the absorption of inhaled BoNTs do not exist.

Toxin Binding and Uptake into Target Tissues

The remaining steps of BoNT pathogenesis following neurotoxin absorption are thought to be similar for both the respiratory and gastrointestinal exposure routes. After oral or inhalational exposure, the neurotoxins are absorbed from the gut or respiratory tract, respectively, into the lymphatics and circulation for transport to peripheral cholinergic synapses (Simpson, 2004). Figure 28.3 illustrates the NMJ, a major target for the actions of BoNTs. BoNTs are taken up presynaptically at the endplate region of NMJs (Verderio et al., 1999) and at other cholinergic synapses. Toxin binding involves high-affinity presynaptic receptors. These receptors have recently been identified as a combination of polysialogangliosides, SV protein 2 (SV2), and synaptotagmin (Verderio et al., 2006). Each serotype displays an affinity for a unique combination of receptors. For example, BoNT/B recognizes synaptotagmin II (and I) and ganglioside lipids (Dong et al., 2003) (see Figure 30.3). BoNT/A involves recognition of SV2C, SV2A, and SV2B (Dong et al., 2003); binding to SV2C also involves a lipid. After toxin binding, the complex is internalized by what is believed to be a clathrin-mediated endocytotic process.

TOXICOKINETICS

The onset of symptoms in botulism depends upon the amount of toxin ingested or inhaled and the related kinetics of absorption. Time to onset can range from as short as 2 h to as long as 8 days, although symptoms typically appear between 12 and 72 h after consumption of toxin-contaminated food (Lecour et al., 1988; Arnon et al., 2001). In a review of 13 foodborne botulism outbreaks involving 50 patients from 1970 to 1984, the incubation period ranged from 10 h to 6 days (Lecour et al., 1988).

Foodborne Toxicity

Toxin Persistence in Circulation and Transit to Target Tissues

Case reports of human foodborne botulism incidents offer some information on toxin persistence and transit after oral exposure in humans. Koenig et al. (1964) reported that circulating toxin was detected in five out of six patients suffering from type E botulism after consuming contaminated fish by the mouse lethality assay on serum samples collected from the patients from 1 to 10 days after foodborne exposure. Serum from one of the patients who rapidly succumbed to disease contained approximately 8 MIPLD$_{50}$/mL; extrapolation of this value yields an estimate that 20,000–24,000 human LD$_{50}$s were in this individual's circulation (Koenig et al., 1964). The toxin isolated from the serum of these clinically ill patients was not further activated *in vitro* by trypsin treatment. This observation was in agreement with other studies demonstrating cleavage of the single-chain prototoxin to the active dichain form within the gastrointestinal tract. Importantly, circulating toxin was not detected in a patient with minimal disease 11 days after ingestion of contaminated food (Koenig et al., 1964). Six out of seven individuals who had consumed the contaminated fish but did not develop clinical illness also lacked circulating toxin. Circulating toxin, therefore, was detected much more consistently in symptomatic patients associated with this outbreak than in subjects who were unaffected after toxin ingestion (Koenig et al., 1964).

Koenig et al. (1964) also reviewed previously published literature on the detection of circulating toxin in

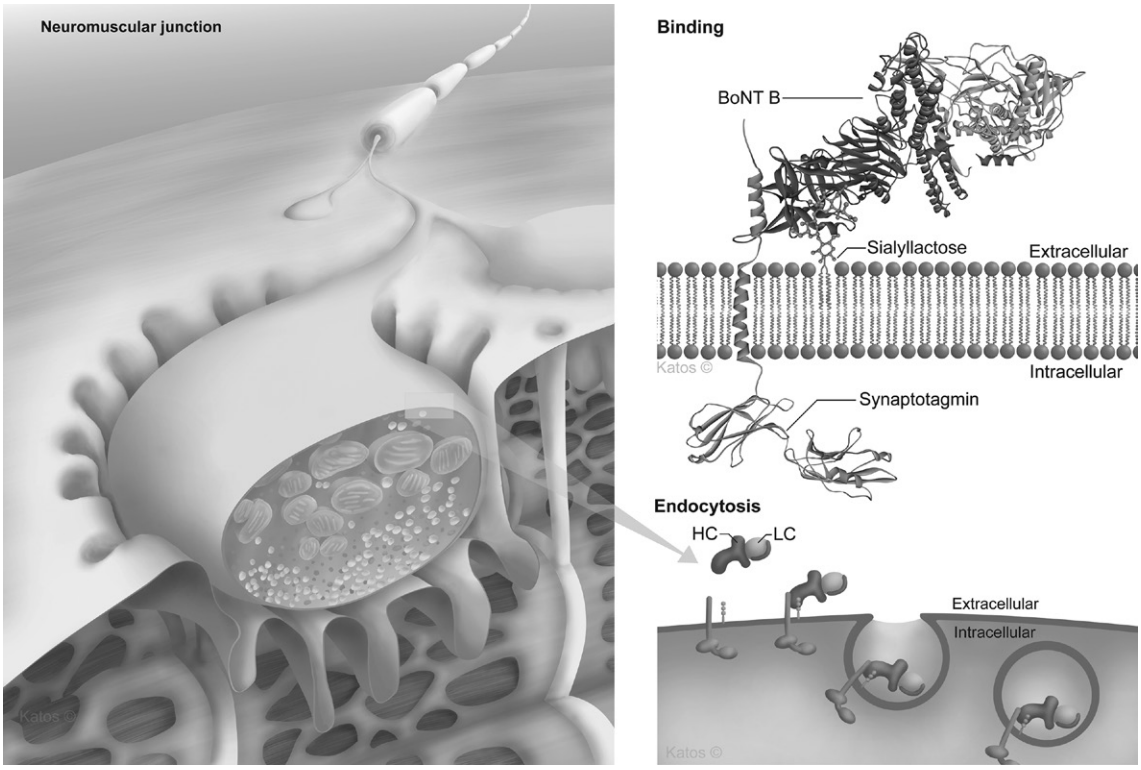

FIGURE 28.3 Toxin binding and internalization at the NMJ. Left panel: A mammalian NMJ is illustrated with the alpha motor neuron innervating skeletal muscle at specialized junctional folds in the membrane (Couteaux, 1973). Invaginations of the T system are also illustrated at the level of transition between the A and I bands. The axon loses its myelin sheath and dilates to establish irregular contact with the muscle fiber. Muscle contraction begins with the release of ACh from SVs (tiny spheres) at the motor endplate region. ACh binds to postsynaptic, muscle-type nicotinic ACh receptors and causes an increase in the permeability of the sarcolemma. This process is propagated to the rest of the sarcolemma and ultimately to the sarcoplasmic reticulum (SR) by the T system. An increase in SR permeability liberates calcium ion (Ca^{2+}) stores, resulting in the sliding of illustrated muscle filaments and muscle contraction. BoNTs bind and internalize at the presynaptic side of the NMJ (Verderio et al., 1999). Release of BoNTs into the cytosol results in inhibition of ACh release and flaccid paralysis of innervated muscle. Top-right panel (Toxin binding): A three-dimensional ribbon structure of BoNT/B is illustrated. The receptor-binding domain of BoNT/B HC binds to synaptotagmin (Syt-II) and ganglioside (sialyllactose) receptors of the presynaptic motor endplate. Each BoNT serotype binds to a different set of receptors in the membrane (Verderio et al., 2006). Bottom-right panel (endocytosis): Receptor-mediated endocytosis of BoNT/B holotoxin is illustrated in this panel. The remaining steps in BoNT toxicity involve acidification of the endosome, pH-induced conformational change in the toxin, translocation of BoNT LC across the endosomal membrane with the aid of BoNT HC, and proteolytic degradation of target SNARE proteins by LC. *Source: Illustrations are copyright-protected and printed with permission by Alexandre M. Katos.*

botulism patients. Circulating toxin (primarily serotype B) had been detected in select patients from 2 to 25 days after consumption of contaminated food and was rarely detected in type A botulism patients (Koenig et al., 1964). The authors suggested that serotype-specific differences in the persistence of circulating toxin might be attributed to their unique avidities to target tissues. Circulating toxin is generally detected only at very low levels at or immediately prior to death in lethally intoxicated patients (Ono et al., 1970).

Efforts have been made to determine the kinetics of the accessory components of the progenitor toxin complexes after systemic absorption of BoNTs. Iida et al. (1970) found that circulating type E toxin was shown to exist in the 7S form after oral administration of the progenitor toxin to rabbits, suggesting that the larger toxin complex dissociated at some point during or after absorption from the gastrointestinal tract. Similar findings were reported on the absorption and persistence of progenitor type A toxin in the rat; the mean sedimentation value of toxin in the lymph after intraduodenal instillation was 7.9S, significantly lower than that of the crystalline toxin (Heckly et al., 1960).

Inhalation Toxicity

Toxin Persistence in Circulation and Transit to Target Tissues

Very limited data are available on the persistence of BoNTs in circulation following inhalation exposure in any animal species. These data indicate that circulating toxin can be detected soon after exposure but is

subsequently cleared rapidly from the circulation. Park and Simpson (2003) reported on the time course for appearance (and amount) of either purified BoNT/A or type A HC in the circulation of mice after intranasal exposure. Maximum serum levels were observed at 2 h postexposure for both proteins although the peak values were higher for BoNT/A than for HC. Rapid clearance was observed over the next few hours.

An earlier study showed that type A toxin could be detected primarily in the lungs and liver rather than the serum of guinea pigs after i.n. exposure (Sergeyeva, 1962). The same group reported on the correlation between administered toxin dose and detection of toxin in the blood, lungs, and liver of guinea pigs intoxicated via the i.n. route (Sergeyeva, 1966). Type E toxin was detected in the lungs of guinea pigs after i.n. administration of two lethal doses, while toxin appeared in the blood or liver only following i.n. administration of at least five lethal doses. The organ distribution patterns were similar in guinea pigs after inhalation exposure to types A, B, or C toxins (Sergeyeva, 1966). These studies did not address the potential for persistent toxin detection in the lymph after inhalational intoxication, despite the fact that other routes of exposure result in significant absorption into the lymphatics.

While scant literature is available on persistence and distribution after inhalation exposure, several studies have evaluated the systemic behavior of parenterally administered toxins. One group investigated toxin persistence in serum and tissue distribution in white mice following IV administration of 1,000 lethal doses of ^{35}S-labeled type B toxin (Pak and Bulatova, 1962). Mice were sacrificed at 20, 60, and 150 min after toxin administration, and blood and tissues were harvested for toxin distribution analysis. These mice showed symptoms of severe intoxication, including atypical breathing patterns and paralysis, at 150 min postexposure. Toxin levels (as determined by radioactivity) were highest in the lung 20 min after toxin injection, followed by the liver, heart, kidneys, intestines, and brain (Pak and Bulatova, 1962). Radioactivity levels in the blood, as well as the liver, heart, intestines, and brain, were further reduced after 60 min post-toxin injection. Serum toxin concentrations were lower than those detected in any other tissue at all times (Pak and Bulatova, 1962). The authors concluded that the toxin rapidly escaped from blood to various other tissues, suggesting the capacity for unimpeded passage of the toxin through the vasculature and cellular membranes.

Somewhat slower kinetics for toxin clearance from the circulation were observed in dogs following parenteral [IV, i.p., or intramuscular (i.m.)] exposure to type A toxin (House et al., 1964). Serum toxin persistence was evaluated in mongrel dogs receiving 8,000–10,000 mouse units/kg of type A toxin. Peak serum toxin levels were detected 5 h after i.p. administration (13% of injected dose), 12 h after i.m. administration (9% of the injected dose), and within only 3 min after IV administration (79% of the injected dose) (House et al., 1964). The relative clearance kinetics were slower after i.m. and i.p. exposure than for IV administration, as serum toxin levels were identical 22 h after injection via all three rounds (approximately 6% of the injected dose). Some serum toxin activity could be detected by the mouse lethality assay for 2–4 days after parenteral administration. Serum toxin patterns were also evaluated in rhesus monkeys following IV administration of type A toxin (Stookey et al., 1965). Serum toxin levels dropped by about 50% of maximum within 16–24 h after IV injection, and previous exposure did not affect toxin clearance rates after the administration of subsequent doses.

Another study investigated circulating toxin levels in weanling pigs (5–12 weeks old) following parenteral administration of toxin types A, B, C1, and D (Smith et al., 1971). Toxin was cleared from circulation less than 24 h after IV injection of type B (560 $MIPLD_{50}$/kg), type C1 (5,000 $MIPLD_{50}$/kg), or type D (60,000 $MIPLD_{50}$/kg) toxin. In contrast, toxin could consistently be detected in the serum over the entire 4-day period prior to death in pigs injected with serotype A (21,400 $MIPLD_{50}$/kg) (Smith et al., 1971). Serum toxin levels were 100 MIP_{50}/mL at 24 and 48 h after injection of type A toxin, 30 $MIPLD_{50}$/mL after 3 days, and 10 $MIPLD_{50}$/mL after 4 days. These findings indicated serotype-specific differences in the persistence of circulating BoNTs, at least in systemically intoxicated pigs.

Although these studies provide some insight into the persistence of circulating toxin after parenteral administration, they do not necessarily reflect the behavior of absorbed toxin after respiratory exposure. The route of administration may not have a significant impact on the behavior of toxin once absorbed into the serum and lymph, but the patterns and kinetics of absorption into the circulation might be quite different after inhalational versus parenteral exposure. Respiratory exposure could lead to a different proportion of toxin taken up into the circulation, lymphatics, or both over a given time period than that seen after systemic injection. Such discrepancies might affect both the quantitative persistence of circulating toxin and its transit to peripheral target tissues. At this point, information is not yet available on the homing and distribution of toxins to target nerve tissues. The available literature also provides no insight on the mechanisms by which toxin is removed from the circulation, either through extravasation and uptake in target tissues or by metabolic processes. In the future, such data will be important in characterizing the pathogenesis of botulism after respiratory intoxication and other routes of exposure.

