Note: The number in square brackets [] is that previously assigned (3266) to the tobacco ingredient component listed by Doull et al. (1053). The number with an A in square brackets [] is that previously assigned (3266) to the tobacco ingredient component listed by Baker et al. (174b, 174c, 24A01).
The symbol (0) indicates the component identified in tobacco substitute smoke was not detected in tobacco smoke.

Despite their criticism of the possible increased use of flavorants in the filler of low-"tar," low-nicotine cigarettes, the authors' admitted that prior to 1980, the U.S. cigarette manufacturers had apparently achieved a "reduction of toxic and tumorigenic effects in the smoke of low-'tar,' low-nicotine cigarettes."

In the U.S. Surgeon General's 1979 report [see pp. 63–64 in (4005)], the following was written:

> The trend toward low-tar, low-nicotine cigarettes and toward a reduction of undesirable volatile smoke compounds has brought about major changes in the smoke flavor of cigarettes. The use of rolled stems and reconstituted tobacco sheet admixed with leaf lamina and the use of effective filter tips are major factors inducing changes in smoke flavor. All of these developments have led to increased use of flavor additives, especially for low-tar, low-nicotine cigarettes. In fact, these new cigarettes require flavor corrections by additives in order to be acceptable to the consumer. Tobacco extracts as well as nontobacco flavors, such as licorice, cocoa, fruit, spices, and floral compositions, are used… At present, the selection of tobacco flavor additives from the GRAS (Generally Regarded As Safe) List or from natural extract and the screening of their smoke decomposition products for toxicity or other biological activity are not required by law and are done voluntarily by manufacturers.

Temperatures to which flavorants added to tobacco are exposed and the duration of the exposure during the smoking process range from 500°C to 700°C and the few seconds of the puff duration, respectively. Many of the flavor additives listed by the Surgeon General are used in cooking and/or baking where the exposure temperatures are lower than in the smoked cigarette, but the exposure time to the elevated temperature is much longer. This raises the question: Will more toxic compounds be formed from a given flavorant during foodstuff preparation or during cigarette smoking? When questioned about the need to determine the generation of toxic substances from a GRAS list additive used in cooking and/or baking, the FDA stated such studies were not required of the foodstuff manufacturer nor could they be done by the FDA since it had neither the staff, facilities, nor funds to undertake such studies.

In the U.S. Surgeon General's 1981 report [see pp. 51–52 in (4009)], it was noted

> Humectants and flavoring agents have long been used as additives in cigarette manufacture…In recent years, cigarette manufacturers' advertisements have focused on the flavor of new lower "tar" and nicotine cigarettes, enhanced presumably by the addition of tobacco constituents or by the addition of new flavoring materials, such as natural and synthetic chemicals. The identities and amounts of the additives actually used in the manufacture of U.S. cigarettes are not known. Systematic information has not been published or made available on the influence of these additives on the composition or biological activity of cigarette smoke.

A similar comment was made in the 1982 Surgeon General's report [see pp. 217–218 in (4010)]:

> The development of the low-tar cigarette required enrichment of smoke flavors in order to make the product acceptable to the consumer. The flavor is enhanced by addition of undescribed materials that may include concentrates of flavor precursors obtained from tobacco, licorice, extracts from other plants, or semisynthetic or fully synthetic flavor components. Because these additives have not been identified, no judgment can be made as to whether they result in new compounds or higher concentrations of hazardous components in the smoke. The practice of flavor enrichment requires detailed toxicological studies that are not available at present for scientific evaluation of their impact [LaVoie et al. (2314c); USPHS (4005)].

In the 1994 report by Doull et al. (1053) and the 2000 report by Paschke et al. (2895) on their analysis of reports on the effects of added cigarette tobacco ingredients on the chemical and biological properties of its MSS, both groups essentially reached the same conclusion: the added ingredients under the conditions of use contributed no adverse chemical or biological properties to the MSS.

In their 1997 review of the "changing cigarette," Hoffmann et al. (1716) did not discuss low-"tar" cigarettes or the presumed use of additional flavoring materials, identity unknown. In a second 1997 article on cigarette design changes implemented between 1950 and 1995, Hoffmann and Hoffmann [see pp. 345–346 in (1740)] discussed the casing additives sugars and humectants (glycerol, propylene glycol, diethylene glycol) but did not mention that some cigarette manufacturers do not use diethylene glycol. The transfer of humectants to cigarette MSS and their significant contribution to FTC "tar" yield were ignored. On flavor additives, they wrote

> In April 1994, the major U.S. cigarette companies released a list of 599 additives used at that time for the manufacture of cigarette [Doull et al. (1053)]. However, in the past, additional reactive flavor additives have been used (such as angelica lactone and linalool oxide; Leffingwell (2336)). An exception is menthol, which amounts to less than 2.5 mg in U.S. mentholated cigarette [Perfetti and Gordin (2923)]. Menthol is not carcinogenic in rodents [National Cancer Institute (24A10)], nor does this readily volatilized compound give rise to measurable amounts of carcinogenic hydrocarbons during smoking of cigarettes [Jenkins et al. (1936)]. Yet it is possible that the spraying of tobacco with menthol affects the burning characteristics of a cigarette and thus changes the concentration of toxic and/or tumorigenic agents in the smoke.

The Hoffmanns obviously ignored what Wynder and Hoffmann [see p. 527 in (4332)] wrote about the findings of Bock et al. (355) on the specific tumorigenicity of the MSS from menthol cigarettes:

> The results of Bock et al. [355] suggest no difference in tumorigenic activity of heptane-soluble "tar" from a mentholated cigarette compared with a plain cigarette when tested on a gram-to-gram basis.

Over the years, it has been repeatedly asserted that cigarette ingredients added at normal levels to pre-1980 cigarettes or at slightly increased levels to more recent lower-"tar" cigarettes might adversely modify the chemistry and biology of the MSSs from such cigarettes. However, despite these repeated assertions, no chemical or biological evidence has been presented by those authorities making such assertions in support of their assertions.

Table 24.4 summarizes many of the chemical and biological studies conducted since 1994 on the effect of tobacco ingredients on the chemical and biological properties of the MSS from cigarette containing a particular added ingredient or ingredient mixture. Many of the scientific criteria suggested by the Life Sciences Research Office (LSRO) personnel (24A08) are incorporated in the tabulated investigations. It is interesting that the LSRO in its 2004 monograph [see p. 50 in (24A08)] wrote about the Doull et al. list of 460 individual compounds: "However, the fate of very few of these chemicals has been studied in cigarettes."

This statement was made about the "very few" chemicals despite the listing by LSRO [see pp. 45–46 in (24A08)] of the studies by Baker et al. (174b, 174c), Massey et al. (24A09), and Baker and Smith (24A01) on 482 ingredients; the studies by Gaworski et al. (24A03, 24A04, 24A05) and Heck et al. (24A06) on over 170 ingredients; and the studies by Carmines (603), Roemer et al. (24A11), Rustemeier et al. (3370), and Vanscheeuwijck et al. (24A12) on 333 ingredients. In the latter studies (603, 3370, 24A11, 24A12), over 210 of the 333 ingredients (63%) were listed by Doull et al. as individual tobacco ingredients. Can more than 210 *vs*. 333 be considered "very few" agents in the smoke? LSRO is probably correct in its assessment of the number of individual components with a precise fate study, but examination and understanding of the pyrolysis data and effect of many of them on MSS chemical and biological properties provide much significant data on their behavior in a smoked cigarette. To date, there is much more known on the effect of added tobacco ingredients on MSS properties than there is on the effect of foodstuff additives on the properties of cooked foodstuffs.

Despite the wealth of information now available from the studies outlined in Table 24.4 that indicate that the ingredients—whether tobacco compounds or nontobacco compounds—added to cigarette tobacco do not significantly alter the MSS chemical or biological properties, none of the critics of tobacco ingredients has challenged the scientific findings presented in the publications listed, provided any contradictory scientific data, or suggested any additional definitive studies. This raises the question: Is this oft-repeated assertion about the deleterious effect of added tobacco ingredients like the many other antitobacco smoking assertions that have no supporting data or for which contradictory data or equivocal data have been generated [see Table 1 in Rodgman et al. (3307)]?

ACKNOWLEDGMENT

The authors are extremely grateful to the late Richard R. Baker for his meaningful contributions to several sections of this chapter that were included in part in previous ingredient publications.

TABLE 24.4
Summary of Tobacco Ingredient Studies Conducted from 1997 to Date

Analysis	Date	Number of Ingredients Studied	Reported Findings/Conclusions	Reference
Detailed literature survey of ingredients added to U.S. tobacco products	1994	599	It was concluded that there was no evidence that any ingredient added to commercial cigarette tobacco produces harmful effects under the conditions of use in cigarettes	Doull et al. (1053)
Effect of added tobacco ingredients on cigarette MSS chemistry	2002	333	The smoke chemistry data revealed changes toward both higher and lower amounts of various smoke constituents…. This suggests that the addition of 333 commonly used ingredients to cigarettes in three groups did not add to the toxicity of the smoke, even at the exaggerated levels tested… An overall assessment of our data suggests that these ingredients, when added to the tobacco, do not add to the toxicity of smoke, even at the elevated levels used in this series of studies	Carmines (603); Rustemeier et al. (3370)
	2002	482	In most cases, the flavor mixtures had no statistically significant effect on the smoke yields relative to the control cigarette. In a few cases, the small increases or decreases were observed for some analytes relative to the control cigarette. The smoke yields of the experimental cigarettes were well within the ranges observed in the three reference cigarettes	Baker and Smith (24A01)
	2004	450	The significances of differences between the test and control cigarettes were determined using both the variability of the data on the specific occasion of the measurement, and also taking into account the long-term variability of the analytical measurements over the 1-year period in which analyses were determined in the present study. This long-term variability was determined by measuring the levels of the 44 "Hoffmann analytes" in a reference cigarette MSS on many occasions over the 1-year period of this study The effects of 450 tobacco ingredients (many were individual compounds listed in Tables 24.1 and 24.2) added to tobacco as seven different mixtures on the yields of 44 "Hoffmann analytes" in cigarette MSS were determined. In most cases, the flavoring ingredient mixtures had no significantly statistical effect on the MSS "Hoffmann analyte" yields *vs*. those from the control cigarette. Occasionally, with some mixtures, differences would be observed in some "Hoffmann analyte" yields	Baker et al. (174b)
	2004	32	The effects of 29 casing ingredients and three humectants added to tobacco as 8 different mixtures on the yields of 44 "Hoffmann analytes" were determined. Many of the ingredient mixtures had no statistically significant effect on the MSS "Hoffmann analyte" yields *vs*. those from the control cigarette. An increase in one "Hoffmann analyte," formaldehyde, was reported when the ingredient mixture contained sugar	Baker et al. (174c)
Effect of added tobacco ingredients on cigarette MSS biology: (a) in vitro genotoxicity and cytotoxicity	1997, 2002	≈152	Although the mutagenic activities appeared to be similar, there were statistically significant differences in mutagenic activities among the samples (The differences were primarily due to the increase in mutagenicity of the CSC when the humectants [glycerol, propylene glycol] were not added to the cigarette tobacco and thus were not present as diluents in the CSC)	Bioresearch [for RJRT] (24A02); Rodgman (3263, 3264)
	2002	333	Within the sensitivity and specificity of the test systems, the in vitro mutagenicity and cytotoxicity of the cigarette smoke were not increased by the addition of the ingredients	Carmines (603); Roemer et al. (24A11)

(*continued*)

TABLE 24.4 (continued)
Summary of Tobacco Ingredient Studies Conducted from 1997 to Date

Analysis	Date	Number of Ingredients Studied	Reported Findings/Conclusions	Reference
	2002	482	The data have been analyzed and demonstrate no additional activity from the flavored cigarettes above that of the control products	Massey et al. (24A09)
(b) MSS smoke inhalation	1997, 2002	2 (Glycerol, propylene glycol)	It was concluded that addition of the tested humectants singly or in combination had no meaningful effect on the site, extent or frequency of respiratory tract changes associated with smoke exposure in rats	Heck et al. (24A06)
	1997	1 (Menthol)	The results of this 13-week inhalation study indicated that the addition of 5000 ppm menthol to tobacco had no substantial effect on the character or extent of the biological responses normally associated with inhalation of mainstream cigarette smoke in rats	Gaworski et al. (24A03)
	1998	170	The results indicate that the addition of flavoring ingredients to cigarette tobacco had no discernible effect on the character or extent of the biologic responses normally associated with inhalation of mainstream cigarette smoke in rats	Gaworski et al. (24A04)
	2002	333	The data indicate that the addition of these 333 commonly used ingredients, added to cigarette in three groups, did not increase the inhalation toxicity of the smoke, even at the exaggerated levels used	Carmines (603); Vanscheeuwijck et al. (24A12)
(c) MSS CSC and skin painting	1999	150	While tumor incidence, latency and multiplicity data occasionally differed between test and comparative reference CSC groups, all effects appeared to be within normal variation for the model system. Furthermore, none of the changes appeared to be substantial enough to conclude that the tumor promotion capacity of CSC obtained from cigarettes containing ingredients was discernibly different from the CSC obtained from reference cigarettes containing tobacco processed without ingredients	Gaworski et al. (24A05)
Pyrolysis of tobacco ingredients under conditions simulating those in the cigarette burning zone	2002/2004	291	The results are compatible with parallel studies in which the ingredients are added to tobacco and the effect on cigarette smoke constituents are measured. In general, the number of "Hoffmann analytes" detected among the pyrolysis products of the ingredients, and their levels, are low…. Of the 291 tobacco ingredients pyrolyzed, almost a third transfer out of the pyrolysis zone intact, and almost two thirds transfer at least 95% intact	Baker and Bishop (172a)
	2003		A review of the pre-2003 studies on the effect of added ingredients on the chemical and biological properties of cigarette MSS with emphasis on the yields of the "Hoffmann analytes." Their discussion included various published (603, 1053, 3263, 3264, 3266, 24A03, 24A04, 24A05, 24A06) and pre-published (172a, 174a, 174b, 3314a, 3370, 24A09, 24A11, 24A12) manuscripts on tobacco ingredients	Baker and Smith (174e)
	2004	482	This publication summarized the reported findings on the 482 tobacco ingredients studied by Baker et al. (174b, 174c). The major conclusion: Many of the added tobacco ingredient mixtures produced no significant effect on the yields of many of the "Hoffmann analytes" in the cigarette MSS. In a series of three biological studies on genotoxicity and cytotoxicity, the response due to MSS exposure was not distinguishable between the ingredient-treated cigarette and the control	Baker et al. (174a)

TABLE 24.4 (continued)
Summary of Tobacco Ingredient Studies Conducted from 1997 to Date

Analysis	Date	Number of Ingredients Studied	Reported Findings/Conclusions	Reference
	2004	1 (Glycerol)	A study to determine the effect of different levels of added glycerol on cigarette MSS yields: The glycerol transfer was proportional to that added to the tobacco blend.	Liu (2380)
	2005	159 Nonvolatile and complex ingredients (these ingredients were not individual compounds)	With a system simulating cigarette combustion conditions, pyrolysis of many of the nonvolatile ingredients gave no "Hoffmann analytes." When occasionally formed, the "Hoffmann analytes" included phenols, benzene, toluene, and styrene. Biologically active furfural, never listed as a significant biologically active smoke component by Hoffmann and his colleagues (1727, 1740, 1741, 1743, 1744, 1773, 1808), was occasionally formed	Baker and Bishop (172b)
	2006	1 (Sugar)	This study was an extension of the previously reported effect (174c) of sugar ingredients on the MSS yield of formaldehyde	Baker et al. (172c)

25 Pyrolysis

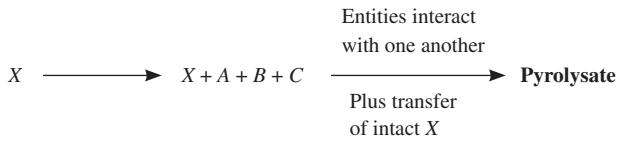
For many years, the fate during smoking of a compound added to cigarette tobacco was defined by its fate during pyrolysis as an individually pyrolyzed compound. The stimulus for this assertion was twofold: (1) Many publications were available that indicated the pyrolysis of many compounds—from relatively low-molecular-weight ones such as acetylene to much higher-molecular-weight ones such as the sterols—yielded tumorigenic polycyclic aromatic hydrocarbons (PAHs); (2) the ingredients to improve the smoking quality of a cigarette were added at such a low level that analytical data on their effect on smoke composition were almost impossible to generate. Because of this analytical problem with additives to the cigarette filler, many investigators utilized pyrolysis of individual tobacco components or additives in an attempt to define the spectrum of products and their influence on tobacco smoke composition and properties.

The assertion of the equivalence of the fate of a compound on pyrolysis *vs.* its fate in a cigarette tobacco filler during smoking persisted for over 20 years after the mid-1950s. As proponents of this equivalence, Wynder and Hoffmann [see pp. 346–347 in (4332)] wrote:

> Most pyrolysis studies with tobacco, tobacco extracts, extract fractions, individual components, and tobacco additives are performed in a nitrogen atmosphere. This procedure has often been criticized on the grounds that many of the toxic constituents formed during smoking of tobacco products occur as a result of combustion in air rather than in a nitrogen atmosphere. This criticism, however, cannot be maintained in view of studies by Newsome and Keith (2780) which demonstrated that a reducing rather than an oxidizing atmosphere exists at the cone region of a burning cigarette.

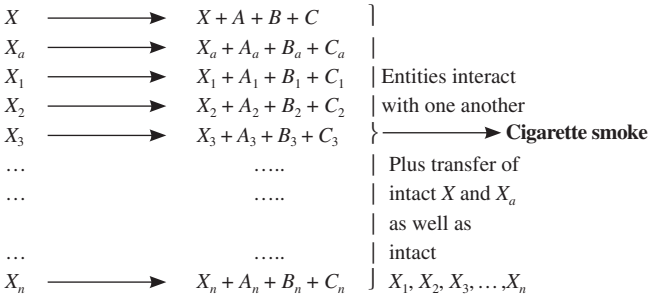
Consideration of the effect of pyrolysis and the cigarette smoking process reveals the following: In both cases, a given compound may undergo a variety of reactions. In the pyrolysis case, fragments produced from the compound during pyrolysis only have the opportunity to react with the unchanged compound itself or with each other. In the smoked cigarette case, the added compound, either inherent in tobacco or added, generates fragments during the smoking process which have the opportunity not only to react with intact volatilized tobacco components (over 6000 of which have been identified) but also to react with the reaction fragments produced from them.

If it is assumed that a given compound, compound X, during pyrolysis is not only transferred in part to the pyrolysate but also yields three pyrosynthetic fragments (A, B, and C), then these four entities (X, A, B, and C) may transfer to the pyrolysate intact or interact in a variety of ways to form a mixture of pyrolysate components.



If it is assumed not only that the same type of reaction occurs in a cigarette during the smoking process in the case of compound X, either added (X_a) to or inherent (X) in the tobacco blend, but also that similar degradation reactions occur with the other tobacco components ($X_1, X_2, X_3, \ldots, X_n$), the situation described in the following equations could exist, where n could be as high as or higher than 6000, the approximate number of identified tobacco components.

In the study of the addition of compound X to a cigarette tobacco filler, the added compound is designated as X_a. The inherent tobacco compound X and its fragments A, B, and C plus the added compound X_a and its fragments A_a, B_a, and C_a have the opportunity not only to react with each other but also to interact with $X_1, X_2, X_3, \ldots, X_n$, $A_1, A_2, A_3, \ldots, A_n$, $B_1, B_2, B_3, \ldots, B_n$, and $C_1, C_2, C_3, \ldots, C_n$, the fragments from hundreds of other tobacco components. In both the pyrolysis case and the cigarette smoke formation case, the number of fragments may, of course, be many more than the three designated as A, B, and C.



Obviously, pyrolysis of an individual compound (compound X) at a specific temperature and during the smoking process in a machine-smoked cigarette whose blend contains inherent compound X and added compound X_a are entirely different situations and will yield qualitative and quantitative differences between the compositions of the pyrolysates and the cigarette smoke. Qualitatively, there may be some similarities in the two compositions. Quantitatively, the probability of any similarity is extremely low. It should be noted that during the pyrolysis of compound X, a specific temperature such as 700°C or 600°C is usually maintained. During the smoking process occurring in the compound X- and $(X + X_a)$-containing cigarette, compounds X and X_a and their pyrogenetically generated fragments are exposed to a range of temperatures varying from nearly 1000°C at the fire cone

to 50°C–60°C near the butt. In addition, Britt et al. (435) noted that the residence time during most pyrolysis studies of tobacco components was much longer than that encountered by the tobacco components during the smoking process.

The reactions depicted earlier in pyrolysis of a component *vs*. those in the cigarette smoking process with a component added to the tobacco exist despite the assertion that the pyrolysis procedure has been specifically designed to simulate the smoking process (172b, 1648, 3616).

In 1979, Schmeltz et al. (3512) reported on the fate of radiolabeled nicotine during pyrolysis, and its fate during actual smoking of a cigarette containing the radiolabeled nicotine reveals at least two of the coauthors (Hoffmann, Schmeltz) had changed their long-held view on the supposed equivalence of compound behavior during pyrolysis and actual smoking. Schmeltz et al. wrote:

> Products obtained from the thermal degradation of [^{14}C] nicotine in a combustion tube (under pyrolytic conditions) and in a cigarette (undergoing machine smoking) were examined by gas-liquid chromatography (GLC), by GLC-mass spectrometry, and by radiochromatography. Under pyrolytic conditions in a combustion tube, nicotine underwent extensive degradation to pyridines, quinoline, arylnitriles, and aromatic hydrocarbons. In contrast, in a burning cigarette, a substantial portion of nicotine remained intact (≈41%), 12.5% underwent oxidation to CO_2, up to 11% was degraded to volatile pyridine bases, and negligible amounts were converted to neutral or acidic particulate components. A major portion of nicotine and its degradation products was also diverted to sidestream smoke. These results suggest to us that pyrolysis experiments may be limited for establishing the fate of nicotine and possibly other tobacco components in a burning cigarette.

On the basis of numerous pyrolysis studies, it has been postulated that a number of tobacco leaf components are the major precursors of components in tobacco smoke. Throughout this chapter, smoke components alleged by some investigators to play a role in the smoking–health issue have been emphasized, particularly those smoke components supposedly involved in the causation of lung cancer or other respiratory tract disorders. Carbon monoxide and nicotine have been proposed as cigarette mainstream smoke (MSS) components involved in cardiovascular problems. Nicotine occurs in cigarette smoke as a result of its transfer from the cut tobacco leaf where it is considered to be present in the so-called bound form as a variety of nicotine salts with organic acids (citric, malic, oxalic, palmitic, stearic, etc.). As noted by Perfetti (2918a, 25A47), these nicotine salts may have various structures, depending on the nature of the acid, e.g., the molar ratio of acid to nicotine may be 3:1, 2:1, or 1:1. During the cigarette smoking process, these salts, depending on their composition, are considered to decompose to yield products ranging from mainly nicotine plus the acid in the salt to traces of nicotine plus various nicotine reaction and degradation products plus the acid. It has been proposed that the nicotine in the smoke again "binds" with acidic components of the smoke and is considered to be present primarily in the mainstream particulate phase as "bound" nicotine, but the binding in cigarette MSS is different from that in the tobacco. In cigarette smoke, the "binding" or salt formation is considered to be primarily with the stronger aliphatic organic acids such as formic, acetic, etc., whose levels in smoke are substantial compared to those of palmitic acid, stearic acid, etc.

Table 25.1, modified and updated from similar tables by Chortyk and Schlotzhauer (722) and Baker (171a), summarizes the major precursor relationships proposed and/or demonstrated for tobacco leaf components and tobacco smoke components. These proposals are based in part on the results of a numerous pyrolysis studies. In some cases, the validation of the proposals is based on results obtained by addition of leaf components to tobacco and assessing the effect on the yields of specific MSS components when the "spiked" tobacco is smoked as a cigarette.

As noted previously, equivalence of the reaction mechanisms involved in pyrolysis and those involved in the tobacco smoking process was debated for many years, with the current consensus being that these processes are not equivalent. Also included are the results of research in the mid-1950s on the major tobacco and cigarette paper component, cellulose, either smoked in cigarette configuration [Fredrickson (1228), Fredrickson et al. (1238)] or burned or pyrolyzed in bulk. When the primary focus of the early research was on the pyrogenesis of PAHs, Wright (4281) demonstrated that the amount of benzo[*a*]pyrene (B[*a*]P) generated during bulk burning or bulk pyrolysis of cellulose was much greater than that generated during the burning of the cellulose (cigarette paper) in a cylindrical form, simulating its configuration in the cigarette.

25.1 INDIVIDUAL TOBACCO TYPES

In the early 1930s, Roffo (3320, 25A50, 25A51, 25A52) reported the production of skin tumors in laboratory animals by the repeated application of a "tar" obtained by the "destructive distillation" of tobacco. This "destructive distillate" from tobacco, as noted by Wynder and Hoffmann (4319, 4332), is in no way comparable to the smoke condensate generated from cigarettes during a smoking procedure simulating that used by the human smoker in terms of puff duration, puff frequency, and puff volume. Despite the fact that the puff volume, puff duration, and puff frequency were usually set at 35 mL, 2 s, and 1 puff/min, respectively, after the 1937 publication by Bradford et al. (424) on human smoking parameters, Wynder et al. (4306a) elected to use a puff frequency of 3 puff/min for the generation of cigarette smoke condensate (CSC) for their mouse-skin-painting studies, despite their assertion that the smoking regime simulated that of the human smoker.

In addition, the destructive distillation procedure used by Roffo is not comparable to the pyrolysis procedures used several decades later by other investigators, e.g., Lam (2255, 2257) and Wynder et al. (4355). Roffo's work is presented here for the sake of historical completeness. In later reports,

TABLE 25.1
Precursor Relationships between Tobacco Leaf Components and Tobacco Smoke Components

Smoke Component	Leaf Component	References
Monocyclic Aromatic Hydrocarbons

Roffo (3323, 3325) and his son (3316, 3318) claimed the identification of B[*a*]P in the destructive distillate of tobacco, but these claims were subsequently challenged by Wynder et al. (4306a) who noted:

> Roffo …claimed to have identified benzpyrene in tobacco tar, but this could not be confirmed by Hirst and his coworkers (813), and more recently that substance could not be detected by Waller (25A81). An examination by Eby (25A21) of the tobacco tar used in this study [the mouse skin-painting study by Wynder, Graham, and Croninger (4306a)] did not reveal any spectroscopic evidence of the known carcinogenic hydrocarbons.

Roffo (25A60) also claimed that the biological results in his painting results with the effect on the levels of "destructive distillate" from tobacco were the same no matter which type of tobacco was subjected to his destructive distillation process. That his destructive distillation was not comparable to the actual cigarette smoking process was demonstrated in later studies by Wynder and Hoffmann (4317, 4332) who reported that the different types of tobacco types (flue-cured, burley, Maryland, and Oriental) generated CSCs whose specific tumorigenicities were different as were their contents of B[*a*]P and phenol. The specific tumorigenicities and phenol levels per milligram of CSC were found to be in the sequence

Flue-cured = Oriental > Maryland > burley,

whereas the B[*a*]P levels per milligram of condensate were found to be in the sequence

Flue-cured > Oriental > Maryland > burley.

More recent confirmation of the differences among tobacco types in another bioassay has been obtained with regard to the specific mutagenicities (as measured in the Ames test with *Salmonella typhimurium*) of their smoke condensates generated under standard conditions. Results of both in-house studies [Smeeton et al. (3707)] and external studies [Mizusaki et al. (2568), Yoshida and Matsumoto (4388), Demarini (933)] indicate the response of different strains of *S. typhimurium* in the Ames test to smoke condensates from cigarettes fabricated with different tobacco types not only are dissimilar but also are in a sequence opposite that found for specific tumorigenicities determined in mouse-skin-painting studies, i.e., the mutagenicities based on an equivalent weight of smoke condensate were found to be in the sequence

Flue-cured < Oriental < Maryland < burley.

Critical reviews of the Roffo work have been published by Wynder et al. (4306a), Wynder and Hoffmann (4332), and Larson et al. (2264). All three groups asserted that the "destructive distillate" from tobacco, as prepared by Roffo, is not comparable to CSC generated under conditions more closely approximating those in the human smoking of a cigarette. Larson et al. also noted that the number of malignant tumors produced in all of the Roffo skin-painting studies with the destructive distillate from tobacco was so few (three malignant tumors [two carcinoma, one sarcoma] in nearly 1000 treated animals) as to be almost within experimental error.

Over the years, pyrolysis studies with tobaccos under a variety of conditions have provided diverse results with regard to the level of B[*a*]P found in the pyrolysate, e.g., Kröller (2196), Green and Best (1357), and Severson et al. (3616). The phenol/B[*a*]P ratios were also much compared in pyrolysates and MSSs, and they too provided diverse results, e.g., Wynder and Hoffmann (4319, 4332), R.J. Reynolds Tobacco Company (3190). Adams et al. (31) used catechol rather than phenol as an "indicator" for phenols, provided

MSS and SSS B[*a*]P and catechol data on four different types of commercial cigarettes. From these data, the calculated catechol/B[*a*]P ratios for the combined MSS and SSS were widespread, ranging from 1074:1 to 2680:1. The data reported by Severson et al. on the yields of phenol and benzopyrenes in the pyrolysates (and the ratios derivable from their data) demonstrated that the process involved in the generation of a tobacco pyrolysate is not comparable to the process involved in the generation of CSC from cigarettes made with the same tobacco and smoked under conditions simulating the human smoking process.

25.2 EXTRACTS FROM TOBACCO

The 1953 report of the successful production of carcinomas in mice repeatedly painted for their life span with daily doses of CSC generated by a smoking process supposedly simulating that used by human cigarette smokers [Wynder et al. (4306a)] led to a search for the smoke component(s) responsible for the biological response. No carcinogenic, cocarcinogenic, or promoting compound identified in CSC, when considered at its concentration in CSC, can explain the biological response obtained in mouse-skin-painting studies nor can it be explained when the carcinogenic, cocarcinogenic, and promoting components at their CSC concentrations are considered to be acting in concert.

The finding in 1913 by Staudinger et al. (25A68) that pyrolysis of isoprene yielded a "tar" was utilized a decade later by Kennaway (2073–2076). He reported that heating organic compounds (acetylene, isoprene, cholesterol, foodstuffs) at high temperatures (in air or an inert atmosphere) yielded "tars" or "pyrolysates" which were tumorigenic to the skin of laboratory animals. After the discoveries of the tumorigenicity of dibenz[*a,h*]anthracene (DB[*a,h*]A) and B[*a*]P, many such generated pyrolysates were shown to contain various tumorigenic PAHs [Rodgman (3233, 25A48)]. In the early 1950s, a controversy arose about the presence of such PAHs in CSC, a material generated by the exposure of tobacco—a mixture of many organic compounds—to temperatures ranging from slightly above ambient to over 900°C. By the late 1950s, this controversy was resolved by the identification in CSC of a variety of PAHs, including several [B[*a*]P, chrysene, benz[*a*]anthracene (B[*a*]A), 7,12-dimethylbenz[*a*] anthracene (DMB[*a*]A), DB[*a,h*]A] reported to give positive responses in skin-painted laboratory animals, albeit at dose levels far in excess of the their levels in CSC. Wynder and Hoffmann (4332) reviewed much of the early research on the identification of PAHs in CSC.

Demonstration that PAHs were present in CSC then led to research on their source(s). Cigarette paper [Wright (4281)], the lighting source (matches, flammable organic solvent-charged cigarette lighters), and PAHs in environmental pollutants to which tobacco might be exposed during growth, harvesting, and transportation [Campbell and Lindsey (583), Lyons (2426), Bentley and Burgan (285)] were eliminated as sources or precursors of PAHs in cigarette smoke. Extensive research subsequently determined that tobacco itself and/or its components were precursors of the PAHs in CSC.

As noted previously, in the 1930s, Roffo (3320, 25A50) claimed the production of malignant tumors in laboratory animals skin painted with a "destructive distillate" from tobacco. Roffo (3323, 3325) and his son [Roffo (3316, 3318)] also claimed identification of a benzopyrene or a "benzopyrene-like" substance in the distillate. Subsequently, Roffo reported that organic solvent extraction of tobacco yielded an organic solvent-insoluble tobacco residue whose "destructive distillate" was less tumorigenic in skin-painting studies than the "destructive distillate" prepared from the unextracted (control) tobacco (3327). Roffo postulated that the major tobacco precursor of the "distillate" component responsible for the tumorigenicity observed in laboratory animals was the phytosterols.

Coincident with general acceptance of biologically active PAHs in CSC were extensive pyrolysis studies not only on organic solvent-extractable materials from tobacco but also individual components and classes of components in the solvent-extracted materials. The organic solvent (pentane, hexane, heptane, petroleum ether) used as extractant removed waxlike organic components from the tobacco. These waxy materials comprised several series of long-chained saturated (1308, 3807) and unsaturated aliphatic hydrocarbons (3247, 3345) and alcohols (812, 3276), phytosterols and their long-chained fatty acid esters (3247), terpenoid alcohols such as solanesol (3344, 3359) and the duvanediols (3195, 3220, 3221, 3283, 3351, 3361), solanesyl esters with long-chained fatty acids (3296, 3358; 3616), and a series of esters of long-chained alcohols and long-chained fatty acids (3294).

Contradictory results were obtained on the yields of the allegedly tumorigenic PAHs and the biological properties of the CSCs from cigarettes fabricated from organic solvent-extracted tobaccos. With relatively nonpolar solvents such as pentane, hexane, and heptane, from 5% to 10% of the tobacco weight was removed by extraction with these solvents. Reductions in per cigarette PAH yields were reported for the MSSs from solvent-extracted tobaccos by numerous investigators, e.g., Campbell and Lindsey (583), Neukomm and Bonnet (2716), Rodgman (3241–3243, 3246, 3251), and Wynder et al. [Wynder (4294), Wright (4282), Wynder et al. (4355), Wynder and Hoffmann (4307, 4309)] on solvent extractions of tobaccos and their effect on the PAH yields in the CSC. Initially, the reductions in the MSS yields of the PAHs, particularly those with four or more fused rings, were reported as being significant when considered on a per cigarette yield basis. Subsequently, the same investigators (Wynder et al.) claimed that the reductions in PAH yields should be viewed as only marginal when the PAH yields were considered on a per gram of CSC basis. The % reduction in tumorigenicity [expressed as % tumor-bearing animals (TBA) in skin-painting experiments] of the mainstream CSCs from cigarettes fabricated with solvent-extracted

TABLE 25.2
Pyrolysis Studies on *n*-Hexane Extract from Tobacco

880	Air	30	Present	67	67

[a] % TBA (mice) with carcinoma at skin-painted site; similar percentages were found with skin-painted rabbits.

tobaccos was usually less than the % reduction in the levels of PAHs (with B[*a*]P, expressed in µg/g or ng/g of CSC, used as an "indicator" or for the levels of PAHs with four or more fused rings). It was obvious from data already in the literature describing tobacco smoke and tobacco pyrolysate compositions that B[*a*]P was not a valid "indicator" for the tetracyclic and higher PAHs demonstrated to be tumorigenic to mouse skin.

American investigators [Rayburn and Wartman (3091), Rayburn et al. (3092)] as well as French investigators [Cuzin et al. (885)] reported slight to no reductions in the levels of mainstream CSC PAHs, particularly B[*a*]P, as a result of organic solvent extraction of tobacco. Much of the early research on organic solvent extraction of tobacco to reduce the yields of PAHs in mainstream CSCs was reviewed by Wynder and Hoffmann (4319, 4332) and Hoffmann and Wynder (1798).

Organic solvent extraction of tobacco to control PAH levels in MSS fell from grace around 1960 when it was described by its early proponents, Wynder and Hoffmann (4309), as a process "impractical both technically and economically" and later was classified as "only of academic interest" by Wynder and Hecht (4306d), a view reported by the U.S. Surgeon General [see Table 26, p. 14: 114 in (4005)]. Pyrolysis studies have been conducted not only on the material extracted from the tobacco but also on the unextracted (control) tobaccos and the residual extracted tobaccos in attempts to define the precursor(s) of PAHs (and phenols) in cigarette MSS. In some respects, the differences between the compositions of the pyrolysates from solvent-extracted tobacco and from unextracted tobacco paralleled the differences between the compositions of the MSSs from cigarettes fabricated with solvent-extracted tobacco and with unextracted tobacco.

In 1958, Wynder et al. (4355) described the effect of varying the pyrolysis temperature on the yield of pyrolysate from an *n*-hexane extract from tobacco. The extracted material constituted 5.4% of the original tobacco weight and consisted of long-chained saturated and unsaturated aliphatic hydrocarbons, glycerides and other esters, solanesol and phytosterols and their esters, long-chained aliphatic esters, and α-tocopherol. Major findings from their study included the following (see also Table 25.2):

> The pyrolysate yields varied inversely as the pyrolysis temperature, i.e., the pyrolysate yield decreased as the temperature of pyrolysis was increased. Presumably, this is due to less decomposition of the extracted components to vapor-phase components (water, carbon monoxide, carbon dioxide, methane, etc.) at the lower pyrolysis temperatures.
>
> The percent conversion of the extracted components to PAHs decreased as the pyrolysis temperature decreased.
>
> The specific tumorigenicities of the pyrolysates, applied as 1% and 5% solutions in acetone in skin-painting studies involving both mice and rabbits, decreased as the pyrolysis temperature was lowered.
>
> Pyrolysis of the extract in either an inert atmosphere (nitrogen) or an oxygenated atmosphere (air) at 880°C did not markedly affect the findings with respect to the yield of pyrolysate, the generation of PAHs, or the specific tumorigenicity (mouse skin-painting bioassay) obtained with a solution of 1% pyrolysate in acetone.

Studies on organic solvent extraction of tobacco conducted from the mid- to late 1950s by Rodgman (3241, 3242, 3246, 3251), Ashburn (116, 117), and Ashburn and Rodgman (121) provided analytical data on the PAHs in mainstream CSC that in some ways paralleled the findings reported by Wynder (4294). Rodgman (3251) summarized the RJRT R&D findings as follows:

> Organic-solvent extraction of various tobacco types (flue-cured, burley, Oriental) and blends reduced the yields of both total and individual PAHs, e.g., B[*a*]P in mainstream CSC both on a per cigarette basis and on a weight of tobacco consumed basis. The per cigarette "tar" yields were also reduced in every instance.