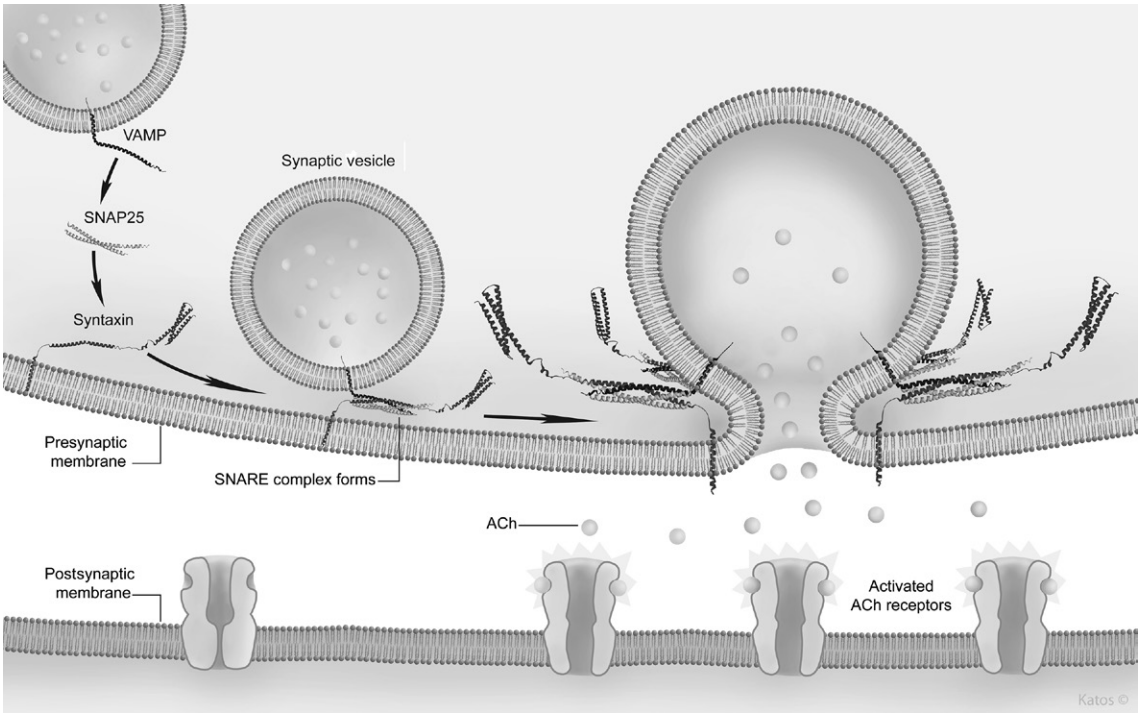

FIGURE 28.4 Neuromuscular transmission in the absence of BoNT. A nerve impulse is transmitted to the effector (muscle) cell by neurotransmitter liberated at the synapse. When the action potential arrives at the axonal terminus to depolarize the presynaptic membrane, Ca^{2+} ions enter through voltage-dependent Ca^{2+} channels. Ca^{2+} ions facilitate the fusion of SVs, containing the neurotransmitter ACh, with the presynaptic membrane. Three SNARE proteins (syntaxin, synaptobrevin, and SNAP-25) are critical for SV fusion. So long as the SNARE complex is intact, ACh releases by exocytosis, diffuses across the synaptic cleft, and binds to postsynaptic muscle-type nicotinic ACh receptors. Binding of ACh makes the sarcolemma of the muscle cell more permeable to sodium, which results in membrane depolarization. Excess ACh is hydrolyzed by the enzyme cholinesterase bound to the synaptic cleft basal lamina. ACh breakdown is necessary to avoid prolonged activation of ACh receptors. *Source: Illustrations are copyright-protected and printed with permission by Alexandre M. Katos.*

MECHANISM OF ACTION

ACh release from presynaptic vesicles depends upon a propagated action potential, localized depolarization at the presynaptic motor endplate, proper SNARE complex formation (i.e. SNAP-25, syntaxin, and synaptobrevin), and SV docking with the presynaptic membrane (see neuromuscular transmission in the absence of BoNT; Figure 28.4). Regardless of the exposure route, BoNTs lead to inhibition in the release of ACh from peripheral cholinergic nerve terminals resulting in flaccid paralysis (Simpson, 1986; see Figure 28.5). The specific target for BoNT/A and /E is the 25-kDa vesicle-docking protein SNAP-25; BoNT/A cleaves the last 9 residues, whereas BoNT/E cleaves a larger 26-residue fragment from the C-terminus of this protein (Blasi et al., 1993; Montecucco et al., 1994). The target of BoNT/B is the small transmembrane protein synaptobrevin/VAMP located on the surface of small SVs (Schiavo et al., 1995). The enzymatically active portion of the 150-kDa BoNT is the 50-kDa LC; the role of the 100-kDa HC involves binding to cholinergic nerve endings and intracellular penetration via receptor-mediated endocytosis (Simpson, 1986, 2004; Montecucco et al., 1994).

Heavy Chain

The HC of the BoNTs has been shown to mediate toxin binding and internalization at cholinergic nerve terminals (Daniels-Holgate and Dolly, 1996; Simpson, 2004). The mostly β-strand-containing carboxy-terminus of the HC appears to be directly involved in toxin binding, while the mostly α-helical amino-terminal region mediates translocation across the endosomal membrane (Simpson, 2004). Through mechanisms that have yet to be fully characterized, the toxins gain entry into the nerve terminal through receptor-mediated endocytosis followed by pH-induced translocation from the endosome to the cytosol. The ability of the Hn region to form transmembrane ion channels raises the possibility that they are intimately involved in translocating the toxic moiety into the cytoplasm (Koriazova and Montal, 2003). Once translocated into the cytosol, the toxic fragments exert their paralytic effects by inhibiting ACh

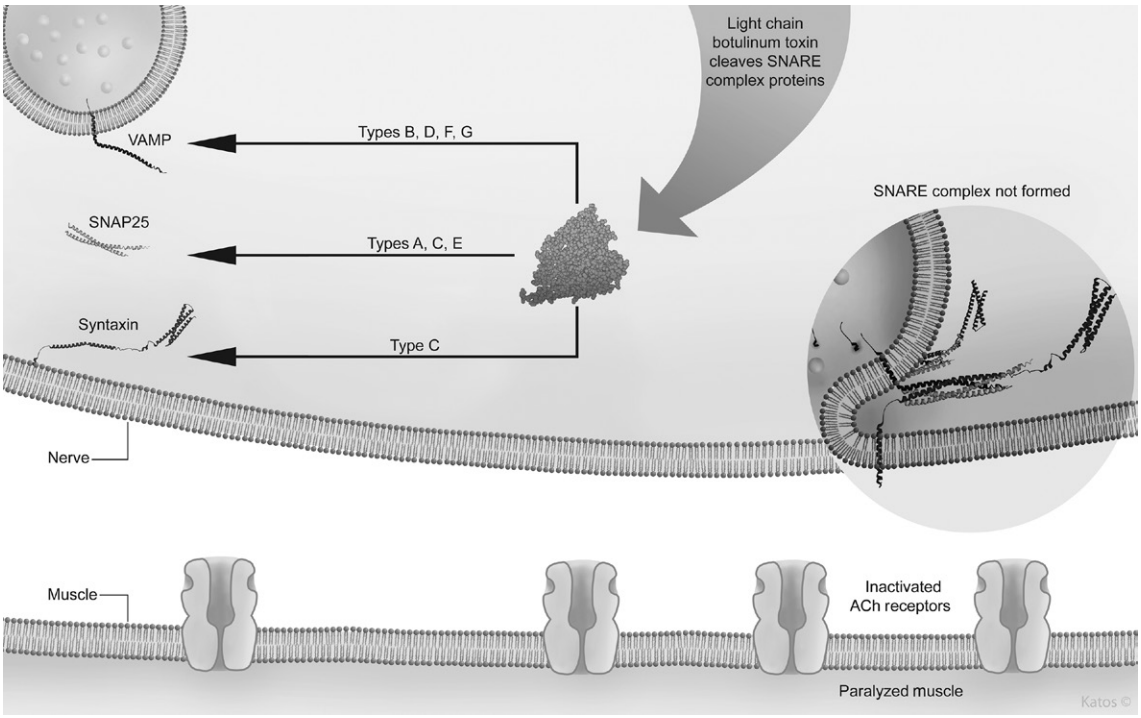

FIGURE 28.5 Neuromuscular transmission in the presence of BoNT. The catalytic LCs of the various serotypes cleave specific SNARE proteins. The SNARE complex does not form if any of the proteins are cleaved. In the presence of BoNT LC inside the axonal terminus, SVs will not fuse with the presynaptic membrane, ACh will not be released, and the muscle will not contract, resulting in paralysis at the NMJ. *Source: Illustrations are copyright-protected and printed with permission by Alexandre M. Katos.*

release from NMJs as well as other peripheral cholinergic sites, including sympathetic and parasympathetic ganglia and postganglionic parasympathetic synapses (Lamanna, 1959; Simpson, 2004).

Light Chain

These paralytic effects have been attributed to the proteolytic activity of BoNT LC on protein substrates required for vesicular exocytosis. BoNT LC inhibits neurotransmitter exocytosis through its zinc-dependent endoproteolytic activity. The LCs of the various neurotoxin serotypes possess distinct molecular targets within the peripheral cholinergic nerve terminals (Schiavo et al., 1992, 1993a,b, 1995). The endoproteolytic activities of the different toxin LCs produce similar flaccid paralytic effects.

The intracellular proteins SNAP-25, syntaxin, and synaptobrevin (or VAMPs) normally interact with each other in mediating neurotransmitter release from cholinergic and other nerve terminals (see Figure 28.4). Toxin types B, D, F, and G cleave the VAMPs, while types A, C1, and E act on SNAP-25; type C1 toxin also cleaves syntaxin (Dong et al., 2003). The functions of the various neurotoxins are even more specialized, in that one toxin type can cleave its substrate at a different site than that targeted by other toxin serotypes. For example, BoNT/A cleaves SNAP-25 between residues 197 and 198, resulting in the loss of 9 amino acids, while BoNT/E cleaves the same protein between residues 180 and 181, thereby removing 26 amino acids (Schiavo et al., 1993a).

Although the LCs of both BoNT/A and /E target SNAP-25, these two serotypes exert significantly different potencies and paralytic profiles in cultured neurons and *in vivo*. A potential molecular basis for this discrepancy was established by the finding that these neurotoxins target different cleavage sites within the SNAP-25 protein. BoNT/A cleavage generates a 197-residue truncated protein (P197) by cleaving the last 9 amino acids from the C-terminus of SNAP-25 while BoNT/E cleavage produces a 180-residue species (P180) by removing the final 26 residues (Schiavo et al., 1993a). A series of studies by Keller et al. (1999) and Keller and Neale (2001) provided additional insight into the molecular mechanisms associated with the potent and persistent action of type A neurotoxin relative to type E.

Serotype-specific cleavage events provide insights into the differential activities of the toxins at nerve terminals. In some cases, substrate cleavage studies also revealed important information regarding interspecies differences in the activity of certain toxins. BoNT/B was shown to block neuromuscular transmission by cleaving VAMP proteins between residues Q76 and F77 in humans and mice (Bakry et al., 1997). However, the rat

VAMP1 (synaptobrevin) protein sequence differs at this critical cleavage site, in that the glutamine at position 76 is replaced by a valine, rendering the region more resistant to proteolysis by BoNT/B (Bakry et al., 1997; Verderio et al., 2006). On the other hand, rats and mice were shown to have similar susceptibilities (body weight adjusted) to i.m. injection of type A toxin; rats have also been shown to be much more resistant than mice to type F toxin (Kauffman et al., 1985).

The specific paralytic profiles associated with each of the BoNTs are typically attributed to their unique proteolytic activities within the nerve terminal. These activities are known to be mediated by the LC components of the various neurotoxins. The various nontoxic components within the multimeric progenitor toxin complexes have traditionally been considered accessory proteins that primarily function to increase neurotoxin stability and, in some cases, to facilitate absorption. Yet studies over the past few years have suggested a potential role for the HA constituents in enhancing the endopeptidase activity of the LC (Cai et al., 1999; Sharma and Singh, 2004). It is widely believed that pure BoNT/A requires either proteolytic nicking or chemical reduction for significant SNAP-25 cleavage activity. However, new evidence suggests that the type A progenitor toxin complex is apparently highly active even in nonreduced form (Cai et al., 1999). Further research is needed to substantiate this preliminary work and to establish a more detailed understanding of the prerequisites for LC proteolytic activity.

A recent study by Sharma and Singh (2004) provided additional support for the expanded roles of at least one neurotoxin-associated protein within the type A progenitor complex. The HA-33 component, representing 25% of the accessory protein content of progenitor neurotoxin, significantly increases the proteolytic activity of both BoNT/A and /E *in vitro* and in rat synaptosome preparations. The addition of HA-33 to nonreduced BoNT/A leads to a 21-fold increase in GST-SNAP-25 fusion protein cleavage activity *in vitro* and a 13-fold enhancement of endopeptidase activity in rat synaptosomes (Sharma and Singh, 2004). Similar enhancement of proteolytic activity was seen when HA-33 was added to BoNT/E both *in vitro* and in rat brain synaptosomes.

The enhancement of SNAP-25 cleavage activity by HA-33 in rat brain synaptosomes was taken as evidence that the neurotoxin and the accessory protein both gain entry to the nerve terminal (Sharma and Singh, 2004). The possibility that an accessory component of the progenitor toxin complex could exert direct effects on LC endopeptidase activity within the nerve terminal could have important implications with respect to neurotoxin function *in vivo*.

Two recent reports revealed additional layers of complexity regarding the mechanisms involved in the distinct durations of action associated with the different toxin serotypes. Fernández-Salas et al. (2004) investigated the subcellular localization of BoNT/A, /B, and /E LC-GFP fusion proteins following overexpression in several different mammalian cell lines. The LC/A fusion protein was shown to localize within discrete plasma membrane compartments in both neuronal (PC12) and nonneuronal (HEK293, HeLa, and HIT-T15) cell lines, while LC/B was detected throughout the cell and LC/E was primarily found within the cytosol.

TOXICITY

Lethality

BoNTs are the most potent substances known to humans. A comparison of the lethal nature of BoNTs in relation to other toxic chemicals and substances discussed throughout this book is provided in Table 28.2. The toxicity associated with oral exposure of a given species to BoNTs is significantly lower than that resulting from parenteral administration (see Table 28.3). The

susceptibility of various animal species to parenteral intoxication does not provide adequate indication of their sensitivity to gastrointestinal exposure (Lamanna, 1961). The estimated human LD_{50} of approximately 1 ng/kg for parenteral botulinum intoxication is similar to that reported for most laboratory animals (Arnon, 1995; Middlebrook and Franz, 2000). In contrast, the relative susceptibilities of humans and other animal species to oral intoxication vary significantly (Morton, 1961). A recent clinical review of human botulism reported that the ingestion of as little as 0.05–0.1 μg of BoNT/A may be sufficient to cause death in humans (Cherington, 1998). Human lethal doses have also been extrapolated from primate studies, yielding an oral lethal dose of approximately 70 μg for crystalline type A toxin for a 70-kg human (Arnon et al., 2001). The lethal human respiratory dose is estimated to be 0.7–0.9 μg and the IV or i.m. dose is 0.05–0.15 μg (Middlebrook and Franz, 2000; Arnon et al., 2001).