Partition of the organic solvent extractables between a solvent system consisting of a polar solvent (aqueous ethanol) and

a nonpolar solvent (hexane or pentane) and returning each partition fraction separately to the organic solvent-extracted tobacco residue indicated:

> Addition of the nonpolar solvent-soluble material (which contained the bulk of the tobacco waxes) to the extracted tobacco residue returned the CSC PAH yield almost to that of the CSC from the unextracted (control) tobacco, and
>
> Addition of the polar solvent-soluble material (which consisted primarily of oxygen- and/or nitrogen-containing flavor-contributing tobacco components) to the extracted tobacco produced very little change in the PAH (both total and individual) level of the CSC.

These results were interpreted as an indication that the relatively high-molecular-weight, nonvolatile tobacco wax components were the major precursors in tobacco of the PAHs in smoke, whereas the moderate to low molecular weight and volatile flavorful components in tobacco did not contribute significantly to the PAH levels in smoke.

Addition of the organic solvent-soluble tobacco components, e.g., long-chained aliphatic hydrocarbon fraction, solanesol, or β-sitosterol, to unextracted (control) tobacco increased the levels of the total and some individual PAHs in the CSC. Thus, removal of tobacco wax components reduced the levels of both the total and individual PAHs in CSC, whereas addition of tobacco wax components increased the levels of both the total and individual PAHs in CSC (3251, 3269).

Examination of the relationship of the level of B[*a*]P to that of other individual PAHs in the various CSCs from the solvent-extracted tobaccos or from the component-"spiked" tobaccos confirmed what was already obvious from other literature data: B[*a*]P is not a valid "indicator" for either total PAHs or other individual PAHs with fewer than four fused rings, with four fused rings, or with more than four fused rings.

From the mid-1960s to the early 1970s, the USDA group described the pyrolysis of organic solvent extractables from tobacco. In the earlier studies, the pertinence of the pyrolysis results in defining the precursors in tobacco of the PAHs in the CSC was emphasized (3465, 3455), but subsequent research dealt with the precursors in tobacco of the simple phenols in cigarette smoke (3456, 3468).

In 1968, Schlotzhauer and Schmeltz (3465) noted that hexane extractables from tobacco constituted about 6% of the original tobacco weight, whereas the extracted tobacco residue constituted about 94% of the original tobacco weight. Pyrolysis of the hexane extractables and the extracted tobacco residue indicated that, of the total B[*a*]P determined in these two pyrolysates, about 60% was found in the hexane extractables pyrolysate (6% of the original tobacco) and 40% in the pyrolysate of the extracted tobacco residue (94% of the original tobacco). Schlotzhauer and Schmeltz (3466) also demonstrated by pyrolysis of individual components isolated from the hexane extract that the following were precursors of the PAHs in the pyrolysates: *n*-dotriacontane, stearic acid and linoleic acid, phytol, squalene, and β-sitosterol.

In 1973, Chortyk and Schlotzhauer (722) reviewed the pyrogenesis of tobacco smoke components. They discussed the extraction/pyrolysis results described earlier plus results of their studies on the pyrolysis (800°C) of fractions sequentially extracted from tobacco with a series of increasingly polar solvents (hexane, acetone, ethanol, water) (3458). Chortyk and Schlotzhauer (722) noted:

> The sources of about 70% of the aromatic hydrocarbons ranging from benzene to BaP, in the pyrolysates, were due to leaf components extractable with hexane and acetone: these extracts amounted to less than 25% of dry leaf weight. The hexane extractables (7.2% of leaf weight) accounted for 33% of the neutral products. The hexane-soluble material of cured leaf tobacco is known to include aliphatic and cyclic paraffins, fatty acids, phytosterols, steryl esters, and terpenes, all preferred precursors of aromatic hydrocarbons. The acetone extract (17.5% of leaf weight) contributed another 35% of aromatic hydrocarbons to the pyrolysate, indicating a further extraction of similar polycyclic aromatic hydrocarbons precursors. Together, these two extracts contributed 86% of the BaP content of the tobacco pyrolysate. The disproportionate contribution of these fractions to BaP formation becomes apparent from the following data: the hexane and acetone fractions, containing hydrocarbons and lipids, yielded about 700 mg [sic]* BaP per gram of material pyrolyzed, while the residual tobacco, consisting mostly of cellulose materials, yielded less than 34 mg [sic]* of BaP per gram pyrolyzed.

They also demonstrated that the major volatile phenols (phenol, cresols) were produced primarily by pyrolysis of the alcohol extractable and the final tobacco residue. These fractions accounted for 38% and 44%, respectively, of the total phenols yield. The alcohol extractables included polyphenolic tobacco pigment and low-molecular-weight sugars, whereas the final tobacco residue contained the polysaccharides celluloses, starch, pectins, and lignin. All these yield the simple phenols on pyrolysis or during tobacco smoking (248, 2043, 3277, 3305, 3453, 3468, 3767).

In 1978, Severson et al. (3616) revisited the organic solvent extraction of tobacco. They noted [see p. 277 in (3616)]:

> Numerous pyrolytic studies have shown that the hexane or petroleum ether…extract of tobacco contains the major precursors of smoke polycyclic aromatic hydrocarbons [Wynder et al. (4355), Schlotzhauer et al. (3468), Schlotzhauer and Chortyk (3451)]. However, many of these studies were made under conditions which produced optimum PAH yields [Schmeltz and Hoffmann (3489)]; thus, the PAH distributions were not comparable to those in [CSC] and the data obtained could not be exactly correlated with PAH production during the smoking process.

Severson et al. (3616) determined the pyrolytic conditions that gave the PAH profiles of tobacco pyrolysates that they claimed "could be correlated with [CSC] PAH profiles." Examination of their data indicates that this claim is not

* Obviously the reports of 700 mg of BaP and 34 mg of BaP formed from a gram of material pyrolyzed are in error.

valid. Severson et al. conducted two major experiments. They examined:

1. The effect of petroleum ether extraction on the PAH levels in the pyrolysates from the petroleum ether extractables PEE (8% of the original tobacco weight), the extracted tobacco residue (92% of the original tobacco weight), and the original tobacco.
2. The effect of chromatography of the petroleum ether extractables PEE with eight increasingly polar solvent systems, ranging from petroleum ether to an acetone:methanol solution, on the composition of each of the eight chromatographic fractions and on the PAH levels in the pyrolysates from each of the eight fractions.

Table 25.3, adapted from (3616), indicates that, at the optimum pyrolysis conditions specified (700°C, N_2), the totals of the PAH groups (except for the benzopyrene group) in the pyrolysates from the petroleum ether extractables (PEE) and the extracted tobacco residue (RES) are substantially higher (42%–89%) than the levels of the same PAH groups in the pyrolysate from unextracted tobacco. Table 25.3 also shows that the sum of the total PAHs in the pyrolysates from the two fractions [PEE and extracted tobacco residue (RES)] was 61% greater than the total PAHs in the control tobacco pyrolysate. Similar studies on individual and total acids and individual and total phenols in the same pyrolysates reveal that the sum of the total phenols in the pyrolysate of the PEE and the total phenols in the extracted tobacco residue (RES) was 21% less than the total phenols in the control tobacco pyrolysate; for acids, the sum of total acids in the pyrolysates from the two fractions (PEE plus residue) was 13% greater than the total acids in the control tobacco pyrolysate.

If this situation prevails in the relatively simple situation (PEE, extracted tobacco residue, and unextracted control tobacco) described earlier, then it is highly likely that the discrepancy will be enhanced when individual compounds are considered, i.e., there will be substantial uncertainty in any attempt to extrapolate from pyrolysis data on a specific compound, either present in or proposed to be added to tobacco, to what will actually happen to that compound during the smoking of a cigarette.

Since Severson et al. (3616) defined the composition of the eight chromatographic fractions, the remainder of their research findings will be discussed in the following section.

25.3 INDIVIDUAL TOBACCO COMPONENTS

The research conducted from the early 1950s to the mid-1960s on the organic solvent-soluble precursors in tobacco of the PAHs in cigarette MSS has been described in detail

TABLE 25.3
Comparison of PAH Fraction Levels, Phenol Yields, and Acid Yields in 700°C Pyrolysates from Tobacco, PEE, and the Tobacco Residue (RES) after Extraction

by Wynder and Hoffmann [see pp. 345–351, 518 in (4332)] and Hoffmann and Wynder (1798). Despite the fact that the tumorigenic PAHs at their levels in cigarette smoke and acting in concert with promoting and/or cocarcinogenic but nontumorigenic PAHs, phenols, acids, etc., at their levels in cigarette smoke explain only a small fraction (less than 2%) of the biological response (measured as % TBA) observed in skin-painted laboratory animals, efforts to define the major precursors in tobacco of the tumorigenic PAHs in cigarette smoke were continued into the late 1970s, particularly by the USDA group at Athens, GA (3616). Despite the advances during this period in the laboratory techniques for (1) successful fractionation of complex mixtures such as those found in cigarette MSS and in the pyrolysates from various tobaccos, tobacco fractions, and tobacco components and (2) the quantitation of the levels of individual identified PAHs, phenols, aldehydes, ketones, etc., no revolutionary new precursor in tobacco of PAHs in tobacco smoke was discovered: The organic solvent-soluble tobacco components that yielded PAHs on pyrolysis were essentially those or structurally similar to those that had been proposed several decades earlier in the 1950s. Several tobacco components, structurally similar to those proposed earlier had not been identified as tobacco components in the 1950s, but once they were identified, logic dictated they would yield PAHs either on pyrolysis or during the tobacco smoking process. For example, in the late 1950s, Wright [(4282), cf. Rodgman (3243)] theorized that the high-molecular-weight terpenes (other than the phytosterols) and the phytosterols themselves were major precursors in tobacco of the PAHs in tobacco smoke. These proposals were subsequently confirmed: In 1958, Rodgman and Cook (3269, 3291) demonstrated in a "spiking" experiment with solanesol that it was an effective precursor of total and individual PAHs in cigarette MSS as indicated by the increased levels in the PAHs in the MSS from solanesol-"spiked" tobacco cigarettes *vs*. those in the MSS from control tobacco cigarettes. Similarly, Rodgman and Cook reported that results from phytosterol-"spiked" tobacco cigarettes indicated the phytosterol was a major precursor of PAHs in MSS. In 1979, Severson et al. (3616) demonstrated that solanesol pyrolysis generated substantial amounts of PAHs *vs*. other organic solvent-soluble tobacco components.

In subsequent sections, pyrolysis studies on various tobacco components categorized as follows will be discussed:

Nicotine
Organic solvent-soluble components: long-chained aliphatic saturated and unsaturated hydrocarbons; terpenoid alcohols such as the duvanediols, phytosterols, phytol, and solanesol; normal long-chained aliphatic alcohols; esters of these groups of alcohols with long-chained aliphatic acids (palmitic, stearic, oleic, etc.)
Structural components of tobacco (the biopolymers such as lignin and the polysaccharides cellulose, starch, and pectins and their constituent monosaccharides such as glucose and fructose)
Acids
Proteins and amino acids

Nicotine (as well as the other nicotine-related alkaloids in tobacco, usually present in trace amounts) is the one tobacco component whose level in tobacco is sometimes controlled by removal in a denicotinization process. In contrast to the removal or reduction of its level in the case of nicotine, materials such as simple sugars, glycerol, and some flavorants are added to the tobacco blend to augment their existing levels in the tobacco and to enhance certain consumer acceptable organoleptic properties of the MSS. Materials such as licorice, cocoa, and other flavorants are added to impart other consumer acceptable organoleptic properties to the smoke (2341).

25.3.1 Nicotine

Over the years, the results of numerous studies on the pyrolysis of nicotine have been published. Many of them, e.g., those of Frank et al. (25A22) and Woodward et al. (4275a, 25A84, 25A85) in the early 1940s, preceded the escalation in the 1950s of the interest in the cigarette smoke–health issue. Other early studies of nicotine pyrolysis in air or nitrogen included those in the early 1960s by Jarboe and Rosene (1923a) and Kobashi et al. (25A37, 25A38). In 1964, pyrolysis products generated from nicotine during the tobacco smoking process were summarized by Kuhn (2228).

In 1960, Van Duuren et al. (4027) extended their studies on tumorigenic PAHs in mainstream CSC to identify three tumorigenic *N*-heterocyclic compounds: the aza-arenes dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]-carbazole. Their yields were 0.1, 2.7, and 0.7 ng/cig, respectively, substantially less than that of the ng/cig yield reported for B[*a*]P in the early 1960s. These three *N*-heterocyclics had also been reported as mouse-skin tumorigens [see tabulation in Hartwell (1544)]. Dibenz[*a,h*]acridine and dibenz[*a,j*]acridine were also identified by Van Duuren et al. in pyrolysates from nicotine and pyridine (750°C, N_2).

However, the presence of these aza-arenes in tobacco smoke or nicotine pyrolysate has been questioned. Of the numerous reports on this class of compound in tobacco smoke, only one report describes the identification of one of the three, dibenz[*a,j*]acridine: Wynder and Hoffmann (4319, 4332) reported that their group, Candeli et al. (587), was able to confirm the presence of dibenz[*a,j*]acridine but not dibenz[*a,h*]acridine in mainstream CSC. The per cigarette yield for dibenz[*a,j*]acridine reported by Candeli et al. (587) was almost four times that reported by Van Duuren et al. Since 1963, no other investigator has reported these three compounds in tobacco smoke or a nicotine pyrolysate.

In 1970, Kaburaki et al. (2006) reported the results of their pyrolysis of nicotine at various temperatures in air and

in N_2. The two tumorigenic benzacridines reported in a nicotine pyrolysate by Van Duuren et al. as components of their nicotine pyrolysate were not found by Kaburaki et al.

Schmeltz et al. (3499) described the results of their pyrolysis of several nitrogenous tobacco components, including nicotine:

> We could not detect benzo(a)pyrene in nicotine pyrolyzates, nor could we confirm the presence of the physiologically active dibenzacridines and dibenzcarbazole reported in tobacco smoke and in nicotine and pyridine pyrolyzates by Van Duuren [4027].

In their review of the pyrogenesis of tobacco smoke components, Chortyk and Schlotzhauer (722) emphasized the failures of several investigators to confirm the two dibenzacridines and 7*H*-dibenzo[*c,g*]carbazole in nicotine pyrolysates:

> Since nicotine is the most abundant and best known tobacco alkaloid, its pyrolysis has been thoroughly studied [Woodward et al. (4275a), Jarboe and Rosene (1923a)]. More recent work [Kaburaki et al. (2006)] on the pyrolysis of nicotine and various alkylpyridines has resulted in a proposed mechanism for the thermal degradation of nicotine… Schmeltz [Schmeltz et al., (3499)] also studied nicotine and identified a number of previously unreported compounds in the nicotine pyrolysates… These included pyrrole, acenaphthene, indole, skatole, and anthracene and/or phenanthrene. However, the presence of dibenzacridines and dibenzcarbazole, previously reported in nicotine and pyridine pyrolysates, could not be confirmed [Van Duuren et al. (4027)].

In 1977, Schmeltz and Hoffmann (3491) in their review of *N*-containing components of tobacco and tobacco smoke discussed the generation of various pyridines from nicotine during both the actual smoking process and pyrolysis. Schmeltz and Hoffmann (3491) did report the identification by Van Duuren et al. (4027) of the two dibenzacridines in cigarette smoke and nicotine pyrolysate. They did not, however, comment on the inability of other investigators (587, 2006, 3499) to confirm the findings of Van Duuren et al.

In 1979, Schmeltz et al. (3512) reported their major findings from a study of the fate of radiolabeled nicotine during pyrolysis and during the actual smoking of a radiolabeled nicotine-treated cigarette:

> Under combustion tube pyrolysis conditions, nicotine in either silica gel matrix (pyrolysis temperature = 600°C, 750°C, or 900°C) or tobacco matrix (600°C) underwent extensive degradation to pyridines, quinolines, arylnitriles, and aromatic hydrocarbons.
>
> In a burning cigarette during actual smoking, a substantial portion of the nicotine (about 41%) remains intact, 12.5% is oxidized to carbon dioxide, as much as 11% is degraded to volatile alkylpyridines, and negligible amounts are converted to neutral or acidic components of the particulate phase.
>
> Dibenz[*a,h*]acridine and dibenz[*a,j*]acridine reported nearly two decades earlier by Van Duuren et al. (4027) were not identified in this study.

Schmeltz et al. (3512) noted:

> In ongoing studies we are now identifying those compounds that are formed from nicotine only as minor compounds (<0.1%) which nevertheless can contribute to the toxicity of the smoke. To this group of minor smoke constituents having nicotine as a precursor belong the dibenzacridines.

From their experimental results, Schmeltz et al. (3512) concluded that pyrolysis experiments may be of limited value for establishing the fate of nicotine and possibly other tobacco components in a burning cigarette.

The pyrolysis system in this study [cf. Higman et al. (1648)] was designed to be the optimum simulation of the smoking process. Obviously, nicotine did not behave in this pyrolysis system as it did in the burning cigarette during actual smoking. Examination of the 1979 Schmeltz et al. publication on the fate of nicotine during pyrolysis *vs*. actual smoking reveals at least two of the authors (Hoffmann, Schmeltz) definitely changed their opinion on their long-held view on the equivalence of compound behavior during pyrolysis and actual smoking, e.g., Wynder and Hoffmann (4332) earlier wrote:

> Most pyrolysis studies with tobacco, tobacco extracts, extract fractions, individual components, and tobacco additives are performed in a nitrogen atmosphere. This procedure has often been criticized on the grounds that many of the toxic constituents formed during smoking of tobacco products occur as a result of combustion in air rather than in a nitrogen atmosphere. This criticism, however, cannot be maintained in view of studies by Newsome and Keith [2780] which demonstrated that a reducing rather than an oxidizing atmosphere exists at the cone region of a burning cigarette.

With regard to the dibenzacridines and dibenzocarbazole from nicotine during pyrolysis and the smoking process, Table 25.4 summarizes the state of knowledge: None of the investigations conducted from 1963 through 2000 on the levels of these three aza-arenes in mainstream CSC confirmed the 1960 findings of Van Duuren et al. (4027).

Another aspect of the involvement of nicotine (and related tobacco alkaloids) in the generation of allegedly harmful tobacco and/or smoke components is the formation of tobacco-specific *N*-nitrosamines (TSNAs).* It is claimed by Hoffmann et al. that TSNAs such as *N′*-nitrosonornicotine (NNN) and 4-(*N*-methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) are formed from nicotine and other minor nicotine-related alkaloids during various stages of tobacco development and treatment (growing, curing, aging) [Hecht et al. (1563, 1564), Adams et al. (22)]. TSNAs appear in cigarette MSS as a result of two mechanisms: (1) direct transfer of the TSNAs from the tobacco to the smoke, (2) pyrogenesis during the smoking process. For example, Hoffmann et al. (1734) and Adams et al. (29) estimated that 40%–46% of the

* TSNAs include NNN from nicotine and nornicotine, NNK from nicotine, *N′*-nitrosoanatabine (NAT) from nicotine and anatabine, and *N′*-nitrosoanabasine (NAB) from anabasine.

NNN in MSS was a result of its transfer from the tobacco blend. The remainder—54%–60%—in MSS was due to pyrogenesis of NNN from nicotine and nornicotine during the smoking process. Similar data were generated for NNK: 26%–37% by direct transfer, 63%–74% by pyrogenesis.

The levels in MSS of TSNAs such as NNN can presumably be reduced by reduction in the level of nicotine and/or nitrate in the tobacco blend (499). However, Brunnemann et al. (511) have presented contradictory data on the significance of the correlations among the levels of nitrate, nicotine, and TSNAs in tobacco.

Since the TSNAs are components of the MSS particulate phase, control of their levels in smoke is also possible by any means that controls the yield of the MSS particulate matter. These include the following:

- Use of reconstituted tobacco sheet
- Expanded tobacco
- High filtration efficiency
- Air dilution by increased paper porosity and/or ventilated filter tips [Hoffmann et al. (1719)]

Unlike the volatile *N*-nitrosamines such as dimethylnitrosamine (DMNA), the TSNAs are not amenable to selective filtration by use of plasticized filter tips.

25.3.2 Organic Solvent-Soluble Components (Long-Chained Aliphatic Hydrocarbons, Phytosterols, Solanesol, High-Molecular-Weight Esters, etc.)

The tobacco smoke components "known" in 1954 numbered fewer than 100 (2170). At that time, the chemical composition of tobacco was as equally ill defined as that of its smoke. Pyrolyses conducted throughout the 1950s involved the organic solvent-soluble material from tobacco and were limited either to the total extractables or to a few classes of known tobacco components, e.g., phytosterols, long-chained saturated aliphatic hydrocarbons. These relatively high-molecular-weight compounds were present in tobacco at levels usually exceeding 0.5% and presented little problem in collecting sufficient material for study. Subsequent research on tobacco (and tobacco smoke) composition resulted in the isolation and elucidation of the structures of numerous classes of organic solvent-soluble compounds, including those listed in Table 25.5.

The early work of Roffo (3327) on the reduction of tumorigenicity of a "destructive distillate" from a solvent-extracted tobacco (ethyl alcohol), his claim that alcohol extraction removed the tumorigen precursor from the tobacco, and his proposal of the phytosterols as the tumorigen precursor(s) were described previously. Despite the fact that the "destructive distillate" from tobacco was not equivalent to cigarette smoke particulate matter, the proposal of the phytosterols as precursors in tobacco of PAHs was based on sound reasoning and previous experimental findings. Nearly two decades earlier, Kennaway (2073–2075) had demonstrated that pyrolysis of isoprene, acetylene, and cholesterol, yielded pyrolysates tumorigenic to mouse skin. Cholesterol was once considered unique to animal tissue, but subsequently, trace amounts were found in plant tissue, including tobacco [Stedman (3797), Grunwald et al. (1434)]. Of the tobacco and tobacco smoke sterols, the two present at the highest level are stigmasterol and β-sitosterol. These differ from each other and cholesterol in the structure and configuration of the side chain on the cyclopentane ring. They occur in tobacco as free phytosterols and phytosteryl derivatives (esters, glycosides). Pyrolysis of sterols generates high levels of chrysene. Its four rings are configurationally similar to that of the sterol ring system.

In the mid-1920s, Kennaway and others were concerned about the fate of cholesterol when animal tissue was heated during roasting and broiling. Cholesterol pyrolysis experiments were crude attempts to duplicate what happened to it

[a] Wynder and Wright (4354) reported geraniol as a cigarette smoke constituent. However, the infrared spectrum of the isolate was identical with that of solanesol, not geraniol (Wright, private communication to A.R.).

during the cooking process. Here again, the presence of other tissue components (amino acids, proteins, lipids, carbohydrates) with cholesterol during cooking would certainly have affected the results when compared to the results obtained from pyrolysis of cholesterol alone.

In 1928, Kennaway and Sampson (2080) also demonstrated that the specific tumorigenicities of pyrolysates from cholesterol and other organic compounds increased as the pyrolysis temperature was increased. This observation was later confirmed with saturated aliphatic hydrocarbons (2257) and phytosterols [Wynder et al. (4355, 4356)] isolated from tobacco. In the latter two studies, the yield of PAHs generated during pyrolysis of the compounds in question increased as the pyrolysis temperature increased. Wynder et al. (4355) and Wynder and Hoffmann (4332) reported that pyrolyses of a hexane extract of tobacco gave decreasing yields of pyrolysate "tar" as the pyrolysis temperature increased: 560°C, 50%; 640°C, 35%; 720°C, 32%; 800°C, 28%; and 880°C, 28%. They also reported that pyrolysis at 880°C of the hexane extractables in air *vs.* their pyrolysis in N_2 gave pyrolysates whose yields were essentially the same [30% (air) *vs.* 28% (N_2)] and whose specific tumorigenicities were comparable in skin-painting studies with the mouse and rabbit. Similar findings were reported for aliphatic tobacco hydrocarbons pyrolyzed either in air or in N_2 at 800°C with regard to PAH composition and specific tumorigenicity in skin-painting studies.

Table 25.6, adapted from Lam (2257), demonstrates the relationship between PAH generation and pyrolysis temperature for aliphatic tobacco hydrocarbons pyrolyzed in air at several temperatures. Calculation of the yield ratios [PAH, mg/g/B[*a*]P, mg/g] of the other PAHs *vs.* B[*a*]P reveals significant information: In this case of pyrolysis, there was no consistency between the change in ratios of PAH/B[*a*]P as the temperature was increased from 700°C to 800°C, e.g., in the case of the tetracyclic PAHs, the PAH/B[*a*]P ratio decreased for pyrene and chrysene but increased for fluoranthene; for the pentacyclic PAHs, the ratio decreased for both perylene and B[*e*]P; for the hexacyclic PAH dibenzo[*def,mno*]chrysene, the ratio increased. These same trends existed whether PAH/B[*a*]P ratios were calculated as molar yields or, as in Table 25.6, as absolute quantities (μg of PAHs generated per gram of aliphatic tobacco hydrocarbons pyrolyzed).

The significance of these data and calculations is their demonstration in 1956 that in even the simplest pyrolysis situation, B[*a*]P is not a valid "indicator" for the PAHs with four or more rings and their supposed relationship to tumorigenic activity [Wynder and Hoffmann (4317, 4319, 4332)]. In addition to these data by LAM, other contrary data which demonstrated the invalidity of the concept of B[*a*]P as an "indicator" for PAHs with four or more rings and the tumorigenicity of the substrate (CSC, pyrolysate) containing them were generated not only by Wynder et al. (4355, 4356) but also by Campbell and Lindsey (583), Rodgman and Cook (3286), Gori (1329, 1330, 1332, 1333), NCI (2685), and Severson et al. (3616).

The lack of correlation between CSC content of B[*a*]P and specific tumorigenicity was demonstrated by Lazar et al. (2320) who reported that a 30-fold increase in B[*a*]P content by its addition to CSC produced no increase in the specific tumorigenicity to mouse skin of the B[*a*]P-enhanced CSC *vs.* the control CSC applied at equal dose levels. This lack of correlation between the B[*a*]P concentration in CSC and

its specific tumorigenicity was also recognized by the U.S. Surgeon General who wrote 1981 [see p. 36 in (4009)]:

> The contribution of BaP or PAH in general to mouse skin carcinogenesis by cigarette smoke condensate cannot be fully measured at this time. Wynder and Hoffmann [4332] found a correlation between BaP levels and carcinogenic activity of smoke condensates from several types of cigarettes. A much larger series of experimental cigarettes was studied in the smoking and health program of the National Cancer Institute. No significant dependence of carcinogenic potency on BaP content was observed [Gori (1329, 1330, 1332, 1333), NCI (2683)].

The post-1930 stimulus for PAH research was provided by the following events: the independent syntheses of DB[*a,h*]A in 1929 by CLAR (760) and Fieser and Dietz (1184); the demonstration of its mouse-skin tumorigenicity by Kennaway and Hieger (2078); the early 1930s reports by Cook et al. (726, 727) on several PAH isolates from coal tar, known to be tumorigenic to the skin of mice and rabbits; identification of two coal tar isolates as B[*a*]P and B[*a*]A; and the demonstration of the tumorigenicity to mouse skin of B[*a*]P (194, 726).

In addition to Kennaway and Sampson (2080), numerous investigators after 1932/1933 examined the pyrolysates from sterols in conjunction not only with the alleged tumorigenicity and PAH content of "destructive distillates" from tobacco, CSCs, and pyrolysates of tobacco, tobacco extractables, and individual tobacco components but also with the alleged tumorigenicity and PAH content of heated foodstuffs and their role in digestive tract cancer. For example, Roffo, in addition to his tumorigenicity studies with "destructive distillates" from various tobaccos types (3320, 3324, 25A51) and organic solvent-extracted tobaccos (3327), investigated the tumorigenicity of heated or oxidized fats (25A53, 25A55, 25A59) and the "tars" and phenanthrene derivatives from cholesterol pyrolyzed (25A56, 25A57, 25A58) or irradiated in air (25A54).

Other investigators who examined the chemical and biological properties of cholesterol pyrolysates included Steiner et al. (25A69), Falk et al. (1171), and Bischoff and Rupp (25A10). Previously, Veldstra (4042a) had demonstrated that 3,5-cholestadiene, produced pyrolytically from cholesterol, was tumorigenic to skin-painted laboratory animals. Subsequently, cholesten-4-one was found to be both tumorigenic to mouse skin and a component of the pyrolysate from cholesterol and/or its derivatives. These and other pyrolysate findings on composition (PAHs in the pyrolysate) and properties (tumorigenicity of pyrolysate and/or the components of pyrolysates generated from cholesterol or its naturally occurring derivatives) were summarized by Rodgman (3233, 3242). Although the pentacyclic PAH 1,2-dihydro-3-methylbenz[*j*]aceanthrylene (previously known as 3-methylcholanthrene or 20-methylcholanthrene), a potent mouse-skin tumorigen, may be prepared by a series of chemical reactions from a sterol-derived compound structurally related to cholesterol, it has never been identified in a sterol pyrolysate. Although Kröller (2191) claimed the identification of 1,2-dihydro-3-methylbenz[*j*]aceanthrylene (3-methylcholanthrene) in mainstream CSC, his identification of it was questioned by Wynder

and Hoffmann (4332) who asserted that it and other alkylated PAHs had never been reported as a combustion or pyrolysis product. Wynder and Hoffmann (4332) also questioned the reports by Pietzsch (2962) and Kröller (2191) of the presence in CSC of the methylated PAH DMB[*a*]A. It and other methylated PAHs in mainstream CSC were reported in 1960 by Rodgman and Cook (3273). In addition, in 1963, Grossman et al. (1431, 1432) reported alkylated naphthalenes in the pyrolysate from solanesol, a major tobacco component. In the 1970s, Snook et al. reported not only several dimethylbenz[*a*]anthracenes in CSC (3756) but also a great number of alkylated PAHs in CSC (3757). Thus, the Wynder–Hoffmann assertion about the presence of alkylated PAHs in MSS was incorrect.

Campesterol, stigmasterol, β-sitosterol, and cholesterol have been identified both free and/or bound (as esters, etc.) in tobacco and CSC [see Grunwald et al. (1434) for a summary of the early research on tobacco sterols and their derivatives]. In their study, Grunwald et al. found that these four sterols constituted about 0.16% of the tobacco weight, and about 15% of them were transferred to MSS. According to Grunwald et al., the remainder of the sterols were "Lost in the smoke sidestream, pyrolyzed during the smoking process and/or deposited in the butt." Thus, a cigarette containing 1.0 g of the tobacco studied by Grunwald et al. would contain 1600 µg of these sterols and deliver about 240 µg to MSS. About 82 µg of the 240 µg would be β-sitosterol, a compound reported to be anticarcinogenic to several *N*-nitrosamines [Grunwald et al. (1434)]. This indicates the relative proportions of these four sterols in tobacco: Cholesterol is the least plentiful of the four tobacco sterols in Table 25.7.

Except for minor differences in the side-chain structure, the cholesteryl oleate studied by Veldstra (4042a) is structurally similar to the phytosteryl ester fraction isolated from tobacco by Rowland and Latimer (3358) and from CSC by Rodgman et al. (3296). It was subsequently identified as a mixture of esters of stigmasterol and β-sitosterol with long-chained saturated (palmitic, stearic) and unsaturated (oleic, linoleic) acids. In the late 1950s to early 1960s, Rodgman and Cook were unsuccessful in their CSC study to identify the stigmasterol- or β-sitosterol-derived dienes or ketones corresponding to the tumorigenic 3,5-cholestadiene and cholesten-4-one generated during pyrolysis of cholesterol or its esters. However, Benner et al. (273) subsequently identified 3,5-campestadiene (VIb) and 3,5-stigmastadiene (VId) in tobacco smoke [cf. Eatough et al. (1099, 1100)]. The following paragraphs summarize the relationships, both known and proposed, between a sterol such as cholesterol and its various pyrolysis products:

TABLE 25.7
Total, Free, and Bound Sterols in Cigarette Tobacco

			Total	
Sterol	Free, µg/g Tobacco	Bound, µg/g Tobacco	µg/g Tobacco	%
Stigmasterol	326	262	588	37
β-Sitosterol	185	366	551	34
Campesterol	129	173	302	19
Cholesterol	79	86	165	10
Total	719	887	1606	100

Because of the results of the studies by Kennaway (2073–2076), Kennaway and Sampson (2080), and Roffo (25A56, 25A57, 25A58) on the generation of tumorigenic pyrolysates from cholesterol or cholesterol-containing foodstuffs, the question was raised: What is the relationship between these observations on tumorigenic cholesterol pyrolysates and the incidence of stomach and digestive tract cancers? When many studies, beginning in 1934 [see summary in Hartwell (1544)], revealed that 1,2-dihydro-3-methylbenz[*j*]aceanthrylene (3-methylcholanthrene) was a potent tumorigen equivalent in potency in mouse-skin-painting bioassays to B[*a*]P and DB[*a,h*]A, extensive research was conducted in attempts to determine whether it was generated from cholesterol during various cooking processes. Examination of the entries in the catalogs by Hartwell (1544) and Shubik and Hartwell (3664) for the four PAHs considered to be potent tumorigens revealed 474 studies involving 1,2-dihydro-3-methylbenz[*j*]aceanthrylene (3-methyl-cholanthrene) between 1934 and 1953, 410 studies involving B[*a*]P between 1932 and 1953, 275 studies involving DB[*a,h*]A between 1930 and 1953, and 91 studies involving DMB[*a*]A between 1938 and 1953.

One of the most potent PAHs in mouse-skin-tumor induction is 1,2-dihydro-3-methylbenz[*j*]aceanthrylene (3-methylcholanthrene) which theoretically could be formed pyrogenetically from sterols such as cholesterol {Ia}. In addition to the trace level of cholesterol present in tobacco, tobacco usually contains substantial levels of several phytosterols [campesterol {Ib}, β-sitosterol {Ic}, stigmasterol {Id}, ergosterol {Ie}] structurally similar to cholesterol. These phytosterols differ from cholesterol {Ia} in the structure of the long side chain. Stigmasterol {Id} is structurally similar to β-sitosterol {Ic} except for a double bond at the C_{22} carbon. The legend to Figure 25.1 indicates the differences among cholesterol, campesterol, β-sitosterol, ergosterol, and stigmasterol. These sterols, present in tobacco in both the free and bound form (as glycosides, esters), are transferred intact to MSS.

These sterols constitute about 0.2% of the tobacco weight. Table 25.7, adapted from Grunwald et al. (1971), illustrates the relative proportions of these sterols in tobacco. These data indicate that cholesterol and cholesteryl derivatives are the least plentiful of the free and bound sterols in tobacco. These levels are similar to those of the standard and reference cigarettes in the National Cancer Institute (NCI) "Less Hazardous" Program (1329, 1330, 1332 1333, 2683).

As shown in Figure 25.1, pyrolysis of cholesterol {Ia} yields chrysene {III} and a Diels hydrocarbon {IV}, a methylcyclopentaphenanthrene. Both PAHs have also been isolated from pyrolysates of the major tobacco phytosterols. While cholesterol {Ia} and the tobacco phytosterols [campesterol {Ib}, β-sitosterol {Ic}, stigmasterol {Id}] have not been shown to generate 3-methylcholanthrene {II} on pyrolysis, cholesterol {Ia} and its esters with long-chained acids do generate the mouse-skin tumorigens 4-cholesten-3-one {Va} and 3,5-cholestadiene {VIa} (1171). Veldstra (4042a)

reported that the pyrolysis of cholesteryl oleate also yielded 3,5-cholestadiene {VIa}. Cholesteryl oleate was probably a component of the mixture of steryl esters described in flue-cured tobacco by Rowland and Latimer (3358) and in tobacco smoke by Rodgman et al. (3296). The steryl esters included sterols esterified with a series of saturated (palmitic, stearic, etc.) and unsaturated (oleic, linoleic, etc.) acids.

In the late 1950s, Rodgman proposed that on thermal degradation during the smoking process, campesterol, stigmasterol, and β-sitosterol and their esters might generate the ketones {Vb, Vc, Vd} and dienes {VIb, VIc, VId} analogous to 4-cholesten-3-one {Va} and 5-cholestadiene {VIa}, and they might also be mouse-skin tumorigens like their cholesterol counterparts.

Several PAHs other than chrysene and Diels hydrocarbon (Figure 25.1) were subsequently identified in sterol pyrolysates. In 1959, Wynder et al. (4355, 4356) reported that PAHs were generated at both temperatures when tobacco sterols were pyrolyzed in air at 720°C and 850°C. At these temperatures, the pyrolysates constituted 28% and 22%, respectively, of the phytosterols pyrolyzed; B[*a*]P constituted 0.1% and 1.0%, respectively, of the pyrolysates. These results with phytosterols pyrolyzed at two different temperatures are similar to those reported for the pyrolyses of aliphatic tobacco hydrocarbons (2255–2258).

In 1962, Van Duuren (4022) described the identification of pyrene and B[*a*]P in a stigmasterol pyrolysate. Badger et al. (142) in their pyrolysis study of tobacco phytosterols reported the identification of some 30 PAHs, all previously reported as CSC components. They also noted the accentuated production of chrysene *vs.* its generation by pyrolysis of aliphatic tobacco hydrocarbons. Chrysene, reported to be tumorigenic to mouse skin, is a sterol pyrolysis product characteristically generated at a high level compared to that for other PAHs in the pyrolysate. The four-ring arrangement in chrysene is similar to that of the sterol rings. The International Agency for Research on Cancer (IARC) eventually removed chrysene from the tumorigen list.

From a precursor "spiking" experiment involving addition to tobacco of aliphatic tobacco hydrocarbons, a phytosterol (β-sitosterol), or solanesol, it was noted that the increase in the chrysene yield in the CSC was much more pronounced with phytosterol-treated tobacco than with aliphatic hydrocarbon- or solanesol-treated tobacco (3251, 3269, 3291). Doubling the levels of solanesol, aliphatic tobacco hydrocarbons, and phytosterols by addition of each to a control tobacco blend resulted in increases in the B[*a*]P yields in the mainstream CSCs of 13%, 13%, and 16%, respectively. However, the chrysene yields were increased by 16%, 28%, and 183%, respectively. Tripling the addition levels increased the B[*a*]P levels in the mainstream CSCs by 18%, 20%, and 28%, respectively, and the chrysene levels by 22%, 50%, and 239%, respectively.

In their study of the petroleum-ether-extractable material (8% of tobacco weight) from tobacco which was chromatographically separated into eight fractions (see Table 25.8), Severson et al. (3616) identified PAHs in the pyrolysates from Fractions F-2 and F-3 (containing phytosterol derivatives) and from Fractions F-5 and F-6 (containing unbound phytosterols). Their PAH data for these four pyrolysates from phytosterol-rich tobacco fractions showed high yields of chrysene *vs.* those in the pyrolysates from the essentially phytosterol-free fractions (F-1, F-2, F-7, and F-8).

TABLE 25.8
Component Distribution in Eight Subfractions from a Petroleum Ether Extract of Tobacco (8% of Tobacco Weight) (3616)

Chromatographic Fraction		
No.	**%**	**Major Component(s)**
F-1	5.3	Long-chained saturated hydrocarbons, neophytadiene
F-2	4.3	Esters of sterols and terpenoid alcohols
F-3	8.9	Esters of sterols and solanesol
F-4	29.2	Solanesol
F-5	6.6	Solanesol, sterols, and long-chained fatty acids
F-6	20.3	Sterols and long-chained fatty acids
F-7	15.8	Polar esters of fatty acids
F-8	9.6	Polar esters of fatty acids

TABLE 25.9
Conversion of Tobacco Leaf Constituents to Total MSS PAHs

Leaf Constituent	% Conversion to Mainstream PAHs
Phytosterols	<1.0
Palmitic acid	<1.0
Neophytadiene	0.10
Polar fraction	0.15
Alkaloids	0.10

Although their study dealt with pyrolysis of tobacco phytosterols, Schmeltz et al. (3511) did determine the percent conversion of phytosterols (and other components) to MSS PAHs by use of radiolabeled phytosterols generated by growing tobacco in an atmosphere containing radiolabeled CO_2, isolating radiolabeled tobacco components, and adding them individually to cigarettes which were then smoked and the MSS analyzed. Their data are summarized in Table 25.9. Their 1978 finding with radiolabel techniques (<1% conversion to PAHs) for the tobacco phytosterols is comparable to the 1958 data of Rodgman and COOK (3269, 3291) who, using classical chemical techniques in a "spiking" experiment, reported the conversion of β-sitosterol to PAHs to be about 0.6%,

As noted by Wynder and Hoffmann (4319, 4332), the first group of tobacco components studied by pyrolysis was the "tobacco paraffins." Subsequently, these were shown to consist of a mixture of *n*- (normal), *iso*- (2-methyl-), and *anteiso*- (3-methyl-) saturated hydrocarbons C_nH_{2n+2}, the bulk of which comprised hydrocarbons ranging from 10 or 12 to more than 40 carbon atoms. These hydrocarbons were also extractable from tobacco by pentane, hexane, or petroleum ether. Pyrolysis studies in air or an inert atmosphere (N_2, He) with either the tobacco-derived saturated aliphatic hydrocarbon fraction or individual components of the fraction [see Lam (2255, 2256, 25A39), Wynder et al. (4356)] or individual hydrocarbons [see Lam et al. (2260) for *n*-pentacosane, Haefele and Giles (1480) for *n*-hentriacontane, Badger and Novotny (151) for *n*-decane, Badger et al. (142) and Lam (2256) for *n*-dotriacontane (dicetyl)] indicated that these tobacco components yielded pyrolysates reported to be tumorigenic in mouse-skin-painting bioassays and to contain many PAHs, several of which were tumorigenic in long-term mouse-skin-painting bioassays.

The PAHs identified in the various pyrolysates ranged in complexity from bicyclic (naphthalenes), tricyclic (acenaphthenes, anthracenes, phenanthrenes), tetracyclic (pyrenes, fluoranthenes, chrysenes, benzanthracenes), pentacyclic (perylenes, benzopyrenes, dibenzanthracenes, benzofluoranthenes), hexacyclic (dibenzochrysenes), and heptacyclic (coronene). Eventually, all the PAHs identified in the various pyrolysates were identified in mainstream CSC. In every case where the pyrolysis temperature was lowered, the yields of the PAHs in the pyrolysate also decreased (see Table 25.6).

From data they generated, Rayburn and Wartman (3091) and Rayburn et al. (3092) challenged the concept that the saturated aliphatic hydrocarbons in tobacco were precursors of the PAHs in mainstream CSC. Wynder and Hoffmann (4319, 4332), in turn, criticized the experimental procedures which provided the data upon which Rayburn et al. based their argument:

> The experimental findings [of Rayburn et al.] are partially based on total polycyclic hydrocarbons of similar ultraviolet spectra and not on analytical data. The report did not mention counting techniques for C^{14}-labeled paraffins nor their quenching effects. These, as well as other factors, appear to weaken considerable the challenge of a concept based on extensive experimental data.

In 1979, Severson et al. (3616), in their study of the PEE (8% of tobacco weight) chromatographically separated into eight fractions (see Table 25.8), reported the identification of PAHs in the pyrolysate from Fraction F-1, the fraction containing the saturated aliphatic hydrocarbons extracted from the tobacco.

As recently as 1985, Lam et al. (2260) identified numerous PAHs in the pyrolysate from *n*-pentacosane, a known component of the saturated aliphatic hydrocarbon fraction present in tobaccos.

In 1958, Rodgman and Cook (3269, 3291) added tobacco-derived saturated aliphatic hydrocarbons to a tobacco blend in a "spiking" experiment and determined the effect of the addition on the PAH levels in mainstream CSC. They reported the added saturated hydrocarbons increased the yield of PAHs in cigarette MSS and thus were precursors of the smoke PAHs.

The structure of the unsaturated C_{45} polyisoprenoid alcohol, solanesol, was established in 1956 by Rowland et al. (3359). Despite the fact that solanesol was one of the major individual components of the extractable waxes from tobacco, its pyrolysis was not reported until 1962. While Lam (2255) favored the saturated hydrocarbons as the major precursors in tobacco of PAHs in smoke, Wynder (4294) considered both the saturated hydrocarbons and the phytosterols to be the major precursors. Wright (4282) proposed that the phytosterols and other terpenoids such as solanesol were the major precursors in tobacco of PAHs in smoke. In spite of their differences of opinion on the relative importance of these tobacco components in their contribution to smoke PAHs, they collaborated on several studies in the late 1950s (4355, 4356). Subsequently, the saturated hydrocarbons, the phytosterols, and other terpenoids such as solanesol were shown to be important in the formation of PAHs in tobacco smoke (3251, 3269, 3291, 3616).

In the early 1960s, Grossman et al. (1431, 1432) examined the pyrolysate from solanesol and reported the identification of monocyclic hydrocarbons (benzene and cyclopentene derivatives) (1431) and bicyclic aromatic hydrocarbons (naphthalenes) (1432). No tricyclic PAHs were reported. In 1963, Gil-Av and Shabtai (1286) postulated that solanesol in tobacco was a source of tobacco smoke PAHs and proposed a mechanism for their generation from solanesol: Solanesol and other similarly configured terpenoid compounds, e.g., neophytadiene, squalene, duvane derivatives, depolymerized during the smoking (or pyrolytic) process to produce isoprene which, in turn, reacted with itself and subsequent reaction products to generate a tumorigenic "tar" such as that described in the mid-1920s by Kennaway (2073–2075). This "tar" derived from solanesol via isoprene would contain the requisite tumorigenic PAHs such as B[*a*]P. Although Gil-Av and Shabtai (1286) demonstrated the presence of B[*a*]P in an isoprene pyrolysate, they did not study the pyrolysis of solanesol.

Severson et al. (3616) described the pyrogenesis of PAHs from solanesol in their study of the petroleum ether tobacco extractables (8% of tobacco weight) which they chromatographically separated into eight fractions (see Table 25.8). Fraction F-4 was primarily solanesol. Fraction F-3 contained solanesyl esters. Severson et al. (3616) summarized the contribution of solanesol to PAHs in its pyrolysate (and in CSC):

> The carotenoids and solanesol are most like responsible for the high levels of the multialkylated PAH found in the [petroleum ether]-extract pyrolyzate and, by analogy, in CSC. Because of its relative abundance in leaf, solanesol may contribute as much as 40% of the benzopyrenes produced on pyrolysis of the [petroleum ether] extract of tobacco.

As noted previously, 1958 precursor experiments (3251, 3269, 3291), in which solanesol was added at several levels in a "spiking" experiment and the effect of this addition on the levels of total and individual PAHs in cigarette MSS was determined, demonstrated that solanesol in tobacco was indeed a significant precursor of PAHs in cigarette MSS.

Phytol, a terpenoid alcohol, is a known component of tobacco leaf. It and its structurally similar dehydration product, neophytadiene, probably occur in tobacco leaf through the degradation of chlorophyll whose structure includes phytol (3345). Neophytadiene (3247), phytol (3285), and phytyl esters (3287) are present in tobacco smoke (see Table 25.5). Schmeltz et al. (3511), in their 1978 radiolabel study, determined the contribution of neophytadiene to PAHs in cigarette MSS. They estimated that about 0.1% of the tobacco neophytadiene is converted during the smoking process to PAHs in the MSS (see Table 25.9). The pyrolysis products of neophytadiene and phytol were examined in 1985 by Lam et al. (2260). Numerous PAHs were identified in the pyrolysates of both compounds. However, as a result of their study of the pyrolysis of phytol and a phytol derivative, Moldoveanu et al. (5539) considered in 2010 that phytol was not a significant contributor to PAHs in cigarette smoke, a view that disagreed with the findings of Lam (2260) and Schlotzhauer and Schmeltx (3466) and the earlier views and findings of Wright (4282), Rodgman (3251), Rodgman and Cook (3269, 3291), Schmeltz et al. (3511), and Severson et al. (3616) on the contribution of polyisoprenoid components in tobacco to the levels of PAHs in cigarette smoke.

Normal long-chained aliphatic alcohols, known minor components of tobacco (614, 615, 25A18, 25A80) and tobacco smoke (812), may not play a significant role as PAH precursors. In fact, Carruthers and Johnstone (614, 615), who

[b] Several other PAHs were found in some, but not all, of the pyrolysates, namely, azulene, naphthalene, alkylnaphthalenes, acenaphthene, phenanthrene, and perylene.

[c] Tumorigenic to mouse skin in skin-painting studies.

identified 1-docosanol in tobacco, found little of its dehydration product, 1-docosene, in tobacco smoke. They postulated that long-chained primary alcohols such as 1-docosanol were little affected by pyrolysis. Severson et al. (3616) cataloged the major components in eight chromatographic fractions of the PEE from tobacco (see Table 25.8). Each fraction was subjected to pyrolysis. Surprisingly, Severson et al. did not list long-chained primary alcohols in any of the eight chromatographic fractions!

25.3.3 Structural Components of Tobacco (Cellulose, Lignin, Pectins, etc.)

Since cellulose, pectins, starch, lignin, and proteins—the so-called structural components of tobacco—are organic compounds, i.e., contain carbon, with one or more of the carbons linked to hydrogen,* they will generate PAHs during high-temperature pyrolysis much in the same manner as the compounds studied in the mid-1920s to early 1930s by Kennaway (2073–2076). In his studies, Kennaway demonstrated that pyrolysis of various organic compounds—from simple ones such as acetylene or isoprene to more complex ones—would generate pyrolysates tumorigenic to mouse skin. Subsequently, these and similar organic compound-derived pyrolysates were shown to contain a variety of PAHs (1286, 2264b), some of which were potent mouse-skin tumorigens. Obviously, PAHs should be generated from the structural components of tobacco during the reactions occurring when tobacco is smoked in a cigarette. Interest in the major precursors in tobacco of the PAHs in MSS eventually led to the conclusion that the major precursors in tobacco of cigarette MSS PAHs in cigarette MSS were the organic solvent-extractable, high-molecular-weight tobacco components such as the saturated aliphatic and unsaturated aliphatic hydrocarbons, the phytosterols, terpenoid alcohols such as solanesol (3251, 3269, 3291, 3616, 4332).

During the search for the major PAH precursors in tobacco, all of the previously mentioned organic solvent-soluble tobacco components [*cf.* Table 25.5] that were examined by pyrolysis were shown to yield PAHs. In 1957, Gilbert and Lindsey (1289) reported their results on the amounts of various PAHs in the pyrolysates (650°C, N_2) from the major structural components from flue-cured tobacco. These included cellulose, pectins, starch, and lignin; the simple sugars, sucrose, glucose, and fructose; and the acids, malic acid, citric acid, and oxalic. Their data, modified to indicate nanograms of individual PAHs generated per milligram of tobacco component pyrolyzed,† are summarized in Table 25.10.

Numerous pyrolysis experiments were conducted from the mid-1950s to the mid-1980s on tobacco components and tobacco fractions and residues obtained by solvent extraction of tobacco. However, meaningful comparison of the results has been difficult because of the lack of uniformity in the pyrolysis

* Examination of the data reported by Gilbert and Lindsey (1289) on the pyrogenesis of PAHs from various tobacco constituents would appear to contradict this statement. Gilbert and Lindsey reported the generation of a series of PAHs in the pyrolysate (see Table 25.10) from the dicarboxylic acid oxalic acid [$(COOH)_2$] which obviously has no carbon–hydrogen bond. However, it is known that a major product of the thermal decomposition of oxalic acid is formic acid [H-COOH] via decarboxylation. Formic acid does have the requisite carbon–hydrogen bond.

† Nanogram of PAH generated per milligram of tobacco component pyrolyzed = microgram of PAH generated per gram of tobacco component pyrolyzed = parts per million (ppm) of PAH from the tobacco component pyrolyzed.

conditions employed in the studies. Even when some similarity existed between experimental conditions used in two separate experiments, precise comparison was confounded by the fact that different tobaccos or blends were used in the experiments, e.g., Gilbert and Lindsey (1289) examined the PAH yields in the pyrolysates (650°C, N_2) from the structural components of a flue-cured tobacco grown a year or two prior to their 1957 study; Severson et al. (3616) examined the pyrolysates (produced at a variety of temperatures including 650°C, N_2) from a flue-cured tobacco probably grown a few years before their 1979 publication and from a tobacco blend.

In their detailed study, Severson et al. (3616) examined the following pyrolysates: a flue-cured tobacco; its PEE (8% of the tobacco weight); the tobacco residue after petroleum ether extraction; and eight chromatographic fractions (Fractions F-1 through F-8) derived from the PEE. Unfortunately, Severson et al. conducted several key pyrolysis experiments at 700°C only. It should also be noted that tobaccos, such as the flue-cured tobaccos, used by Gilbert and Lindsey and by Severson et al. would not be identical because of the differences in agronomic conditions and practices for the tobaccos grown in the mid-1950s *vs*. the mid-1970s.

Table 25.11 summarizes pyrolysis data from Lam (2257), Gilbert and Lindsey (1289), and Severson et al. (3616) with particular emphasis on the somewhat similar experimental conditions (pyrolysis temperature, atmosphere) and on the yields of B[*a*]P and B[*e*]P from the pyrolysis of different tobaccos, blend, components, and/or fractions. The data

Flue-Cured CSC (4317)					90[d]			

[a] It is assumed that 1 g of tobacco is consumed during the cigarette smoking.
[b] Total BP = B[*a*]P + B[*e*]P.
[c] Saturated aliphatic hydrocarbons isolated from flue-cured tobacco.
[d] Estimated total of B[*a*]P in MSS (4317) plus SSS from an all-flue-cured tobacco cigarette is 45 ng in MSS plus an estimated 45 ng in SSS.

in Table 25.11, plus additional data in the publications cited, indicated that the structural components as well as other components and fractions (organic solvent-soluble or -insoluble) from tobacco yielded a variety of PAHs on pyrolysis, but the structural components—the biopolymers—such as cellulose, pectins, starch, lignin, on a per unit weight pyrolyzed basis generated much lower yields of PAHs than did the organic solvent-soluble components and/or fractions. Even in the cases where tobacco components are not only soluble in organic solvents but also are relatively highly oxygenated, they show a low propensity to generate PAHs on pyrolysis. This fact was demonstrated by Severson et al. (3616) in their study of the pyrolysates from the eight chromatographic fractions (Fractions F-1 through F-8) from the PEE from flue-cured tobacco. They noted:

> Extraction fractions F-1 and F-8 yielded relatively low yields of PAH on pyrolysis, the former because of its thermally stable hydrocarbon content, and the latter because of its polar oxygenated constituent content. Such oxygenated compounds, having a relatively low carbon content yield low amounts of the alkyl residues essential for PAH formation [see Badger et al. (148), Schmeltz and Hoffmann (3489)]…

The Fraction F-8 components which Severson et al. in their pyrolysis studies demonstrated to have a low propensity to yield PAHs on pyrolysis are similar both structurally and property-wise (molecular weight, volatility) to some of the compounds used in "top dressing" formulations for tobacco smoking products [see tabulations in Doull et al. (1053), Leffingwell et al. (2341)]. Presumably, "top dressing" components applied to tobacco products on pyrolysis would behave similarly during pyrolysis to the Fraction F-8 oxygenated tobacco components described by Severson et al. [see pp. 284–285 in (3616)].

Even though the structural components of tobacco on pyrolysis did yield PAHs, albeit at a much lower level than other classes of tobacco components, their contribution to tobacco smoke composition became important from another point of view: When only a small portion (about 2%–3%) of the biological response observed in mice (or other rodents) skin painted with CSC could be explained by its content of the PAHs reported to be tumorigenic to mouse skin [see pp. 14–51/52 in (4005), Wynder et al. (4303)], additional explanations for the observed biological response were sought. The concepts of promotion and cocarcinogenesis were introduced into the theory of CSC tumorigenicity in an attempt to explain the observed biological response in the mouse-skin-painting studies.

In the 1950s, Boutwell et al. (414) and Boutwell and Bosch (414) reported that low-molecular-weight phenols such as phenol itself and the cresols, nontumorigenic per se in skin-painting experiments, enhanced the tumorigenicity in mouse-skin-painting studies of PAHs reported to be tumorigens. In 1959, Roe et al. (3314) reported the promoting effect of a phenolic fraction from cigarette MSS. Two years later, Wynder and Hoffmann (4313) examined phenol as a promoter of several PAHs (B[*a*]P, DMB[*a*]A) and concluded:

> Promoting substances present in tobacco smoke can increase and accelerate the tumor yield of carcinogenic polynuclear hydrocarbons that by themselves are not present in sufficient concentration to yield any tumors or yield them only after a prolonged latent period.

The low-molecular-weight phenols are extremely low-level components of tobacco but are present in cigarette MSS at levels many times those in tobacco. This led to the search in the late 1950s to early 1960s for precursors in tobacco of the alleged biologically active phenols in tobacco smoke.

Studies by Rodgman and Cook (3277), Rodgman and Mims (3305), and Rodgman (3251) on the effect of tobacco components (lignin, pectin) added to a cigarette tobacco blend on low-molecular-weight phenol levels in MSS and similar studies [Spears et al. (3767), Bell et al. (248)] on the effect of tobacco carbohydrates (glucose, sucrose, starch, cellulose, or pectin) added to cigarette tobacco filler on phenol levels in MSS demonstrated that these tobacco components were major precursors of the simple phenols in cigarette MSS.

From 1962 through 1971, Newell and Best conducted studies with radiolabeled components isolated from tobaccos grown in a radiolabeled CO_2 atmosphere. Among these radiolabeled components studied were the cell wall components or biopolymers [pectin (2764), starch (2764), α-cellulose (2764)] of the tobacco. Each component was added individually to cigarette tobacco, and their contributions to various classes of MSS components, particularly the PAHs and the phenols, were determined. Table 25.12 summarizes the

[a] Benz[*e*]acephenanthrylene was formerly known as benzo[*b*]fluoranthene.

Newell–Best findings on the percent conversion during smoking of these three structural components to specific PAHs and phenols.

Examination of these data indicates that the percent conversion of these structural components to phenol ranges from one (0.0013%) to about four (0.0036%) one thousandths of a percent, whereas the conversion of these three components to B[*a*]P ranges from about 1 (0.0000014%) to about 14 (0.0000136%) one millionth of a percent. Such data may be used to estimate the conversion to PAHs and phenols of a flavorant (structurally similar to but of lower molecular weight and higher volatility than these biopolymers) added to the tobacco blend.

Numerous pyrolysis studies were conducted on these precursors of phenols. In each case, the generation of simple phenols [phenol, cresols, numerous xylenols] was observed. Kato et al. (2043) reported the pyrolysis of tobacco lignin yielded phenol, cresols, xylenols, and guaiacol—all known components of cigarette MSS. Examination of the structure of lignin reveals why it would readily yield these phenols as well as other substituted phenols such as vanillin [Ball (176a)].

From the mid-1960s to the early 1980s, the USDA tobacco research group—initially at Philadelphia, PA, subsequently at Athens, GA—described the pyrolysis of various tobacco components and the yield of phenols in the pyrolysates. Tobacco components examined for their propensity to generate the simple phenols during pyrolysis included the following:

- Cellulose, pectin, lignin, and the so-called tobacco pigment (3468).
- The major tobacco polycarboxylic acids—malic, citric, and fumaric plus the sodium salts of citric and lactic acids (3486). In the late 1950s, a mixture of sodium and potassium citrates was used as an additive on cigarette paper to control its combustion properties.*
- Tobacco and tobacco extracts [Kennedy and Riehl (25A35), Schlotzhauer et al. (3456), Severson et al. (3616)].
- Cellulose, glucose, and fructose [Higman et al. (1647)]. The latter two sugars† are used in casing materials applied to cigarettes during manufacture [Leffingwell et al. (2341)].

With regard to the generation of phenols by the tobacco acids, Schmeltz et al. (3486) noted:

> The data show that citric, malic and related acids give rise to phenols on pyrolysis. The yields, however, are lower than those from other phenol-forming materials present in tobacco leaf.

Despite the repeated assertions of the promoting potency for PAHs of the CSC phenolic fraction [Roe et al. (3314)] and the simple phenols, particularly phenol itself [Wynder and Hoffmann (4313, 4332)], contradictory evidence was reported. In 1962, Bock and Moore (25A11) challenged the concept that the weakly acidic portion of CSC was a tumor promoter. In fact, Wynder and Hoffmann (4319), strong proponents in 1964 of the promoting effect of the phenols in smoke, wrote:

> Definite tumor-promoting activity for a variety of phenols may be regarded as established.

However, this statement was omitted from their 1967 book in which Wynder and Hoffmann [see p. 626 in (4332)] wrote:

> Phenol and some of its derivatives have been shown to possess tumor-promoting activity…However, a reduction of phenols in tobacco smoke condensate has not led to a concomitant reduction of tumorigenicity in the corresponding 'tars'.

In 1971, Van Duuren et al. (4035), in a discussion of tumor promoters and the complexity of CSC and its potential role in carcinogenesis, reported that "Phenol, which is a weak tumor-promoting agent, is indeed an inhibitor of tumorigenesis when applied simultaneously with benzo[*a*]pyrene."

Two years later, Van Duuren et al. (4029) concluded from their cocarcinogenesis research that "Phenol has been regarded as an important 'tumor promoter' in [cigarette smoke condensate]…[but our] work indicates that it is inactive in cocarcinogenesis and, indeed, has a slight inhibitory effect on benzo[*a*]pyrene carcinogenesis."

Chortyk and Schlotzhauer (722) reviewed the studies reported during the preceding two decades on pyrolysis of tobacco components and the relationship of the pyrolysis results to the pyrogenesis of tobacco smoke components.

In 1979, Martin et al. (2468a) not only reported the results of their own research on the generation of a variety of phenols during the pyrolysis of lignin derived from several sources but also reviewed the results of their own and earlier studies by other investigators on lignin pyrolysis.

From their 1981 and 1982 studies on pyrolysis, Schlotzhauer and Chortyk (3453) and Schlotzhauer et al. (3452) reported the pyrogenesis of phenols not only from cellulose and lignin but also from chlorogenic acid and other polyphenols. Cellulose was defined as a major precursor of cresols and xylenols in smoke; lignin as a major precursor of guaiacol, eugenol, and catechol in smoke; the polyphenols, e.g., chlorogenic acid, as major precursors of the catechols in smoke.

* A mixture of sodium and potassium salts of citric acid was used as a cigarette paper additive, initially at RJRT and subsequently throughout the U.S. tobacco industry since the late 1950s. This additive ensured that the cigarette paper combustion char line slightly preceded the tobacco combustion char line. In the late 1950s, Rodgman (3246) demonstrated that inclusion of sodium and potassium citrates in the cigarette paper additive system reduced the levels of PAHs in the MSS.

† Glucose and fructose are naturally occurring components present at relatively high levels (10%–25%) in Oriental and flue-cured tobaccos but at relatively low levels (usually less than 2%) in burley and Maryland tobaccos [e.g., see Wynder and Hoffmann (4332)]. For many years, the two simple sugars glucose and fructose were added as such or in the form of "invert sugars" to the cigarette blend as part of the casing materials formulation. Low levels of the disaccharide sucrose, a known naturally occurring component of tobacco, were also added.

TABLE 25.13
Pyrolysis *vs.* Actual Smoking Conditions: Conversion of Glucose, Fructose, and Cellulose to B[*a*]P

Experimental Conditions	Conversion (ppm or µg/g) of Tobacco Component to B[*a*]P		
	Glucose	Fructose	Cellulose
Pyrolysis (650°C, N_2) [Gilbert and Lindsey (1289)]	0.29	0.33	0.78
Pyrolysis (840°C, N_2) [Higman et al. (1647)]	47.5	98.4	288.8
Actual smoking conditions (35 mL puff, 2 s duration, 1 puff/min) [Newell and Best (2764)]	ND	ND	0.21

ND, not determined.

In 1975, Schlotzhauer and Chortyk (3452), emphasizing the toxicants in tobacco smoke, reported that the yields of PAHs and phenols in the pyrolysate from reconstituted tobacco sheet (RTS) were significantly lower than those from flue-cured tobacco leaf when generated under the same experimental conditions. Extrapolating their pyrolysis results to the formation of specific components of tobacco smoke, Schlotzhauer and Chortyk noted that "…the continued use of reconstituted tobacco sheet in tobacco products appears warranted."

Comparison of data obtained under different pyrolysis conditions with cellulose, glucose, and fructose with data generated under actual smoking conditions reveals the problem of attempting such a comparison. In Table 25.13 are summarized data from Gilbert and Lindsey (1289), Higman et al. (1647), and Newell and Best (2764) on the conversion (ppm or µg/g) of such tobacco components to B[*a*]P during pyrolysis under two different conditions (650°C and 840°C, N_2) and when smoked in a cigarette under actual smoking conditions (35 mL puff, 2 s puff duration, 1 puff/min). The degree of conversion of tobacco components, such as cellulose, to B[*a*]P under different pyrolysis conditions parallels the degree of conversion of other tobacco components such as the saturated aliphatic hydrocarbons to B[*a*]P under different pyrolysis conditions, e.g., Lam (2257) and his findings summarized in Table 25.11. The conversion of cellulose to B[*a*]P increases several hundredfold as the pyrolysis temperature increased nearly 200°C (from 650°C to 840°C). Under actual smoking conditions, the cellulose-to-B[*a*]P conversion was less than 30%* of the conversion at 650°C. Similarly, under actual smoking conditions, the conversion of cellulose to B[*a*]P was only 0.073% of the conversion at 840°C. Thus, these data from several sources indicate that the fate of a tobacco component on pyrolysis is not equivalent to its fate under actual smoking conditions [cf. the conclusion of Schmeltz et al. (3512) on the fate of nicotine on pyrolysis *vs.* its fate during actual smoking].

As noted in reviews of the thermal degradation products from tobacco carbohydrates (cellulose, pectins, starch, sugars) by Roberts et al. (3225) and by Schumacher (3551), pyrolysis of the carbohydrate components of tobacco results in generation of several classes of compounds other than PAHs and phenols. Among these were aldehydes and ketones, considered significant in smoking–respiratory tract issues. It was asserted during the 1960s that aldehydes and ketones, shown to be ciliastatic in vitro to ciliated tissue, were important because of their significant impairment (by extrapolation) of the action of human respiratory tract cilia. Such impairment was considered part of the mechanism of lung cancer causation by cigarette smoke. However, their importance diminished after the reported findings of Dalhamn et al. (892) that these cigarette smoke-derived, water-soluble in vitro ciliastats were removed in large part by the "scrubbing action" of the fluids coating the surfaces of the oral cavity and laryngeal area, a phenomenon demonstrated several years earlier by Rodgman et al. (3306).

Early studies (1955–1959) on carbonyl components included those of Fredrickson (1228) who examined the volatile MSS components from all-cellulose cigarettes. Many were identified as aldehydes and ketones (1238, 1239). In 1959, Laurene et al. (2310) reported the unequivocal identification of acrolein in cigarette smoke, and cellulose in tobacco was a major precursor of it in smoke. Grob (1413) subsequently demonstrated in 1962 that, during smoking, cellulose generated high levels not only of acrolein but also the ketone 3-buten-2-one.

In 1966, Latimer (25A40) reported several aldehydes (acetaldehyde, acrolein) and ketones (acetone, 2-butanone) in the pyrolysate from tobacco-derived starch. At Philip Morris R&D, Gager et al. (1264, 1265) noted from their study with radiolabeled sugars added to cigarette tobacco that acetaldehyde and acetone were formed during the smoking process in the highest yields from added sugars but their levels were reduced because of the levels generated from other major tobacco components such as cellulose, pectins, and starch.

In their 1976 literature review of pyrolysis products from carbohydrates, Roberts et al. (3225) noted that, of the more than 140 compounds identified in the pyrolysates from glucose, fructose, sucrose, cellulose, and starch, 21 were aldehydes, 30 were ketones. Of these 51 pyrolysis products identified at that time, 40 had been identified as cigarette MSS components.

In 1977, Ohnishi and Kato (2850) described the identification of several carbonyl compounds in the pyrolysates from the tobacco cell wall polysaccharides cellulose, hemicellulose, and pectins. They noted that these biopolymeric polysaccharides constituted 30%–50% of the dry weight of the tobacco they were studying. Sakuma et al. pyrolyzed tobacco-derived cellulose (3401), chlorogenic acid, and rutin (3400) and reported various aldehydes and ketones plus numerous phenols in the pyrolysates. Many of the pyrolysate components identified have also been identified in cigarette MSS.

* Conversion of cellulose to B[*a*]P under actual smoking conditions = 0.21 mg/g; conversion of cellulose to B[*a*]P at 650°C = 0.78 mg/g. Percent ratio for 650°C pyrolysis = 100 × 0.21/0.778 = 27%; for 840°C pyrolysis = 100 × 0.21/288.8 = 0.073%.

25.3.4 Acids

The research findings of Gilbert and Lindsey (1289) on the generation of a variety of PAHs during the pyrolysis of major components of tobacco, including several polycarboxylic acids (oxalic, malic, and citric acids), were discussed previously (see Table 25.10). These acids may constitute from 3% to 12% of dry tobacco weight (1289, 1329, 1330, 1332, 1333). At RJRT R&D, the fate of these acids during smoking in a cigarette was determined by Newell and Best in studies with radiolabeled acids added individually to cigarette tobacco (2763). In 1967, Schmeltz et al. (3486), in their attempt to define precursors in tobacco of several classes of compounds in cigarette smoke, studied the nature and levels of phenols generated in the pyrolysates of malic, citric, aconitic, and fumaric acids or their sodium salts. Thus, pyrolysis of tobacco leaf acids yielded phenols (3486) and PAHs (1289). Although direct comparison is somewhat difficult because of the 50°C pyrolysis temperature difference in the Gilbert–Lindsey *vs.* Schmeltz et al. studies, the PAHs appeared to be generated in much lesser amounts per gram of tobacco leaf acid pyrolyzed than were the phenols. Table 25.14 summarizes data obtained from the studies.

Pyrolysate products obtained from several short-chained aliphatic acids or their sodium salts were examined. Schmeltz and Schlotzhauer (3498) pyrolyzed sodium acetate at 500°C and 800°C. The 800°C pyrolysate was much more complex than that produced at 500°C. This was true for the numbers of pyrolysate components generated and those with aromatic structures. Among the latter were several alkylbenzenes and phenols. Rudenko and Konsinska (25A61) reported similar findings from their pyrolysis of propionic acid, present in tobacco in bound form. At the USDA, Geisinger et al. (1279) demonstrated that pyrolysis of malic and lactic acids at temperatures from 500°C to 900°C (in 100°C increments) yielded both aromatic hydrocarbons and phenols. With malic acid, the aromatic hydrocarbon complexity increased (increased methylation) as the temperature increased. Bicyclic indene was the only PAH detected in the 500°C and 600°C pyrolysates. Indene and naphthalene were detected in the 700°C pyrolysate. Tricyclic acenaphthylene, anthracene, phenanthrene, and fluorene were detected in the 800°C pyrolysate, tetracyclic pyrene, and chrysene in the 900°C pyrolysate. Pyrolytic products from several aromatic acids present either free or bound in tobacco were investigated, e.g., Zane and Wender (4403) demonstrated in 1963 that pyrolysis of rutin, quercetin, and chlorogenic acid (tobacco polyphenols with bound caffeic acid) yielded catechol as the major product, alkylcatechols, resorcinol plus several furancarboxaldehydes. Similar results were reported by the USDA group (3462) at Athens, GA.

In 1969, Jones and Schmeltz reported catechol as the major pyrolysis product (32%) from free caffeic acid (1981) and stilbene as the major pyrolysis product from *trans*-cinnamic acid (1983). *trans*-Cinnamic acid pyrolysate also contained low yields of several bicyclic and tricyclic PAHs. The results of these and similar pyrolysis studies with tobacco acids were reviewed by Chortyk and Schlotzhauer (722).

Indirect evidence that major leaf acids such as malic, citric, and oxalic acids in tobacco contributed low PAH levels to pyrolysates from tobacco fractions was provided by Severson et al. (3616). When tobacco was extracted with hexane or petroleum ether, the bulk of these acids did not appear in the extract but remained in the insoluble tobacco residue. Severson et al. reported that the pyrolysate from the extractables (8% of tobacco weight) contained more than twice the amount of total PAHs than did the pyrolysate from residual tobacco (92% of tobacco weight). In the same study, Severson et al. (3616) examined the levels of a various PAHs (bicyclic to pentacyclic) in the pyrolysates of eight chromatographic fractions from the PEE. Several fractions consisted primarily of free fatty acid mixtures such as myristic, palmitic, stearic, oleic, and linoleic acids (Fractions F-5 and F-6) and esters of long-chained saturated and unsaturated alcohols with these acids (Fractions F-7 and F-8, see Table 25.8). As described previously, Schmeltz et al. (3511) demonstrated that less than 1% of radiolabeled palmitic acid, isolated from tobacco grown in a radiolabeled CO_2 atmosphere and added to cigarette tobacco filler, was converted to PAHs during the smoking process.

Pyrolysis products from esters such as ethyl acetate and isobutyl acetate, both possible flavorants for tobacco smoking products, have been reported [Leffingwell et al. (2341), Miyagawa (2563)]. The principal pyrolysis products from both acetates were CO, CO_2, methane, acetic acid, and acetone. Isobutyl acetate yielded isobutylene as a major product. Products from pyrolysis of the esters formed from long-chained fatty acids* and glycerol (triglycerides) were

TABLE 25.14
Pyrolysis of Leaf Acids: Generation of Selected Phenols and PAHs

Compound Generated, ng/mg of Acid Pyrolyzed	Pyrolysis Conditions		Acid Pyrolyzed		
	T,°C	Atm.	Malic	Citric	Oxalic
PAHs [Gilbert and Lindsey (1289)]

m-Cresol + *p*-Cresol	700	N_2	79	51	ND

ND, not determined.

* The major long-chained fatty acids, either free or bound, in tobacco are lauric acid (C_{12}), myristic acid (C_{14}), palmitic acid (C_{16}), stearic acid (C_{18}), oleic acid (C_{18}, 1 carbon–carbon double bond), linoleic acid (C_{18}, 2 carbon–carbon double bonds), and linolenic acid (C_{18}, 3 carbon–carbon double bonds). However, bound and free acids in tobacco (and in tobacco smoke) are not limited to acids with even-numbered carbon chains [Bellin (258, 259), Rodgman et al. (3294), Swain and Stedman (3842, 25A72), Wynder and Hoffmann (4332)].

TABLE 25.15
Conversion of Trimyristin Added to Tobacco to PAHs during Actual Cigarette Smoking (3269)

	MSS Delivery of PAH, µg/cig, at Trimyristin Addition Level to Tobacco Blend, mg/g		PAH Increase	
PAH	0	4.0	In ng/4.0 mg of Trimyristin Added	In ng/mg[a] of Trimyristin Added
Naphthalenes[b]	15.8[c]	17.7[c]	1900	475

described by Higman et al. (1646) (tripalmitin, tristearin) and Kitamura (2111a) (trilaurin, tripalmitin). In the early 1970s, Halaby and Fagerson (25A28) pyrolyzed palmitic, oleic, and linoleic acids plus their triglycerides. Numerous PAHs were identified in the pyrolysates. They reported that B[*a*]P was generated from each acid and from each triglyceride at about 100 ppm of the compound pyrolyzed. In their studies on precursors in tobacco of PAHs in tobacco smoke, Rodgman and Cook (3269) demonstrated that addition of 0.4% (4.0 mg/g of tobacco) of trimyristin to tobacco produced, under actual smoking conditions, a 6% increase in total PAHs in the MSS. The changes in individual PAH yields are shown in Table 25.15. These changes are also expressed in Table 25.15 in terms of the conversion (ng/mg or ppm) of the added trimyristin to individual PAHs. The changes observed in the levels of individual PAHs are well within the experimental error for PAH analyses in the late 1950s.

25.3.5 Proteins and Amino Acids

Amino acids, both as free acids and as acids bound within protein molecules, are present in all of the tobacco types (flue-cured, burley, Oriental, Maryland). The diversity and levels of amino acids in various tobaccos have been presented by Gori (1329, 1330) and Tso and Chaplin (3975). The amino acids occurring free and/or bound in tobaccos include alanine, α-aminobutyric acid, arginine, aspartic acid, cystine, glutamic acid, glycine, histidine, isoleucine, leucine, lysine, methionine, ornithine, phenylalanine (Phe), proline, serine, threonine, tryptophan (TRY), tyrosine, and valine.

The presence in cigarette MSS of numerous free amino acids and amino-acid-derived compounds was demonstrated in the mid-1950s. This occurred soon after the publication of the results of several cigarette-smoke-related epidemiological and biological studies led to a massive escalation in tobacco smoke composition studies; e.g., Buyske et al. (562) identified glutamic acid and its derivative glutamine (glutamic acid 5-amide) in tobacco smoke. Other amino acids identified in tobacco smoke [cf. Ishiguro and Sugawara (1884)] include alanine, aspartic acid (and asparagine), cysteine, glycine, leucine, ornithine, Phe, proline, serine, threonine, and valine.