Oral Toxicity

An earlier report suggested that humans are more susceptible than monkeys to type A toxin by the oral route based on toxin dose estimates in foodborne botulism case studies (Morton, 1961). This same study also summarized the susceptibility of numerous other animal species to oral botulinum intoxication. Mice, monkeys, and guinea pigs were considered highly susceptible, while chickens, rabbits, horses, dogs, rats, and cattle were classified as more resistant and ferrets, minks, and hogs were deemed resistant. The oral lethal doses of type A toxin in guinea pigs (1000–3000 MIPMLD) and monkeys (2000 MIPMLD) (Morton, 1961) are similar to the estimated oral lethal dose for humans (7000 MIPMLD).

Morton (1961) provided evidence for an estimated human oral lethal dose of much less than 3500 MIPMLD for type B toxin. This estimate was based on an earlier report describing a fatal type B human botulism case resulting from the ingestion of 3500 MIPMLD in toxin-contaminated cheese (Meyer and Eddie, 1951). A man weighing 104 kg consumed approximately 70 g of contaminated cheese; repeated tests of the cheese indicated that it contained only 50 MLD/g of type B toxin. The patient first developed somewhat atypical disease symptoms of nausea, vomiting, diplopia, dysphagia, phagodynia, and instability within 7 h of exposure (Meyer and Eddie, 1951). The man was later hospitalized and developed symptoms more characteristic of foodborne botulism within 18–20 h. He died 57 h after toxin ingestion despite receiving 35,000 units each of both type A and B antitoxins (Meyer and Eddie, 1951). Therefore, it was determined that 3500 MIPMLD is much greater than the minimum lethal dose of type B toxin for humans due to the rapid onset of illness and severity of disease (Morton, 1961). The same study reported a woman who died from botulism 42 h after consuming a small piece of toxin-contaminated pear.

Inhalation Toxicity

Naturally occurring botulism cases in humans and other animal species are almost exclusively associated

with the ingestion of toxin- or spore-contaminated foods. The level of knowledge in the published literature on toxin absorption following inhalational exposure is, therefore, much more limited than that associated with gastrointestinal intoxication. The potencies of inhaled BoNTs have been investigated in several experimental animal species. In a review of the early literature on this topic, Morton (1961) reported comparatively similar ratios (5.9:1) of oral to respiratory toxicity (the comparative lethal doses for toxin administered via the oral versus the respiratory route) for type A toxin in guinea pigs and mice. Iakovlev (1958) concluded that guinea pigs were more susceptible than mice to type A toxin by inhalation because they succumbed to intoxication after a shorter incubation period (1–2 days, versus 3–4 days for mice). Several technical reports established more specific guinea pig inhalation toxicity data for serotypes A through E (Jemski, 1960, 1961b).

Clinical Toxicity

The natural occurrence of human foodborne and infant botulism translates into a wealth of information on the clinical signs and symptoms of disease. This information can be compared to the array of physiological and pathological findings in various species of experimental animals after oral administration of BoNTs. The ability of inhaled BoNTs to produce illness has also been documented in humans and in several experimental species. The primary neurophysiological signs and symptoms associated with respiratory exposure parallel those observed in cases of foodborne botulism; however, infants display a unique clinical picture of botulism. In addition, the various toxin serotypes are usually associated with analogous clinical presentations, with the most severe cases of foodborne botulism being caused by the ingestion of type A toxin.

Exposure to BoNT via oral or inhalational routes results in symptoms indicative of an inactive peripheral cholinergic system due to inhibition of ACh release from the nerve terminal. The time to onset of disease depends on the amount of toxin ingested and ranges from several hours to a few days after oral exposure (Lecour et al., 1988; Arnon et al., 2001). Prominent signs and symptoms of intoxication common to all serotypes and various routes of exposure include the following, in order of descending frequency: dysphagia, xerostomia, diplopia, dysarthria, fatigue, ptosis of the eyelids, constipation, arm weakness, leg weakness, gaze paralysis, blurred vision, diminished gag reflex, nausea, facial palsy, dyspnea, emesis, tongue weakness, sore throat, dizziness, dilated or fixed pupils, abdominal cramps, reduced or failed reflexes, nystagmus (involuntary rapid eye movement), diarrhea, ataxia, and paresthesia (reviewed by Arnon et al., 2001).

Foodborne Botulism

Human foodborne botulism presents as an acute, symmetric, flaccid paralysis that generally involves multiple cranial nerve (CN) palsies initially, termed *bulbar involvement.* Early symptoms involve paralysis of the motor components of the CNs. The motor components are derived from cell bodies located in the brain, with axons that exit the cranium to control muscles, glandular tissue, or specialized muscle in the heart and gastrointestinal tract. Paralysis by BoNTs leads to ptosis and dilated pupils (CN III); disconjugate gaze and blurred vision (CN III, IV, VI); facial droop or palsy (CN VII); dysphagia, dysarthria, and absence of gag reflex (CN IX, X); tongue weakness (CN XII); and weakness of neck strap muscles (CN XI). Botulism patients typically develop difficulty in seeing, speaking, or swallowing in the early phases of intoxication. As paralysis extends caudally, toxic signs and symptoms include loss of head control, hypotonia, generalized weakness, and flaccid paralysis or floppy appearance (infants and children). In infants and young children exposed to BoNT, floppy appearance and constipation may be the only presenting signs to warrant a diagnosis of BoNT exposure, since obtaining a reliable history may not be possible in this population.

Loss of the gag reflex and dysphagia may require intubation and mechanical ventilation. Deep tendon reflexes are often lost during later stages of intoxication, and death in untreated patients results from airway obstruction or inadequate tidal volume (Arnon et al., 2001). Respiratory failure is the most serious clinical manifestation of botulism, and the decline in mortality associated with foodborne botulism is primarily due to improvements in ventilatory support (Lecour et al., 1988). Around 60% of botulism patients in the United States require mechanical ventilation at some point during their hospitalization and treatment (Varma et al., 2004). In severe botulism cases (as in the previously mentioned case of the Florida physician involving research grade type A toxin instead of BOTOX for facial muscle paralysis), respiratory support may be required for prolonged periods of time, and autonomic dysfunction may persist for a period ranging from months to years (Mackle et al., 2001).

Other clinical forms of the disease share many of these signs and symptoms. The presentation and duration of the disease are coupled to the relative persistence of the toxin in blocking the release of ACh at peripheral nerve synapses. Although untreated botulism is potentially deadly, the availability of antiserum has dramatically reduced the mortality rates for the common clinical manifestations of the disease. Severe cases of foodborne botulism may still require ventilatory support for over a month, and neurological symptoms can sometimes persist for more than a year (Mackle et al., 2001).

Infant Botulism

The characteristic symptoms of infant botulism are poor sucking, constipation, generalized weakness, floppy appearance, and respiratory insufficiency (Cox and Hinkle, 2002). Infant botulism may quickly progress to respiratory failure if not treated. The development of the intestinal flora has been demonstrated to suppress the germination and growth of *Clostridium botulinum* spores in mice (Sugiyama and Mills, 1978). Ingestion of honey by infants is the classic scenario cited in infant botulism; therefore, honey is not recommended in this susceptible population (Arnon, 1998).

RISK ASSESSMENT

BoNTs present a very real threat to the public health and are the most toxic substances known to humans. In a military or bioterrorist incident, intoxication by BoNT is likely to occur by inhalation of aerosolized toxin or by ingestion of contaminated food or beverages (Franz, 1997; Sobel et al., 2004). Although the municipal water systems are considered to be safe from BoNT attacks, due to chlorination and dilution, it is not known whether current water treatments adequately decontaminate the toxin. Furthermore, bottled mineral water and milk (Sobel et al., 2004; Kalb et al., 2005) are obvious targets for terrorist groups. The vulnerability of the nation's milk supply was highlighted in a recent modeling study, where its complex distribution system would magnify the consequences of poisoning by BoNT (Kalb et al., 2005; Wein and Liu, 2005). BoNTs are a serious threat to the US national security due to their potency, remarkable stability, and persistence in the body.

Wein and Liu (2005) modeled a bioterror attack using BoNTs on the nation's milk supply. Modeling of toxins for dispersal into a liquid medium has been previously computed in a terrorist scenario (Dembek, 2005) involving a water fountain and contamination at a recreational center (CDC, 1999). Wein and Liu's assessment estimates the amount of toxin required, critically evaluates entry points into the milk supply industry, and details deficiencies in our current detection capabilities required to thwart such an attack (Wein and Liu, 2005).

The most prevalent BoNTs isolated in human botulism are serotypes A, B, and E. The ability of serotypes C and D, in addition to F, to paralyze human skeletal muscle should also be noted (Hilmas, unpublished). Complicating matters is the fact that all BoNTs remain stable in common beverages and retain significant potency for prolonged periods of time (>90 days) at room temperature and in biological fluids (human whole blood and serum) at physiological temperatures (Hilmas et al., 2006b; Williams et al., 2007). In addition, BoNTs possess a remarkable ability to remain within the nerve terminal for extended periods. Keller et al. (1999) showed BoNT protein detectable by western blot for 90 days in rat spinal cord cultures.

Stability of the BoNT protein should be considered in an assessment of the threat posed by intentional release of the toxins. In addition to the remarkable persistence of the toxin in biological fluids and beverages described previously, BoNT remains a potent environmental threat. BoNT/A was subjected to desiccation to simulate the residue of an intentional release. Following 28 days of drying, the toxin still possessed remarkable paralytic properties (Williams et al., 2007).

The duration of muscle paralysis following intoxication by BoNT/A exceeds that resulting from exposure to other BoNT serotypes (Keller et al., 1999; Fernández-Salas et al., 2004). The remarkable persistence of BoNT/A action has led to its widespread use in the treatment of disorders of muscle tone and movement (Jankovic and Brin, 1997). Although a long duration is desirable in clinical use, the prolonged action of BoNT/A would also make intoxication by this serotype difficult to treat, particularly if it is used as a bioweapon (Franz, 1997). The duration of intoxication by BoNT/E is relatively brief (several weeks), whereas BoNT/B is of intermediate duration (Keller et al., 1999). The basis for the differences in serotype persistence is currently unknown. In any case, a bioterrorist attack, involving the most lethal substance known to humankind, would overwhelm the limited resources (i.e., mechanical ventilators) available to treat botulism patients.

TREATMENT

There are currently seven known antigenic serotypes of botulinum toxin, designated with the letters A through G, whereby antitoxin to one type does not cross-neutralize any of the others. Only early administration of antitoxin antibody in cases of suspected botulism will minimize the neurologic damage but will not reverse any existing paralysis. Paralysis could persist for weeks to months, and the available treatment consists of supportive care including fluids, TPN, and mechanical ventilation.

Antitoxin

The administration of a heterologous antitoxin was one of the first therapeutic approaches developed for botulism patients and remains the most effective when initiated in the early stages of intoxication. The primary limitation of antitoxin treatment was established in some of the earliest published reports on experimental botulism. One of these reports evaluated the pathogenesis of oral intoxication and the efficacy of antitoxin therapy in

monkeys (Dack and Wood, 1928). Antitoxin treatment was not effective when administered after symptoms of botulism were already apparent, despite the fact that circulating toxin could still be detected in many of the animals.

Oberst et al. (1967) investigated the effectiveness of antitoxin therapy, artificial respiration, and supportive treatment in rhesus monkeys after IV type A toxin injection. These treatments were administered to the animals, either alone or in combination, after signs of intoxication were observed. Only 1 in 6 monkeys survived after receiving antitoxin injections alone as treatment for overt intoxication with 2.5 LD_{50} of type A toxin (Oberst et al., 1967). A combination of antitoxin therapy and supportive treatment initiated soon after the development of toxic signs protected 8 of 10 animals from death after IV injection of 4–5 LD_{50}. Artificial respiration prolonged survival in monkeys with respiratory paralysis but was ineffective as a primary treatment after lethal intoxication; no animals receiving only artificial respiration survived intoxication with 5–24 LD_{50} (Oberst et al., 1967). Untreated animals developed overt signs of intoxication within 20–38 h and died 32–135 h after toxin injection.

While antitoxin treatment was generally ineffective in experimental animals displaying significant clinical signs, several case studies of foodborne botulism indicated that antitoxin therapy remained potentially beneficial in humans even after the onset of illness. Iida (1970) reviewed the high efficacy of antitoxin therapy in type E botulism outbreaks associated with contaminated fish consumption in Japan. A mortality rate of only 3.5% was observed among 85 antitoxin-treated patients in 9 recent foodborne botulism outbreaks, while a rate of 28.9% was reported among 135 untreated patients in 19 previous outbreaks. Iida et al. (1970) noted that all moderately and seriously ill patients in a 1962 foodborne type E botulism outbreak survived after antitoxin treatment. Hatheway et al. (1984) reported on the effectiveness of trivalent (ABE) antitoxin therapy during a 1978 outbreak of type A botulism. Four of seven patients with confirmed disease from type A toxin ingestion were treated with two to four vials of trivalent antitoxin (Hatheway et al., 1984). All four treated patients survived, although one of these individuals continued to suffer from severe paralysis and required ventilatory assistance for several months.

The current CDC therapy for the public is an FDA-approved, bivalent, botulinum equine antitoxin against serotypes A and B. The trivalent antitoxin against types A, B, and E is no longer available. In cases of exposure to any of the other botulinum toxin serotypes, the US Army can provide an investigational heptavalent (ABCDEFG) equine antitoxin, but the time required for typing a toxin subtype would limit its effectiveness in certain cases, such as an outbreak. A parenteral vaccine against the toxin is currently available, but the need exists for newer, nonparenteral vaccines that could be administered orally or via inhalation.

Treatment for Infant Botulism

Administration of equine antitoxin is not recommended for pre-exposure prophylaxis. The heterologous serum of antitoxin therapy can lead to a high frequency of adverse reactions. The equine antitoxin available for use in humans has been reported to cause adverse reactions, such as anaphylaxis, in over 20% of treated patients (Lewis and Metzger, 1980). This problem has been circumvented in the development of a safer approach to the treatment of infant botulism using plasma isolated from human subjects repeatedly immunized with pentavalent toxoid. Equine antitoxin is not used as a treatment for infant botulism due to the high risk of serious adverse reactions and the possibility of long-term sensitization to horse serum-based therapeutics (Arnon, 1998). An antiserum product termed BabyBIG (botulism immune globulin), derived from human volunteers immunized with pentavalent toxoid, is available for infant botulism patients. Intravenous BabyBIG therapy has proven extremely effective in counteracting the toxic effects of *C. botulinum* colonization in infants and in avoiding the risk of adverse reactions to equine antitoxin. It is also most effective when administered within 24 h of a high-dose aerosol exposure to the toxin (Gelzleichter et al., 1998a,b).