In the early 1960s, pyrocoll (dipyrrolo[*a,d*]pyrazine-5,10-dione) was identified in cigarette MSS by Mold et al. (2592) who proposed that either free or bound proline was its precursor. During their study of the isolation and identification of *N*-heterocyclic components (the indoles and carbazoles) in cigarette MSS, Rodgman and Cook (3279) confirmed the presence of pyrocoll. Two decades earlier, Van Order and Linwall (25A78) had demonstrated that dry distillation of TRY yielded indole and 3-methylindole (skatole), both of which were subsequently identified in tobacco smoke (3279) and in burley tobacco by Roberts [see citation in Rodgman and Cook (3279)].

From their pyrolysis studies (850°C, N_2) with lysine, leucine, and TRY, Patterson et al. (2902) reported that each yielded the *N*-heterocyclic compounds indole, quinoline, isoquinoline, several nitriles, and PAHs ranging from bicyclic to tetracyclic (see Table 25.16). B[*a*]P was found only in the leucine pyrolysate. From their own findings and from a previous report by Jarboe and Rosene (1923a) that quinoline and isoquinoline were components of a nicotine pyrolysate Patterson et al. suggested that the precursors in tobacco of quinoline and isoquinoline in tobacco smoke might be nicotine and/or the amino acids. They also reported that TRY, per mole pyrolyzed, yielded a phenol fraction weighing about five times that generated from lysine and about 30 times that from leucine.

Patterson et al. (2903) reported the effect of temperature on the pyrolysate composition from Phe, with emphasis on PAHs yields, and the effect of TRY or pyrrole (PYR) on the pyrolysate composition when equimolar quantities of

TABLE 25.16
Components in Pyrolysates from Lysine, Leucine, and TRY (2902)

+ Indicates the presence of compound; – indicates the absence of the compound.

[a] Pyrolyzed as lysine monohydrochloride.

Phe + TRY or Phe + PYR were pyrolyzed (see summary of results in Table 25.17). The difference between the pyrogenesis of PAHs from Phe and equimolar quantities of Phe + TRY mixture prompted Patterson et al. (2903) to propose amino acid addition to tobacco to control the PAH content of the CSC:

> These results suggest the possibility that aromatic hydrocarbon content of tobacco "tar" may be affected by the amino acid composition of the tobacco and that it might be possible to affect deliberately the amount of aromatics and bases formed by adding suitable additives, such as amino acids, to the tobacco.

In 1971, when Patterson et al. made this suggestion, the presence in amino acid pyrolysates of the *N*-heterocyclic amines and the inordinately high mutagenicity of several of them were unknown.

Higman et al. (1647) reported the generation of PAHs, phenols, pyridines, indole, quinoline, and other aromatic bases during pyrolysis of tobacco amino acids and proteins [cf. review on pyrogenesis of smoke components by Chortyk and Schlotzhauer (722)]. The results reported by Higman et al. are summarized in Table 25.18.

TRY was found to be the precursor in tobacco of harman (1-methyl-9*H*-pyrido[3,4-*b*]indole) and norharman (9*H*-pyrido[3,4-*b*]indole) in tobacco smoke, compounds originally identified in tobacco and tobacco smoke by Poindexter and Carpenter (2972). That TRY was indeed a precursor in tobacco of the harmans in smoke was demonstrated by addition of radiolabeled TRY to tobacco and identification of radiolabeled harman and norharman in the MSS.

More recent amino acid pyrolysis studies led to the isolation and identification of several *N*-heterocyclic amines reported not only to be tumorigenic to mouse skin but also to show inordinately high mutagenicity [Ames bioassay (*S. typhimurium*)]. Initial impetus for amino acid pyrolyses was not the definition of the relationship between tobacco precursors and smoke components but the observation that extracts of broiled, fried, or roasted foodstuffs were highly mutagenic (Ames bioassay). These *N*-heterocyclic amines, derived from amino acids and/or proteins in heated foodstuffs, were defined as "cooked food" mutagens. These studies in the 1970s on the tumorigenicity and mutagenicity of extracts of cooked foodstuffs are reminiscent of the studies in the 1920s by Kennaway (2073–2076) who reported the tumorigenicity of extracts of heated foodstuffs or pyrolysates from compounds such as cholesterol and by Roffo (25A56, 25A57, 25A58) who reported the tumorigenicity of pyrolyzed cholesterol. Subsequently, pyrolysates from many foodstuffs and cholesterol were shown to contain various PAHs, including B[*a*]P. Identification of highly mutagenic *N*-heterocyclic compounds in amino acid pyrolysates was followed by their identification not only in heated foodstuffs but also in mainstream CSC.

In 1977, Sugimura et al. (3829) reported the identification of the potent mutagens 3-amino-1-methyl-5*H*-pyrido[4,3-*b*] indole (Trp-P-2) and 3-amino-1,4-dimethyl-5*H*-pyrido [4,3-*b*]indole (Trp-P-1) in TRY pyrolysate. The next year, Yamamota et al. (4365a) identified two potent mutagens in glutamic acid pyrolysate: aminodipyrido[1,2-*a*:3′,2′-d]imidazole (Glu-P-2) and 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*] imidazole (Glu-P-1).

Table 25.19 lists several *N*-heterocyclic amines which exhibit high mutagenicity in the Ames bioassay, are amino acid pyrolysis products, and have been identified in heated foodstuffs and CSC (3828c). On a per μg basis, B[*a*]P in the Ames bioassay with *S. typhimurium* (TA 98 strain) shows about 200 revertants/μg. Several of the amino-acid-derived compounds in Table 25.19 exceed the B[*a*]P effect (TA 98 strain) by factors ranging from about 10 to over 2100.

Yoshida and Matsumoto (4387a) reported the identification of two α-carbolines in CSC: 2-amino-9*H*-pyrido[2,3- *b*] indole (AαC) and 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (MeAαC). These and several other compounds were reported in CSC by Yamashita et al. (4367, 4368). The quantitative levels of the possibly amino-acid-derived, mutagenic *N*-heterocyclics in CSC are shown in Table 25.19. In their studies, they emphasized in particular the identification and quantitation of 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ) because of its inordinately high mutagenicity (433,000 and 490,000 revertant/µg in the Ames bioassay, *S. typhimurium* strain TA 98).

Demonstration of the mutagenicity of the compounds in Table 25.19 was followed by demonstration of their tumorigenicity in laboratory animals. Ohgaki et al. (2849a) demonstrated the tumorigenicity of IQ in mice. Takayama et al. (3862c) and Tanaka et al. (3865c) reported its tumorigenicity in rats. Trp-P-1 and Trp-P-2 were reported to be tumorigenic in mice by Matsukura et al. (2491a) and in rats by Hosaka et al. (1835a) and Takayama et al. (3862d). Ohgaki et al. (2849b) reported that Glu-P-1, Glu-P-2, AαC, and MeAαC were tumorigenic in mice, and Takayama et al. (3862b) reported Glu-P-1 and Glu-P-2 to be tumorigenic in rats.

Hoffmann and Hecht (1727) discussed the amino-acid-derived aromatic amines in cigarette smoke as follows:

> Of the known carcinogenic pyrolysis products of the amino acids, so far only 2-amino-3-methylimidazo(4,5-*f*)quinoline has been detected in trace amounts of 0.26 ng in the smoke of a Japanese filter cigarette [Yamashita et al. (4368)].

Apparently, Hoffmann and Hecht had overlooked not only the reports of the identification in CSC of several other known "carcinogenic" pyrolysis products of amino acids, e.g., A*a*C and MeA*a*C [Yoshida and Matsumoto (4387a)] or Trp-P-1 and

Trp-P-2 [Yamashita et al. (4367)], but also the reports on their tumorigenicity in several animals species [Matsukura et al. (2491a), Hosaka et al. (1835a), Ohgaki et al. (2849a, 2849b), Takayama et al. (3862c, 3862d), Tanaka et al. (3865c)].

Table 25.20 summarizes the MSS yields of *N*-heterocyclic amines considered to be significant tumorigens [Hoffman and Hoffmann (1740, 1741)] plus the assessment of the IARC (1870) on their tumorigenicity in laboratory animals and humans.

Table 25.21 illustrates precursor relationships, either demonstrated or proposed, between *N*-containing components such as the amino acids and proteins and tobacco smoke components. The tabulation of possible flavorants for tobacco smoking products by Leffingwell et al. (2341) included contributions to tobacco smoke taste and aroma of 23 amino acids added individually to the cigarette filler.

During tobacco growth, curing, aging, and/or the smoking process, tobacco sugars may react with ammonia and/or amino acids to yield Amadori compounds which, when heated during the smoking process, will generate a variety of pyrazines [Green et al. (1369)]. Many pyrazines identified in tobacco smoke are highly flavorful and contribute uniquely to the aroma and taste not only of tobacco smoke but also of a variety of consumer food products such as coffee, tea, cocoa, roasted peanuts, and roasted, broiled, or fried meats, poultry, and fish [Maga and Sizer (2439)].

25.4 TOBACCO ADDITIVES

25.4.1 Additives Used in Tobacco Production

Much information exists in the tobacco literature on the use and levels of use of various materials added to tobacco during growth, harvesting, and storage and on such materials that either remain unchanged on the tobacco as residual material or are chemically altered. These materials include insecticides, herbicides, fungicides, fumigants, and sucker growth inhibitors (see Chapter 21). Acceptable use levels of these are prescribed in the United States by appropriate government agencies. Comments, e.g., see Wynder and Hoffmann* (4332), Guthrie (1457), and Guthrie and Sheets (1460) on the use of pesticides, etc., were published in increasing numbers, after the mid-1960s when smoke components or classes of components allegedly responsible for the effects of cigarette smoke in smoke–disease association could not explain the observed effects at the levels in cigarette smoke.

Two types of materials have been examined in greater detail than most of the others. These are discussed in this section because there is substantial information on their pyrolysis products, their transfer per se from cigarette tobacco to its MSS, their degradation during the actual smoking process, and/or their effect as either transferred or degraded materials on the biological activity. Even in these two cases, no attempt has been made to include all the available references. These include the following classes of materials:

- *Sucker growth inhibitors*: Representative sucker growth inhibitors or suckering agents include maleic hydrazide, currently used as an alkali metal salt, and the *normal*, even-numbered carbon chain saturated alcohols, ranging in carbon chain length from (C_6) 1-hexanol through C_{12} (1-dodecanol) (4332).
- *Pesticides*: Particularly those pesticides that are chlorinated, e.g., DDT, Aldrin®, Dieldrin® (4332).

25.4.1.1 Sucker Growth Inhibitors

The pyrolysis of long-chained saturated alcohols such as 1-docosanol and long-chained unsaturated alcohols such as

* It should be noted that, in their earlier review, Wynder and Hoffmann (4319) discussed pesticide-derived arsenic in tobacco and tobacco smoke, but they did not discuss tobacco production additives such as sucker growth inhibitors, pesticides, etc., and their effects on tobacco and tobacco smoke properties.

[a] Data from Hoffmann and Hoffmann (1740, 1741).

phytol and solanesol, known to be naturally occurring components of tobacco, was discussed previously.

One of the most widely used and effective commercial preparations used for inhibition of sucker growth is "Off-Shoot-T," a mixture consisting primarily of the even-numbered straight-chained alcohols 1-hexanol, 1-octanol, 1-decanol, and 1-dodecanol [Collins et al. (25A16)]. Pyrolysis studies by Higman et al. (1644, 1645) with individual alcohols of "Off-Shoot-T" revealed that much of the alcohol was transferred intact to the pyrolysate. Much of the remainder was converted to the corresponding alkene; e.g., 1-decanol yielded 1-decene. Because of their volatility and low molecular weight, conversion of the alcohols to PAHs was minimal.

Definitive evidence that the alcohol sucker growth inhibitors added to tobacco did not augment the tumorigenicity of cigarette MSS was provided in the second set of experimental cigarettes studied in the NCI "Less Hazardous" Cigarette Program (1330, 2683). The chemical and biological properties of the MSSs from three samples (hand-suckered tobacco, tobacco treated with the recommended level of alcohol sucker growth inhibitor, and tobacco treated with 100 times the recommended level) were compared among themselves and with the Standard Experimental Blend, SEB II. Data obtained are shown in Table 25.22. Examination of the data indicates that neither the normal use level of the alcohol nor a use level 100 times normal had any significant adverse effect on the mainstream CSC properties. The MSS phenol yields were increased from the hand-suckered and both alcohol-treated tobacco samples, but the increase elevation had no significant effect on the CSC biological properties. The results were described by Gori (1330) as follows:

> No statistically significant differences were observed among Hand-suckered, Fatty Alcohol-Normal and Fatty Alcohol *x* 100 Blends (variables 60, 61, and 62).

[a] Acetonitrile has been designated as a mutagen precursor.

In the summary report (2683) on the four sets of NCI Tobacco Working Group (TWG) experimental cigarettes, this statement was expanded:

> The fatty alcohol, fatty alcohol x 100, and hand-suckered blends showed no significant differences among themselves or from the SEB II blend.

It is interesting to note that biological responses (% TBA), ranging from a high of the average of 48% for the four replicate SEB II CSCs to a low of 36% for the CSC from the sample treated with alcohol at the normal use level, were considered to show "no significant difference."

Maleic hydrazide, another growth inhibitor used as a suckering agent on tobacco, is used in the United States as its potassium salt. Prior to 1982, use on tobacco involved application of maleic hydrazide as its diethanolamine salt. Such use was banned in 1981 by the Environmental Protection Agency (EPA) (1147) soon after it was reported that tobacco treated with it generated *N*-nitrosodiethanolamine (NDELA) during smoking. NDELA was subsequently reported to be a potent, tissue-specific tumorigen in laboratory animals [see Hoffmann et al. (1696) and references therein].

Over the years, the pyrolysis of maleic hydrazide has been much studied, e.g., by Patterson et al. (2907), Smith et al. (3728), Harke et al. (1507), and Clough et al. (25A13). Also studied have been its transfer (estimated at ≤4%) as intact maleic hydrazide from tobacco to cigarette MSS [Haeberer (1470), Liu and Hoffmann (2383, 2384)] and its generation of hydrazine during smoking (2385).

TABLE 25.22
NCI Study (Second Set of Experimental Cigarettes): Effect of Long-Chained Alcohol Sucker Growth Inhibitors on Cigarette Smoke Properties (1330, 2683)

Code No.	Cigarette Filler	Phenol, µg/g of CSC	PAH, µg/g of CSC		% TBA at Daily CSC Dose of

CSC, cigarette smoke condensate; B[*a*]A, benz[*a*]anthracene; B[*a*]P, benzo[*a*]pyrene; TBA, tumor-bearing animals.
[a] Alcohol, long-chained alcohols in sucker inhibiting reagent.

However, in his 1979 report, the U.S. Surgeon General (4005) noted that maleic hydrazide was not a significant precursor of either hydrazine or 1,1-dimethylhydrazine in cigarette smoke. Smith et al. (3728) reported that the pyrolysis of maleic hydrazide at 600°C yielded CO_2 (24%), CO (2%), HCN (3%), NH_3 (9%), N_2 (3%), hydrazine (trace), and a black residue (50%), structure unknown, whose empirical formula was $C_{15}H_{15}N_5O_2$.

In the fourth set of experimental cigarettes in the NCI's "Less Hazardous" Cigarette Program, the chemical and biological (mouse-skin-painting bioassay) properties of mainstream CSC from a "pesticide"-treated tobacco cigarette were compared to those of the CSC from a control cigarette, SEB IV (1333, 2683). Gori (1333) listed the pesticides, sucker growth inhibitors, etc., used and described the chemical analyses and bioassays of the pesticide-treated and control tobaccos and their MSSs. Among the additives used in the treatment of the "pesticide"-treated tobacco were maleic hydrazide (MH-30), a 10-carbon alcohol ("Contak"), and DDT. Because both maleic hydrazide and DDT were on the tobacco, the chemical and biological results from the MSSs from these samples are discussed later.

25.4.1.2 Pesticides

As mentioned in earlier chapters, the biological response observed in mice skin painted with CSC or its fractions cannot be explained on the basis of the identified components and their levels in the CSC. In an attempt to define the biological response, Wynder and Hoffmann fractionated CSC and determined that the major part of the tumorigenicity that could be accounted for (only a few percent) arose from a PAH-rich fraction designated as Fraction B [Wynder and Hoffmann (4332, 4342), Hoffmann and Wynder (1798, 1800)]. In addition to 39 PAHs, totally or partially identified, among which were several known to be mouse-skin tumorigens, Fraction B contained 27 *N*-heterocyclic compounds (indoles, carbazoles, acridans), 5 *O*-heterocyclic compounds (dibenzofurans), and 6 chlorinated compounds that were either insecticides (DDD, DDT) or their chlorinated derivatives (*trans*-4,4′-dichlorostilbene) [Hoffmann and Wynder (1800)]. According to Hoffmann and Wynder (1800), *trans*-4,4′-dichlorostilbene (DCS) is one of the major pyrolysis products of the most important tobacco insecticides DDT and DDD. They also stated:

> DCS is neither a complete carcinogen nor a tumor initiator, nor a tumor promoter, but the DCS (0.3%) can accelerate significantly the tumorigenicity of a B*a*P solution (0.003%) when both agents are applied concurrently.

However, it should be noted that the use in tobacco culture of chlorinated insecticides such as DDD and DDT in the United States was discontinued in the late 1960s. For example, between 1968 and 1974, the residual DDT levels per gram of U.S. flue-cured tobacco decreased rapidly and substantially (over 200-fold) as follows: 1968, 52 µg/g; 1970, 6 µg/g; 1974, 0.23 µg/g [USPHS (4005), IARC (1870)].

From 1967 through 1973, the organochlorine-containing pesticides such as DDT and TDE were subjected to detailed examination not only for their contribution to cigarette MSS composition by direct transfer and/or degradation to simpler compounds during the smoking process but also to the composition of their pyrolysates. Investigators involved included Nesemann et al. (1968) from BAT (West Germany), Hoffmann et al. (1756, 1767) from the Sloan Kettering Institute and American Health Foundation, Carpenter and Frost (606) from Carreras Tobacco, Chopra et al. from North Carolina A&T [Chopra and Osborne (709, 25A12), Chopra and Domanski (707), Chopra et al. (708), Chopra and Thekkekandam (713, 714)], and Kennedy et al. (25A36) from Mississippi State.

Chopra and Osborne (709) initially studied the pyrolysis of *p,p′*-DDT to identify degradation products. They compared the pyrolysis data with those from actual smoking studies and commented on the differences observed:

> There are two differences in the pyrolysis of DDT reported earlier and the degradation of DDT in tobacco smokes: the concentration of DDT is much greater in the former and hydrogen in the latter. The DDT degradation products as we have found are as would be expected from the difference in the reaction conditions. It is thus possible to predict the fate of a pesticide in tobacco smoke by studying its pyrolysis pattern. Also these investigations show that at the combustion zone hydrogen plays a very important role in the reactions taking place.

Chopra et al. employed these pyrolysis data to identify the transfer and degradation products generated from pesticide-treated tobaccos during the smoking process [Chopra and Domanski (707), Chopra et al. (708), Chopra and Osborne (25A12), Chopra and Thekkekandam (713, 714)]. The results reported indicated the effect of added pesticides on MSS composition primarily in terms of the transfer of intact pesticides from tobacco to smoke or the products generated from them during the smoking process. In the NCI study of the fourth set of cigarettes (1333, 2683), the effect of added pesticides on chemical and biological properties (mouse-skin painting) was examined. As noted previously, the "pesticides" included the sucker growth inhibitors maleic hydrazide (MH-30) and "Contak®" (1-decanol) in addition to DDT (1333). Other compounds present in the mix used in the tobacco treatment according to government-approved procedures and treatment levels included Lorsban®, Dylox®, Enide®, Lannate®, and Carbaryl®. According to Smith et al. (3727), pyrolysis of Carbaryl® (methyl carbamic acid, 1-naphthyl ester) gave three major products in the pyrolysate: unchanged Carbaryl (»40%), 1-naphthol, and methyl isocyanate.

Some results from the NCI study of the MSS from the "pesticide"-treated tobacco are shown in Table 25.23. The conclusions were [see p. 29 in (1333)] as follows:

> Pesticide-Free and Pesticide-Treated Tobaccos: Two cigarettes tested in the fourth experiment were made from tobacco grown [in] Prince Edward Island (PEI) [Canada]. One of the tobaccos was pesticide-free and the other was pesticide-treated… There are no statistically significant differences among the [probability of survival] values at either dose level… Relative condensate yields from these cigarettes are presented… These yields confirm the [probability of survival] values, namely: there is no clear cut difference between the pesticide-free and pesticide-treated tobaccos.

It was also noted in the summary (2683) of the NCI 10-year "Less Hazardous" Cigarette Program:

> No significant differences were observed between cigarettes made from pesticide-treated tobacco leaves and pesticide-free tobacco leaves.

These findings, at least with respect to the maleic hydrazide added, are in agreement with the comments of Chopra (704) in his theoretical discussion of the relationships among pyrolysis, maleic hydrazide, the actual smoking of tobacco treated with maleic hydrazide, and B[*a*]P:

> Evidence and data so far available on maleic hydrazide are not sufficient to suggest the MH [maleic hydrazide] is a health hazard to the smoker… Thus far it is reasonable to assume that there is not enough data or justification to consider the use of MH as a health hazard to the smoker.

In the late 1970s, two excellent reviews on reagents used to treat tobacco and their effects on tobacco chemistry were authored by Steffens (3911a) and by Sheets and Leidy (3634). The latter review included considerable information on the effect of such compounds added to tobacco on MSS composition. Sheets and Leidy (3634) summarized the data which indicated the gradual decline in the levels on tobacco of insecticides such as DDT following the government's proscription of their use on tobacco (and other crops) in the United States. Their summary is similar to that

TABLE 25.23

provided earlier by Guthrie (1457) on the gradual decline of the tobacco arsenic level following the discontinuance in 1952 of arsenate use on tobacco. By 1968, the arsenic level in U.S. tobacco had decreased from a 1951 level of ≈50 µg/g of tobacco (dry weight) to 0.5–1.0 µg/g [USPHS (4005) 1979d; IARC (1870)]. In 1975, Griffin et al. (1391) reported arsenic values of 0.5–0.9 µg/g for U.S. tobaccos.

A pesticide used to control cigarette beetles in stored tobaccos and tobacco products was methoprene (Altosid®) or in the formulation Kabat®. The use of the well-studied methoprene (5-isopropyl(2*E*,4*E*)-11-methoxy-3,7,11-trimethyl-2,4-dodecadienoate) escalated markedly in the 1990s. Methoprene is also acceptable for controlling pests on various foodstuffs as well as mosquito larvae in water supplies. Using radiolabeled methoprene in a cigarette, Frisch et al. (1242, 1243) reported that 38.2%–39.4% of the activity was found in the MSS, 52.3%–52.4% in the sidestream smoke (SSS), and 8.1%–8.4% in the 23 mm butt. Of the activity in the MSS, 96.8% was due to methoprene transferred from the treated tobacco. Of 1.3% total activity found in mainstream vapor phase, 86% consisted of radioactive CO plus CO_2; the remaining 14% of the activity was distributed among 10 vapor-phase components, all normally found as vapor-phase components of cigarette MSS.

25.4.2 Additives Used in Cigarette Manufacture

The pyrolysate compositions from various tobacco additives, including casing materials and humectants, and their effect on cigarette MSS composition and properties were described by Roberts et al. (3225, 3226) and by Schumacher (3551). In this section, additional data are discussed.

25.4.2.1 Casing Materials (Sugars, Cocoa, Licorice)

Casing materials used in cigarette products in the United States are licorice, cocoa, and the sugars—including the invert sugars (glucose plus levulose) and sucrose. While they did not discuss the topic in their 1964 review (4319), Wynder and Hoffmann (4332) did discuss the possible effects on cigarette MSS properties of inclusion of casing materials in the tobacco filler with particular emphasis on licorice because of its glycyrrhizin content. Glycyrrhizin, the potassium and calcium salt of glycyrrhizic acid, is polycyclic with five cyclohexane rings in the picene configuration. (Figure 25.2). Picene is a PAH identified in several pyrolysates by Badger et al. (142) and Kröller (2195) and in CSC by Snook et al. (3756).

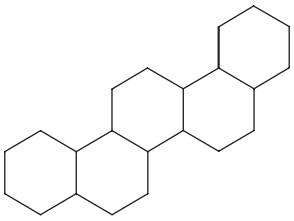

FIGURE 25.2 The picene configuration present in glycyrrhizic acid.

TABLE 25.24
Pyrolysis of Licorice *vs.* Flue-Cured Tobacco: B[*a*]P Generation

Material Pyrolyzed	Pyrolysate wt., mg/g Pyrolyzed	B[*a*]P	
		Total, ng	ng/mg of Pyrolysate
Licorice	117	24.8	0.21
Flue-cured tobacco	133	70.5	0.53

According to an assertion by Wynder and Hoffmann (4332), glycyrrhizin in licorice added to tobacco could be a precursor of PAHs in smoke. In an ill-defined experiment, Hoffmann et al. (1766) compared the B[*a*]P yield in the MSS from pipe tobacco (containing 30% casing materials, including licorice [level unspecified]) smoked in a pipe (2 puff/min) with the B[*a*]P level in the MSS from cigarette tobacco (no licorice added) smoked identically, i.e., in a pipe. The B[*a*]P levels were 27 and 10.5 µg/100 g of tobacco smoked, respectively. Later, Hoffmann and Rathkamp (1754) stated that the pyrolysis of licorice yielded PAHs. This finding was subsequently confirmed by Green and Best (1356, 1357) whose data on B[*a*]P generated during identical pyrolyses of licorice and flue-cured tobacco are summarized in Table 25.24. They also identified 35 other compounds in the licorice pyrolysate [Green and Best (1356, 1357)], all of which had previously been identified in cigarette MSS. Ten of the licorice pyrolysate components were phenols; four were dimethyl- or trimethylnaphthalenes.

Many of the compounds identified in licorice are the same as those identified in tobacco (3551, 3555). Thus, there will be similarities in their contributions to the composition of either pyrolysates from licorice *vs.* tobacco or the MSSs from a licorice-containing *vs.* a licorice-free tobacco blend. Differences will be reflected by the components unique to the material being investigated, e.g., glycyrrhizin in licorice, theobromine in cocoa, and nicotine in tobacco. As noted by Schumacher et al. (3555), 172 (83%) of the 209 components identified in licorice by 1981 had also been identified in tobacco and/or tobacco smoke. Later, a similar situation between cocoa composition and tobacco/tobacco smoke compositions will be discussed.

Sakuma et al. (25A62) reported the pyrolysis products from several naturally occurring polyphenols (chlorogenic acid, rutin). Rutin is a major polyphenol in both licorice and different tobacco types. It and chlorogenic acid yield substantial levels of catechol and substituted catechols on pyrolysis. All the identified volatile pyrolysis products from rutin have been identified in cigarette MSS.

In the late 1970s, Harllee and Leffingwell (1512, 1513) cataloged cocoa components identified to that date with particular emphasis on the volatile, flavorful components common to cocoa and tobacco or its smoke. Both tobacco and tobacco smoke as well as cocoa contain numerous fatty acid triglycerides (1512) and many of the same fatty acids (1512). At least 19 amino acids are common to cocoa and tobacco

(1512). Of 352 volatile components identified in cocoa by 1979, 209 (59%) had also been identified in tobacco and tobacco smoke (1513).

From his pyrolysis study on cocoa, Schlotzhauer (3447) reported that his results suggested the following:

> Cocoa powder added as tobacco flavorant would not significantly increase the phenol yield of smoke, but may affect the higher fatty acid content…

In the NCI study of the third set of experimental cigarettes (1332), the cigarette MSS composition and biological properties (mouse-skin-painting studies) of four cigarette samples were compared. These included three samples to each of which had been added individually a specified amount of glycerol (Code No. 80), sugar (Code No. 81), and cocoa (Code No. 82). The fourth sample was a control (Code No. 83) to which none of these casing materials/humectants had been added (1332, 2683). The results are summarized in Table 25.25 together with data from four Standard Experimental Blend III samples (SEB III, Code Nos. 72–75), the controls for the third set of experimental cigarettes. Variations in the analytical and biological data among these four control samples (Code Nos. 72–75) raised questions about any attempt to compare on a one-to-one basis the data from individual samples, e.g., the cocoa-treated sample (Code No. 82) *vs*. its control (Code No. 83), the sugar-treated sample (Code No. 81) *vs*. its control (Code No. 83), etc. Additional comments will be made about these data in the following section where humectants are discussed.

The phenol data (Code No. 82 *vs*. Code No. 83) in Table 25.25 indicate the prediction by Schlotzhauer (3447) appears to be valid: Inclusion of nominal levels of cocoa in the cigarette blend produced little change in the MSS phenol yield. Addition of 1% cocoa (Code No. 82 *vs*. Code No. 83) increased the phenol yield [mg/g of CSC] by 0.13 mg/g. This is about a 3% increase relative to Cigarette Code No. 83, well within the experimental error of the phenol determination.

25.4.2.2 Humectants (Glycerol, Propylene Glycol)

Humectants (glycerol, propylene glycol) are added to the tobacco blend to diminish the rate of postcigarette manufacture moisture loss. Cigarettes are usually manufactured with the blend at a 12% moisture content. As the cigarette loses moisture, i.e., becomes "dry" during transportation, shelf storage, its yield of smoke components changes adversely with increased yields not only of particulate-phase entities such as "tar" and nicotine but also vapor-phase components such as the aldehydes (acetaldehyde, acrolein) and ketones (acetone, methyl vinyl ketone) [Green et al. (1364)]. These changes usually are perceived by the consumer to be detrimental and unacceptable [Townsend (25A76)].

The pyrolysis of humectants, including glycerol and propylene glycol, was studied in the mid-1960s by Doihara et al. (1023, 1024) and Kröller (2192, 2195, 2196). Kröller examined the pyrolysates from nine humectants (including glycerol and propylene glycol, the most commonly used in the United States) for the yields of B[*a*]P and other PAHs generated during the pyrolysis. His B[*a*]P data are summarized in Table 25.26.

In the early studies of methods to control cigarette MSS composition and yield, particularly with regard to PAHs, Bentley and Burgan (286) asserted addition of glycerol at the 3% level to the tobacco blend substantially decreased (by as much as ≈60%) the B[*a*]P yield when the CSCs from glycerol-treated cigarettes *vs*. untreated tobacco were compared. Their finding was challenged by Wynder and Hoffmann (4332). Subsequently, with a reproducible analytical method

Tobacco, no additives	20–40

for B[*a*]P determination, Scherbak et al. (3440) and de Souza and Scherbak (953) reported that such levels of added glycerol did not have the dramatic effect claimed by Bentley and Burgan on PAHs (or B[*a*]P) generation during smoking. Scherbak et al. (3440) reported:

> Addition of glycerol to flue-cured tobacco up to the 6% level does not modify the formation of 3,4-benzpyrene or smoke particulate.

The effect of glycerol added to the cigarette blend on MSS composition and properties was studied by the NCI TWG in the third set of experimental cigarettes (1332, 2683). The results were summarized in Table 25.26. At the glycerol level (nearly 3%) used in the glycerol-treated sample (Code No. 80), it would be expected that the total particulate matter (TPM) would contain sufficient transferred glycerol to dilute other components by about 10%–12% [Greene et al. (1382), Laurene et al. (2300), Wynder and Hoffmann (4332), Hege (1603)]. This was not observed with B[*a*]A and B[*a*]P yields but was with the phenol yield [cf. data in Table 25.26 for samples of Code Nos. 80 and 83]. The effect of transfer of humectants from the tobacco blend to smoke plus their dilution of the products formed during the cigarette smoking process affects the biological properties (mutagenicity in the Ames bioassay with *S. typhimurium*) of the MSS particulate matter.

In a detailed study of the effect of various casing ingredients (sugars, cocoa, humectants) on smoke chemistry, Baker et al. (174c) determined the yields of various "Hoffmann analytes" when such ingredients were added in various mixtures. They concluded:

> Many of the casing ingredient mixtures either had no statistically significant effect on the level of analytes investigated in smoke relative to a control cigarette or the produced decreases of up to 44% in some case.

Sugars did increase the yield in MSS of formaldehyde.

25.5 CIGARETTE CONSTRUCTION MATERIALS (PAPER, ADHESIVES, ETC.)

Interest in cigarette MSS components possibly responsible for the epidemiological cigarette smoking–lung cancer association and the biological response observed in mice skin painted with massive CSC doses led to studies of the contribution of cigarette paper to MSS composition, primarily because as a cigarette construction factor, other than the tobacco blend, it contributed substantially (6%–7%) to the weight of a 1.0 g cigarette. In 1954, Cooper and Lindsey (819), based on fragmentary UV data, reported the presence of several PAHs, including B[*a*]P, in a "tar" obtained by burning cigarette paper in bulk. Similar findings on PAHs (and B[*a*]P) in the combustion products of cigarette paper, tobacco, and cigarettes were reported by Lefemine et al. (2335), Cardon et al. (594), and Alvord and Cardon (57). They also proposed an additive (ammonium sulfamate) for paper and/or tobacco to reduce pyrogenesis of PAHs. The ammonium sulfamate efficacy in decreasing B[*a*]P production in a burning cigarette was discussed by Wynder and Hoffmann [see pp. 521–523, 528 in (4322)] who noted that the additive gave discordant results in different investigations [no significant B[*a*]P reduction reported by Bentley and Burgan (286) or Pyriki et al. (3046) *vs.* substantial B[*a*]P reduction reported by Alvord and Cardon (57), Lindsey et al. (2370), and Candeli et al. (589)].

Whether cigarette paper contributed significantly to the PAHs in cigarette MSS was finally resolved by Wright (4281) who reported that PAHs (and particularly B[*a*]P) were indeed generated when cigarette paper was burned in bulk or pyrolyzed, but when it was burned in a cylindrical configuration such as that encountered around the cigarette tobacco rod, the yields of PAHs (particularly B[*a*]P) were insignificant.

Between 1963 and 1966, Kröller (2184–2195, 2200, 2203) reported the pyrolysis products from cigarette components permitted in cigarette fabrication in Germany. He estimated the amount of B[*a*]P generated by pyrolysis of each material at 700°C in air. In addition to tobacco itself (2191), the materials he studied included cellulose, starch, and a number of humectants, adhesives, and dyes consumed during the actual cigarette smoking process.

Kröller (2191, 2192) asserted his pyrolysis and the actual cigarette smoking process were qualitatively and quantitatively identical processes. Kröller's opinion of the equivalence of the fate of a material on pyrolysis in an inert atmosphere *vs.* its fate in the tobacco rod of a smoked cigarette parallels that of Wynder and Hoffmann (4332). In addition to phenanthrene, 4,5-methylenephenanthrene, and fluoranthene, Kröller reported the identification of four potent PAH mouse-skin tumorigens in his tobacco pyrolysate: DMB[*a*]A, 3-methylcholanthrene (now known as 1,2-dihydro-3-methylbenz[*j*]aceanthrylene), B[*a*]P, and DB[*a,h*]A. Despite their agreement with Kröller (2191, 2192) on the equivalence of the fate of a material in an inert atmosphere pyrolysis and the smoking process, Wynder and Hoffmann were critical of several Kröller's findings. For example, Wynder and Hoffmann (4332) questioned Kröller's identification of the

methyl derivatives (DMB[*a*]A, 30-methylcholanthrene) in his pyrolysates and smoke samples. However, a methylbenz[*a*]anthracene had been identified in CSC by Rodgman and Cook (3273) in the late 1950s, and numerous methyl- and dimethylbenz[*a*]anthracenes were subsequently reported in CSC in the late 1970s by Snook et al. (3756, 3757).

Table 25.27, adapted from Kröller (2195), summarizes his data on the amounts of B[*a*]P generated during the pyrolysis of tobacco and numerous components used in cigarette fabrication.

More recently, several studies on the pyrolysis of various adhesives either used or proposed for use as seam pastes in cigarette fabrication were conducted by Best (25A06, 25A07). He reported that, in contrast to a starch pyrolysate, the pyrolysate from polyvinyl acetate showed high levels of acetic acid and B[*a*]P. BEST also examined the pyrolysates from a variety of proposed new cigarette papers (25A04, 25A05, 25A08).

In 1967, Wynder and Hoffmann [see pp. 350–351 in (4332)] noted that pyrolysis data on cigarette components should be considered carefully:

> Certain casing agents, saucing materials, and humectants are widely used in the manufacture of tobacco products. For all we know at this time, it is certainly a possibility that PAH may also be formed from these agents. One should keep in mind, however, that only small amounts of these materials are used for most smoking products.

Their latter statement would also apply to cigarette fabrication materials consumed during the smoking process such as the adhesives used on the cigarette paper seam and printing inks on the paper.

The data from Kröller (2195) on the B[*a*]P yields generated during cellulose and starch pyrolysis may be compared with those of Gilbert and Lindsey (1289), see Table 25.28. This provides an excellent example of the effect of changing pyrolysis conditions (pyrolysis at 650°C in air *vs.* pyrolysis at 700°C in N_2) when two different materials are considered. The different pyrolysis conditions give a ratio of 9.75 (0.78/0.080) for the B[*a*]P yields from cellulose, but a ratio of 2.43 (0.17/0.070) for the B[*a*]P yields from starch.

Inclusion of cellulose in the Kröller studies was because it constitutes the major part of cigarette paper, much of which is consumed during the smoking process. It was not included because cellulose, as wood pulp, is sometimes added by some manufacturers to their reconstituted tobacco sheet (RTS) to improve integrity and reduce fragmentation.

The effect of cellulose added to cigarette filler on cigarette MSS composition and properties in a mouse-skin-painting bioassay was examined in the mid-1970s in the NCI study of the first set of cigarettes (1329, 2683). The results are poorly defined because the cellulose was added (as wood pulp) at a 7.5% level to fillers made from the Standard Experimental Blend (SEB I) reconstituted into sheet material at three different densities.