Vaccines

There are as yet no FDA-approved vaccines to prevent botulism. An investigational pentavalent botulinum toxoid (PBT) product, developed at Fort Detrick, Maryland, is available for persons at risk for botulism (i.e., laboratory workers and soldiers). While determined to be safe and immunogenic, PBT is not useful, nor is it recommended, for post-exposure prophylaxis. Antitoxin titers do not develop until a month after the third dose in the vaccine schedule. PBT is reserved for employees at high risk for BoNT exposure, not for the general population. Several factors limit the usefulness of PBT as a vaccine for inoculating the general population. These include a declining potency and immunogenicity in recent years, the need to take multiple doses to maintain titers, and the limited supply of the vaccine.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The toxicity of botulinum toxins leading to paralysis is due to their ability to block ACh release from peripheral cholinergic nerve endings (Simpson, 2004). Once

ingested or inhaled, the toxin binds to epithelial cells, transports to target tissues via the circulatory system, targets the NMJ, and penetrates cellular and intracellular membranes. BoNTs bind to the lipid bilayer of the neuronal cell surface, gain access by receptor-mediated endocytosis, and cleave polypeptides involved in exocytosis of ACh. As a result, botulism leads to a descending flaccid paralysis, starting usually in the bulbar musculature to involve deficits in sight, speech, and swallowing. Paralysis eventually progresses beyond CN palsies to include generalized muscle weakness and loss of critical accessory muscles of respiration. If untreated, death is inevitable from airway obstruction secondary to paralysis of pharyngeal, diaphragm, and accessory respiratory muscles, as well as loss of the protective gag reflex.

The CDC-recommended therapy for the public is a trivalent equine antitoxin against types A, B, and E. In cases of exposure to other BoNT serotypes, the US Army can provide an investigational heptavalent (ABCDEFG) antitoxin. However, the antitoxins are in limited supply and would need to be retrieved from stockpiles. Therefore, the development of safe and effective post-exposure therapeutic compounds for BoNT intoxication is of paramount importance to serve the requirements of the military and civilian populations. In conjunction with drug discovery efforts, there is a parallel exigency to develop appropriate animal models to test the usefulness of various strategies for protection against BoNT intoxication.

Development of Animal Model Test Systems

Inadequacies of Current Animal Model Test Systems

Currently, a large number of animal models (mice, rats, guinea pigs, rabbits, and nonhuman primates) have been used for BoNT research, and it is not clear which species is the most appropriate. This is especially problematic since there are marked species differences in the relative potencies of the different serotypes and in their latency of action (the effect of BoNT/B in mice, rabbits, or guinea pigs versus rats; Erdal et al., 1995; Hilmas et al., 2006a). Mice, in particular, are desirable in BoNT research because they offer the most favorable balance between the scientific needs of the experiment and consistency with the existing literature. A variety of mouse strains and sexes have been used for other BoNT studies. The mouse LD_{50} is still used to quantitate the purity of BoNT batches and is the basis of the international standard used in serum neutralization assays of BoNT antitoxin. The mouse phrenic nerve–hemidiaphragm assay has been used to measure the effect of BoNTs on skeletal muscle contraction, and the doses necessary for inhibition are well characterized. The mouse has further advantages over other rodent species like rats.

Rats are not a valuable test system for BoNTs, as they are widely recognized as being insensitive to serotype B (Verderio et al., 2006). On the other hand, skeletal muscles of CD-1 mice, Hartley guinea pigs, and New Zealand white rabbits have similarities to humans, in that their muscles are sensitive to serotypes A, B, C, D, and E (Hilmas et al., 2006b). *In vivo* and *in vitro* physiological assessments of BoNT action in rat have also proved to show inconsistent and erroneous results. *In vivo* experiments using the rat extensor digitorum longus (EDL) muscle assay showed sensitivities of rat muscle to the B serotype at low doses (10 MU, corresponding to approximately 1–10 pM) (Adler et al., 1996), despite the wide body of literature on the rat to the contrary. In addition, *ex vivo* rat phrenic nerve–hemidiaphragm preparations are insensitive to BoNT/B, even at very high concentrations in the nanomolar range (Williams et al., 2007).

Another physiological model to evaluate therapeutic candidates against BoNT intoxication is the rat toe spread assay. The rat toe spread assay is problematic as a model test system, however. First, it will not allow for the evaluation of therapeutic candidates against the B serotype since rats are insensitive to BoNT/B. Second, the rat toe spread assay does not involve focal application of BoNT; neighboring muscles are paralyzed due to local diffusion of toxin from the site of i.m. injection. Toe spread in the rat is mediated predominantly by digiti minimi abductor muscles and to a lesser extent by the EDL, the actual muscle injected in the assay. Intramuscular injection of rat EDLs with BoNT will primarily paralyze the EDL and, to a lesser extent, the digiti mini muscles, the true abductors of toe spread, by local diffusion. Therefore, EDL muscles injected with BoNTs would tend to show an erroneously early recovery of toe spread as the primary effectors of toe spread recover sooner compared to injected EDL muscles. To date, there is no acceptable *in vivo* model to test the efficacy of inhibitory compounds.

Advantages of the Mouse Hemidiaphragm Assay

Current approaches to the inhibition of BoNT activity involve a number of strategies, each with potential advantages and disadvantages. Ultimately, model test systems that can incorporate each of these potential approaches are needed to evaluate the relative merit of potential therapeutic compounds. Since the presynaptic terminal is the primary target for BoNTs, a test system based on toxin action at presynaptic terminals is indicated. Such systems should permit testing of all relevant aspects of toxin (internalization, activity, and overcoming the inhibition of transmitter release), should be simple and reliable and should permit rapid evaluation of novel therapeutics or their precursor compounds.

Due to the high sensitivity of mammalian synapses to the actions of BoNTs, due in part to the presence

of high-affinity binding sites for toxin on the cell surface and to the intracellular presence of the appropriate enzymatic substrates, the test model systems should be of mammalian origin. Muscle is the ideal test system for BoNT since it is the most sensitive *in vivo* target for neurotoxin action. In addition, inhibition of the diaphragm muscle is the proximal cause of death in botulism (Simpson, 1986). Furthermore, a positive result with BoNT on muscle implies that the toxin is correctly folded and the binding, catalytic, and translocation domains are all intact. Enzyme-linked immunosorbent assays (ELISAs), on the other hand, detect only components of the toxin and may provide positive results when the toxin has in fact lost its ability to intoxicate (Kalb et al., 2005). The mouse phrenic nerve–hemidiaphragm assay is a favorable model test system to evaluate therapeutics against BoNT-induced paralysis.

Anthrax

Corey J. Hilmas and Jaime Anderson

INTRODUCTION

Anthrax is a virulent, contagious, and potentially fatal disease. The first accounts of anthrax infection were written by the Roman poet Vergil in early antiquity. Although its lethal effects were ascribed to the actions of an exotoxin more than a half century ago, the pathogenesis and mechanism of anthrax toxicity continue to be refined. Depending on the route of exposure, anthrax can cause a different disease, including inhalational, cutaneous, and oral/ingestional forms. Anthrax infection involves a complex set of steps in its pathogenesis from spore uptake by immune cells, germination, transport to local lymph nodes, production of deadly toxins, systemic spread, and, ultimately, death of the host. The details of each step are continually being debated. Even today, debate ensues regarding the mechanisms of macrophage killing by the toxins and the importance of other cell types involved in toxin-induced fatality.

Although anthrax infection causes high numbers of bacilli and overt septicemia, it is the exotoxins that are responsible for the intoxicating symptoms and death. Birth of the molecular age in modern research led to the identification and enzymatic characterization of three proteins that constitute two anthrax exotoxins. These are the protective antigen (PA), edema factor (EF), and lethal factor (LF). A better understanding of the precise mechanisms of toxicity initiated by anthrax toxins will uncover many of the unsolved mysteries surrounding *Bacillus anthracis* infection. Moreover, nature's clever engineering will be evident from the sometimes contradictory actions of the spore form, vegetative bacilli, and bacterial toxins.

HISTORY

Anthrax has plagued humans and animals since early recorded history. Scholars have attributed several plagues in antiquity to anthrax. The Plague of Athens (430–427 BC) and two of the plagues of Egypt (the fifth (death of livestock) and sixth plagues (boils)) during the time of the Israelites' captivity have both been ascribed to outbreaks of anthrax (McSherry and Kilpatrick, 1992). Publius Vergilius Maro or Vergil (70–19 BC) provided the earliest, definitive, and detailed descriptions of an anthrax epidemic in his four-volume *Georgics*, a narrative on agriculture and animal husbandry (Sternbach, 2003). Vergil described the same disease ravaging sheep, horses, cattle, dogs, and various other animals. In addition to signs of toxicity, he provided insight into knowledge of how the disease was transmitted, namely wool. He even noted the virulent and contagious nature of anthrax, as well as its ability to spread to humans (Dirckx, 1981).

> The pelts of diseased animals were useless, and neither water nor fire could cleanse the taint from their flesh. The sheepmen could not shear the fleece, which was riddled with disease and corruption, nor did they dare even to touch the rotting strands. If anyone wore garments made from tainted wool, his limbs were soon attacked by inflamed papules and foul exudates. (Dirckx, 1981)

During the course of the next 1500 years, Europe witnessed sporadic outbreaks of anthrax as they occurred in fourteenth century Germany and seventeenth century central Europe and Russia. The disease was classified as anthrax or charbon malin (Morens, 2003) in 1769 by the French physician Nicholas Fournier (Fournier, 1769; Morens, 2003). The name is derived from the black eschar lesions, the hallmark of cutaneous infection. Fournier also noted a link between those who worked with raw animal hair or wool and an increased susceptibility to disease. In the eighteenth century, an epidemic destroyed half of the sheep in Europe, possible evidence that anthrax was a major problem. Inhalation anthrax became known in the Victorian era as woolsorters'

Handbook of Toxicology of Chemical Warfare Agents.
DOI: http://dx.doi.org/10.1016/B978-0-12-800159-2.00029-4

disease; however, infection was more often the result of contact with goat hair or alpaca than with wool.

In 1850, Pierre-Francoise Olive Rayer (Rayer, 1850) and Casimir-Joseph Davaine (Davaine, 1863) reported the presence of "small filiform bodies" in the blood of anthrax-infected sheep (Carter, 1988). By 1855, Franz Aloys Antoine Pollender confirmed this discovery and implicated their role in producing anthrax disease (Pollender, 1855). In 1858, Freidrich August Brauell noted the "bodies" to be absent from healthy animals or animals infected with diseases other than anthrax. Brauell also noted their inability to be transmitted from pregnant sheep to fetus (Brauell, 1857).

In the 1870s, Robert Koch, a Prussian physician, isolated the anthrax bacillus and traced the complete lifecycle using suspended-drop culture methods. Koch determined the bacillus could form spores that remained viable, even in hostile environments (Koch, 1876). Louis Pasteur provided demonstration of infectious disease transmission. He inoculated one cohort of cattle with live attenuated vaccine and a control cohort without vaccine. When all animals were injected with virulent anthrax, only the control cattle died.

Modern History: Weaponizing Anthrax and Terrorism

Research into the utilization of anthrax spores as a biological weapon began in the early twentieth century. During World War I, German development of *B. anthracis* and other disease-causing organisms gave rise to covert programs intended to infect livestock and animal feed to be exported to the Allies. These plans included contaminating feed for horses and cattle to be exported from the United States to England, infecting sheep from Romania to be exported to Russia, and exporting contaminated livestock from Argentina to various Allied nations (Merck, 1946; Hugh-Jones, 1992).

During World War II, the pace of anthrax and biological weapons research in general accelerated. Imperial Japan had a large, active bioweapons program that included a substantial anthrax component. The central Japanese research facility was located in Manchuria, known as Unit 731. It is believed that in excess of 10,000 prisoners of war died either by direct experimental exposure to *B. anthracis*, among other pathogens, or by execution after exposure (Harris, 1992, 1994). Much of the Japanese bioweapons research transitioned to the battlefield. Operations such as Nomonhan in 1939, where Japanese troops entered the Soviet Union to infect Russian herds, met with only partial success. As it turned out, Japanese troops were unprepared to operate in a biological weapons environment. Their actions resulted in many inadvertent friendly casualties (Harris, 1992).

The Allies were pursuing biological weapons programs at the same time as the Axis powers. In 1942, the United Kingdom conducted anthrax experiments off the coast of Scotland at Gruinard Island. British scientists working at the biological weapons laboratory at Porton Down had demonstrated the lethality and military utility of the bacillus. Spores persisted and remained theoretically capable of infection for decades afterwards. A subsequent decontamination effort took nearly 10 years to clean the island (Carter, 1992). The United States began developing anthrax as a biological weapon in 1943. A civilian agency, the War Reserve Service, constructed a research facility at Camp Detrick (later Fort Detrick in 1956) and conducted research on a number of pathogens, including *B. anthracis*.

In April and May 1979, an anthrax epidemic occurred in Sverdlovsk, a city of then 1.2 million people, 1,400 km east of Moscow. The Soviet medical community reported an outbreak in livestock south of the city, and human exposures by ingestion of infected meat and contact with diseased animals led to cases of gastrointestinal and cutaneous anthrax. According to Soviet medical reports, 96 cases of human anthrax were identified; of these, 79 were said to be gastrointestional and 17 were cutaneous. These cases resulted in 64 deaths, all reported to be gastrointestional exposures (Meselson et al., 1994). In 1986, the Soviet Union invited a group of American scientists to visit Russia and investigate the outbreak. In collaboration with the Russian clinicians who treated the victims, the panel concluded that the outbreak was the result of inhalation exposure attributable to the accidental release of an estimated 10 kg of military-grade anthrax from the Soviet military microbiological facility in Sverdlovsk. This event remains the largest documented outbreak of inhalation anthrax (Sternbach, 2003).

In 2001, the first case of intentional anthrax release in the United States occurred. In October and November of that year, 11 confirmed cases of inhalation anthrax, and 11 confirmed or suspected cases of cutaneous anthrax were reported in postal workers and others who handled mail that had been deliberately contaminated with anthrax spores (Abalakin et al., 1990). These contaminated letters were mailed anonymously to several news media and Federal government offices. The letters contained handwritten threats as well as cryptic references to the terrorist attacks on September 11 of that year. The anthrax spores were analyzed and determined to be of the "Ames" variety, the strain that originated in the United States and had been acquired by Army research institutes for vaccine development.

Anthrax remains both a serious public health hazard and a very real biological weapon threat. Deliberate release of an anthrax weapon in a populated area could have catastrophic implications. An economic model developed by the Centers for Disease Control

and Prevention (CDC) suggested a cost of $26.2 billion to treat 100,000 people exposed to anthrax (Kaufmann et al., 1997). A risk assessment, provided at the end of this chapter, serves to highlight the dangers of a realistic scenario involving anthrax spores.

EPIDEMIOLOGY

Persistence

B. anthracis can remain for extended periods of time in soil. The mechanism responsible for its persistence is unclear. Therefore, persistence may involve multiplication cycles and sporulation. It may involve multiplication of the organism in the soil or bacterial amplification in infected animals before soil contamination by the carcass. Spores may germinate simply on application of water to soil (Hanna and Ireland, 1999; Oncul et al., 2002).