Kröller (2195)	700	Air	0.080	0.070

25.6 FLAVORING INGREDIENTS

As outlined in Chapter 24 dealing with tobacco and/or smoke components used as flavorful additives, the numerous assertions about the possibly adverse effect of flavorful compounds added to tobacco were never accompanied by any supporting laboratory evidence. None of the information generated over the past decade that the added flavorants had little, if any, adverse effect on the chemical and biological properties of the smoke generated from the treated tobacco has been criticized by any investigator, governmental agency, or medical institute or any contradictory data presented. In an exemplary study by Baker and Bishop (172a), 291 flavorful additives were pyrolyzed, and in each case, the yields of the major components of the pyrolysate were determined. As outlined in Chapter 24, many of the compounds used as flavor additives are already components of tobacco and/or its smoke. The behavior of such an additive will not differ from its tobacco inherent counterpart. In addition to the pyrolysis study of Baker and Bishop (172a), there are also many studies in which the effect of added flavorants on the chemical and biological properties of cigarette MSS was determined. Many were summarized in 2004 by Rodgman [see Tables 1 and 7A in (3266)], but since then, much additional data have been published. Table 25.29 lists a variety of references pertinent to the use of tobacco and/or smoke components as additives, their pyrolysis, their effect on smoke composition when added individually to tobacco, and their effect on smoke composition when added as a component of a flavorant formulation. Among the references cited is that of Paschke et al. who, in their report on the effect of ingredients on the chemical and biological properties of MSS, tabulated detailed pyrolysis data on a number of individual tobacco and/or smoke components plus detailed pyrolysis data on a variety of materials studied as tobacco additives [see pp. 226–241, Table 5 in (2896)].

Table 25.30 lists a variety of references pertinent to compounds used as tobacco additives where the compounds are not known to be present in tobacco or its smoke. Included are references to their pyrolysis plus their effect on smoke composition when added as a component of a flavorant formulation.

Although Table 25.31 does not involve individual tobacco and/or tobacco smoke compounds, it is included because of the relationship of the entities to tobacco and/or tobacco products. The results of many of the studies cited were published in the early days of the examination of tobacco composition and the attempts to define the precursors in tobacco of various components in MSS. The studies on cocoa and licorice are included because of their level of use in tobacco products.

Table 25.29 deals with individual components that are either tobacco and/or tobacco smoke components, many of which are listed and discussed by Doull et al. (1053), Baker et al. (172a, 174a), Carmines (603), and Rodgman (3266) as additives in tobacco products. Table 25.30 deals with compounds not identified to date in tobacco and/or tobacco smoke but are listed as tobacco product additives. Since our primary concern throughout this project was the discussion of the contribution of individual tobacco components to smoke properties, neither Table 25.29 nor Table 25.30 includes the many complex mixtures (oils, extracts, resins, etc.) used as flavorful cigarette tobacco additives that have also been studied in detail with regard to their pyrolysates (172a, 172b) and their effect as tobacco additives on the chemical (174a, 174b, 630, 3370) and biological properties (174a, 25A24, 25A25, 25A27, 25A43, 25A49, 25A79) of cigarette smoke. Table 25.32 [updated from Table 6 in (3266)] summarizes the specific conclusions from many of such studies conducted between 1994 and 2005. A more detailed summary of the chemical and biological studies through mid-2004 of the complex mixture additives was presented by Rodgman [see Tables 2 and 7B in (3266)].

Pyrolysis of Nontobacco and Nontobacco Smoke Components and/or Their Effect on Smoke Composition When Added to Tobacco

			References to	
	CAS No.	Name (per CA Collective Index)	Pyrolysis of Individual Component	Effect on MSS Composition, When Component Added in a Mixture
1.	105-87-3	Acetic acid, 3,7-dimethyl-2,6-octadien-1-yl ester {geranyl acetate}	172a	174a, 174b, 603, 3370
2.	150-84-5	Acetic acid, 3,7-dimethyl-6-octenyl ester {citronellyl acetate}	172a	174a, 174b
3.	151-05-3	Acetic acid, 1,1-dimethyl-2-phenylethyl ester {α,α-dimethylphenethyl acetate}		603, 3370
4.	3681-71-8	Acetic acid, 3-hexen-1-yl ester, (*Z*)- {*cis*-3-hexen-1-yl acetate}	172a	174b
5.	140-39-6	Acetic acid, 4-methylphenyl ester {*p*-tolyl acetate}	172a	174b, 603, 3370
6.	143-13-5	Acetic acid, nonyl ester {nonyl acetate}		603, 3370
7.	2442-10-6	Acetic acid, 1-octen-3-yl ester {1-octen-3-yl acetate}		603, 3370
8.	24851-98-7	Acetic acid, 2-pentyl-3-oxo-1-cyclopentyl-, methyl ester {methyl dihydrojasmonate}	172a	174a, 174b
9.	103-54-8	Acetic acid, 3-phenyl-2-propenyl ester {cinnamyl acetate}	172a	174a, 174b
10.	76-49-3	Acetic acid, *endo*-1,7,7-trimethylbicyclo[2.2.1]heptan-2-yl ester {bornyl acetate}		603, 3370
11.	141-97-9	Acetoacetic acid, ethyl ester {ethyl acetoacetate}	172a	174a, 174b
12.	53956-04-0	Ammonium glycyrrhizinate[a]		174a, 174b
13.	1336-21-6	Ammonium hydroxide	172a	
14.	10031-82-0	Benzaldehyde, 4-ethoxy- {*p*-ethoxybenzaldehyde}	172a	174a, 174b
15.	1319-88-6	Benzaldehyde glyceryl acetal	172a	174a, 174b
16.	698-27-1	Benzaldehyde, 2-hydroxy-4-methyl-{2-hydroxy-4-methylbenzaldehyde}	172a	174a, 174b
17.	151-10-0	Benzene, 1,3-dimethoxy- {*m*-dimethoxybenzene}	172a	174a, 174b, 603, 3370
18.	1076-56-8	Benzene, 3-methoxy-1-methyl-4-(1-methylethyl)- {4-isopropyl-3-methoxy-1-methylbenzene}	172a	174a, 174b
19.	104-87-0	Benzeneacetaldehyde, 4-methyl- {*p*-tolylacetaldehyde}		174b
20.	122-43-0	Benzeneacetic acid, butyl ester {butyl phenylacetate}		603, 3370
21.	102-22-7	Benzeneacetic acid, 3,7-dimethyl-2,6-octadieny-1-yl ester {geranyl phenylacetate}		603, 3370
22.	5421-17-0	Benzeneacetic acid, hexyl ester {hexyl phenylacetate}		603, 3370
23.	101-94-0	Benzeneacetic acid, 4-methylphenyl ester {*p*-tolyl phenylacetate}		603, 3370
24.	102-13-6	Benzeneacetic acid, 2-methylpropyl ester {isobutyl phenylacetate}	172a	174a, 603, 3370
25.	105-13-5	Benzenemethanol, 4-methoxy- {anisyl alcohol}	172a	174a, 174b, 603, 3370
26.	122-91-8	Benzenemethanol, 4-methoxy-, formate {anisyl formate}	172a	174a, 174b, 603, 3370
27.	102-17-0	Benzenemethanol, 4-methoxy-, phenylacetate {anisyl phenylacetate}	172a	174a, 174b, 603, 3370
28.	7549-33-9	Benzenemethanol, 4-methoxy-, propanoate {anisyl propionate}	172a	174a, 174b
29.	93-92-5	Benzenemethanol, α-methyl-, acetate {α-methylbenzyl acetate}	172a	174a, 174b
30.	104-53-0	Benzenepropanal {3-phenylpropionaldehyde}	172a	174a, 174b
31.	13341-72-5	Benzofuranone, dimethyltetrahydro- {dimethyltetrahydrobenzofuranone-}		603, 3370
32.	134-20-3	Benzoic acid, 2-amino-, methyl ester {methyl anthranilate}		603, 3370
33.	87-19-4	Benzoic acid, 2-hydroxy-, 2-methylpropyl ester {isobutyl salicylate}		603, 3370
34.	118-58-1	Benzoic acid, 2-hydroxy-, phenylmethyl ester {benzyl salicylate}		603, 3370
35.	120-47-8	Benzoic acid, 4-hydroxy-, ethyl ester {ethyl *p*-hydroxybenzoate}	2208, 2896	
36.	94-13-3	Benzoic acid, 4-hydroxy-, propyl ester {propyl *p*-hydroxybenzoate}		603, 3370
37.	121-98-2	Benzoic acid, 4-methoxy-, methyl ester {methyl anisate}	172a	174a, 174b
38.	94-46-2	Benzoic acid, 3-methylbutyl ester {isoamyl benzoate}		603, 3370
39.	126-64-7	Benzoic acid, 3,7-dimethyl-1,6-octadien-3-yl ester {linalyl benzoate}	172a	174a, 174b
40.	532-32-1	Benzoic acid, sodium salt {sodium benzoate}	2208, 2896	174a, 174b
41.	125-12-2	Bicyclo[2,2,1]heptan-2-ol, 1,7,7,-trimethyl-, acetate {isobornyl acetate}	172a	174a, 174b
42.	87-69-4	Butanedioic acid, 2,3-dihydroxy- {*l*-tartaric acid}	172a, 2201, 2896,	174a, 174c
43.	7492-70-8	Butanoic acid, 2-butoxy-1-methyl-2-oxoethyl ester {butyl butyryl lactate}		603, 3370
44.	109-21-7	Butanoic acid, butyl ester {butyl butyrate}	172a	174a, 174b, 603, 3370

TABLE 25.30 (continued)
Pyrolysis of Nontobacco and Nontobacco Smoke Components and/or Their Effect on Smoke Composition When Added to Tobacco

	CAS No.	Name (per CA Collective Index)	References to: Pyrolysis of Individual Component	References to: Effect on MSS Composition, When Component Added in a Mixture
45.	106-29-6	Butanoic acid, 3,7-dimethyl-2,6-octadien-1-yl ester {geranyl butyrate}	172a	174a, 174b, 603, 3370
46.	10094-34-5	Butanoic acid, 1,1-dimethyl-2-phenylethyl ester {α,α-dimethylphenethyl butyrate}		603, 3370
47.	539-90-2	Butanoic acid, 2-methylpropyl ester {isobutyl butyrate}	172a	174a, 174b
48.	540-18-1	Butanoic acid, pentyl ester {amyl butyrate}	172a	174b, 603, 3370
49.	106-27-4	Butanoic acid, 3-methylbutyl ester {isoamyl butyrate}	172a	174a, 174b, 603, 3370

TABLE 25.32
Summary of Tobacco Ingredient Studies from 1994 to 2005

Analysis	Date	Number of Ingredients Studied	Reported Findings/Conclusions	Reference
Detailed literature survey of ingredients added to U.S. tobacco products	1994	599	"…it was concluded that there was no evidence that any ingredient added to cigarette tobacco produces harmful effects under the conditions of use in cigarettes"	Doull et al. (1053)
Effect of added tobacco ingredients on cigarette MSS chemistry	2002	333	"The smoke chemistry data revealed changes towards both higher and lower amounts of various smoke constituents… This suggests that the addition of 333 commonly used ingredients to cigarettes in three groups did not add to the toxicity of the smoke, even at the exaggerated levels tested…" "An overall assessment of our data suggests that these ingredients, when added to the tobacco, do not add to the toxicity of smoke, even at the elevated levels used in this series of studies."	Carmines (603); Rustemeier et al. (3370)
	2002	482	"In most cases, the flavour mixtures had no statistically significant effect on the smoke yields relative to the control cigarette. In a few cases, the small increases or decreases were observed for some analytes relative to the control cigarette. The smoke yields of the experimental cigarettes were well within the ranges observed in the three reference cigarettes."	Baker and Smith (25A03)
	2004	482	"The significances of differences between the test and control cigarettes were determined using both the variability of the data on the specific occasion of the measurement, and also taking into account the long-term variability of the analytical measurements over the one-year period in which analyses were determined in the present study. This long-term variability was determined by measuring the levels of the 44 'Hoffmann analytes' in a reference cigarette on many occasions over the one-year period of this study." "…It was found that, in most cases, the mixtures of flavouring ingredients (generally added in parts per million levels) had no statistically significant effect on the analyte smoke yields relative to the control cigarette."	Baker et al. (174b)
Effect of added tobacco ingredients on cigarette MSS biology:	1997	≈152	"Although the mutagenic activities appeared to be similar, there were statistically significant differences in mutagenic activities among the sample."	Bioresearch [for RJRT] (25A09); Rodgman (3263, 3264)
(a) In vitro genotoxicity and cytotoxicity	2002		[*Note*: The differences were primarily due to the increase in mutagenicity of the CSC when the humectants (glycerol, propylene glycol) were not added to the cigarette tobacco and thus were not present as diluents in the CSC]	
	2002	333	"Within the sensitivity and specificity of the test systems, the in vitro mutagenicity and cytotoxicity of the cigarette smoke were not increased by the addition of the ingredients."	Carmines (603); Roemer et al. (25A49)
	2002	482	"The data has been analyzed and demonstrates no additional activity from the flavoured cigarettes above that of the control products."	Massey et al. (25A43)
(b) MSS inhalation	1997 2002	2 (Glycerol, propylene glycol)	"It was concluded that addition of the tested humectants singly or in combination had no meaningful effect on the site, extent or frequency of respiratory tract changes associated with smoke exposure in rats."	Gaworski et al. (25A27)

TABLE 25.32 (continued)
Summary of Tobacco Ingredient Studies from 1994 to 2005

Analysis	Date	Number of Ingredients Studied	Reported Findings/Conclusions	Reference
	1997	1 (Menthol)	"The results of this 13-week inhalation study indicated that the addition of 5000 ppm menthol to tobacco had no substantial effect on the character or extent of the biological responses normally associated with inhalation of mainstream cigarette smoke in rats."	Gaworski et al. (25A24)
	1998	170	"The results indicate that the addition of flavoring ingredients to cigarette tobacco had no discernible effect on the character or extent of the biologic responses normally associated with inhalation of mainstream cigarette smoke in rats."	Gaworski et al. (25A25)
	2002	333	"The data indicate that the addition of these 333 commonly used ingredients, added to cigarette in three groups, did not increase the inhalation toxicity of the smoke, even at the exaggerate levels used."	Carmines (603); Vanscheeuwijck et al. (25A79)
(c) Mainstream CSC and skin painting	1999	150	"While tumor incidence, latency and multiplicity data occasionally differed between test and comparative reference CSC groups, all effects appeared to be within normal variation for the model system. Furthermore, none of the changes appeared to be substantial enough to conclude that the tumor promotion capacity of CSC obtained from cigarettes containing cigarettes with ingredients was discernibly different from the CSC obtained from reference cigarettes containing tobacco processed without ingredients."	Gaworski et al. (25A26)
Pyrolysis of tobacco ingredients under conditions simulating those in the cigarette burning zone	2004	291	"The results are compatible with parallel studies in which the ingredients are added to tobacco and the effect on cigarette smoke constituents are measured. In general, the number of "Hoffmann analytes" detected among the pyrolysis products of the ingredients, and their levels, are low…Of the 291 tobacco ingredients pyrolysed, almost a third transfer out of the pyrolysis zone intact, and almost two thirds transfer at least 95% intact."	Baker and Bishop [see pp. 245–246 in (172a)]
	2005	159	"…a further 159 non-volatile and complex ingredients, as well as ingredient mixtures have been pyrolyzed…For the pyrolysis of many of the non-volatile ingredients, no 'Hoffmann analytes' were detected among the products."	Baker and Bishop (172b)

26 Carcinogens, Tumorigens, and Mutagens *vs.* Anticarcinogens, Inhibitors, and Antimutagens

26.1 CARCINOGENS, TUMORIGENS, AND MUTAGENS

In 1990, the U.S. Environmental Protection Agency (EPA) issued several draft documents in which it defined environmental tobacco smoke (ETS) as a carcinogen and designated it as a "group A carcinogen" (1148, 1148a). Subsequently, EPA issued a final report on this topic (1148b). Data from various epidemiological studies on the incidence of lung cancer in nonsmokers exposed to ETS were interpreted by the EPA as indicating that ETS was causally related to lung cancer in the ETS-exposed nonsmokers. In addition to these epidemiological data, EPA relied on data from studies on tobacco smoke composition, particularly the many studies dealing with the composition of mainstream smoke (MSS) as well as the smaller number of studies dealing with sidestream smoke (SSS) composition. Of the limited number of SSS components for which quantitative data have been obtained on per cigarette yields, many are delivered at higher per cigarette levels in SSS than in MSS. Many of the SSS components quantified are those that have been considered as contributors to respiratory tract or other disease problems, based upon results reported from laboratory animal experiments with individual compounds. EPA extrapolated these SSS (and MSS) qualitative and quantitative composition data directly to ETS with little regard for the profound quantitative differences between MSS and SSS composition and the highly diluted ETS system and the biological implications of these differences (3255, 3255a, 3257). Of prime concern to EPA were those MSS and SSS components which, in one biological system or other, had been described as tumorigenic at doses far in excess of those encountered in MSS or SSS (1148).

The cigarette MSS components of greatest concern to EPA were 35 MSS components listed by Hoffmann and Wynder (1808) in 1986, a list derived from the 1986 International Agency for Research on Cancer (IARC) monographs on tobacco smoking (1869, 1870) and expanded in 1990 to 43 MSS (and tobacco) components by Hoffmann and Hecht (1727). The Hoffmann and Hecht list was the first of many lists issued from 1990 through 2001 by Hoffmann et al. (1727, 1740, 1741, 1743, 1744, 1773), by the Occupational Safety and Health Administration (OSHA) in 1994 (2825), and by Fowles and Bates in 2001 (1217). These listings involved tobacco and tobacco smoke components previously reported to be tumorigenic, carcinogenic, or biologically active in various bioassays with individual components. The components of tobacco smoke were particularly emphasized (3265). Eventually, many of the listed MSS components, because of their multiple listings by Hoffmann et al., became defined as "Hoffmann analytes."

Table 26.1 is a tabulation of toxicants in tobacco and tobacco smoke from the IARC 1986 publication (1870) plus the seven lengthy publications coauthored from 1986 through 2001 by Hoffmann and his American Health Foundation colleagues (1727, 1740, 1741, 1743, 1744, 1773, 1808).

In their 1990 list, Hoffmann and Hecht (1727) classified 43 tobacco and/or tobacco smoke components as "tumorigenic agents in tobacco smoke." It is interesting to note that Hoffmann and Hecht used the term "tumorigenic" rather than "carcinogenic" to define the components. A similar list was issued by Hoffmann et al. (1773) in 1993. In 1994, OSHA (2825) tabulated 43 tobacco smoke components for which it claimed there was "sufficient evidence" of carcinogenicity in humans or animals. For some unknown reason, the OSHA list included only 42 items. Obviously, polonium-210 was inadvertently omitted. OSHA listed many of the same components as Hoffmann and Hecht but included several components not listed by Hoffmann and Hecht (1727) and vice versa.

In 1997, Hoffmann and Hoffmann (1740) classified 60 tobacco and/or tobacco smoke components as "carcinogens in tobacco and cigarette smoke." Several components listed by Hoffmann and Hecht but omitted by OSHA were also omitted by Hoffmann and Hoffmann. A major addition, accounting for much of the increase from 43 to 60, was the inclusion of the highly mutagenic *N*-heterocyclic amines.

EPA (1148) incorrectly assessed the health consequences with regard to lung cancer of the components in the Hoffmann–Hecht list by stating:

> Of the 99 compounds in tobacco smoke that have been studied in detail, at least 43 are complete carcinogens,* each able on its own to cause the development of cancer in humans or animals.

The EPA erred in its assessment of the 43 components in the Hoffmann–Hecht list since most have been shown not to be (1) tumorigenic to any human tissue or (2) tumorigenic to lung tissue in laboratory animals. These facts are addressed by comments from Hoffmann and Hecht in the text accompanying their tabulation. In addition, the few compounds that

* OSHA cited the U.S. Surgeon General's 1989 report (4012) which, in turn, reproduced the table subsequently presented in Hoffmann and Hecht (1727).

[u] See Table 2 in (1740).
[v] See Table 5-2 in (1743).

have been reported to produce tumors in laboratory animals have done so at dose levels far in excess of those encountered in MSS, SSS, or ETS.

Careful examination of the Hoffmann–Hecht list reveals significant flaws which, if they had been considered at all by the EPA, would have profoundly affected its conclusions concerning ETS. It has been known for over five decades that classifying a substance as "tumorigenic" or "carcinogenic" can be misleading. These terms should not be misinterpreted or overinterpreted. Users of tables with headings "tumorigenic" or "carcinogenic" must be aware of the meaning and limitations of the terms "tumorigenicity" and "carcinogenicity" when applied to specific compounds or elements.

The misunderstanding and misinterpretation of these terms are not new. The term "carcinogenesis" and by extension derivative terms were defined precisely as early as 1923, and its original definition is still listed in various medical dictionaries: *Carcinogenesis is the process whereby a carcinoma is generated*. In the 27th edition (1051c) of Dorland's medical dictionary, this definition of carcinogenesis is the same as that listed in the 13th edition (1051b). Some investigators incorrectly use the term "carcinogenesis" for the production of any tumor type not just a carcinoma. The correct term, if used in this manner, is "tumorigenesis." The term "carcinogen" is often applied, again often incorrectly, to any factor that induces any type of tumor. Common in the past, but seldom used now, was the term "sarcogenesis" used to describe sarcoma production, the end point in studies in which a compound injected subcutaneously induced a sarcoma.

Within 25 years of the first successful experiments to produce tumors in animals by skin painting with solutions of coal tar by Yamagiwa and Ichikawa (4361) and within a decade of the first successful skin-tumor inductions with pure compounds such as dibenz[*a,h*]anthracene (DB[*a,h*]A) [Kennaway and Hieger (2078)] and benzo[*a*]pyrene (B[*a*]P) [Cook et al. (796a, 797), Barry et al. (194)], the misuse and misunderstanding of the term "carcinogenicity" had reached such proportions that Shear, an outstanding and highly regarded U.S. investigator of chemical carcinogenesis, was invited to put the term in perspective. In 1941, Shear and Leiter (3627) published an article in which their admonitions regarding overinterpretation of these terms are as significant today as they were then:

> The term 'carcinogenic potency' … is not to be considered as an invariable property inherent in a compound but is merely a summary of the results of particular experiments and is valid only for animals of the species, strain, sex, age, diet, etc., of the particular animal employed as well as the dose, menstruum, mode and site of application, etc., of the compound in question … Conclusions regarding the potency of any given compounds should therefore be interpreted in the light of the data upon which they are based.

In 1951, Hartwell compiled the 2nd edition (1544) of his survey on compounds tested for carcinogenicity since the demonstrated carcinogenicity of DB[*a,h*]A and B[*a*]P in mouse-skin-painting experiments. To further the understanding of the terms "carcinogen" and "carcinogenicity" and to minimize their future misuse, Hartwell quoted liberally from the Shear–Leiter publication. He added several important points, one of which was the following: There is a tendency on the part of some to consider carcinogenicity or lack of carcinogenicity as characteristic properties of chemical compounds. In other words, some researchers treat carcinogenicity as a fixed property of a compound. This is not a valid approach to thinking about "carcinogens." Carcinogenicity is a variable property, depending on a number of factors. It differs from other properties of a compound that are fixed, e.g., melting point, boiling point, refractive index, specific gravity, crystalline form. As noted by Shear and Leiter (3627), by Hartwell (1544), and by many others, a substance or factor can show a range from carcinogenicity to noncarcinogenicity to anticarcinogenicity, and the response will differ in the laboratory depending on the animal used (species, strain, sex, age), route of administration (inhalation, ingestion, injection [subcutaneous, intravenous, intraperitoneal], skin painting, douching), mode of administration (single *vs*. multiple doses, neat, in solution, as an aerosol or as a vapor), diet supplied to the animals, and cage care.

Hartwell also cautioned:

> Another pitfall is the attempt to carry over, without reservation, to man, conclusions based on animal experiments. We do not know whether man is more or less susceptible than mice to particular carcinogens. Some animal species, such as the rat, rabbit, and dog are much more resistant than is the mouse, and vice versa, while in the monkey none of the powerful carcinogens has been shown to produce tumors.

From an examination of Table 26.1, it is obvious that several classes of components account for the greatest number of tumorigens classified as significant in tobacco smoke. Further examination of the number of references cited for each of them in the pertinent chapters of this book indicates the magnitude of the research conducted on each class both within and outside the tobacco industry since the early 1950s. Sequentially, polycyclic aromatic hydrocarbons (PAHs), azaarenes, *N*-nitrosamines (NNAs), and *N*-heterocyclic amines in tobacco smoke have attracted much attention on their identification, quantitation, precursors, and reduction or elimination. Tumorigenic components in these four classes account for nearly 60% of the total listed. The following pages contain brief descriptions of the history and chronology of the four classes of tobacco smoke components.

The components listed in Table 26.1 and by Osha (2825) and Fowles and Bates (1217) raise numerous questions as to why many of them were included. First, attempts to attribute the "carcinogenicity" of cigarette MSS to a particular component are questionable. Scores of citations over the past five decades have been issued by eminent scientists and health organizations in which it is stated that no single MSS component or class of components acting either individually or in concert can explain observations in human smokers or in laboratory animals treated with heroic doses of MSS. For example, comments on B[*a*]P in particular or other tumorigenic PAHs in general include

those by Cook (793) [cf. (796a, 797)] who wrote the following about B[*a*]P in cigarette smoke:

> The tarry condensates of the smoke obtained by smoking cigarettes in machines … have 3,4-benzpyrene, but the amount is exceedingly small and there is considerable doubt about whether the concentration is high enough to produce carcinogenic action.

In 1981, the U.S. Surgeon General [see p. 36 in (4009)] stated:

> The contribution of BaP or PAH in general to mouse skin carcinogenesis by cigarette smoke condensate cannot be fully measured at this time … In the smoking and health program of the National Cancer Institute … no significant dependence of carcinogenic potency on BaP content was observed.

The American Association for Cancer Research (26A02) in its 1984 position paper on smoking wrote:

> Studies have presented the profile of the known carcinogens in tobacco. At present, there is no direct method to assign priority to any of these substances as putative causal agents in human lung cancer.

That year, Peto and Doll (26A127) stated the following: But 30 years of laboratory research has yet to identify reliably the important carcinogenic factors in cigarette smoke.

The U.S. Surgeon General [see p. 200 in (4010)], on the subject of NNAs in tobacco smoke, stated:

> There is lack of direct evidence that these compounds are also human carcinogens. This was also the view of Magee who first demonstrated the tumorigenicity of *N*-nitrosamines in laboratory animals. In 1983, Magee (26A89) noted: A role for nitrosamines in the causation of human cancer has not been established.

On the basis of the data available, the aromatic amines, including β-naphthylamine, were discounted in the U.S. Surgeon General's 1981 and 1982 reports:

> The presence of β-naphthylamine in cigarette smoke has been demonstrated [Hoffmann et al. (1747)], along with other carcinogenic aromatic amines [Patrianakos et al. (2900)]. The yield was so low that [the researchers] did not believe these agents contributed significantly to the risk of bladder cancer in smokers [see p. 41 in (4009)].

> On the basis of quantitative data for aromatic amines in cigarette smoke, an etiological significance of these traces of carcinogenic amines in bladder cancer is questionable, even if one were to consider the total of the aromatic amines and their metabolites [see pp. 207–208 in (4010)].

Similar comments about other components on the various lists have been published: arsenic (4010), nickel (4010), polonium-210 (4009, 4010), and benzene (4005).

Many of these MSS and/or tobacco components should be excluded from the lists on the basis of explicit comments in the literature by numerous knowledgeable authorities on their tumorigenicity to laboratory animals at levels determined in MSS, their lack of tumorigenicity in most instances on inhalation, and the equivocal evidence showing their tumorigenicity in humans at levels in MSS. All but 4 of the 43 components have never produced respiratory tract tumors in laboratory animals exposed to the component via inhalation. Many have never been tested in an inhalation system, and one component of great interest (B[*a*]P) has only produced lung carcinoma via inhalation in animals at an extraordinarily massive dose.

The following situation should not be overlooked: the MSS yield determined two, three, or four decades ago for a component is not relevant to the MSS yield found by analysis for the component from more recent or current cigarettes. For example, MSS values for dibenz[*a,h*]acridine and 7*H*-dibenzo[*c,g*]carbazole were obtained with 1959–1960 cigarettes, MSS values for dibenz[*a,j*]acridine from 1959 to 1960 and from 1963 cigarettes, the MSS value for DB[*a,h*]A is from 1963 cigarettes, the MSS value for 5-methylchrysene (5-MeC) is from 1973 cigarettes, and the MSS value for *N*-nitrosodiethanolamine (NDELA) is from commercial cigarettes manufactured in or before 1981. It is well recognized, as indicated in Figure 26.1, that the variety of cigarette design technologies (efficient filtration, filter-tip additives, processed tobacco materials [reconstituted tobacco sheet, RTS, expanded tobaccos], air dilution [porous paper, filter-tip perforations], and paper additives) has progressively reduced the sales-weighted average MSS total particulate matter (TPM) by almost 70% from 40 mg/cig in the early 1950s to less than 12 mg/cig in the late 1980s. These eight cigarette design technologies have been defined, even by various opponents of cigarette smoking, as significant in the design of a "less hazardous" cigarette [Wynder and Hoffmann (4319, 4332), USPHS (4005, 4009), Gori (1333), Hoffmann and Hoffmann (1740, 1743, 1744)].

At the same time that the reduction of delivery of MSS TPM was accomplished, the composition of the MSS was altered. For example, for MSS TPM, the B[*a*]P content—expressed as ng B[*a*]P/mg TPM—has decreased about 33% (from 1.2 to 0.8 ng/mg TPM) during the same time period. The U.S. Surgeon General in his 1979 report (4005) summarized the B[*a*]P data for a commercial cigarette sold in the United States from 1954 to 1979.

As noted by Rodgman and Green (3300), Gold et al., colleagues of Ames, as recently as 1998, questioned the extrapolation of laboratory animal tumorigenesis data generated by the use of a maximum tolerated dose (MTD) to a human situation. They stated (1318a):

> Extrapolation of cancer potency results from MTD studies to real-life exposures is not scientifically supportable.

From these considerations and the information presented later, it is obvious that many of the components could and should be removed from the various Hoffmann et al. lists that subsequently led to the "Hoffmann analyte" phenomenon.

In its 1994 report on indoor air quality, OSHA (2825) dealt at some length with ETS. It presented a list of 43 tobacco smoke components for which it claimed "there is 'sufficient evidence' of carcinogenicity in humans or animals." Comparison of the OSHA list with that of Hoffmann–Hecht (Table 26.1) reveals

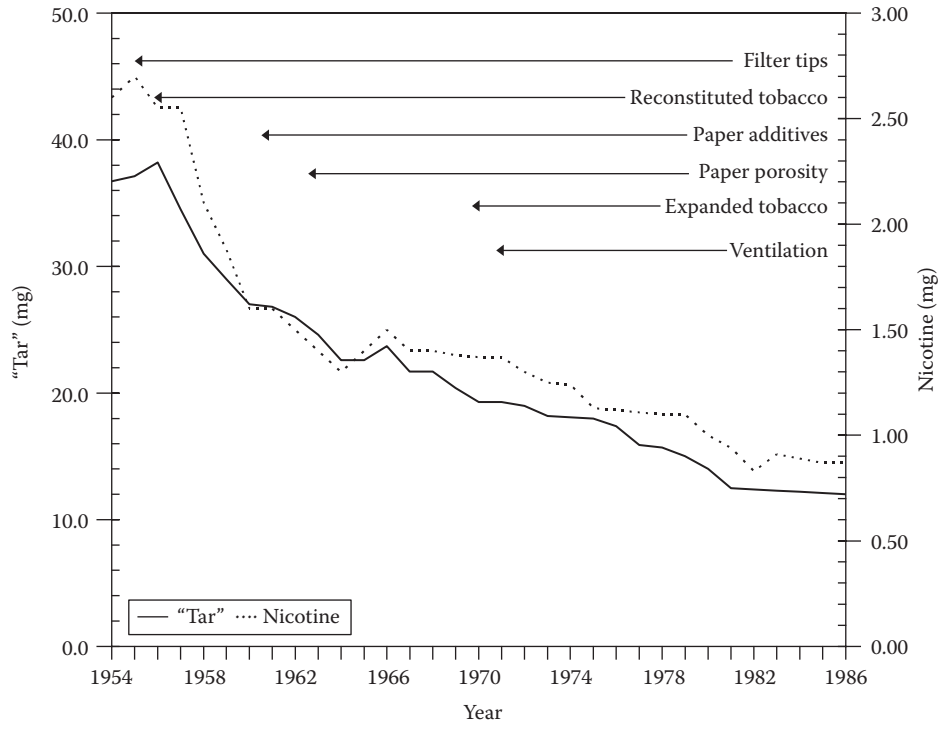

FIGURE 26.1 "Tar" and nicotine deliveries, sales-weighted average basis.

numerous similarities plus some differences. OSHA (2825) described 10 of its listed 43 tobacco smoke "carcinogens" in the following less-than-positive terms:

Formaldehyde	*Probable* human carcinogen
N-Nitrosodimethylamine (NDMA)	*Probable* human carcinogen
N-Nitrosodiethylamine (NDEA)	*Probable* human carcinogen
N-Nitrosopyrrolidine (NPYR)	*Probable* human carcinogen
2-Toluidine	Listed only as an irritant, *not as a carcinogen*
Benz[*a*]anthracene (B[*a*]A)	*Listed only* as an animal carcinogen
N′-Nitrosonornicotine (NNN)	*Listed only* as an animal carcinogen
4-(*N*-Methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK)	*No relevant information available* on health effects
NDELA	*Probable* human carcinogen
Cadmium	*Probable* human carcinogen

Despite these and other equivocal statements, OSHA stated with great certainty:

> The corroborative evidence of the carcinogenic activity of tobacco smoke provided by animal bioassays and in vitro studies and the chemical similarity between mainstream smoke and ETS clearly establish the plausibility that ETS is … a human lung carcinogen …

Of the components in the various lists, the four classes of tobacco smoke components investigated in greatest detail during the past five decades were the PAHs, aza-arenes, NNAs, and the *N*-heterocyclic amines. Because of the wealth of background information available on PAHs demonstrated to be tumorigenic in laboratory animals, extensive research (isolation, identification, quantitation, precursors, removal, prevention of formation, etc.) was conducted in the 1950s and 1960s on this compound class in tobacco smoke. The reason for selection of this class of compounds was obvious.

It has been estimated that more research funds were expended since the 1930s on the study of tumorigenic PAHs in general (and B[*a*]P in particular) than on any other class of compounds. The results of thousands of investigations on PAHs (their synthesis, biological properties [tumorigenicity, mutagenicity], metabolism, sources [air pollutants, industrial oils and tars, tobacco smoke, foodstuffs, beverages, etc.], isolation, quantitation, reduction, etc.) have been published. Similar studies, but to a much lesser degree, have been conducted on the aza-arenes. Since the early 1950s, over 500 PAHs and slightly fewer than 300 aza-arenes have been reported as tobacco smoke components. The per cigarette yields of most of the PAHs and aza-arenes are in the subnanogram range.

In the early 1950s, the discovery of the tumorigenicity by Barnes and Magee (192) of an NNA in laboratory animals initiated a flurry of research on the NNAs, initially in foodstuffs and subsequently (mid-1960s) in tobacco smoke. In contrast to the great number of PAHs and aza-arenes identified in tobacco smoke, fewer than 70 NNAs have been identified in tobacco and/or tobacco smoke to date (see Table 15.8). In the mid-1970s, Japanese investigators in their investigations of various cooked foodstuffs reported the isolation and identification of several *N*-heterocyclic amines derived pyrogenetically from amino acids and proteins [Sugimura et al. (3829, 3829a), Sugimura (3828b, 3828c)]. Subsequently, several of the *N*-heterocyclic amines were reported to possess inordinately high mutagenicities in the Ames test with

Salmonella typhimurium, be tumorigenic in the mouse-skin-painting bioassay, and to be present in cigarette smoke condensate (CSC) at low nanogram or subnanogram levels [Sato et al. (3415a), Yamashita et al. (4367, 4368)]. Fewer than a dozen of the highly mutagenic *N*-heterocyclic amines have been reported as CSC components.

26.1.1 Polycyclic Aromatic Hydrocarbons

In the case of the PAHs in general and the 13 specific PAHs listed in Table 26.1, many of the assertions about them in tobacco smoke since the early 1950s have either been shown to be incorrect or, in several instances, highly equivocal.

Several sources of PAHs in cigarette MSS, originally considered to be the major sources of the PAHs, were shown to be either incorrect (effluents from lighting source [matches, butane- or hexane-fueled lighters]) or insignificant (PAH-containing air pollutants deposited on the surface of the tobacco leaf during growing, harvesting, and curing) or primarily derived from cigarette paper combustion.

Long-chained saturated hydrocarbons (SHCs) were originally defined as the major precursors in tobacco of PAHs in tobacco smoke. Subsequently, it was shown that the contributions of tobacco terpenes and phytosterols to the levels of MSS or SSS PAHs exceeded those of the SHCs.

In the mid- to late 1950s, it was proposed (3241, 3242) that the per cigarette yields of MSS PAHs would be diminished by removal of SHCs, phytosterols, and terpenes from the tobacco by extraction with nonpolar solvents such as hexane, a process dubbed the "dry cleaning" of tobacco.* It was proposed that the reduced MSS PAH level in the CSC from cigarettes fabricated with extracted tobacco would be accompanied by reduced tumorigenicity to mouse skin of the extracted tobacco CSC [Wynder and Wright (4354)]. In 1982, Brunnemann and Hoffmann, members of a research group that formerly proposed removal of waxlike compounds considered to be the precursors of the PAHs in smoke, advocated addition of such compounds to tobacco (480).

Also in the late 1950s, it was proposed to use high-nitrate tobacco in the tobacco blend or add nitrate to the blend to modify the combustion process during smoking to decrease the MSS PAH yields [Hoffmann and Wynder (1797, 1798)]. In direct contrast was a 1982 proposal: Because of the involvement of nitrate and nitrogen oxides generated from it in the pyrogenesis of NNAs, use low-nitrate tobaccos in the blend or remove the nitrate from tobacco as a means to control NNAs in MSS (and SSS) (480).

* The concept of extraction of tobacco with an organic solvent to remove PAH precursors was not new. Roffo (3327) reported that extraction of tobacco with organic solvents such as ethyl alcohol, chloroform, acetone, petroleum ether, paraffin hydrocarbons, or benzene resulted in a reduction of the tumorigenicity of the tar generated by destructive distillation of the extracted tobacco compared to the tar generated by destructive distillation of the unextracted (control) tobacco. Roffo did not study the smokes from cigarettes fabricated with the extracted and unextracted tobaccos. Roffo suggested that the extraction removed the phytosterols from the tobacco which he considered the major precursor of the PAHs in the destructive distillate and in tobacco smoke.