Infection

Infection typically results from herbivores grazing on soil or feed contaminated with spores. Oral consumption may produce oropharyngeal or gastrointestinal infection, an invariably fatal condition. Terminally ill herbivores generally bleed from the nose, mouth, and bowel, resulting in further contamination of the soil or drinking source (Shafazand et al., 1999). Although the actual number of cells or spores shed by an infected animal is unknown, studies have shown that counts of 10^4–10^6 spores/g of soil can be found near infected carcasses (Turnbull et al., 1998).

Dissemination

Dissemination of anthrax spores may result from biting flies or vultures (De Vos, 1990). Flies and mosquitoes contaminated with the vegetative cells, as a result of feeding on blood, can remain infectious for hours. The infectious material is deposited onto leaves through defecation, leading to contamination of herbivore species such as cattle, sheep, horses, and goats. Vultures often feed on contaminated carcasses and disseminate the organism to other birds or common drinking sources shared by various animals.

Forms of Anthrax Disease

Anthrax in humans is associated with agricultural, horticultural, or industrial exposure to infected animals or animal products. Three forms of anthrax can be diagnosed in humans: cutaneous, gastrointestinal, and inhalational. Cutaneous anthrax infection can occur through handling of contaminated hides, wool, bones, and carcasses. Cutaneous anthrax is the most common form of natural human infection, consisting of more than 95% of anthrax cases, and is treatable if recognized early. Infection occurs as a result of direct contact with infected animals or animal products. The skin is typically damaged or abraded before establishment of successful skin lesions by the bacteria. The persons most at risk for a natural cutaneous exposure are industrial or agricultural workers, such as herders, butchers, slaughterhouse workers, or processing mill workers (Pile et al., 1998). Infection can also occur through an insect bite (Spencer, 2003). Although cutaneous anthrax is rarely fatal (mortality <1% in treated cases) (Anon, 2000), it can progress to a systemic infection with a mortality rate of 5% to 20% in untreated cases (Pile et al., 1998). In general, cutaneous anthrax is not as life-threatening as the inhalational form, which results in much higher mortality. However, it is still important to study dermal pathogenesis models, particularly because cutaneous anthrax cases may result from an aerosol release, a method most likely to be used by bioterrorists.

Inhalational anthrax may occur after inhaling aerosols of spores, formed from processing contaminated animal products (wool) or as the result of direct bioweaponization. Inhalational anthrax contributes to only 5% of all reported cases but is by far the most lethal form. The estimated mortality is approximately 90% in untreated patients (Meselson et al., 1994; Dixon et al., 1999; Friedlander, 1999; Atlas, 2002; Bales et al., 2002; Oncu et al., 2003). Inhalational anthrax is typically reported in industrial settings where animal products are handled in enclosed spaces, allowing for exposure to aerosolized spores. Individuals passing by these industrial facilities have been stricken with inhalational anthrax. In one study of 27 anthrax cases involving textile mills, 21 cases were cutaneous and six were inhalational. All but one of the inhalational cases was fatal. One case of inhalational anthrax occurred in a secretary at a goat hair–processing facility.

Gastrointestinal anthrax is far less common than inhalational anthrax, but the mortality rate is extremely high, from 50% to 75%, even with early treatment (Mansour-Ghanaei et al., 2002). Oropharyngeal or gastrointestinal forms of anthrax can result from ingestion of contaminated meat (Dixon et al., 1999; Friedlander, 1999; Atlas, 2002; Bales et al., 2002). Gastrointestinal anthrax has never been confirmed in the United States, but this may be the result of cases being unreported in rural communities, where physicians may not be aware of this form (Pile et al., 1998; Dixon et al., 1999; Friedlander, 1999; Shafazand et al., 1999; Atlas, 2002; Bales et al., 2002; Oncu et al., 2003). Two out of 53 persons in a 1998 Kazakhstan outbreak developed the gastrointestinal form, resulting from the consumption of contaminated raw meat. In Minnesota, several family members

consumed steer meat and fell ill with gastrointestinal symptoms (Bales et al., 2002). The meat was later confirmed to contain *B. anthracis*, but the bacteria could not be cultured to confirm the presence of the gastrointestinal pathogen. According to one case of a 15-year-old boy who was infected after ingesting half-cooked sheep meat, the incubation period for gastrointestinal anthrax varies from 2 to 5 days (Mansour-Ghanaei et al., 2002).

Worldwide, the annual incidence of human anthrax infection is estimated to be between 20,000 and 100,000 (Pile et al., 1998; Oncu et al., 2003). The majority are cutaneous anthrax. In the United States, less than one case is diagnosed per year, as compared with 127 cases per year diagnosed in the early twentieth century (Pile et al., 1998; Shafazand et al., 1999; Oncu et al., 2003). Occasionally, outbreaks of anthrax will occur as a result of breakdown in public health standards and practices or lack of public health services.

PATHOGENESIS

Overview

Themes common among all anthrax infections are the following: uptake by macrophages and other immune cells; germination to the vegetative form at or near the site of inoculation before transit to target tissues; time course of transport to target organs; organs targeted for toxicity; overwhelming septicemia; and release of soluble factors responsible for death. Two types of *B. anthracis* have been identified: a spore form and a vegetative form. Unless stated otherwise, the vegetative bacillus will be referred to as *B. anthracis* because this is the form that produces the deadly toxins; however, both forms are discussed at length. The spore form is essential for uptake by host cells.

Uptake of Spores

Anthrax infection typically results from entry of *B. anthracis* spores into the host through a minor abrasion, insect bite, ingestion of contaminated meat, or inhalation of airborne spores. These routes of exposure lead to cutaneous, intestinal/oropharyngeal, and inhalational anthrax diseases (Figure 29.1). Although *B. anthracis* is not categorized as an intracellular pathogen, it uses tissue macrophages as a sanctuary where the engulfed spores can germinate during the early phase of infection (Guidi-Rontani and Mock, 2002). Successful infection and eventual disease require uptake of spores. Although spores are resistant to phagosomal superoxide, they have evolved to recognize receptors contained on host phagocytic cells through their pathogen-associated molecular patterns (PAMPs). Whereas most studies have shown uptake of the bacterium by macrophages, one study showed that human dendritic cells can be triggered to internalize *B. anthracis* spores (Brittingham et al., 2005).

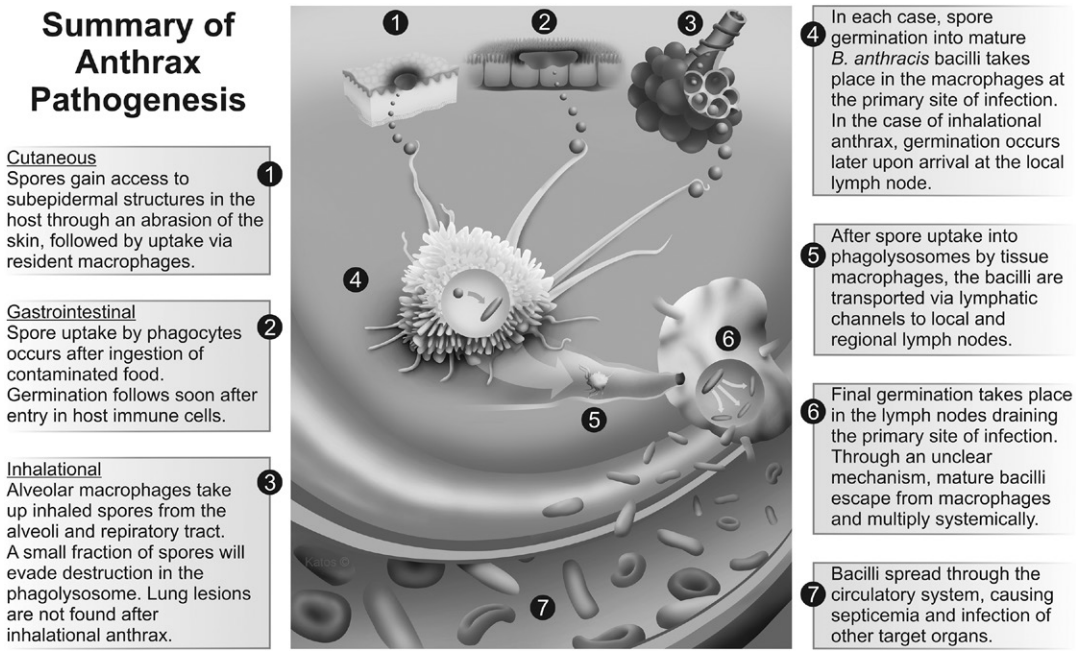

FIGURE 29.1 Overview of anthrax disease and pathogenesis. The steps of anthrax intoxication including spore uptake by macrophages, germination to the vegetative form, migration to lymph nodes, bacillus multiplication, release into the circulatory system, and septicemia are illustrated. *Source: Illustrations are copyright protected and printed with permission by Alexandre M. Katos.*

This led to the hypothesis that these cells may take part in bacterial transport to the lymph nodes, similar to macrophages. Spore PAMPs are antigenic determinants containing highly conserved molecules that interact with cell surface Toll-like receptors (TLRs) on tissue macrophages, dendritic cells, polymorphonuclear leukocytes (PMNs), and other cell types (Janeway and Medzhitov, 2002). PAMPs typically include lipopolysaccaride (LPS) from Gram-negative bacteria and lipoteichoic acid and peptidoglycan from the cell wall of Gram-positive bacteria such as *B. anthracis*. Anthrax spores can trigger a strong inflammatory response by activating TLR4 on antigen-presenting cells of the immune system at the entry site into the host (Hsu et al., 2004). In addition, anthrolysin O, a protein secreted by *B. anthracis*, is a potent agonist for TLR4 (Park et al., 2004).

Uptake via Lungs

Anthrax spores are approximately 1–2 μm in diameter, optimal for inhalation and deposition in the alveolar spaces (Brachman, 1980; Penn and Klotz, 1997). In the case of inhalational anthrax, inhaled spores reach the respiratory bronchioles and alveoli (Figure 29.2). Although most spores are internalized rapidly into phagolysosomes by resident macrophages in the alveolar space (Ross, 1957; Guidi-Rontani et al., 1999b), the exosporium layer of anthrax, discovered by Flügge (1886), prevents its degradation. It should be noted that the exosporium is not present on vegetative forms of anthrax bacteria and therefore only spores contain the antigenic determinants recognized by TLR4 receptors of immune cells. In any case, spores will escape destruction due to their resistance to superoxide and enzymes of the phagolysosome. Spore-bearing alveolar macrophages migrate along lymphatic channels to mediastinal, peribronchial, and tracheobronchial lymph nodes (Ross, 1957) while germinating *en route*.

Uptake via Skin

The cutaneous infection process initiates as a result of anthrax spores colonizing an abrasion in the skin (Figure 29.3). A small eruption or lesion develops into a painless, black eschar. Eschars usually develop within 2–5 days after exposure. During this stage of infection, low-level spore germination can occur at the primary site of infection, leading to localized edema and necrosis. Although this infection often remains localized, some patients experience systemic symptoms.

Systemic disease, a rare secondary occurrence of cutaneous anthrax, is likely attributable to phagocytosis by macrophages in the dermis that marginate out of lymphatic channels and blood capillaries (Figure 29.3). In cutaneous anthrax, germination typically occurs immediately inside the host macrophage. Macrophages

Katos.*

carrying *B. anthracis* cells migrate back into lymphatic ducts *en route* to regional lymph nodes draining the primary site of infection (Dixon et al., 1999). The anthrax bacilli spread through the blood and lymph and proliferate to high concentrations, creating acute septicemia.

Uptake via Gastrointestinal Route

The infection process of gastrointestinal anthrax starts with ingestion of spore-contaminated food/drink or ingestion of inhaled spores. In general, gastrointestinal anthrax is similar to cutaneous anthrax, but gastrointestinal anthrax occurs in the intestinal mucosa. As in cutaneous anthrax, the organisms probably invade the mucosa through a preexisting wound or lesion, or possibly through interaction with a cell surface receptor on epithelial cells. Presumably, the mucosal lining is the entry point for the endospores (Figure 29.4), but the exact germination location is yet unknown in cases of gastrointestinal anthrax infection. The bacteria may spread from the mucosal lesion to the lymphatic system by way of macrophages migrating to the primary site of infection. Germination can occur inside host macrophages after uptake before macrophage migration back to lymphatic channels draining to lymph nodes (Figure 29.4). Ulcer formation is a typical symptom during gastrointestinal anthrax, and ulcers may be present at various locations along the gastrointestinal tract from the oral cavity to the cecum. However, it is not known whether ulceration occurs only at sites of bacterial infection or if it is caused by the anthrax toxins and therefore has a less restricted occurrence (Dixon et al., 1999).

Spore Function

Several studies have examined the molecular mechanisms by which *B. anthracis* spores undergo phagocytosis, germination, and subsequent escape to mediate systemic infection. Time-lapse microscopy suggested that the number of spores per macrophage can affect whether any spores are able to outlast the macrophage's inhibitory action of the bacteria. Macrophages that have engulfed a larger number of spores are more likely to have a few that survive to germinate and become vegetative bacilli (Ruthel et al., 2004). Inside the macrophage, the spores must first avoid cellular nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activation. This enzyme, which is present in the phagosomal membrane, initiates the reduction of oxygen to superoxide anion through NADPH oxidation. The superoxide anion is further converted to other reactive oxygen species (ROS), including hydrogen peroxide. To date, no *B. anthracis* enzymes have been discovered that are involved in the removal of ROS (Guidi-Rontani and Mock, 2002).