The proposal that high-molecular-weight PAHs, including B[*a*]P, could be removed from MSS by selective filtration was shown to be incorrect. Selective filtration from MSS is possible only with compounds that have an appreciable vapor pressure, i.e., they are found in both the particulate and vapor phases of MSS. For example, the low-molecular-weight phenols and the volatile NNAs are sufficiently volatile to be selectively filtered from MSS, but the vapor pressures of most PAHs of interest (B[*a*]P, DB[*a,h*]A, B[*a*]A) are too low for selective filtration to be effective.

B[*a*]P in MSS was proposed as an "indicator" of (1) the tumorigenicity of mainstream CSC to mouse skin, (2) the levels of PAHs with four or more rings, and (3) the levels of tumorigenic PAHs. In none of these cases is the level of B[*a*]P a valid "indicator." (Similarly, phenol, proposed as an "indicator" of the level of low-molecular-weight promoting phenols in cigarette MSS, was shown not to be a valid "indicator.")

Assertions that the probability was extremely low that alkylated PAHs (methyl- and dimethyl-PAHs) would occur in tobacco smoke were demonstrated to be incorrect. Subsequently, even polyalkylated PAHs such as pentamethyl- and hexamethyl-PAHs were identified in tobacco smoke, their major precursor being the high-molecular-weight tobacco terpenes such as solanesol [Snook et al. (3757)].

Assertions that cyclopentabenzanthracenes could not occur in tobacco smoke were incorrect. Numerous cyclopentabenzanthracenes were identified in MSS, their major precursor being the phytosterols [Snook et al. (3736, 3756, 3758, 3759)].

PAHs in tobacco smoke are formed by either (1) a degradation-combination mechanism or (2) an aromatization mechanism involving a single molecule. Studies showed that both mechanisms are operative.

To bolster several arguments concerning PAHs in MSS, it was incorrectly asserted by some investigators that the fate of an individual tobacco component during experimental pyrolysis in an inert atmosphere and at a temperature approximating that of the cigarette coal was the same as its fate in the tobacco matrix during the cigarette smoking process. This assertion was shown to be incorrect by several investigators, including Schmeltz et al. (3512), members of the same group that originally proposed the equivalency of the fate of tobacco components during pyrolysis and the smoking process.

The tumorigenicity of CSC to mouse skin is due to its content of PAHs with four or more fused rings. Even though it was claimed that the PAHs are the only initiators in CSC, the levels and tumorigenicities of the PAHs in CSC accounted for no more than 2%–2.5% of the observed tumorigenic response in mouse or other rodent-skin-painting bioassays.

With so many incorrect or equivocal assertions about the MSS PAHs issued by antitobacco smoking investigators over the last four decades (see Table 26.2), it was somewhat surprising that either OSHA or EPA was so willing to accept the premise that the 13 PAHs in the Hoffmann–Hecht and/or the OSHA lists contributed significantly to the alleged tumorigenic effects of MSS and ETS in the respiratory tract of active and passive smokers, respectively.

TABLE 26.2
PAH Paradoxes

Assertion	Contradiction
Major source of PAHs in cigarette MSS is the lighting source (match, flammable fuel-charged lighter, gas burner in laboratory)	The PAH level in cigarette MSS was independent of lighting source: Cigarettes lit by an electric lighter gave the same PAH levels as those lit by matches, fuel-charged cigarette lighters, or a gas flame
Because bulk pyrolysis of cigarette paper yielded PAHs, cigarette paper (representing about 5% of the cigarette weight) was defined as the major source of PAHs in cigarette MSS [Cooper et al. (817), Cardon et al. (594)]	Comparison of PAH yields, including B[*a*]P, produced by bulk pyrolysis of cigarette paper *vs*. pyrolysis of the paper in a cylindrical form approximating its configuration in the cigarette revealed that the cylindrical configuration combustion produced very little PAHs (or B[*a*]P) *vs*. bulk pyrolysis [Wright (4281)]
PAHs in cigarette MSS are the result of transfer of PAHs from the surface of air-pollutant-contaminated tobacco to MSS	MSS PAH level was not due to transfer of contaminant PAHs transfer from the tobacco rod to smoke: B[*a*]P injected into the tobacco rod produced very little increase in the MSS B[*a*]P level. Most of the injected B[*a*]P was destroyed during smoking process
Since none of the factors noted earlier (means of cigarette lighting, cigarette paper, air pollutant contamination) were the source of PAHs in cigarette MSS, the source must be one or more of the tobacco components. However, even in 1957, the presence of B[*a*]P in tobacco smoke was questioned [cf. Fieser (1181)]	Because the fragmentary evidence presented, the presence of PAHs, particularly B[*a*]P, in tobacco smoke was questioned by such noted PAH experts as Fieser (1181) whose colleagues identified B[*a*]P in roasted coffee beans but were unable to identify it in tobacco smoke. Eventually, because of the isolation by Hoffmann of B[*a*]P in crystalline form from cigarette MSS (4307), its presence in MSS became universally accepted
According to Wynder and Hoffmann, PAHs in cigarette smoke were the only major tumor initiators in mouse-skin carcinogenesis (4332): "The many detailed data obtained in studies of tobacco carcinogenesis on mouse skin exclude with some certainty that major tumor initiators other than the PAH type play a role in this assay system."	Mouse-skin-painting studies with B[*a*]P solutions at concentrations much in excess of that in CSC produced no skin carcinomas in rabbits or mice
B[*a*]P, because of its potency in skin-tumor carcinogenesis and level in MSS, was considered the major PAH of concern in tobacco smoke. In the 1981 Surgeon General's report (4009), it is stated: "Benzo[*a*]pyrene] appears to be the most important single member of this class of compounds [the PAHs], taking into consideration both its concentration and its relative carcinogenic potency."	[Wynder et al. (4351), Warshawsky et al. (26A180)]. Similarly, use of more reasonable doses of CSC in skin-painting studies instead of the massive doses usually used resulted in neither papilloma nor carcinoma formation [Wynder et al. (4351), Gori (1329, 1330, 1332, 1333), NCI (2683)].
Initially, Fieser did not believe the evidence was sufficient to demonstrate that B[*a*]P was present in tobacco smoke. He stated that if B[*a*]P were present, its precursor would be tobacco cellulose (1181)	Subsequent studies indicated the major precursors in tobacco of PAHs in its smoke were not cellulose and lignin but were the lipophilic tobacco components. Rodgman and Cook (3269, 3286, 3291) and Severson et al. (3616) reported that terpenoids, phytosterols, and SHCs were PAH precursors
Removal of lipophilic PAH precursors from tobacco by solvent extraction reduced the MSS PAH levels and the tumorigenicity (mouse-skin-painting) of the CSC [Wynder (4294), Wright (4282), Wynder and Wright (4354)]. This led to recommendations to remove the lipophilic tobacco components. Later, Wynder et al. (4332) minimized the effectiveness of the removal of the lipophilic tobacco components. Wynder and Hoffmann (4310) defined tobacco extraction as "impractical both technically and economically." Wynder and Hecht (4306d) and the Surgeon General (4005) described tobacco extraction as "of academic interest." Eventually, Wynder's colleagues recommended addition of lipophilic compounds, e.g., *n*-hentriacontane, to tobacc*o* (480) to offset effect of nitrate-derived NO_x in NNA formation	Biological activity of CSC from extracted tobacco was decreased but to a much lesser extent than decrease in MSS PAH (and B[*a*]P) yields. This resulted from two unanticipated effects of extraction on the tobacco and its smoke: Extracted lipophilic compounds included various inhibitors (SHCs) and anticarcinogens (α-tocopherol, β-sitosterol, cholesterol, *D*-limonene, duvanediols) which have been reported to offset the tumorigenicity of PAHs.\ • Residual tobacco after extraction contains higher levels of lignin, cellulose, and pectins. All of these generate promoting/cocarcinogenic phenols during the smoking process: levels of low-molecular-weight phenols in MSS were increased
PAHs in cigarette smoke are generated by one or other of the following mechanism: • Organic compounds in tobacco are degraded to simpler molecules during the pyrolysis processes occurring in the burning cigarette, and these simpler molecules recombine to PAHs (degradation-combination mechanism) [cf. Badger et al. (142, 143) and earlier papers]. • During the pyrolysis processes occurring in the burning cigarette, high-molecular-weight compounds in tobacco undergo unimolecular cyclization, dehydration, aromatization, ring expansion, etc., to form PAHs (aromatization reaction) [Rodgman and Cook (3269, 3286)]	The mechanism of PAH formation is not an either-or situation. Laboratory data indicated that both mechanisms were operative in PAH formation in the burning cigarette. Evidence for the unimolecular aromatization reaction was provided by pyrolysis data and cigarette "spiking" data with phytosterols. In this instance, the relatively high levels of chrysene and cyclopentaphenanthrene *vs*. B[*a*]P were more readily explained by the unimolecular aromatization of the tetracyclic sterol

(*continued*)

TABLE 26.2 (continued)
PAH Paradoxes

Assertion	Contradiction
Inhaled cigarette smoke is the responsible agent for respiratory tract cancer, particularly squamous cell carcinoma of the lung, in smokers. It was implied in the late 1950s and in the 1960s that the responsible agent in MSS may be the PAHs, particularly B[*a*]P	Inhalation experiments with laboratory animals exposed for their lifetime to cigarette MSS consistently failed to produce pulmonary squamous cell carcinoma [Essenberg (1161–1163), Leuchtenberger et al. (26A81, 26A82, 26A83), Henry and Kouri (1621, 1622)], the lung tumor type reported to be associated with smoking in humans. Similar exposures of laboratory animals to vehicular exhaust gases produced pulmonary squamous cell carcinoma [Mauderly et al. (2505)]. Inhalation studies with B[*a*]P at levels comparable to those in cigarette MSS were consistently negative. Tumor production at extremely high levels of inhalation exposure to B[*a*]P was described as "equivocal" [RTECS (3085)]. From a study with roofers exposed via inhalation to levels of B[*a*]P equivalent to the daily inhalation of MSS from over 700 cigarettes, Selikoff et al. (3584a) concluded: "If a high level of exposure to benzo[*a*]pyrene has any relation to lung cancer, the effect must be small… If a high level of occupational exposure to benzo[*a*]pyrene by way of inhalation results in little if any increase in the risk of lung cancer—then it seems unlikely that the extremely small amount of benzo[*a*]pyrene in cigarette smoke can account for the high degree of association between cigarette smoking and lung cancer."
Since B[*a*]P and other known tumorigenic PAHs account for so little (<2%) of the observed biological effect in mouse-skin-painting studies, two possibilities were proposed: A PAH whose tumorigenicity was equivalent to that of B[*a*]P was present at a substantially higher level (25–50 times) than B[*a*]P, or there was an unknown "supercarcinogenic" PAH in CSC, present at a level similar to that of B[*a*]P but whose activity was 25–50 times that of B[*a*]P [Wright (4282)]	After a year and a half unsuccessful search, attempts to find either the highly tumorigenic PAH present at a high level or the "supercarcinogenic" PAH were discontinued [Wright (4282)]. Neither proposal has resurfaced since the late 1950s
Since B[*a*]P in CSC acting alone accounts for less than 2% and the total PAH fraction accounts for less than 3% of the observed biological response in mouse-skin-painting studies and no "supercarcinogenic" PAHs is present, additional mechanisms are needed to explain the biological effect: The mechanisms of promotion and cocarcinogenesis of tobacco smoke components (phenols, etc.) may explain the observed effect in skin-painting studies with CSC	The promoting/cocarcinogenic effect of phenols on PAH tumorigenicity was offset by the following: • Removal of the low-molecular-weight phenols by selective filtration of smoke "does not change significantly the biological activity of the resulting condensate." [Hecht et al. (1582, 1583)]. • Phenol inhibited the tumorigenicity of PAHs such as B[*a*]P [Van Duuren et al. (4029, 4035)]. • Inclusion of known initiators, promoters, and cocarcinogens in tobacco smoke in the calculation explained less than 5% of the observed biological effect in skin-painting studies
Wynder and Hoffmann (4317) reported that doubling the level of tumorigenic 17 PAHs in CSC produces "a statistically significant increase in tumor yield."	The following contradictory evidence was reported: Increasing the B[*a*]P level in CSC by a factor of 10 produced no increase in the tumorigenicity of CSC [Roe (3310, 3311)]. Increasing the level of B[*a*]P by a factor of 30 produced no increase in the tumorigenicity of the CSC in mouse-skin-painting studies [Lazar et al. (2320)]
As proposed many times by Wynder, Hoffmann et al. (1766, 4304, 4317, 4319, 4330, 4355), the B[*a*]P level in CSC is an "indicator" (or "marker") of the following: • The levels of the tetracyclic and higher PAHs, particularly those that are tumorigenic • The tumorigenicity of the CSC in mouse-skin-painting studies	Ample evidence indicated these premises are invalid: • No significant correlation between levels of B[*a*]P and other PAHs in pyrolysates from pyrolysis studies [Lam (2255, 2257)] • Contradictory data provided from the studies of Wynder et al. (4355, 4356), Campbell and Lindsey (583), and Severson et al. (3616) • No significant correlation between levels of B[*a*]P and chrysene as reported by Rodgman and Cook (3269) or B[*a*]P and B[*a*]A [Gori (1329, 1330, 1332, 1333)] in cigarette smoking studies • No significant correlation between tumorigenicity of over 130 test and reference CSCs to mouse skin and their B[*a*]P and/or B[*a*]A content [Gori (1329, 1330, 1332, 1333), NCI (2683)] • In non-CSC-related studies, Warshawsky et al. (26A180) found in their study of the carcinogenic potential of mixtures that the carcinogenic "activity of a mixture cannot be accounted for by the level of benzo[*a*]pyrene present."

TABLE 26.2 (continued)
PAH Paradoxes

Assertion	Contradiction
Tumorigenicity of PAHs, e.g., B[*a*]P, is inhibited by representative hydrocarbons ($C_{31}H_{64}$ and $C_{35}H_{72}$) in the SHC fraction of CSC at SHC–B[*a*]P ratios much less than that found in CSC [4314, see p. 370 in (4332)]	Inhibitors and anticarcinogens more potent in their effect against PAHs than the SHC fraction in mouse-skin carcinogenesis were identified in CSC (phytosterols, α-tocopherol, duvanediols, *D*-limonene): their concentrations relative to that of the PAHs are far in excess of that required to elicit anticarcinogenesis
Reports of the presence of DMB[*a*]A in MSS CSC [Pietzsch (2962), Kröller (2191)] were criticized because "the formation of a dialkylated benz[*a*] anthracene during pyrolysis appears questionable." [Cook (796), Wynder and Hoffmann (4332)]	Snook et al. (3756, 3757) reported identification of numerous alkyl-, dialkyl-, and multialkyl-B[*a*]As in CSC. Subsequent research indicated a host of mono- to penta-alkyl-PAHs in the CSC. Their major precursors were tobacco terpenoid compounds, e.g., solanesol, neophytadiene
Report of presence of 1,2-dihydro-3-methylbenz[*j*]aceanthrylene (3-methylcholanthrene) in CSC [Kröller (2191)] was criticized by Wynder and Hoffmann (4332): "Since this carcinogenic hydrocarbon has not yet been found in any other combustion product, it remains a doubtful assumption that it is present in tobacco smoke."	Several benzo[*a*]cyclopentanthracenes, structurally similar to 1,2-dihydro-3-methylbenz[*j*]aceanthrylene (3-methylcholanthrene, a methylbenzo[*a*]cyclopent[*fg*]anthracene), have been identified in CSC: These included an unmethylated benzocyclopentanthracenes, originally reported erroneously as 1,2-dihydrobenz[*j*]aceanthrylene (cholanthrene) by Rodgman and Cook, (3273), 2,3-dihydro-1*H*-benzo[*a*]cyclopent[*h*]anthracene, and 9,10-dihydro-9*H*-benzo[*a*]cyclopent[*j*]anthracene [Bonnet and Neukomm (394, 397–399), Ahlmann (39), Bonnet (392), Pyriki (3033), Rodgman and Cook (3273)]
Dibenzo[*a,l*]pyrene (dibenzo[*def,p*]chrysene) is present in CSC and the pyrolysate from saturated tobacco hydrocarbons [Wynder et al. (4355)]. It was identified on the basis of agreement between spectral data for the isolate and those published for a synthetic PAH [Lyons and Johnston (2430), Lyons (2427, 2428), Wynder and Wright (4354), Rodgman and Cook (3273), Pyriki (3033), Bonnet and Neukomm (398, 399)]	Lavit-Lamy and Buu-Hoï (2314) demonstrated that the synthetic PAH originally defined as dibenzo[*a,l*]pyrene (dibenzo[*def,p*]chrysene) and spectrally identical with the tobacco smoke isolate was actually dibenz[*a,e*]aceanthrylene (dibenzo[*a,e*]-fluoranthene), a fact accepted by Hoffmann and Wynder (1798). Dibenzo[*def,p*]chrysene (dibenzo[*a,l*]pyrene) was subsequently identified in tobacco smoke by Snook et al. (3756), but no quantitative data were reported. In citations of dibenzo[*a,l*]pyrene as a "tumorigenic agents in tobacco smoke," Hoffmann et al. (1727, 1740, 1741, 1743, 1744, 1773), IARC (1869, 1870), and EPA (1148) indicated only that it was "present." Whether its "presence" was based on the erroneous dibenzo[*a,l*]pyrene reports from the 1950s or the authentic dibenzo[*a,l*]pyrene report of Snook et al. (3756) is unclear
Addition of nitrate to the tobacco blend significantly reduced MSS yields of "tar," PAHs, and phenols. The odd-electron compound NO generated during the smoking process interrupted the free radical mechanism of formation of PAHs [Hoffmann and Wynder (1797)]. The % TBA of the resulting CSC was also reduced by about 80%. On the basis of these results, nitrate addition or use of high-nitrate tobaccos was proposed	Reductions in these deliveries were confirmed (3246, 3286), but they were less than those originally proposed. In fact, in the first NCI–TWG study (1329), doubling the nitrate level produced the following changes: "Tar," −7%; phenanthrene, −9%; B[*a*]P, +23%; B[*a*]A, −17%; phenol, −10%; nitric oxide; +111%. Doubling the nitrate level decreased the % TBA by about 20%. Later data showed that adding nitrate increased volatile NNAs and TSNAs in smoke. Nitrate removal or use of low-nitrate tobaccos was proposed [Brunnemann and Hoffmann (480)]. Hoffmann et al. included NNAs and TSNAs in their list of tumorigens or carcinogens in tobacco smoke
According to Hoffmann and Wynder, increasing the number of cuts/inch (decreasing the cut width) for the tobacco filler reduces the delivery of CSC and B[*a*]P (1793)	The 1963 Hoffmann–Wynder findings were not confirmed either at RJRT or in the NCI–TWG study on the first set of experimental cigarettes [Gori (1329)]. In the latter study, the B[*a*]P and B[*a*]A yields for the normal filler cut (32 cpi) were less than those for the coarse (20 cpi) and fine (60 cpi) cuts
PAHs are removed selectively by filters treated with reagents (chloranil, picric acid, 2,4,7-trinitrofluorenone) that form stable complexes with individual PAHs[Szent-Gyorgi (3847)]	Complexing reagents such as chloranil or 2,4,7-trinitrofluorenone did not selectively reduce MSS yields of individual PAHs [Rodgman and Cook (3275)]. The complexing agent is unable to react with the nonvolatile individual PAHs in the milieu of thousands of compounds in the particles of the smoke aerosol

(*continued*)

TABLE 26.2 (continued)
PAH Paradoxes

Assertion	Contradiction
Because of the nature of the cigarette smoke aerosol, Wynder and Hoffmann (4311) considered selective filtration of a specific smoke component or class of smoke components such to be an "impossibility." However, the next year, they reversed their view, noting that selective filtration is not "impossible" [Wynder and Hoffmann, (4314)]	Wynder and Hoffmann (4314) reversed their view on the impossibility of selective filtration when they found that relatively volatile smoke components, e.g., low-molecular-weight phenols, are selectively removed from the MSS by filters incorporating certain plasticizers such as triacetin [cf. Laurene et al. (2312)]. Some years later, the same phenomenon was observed with volatile NNAs [Fredrickson (1236), Brunnemann et al. (514)]
Single compound pyrolysis at 800°C in an inert atmosphere (N_2 or He) is equivalent to the conditions existing in a smoked cigarette [Wynder and Hoffmann (4319, 4332)]. This proposal was an attempt to justify drawing conclusions on PAHs in MSS on the basis of pyrolysis data	On the basis of numerous laboratory data, this premise was criticized by several investigators [Bell et al. (248), Benner et al. (276, 277), Schlotzhauer and Schmeltz (3466, 3467), Chortyk and Schlotzhauer (722), Baker (163, 166, 167, 171a, 171b), Baker and Robinson (174d)]. Proponents of the equivalence of inert-atmosphere pyrolysis of a tobacco component and its behavior in a burning cigarette during the smoking process misinterpreted one set of data and disregarded another: "The atmosphere immediately behind the burning coal is oxygen-deficient compared to the oxygen level of the air entering the cigarette at the lit end and the smoke exiting the cigarette at the mouth end but it is *not* oxygen-free. The oxygen level in the tobacco rod a short distance (1–2 mm) behind the tobacco rod–fire cone interface is influenced by diluting air entering the tobacco rod through the cigarette paper and this diluting air increases as the cigarette paper porosity increases." The ultimate contradiction was provided from the laboratory of the original claimants. Schmeltz et al. (3512) reported that the fate of radiolabeled nicotine on pyrolysis was entirely different from its fate in the smoking process: "These results suggest to us that pyrolysis experiments may be of limited value for establishing the fate of nicotine and possibly other tobacco components in a burning cigarette."
Severson et al. (1979) describe "the pyrolytic conditions that yielded [PAH] profiles of tobacco pyrolyzates that could be correlated with [cigarette smoke condensate] profiles…"	The anticipated correlation was not attained: When the tobacco, a tobacco extract, and the residual extracted tobacco were pyrolyzed, neither the amounts obtained for the individual PAHs other than B[*a*]P, the phenols, nor the acids (volatile or nonvolatile) in the tobacco pyrolysate matched the totals of the amounts in the extract pyrolysate plus the amounts in the residual tobacco pyrolysate. For the individual PAHs (except for B[*a*]P) and the acids, the totals of the amounts from the extract pyrolysate plus residue pyrolysate were higher than the amounts from the tobacco pyrolysate. For the individual phenols, the opposite was the case: The totals were less!
Between the early 1950s and 1984, literally hundreds of articles were published on PAHs in tobacco smoke with particular emphasis on the tumorigenicity of many of them (3262, 3306a, 3306b, 3307, 3713, 3714)	Despite the many published articles prior to 1984 on PAHs in tobacco smoke, none of the authors contributing to the Searle-edited over 1400-page American Chemical Society's monograph on chemical carcinogens (3568) mentioned any of the tumorigenic PAHs reported in cigarette smoke

26.1.2 Other Classes of Carcinogens, Tumorigens, and Mutagens

26.1.2.1 Aza-Arenes

Within a few years of the discovery of the tumorigenicity to mouse skin of the PAHs DB[*a,h*]A (2078) and B[*a*]P (194, 796a, 797), investigations on the tumorigenicity of aza-arenes began. The aza-arenes selected for study were those structurally related to the PAHs already demonstrated to be tumorigenic. The first aza-arenes studied were those corresponding structurally to the dibenzanthracenes in which one *mesocarbon* was replaced by a nitrogen atom. From a comparison of their tumorigenicities (mouse-skin-painting experiments), Barry et al. (194) reported that the tumorigenicity of several dibenzacridines was much less than the corresponding PAH, e.g., dibenz[*a,h*]acridine (I) was reported to be much less tumorigenic than DB[*a,h*]A (IV) under the same experimental conditions (Figure 26.2).

For the PAHs, much of the early research on their synthesis and tumorigenicity was conducted by the Kennaway group

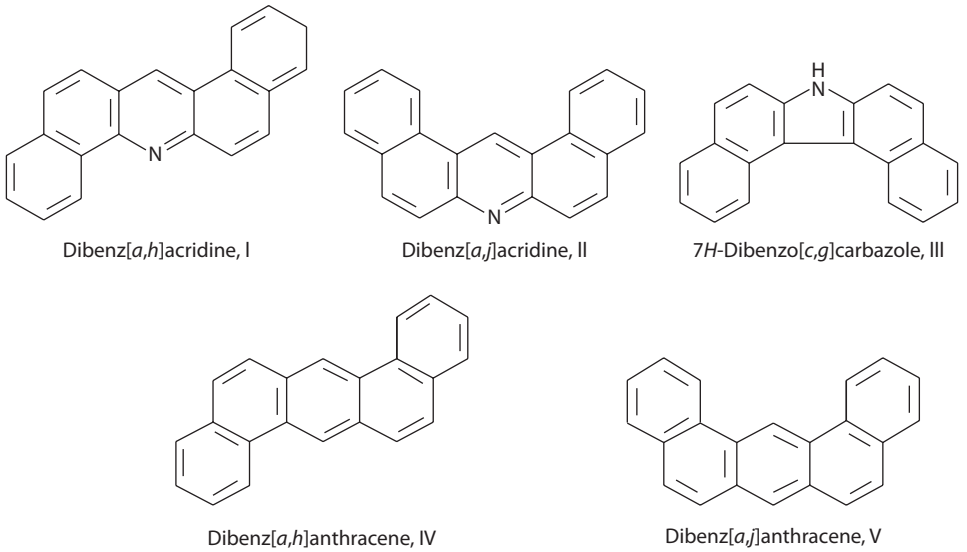

FIGURE 26.2 Structural similarity of several PAHs and aza-arenes.

(Barry, Cook, Hewett, Hieger, Lindsey, Schoental) in the United Kingdom, by groups headed by Fieser and Newman in the United States, and by the Clar group in Germany. For the aza-arenes such as the benzacridines, much of the early research was conducted by the Lacassagne group (Buu-Hoï, Daudel, Lavit-Lamy, Zajdela) in France.

It has been known for nearly six decades [cf. review by Lacassagne et al. (2247a)] from the comparative tumorigenicity studies involving structurally similar PAHs and aza-arenes that the aza-arenes are much less tumorigenic than the PAHs to mouse skin [cf. DB[*a,h*]A (IV) *vs*. dibenz[*a,h*]acridine (I) and DB[*a,j*]A (V) *vs*. dibenz[*a,j*]acridine (II) or 7*H*-dibenzo[*c,g*]carbazole (III)]. These observations on tumorigenicity plus the reported amounts of the three aza-arenes in cigarette MSS relative to the amount of B[*a*]P certainly raise doubts as to the importance of the aza-arenes as significant tobacco smoke tumorigens. In Table 26.1, B[*a*]P is listed as occurring in cigarette MSS in yields ranging from 20 to 40 ng/cig, whereas the yields of aza-arenes I, II, and III are listed at 0.1, 3–10, and 0.7 ng/cig, respectively. Even though a more realistic range for B[*a*]P in the MSS of cigarettes marketed over the past two decades would be 5–20 ng/cig rather than 20–40 ng/cig, the ratios of B[*a*]P yield to those of dibenz[*a,h*]acridine and 7*H*-dibenzo[*c,g*]carbazole are substantial. This of course assumes that the yields for the three aza-arenes that were included in Table 26.1 are correct! It is obvious that the listed aza-arene yields are not meaningful for recently manufactured cigarettes whose design includes technologies not used in the late 1950s and early 1960s when Van Duuren et al. (4027) reported their findings on aza-arenes in cigarette MSS.

The listing of single delivery values rather than a range for dibenz[*a,h*]acridine (0.1 ng/cig) and 7*H*-dibenzo[*c,g*]carbazole (0.7 ng/cig) indicates the MSS yields cited are those reported from a single study, which appears to be that of Van Duuren et al. (4027). Wynder and Hoffmann (4319, 4332) cited their own unpublished 1963 findings [Candeli et al. (587)] that they could not detect dibenz[*a,h*]acridine in cigarette MSS. Such findings were never published in a peer-reviewed journal. Thus, the upper limit (10 ng/cig) of the range for MSS yield of dibenz[*a,j*]acridine is that reported by Hoffmann, coauthor of all but one of the lists in Table 26.1.

Single MSS yields for dibenz[*a,h*]acridine and 7*H*-dibenzo[*c,g*]carbazole in MSS based on a cigarette manufactured in 1959–1960 or 1963 are hardly representative of more recently manufactured cigarettes. It is well recognized that a variety of cigarette design technologies (efficient filtration, filter-tip additives, processed tobacco materials [RTS, expanded tobaccos], air dilution [porous paper, filter-tip perforations], and paper additives) have progressively reduced the sales-weighted average mainstream TPM by almost 70% from 40 mg/cig in the early 1950s to less than 12 mg/cig currently. At the same time that the reduction of delivery of mainstream TPM was accomplished, the composition of the MSS was also altered. For example, for mainstream TPM, the B[*a*]P content—expressed as ng B[*a*]P/mg TPM—has decreased about 33% (from 1.2 to 0.8 ng/mg TPM) during the same time period. The 1979 U.S. Surgeon General's report (4005) summarized the B[*a*]P data for a commercial cigarette sold in the United States from 1954 to 1979. In addition to changes in the composition of mainstream TPM, changes in mainstream vapor-phase composition also occurred.

Nicotine and the tobacco proteins and amino acids are proposed as the major precursors of aza-arenes [Chortyk and Schlotzhauer (722)]. Thus, the decrease in cigarette nicotine content and delivery since 1960 should certainly influence the pyrogenesis of the dibenzacridines and dibenzocarbazole during the tobacco smoking process. The levels of nicotine in U.S. cigarette tobacco blends (and MSS) decreased on average more than 40% between 1960 and the late 1980s.

In addition, inconsistencies among numerous isolation studies raise serious questions about the actual presence of

these three aza-arenes in the MSS (or SSS) from cigarettes manufactured after the mid-1960s. Results from German, Japanese, and American groups of investigators on their search for dibenz[*a,h*]acridine (I), dibenz[*a,j*]acridine (II), and 7*H*-dibenzo[*c,g*]carbazole (III) in mainstream CSC and/or nicotine pyrolysates are summarized in Table 26.3. Only Van Duuren et al. (4027) in their published report and Candeli et al. (587) in their unpublished report have detected any of these three aza-arenes in cigarette MSS!

Examination of the results summarized in Table 26.3 indicates that Van Duuren et al. (4027) reported the identification of the three aza-arenes in mainstream CSC and two of them (I and II) in a nicotine pyrolysate. However, Candeli et al. (587) failed to identify I but did identify II in mainstream CSC. The Candeli et al. findings reported in 1963 on II in mainstream CSC were not confirmed in 1979 by investigators from the same laboratory [Schmeltz et al. (3512)]. Two later studies (3499, 3512) confirmed the 1960 finding by Van Duuren et al. that 7*H*-dibenzo[*c,g*]carbazole was not present in a nicotine pyrolysate.

Examination of the detailed chromatograms presented in a study on aza-arenes in MSS and SSS by Grimmer et al. (1409) indicates the presence of several benzacridines (benz[*a*]acridine, benz[*c*]acridine). However, no gas chromatographic peaks corresponding to standard dibenz[*a,h*]acridine and dibenz[*a,j*]acridine peaks are visible in the chromatograms of the aza-arene fraction from either the MSS or SSS.

The failures by numerous talented research groups (Table 26.3) to detect the two dibenzacridines, I and II, in tobacco smoke cannot be attributed to difficulties or problems in the analytical procedures. Motohashi et al. (26A113) reviewed the analytical procedures that enabled investigators to identify several benzacridines and their homologs plus dibenz[*a,h*]acridine and dibenz[*a,j*]acridine in a variety of environmental samples (urban air; gasoline engine exhaust; diesel engine exhaust; street dust; sediment from lake, river, and saltwater sources). Motohashi et al. (26A113) also reviewed in some detail the reports by Schmeltz et al. (3499), Snook et al. (3750), Grimmer et al. (1409), and Kamata et al. (2021) on the identification of various benzacridines in tobacco smoke, but they did not mention the reported identification of dibenz[*a,h*]acridine and dibenz-[*a,j*]acridine in MSS by Van Duuren et al. (4027).

In summary, the situation with regard to the four aza-arenes considered to be significant "tumorigens" in tobacco smoke by Hoffmann et al., OSHA (1994), and/or EPA (which relied on the 1990 Hoffmann–Hecht list) is as follows:

- OSHA did not list quinoline as a significant tumorigen, whereas EPA did.
- Only one laboratory, that of Van Duuren, reported the presence of dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole, listed in Table 26.1 as tumorigens in tobacco smoke.

TABLE 26.3

	Dibenz[*a,h*]acridine		Dibenz[*a,j*]acridine		7*H*-Dibenzo[*c,g*]carbazole	
Investigators	**Pyr**	**CSC**	**Pyr**	**CSC**	**Pyr**	**CSC**
Van Duuren et al. (4027)	Yes	Yes	Yes	Yes	No	Yes
Candeli et al. (587); Wynder and Hoffmann (4319, 4332)	NE	No	NE	Yes	NE	NE
Kaburaki et al. (2006)	No	NE	No	NE	NE	NE
Schmeltz et al. (3499)	No	NE	No	NE	No	NE
Schmeltz et al. (3512)	No	No	No	No	No	No
Snook (3733)	NE	No	NE	No	NE	No
Snook et al. (3750)	NE	No	NE	No	NE	No
Grimmer et al. (1409)	NE	No	NE	No	NE	No
Kamata et al. (2021)	NE	No	NE	No	NE	NE
Sasaki and Moldoveanu (3414)	NE	No	NE	No	NE	NE
Rustemeier et al. (3370)	NE	No	NE	Yes	NE	NE

Yes, compound identified; No, compound not found or identified; NE, substrate not examined for compound in question.

Examination of these results indicates that Van Duuren et al. (4027) reported the identification of the three *N*-heterocyclic compounds {I, II, and III} in mainstream CSC and two of them {I and II} in a nicotine pyrolysate; whereas, Candeli et al. (587) failed to identify I but did identify {II} in mainstream CSC. The 1963 Candeli et al. findings on {II} in mainstream CSC were not confirmed in 1979 by investigators (3512) from the same laboratory: Hoffmann participated in both the 1963 and 1979 studies. Two studies (3499, 3512) confirmed the 1960 report by Van Duuren et al. that 7*H*-dibenzo[*c,g*]carbazole {III} was not present in a nicotine pyrolysate.

- One other laboratory reported the presence of dibenz[*a,j*]acridine in MSS but not the other two aza-arenes [Candeli et al. (587), see Wynder and Hoffmann (4319, 4332)]. Candeli et al. reported the MSS yield for dibenz[*a,j*]acridine to be roughly four times that reported by Van Duuren et al. (4027). This disparity in per cigarette MSS yield should have triggered additional research on its presence and level in MSS. However, the 1963 finding by Candeli et al. has never appeared in a peer-reviewed journal.
- Failure to detect the three aza-arenes dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole in cigarette MSS and/or in nicotine pyrolysates was reported in at least nine studies conducted periodically between 1970 and 2002 (Table 26.3).
- In comparable tumorigenicity studies, the aza-arenes are much less tumorigenic to mouse skin than their corresponding PAH analogs and much less tumorigenic than B[*a*]P [Barry et al. (194)]. The MSS yields of the three aza-arenes listed by OSHA and EPA, if they are present at all in MSS, are much less than that of B[*a*]P.
- Even when the repeated failure to confirm their presence in tobacco smoke is ignored, the combination of their significantly lower levels *vs*. that of B[*a*]P of the three aza-arenes in cigarette MSS plus their significantly lower tumorigenicity in the mouse-skin-painting bioassay raises serious questions about their inclusion in a table listing the "significant tumorigens in tobacco smoke."

26.1.2.2 *N*-Nitrosamines

Hoffmann and Hecht (1727) did not acknowledge that the MSS yields listed for both the volatile NNAs and the tobacco-specific *N*-nitrosamines (TSNAs) could be incorrect (and high) because of the artifactual formation of both types of NNAs during MSS (and SSS) collection for analysis as reported by Caldwell and Conner (573). EPA and OSHA accepted without question the mainstream volatile NNA and TSNA yields tabulated by Hoffmann and Hecht (1727) and cited by the U.S. Surgeon General in his 1989 report (4012).

The artifactual formation of NNAs during the collection and analysis of MSS and SSS has been noted many times over the years, and it has not been limited to the determination of NNAs in cigarette smoke. A similar problem was noted with the determination of NNAs in foodstuffs. Neurath et al. (2750) were one of the earliest groups of investigators to discuss this problem in cigarette smoke. More recently, Brunnemann et al. (457), from their study of the levels of NNAs in MSS and SSS, reported lower levels than previously reported for volatile NNAs in MSS, attributing the lower levels to the avoidance of artifactual formation of NNAs during smoke collection and analysis. They wrote

> In fact, several of the cigarettes which were machine smoked earlier and analyzed without precautions, when smoked by us under the same conditions but with precautions, yielded 25 to 100% lower values for DMN [*N*-nitrosodimethylamine] and NPY [*N*-nitrosopyrrolidine] for the mainstream smoke …
>
> The nitrate content of the tobacco appears to be a determining factor for the concentration of volatile nitrosamines in the smoke. Selective removal of these nitrosamines does occur with cellulose acetate filter tips but not with charcoal filter tips.

Guerin et al. [see p. 236 in (1445)], in their review of NNAs in ETS commented on four ETS-related studies, those of Brunnemann et al. (457), Stehlik et al. (3812), Matsushita and Mori (2495), and Klus et al. (2134a). Guerin et al. summarized the results on the determination of NNAs in natural and artificial ETS environments as follows:

> The concentration of nitrosodimethylamine in commonly encountered ETS-contaminated indoor air is likely to range from <10–40 ng/m^3. Nitrosodiethylamine and nitrosopyrrolidine are likely to be present at similar but lower concentrations. Extrapolating from studies of artificial environments suggest NNN and NNK concentrations in common environments will range from <1–3 ng/m^3.

They also noted that occasionally, NDMA concentrations may show excursions to be 100 ng/m^3 or more.

It was noted previously (Table 26.1) that many claims about PAHs in tobacco smoke, particularly those demonstrated to be tumorigenic to the skin of rodents, were subsequently demonstrated to be either incorrect or equivocal. However, the points of contention about NNAs in tobacco smoke are fewer than the number listed for tobacco smoke PAHs (see Table 26.4).