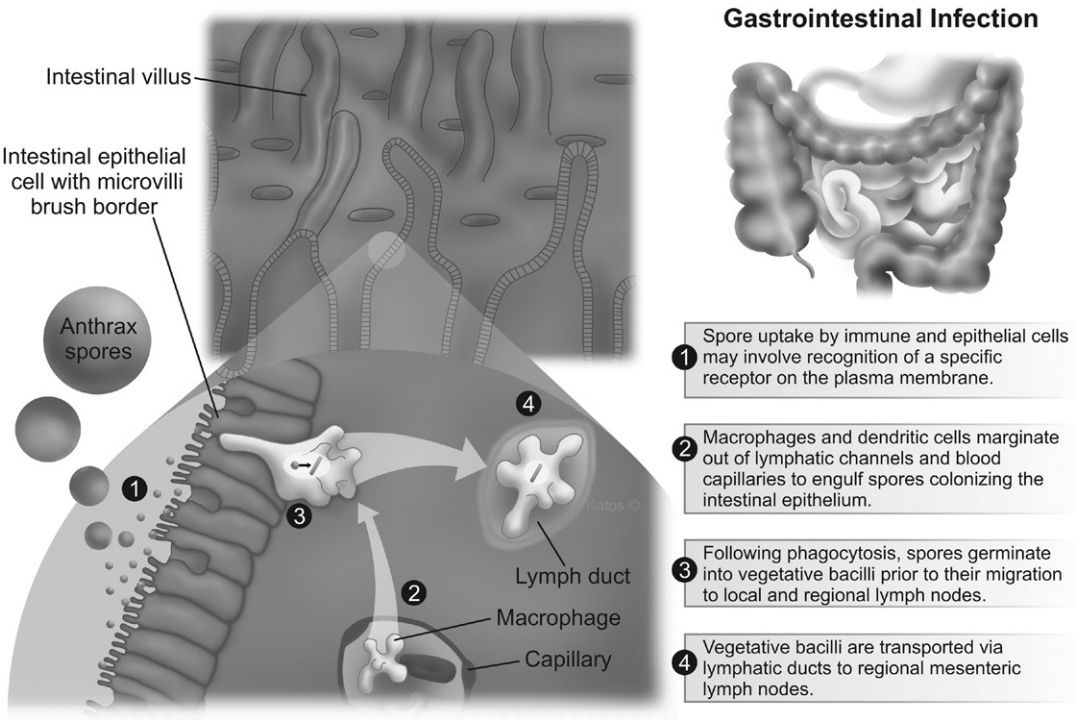

FIGURE 29.4 Spore uptake in gastrointestinal anthrax disease. The steps involving spore colonization of the gastrointestinal mucosa, uptake by phagocytes, germination, and lymphatic spread are illustrated. *Source: Illustrations are copyright protected and printed with permission by Alexandre M. Katos.*

After surviving the initial membrane oxidative burst, the anthrax spores must contend with the acid environment of the phagolysosome to further germinate and multiply. Several pathogens have shown an ability to evade phagolysosomal activity; however, the mechanism by which anthrax spores avoid hydrolysis in the phagolysosome is unclear (Guidi-Rontani and Mock, 2002).

Anthrax spores promote expression of interleukins (ILs) and other pro-inflammatory cytokines in macrophages and dendritic cells (Pickering et al., 2004). Macrophages are important mediators of the inflammatory response and produce tumor necrosis factor alpha (TNFα), IL-1β, and IL-6 in response to infection. Although some spores will be killed by immune cells, many will evade the host cell detection only to initiate germination. The purpose of promoting inflammation here by anthrax spores is to increase their chance for internalization by tissue macrophages and dendritic cells to germinate into the vegetative form of the bacteria (Welkos et al., 1989).

An intact mitogen-activated protein kinase (MAPK) cascade and pro-inflammatory response by macrophages is also necessary for host cell migration to regional lymph nodes and recruitment of additional macrophages to the primary site of infection. Without functional immune cells, the toxin would not be able to enter lymphatics or the general circulation. In fact, dendritic cells that engulf *B. anthracis* spores change their pattern of chemokine receptor expression. Specifically, they lose tissue-retaining receptors (CCR2 and CCR5) and upregulate lymph node homing receptors (CCR7 and CD11c) (Brittingham et al., 2005).

Time Course of Spore Germination

In cutaneous and gastrointestinal anthrax, spore germination takes place at or near the inoculation site after uptake by the macrophage or dendritic cell. It is the vegetative form, not the spore, that produces the deadly factors. After transformation to the vegetative bacilli, these bacteria are free to mediate toxicity at the inoculation site in skin and gastrointestinal tract (Beatty et al., 2003). In inhalational anthrax, germination does not occur until the spores have been transported to the local lymphatics and mediastinal lymph nodes (Riedel, 2005). In the case of inhalational anthrax, spores are not believed to germinate at the site of infection in the alveoli or bronchioles. Instead, they germinate *en route* or after migrating to local nodes of the lymphatic system.

Spore Germination

Although the anthrax endospore has no measurable metabolism, spore germination is a predictor of productive anthrax infection. Similar to endospores from other

species, anthrax spores seem to represent a biologically inert organism with the ability to transform into one of the most lethal organisms on earth. Germination inside the host immune cell is the key step toward this transformation from benign bystander to active infection. The spores have little or no water, no ATP production, no macromolecular synthesis, and no active enzymes. Thus, endospores can remain stable in the environment under adverse conditions for decades. Once inside a host cell, spores start to germinate and initiate early synchronous *de novo* expression of genes vital for infection as well as expression of genes necessary for vegetative growth (Hanna and Ireland, 1999; Oncul et al., 2002).

Several putative germination proteins have been identified (Guidi-Rontani et al., 1999a,b), but their roles in spore germination have yet to be clarified. L-alanine appears to be essential in initiating germination (Foster and Johnstone, 1990), but the mechanism that leads to spore germination is unclear. A germinant receptor locus (*ger S*) essential to *B. anthracis* germination has been identified; without it, the organism could not germinate in macrophages (Ireland and Hanna, 2002). Once the spore has germinated, the vegetative bacilli are free to synthesize deadly bacterial toxins; however, the precise manner in which vegetative bacilli or spores break free from immune cells is still poorly understood. A recently proposed model suggests that an interaction between anthrax toxin from newly germinated spores inside the phagolysosome of macrophages and anthrax toxin receptor 2 promotes escape of the bacilli from the cells (Banks et al., 2005).

Vegetative Anthrax and its Capsule

The role of the vegetative bacillus is in stark contrast to that of the spore form (Table 29.1). The vegetative form functions mainly to produce the deadly toxins lethal toxin (LT) and edema toxin (ET). Germination of *B. anthracis* within macrophages is closely followed by expression of the toxin genes (Guidi-Rontani et al., 1999a). *B. anthracis* contains no capsule *in vitro*, but capsule synthesis begins on host infection (Preisz, 1909). Host signals, including carbon dioxide concentrations greater than 5%, are thought to induce transcription of capsule and toxin genes (Uchida et al., 1997). *In vitro* studies by Ezzell and Abshire (1995) suggest that encapsulated vegetative cells appear within 30 min after germination *in vitro*. The capsule enables vegetative forms to survive as extracellular pathogens and to avoid phagocytosis by macrophages (Guidi-Rontani and Mock, 2002). *B. anthracis* isolates lacking capsules that are significantly less virulent. Vegetative cells move through the bloodstream and lymphatics to cause systemic infection.

TABLE 29.1 Differences Between Spore and Vegetative Forms of *B. anthracis*

Spore Form	Vegetative Form
• Contains an exosporium which promotes immune host detection and uptake • Exosporium promotes internalization by macrophages • Requires phagocytosis, internalization by macrophages, and germination to become pathogenic • Does not produce anthrax toxins • Requires target host cells to remain intact so they can circulate to local lymph nodes • Promotes TNF-α and cytokine production • Enhances host inflammatory response • Can remain dormant for months	• Contains poly-D-glutamic acid capsule, essential for virulence and avoidance of immune detection • Capsule avoids phagocytosis by macrophages • Survives as extracellular pathogen within the body of the host • Produces LT and ET to kill the target host cell • Kills the host cell • Inhibits TNF-α and cytokines • Suppresses the immune system • Unable to survive outside the host for any appreciable length of time

Systemic Infection and Septicemia

Significant numbers of bacilli in the blood are characteristic of the late stages of infection (Shafazand et al., 1999; Atlas, 2002; Oncu et al., 2003; Riedel, 2005). Without an activated immune response due to the release of soluble anthrax toxins that suppress immune function, *B. anthracis* is free to multiply to high concentrations. It is currently unclear whether *B. anthracis* multiplies within the macrophage, as some studies suggest, or the blood stream. Cultured blood from infected rabbits and guinea pigs suggest a continuous increase in bacterial counts until the final hours of life; numbers increase sharply to 10^7 and 10^9 organisms per milliliter of blood for rabbits (Bloom et al., 1947) and guinea pigs (Smith and Keppie, 1954), respectively. Death was shown to be dependent on bacteremia, but death was not shown to be a consequence of mechanical obstruction by large bacterial counts. Regardless of the route of infection, systemic spread results in similar colonization. The lungs and gastrointestinal tract are particular targets of system infection by mature bacilli, with the spleen, brain, liver, and almost any other organ being colonized within hours or days (Riedel, 2005). *B. anthracis* has been isolated from stool specimens of both animals and humans, reflecting its presence in the bowel (Beatty et al., 2003). Although septicemia is important, death is the direct result of soluble factors (discussed later) secreted by the vegetative

bacilli that weaken the immune response and initiate cell death.

Anthrax Infection Cycle

An infection cycle for *B. anthracis* has been proposed previously (Hanna and Ireland, 1999). Phagocytosis of spores by macrophages, germination, vegetative cell proliferation, and toxin release occur within hours after exposure to *B. anthracis* in a productive infection. During the middle stages of infection, the bacilli grow extracellularly and express toxins and other virulence factors. During the final stages of infection, the bacilli, having depleted nutrients from the host, form endospores, which return to the environment for the next cycle of infection (Hanna and Ireland, 1999; Oncul et al., 2002). The precise sequence of events leading to successful establishment of infection is not completely understood. After germination, anthrax bacilli multiply in the lymph nodes, causing an immediate lymphadenitis and hemorrhagic mediastinitis, and spread throughout the body via the circulatory system (Albrink, 1961).

Release of Soluble Factors

B. anthracis possesses four known virulence factors, including an antiphagocytic capsule of the vegetative form, LF (90 kDa), EF(89 kDa), and a PA (83 kDa). These virulence factors acting together play a key role in pathogenesis but are not toxic when present individually. In combination, PA, LF, and EF induce a dangerous cascade of events on cell entry. As early as 1953, toxic factors have been implicated as the cause of death from anthrax infection (Smith et al., 1953, 1955). It has since been shown that these three factors combine to form the two protein exotoxins of anthrax LT and ET.

PA binds to an ill-defined cell receptor/lipid raft, mediating the entry of the other two components inside the cytoplasm via the endosomal pathway. EF is a Ca^{2+}/calmodulin-dependent adenylate cyclase involved in producing a generalized accumulation of fluid into the interstitium, characteristic of anthrax. LF is a proteolytic enzyme involved in the inactivation of MAPK kinases (MAPKK), key players in secondary messenger signal transduction cascades. Both toxins are translocated into the cytosol of target cells by way of endosomes through a pore formed from a heptamer of PA molecules. They interfere with vital cellular responses to bacterial infection, disabling host immunity and promoting bacterial dissemination. As the disease progresses, the toxins accumulate to higher levels, causing respiratory distress, shock, widespread hemorrhage, and death.

TOXICOKINETICS

Inhalational Anthrax

To date, mice, rats, guinea pigs, rabbits, nonhuman primates, dogs, swine, and sheep have been used in inhalational animal model studies for *B. anthracis*. Routes of administration have included aerosol, intranasal, and intratracheal methods. In addition, various animal species differ in their natural resistance to infection (Welkos and Friedlander, 1988). Some of the most common findings in human inhalational anthrax concern the respiratory tract. A majority of patients experience mediastinal widening (70%), pulmonary infiltrates (70%), and pleural effusion (80%). These signs demarcate inhalational anthrax cases from influenza-like illnesses (Oncu et al., 2003). Pathological findings from inhalational anthrax patients in a bioterrorism-related outbreak cited hemorrhage and necrosis in mediastinal lymph nodes, hemorrhage or inflammation of the pleurae and interhilar septae, and prominent intra-alveolar macrophages or inflammation in the lung parenchyma. There were no skin lesions. Bacilli were located in the lung, mediastinal tissues, and thoracic tissues, as identified by staining (Guarner et al., 2003).

Early studies with mice were unable to identify the vegetative form of *B. anthracis* in the alveolar walls of the lungs. Aerosol exposure was achieved by exposing mice (mouse strain unreported) to clouds of spores (Albrink, 1961). Other aerosol studies involving mouse models indicated evidence of the spore form in lung sections but not the vegetative form (Barnes, 1947). The Barnes study highlighted the fact that not all of an aerosolized dose ends up in the lungs; spores can be swallowed to pass through or infect the alimentary tract.

Intratracheal administration of anthrax has demonstrated a respiratory lesion in mice (Lyons et al., 2004). Inoculation of the Ames strain (5,000 versus 10,000 versus 50,000 spores) in Bagg Albino (BALB)/c mice does not produce signs of early pulmonary lesions. Significant numbers of anthrax colony-forming units were found in lung-associated lymph nodes harvested 5 h after inoculation in a dose-dependent manner (Lyons et al., 2004). Airway damage did occur 24 h after inoculation with all anthrax doses; signs of toxicity include widespread edema vacuole formation, degeneration, airway epithelial cell sloughing, and necrosis. After 48 h, bacterial rods (vegetative form) were located within alveolar capillaries, suggesting active bacterial uptake from the respiratory tract.

Drysdale et al. (2005) investigated the role of *B. anthracis* capsule in uptake from the respiratory tract. These investigators deleted the capsule operon *capBCAD* in

mutant strains of *B. anthracis* and inoculated female BALB/c mice intratracheally with approximately 4×10^4 mutant spores. All capsule-deficient strains germinated in the lungs (Drysdale et al., 2005), indicating no role for the capsule at this particular stage in pathogenesis. This contradicts the accepted hypothesis that germination takes place in the lymph nodes for inhalational anthrax exposure.

In the only intranasal mouse model, Guidi-Rontani et al. (1999b) demonstrated uptake of *B. anthracis* by alveolar macrophages. A dose of 2.5×10^7 Sterne strain spores was administered to Balb/c mice. Bronchial alveolar lavage (BAL) fluids were subsequently collected at 1, 3, and 24 h after inoculation. Germination of spores in the fluid was assessed by exposing the material to heat (65°C) for 30 min. Ungerminated spores are resistant to this treatment. Germination was significantly evident in the alveolar macrophage fraction of BAL fluid by 24 h after inoculation. Therefore, the uptake of bacteria by alveolar macrophages occurs rapidly in this system (Guidi-Rontani et al., 1999b).

To date, evidence of respiratory lesions in humans does not exist. Spore cloud exposure studies by Ross (1957) determined the pathogenicity of anthrax in guinea pigs. Guinea pigs were exposed to high numbers of M.36 strain spores for 20 min and killed at various time points to assess spore location. After 1 h, spores were found in alveolar macrophages. Free spores were not, however, isolated from surrounding lymph nodes at this early time point. However, after 18–24 h, bacilli were observed throughout the lymphatic system. The results of these studies led to the idea that spore germination takes place in regional lymphatic nodes (i.e., tracheobronchial nodes) before spreading to the rest of the body via the blood circulatory system (Ross, 1957).

In a guinea pig/aerosol model, 6×10^5 spores of the vaccine anthrax strain STI were detected in the lungs 1 h after infection from a dose of 2.43×10^6 spores. *B. anthracis* was not detectable in the tracheobronchial lymph nodes until 2 days after infection. On day 36 after infection, lung levels were down to 10^3 spores and tracheobronchial lymph nodes were again negative.

Cutaneous Anthrax

Dermal *B. anthracis* pathogenesis has been studied in mice, rats, hamsters, rabbits, guinea pigs, nonhuman primates, and dogs. Several methods of inoculation have been tested, including subcutaneous, intradermal, epicutaneous, footpad, and scarification. Data on uptake/absorption from the skin, persistence in the circulation, transit to target tissues, and lethality are discussed. The only animal models that have been used in bacterial uptake studies after dermal inoculation to date are the mouse and rabbit.

An extensive study of the interaction of *B. anthracis* with mouse skin after epicutaneous inoculation was conducted by Hahn et al. (2005). C57BL/6 and DBA/2 mice were inoculated with the Sterne strain. Epicutaneous inoculations were performed by applying an inoculum of 10^7 spores onto the shaved, tape-stripped, or abraded area of the mouse. A difference in foci development was observed, according to skin treatment before inoculation. Shaved-only inoculation sites did not have foci of vegetative bacilli. In contrast, abraded inoculation sites had readily apparent foci. Germination and proliferation occurred at the skin surface and in the epidermis and hair follicles. Hair follicles had deeper foci of infection, more than 200 μm below the skin surface. In animals inoculated with 2×10^8 spores onto unshaved skin, foci appeared only in the hair follicles and not in the epidermis or dermis (Hahn et al., 2005). According to reviews of human infection, germination and proliferation also occur, to some degree, at the site of inoculation (Cranmer and Martinez, 2001). Proliferation also occurs in the draining lymph nodes near the site of inoculation (Anon, 2000). Zaucha et al. (1998) subcutaneously inoculated New Zealand White rabbits with $43–1.56 \times 10^5$ CFU of the Ames strain of *B. anthracis*. At the inoculation site, the main sign of bacterial uptake involved dermal and subcutaneous edema, signs observed in human cutaneous anthrax.

Gastrointestinal Anthrax

Despite the rarity in documented human cases of gastrointestinal anthrax (Beatty et al., 2003), this form is common in underdeveloped areas of the world where infected carcasses are consumed (Sirisanthana and Brown, 2002). Gastrointestinal anthrax infection carries a 25% to 60% mortality rate (Mansour-Ghanaei et al., 2002). Gastrointestinal anthrax can be divided into intestinal and oropharyngeal forms. In the intestinal form, after an incubation period of 1–7 days, there is severe abdominal pain, hematemesis, melena and/or hematochezia, ascites, and watery diarrhea. Intestinal anthrax carries a greater risk of mortality. In contrast, the milder oropharyngeal form can be contracted after consumption of infected cattle and water buffalo. In this form, there is marked neck edema and ulcerative lesions in the oropharynx. Clinical signs include nausea, loss of appetite, emesis, and fever. In one natural outbreak of oropharyngeal anthrax, only 3 out of 24 patients died (Anon, 2000; Pile et al., 1998).

Limited data regarding the pathogenesis of gastrointestinal *B. anthracis* infection in any animal model system are available. Barnes (1947) observed that 1 h after inhalational exposure to anthrax spores, the majority of spores were found in the stomach. Therefore, regardless of the route of exposure, there is a high risk of spores

transiting to the gastrointestinal tract. Unfortunately, further pathophysiology was absent from the study.

The guinea pig is the only animal model to date for which there are data after oral exposure. There is a need for more oral animal models of *B. anthracis* infection. Gastrointestinal anthrax is perhaps far underdiagnosed in humans; however, it remains an important disease because of the significant risk of ingesting spores after exposure to inhalation anthrax. Because there are limited data regarding pathogenesis of gastrointestinal anthrax in humans, evaluation of future animal models will be difficult. Stability of the organism as a function of pH in the various compartments of the gastrointestinal tract, method of inoculation, presence of stabilizers, and gastrointestinal physiology will become important factors to analyze for oral anthrax.

Aloni-Grinstein et al. (2005) assessed the stability of spores and vegetative cells in the gastric fluid and gastrointestinal tract. Female Hartley guinea pigs were administered 5×10^9 spores or 5×10^8 vegetative cells of the anthrax MASC-13 variety orally. This vaccine strain is nontoxigenic, devoid of capsule, and lacking a nonfunctional form of PA. Bacteria in feces and gastric fluid were charted according to days after ingestion. Gastric fluid incubations were conducted at 37°C, with fluid taken from the guinea pig stomach. Anthrax spores exhibited much greater stability to the harsh environment created by the gastric mucosa than their alternate form. Vegetative cells were barely detectable on day 1 after ingestion in feces and gastric fluid. There are no animal models or human studies that have examined bacterial persistence in circulation and in transit to target tissues after oral exposure to *B. anthracis*. Similarly, there are no animal models that examine oral lethality, clinical signs, or epidemiology after oral exposure.

MECHANISM OF TOXICITY

The significance of the capsule in virulence was demonstrated early last century when anthrax strains lacking a capsule were shown to be avirulent (Bail and Weil, 1911; Bail, cited by Sterne, 1959). The genes encoding synthesis of the capsule were found to be encoded on a 110-kilobase (kb) plasmid. Anthrax strains lacking the plasmid no longer produced the capsule and were attenuated (Ivins et al., 1986), confirming the role of the capsule in pathogenesis.

The capsule contains a polymer of poly-D-glutamic acid, conferring resistance to phagocytosis by macrophages (Keppie et al., 1963). This linear polymer of the capsule is weakly immunogenic. The negatively charged capsule enables the bacterium to inhibit phagocytosis of bacilli by macrophages (Sterne, 1937; Keppie et al., 1963). In conjunction with LF and EF, whose target cells include macrophages, dendritic cells, and other immune cells, the capsule allows *B. anthracis* to grow virtually unimpeded in the infected host. The capsule functions as a "one-way" filter, allowing bacilli to diffuse the other three virulence factors through the capsule, resulting in host cell intoxication without causing self-harm.

Protective Antigen

B. anthracis secretes three plasmid-encoded soluble toxin proteins collectively referred to as anthrax toxin; these are PA, LF, and EF. LF and EF function individually and in combination as catalytic enzymes in susceptible host cells. In an unusual twist of nature, they both have evolved to share PA as a common receptor binding moiety for translocation into the cytosol of the host. PA is a dominant component of the three-part protein toxin secreted by *B. anthracis* (Petosa et al., 1997). The mature form of PA, a secreted 735-amino acid protein, has a molecular weight of 83 kDa. The ribbon structure is illustrated in Figure 29.5 along with a detailed description of its functional domains. PA forms a membrane-insertion heptamer that translocates other toxic enzymes (EF and LF) into the cytosol of host cells.

The mechanisms by which *B. anthracis* toxins work at the cellular level are illustrated in Figure 29.6 and are described elsewhere in great detail (Duesbery and Vande Woude, 1999; Mock and Fouet, 2001). In this model, PA released from the vegetative form of the bacilli binds to cell surface receptors, namely tumor endothelium marker (TEM) 8 and capillary morphogenesis protein (CMG) 2, which are expressed as different isoforms by many cell types, including immune cells (Collier and Young, 2003; Baldari et al., 2006). On binding to the receptor, PA is cleaved into a 20-kDa C-terminal domain (PA_{20}) and a 63-kDa fragment (PA_{63}) by furin or similar host cell surface–associated protease (Molloy et al., 1992). The PA_{20} fragment is released, resulting in spontaneous oligomerization of truncated PA (PA_{63}) into heptamers that bind to EF and LF. It was once thought that a PA heptamer complex may bind up to seven molecules of LF and/or EF (Duesbery et al., 1998; Mock and Fouet, 2001); however, evidence suggests that LF or EF binding sites on the PA_{63} heptamer span the interface between adjacent PA_{67} subunits. Therefore, it is believed that a single heptamer can interact with a maximum of three EF or LF molecules (Baldari et al., 2006). The heptamer PA-LF and PA-EF complexes enter lipid rafts, illustrated as a shaded disc in Figure 29.6, in the membrane. Binding and oligomerization trigger a receptor-mediated endocytotic event followed by internalization of the hetero-oligomeric toxin complex in a membrane-bound vesicle via clathrin-dependent, receptor-mediated endocytosis. The internalized vesicle becomes an acidic endosome. The acidic pH of the endosome triggers a conformational

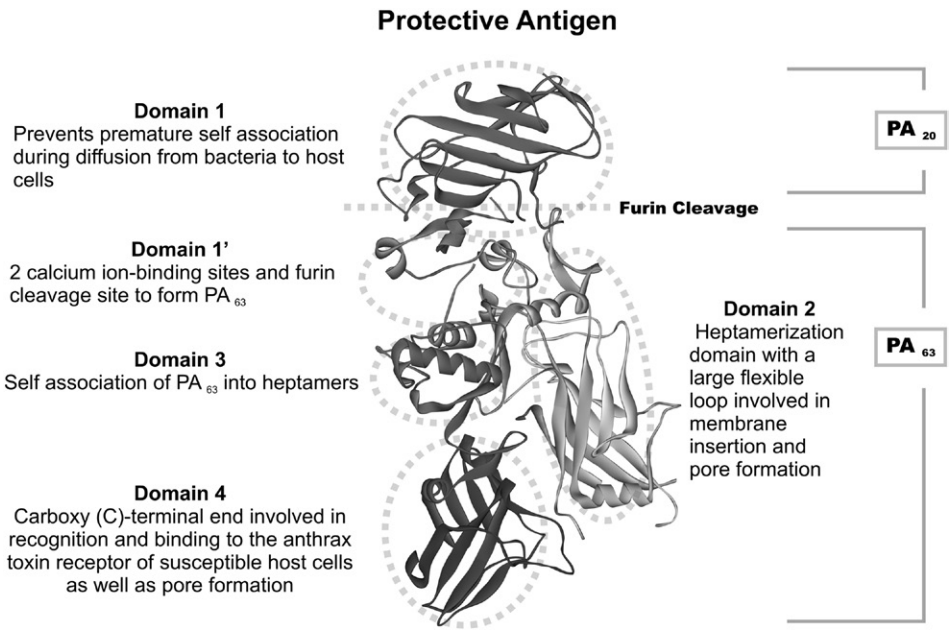

FIGURE 29.5 Three-dimensional ribbon structure of PA. PA, a 83-kDa protein with 735 residues, is organized into antiparallel β-sheets comprising four major domains (Petosa et al., 1997). Domain 1 contains the first 258 residues and the furin enzyme cleavage site between residues 164 and 167. Before translocation of soluble factors into the host cell, PA is cleaved by a cell-surface protease (furin enzyme) into PA20 (20-kDa portion containing residues 1–167) and PA63. PA20 is responsible for maintaining PA as a soluble monomer and preventing premature self-association (Collier and Young, 2003). Domain 1′ (residues 168–258) designates the N-terminal end of PA63. This domain contains two charged calcium (Ca^{2+}) atoms that function to maintain PA63 in a conformation capable of self-association into heptamers and binding to the host ligand anthrax toxin receptor (Petosa et al., 1997; Collier and Young, 2003; Gao-Sheridan et al., 2003). Domain 2, comprising residues 259–487, is illustrated with a β-barrel core structure and large flexible loops. This structure enables membrane insertion and pore formation (Petosa et al., 1997; Benson et al., 1998). Domain 3, comprising residues 488–595, is involved in self-association of PA63 into heptamers. Domain 4 contains the remaining C-terminal end of PA63 (residues 596–735) and binds to the anthrax toxin receptor on the host cell membrane (Singh et al., 1991; Collier and Young, 2003). The various domains of PA63 enable the protein anchor to the plasma membrane of the host, form heptamers, bind EF or LF, and translocate these soluble factors into the cytosol through a pore. The structure of PA was provided free of copyright restrictions from the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank (PDB) (Petosa et al., 1997; PDB ID: 1acc; Berman et al., 2000) and rendered using Accelrys DS Visualizer 2.0 software.

change in the complex, leading to insertion of a flexible loop of each PA molecule into the lipid bilayer to form a pore. Formation of the pore allows for translocation of LF and EF out of the late endosome and into the cytoplasm of the host cell. Once inside the cytoplasm, LF and EF reach their respective targets.

Structure and Activity: Edema factor (EF)

EF (89 kDa) is a calmodulin (CaM)-dependent adenylate cyclase, increasing intracellular cyclic adenosine monophosphate (cAMP) levels in the infected host cell cytosol. The first 261 N-terminal residues of EF are responsible for CaM binding (Duesbery and Vande Woude, 1999). The catalytic domain resides in amino acids 265–570 of the EF peptide sequence (Escuyer et al., 1988). The ribbon structure of EF is illustrated in Figure 29.7. The N-terminal sequence of EF is highly conserved to a similar region in LF; this domain is essential for binding to PA. Fusion of this highly conserved N-terminal sequence to other toxins, such as Shiga and diphtheria, can cause toxic effects in mammalian cells (Arora and Leppla, 1994). ET, the combination of PA and EF, causes edema when injected into the skin of experimental animals (Stanley and Smith, 1961). Injection of EF alone, in contrast, has no toxic activity.