26.1.2.3 *N*-Heterocyclic Amines

While many of the *N*-heterocyclic amine mutagens are present in tobacco smoke, the extensive research on this class of compounds was initiated and extended because of their presence in many foodstuffs consumed by many people. Table 26.5 summarizes some details of these *N*-heterocyclic amines in tobacco smoke.

As in the case of the tumorigens whose activity has been shown to be substantially reduced by administration of anticarcinogens [see reviews (3255, 3257, 3300)], Lee et al. (2327c) reported that the mutagenicities (Ames test) of several *N*-heterocyclic amine mutagens, each of which shows inordinately high mutagenicity, are substantially reduced by CSC. The compounds studied by Lee et al. were 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1), 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2), 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1), and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2), 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ), and 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ).

Table 26.6 summarizes the chronology of the studies dealing with the *N*-heterocyclic amines in tobacco smoke and in commonly consumed foodstuffs.

TABLE 26.4
NNAs in Tobacco Smoke

Assertion	Contradiction
Druckrey and Preussmann (1057) proposed that conditions were appropriate (presence of nitrogen oxides, water, and secondary amines, pH < 7.0) in a burning cigarette for pyrogenesis of NNAs such as NDMA. Boyland et al. (422, 423) proposed that the presence in tobacco smoke of nornicotine and anabasine, nitrogen oxides, and water made it highly likely that NNN and *N′*-nitrosoanabasine (NAB) would be formed	
Serfontein and Hurter (3595, 3597) reported the identification of NNAs in cigarette MSS	First claims by Serfontein and Hurter (3595, 3597) of identification of NNAs in cigarette MSS were challenged with counterclaims that NNAs were artifactually produced during smoke generation, collection, and analysis [cf. Neurath et al. (2751)]. Neurath et al. (2751) reported the presence of an NNA but subsequently discovered the identified compound was produced artifactually during the smoke processing
Since volatile NNAs and TSNAs occur in tobacco, a part of the NNAs in cigarette MSS is a result of direct transfer of NNAs from tobacco to smoke; the remainder results from formation and transport during the smoking process [Adams et al. (29)]. For NNK, the transfer from tobacco to smoke ranges from 6.9% to 11.0% of the amount in the tobacco; this represents about 30% of the NNK in MSS. The remainder in MSS is formed during the smoking process [Hoffmann et al. (1734), Hecht et al. (564)]	The premise of the pyrogenesis of NNN and NNK during the cigarette smoking process was challenged by Fischer et al. (1193, 1199) who reported that these compounds occur in cigarette MSS only by transfer from the tobacco rod
The problem of artifactual formation of NNAs has persisted from the mid-1960s to the present [Neurath et al., (2751), Fredrickson (1236), Krull et al. (26A77), Eisenbrand et al. (26A27), Caldwell and Conner (573)]. Continual improvement in smoke collection and analytical procedures has progressively reduced the analytical error	
TSNAs in CSC have little or no influence on the host response in skin-painting studies. Little of the volatile NNAs remain in the CSC after collection and preparation for the skin-painting bioassay. The only NNAs to consistently elicit a positive response at the application site in skin-painting studies are the alkyl-*N*-nitrosourethanes, none of which has been identified in tobacco or tobacco smoke to date.	
Hundreds of rodent-skin-painting studies with CSC and its fractions have been conducted since the first successful production of carcinoma in mice painted with CSC [see (4319, 4332, and references cited), Gori (1329, 1330, 1332, 1333), NCI (2683)]. Even in the massive NCI decade-long study, no attempt was made to correlate NNA content with bioassay results. It was assumed, from studies with individual NNAs, that they had little if any influence on CSC tumorigenicity to mouse skin. Millions of dollars and thousands of hours expended since 1953 in conducting bioassays—particularly mouse-skin-painting studies—did not adequately define the total tumorigenicity of CSC in laboratory animals	
Precursors of NNAs in both tobacco and tobacco smoke are the proteins and amino acids (plus nitrate) for the volatile NNAs [Brunnemann et al. (481, 482), Hoffmann et al. (1694)] and nicotine and nicotine-related alkaloids (plus nitrate) for the TSNAs [Boyland et al. (422, 423), Rathkamp et al. (3080), Hecht et al. (1563, 1565)]. The levels of NNAs in tobacco and its smoke parallel the tobacco nitrate level [Morie and Sloan (2635), Hecht et al. (1576, 1578), Tso et al. (3985)]	
Removal of lipophilic PAH precursors from tobacco by solvent extraction reduces the PAH yield in MSS and the tumorigenicity (mouse-skin painting) of the CSC [Wynder (4294), Wright (4281), Wynder et al. (4355, 4356)]. This led to their recommendations to remove lipophilic components from tobacco. Confirmation of the reduced levels of PAHs in MSS from cigarettes fabricated with organic solvent-extracted tobaccos was provided by Rodgman (3241, 3242, 3246) and Rodgman and Cook (3286)	Personnel from Wynder's laboratory subsequently recommended the addition of lipophilic compounds, e.g., *n*-hentriacontane, to tobacco [Brunnemann and Hoffmann (480)] to reduce the generation during the smoking process of nitrate-derived nitrogen oxide which was postulated as a reactant in the formation of NNAs

TABLE 26.4 (continued)
NNAs in Tobacco Smoke

Assertion	Contradiction
NNA formation in tobacco smoke involves the reaction of methyl nitrite and secondary amines [Rodgman and Cook (3286), Wynder and Hoffmann (4332)].	The proposal by Rodgman and by Wynder and Hoffmann (4332) that NNAs arise by reaction of methyl nitrite with secondary amines was shown to be invalid: Methyl nitrite in MSS is zero initially, but during the period of tobacco smoke generation, collection, and analysis, it is formed artifactually in tobacco smoke [Vilcins and Lephardt (4058)]
NNA formation in tobacco smoke involves reaction among secondary amines, nitrogen oxides, and water	Individual NNAs, particularly the TSNAs, have little or no influence on CSC tumorigenicity in the skin-painting bioassay. Millions of dollars and thousands of hours have been expended since 1953 in conducting bioassays that do not adequately define the total tumorigenicity of CSC in laboratory animals.
Despite the contradictory evidence that precludes the involvement of NNAs either collectively or individually not only in various bioassays with laboratory animals but also in respiratory tract cancer in cigarette smokers, some investigators still maintain that the "tumorigenicity" of cigarette smoke in humans is due to its PAH content and its content of the TSNA, NNK.	Inhalation studies with NNAs at levels comparable to those in cigarette MSS were consistently negative.
In 1991, Hecht and Hoffmann (1571a) wrote "Polynuclear aromatic hydrocarbons and NNK [4-(*N*-methyl-nitrosamino)-1-(3-pyridyl)-1-butanone] are the major carcinogens involved in lung cancer induction by cigarette smoke…"	Lung tumor production by exposure to extremely high inhalation levels of NNAs was classified as "equivocal" by the Registry of Toxic Effects of Chemical Substances (RTECS) (3095)
Hoffmann and Hecht (1727) also noted that NNK had not been tested in laboratory animals for tumorigenicity via inhalation	Bioassay results in lifetime inhalation studies with laboratory animals exposed to various cigarette MSSs show no relationship between tumor production and volatile NNAs and/or TSNA content
On the basis of the following results, nitrate addition or use of high-nitrate tobaccos was proposed: Addition of nitrate to the tobacco blend significantly reduced MSS yields of "tar," PAHs, and phenols. NO generated from nitrate during the smoking process interrupted the free radical mechanism of formation of PAHs [Hoffmann and Wynder (1797, 1798)]. The tumorigenicity (% TBA) of the resulting CSC is also reduced	Later, data showed that increasing the nitrate increases both the volatile NNAs and TSNAs in MSS. Even though an increased level of TSNAs in mainstream CSC was accompanied by decreased tumorigenicity of the CSC to mouse skin, it was subsequently proposed to remove nitrates from the tobacco or use *low*-nitrate tobaccos [Brunnemann and Hoffmann (480)]. However, several of the NNAs and TSNAs were included in the lists of "tumorigenic agents in tobacco and tobacco smoke."
No volatile NNAs is considered a "marker" for other volatile NNAs in MSS; no TSNA is considered a "marker" for other TSNAs, either individual or total, in MSS. No NNAs—either a TSNA, a volatile NNA, or a nonvolatile NNA—is considered a "marker" for the tumorigenicity of CSC in the mouse-skin-painting bioassay	As noted previously, as the level of nitrate in tobacco and subsequently the levels of the TSNAs in CSC increase, the tumorigenicity of CSC to mouse skin decreases [Wynder and Hoffmann (4332), Hoffmann and Wynder (1801, 1802)], but its mutagenicity in the Ames system with *S. typhimurium* increases [Mizusaki et al. (2569)]
The tumorigenicity of NNAs is inhibited by a variety of tobacco smoke components. For example, *D*-limonene is anticarcinogenic to NNK [Wattenberg and Coccia (26A187)]; ethanol, *n*-butanol, and *tert*-butanol are anticarcinogenic to NNN [Waddell and Marlowe (26A178)]; indole [Matsumoto et al. (26A97)], cholesterol [Cohen et al. (26A12)], β-sitosterol [Wattenberg (4149b)], and 3,4,5-trihydroxybenzoic acid (gallic acid) [Mirvish et al. (2559c)] and its esters [Lo and Stich (26A87), Teel and Castonguay (26A172)] are anticarcinogenic to several of the NNAs in tobacco smoke [*cf.* Rodgman (3255, 3255a, 3257)]. Tobacco smoke not only contains other compounds such as long-chained fatty acids [Takeda et al. (26A171)] reported to diminish the tumorigenicity of various NNAs but also contains components structurally similar to compounds [(+)-catechin, esculetin, esculin] [Liu and Castonguay (26A86), Teel and Castonguay (26A172)] that have been reported to act as antitumorigens and/or antimutagens to NNAs	

(*continued*)

TABLE 26.4 (continued)
NNAs in Tobacco Smoke

Assertion	Contradiction
Various tobacco components and other compounds structurally similar to tobacco or smoke components are known to inhibit the *N*-nitrosation of secondary and tertiary amines to NNAs, a reaction known to occur among the nitrogen oxides, amino compounds, and water during the tobacco smoking process. These inhibitors of NNA formation include several primary amines, ascorbic acid and ascorbates [Mirvish et al. (26A112), Mirvish and Shubik (26A111), Archer et al. (26A03a), Mirvish (2559b, 26A104, 26A105)], indole, the tocopherols (particularly α-tocopherol) [Mergens et al. (26A100), Mirvish (2559b)], the carotenes, several phenols, and polyphenolic compounds such as chlorogenic acid [cf. Brunnemann and Hoffmann (484, 486)]. *Note:* The effect of these compounds on the *N*-nitrosation reaction should be differentiated from the effect of some of the same compounds on the tumorigenicity or mutagenicity of various NNAs, e.g., inclusion of ascorbic acid or ascorbate in the reaction substantially reduces the yield of NNAs; administration of ascorbic acid with a tumorigenic NNA such as NNK substantially reduces the tumorigenicity in laboratory animals. Little study has been devoted to determining whether compounds such as those noted earlier would exert a beneficial effect on MSS properties if added to cigarette tobacco because of diminished *N*-nitrosation with resulting lower NNA yield or because of the simultaneous delivery of the antitumorigen or antimutagen together with the NNAs	
Because of the nature of cigarette smoke aerosol, Wynder and Hoffmann (4311) considered selective filtration of a specific smoke component or class of smoke components such as the PAHs to be an "impossibility."	Selective filtration is not "impossible." Wynder and Hoffmann (4314) reversed their view on the impossibility of selective filtration when they found that relatively volatile smoke components, e.g., low-molecular-weight phenols, are selectively removed from MSS by filters incorporating certain plasticizers such as triacetin [cf. Laurene et al. (3211, 2312)]. Some years later, the same phenomenon was observed with volatile NNAs [Fredrickson (1236), Brunnemann et al. (514), Hoffmann et al. (1711)]
Guerin et al. (1445) estimated the exposure to NNAs in ETS-filled rooms to be low: NDMA <10–40 ng/m^3 NDEA 3 ng/m^3 NNN <1–3 ng/m^3 NNK <1–3 ng/m^3	Consumers are exposed daily to NNAs from a variety of nontobacco sources. Many foodstuffs, beverages, and cosmetics contain appreciable levels of some of the volatile NNAs also identified in tobacco and/or tobacco smoke [Magee and Barnes (2442), Sebranek and Cassens (26A142), Preussmann and Eisenbrand (2990), Maga (2438), Bailey and Williams (158a)]. Daily nontobacco exposure (primarily dietary) to NNAs is estimated to exceed 1800 ng/person; daily nontobacco source exposure to NDMA is estimated to exceed 1100 ng/person [Preussmann and Eisenbrand (2990)]. *Note:* These estimates are based on analytical data that may have included values for NNAs artifactually generated during the analytical procedure

26.2 ANTICARCINOGENS, INHIBITORS, AND ANTIMUTAGENS

In preceding publications and earlier chapters, (1) the listing of numerous MSS components as significant toxicants was questioned [Rodgman and Green (3300)], and (2) the assertions that ingredients added to cigarette tobacco adversely affect the chemical and biological properties of MSS were shown to be in error [Rodgman (3266)]. In this chapter, we will discuss the identified MSS components that have been shown in bioassays to significantly diminish the adverse biological effects of a number of the listed MSS toxicants.

The toxicological properties of an MSS component asserted to adversely affect the smoker have generally been defined in one or more bioassays devoted to the study of the effect of the component administered individually to a host. In most cases other than numerous studies of tumorigenesis, the effect on the toxicological property of a specific compound by other compounds such as those in the complex MSS aerosol has not been studied. The toxicological effect of a specific component in MSS is usually derived by extrapolation from the effect observed in one or more bioassays with the individual component.

It is known that the complex MSS aerosol has a significant effect on the chemistry of components in it. For example, (1) the rate of conversion of NO to NO_2 is significantly less in the MSS aerosol than in a system comprising only NO and O_2 (816) and (2) methyl nitrite reported as an MSS component is not formed during the smoking process but is formed during aging of the MSS during the analytical procedure (4058).

TABLE 26.5
Summary of Tumorigenic *N*-Heterocyclic Amines in Tobacco Smoke

Component	MSS Level, ng/cig[a]	IARC Evaluation of Evidence of Tumorigenicity in	
		Laboratory Animals	Humans
A*a*C	25–260	Sufficient	—
MeA*a*C	2–37	Sufficient	—
Glu-P-1	0.37–0.89	Sufficient	—
Glu-P-2	0.25–0.88	Sufficient	—
PhIP	11–23	Sufficient	Possible
IQ	0.26	Sufficient	Probable
MeIQ	0.28–0.75[b]	Sufficient	Probable
Trp-P-1	0.29–0.48	Sufficient	—
Trp-P-2	0.82–1.1	Sufficient	—

[a] See cigarette MSS yields listed in Table 26.1 (1740, 1741, 1743, 1744).
[b] MeIQ was not listed in (1740, 1741, 1743, 1744) but was listed by Smith et al. (3714).

If the chemistry of an MSS aerosol component be altered by the presence of thousands of other aerosol components, then logic dictates that its toxicology will also be altered.

Except for tumorigenic effects, little has been reported on the effect of other components in the complex MSS aerosol on the toxicological properties of an individual component. The tumorigenicity of many MSS components has been discussed frequently and in great detail, but little has been written about the biological activity of nontumorigenic MSS components reported to counteract the tumorigenicity in laboratory animals of the various tumorigens.

Inhibitors of carcinogens or anticarcinogens are compounds which prevent tumor development. Wattenberg (26A186) divided them into three categories based on the time in the carcinogenic process when they are effective: The first category consists of compounds that prevent the formation of carcinogens from precursor substances, e.g., ascorbic acid [Mirvish (26A103, 26A104)], tocopherols [Newmark and Mergens (26A116)], and phenols [Newmark and Mergens (26A116), Kuenzi et al. (2216)] which inhibit the formation of nitroso tumorigens from precursor amine and nitrite both in vivo and in vitro. The second category includes "blocking agents" which inhibit carcinogenesis by preventing carcinogenic compounds from reaching or reacting with critical target sites in the tissues, e.g., disulfiram [Wattenberg (26A183)] which inhibits the metabolism of symmetrical dimethylhydrazine to its carcinogenic metabolites [Fiala et al. (26A34)]. The last category of inhibitors—the "suppressing agents"—works by suppressing the expression of neoplasia in cells exposed to a carcinogenic agent. Retinoids are an example of this category.

In 1941, Shear and Leiter (3627) described in detail the many factors affecting tumorigenicity of a chemical. In the mid-1940s, several nontumorigenic aromatic hydrocarbons (benzene, naphthalene, anthracene) administered with B[*a*]P or DB[*a,h*]A significantly diminished the B[*a*]P and DB[*a,h*]A tumorigenicity (843, 844, 26A17). In recent lists of MSS toxicants, benzene, B[*a*]P, and DB[*a,h*]A are listed as significant tumorigens. Reported many times, however, is the noncarcinogenicity of benzene in the solvent-control group when it was used as the solvent for known or suspect tumorigens in skin-painting bioassays (1544, 3665).

Steiner and Falk (3814) reported that B[*a*]A, categorized as either an extremely weak or an inactive mouse-skin tumorigen (983), significantly diminishes DB[*a,h*]A tumorigenicity when both DB[*a,h*]A and B[*a*]A are administered simultaneously by subcutaneous injection. Despite this and similar bioassay results plus the presence of B[*a*]A and DB[*a,h*]A in MSS, both are repeatedly categorized as significant tumorigens in cigarette MSS! Similar inhibition was reported with mixtures of DMB[*a*]A and several inactive PAHs (1654).

In subsequent studies, other nontumorigenic PAHs (phenanthrene, fluoranthene, pyrene) were reported to be effective antitumorigens against B[*a*]P and DMB[*a*]A (976, 3686). The nontumorigenic hydrocarbons—benzene, naphthalene, anthracene phenanthrene, fluoranthene, pyrene—are MSS components, present at per cigarette delivery levels far in excess of those of B[*a*]P, DB[*a,h*]A, or any of the other PAHs classified as tobacco smoke toxicants.

Much evidence collected since 1932 on the tumorigenicity of PAHs indicates their tumorigenicity is not inherent but depends on specific metabolites that comprise one or more epoxides, dihydroxy compounds, and dihydroxy epoxides. For B[*a*]P, more than a dozen metabolites are known, and they show a range of tumorigenicities (983).

Conversion of B[*a*]P in an inhaled MSS particle to a particular metabolite cannot be a simple process. The more than 500 PAHs in cigarette MSS range from bicyclic to decacyclic structures. In a variety of chemical reactions, the rate of reaction decreases as the molecular weight (number of rings) of the PAH increases. That is, with stoichiometric levels of the PAH and the reactant, bicyclic PAHs react faster than tricyclic PAHs which in turn react faster than tetracyclic PAHs, etc.

Diol, epoxide, and/or diol–epoxide metabolites structurally similar to those described for B[*a*]P have been reported for many PAHs, e.g., naphthalene, anthracene, phenanthrene, B[*a*]A, benzo[*c*]phenanthrene, pyrene, chrysene, DB[*a,h*]A, benzo[*b*]triphenylene, and DMB[*a*]A (983). All of these and structurally similar PAHs have been reported by Snook et al. as cigarette MSS components (3756).

In a situation, such as the formation of metabolites, where an equimolar mixture of bicyclic through hexacyclic PAHs is present, a pentacyclic aromatic hydrocarbon such as B[*a*]P will form little of its metabolite(s) compared to the levels formed by a more reactive bicyclic or tricyclic aromatic hydrocarbon. Numerous in vitro studies have demonstrated that inclusion of equimolar quantities of lower-molecular-weight PAHs, such as phenanthrene or anthracene, inhibits the hydroxylation–epoxidation of B[*a*]P in hepatic microsomes (26A192). However, PAH data from Hoffmann and Wynder (1798) and Rodgman and Cook (3273) indicate the PAH classes (bicyclic, tricyclic, etc.) in MSS are present at

TABLE 26.6
Chronology of *N*-Heterocyclic Amine Studies

Year	Event
1959	Only one fused ring *N*-heterocyclic compound was listed by Johnstone and Plimmer (1971) as a tobacco smoke component: the bicyclic compound, quinoline
1960	Mold et al. (2592) isolated and identified the tricyclic *N*-heterocyclic 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) from CSC and defined its relationship to its precursor in tobacco, proline
1961/1962	Poindexter and Carpenter (2972) reported the isolation and identification of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) from CSC. They reported that the yield of total harmans in burley and flue-cured MSSs was between 15 and 20 μg/g of tobacco smoked, values which were 40–50 times that of the harmans in the unsmoked tobacco. Since the weight of tobacco in cigarettes sold at that time approximated 1 g, the yield of these two compounds was about 15–20 μg/cig. Poindexter and Carpenter concluded from experiments with radiolabeled tryptophan that the harmans (found to be radiolabeled in the MSS) were generated pyrogenetically by a reaction between aldehydes (formaldehyde for norharman, acetaldehyde for harman) and tryptophan in tobacco
1962	Rodgman and Cook (3279) confirmed the presence in CSC of pyrocoll and also reported the identification of indole, carbazole, and several alkylated indoles and carbazoles. Rodgman and Cook (3279) also reviewed the previously reported biological studies on indole, 3-methylindole (skatole), and carbazole: None of the three were reported to be tumorigenic
1964	Schmeltz et al. (3505) reported 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), 9*H*-pyrido[3,4-*b*]indole (norharman), and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) as tobacco smoke components. Testa and Testa (3886, 3887) also identified 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) as components of CSC
1964	The Advisory Committee to the U.S. Surgeon General (3999) briefly discussed only four fused-ring *N*-heterocyclic compounds in tobacco smoke, quinoline and the two dibenzacridines (dibenz[*a,h*]acridine, dibenz[*a,j*]acridine) and the dibenzocarbazole (7*H*-dibenzo[*c,g*]carbazole) reported by Van Duuren et al. (4027)
1968	In his review of tobacco smoke composition, Stedman (3797) discussed the identification of tumorigenic *N*-heterocyclic compounds (dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, 7*H*-dibenzo[*c,g*]carbazole) reported by Van Duuren et al. (4027) as well as 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) reported by Mold et al. (2592) and 9*H*-pyrido[3,4-*b*]indole (norharman), 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman), and 9*H*-pyrido[2,3-*b*]indole reported by Poindexter and Carpenter (2972)
1971/1972	Wakeham (4103) noted the reported presence of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) in cigarette MSS and discussed their formation from a reaction product of tryptophan and an aldehyde. As noted by Rodgman (3253a), the structure of the aldehyde reacting with tryptophan ultimately dictated the structure of alkylated norharmans found in CSC
1974	In addition to 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), Izard et al. (1899) reported the identification of methyl-5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (methylpyrocoll) in CSC
1974/1975/1977	In a 1974 in-house RJRT report, a 1975 TCRC presentation, and a 1977 publication on their study of the water-soluble portion of CSC, Schumacher et al. (3553) reported the identifications of 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman), 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), octahydro-5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (octahydropyrocoll), and 2-ethyl-9*H*-pyrido[2,3-*b*]indole
1977	Sugimura et al. (3829) reported the isolation and identification of the *N*-heterocyclic amines 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) from tryptophan pyrolysates
1977	In separate studies, Levitt et al. (2355a) and Nagao et al. (2667b) demonstrated the mutagenicity of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) in the Ames test
1978	Yamamoto et al. (4365a) reported the isolation and identification of Glu-P-1 and Glu-P-2 from glutamic acid pyrolysates
1978/1981	Heckman and Best (1587) reported the identification of 268 previously unidentified and over 150 previously identified *N*-containing components in CSC. These included several components structurally similar to the mutagenic *N*-heterocyclic amine: 9*H*-pyrido[2,3-*b*]indole, 2-methyl-9*H*-pyrido[2,3-*b*]indole, 2-(2-methylpropyl)-9*H*-pyrido[2,3-*b*]indole, 2-pentyl-9*H*-pyrido[2,3-*b*]indole, 1-butyl-9*H*-pyrido[3,4-*b*]indole, 9*H*-1-propenyl-pyrido[3,4-*b*]indole, and a partially characterized norharman isomer
1979	In the 1979 U.S. Surgeon General's report (4005), the aza-arenes dibenz[*a,h*]-acridine, dibenz[*a,j*]acridine, 7*H*-dibenzo[*c,g*]carbazole, quinoline, and alkylated quinolines in CSC were discussed but not the presence or properties of the mutagenic *N*-heterocyclic amines identified in tobacco smoke
1980/1981	Yoshida and Matsumoto (4388) and Matsumoto et al. (2492) reported the identification of A*a*C and MeA*a*C in CSC
1981	Matsukura et al. (2491a) demonstrated the tumorigenicity in mice of Trp-P-1 and Trp-P-2. Hosaka et al. (1835a) demonstrated the tumorigenicity in rats of Trp-P-1 and Trp-P-2
1982	In the 1982 Surgeon General's report (4010), 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) were classified as "toxic and tumorigenic agents of cigarette smoke" in amounts of 3.2–8.1 and 1.1–3.1 μg/cig, respectively, in cigarette MSS. None of the other mutagenic *N*-heterocyclic amines in tobacco smoke were discussed
1982/1984	Snook and Chortyk (3739, 3740) reported the MSS yield of 9*H*-pyrido[3,4-*b*]indole (norharman) to be 1.2–13.4 μg/cig and that for 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) to be 0.3–3.8 μg/cig. They found a linear relationship between the yield of cigarette MSS "tar" and the yields of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman). In contrast to the 1962 findings of Poindexter and Carpenter (2972), Snook and Chortyk reported that the MSS yields of these two compounds were not influenced by the tobacco type

TABLE 26.6 (continued)
Chronology of *N*-Heterocyclic Amine Studies

Year	Event
1983	Demarini (933) reviewed the studies on the mutagenicity of CSC. He discussed the studies of Yoshida and Matsumoto (4388) and Matsumoto et al. (2492) on the mutagens A*a*C (80 ng/cig) and MeA*a*C (7 ng/cig)
1984	None of the authors contributing to the Searle-edited 1400-page American Chemical Society's monograph on chemical carcinogens (3568) mentioned the tumorigenic and mutagenic *N*-heterocyclic amines reported in cigarette smoke and numerous cooked foods
1984	Ohgaki et al. (2849b) demonstrated the tumorigenicity in mice, and Takayama et al. (3862b) demonstrated the tumorigenicity in rats of Glu-P-1 and Glu-P-2. Takayama et al. (3862c) demonstrated the tumorigenicity in rats of the tobacco smoke component IQ
1984/1985	Ohgaki et al. (2849, 2849a) demonstrated the tumorigenicity in mice of IQ and MeIQ, found in broiled fish, fried beef, beef extract, and CSC
1985	Takayama et al. (3862d) demonstrated the tumorigenicity in rats of Trp-P-1 and Trp-P-2. Tanaka et al. (3865c) demonstrated the tumorigenicity of IQ
1985/1986	The IARC (1870) listed several tryptophan-derived tobacco smoke isolates including 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman). The levels in cigarette MSS of these two components were listed as 9.5–14.1 and 2.5–5.8 μg/cig, respectively. No mention was made of the mutagenic *N*-heterocyclic amines in CSC or the degree of evidence for their carcinogenicity in animals and humans
1985/1986	Yamashita et al. (4367, 4368) identified and quantitated the following mutagenic *N*-heterocyclic amines in CSC: IQ 0.3 ng/cig Trp-P-1 0.3 ng/cig Trp-P-2 0.2 ng/cig A*a*C 16.9 ng/cig MeA*a*C 1.6 ng/cig
1986	Sugimura (3828c) reviewed the isolation and identification of the mutagenic *N*-heterocyclic amines, their high mutagenicity in the Ames test (*S. typhimurium*) of several of them, their tumorigenicity, and their various sources—including CSC for many. However, Sugimura did write the following about the importance of the mutagenic *N*-heterocyclic amines as human carcinogens: "Taking various factors into consideration, it is probably impractical and not realistic to make risk estimations from the carcinogenicity data on rodents given a single carcinogen. However, for a simple extrapolation of animal data for risk estimation, TD_{50} values, which are the doses needed to develop cancers in 50% of animals fed on carcinogens [IQ, Trp-P-1, Trp-P-2, Glu-P-1, Glu-P-2, A*a*C, and MeA*a*C] for their life time, have been calculated based on mouse experiments… If we assume the average TD_{50} value of heterocyclic amines should be about 8 mg/kg/day, we can roughly estimate the risk of these carcinogenic heterocyclic amines for human beings. The intake of heterocyclic amines was calculated from available data on their quantities in foods. Apparently the human intake is about 0.0002% times the TD_{50} obtained from animal data. This means that heterocyclic amines may not be so serious for human cancer development… On the other hand, it is also true that human beings are being exposed to many heterocyclic amines and many other carcinogens with tumor promoters and/or suppressing factors for carcinogenesis. At this moment, it is honest to state that no solid information on the estimation of risk of heterocyclic amines has been obtained in any direction, either positive or negative."
1990	Felton and Knize (1177d) reviewed the results of numerous studies on the mutagenicity and tumorigenicity of the mutagenic *N*-heterocyclic amines
1994	Lee et al. (2327c) reported that the condensate from cigarette MSS significantly inhibited the mutagenicity of several *N*-heterocyclic aromatic amines as measured in the Ames assay with *S. typhimurium* strain TA 98 in presence of S-9 mix. The mutagenic *N*-heterocyclic amines tested included: IQ MeIQ Glu-P-1 Glu-P-2 Trp-P-1 Trp-P-2 The mutagenic activities of these mutagens were suppressed as much as 80% by addition of 50–100 μg of CSC per plate
1997	Hoffmann and Hoffmann (1740) issued a revised list of tumorigenic components in tobacco and tobacco smoke. Their revision of the Hoffmann–Hecht (1727) list included, in addition to several vapor-phase components, eight of the mutagenic *N*-heterocyclic amines: IQ MeIQ Glu-P-1 Glu-P-2 Trp-P-1 Trp-P-2 A*a*C MeA*a*C

significantly higher molar levels than the pentacyclic PAHs which include B[*a*]P and DB[*a,h*]A.

In an in vitro study, the nontumorigenic PAHs pyrene and fluoranthene significantly inhibited the binding of a tumorigenic PAH to calf thymus DNA (enzyme source—mouse-skin homogenate) [Slaga and Boutwell (3683), Slaga et al. (3688)]. The in vitro inhibition of the hydroxylation reaction is paralleled by a reduction of in vivo tumorigenicity.

Because of their vapor pressure properties, tumorigenic PAHs (B[*a*]P, DB[*a,h*]A, etc.) and aza-arenes are present primarily in the MSS particulate phase. Similarly, many of the reported anticarcinogens or inhibitors occur in the MSS particulate phase (3255, 3255a, 3257), e.g., high-molecular-weight alkanes (1099), β-sitosterol and cholesterol (1099), α-tocopherol (3271, 3347), indole (3279), indole-3-acetonitrile (1898), duvatrienediols (3361), and PAHs (anthracene, phenanthrene, pyrene, fluoranthene, B[*e*]P) [see (3255a)].

Despite the fact that the anticarcinogenicity of certain components of tobacco (1171) and tobacco smoke (1672A, 1824) and of tobacco smoke itself (1824) has been known for over four decades, most discussions are directed at them as toxicants. Seldom is any significant discussion directed at smoke components known to possess anticarcinogenic properties. In a brief 1964 review of the possibility of anticarcinogenic agents in tobacco smoke, Wynder and Hoffmann [see 296, 330 in (4319)] discussed the findings of Steiner and Falk (3814) and Kotin and Falk [see 489–490 in (26A76)] in their studies with potent and weakly tumorigenic PAHs in the subcutaneous injection bioassay as well as their own findings in the mouse-skin-painting bioassay (4314, 4316). Ignored was the discussion by Kotin and Falk (26A76) on the anticarcinogenicity *vs.* B[*a*]P or *vs.* DB[*a,h*]A of nine PAHs (anthracene, benzo[*a*]fluorene, B[*a*]A, chrysene, pyrene, B[*e*]P, benzo[*k*]fluoranthene (B[*k*]A), benzo[*ghi*]fluoranthene, perylene), two aza-arenes (benzo[*a*]carbazole, benz[*c*]acridine), and 2-naphthol. All but the two aza-arenes had been identified in cigarette MSS prior to their 1964 review. Subsequently, the aza-arenes noted were identified as MSS components (3339, 3750).

Earlier, Wynder and Hoffmann (4311) had reported on MSS components that inhibited the action of a "tumorigen" invariably listed as significant. The finding was an outgrowth of their investigation of the effect of organic solvent extraction of tobacco on the PAH content of MSS. Cigarettes fabricated from the extracted tobacco yielded lower quantities of B[*a*]P and DB[*a,h*]A in MSS (3240, 3242, 3262). Skin-painting bioassays with MSS CSCs from the control and extracted tobaccos gave a lower percentage of tumor-bearing animals (% TBA) in the group treated with the extracted tobacco CSC. However, the decrease in % TBA was considerably less than the percent decrease in the level of tumorigenic PAHs in the CSC (4307). One explanation for the difference was that the solvent extracted almost all the alkanes from the tobacco. Thus, the alkanes were absent from the MSS from extracted tobacco cigarettes. This fraction (constituting about 3% of MSS CSC) was reported to significantly inhibit the tumorigenicity of B[*a*]P (4311, 4314, 26A59).

Mouse-skin-painting studies with B[*a*]P and the alkanes *n*-hentriacontane and *n*-pentatriacontane at ratios of alkane/B[*a*]P of 20:1 and 100:1 for each alkane showed they significantly inhibited B[*a*]P tumorigenicity (4311, 4314, 26A59). The MSS of a cigarette delivering 20 mg of CSC contains about 0.6 mg (600,000 ng) of the alkane fraction and 10 ng of B[*a*]P, an alkane fraction/B[*a*]P ratio of 60,000:1, far in excess of the ratios that produced significant inhibition of B[*a*]P tumorigenicity [Wynder and Hoffmann (4311, 4319, see pp. 370–371) in (4332)]. Increasing the long-chained alkane level in CSC by 1% from ~3% (C_{12} to C_{30}) to 4% by addition of crystalline alkanes isolated from CSC resulted in reduction of the tumorigenicity of the CSC from 40% to 24% TBA. This result was dismissed as "not statistically significant."

Wynder and Hoffmann [see 245–247, 628 in (4332)] again discussed anticarcinogenic components of tobacco smoke:

> Any discussion of as complex a carcinogen as tobacco smoke should at least mention the existence of anticarcinogens. These are substances that reduce or "neutralize" the effect of a carcinogen by reacting with the carcinogen or a carcinogenic metabolite, thereby deactivating it, or by competing for reaction with cell constituents, or by interfering with the resorption of a carcinogen … The existence of anticarcinogens, however, must be considered in evaluating any complex mixture such as tobacco smoke condensate … An explanation of the tumorigenic activity of tobacco smoke condensate in terms of single constituents is made more difficult by the presence of substances that may act as anticarcinogens and/or absorption retarders, especially for tumorigenic agents. It is known that structurally related noncarcinogenic hydrocarbons can inhibit the effect of carcinogenic hydrocarbons … Several investigators have noticed some inhibition of tumor growth by tobacco smoke condensate … [including] Hoffman and Griffin [1672a] … Falk et al. [1174] … [and] Homburger and Treger [1823b] … it should not come as a surprise that a material which has been proved to be carcinogenic may also interfere with tumor development, if not with tumor initiation …

They also noted [see pp. 370–371, 628–629 in (4332)]:

> An explanation of the tumorigenic activity of tobacco smoke condensate in terms of single constituents is made more difficult by the presence of substances that may act as anticarcinogens and/or absorption retarders, especially for tumorigenic agents. It is known that structurally related noncarcinogenic hydrocarbons can inhibit the effect of carcinogenic hydrocarbons. The same interrelationship may apply to tumor-promoting and nontumor-promoting phenols.

Numerous compounds demonstrated in various bioassays to be highly effective anticarcinogens against many MSS toxicants have been identified in tobacco smoke at per cigarette delivery levels far in excess of those of the alleged tumorigens. Seldom have these anticarcinogenic MSS components been discussed in the numerous reviews of the biological properties of MSS. Even though some of the earliest data on MSS components, e.g., the alkanes, that inhibit B[*a*]P tumorigenicity in the skin-painting bioassay were provided by Wynder and Hoffmann [4314, see 370–371, 628–629

in (4332)], they more often preferred to discuss alkanes as major precursors of tumorigenic PAHs in MSS [see 496–501 in (4332), 1798, 4314, 4342] rather than inhibitors of B[*a*]P tumorigenicity. MSS components reported to possess significant inhibitory or anticarcinogenic action against various tumorigenic PAHs and NNAs in MSS have been cataloged (3255, 3255a, 3257).

Those opposed to cigarette smoking view the complex mixture MSS differently from other complex mixtures such as raw or cooked foods, gasoline and diesel engine exhausts, and factory effluents [see (1345, 3685)]. Most are reluctant to accept the premise that a nontumorigenic component will offset the tumorigenicity of a tumorigen in animals treated with the complex mixtures CSC, MSS, SSS, or ETS containing the two (1773).

Other MSS components may have also influenced the mouse-skin-painting results obtained with control tobacco and extracted tobacco CSCs. Hexane extraction of tobacco not only removes alkane inhibitors thus making impossible their transfer to MSS but also removes substantial amounts of β-sitosterol (4356), α-tocopherol (3271, 3347), indole (3279), duvatrienediols (3361, 3389), and *D*-limonene (765, 2174), thus eliminating or drastically reducing their transfer to MSS during smoking. Subsequently, it was demonstrated that (1) these smoke components are present by transfer from tobacco to MSS during smoking and to SSS during smolder between puffs, or they are generated during smoking, and (2) the compounds listed are anticarcinogenic *vs*. several of the listed tumorigens, e.g., PAHs, NNAs, ethyl carbamate. However, in the 1950s, neither the identity of several of these tobacco or smoke components nor their anticarcinogenicity was known.

Comparison of identified MSS components (1373) with lists of compounds (1177a, 3685) that possess inhibitory or anticarcinogenic action in tumorigenesis studies reveals not only that MSS contains many anticarcinogens but also that their MSS levels often exceed those of the components listed as significant tumorigens. Previously, we discussed a few inhibitory and anticarcinogenic MSS components, but they represent a small sample of the MSS components reported to exhibit such properties. From the review by Slaga and DiGiovanni (3685) and other reports (1177a), we compiled a list of MSS (and tobacco) components reported to counteract the tumorigenicity of MSS toxicants (Table 26.7).