Structure and Activity: Lethal Factor (LF)

LF has a molecular weight of 90 kDA and is one of the key agents of anthrax disease. The structure of LF is illustrated in Figure 29.8. LF consists of several domains, including a PA-binding domain, a Zn^{2+}-binding domain, an imperfect repeat region, and a catalytic domain. LF functions as a highly specific Zn^{2+}-binding metalloprotease that can cleave MAPKKs near their amino (N)-termini. This cleavage reaction can potentially inactivate one or more host cellular signaling pathways (Pannifer et al., 2001). Similar to EF, the LF N-terminal residues (1–254) serve as the binding domain for PA (Arora and Leppla, 1994). Adjacent to the PA-binding domain is a region of imperfect repeats containing 19

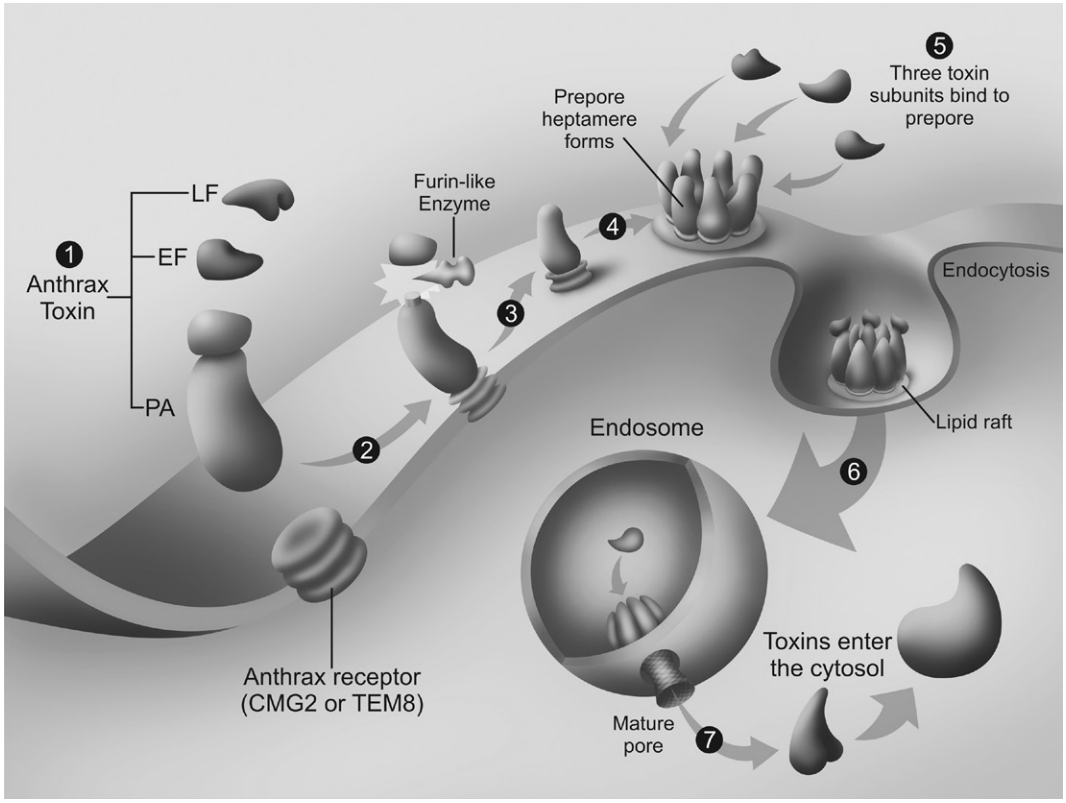

FIGURE 29.6 Anthrax toxin entry. Cellular entry of LF and EF into susceptible host cells involves an unusual mechanism for sharing PA. Binding of PA to the host cell, cleavage to form PA63, heptamerization of PA in the plasma membrane, organization into lipid rafts, binding of EF and LF to PA, internalization, PA pore formation, and translocation of anthrax-soluble factors across the vesicle membrane are illustrated. *Source: Illustrations are copyright protected and printed with permission by Alexandre M. Katos.*

amino acids each. This region was demonstrated to be essential for toxic activity. Deletion of the first of the four imperfect repeats of residues 308–383 eliminated LF toxicity. The LF catalytic domain resides in the C-terminus, where a zinc-metalloprotease consensus sequence has been identified within residues 686–692 (Klimpel et al., 1994). The zinc metalloprotease activity is responsible for the cytotoxicity of LF. LF binds Zn^{2+} (Klimpel et al., 1994), and mutations in LF that decrease zinc binding are poorly cytotoxic to cultured cells (Klimpel et al., 1994).

LF interferes in the MAPK pathway, which relays environmental signals to the machinery required for transcription in the nucleus and therefore modulates gene expression and protein synthesis. Specifically, LF inhibits MAPKKs; the identified substrates for LF enzymatic activity are MAPKK1, MAPKK2, MAPKK3 (Duesbery et al., 1998; Pellizzari et al., 1999), MAPKK4, MAPKK6, and MAPKK7 (Vitale et al., 2000). MAPKK5 has never been demonstrated to be cleaved by LF. MAPKK cleavage occurs within the N-terminal proline-rich region preceding the kinase domain, subsequently inhibiting protein–protein interactions essential for assembly of host cell signaling complexes (Hammond and Hanna, 1998).

Mechanism of Toxicity: Edema Toxin (ET)

ET does not produce major tissue damage. In fact, its major role is to impair phagocyte function (Leppla, 2000). This is consistent with other toxins that function to elevate cAMP concentrations. ET inhibits phagocytosis of spores by human PMNs similar to LF; this is in contrast to spores which promote immune cell uptake (see Table 29.1). Increased intracellular cAMP induced by EF inhibits neutrophil chemotaxis, phagocytosis, superoxide production, and microbicidal activity (Turk, 2007). EF has been shown to inhibit TNFα and to increase IL-6 production (Hoover et al., 1994). Increased cAMP levels also block LPS-induced activation of extracellular signal regulated kinase (ERK) and c-Jun N-terminal kinase (JNK) MAPK pathways in monocytes through protein kinase A (PKA) activation. This might explain suppression of cytokine production by EF (Willis and Nisen, 1996). EF also activates guanine nucleotide-exchange proteins directly activated by cAMP 1, known as Epac1, through elevated cAMP levels. Epac1 inhibits phagocytosis by both alveolar macrophages and monocyte-derived macrophages (Bryn et al., 2006). EF also inhibits T-cell proliferation and subsequent cytokine production

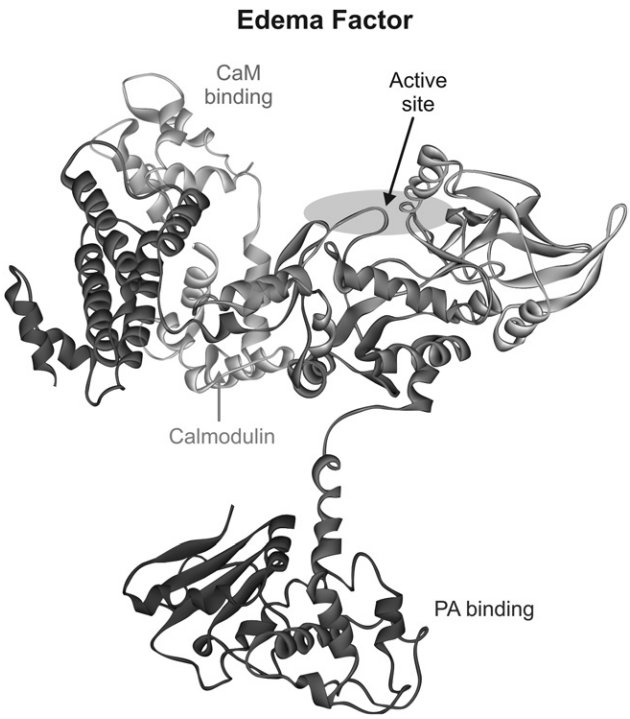

FIGURE 29.7 Three-dimensional ribbon structure of EF. The purified and crystallized structure of EF has been previously reported (Shen et al., 2005). EF is a calmodulin (CaM)-activated adenylyl cyclase and is another key factor in anthrax pathogenesis. EF contains a finger-like projection comprising a CaM-binding region, an active site to bind Mg^{2+} and 3′ deoxy-ATP, and a separate PA63 binding region. The structure of EF with bound CaM is illustrated. CaM binding causes a conformational change and activation of EF. The PA63 binding region of EF is separate from the remainder of the protein. It is shown in the same approximate position as the homologous PA-binding domain of LF in Figure 29.8 for comparison. The structure of EF was provided free of copyright restrictions from the RCSB PDB (Berman et al., 2000; PDB ID: 1xfv; Shen et al., 2005) and rendered using Accelrys DS Visualizer 2.0 software.

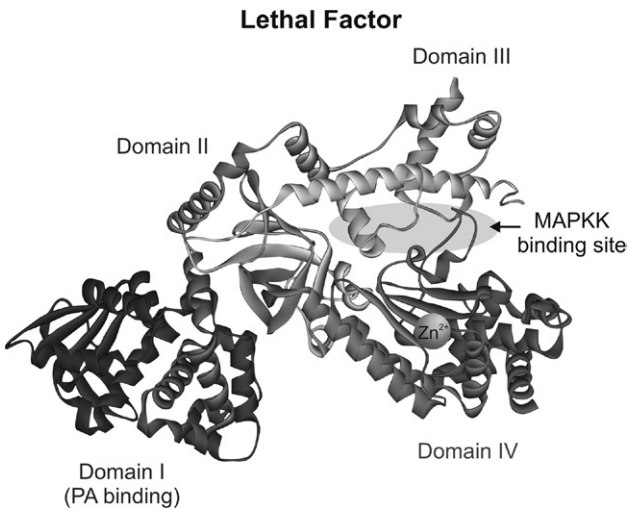

FIGURE 29.8 Three-dimensional ribbon structure of LF. The purified and crystallized LF has been reported (Bernardi et al., 2000; Pannifer et al., 2001). LF contains four recognized regions, termed domains I to IV. Residues 28–263 comprising domain I are illustrated as being entirely separate from the rest of the protein. Domain I binds the membrane-translocation component of PA63 (Lacy et al., 2002). It is homologous to the same PA binding domain of EF. Domains II to IV function together to create a long, deep pocket that holds the 16-residue N-terminal tail of MAPKK before the cleavage reaction takes place. Members of the MAPKK proteins are the only known cellular substrates of LF. The cleavage reaction removes the docking sequence for the downstream MAPK and therefore blocks cellular signaling via the MAPK pathway. Domain II has an ADP-ribosyltransferase active site. Domain III contains an α-helical bundle, and domain IV contains both a Zn^{2+}-binding motif and a catalytic center of the protease. The structure of LF was provided free of copyright restrictions from the RCSB PDB (Berman et al., 2000; PDB ID: 1jky; Pannifer et al., 2001) and rendered using Accelrys DS Visualizer 2.0 software.

through inhibition of ERK and JNK MAPK pathways (Comer et al., 2005). Therefore, EF impairs the adaptive immune response as well. EF affects other cell types; it causes endothelial cell barrier dysregulation, coagulopathy, and RBC death (Banks et al., 2006).

Mechanism of Toxicity: Lethal Toxin (LT)

The mechanism of death accredited to LT is unclear. A summary of the cellular targets and effects of lethal and ETs is provided in Table 29.2. LF has similar actions on phagocytes; it disables phagocytosis by macrophages and dendritic cells. Once internalized, LF cleaves the N-termini of MAPKKs, kinases for MAPKs and ERKs, and MEKs (MAPKs and ERKs) (Collier and Young, 2003; Turk, 2007). As a result, LF blocks three critical cell signaling pathways downstream of MAPKKs and MEKs. These include the ERK1/2, JNK, and p38 MAPK pathways. In addition, LF has additional targets within host cells.

There is evidence that LT suppresses pro-inflammatory cytokine production in macrophages and decreases TNFα (Pellizzari et al., 1999). These reports, which suggest impairment of innate immunity in the host cell, are in contrast to those that suggest LT functions to increase cytokines by macrophages (Hanna et al., 1993). LT has also been shown to cause an increase in ion permeability and rapid depletion of ATP in J774 macrophage-like cells, leading to cell lysis by osmotic mechanisms (Hanna et al., 1992). Inhibition of MAPKKs may block induction of NF-κB target genes, causing apoptosis of activated macrophages (Park et al., 2002).

LF effects on monocytes and macrophages are multiple. LF seems to decrease innate immune responses by blocking maturation of monocytes, which differentiate into both macrophages and dendritic cells and promote

TABLE 29.2 Effects of Anthrax Bacilli and Toxins on Various Cell Types

death of activated macrophages (Banks et al., 2006). LF causes reductions in pro-inflammatory cytokines and inhibits the ability of dendritic cells to activate T cells *in vivo* (Agrawal et al., 2003). This negates an important mechanism of inducing adaptive immunity. Alileche et al. (2005) demonstrated that LF can be cytotoxic to human and murine dendritic cells. Cytotoxicity was demonstrated to be through either a caspase-dependent apoptotic mechanism in the case of human dendritic cells or a necrotic pathway. LF alters PMNs, important mediators of the adaptive and innate immune response. LT also slows neutrophil mobility (During et al., 2005).

LF promotes lysis of red blood cells (RBCs) when PMNs are present (Banks et al., 2006). It is believed that LT induces these immune cells to release toxic factors that are hemolytic, causing RBC lysis. Vascular damage is pathognomonic of anthrax disease. Signs of endothelial damage include hemorrhages and leaky blood vessels, leading to vascular collapse, shock, and death. LF appears to induce a caspase-dependent apoptotic pathway in endothelial cells derived from large vessels or so-called human umbilical vein endothelial cells. LF has been shown to cause similar apoptosis in small vessels, namely neonatal dermal vascular endothelial cells (Kirby, 2004).

Interactions Between LT and ET

Because their expression is coordinately regulated, both anthrax toxins circulate together during infection (Turk, 2007). These toxins have distinct mechanisms of toxicity, yet they target similar cell types. Both LF and EF cause endothelial cell barrier dysregulation, coagulopathy, RBC death, inhibition of neutrophil mobility and phagocytosis, and alterations in cytokine modulation. Acting together, EF and LF inhibit superoxide production by neutrophils and cytokine production by dendritic cells (Tournier et al., 2005). EF upregulates PA receptors, TEM 8 and CMG 2, in macrophages and increases their sensitivity to LF cytotoxicity (Comer et al., 2005). Finally, the appearance of black pigmentation characteristic of anthrax disease might be explained by the combined effects of LF and EF on melanocytes. LF has been shown to produce melanin in melanoma cell lines, an effect enhanced by the addition of EF (Koo et al., 2002).

TOXICITY

Cutaneous Anthrax

Cutaneous anthrax is the most common form of anthrax encountered worldwide, consisting of more

than 95% of anthrax cases. The most obvious sign of bacterial uptake/absorption from the skin in human anthrax cases is the developing papule. This papule progresses to become vesicular in nature and then ulcerative. Finally, a black eschar forms, which is the hallmark of human cutaneous anthrax infection (Bell et al., 2002). A more detailed look at the lesion discloses subepidermal edema, vessel thrombosis, tissue destruction, and hemorrhagic interstitium (Oncu et al., 2003).

Symptoms of cutaneous anthrax infection begin with a painless papule at the site of infection 3–5 days after exposure. After 24–36 h, the papule progresses to a vesicle 1–2 cm in diameter. Once the lesion ruptures, it slowly erodes, leaving a necrotic ulcer with a black central scab, termed an eschar. Eschar lesions typically form at exposed areas of the body (arms, hands, neck, and face). The formation of edema around the eschar lesion is also characteristic of cutaneous anthrax. Two to three weeks later, the eschar sloughs off the skin. Other signs and symptoms of cutaneous disease in humans include fever, headache, malaise, toxemia, and regional lymphadenopathy. Painful swelling of regional adrenal glands can occur.

Inhalational Anthrax

Signs and symptoms of inhalational anthrax follow a biphasic course. The initial phase is characterized by fever, malaise, and unproductive cough characteristic of an upper respiratory infection. After this flu-like phase, the patient will typically recover after 2–4 days. The second phase proceeds rapidly with the following constellation of signs and symptoms: acute dyspnea, pleural effusion, fever, progressively worsening respiratory failure, cyanosis, circulatory collapse, shock, and death, if left untreated. Death occurs 24 h after the onset of this second phase secondary to toxemia and suffocation (Dixon et al., 1999; Friedlander, 1999; Atlas, 2002; Bales et al., 2002). Although the lung is the primary site of infection here, inhalational anthrax is not considered a true pneumonia. In most, but not all cases, there is no infection in the lungs (Albrink, 1961). An infectious dose is estimated at 8,000–50,000 spores via aerosol (Franz et al., 1997).

Gastrointestinal and Oropharyngeal Anthrax