From the per cigarette MSS deliveries (Table 26.7), it may be calculated that the tumorigenic PAHs listed contribute from 4 to 10 μg/g of mainstream CSC. Nontumorigenic PAHs (naphthalene, anthracene, pyrene, phenanthrene, fluoranthene, benzo[*e*]pyrene, benzo[*b*]triphenylene) total 90–180 μg/g of CSC. The anticarcinogenic effect of nontumorigenic PAHs and weakly tumorigenic or nontumorigenic aza-arenes *vs*. carcinogenic PAHs has been known since the 1940s (3685, 3814).

An interesting aspect of Table 26.7 is that it includes the dioxins as antitumorigens. Slaga and DiGiovanni (3685) summarized the studies in which dioxins were shown to interfere with the enzyme pathways responsible for tumorigenesis of several of the most potent PAHs. The dioxins were not listed as MSS toxicants in previous tabulations similar to Table 26.7 (3255, 3255a, 3257). In fact, only the 2001 Fowles–Bates toxicant list issued since 1990 (1217) included the dioxins even though their presence in MSS was known in 1980 (854). Is the omission of such MSS toxicants related in any way to the fact that dioxins are significant antitumorigens *vs*. some of the most potent mouse-skin tumorigenic PAHs present in MSS? The 1964 advisory committee in Chapter 6 of its 1964 report mentions that 27 nontumorigenic PAHs had been identified in MSS, but none by name [see Chapter 6, p. 55 in (3999)]. Was the omission of their identities related to the fact that several were known to be antitumorigenic to several potent mouse-skin tumorigens such as B[*a*]P?

In Table 26.7 are listed only the two *n*-alkanes (C_{31} and C_{35}) shown experimentally by Wynder and Hoffmann to reduce the tumorigenicity of B[*a*]P to mouse skin. However, the alkane listing in Table 26.7 could logically be increased because the total alkane fraction consisting of *n*-, *iso*-, and *anteiso*-alkanes reduced the tumorigenicity of B[*a*]P, and presumably all of the alkanes could be involved in the tumorigenicity reduction. The number of identified components in the alkane fraction in tobacco smoke approximates 70. The complete list of the identified tobacco smoke alkanes appears in Table 1.10.

The antitumorigens and antimutagens in Table 26.7 are presented in a slightly different way in Table 26.8. Several of the significant PAH, NNA, and *N*-heterocyclic amine tumorigens or mutagens are listed in the same sequence as in Table 26.1, and the tobacco smoke components that reduce or nullify their tumorigenicity or mutagenicity are listed for each. It is interesting to see how many tobacco smoke components have been reported to inhibit or reduce the potent tumorigenicity of B[*a*]P (18 in all) or DB[*a,h*]A or DMB[*a*]A (20 in all). Here again, only 2 of the 70 alkanes examined for their inhibition of B[*a*]P tumorigenicity are included; these are the *n*-hentriacontane ($C_{31}H_{64}$) and *n*-pentatriacontane ($C_{35}H_{72}$) studied in detail by Wynder and Hoffmann (4314, 4319, 4332).

In Table 26.9, references are listed on various aspects (identification, quantitation, tobacco precursors, biological results, etc.) of the tobacco and tobacco smoke components listed in Table 26.7 as known inhibitors, anticarcinogens, and antimutagens. For the reader's benefit, the sequence of the 59 components in Table 26.9 is identical with that in Table 26.7, and the CAS nomenclature has been included in each case.

In a review of antimutagens and inhibitors of mutagenesis, Ramel et al. (26A133) discussed the many antimutagens found naturally occurring in plants. They did not discuss tobacco specifically but did discuss the natural occurrence of the following antimutagens: α-tocopherol, 2*H*-1-benzopyran-2-one, 7-hydroxy-2*H*-1-benzopyran-2-one, and 3-phenyl-2-propenal. All four have been identified as tobacco components; all but 7-hydroxy-2*H*-1-benzopyran-2-one have been identified in MSS.

Lee and Reed (2327d) investigated the antimutagenicity of nicotine *vs*. NDMA and nicotine *vs*. B[*a*]P in the Ames test (*S. typhimurium* TA 100). They observed that nicotine

[a] AT, test for antitumorigenicity; AM, test for antimutagenicity.

[b] This fraction consists primarily of the *n*-, *iso*- (2-methyl-), and *anteiso*- (3-methyl-) alkanes from C_{15} to C_{40}.

[c] Benzo[*b*]triphenylene was formerly known as dibenz[*a,c*]anthracene.

[d] Several of the highly mutagenic *N*-heterocyclic amines identified in cigarette smoke (and foods) by Sugimura et al. (see Section 17.6).

inhibits the mutagenicity of NDMA but not that of B[*a*]P. Although the mechanism of this antimutagenicity was not elucidated, the report by Murphy and Heilbrun (26A115) on the inhibition of NNN metabolism by nicotine suggests nicotine inhibition of NNA activation may be involved. Lee et al. (2327b) repeated their earlier experiment and not only confirmed the antimutagenic effect of nicotine on NDMA but also demonstrated the similar activity of nornicotine and cotinine. Brown et al. (437) reported the antimutagenicity of nicotine and cotinine *vs.* 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL).

Lee et al. (2327c) reported that CSC inhibits the mutagenic activity of several *N*-heterocyclic amines when tested in the Ames assay with *S. typhimurium* TA 98 in the presence of the S-9 activation system. The mutagenic *N*-heterocyclic amines tested included Glu-P-1, Glu-P-2, Trp-P-1, Trp-P-2, IQ, and MeIQ. These compounds are among the most potent mutagens known (3828c, 3829. 3829a, 4365a, 4357, 4368). Several have also been reported to be tumorigenic in mammalian bioassays (1177d). In one of the first demonstrations of antimutagens in tobacco smoke, Lee et al. (2327c) reported that 50–100 µg of CSC per plate suppresses the mutagenic activity of these compounds by as much as 80%. Enzymatic studies indicate that CSC is a potent inhibitor of cytochrome P-450-dependent monooxygenase. Therefore, it appears that CSC exerts its antimutagenicity by inhibiting the P-450 system.

[a] 1,2-Dihydro-3-methylbenz[*j*]aceanthrylene = 3-methylcholanthrene is regarded as one of the most potent tumorigens to mouse skin known. Although it does not appear in any of the lists in Table 26.1 by Hoffmann et al., it is a tobacco smoke component.

[b] DMB[*a*]A is regarded as one of the most potent tumorigens to mouse skin known. Although it does not appear in any of the lists in Table 26.1 by Hoffmann et al., it is a tobacco smoke component.

Lee et al. (2327c) subsequently reported that fractionation of CSC gave fractions that showed low mutagenicity themselves but were significantly antimutagenic.

Only a few of the listed MSS tumorigens have ever been tested for tumorigenicity to lung tissue by exposure of animals via inhalation. The results with all but one of the four MSS components [B[*a*]P, NDMA, NDEA, ^{210}Po], tested via inhalation at dose levels substantially exceeding those in MSS, were rated "equivocal" (3095). Only ^{210}Po, administered via inhalation at massive dose levels to rats, produced squamous cell carcinoma, the lung tumor type similar to that associated statistically with cigarette smoking. However, the U.S. Surgeon General (4005, 4010) and Hoffmann and Hecht (1727) discounted the effect of ^{210}Po in MSS in lung cancer causation in active smokers. From the type of evidence available presently, it is doubtful that many of the toxicants should be included in the various lists. Examination of data and reports on the tobacco smoke components present in one or more of the many lists sustains the premise that it is inappropriate to use such lists as evidence of any relationship between exposure to MSS and lung cancer induction in smokers or exposure to ETS and lung cancer induction in nonsmokers.

Several specific components could and should be excluded from the toxicant lists for reasons other than the failure to induce lung tumors via inhalation:

1. By the early 1960s, dibenzo[*a,l*]pyrene had been reported in MSS by several groups [see account in (3262)]. For its identification, the investigators relied on a published UV spectrum purportedly that of synthetic dibenzo[*a,l*]pyrene (dibenzo[*def,p*]chrysene). However, in 1966, it was demonstrated that the published spectrum was that of an isomer, dibenz[*a,e*]aceanthrylene (dibenzo[*a,e*]fluoranthene) (2314).
2. Previously was noted the failure by many research groups between 1963 and 2000 to confirm the presence in MSS of the tumorigenic aza-arenes reported by Van Duuren et al. (4027). Dibenz[*a,j*]acridine was reported recently by Rustemeier et al. (3370).
3. The precursors of arsenic and NDELA in MSS have been banned from U.S. tobacco agronomy since 1952 and 1981, respectively.

Note: The symbol (0) indicates the component identified in tobacco substitute smoke was not detected in tobacco smoke or vice versa.

26.2.1 Alternate Exposures to Carcinogens, Tumorigens, and Mutagens

Examination of the tumorigens listed in Table 26.1 logically leads to the questions: What, if any, are the human exposures to the listed tumorigens other than MSS and/or ETS? Is the exposure to a given tumorigen less, more, or equal to that from cigarette smoke? A detailed account of such alternate exposures requires many pages and tables. Most tumorigens in Table 26.1 have many alternate sources. The one obvious exception is the TSNAs which, by definition, being tobacco specific, have no alternate.

Table 26.10 is a brief list, with references, of alternate exposures to the major classes of tumorigens in tobacco smoke. The cited references provide tabulated details of the human exposures to them. Subsequent to Table 26.10 are discussions and tables in which the alternate exposures to the four major tumorigen classes in tobacco smoke are presented in more detail.

26.2.1.1 Alternate Exposures to Polycyclic Aromatic Hydrocarbons

Despite the ubiquity of PAHs in modern society, their presence in and their contribution to the alleged hazard of tobacco smoke have been repeatedly emphasized for over half a century, but seldom are the other many sources and/or levels of exposure to PAHs currently acknowledged as they were in the 1930–1950 period. Daily exposure to PAHs by inhalation (MSS, ETS, air pollutants) may represent only a small part of the total daily exposure; other exposures to PAHs often substantially exceed exposure via inhalation. Exposures to various PAHs are summarized in two different forms in Tables 26.11 and 26.12.

Results from many studies have been reported on the types and levels of PAHs, with particular emphasis on B[*a*]P, B[*a*]A, chrysene, benz[*e*]acephenanthrylene (B[*e*]A) (benzo[*b*]fluoranthene), B[*k*]A, indeno[1,2,3-*cd*]pyrene, DB[*a,h*]A, and benzo[*ghi*]perylene. As noted by Menzie et al. (2533), all of these PAHs have been identified in exhausts or effluents from fossil fuel combustion sources; in soils, sediments, and water; and in a variety of commonly used foodstuffs.

Although concern about PAHs in foodstuffs, particularly those arising pyrogenetically during cooking (grilling, broiling, roasting, etc.), predates the major concern of their presence in tobacco smoke, efforts to identify them in foodstuffs have been much less than the tobacco smoke effort: The number of PAHs identified in tobacco smoke exceeds 500, including several hundred derivatives where the positions of the alkyl groups have not been precisely defined (3757, 3758). PAHs identified in foodstuffs, both cooked and uncooked, number fewer than 150. Whether one considers the overall composition in general or the PAH fraction in particular, no other commercial product has been examined as extensively as tobacco or tobacco smoke.

Many PAHs are components of foodstuffs in the average diet (see Tables 26.11 and 26.12). Except for 5-MeC, PAHs listed in the many reports by Hoffmann et al. (1727, 1740,

[d] Grimmer et al. (1405).
[e] Mumford et al. (26A114).

1741, 1743, 1744, 1773, 1808) and OSHA (2825) as tobacco and tobacco smoke "tumorigens" have been identified in many foodstuffs. Grasso discussed the PAHs in foods and their significance as follows [see p. 1213 in (1345)]:

> The significance of these low levels of PAH carcinogens in food is difficult to assess. Undoubtedly, they are among the most potent carcinogens known, and every effort should be made to reduce their concentration in food. There are no clear indications, however, that they cause human cancer… Furthermore, there are indications that low levels of [benzo[a] pyrene], probably one of the most potent of the PAH found in food, do not produce tumors in experimental animals. The repeated application of 1.25 µg of [benzo[a]pyrene] in acetone to the skin of mice for 68 weeks failed to produce tumors [Roe (3310, 3311)]; dietary intake of 100 ppm of [benzo[a]pyrene] or less also had no effect in mice [Neal and Rigdon (2687)].

His comments on the carcinogenicity to humans of PAHs in ingested foods are equally applicable to the carcinogenicity to humans of the PAHs in inhaled cigarette MSS or ETS. Grasso noted that the following five PAHs were commonly found in foods: B[*a*]A, B[*a*]P, DB[*a,h*]A, B[*e*]A (benzo[*b*]-fluoranthene), and B[*k*]A; all listed by Hofmann et al. (1727, 1740, 1741, 1743, 1744, 1773, 1808) and OSHA (2825) as "tobacco smoke tumorigens." Grasso also listed the ranges of B[*a*]A and B[*a*]P levels found in a variety of commonly consumed foodstuffs.

Maga (2438) listed 65 common PAHs-containing foodstuffs. These, as did the list compiled by Grasso, included fruits and vegetables, dairy products, cereal products, legumes, beverages (including water), cooking oils, meat products, seafood products, and miscellaneous foodstuffs such as eggs, sugar, and olives. When many foodstuffs are heated during preparation, their PAH content increased dramatically, e.g., a single serving of charcoal-broiled meat contains more than 600 times the B[*a*]P level in the MSS from one cigarette [Lijinsky and Shubik (2364a, 2364b)].

Estimates such as this one are usually based on the Federal Trade Commission's (FTC) listing of TPM, "tar," nicotine, and CO deliveries plus an average value for the level of the B[*a*]P in the MSS TPM. Such comparisons between cigarettes and foodstuffs may yield estimates that are actually too low. For a given cigarette brand, the FTC numbers are obtained via precisely defined smoking regime and analytical methods (preconditioned cigarettes [25°C; relative humidity, 60%; conditioning time, 24 h]; smoking parameters—35 mL puff volume, 2 s puff duration, 1 puff/min; 25°C, 60% relative humidity, cigarette smoked to a defined butt length). On the other hand,

- Few smokers, if any, in the smoking of a cigarette take in the TPM amount found in the FTC determination.
- Few smokers smoke their cigarettes to as short a butt length as in the FTC procedure.
- Because of involvement in other tasks, smokers often place their cigarette in an ash tray for a brief time, thus missing one or more puffs on the cigarette. Few smokers take the number of puffs obtained for a given cigarette brand in the FTC procedure.

[a] Wynder and Hoffmann (4315), Hoffmann and Wynder (1790. 5943, 26A59), Hoffmann et al. (5942).
[b] Maga (2438).
[c] Also contains a high level of NDMA.
[d] Previously known as cholanthrene.
[e] Previously known as 3-methylcholanthrene.
[f] Previously known as benzo[*b*]fluoranthene.
[g] Previously known as dibenzo[*a,i*]pyrene (DB[*a,i*]P).
[h] Previously known as dibenz[*a,c*]anthracene.
[i] Also known as dibenzo[*fg,op*]naphthacene.

The smoking machine used in the method never misses a puff on the cigarette under test!

- The smoking machine used in the FTC procedure does not "exhale" as do smokers. It has been determined in numerous studies that cigarette smokers exhale between 10% and 50% of the TPM inspired during the puffs needed to consume the cigarette, thus retaining between 50% and 90% of the inspired TPM.

All of these factors, if taken into account for a foodstuff–cigarette comparison such as the one noted previously, will increase the calculated number of cigarettes in the B[*a*]P comparison.

Analysis of a foodstuff as elementary as bread reveals a B[*a*]P level of 0.23 ng/g (mainly in the crust); light toasting raised the B[*a*]P level to 0.39 ng/g; darker toasting raised it to 0.56 ng/g. For an average slice of bread (weight one ounce or approximately 30 g), these values would be about 7, 12, and 17 ng/slice. Maga also reported the dietary intake of B[*a*]P (charcoal-broiled meat excluded) averaged about 500 ng/day. From their analysis of human exposure to B[*a*]P, Waldman et al. (4106) reported in 1991 that "the range and magnitude of dietary exposures to benzo[*a*]pyrene" ranged from 2 to 500 ng/day and "were much greater than for inhalation (10–50 ng/[day])." For some subjects, however, they found a dietary maximum of 1149 ng/day, despite omission of the contribution of B[*a*]P-containing beverages such as coffee. These B[*a*]P-intake estimates [Maga (2438), Waldman et al. (4106)] were lower than that reported by Hattemeyer-Frey and Travis (1551): 2200 ng/day (97% from diet, 3% from inhalation and water contamination). If B[*a*]P were tumorigenic in man and its threshold limit value were "zero," the incidence of digestive tract cancer would be substantially higher than it is.

The data tabulated in Table 26.13 on B[*a*]P and B[*a*]A from Maga, Grasso, and other investigators of the PAHs in frequently consumed foodstuffs have been expanded in Table 26.14 to include the cigarette equivalents of various dietary items consumed at estimated per meal levels. The inhaled cigarette MSS particulate phase from one cigarette is assumed to deliver 10 ng of B[*a*]P and 12.5 ng of B[*a*]A to the smoker. The following situation, known to be contrary

TABLE 26.13
Levels of B[*a*]P and B[*a*]A in Common Foodstuffs

Foodstuff	B[a]P, ng/g	B[a]A, ng/g
Fresh vegetables	2.85–24.5	0.3–43.6
Vegetable oils	0.4–1.4	0.8–1.1
Coconut oil	43.7	98.0
Margarine	0.4–0.5	1.4–3.0
Mayonnaise	0.4	2.2
Coffee	0.3–1.3	1.3–3.0
Tea	3.9	2.9–4.6
Grain	0.19–4.13	0.40–6.85
Oysters and mussels	1.5–9.0	…
Smoked ham	3.2	2.8
Smoked fish	0.83	1.9
Smoked bonito	37	189
Cooked sausage	12.5–18.8	17.5–26.2
Singed meat	35–99	28–79
Broiled meat	0.17–0.63	0.2–0.4
Charcoal-broiled steak	8.0	4.5
Broiled mackerel	0.9	2.9
Barbecued beef	3.3	13.2
Barbecued ribs	10.5	3.6
Cigarette MSS[a]	20–25	20–35

[a] The total MSS (particulate phase plus vapor phase) from an 85 mm filtered cigarette smoked under FTC conditions approximates 0.5 g.

to experimentally determined fact, is also assumed: None of the MSS particulate phase, nor its B[*a*]P content, nor its B[*a*]A content is exhaled by the smoker.

How do these exposures to B[*a*]P in the diet, etc., compare to the exposure to B[*a*]P in ETS? It is obvious that dietary intake of B[*a*]P far outweighs the intake of B[*a*]P via inhalation, including that inhaled in ETS. Guerin et al. (1445) of the Oak Ridge National Laboratory discussed the contribution of ETS to indoor air PAH concentrations and tabulated their assessments of the situation. They noted:

> The data suggest that ETS contributes between 0.5 and 1 ng/m^3 of BaP to indoor environments containing measurable ETS-contamination … Excursions in BaP concentrations due to ETS in such environments reach approximately 2.5 ng/m^3 … The magnitude of ETS-contribution [to PAH and BaP concentration] is generally small and is often difficult to consistently detect in most environments.

The daily intake of B[*a*]P from ETS may be estimated if the following assumptions are made:

- The average hourly intake of air is independent of whether the host is awake or asleep and is 1 m^3.
- The B[*a*]P level due to ETS is at the high end of the range estimated by Guerin et al. (1992) to be 0.5–1 ng/m^3.
- None of the daily intake of B[*a*]P, whether from diet, ETS, and the like, is eliminated by exhalation, etc.

Table 26.15 shows a comparison of the intake of B[*a*]P from ETS *vs.* the other B[*a*]P intakes discussed previously.

26.2.1.2 Alternate Exposures to Aza-Arenes

Even though, as indicated in Table 26.3 and the text accompanying it, the presence of the three pentacyclic *N*-heterocyclic compounds in tobacco smoke is equivocal, the alternate exposure to them and similar components is discussed later.

In their 1956 review of angular benzacridines and dibenzacridines and their tumorigenicity, Lacassagne et al. (2247a) made the following interesting observation, pertinent to the alleged "carcinogenicity" of benzene, frequently used as a solvent in tumorigenicity studies in the 1930s, 1940s, and 1950s:

> These molecules [the angular benzacridines] are very soluble in benzene and acetone (two solvents currently used for the investigations of carcinogenic activity) …

In addition to the exposure to acridines and benzacridines in tobacco smoke, other exposures to various acridines and benzacridines have been cataloged in the scientific literature. Many of the sources (Table 26.16) comprise environmental pollutants.

Unlike the PAHs and the NNAs, nontobacco smoke exposure to the acridines/benzacridines does not include foods. However, exposures other than tobacco smoke to polycyclic nitrogen compounds include exposures to the mutagenic *N*-heterocyclic amines in a variety of foods.

26.2.1.3 Alternate Exposures to *N*-Nitrosamines

Among several groups who have been involved in research on NNAs since soon after their tumorigenicity in laboratory animals was first reported by Magee and Barnes (2441a) are Barnes, Magee, and Schoental in the United Kingdom and Dontenwill, Druckrey, Preussmann, and Schmähl in Germany. From the German group, Preussmann has been a key contributor to our knowledge of NNAs. He has authored/coauthored research results and review articles continuously on NNAs since 1959. Initially, Preussmann was involved with the investigation of the relationship between the structure of a NNA and its tumorigenicity [Druckrey et al. (1059)]. In 1962, Druckrey and Preussmann (1057) proposed the possibility of the formation of NNAs in tobacco smoke from the secondary amines, nitrogen oxides, and water present. For the next two decades, Preussmann investigated methods of NNA analysis [Preussmann et al. (26A129), Egan et al. (1112a)], tumorigenicity of various NNAs [Druckrey et al. (1056a, 1058), Habs et al. (1469a), Magee et al. (2443), Janzowski et al. (1921a, 1921b), Ketkar et al. (2086c, 2086d), Zerban et al. (26A197)], the involvement of nitrate and nitrite in NNA formation [Spiegelhalder et al. (26A165)], NNAs in foods [Spiegelhalder et al. (26A167)], beverages [Spiegelhalder et al. (26A166, 26A168)], and toiletries [Spiegelhalder and Preussmann (26A169)].

In the late 1980s, Preussmann returned to the study of NNAs in tobacco and tobacco smoke and the question of the

TABLE 26.14
Cigarette Equivalents of B[*a*]P and B[*a*]A in Common Foodstuffs

possible endogenous formation of TSNAs in smokers [Tricker et al. (3944. 3945, 3953, 3954), Tricker and Preussmann (3946–3951), Fischer et al. (1191–1200); Spiegelhalder et al. (3773, 3774), Kumar et al. (2235)].

Discussing the escalation in publications on *N*-nitroso compounds, Preussmann (2989a) wrote:

> At present (1981), more than 1400 papers are published annually on the analysis, formation, chemistry, biochemistry, metabolism and biological effects of *N*-nitroso compounds.
>
> There is no equivocal and convincing evidence of carcinogenicity in humans of *N*-nitroso compounds. Therefore, an answer is needed to the question whether exposure to traces of these compounds from the general environment … poses a risk to human health. In this situation animal data must be extrapolated to man, with all the inherent uncertainties.

Preussmann and Stewart (2991) noted the exponential increase in publications on NNAs between 1972 and 1984 and estimated that about three papers were published daily on this topic in the scientific literature in 1983. They also cautioned:

> Patterns of investigations established with nitroso compounds are being extended to more structurally complex carcinogens. Yet the contribution of nitroso compounds to the burden of environmentally determined neoplasia in humans remains to be determined … The priority that might reasonably be placed on reducing human exposure to nitroso compounds could be better judged if the number of cancers likely to be affected by such measures were known.

Discussions in this chapter are limited primarily to the NNAs common to tobacco/tobacco smoke and the other exposures (foodstuffs, beverages, cosmetics, drugs, etc.). As described by Preussmann and Stewart (2991), various bioassays on laboratory animals have been conducted on over 220 different NNAs and 110 *N*-nitrosamides, over 330 in all. Fewer than 60 of these *N*-nitroso compounds have been identified in tobacco and/or tobacco smoke.

Historically, the search for tumorigenic compounds in foodstuffs and beverages began in the early 1930s, shortly after the demonstration that the synthetic PAH DB[*a*,*h*]A [Kennaway and Hieger (2078)] and the coal tar isolate B[*a*]P [Cook et al. (796a, 797), Barry et al. (194)] were carcinogenic when painted on mouse skin and sarcogenic when injected subcutaneously. The initial investigations were limited to attempts to demonstrate the presence of these and similar PAHs in heated foodstuffs (meat, fish, etc.), particularly those containing cholesterol and its derivatives.

Subsequent to the demonstration of the tumorigenicity in laboratory animals of NNAs such as NDMA [Barnes and Magee (192), Magee and Barnes (2441a)], the search for NNAs in commonly used foods and beverages began. Despite nearly half a century of study of food components tumorigenic to laboratory animals, caution was recommended as recently as 1984 in the interpretation of the laboratory findings, e.g., Grasso (1345) in his review of carcinogens in food noted:

> Carcinogens occur at very low concentrations in food so that if any type of tumors result at all, the number is expected to be very low indeed. At present much thought is being given to the relative hazards of these levels and how they can be assessed. Certainly no firm association has been established between any human cancer and the low levels of carcinogens in food, but this problem may only reflect the imperfect state of current epidemiological investigations.

Despite hundreds of publications on the presence of NNAs in foods and beverages and the results of bioassays with NNAs in laboratory animals, Grasso also wrote:

> Despite intensive experimental investigations, however, the hazard to humans from small doses of nitrosamines present in our food and water are difficult to assess, and until further experimental evidence is available, no firm opinion can be given.

This opinion is almost identical with that of Preussmann and Stewart (2991) who reviewed not only the human exposure to NNAs in foods, beverages, water, drugs, cosmetics, etc., but also exposure to the NNAs (volatile, nonvolatile, and tobacco-specific) in tobacco products:

> Although estimates of the total human burden caused by exposure to nitroso carcinogens have been attempted … , we do not think that sufficient data exist for meaningful evaluation; therefore, estimation of nitrosamine contribution to human cancer risk is largely speculative. Premature calculations are liable to be misinterpreted by those who are not thoroughly familiar with the multitude of uncertainties and difficulties inherent in such calculations, especially when estimates of lifetime risks are based on such figures.

Table 26.17 lists the levels (ng/g) of several NNAs identified in commonly used foods and beverages. Table 26.18

TABLE 26.17
NNAs in Foods and Beverages (ng/g)

Food or Beverage	NDMA	NDEA	NPYR	NPIP
Meat				
Bacon, uncooked	1–9.5	1–4	≤17	0
Bacon, fried	0.1–28	≤40	3–44	1
Cured meats	1–80		10–105[a]	≤60[a]

Cigarette MSS (ng/cig)[d]	0.1–180	ND–25	30–60	ND–9

NDMA, *N*-nitrosodimethylamine; NDEA, *N*-nitrosodiethylamine; NPYR, *N*-nitrosopyrrolidine; NPIP, *N*-nitrosopiperidine.

[a] Levels in sausage.

[b] Sixteen different vegetable species tested.

[c] Freshly refined.

[d] See Table 26.1.

summarizes the studies in which various NNAs were identified in foods and beverages. One of the earliest investigators of NNAs in foodstuffs was Kröller (2205) who identified NDMA in cheese. Kröller's studies were not limited to possible tumorigens in foodstuffs. From 1963 through 1966, he also investigated the pyrosynthesis of PAHs, particularly B[*a*]P, in cigarette smoke and from various materials used in cigarette fabrication, e.g., cigarette paper, adhesives, humectants, dyes, inks, flavorants, tobaccos [see summary in Wynder and Hoffmann (4332)].

Also included in Table 26.17 are data for the per cigarette deliveries of several NNAs identified in foods and beverages. From these data, comparisons of the relative exposures from foods, etc., and cigarette smoke are possible, e.g., the per cigarette MSS range for NDMA has been reported as 0.1–180 ng (see Table 26.1). Since one ounce is approximately 30 g, a person eating 1 oz of fried bacon would be exposed to 30 (0.1–28) or 3–840 ng of NDMA. Similarly for cured meat, the per cigarette exposure of 0.1–180 ng should be compared to the dietary exposure of 30–2400 ng from eating 1 oz of cured meat. Also, compare the exposure to 30–60 ng/cig of NPYR *vs*. 300–3150 ng NPYR from eating 1 oz of sausage!

Over the years, numerous reports [cf. Neurath et al. (2751), Fredrickson (1236), Krull et al. (26A77), Eisenbrand et al. (26A27), Caldwell and Conner (573)] on the artifactual formation of NNAs during the collection and analysis of tobacco smoke and the various remedial procedures taken to minimize this problem have been published. Similar problems were noted by Wolff and Wasserman (26A195) on inflated levels of NNAs reported in foodstuffs and beverages. They expressed reservations about the validity of pre-1972 analytical methodology since later studies demonstrated that the earlier procedures introduced both artifact and error. Thus, the levels of NNAs reported in foodstuffs were actually lower than those reported prior to 1972. In 1986, Sen et al. (26A150) proposed improvements in analytical methodology to prevent artifactual formation and subsequent inflated levels of NNAs in rubber products; propyl gallate was demonstrated to be an effective inhibitor of *N*-nitrosation during the analytical procedure.

A variety of investigations have been conducted during the past decade on exposures to NNAs, and a few will be cited here. Okieimen et al. (26A120) reported on the total NNAs content of beer, dairy products, bouillon cubes, and tobacco products. They reported that dairy products showed the lowest total value; bouillon cubes, the highest. Mandagere (2450a) reported on the high NNA levels in a variety of meats cured via a smoking process.

Coker et al. (26A16) tested some 200 commercial foodstuffs for NNAs and noted the values for beverages were high, those for dairy products low. Craddock (26A18) and Sen (26A143) found NNA levels in Canadian foodstuffs and beverages to be similar to those of U.S. products. Since the review by Preussmann and Stewart (2991) on the tumorigenicity of NNAs and that by Preussmann and Eisenbrand (2990) on exposure to NNA tumorigens in the environment, numerous detailed reviews of NNA exposures (alcoholic beverages, meats, seafood, cosmetics, tobacco, rubber goods, metal cutting oils, pharmaceuticals, environment, water) have been presented by Mejstrik et al. (26A99), Tricker and Preussmann (3946), Tricker et al. (3954), Ellen (26A30), and Matsui and Kaya (26A95).

The daily intake of NNAs from ETS may be estimated if the following assumptions are made:

- The average hourly intake of air is independent of whether the host is awake or asleep and is 1 m^3.
- The NNA level due to ETS is at the high end of the range estimated by Guerin et al. (1445) for the various NNAs, i.e., 40 ng/m^3 for NDMA, 3 ng/m^3 for NDEA, NPYR, NNN, and NNK.
- None of the daily intake of the NNAs, whether from diet, ETS, and the like, is eliminated by exhalation, etc.
- The measured values reported for NNAs in diet, ETS, etc.

From the dietary NNA data of Preussmann and Eisenbrand (2990), Preussmann et al. (26A130), and Spiegelhalder et al. (26A167) and ETS NNA data summarized by Guerin et al. (1445), the comparison in Table 26.19 was developed.

It is obvious that the estimated exposure to the NNAs in diet *vs*. ETS differs from the B[*a*]P exposure case. Whereas the dietary exposure to B[*a*]P was between 20 and 90 times

TABLE 26.19
Comparison of Dietary and ETS

	Dietary Intake, ng/day				
Country	**NDMA**	**NDEA**	**NPYR**	**NPIP**	**Total**
Federal Republic of Germany	1100[a]		100–150	10	1210–1260
United Kingdom					530
Japan					1780
The Netherlands					1100

	Intake from ETS[b], ng/day					
	NDMA	**NDEA**	**NPYR**	**NPIP**	**NNN + NNK**	**Total**
Estimated from German, Japanese, and American ETS studies[c]	960	72	72		144	1248

[a] Because of the reduction in NDMA level in beer after 1979, this number is now probably closer to 700 ng/day.
[b] On basis of the assumptions listed previously.
[c] Brunnemann et al. (457), Stehlik et al. (3812), Matsushita and Mori (2495), Klus et al. (26A75); unfortunately, the TSNAs results from a more recent study on ETS by Brunnemann et al. (1992) were not included in the assessment by Guerin et al. (1445) or Holcomb (26A60).

the exposure to B[*a*]P in ETS, the dietary exposure to NNAs is essentially the same as the exposure to NNAs in ETS.

Previously, the review by Holcomb (26A60), his proportioning of male and female respiration rates during the day, his use of 11% particle retention, and his comments on the contribution of ETS to PAH exposure were discussed. His summary of the NNA situation was as follows:

> Two studies [Stehlik et al. (3812), Hoffmann et al. (1678)] have reported the presence of … (NDEA) and … (NDMA) in smoke-filled rooms … These are not tobacco-specific nitrosamines. The lack of reported background levels and the unusually high level of smoking prevents the evaluation of ETS contribution of these substances. Other nitrosamines reported to be found in tobacco smoke have either not been monitored or not been reported in ambient air where ETS is present.

Unlike the volatile NNAs which are found primarily in the vapor phase, TSNAs are predominantly particulate-phase components.* Thus, their intake and retention should be proportional to the intake and retention of ETS particles. If Holcomb's assigned values for respiration rates during the day and his use of 11% retention are applied to the TSNA

* Although data are sparse, there is some evidence to indicate that TSNAs in ETS may be distributed between the vapor and particulate phases.

TABLE 26.20
TSNAs in Indoor Air

	TSNAs in Indoor Air, ng/m³			
Reference	NNN	NAT	NNK	Total of Three TSNAs
Brunnemann et al. (460)	ND[a]–22.8	ND[a]–9.5	1.4–29.3	1.4–61.6
Hoffmann et al. (1702)	1.8–23	1.5–10	1–29	4.3–62

ND, not detected.

[a] Not detected in 5 of the 10 sites monitored (a restaurant, both trains, the office, smoker's residence).

values in the preceding summary, the intake of NNN plus NNK will be much less than the 144 ng/day indicated. It probably would be less than 10 ng/day. If the more recent data of McAughey et al. (26A98) for the % retention of particulates from aged and diluted SSS be used in the calculations (17%–41%, depending on analytical procedure and subjects' gender), the estimated exposure to NNN plus NNK will not be as low as if the 11% retention from the Hiller et al. (1654a, 1654b) study be used.

Brunnemann et al. (460) determined the levels of several TSNAs in bars (3), restaurants (2), a car, trains (2), an office, and a smoker's private residence. The values reported and the subsequent descriptions of the values found are shown in Table 26.20.

In their discussion of exposure to TSNAs in ETS at various sites, Hoffmann et al. (1702)—perhaps to embellish the situation—apparently disregarded the fact that no NNN nor *N′*-anatabine was detected in half the test sites! Hoffmann et al. (1702) list total TSNAs in the MSS from two different U.S. cigarettes at 979 and 670 ng/cig. Thus, at an exposure level of 62 ng/m³ and a respiration rate of 1 m³/h, it would require a nonsmoker to remain for nearly 16 and 11 h in such an atmosphere to be exposed to similar levels of TSNAs as a smoker who inhales MSS from the two cigarettes, respectively. Such a period surely exceeds the "several hours" noted by Hoffmann et al. (1702).

Analysis of 68 commercially available drug preparations containing aminopyrine indicated that all contained NDMA [Schoenhard et al. (26A140)]. The following ranges for the NDMA levels were reported: 35 samples, 1–10 ppb; 27 samples, 11–50 ppb; 5 samples, 51–100 ppb; 1 sample, 370 ppb. More recently, Preussmann and Eisenbrand (2990), Mejstrik et al. (26A99), Lijinsky (26A85), Ellen (26A30), and Matsui and Kaya (26A95) have reviewed the studies on the detection of NNAs in pharmaceuticals as well as in other consumer products.

Examination by Fan et al. (26A31) of a series of cosmetics widely used in the United States revealed that 27 of 29 samples contained NDELA at levels varying from 1 to 48,000 ppb. From a similar study conducted several years later, Klein et al. (26A73) reported that 5 of 10 cosmetic samples contained NDELA at levels ranging from 20 to 4113 ppb. Despite the concern about the possible tumorigenicity of NDELA, its use in cosmetics has continued since its ban as an agricultural chemical in the United States in 1981 (1147). Although none of the three have been identified in tobacco or tobacco smoke to date, *N*-nitrosomethyldodecylamine (in six of seven products tested), *N*-nitrosomethyloctadecylamine, and *N*-nitrosobenzylmethylamine were identified in 1981 by Hecht (26A56) in various commonly used cosmetics. Fan et al. (26A31) described an analytical method to determine NDELA in various cosmetics and shampoos; this procedure was updated by Fine (26A36). Erickson et al. (1159) reported the presence of NDELA and similar compounds in cosmetics. Preussmann and Eisenbrand (2990) commented on the rapid absorption of NDELA in rats when administered by a variety of routes (subcutaneous, oral, intratracheal).

Preussmann and Eisenbrand (2990), Mejstrik et al. (26A99), Ellen (26A30), Lijinsky (26A85), and Matsui and Kaya (26A95) have reviewed the findings on the detection of NNAs in cosmetics. Spiegelhalder and Preussmann (26A169) described the volatile and nonvolatile NNAs found in many samples of toiletries and cosmetics. Eisenbrand et al. (26B15) reported a series of *N*-nitrosodialkylamines in cosmetics.

Investigations [Spiegelhalder and Eisenbrand (26A164), Spiegelhalder (26A163)] of various rubber products that come in frequent contact with human tissue revealed the presence of several NNAs. Baby-bottle nipples and pacifiers contained appreciable levels of NDMA, NDEA, *N*-nitrosodibutylamine (NDBA) [Thompson et al. (26A174)], and NPIP. NDMA and NDEA were found in various rubber toys. These two NNAs plus NPIP were also found in rubber gloves. In their study of NNAs in rubber products, Sen et al. (26A149), in their analysis of 30 samples, reported the detection of NMOR in various rubber products in addition to NDMA, NDEA, NDBA, and NPIP. Solenova et al. (26A161) reported the presence of NDMA and NDEA.

Several NNAs have been identified in pesticides used on various vegetable crops, e.g., NDMA [Ross et al. (26A137)] and *N*-nitrosodipropylamine (NDPA) [Zweig et al. (26A198)].

Most water supplies show little evidence of volatile or nonvolatile NNAs. However, water deionized by passage through various anion-exchange resins containing trialkylammonium compounds were reported to show NDMA levels ranging from 0.03 to 0.34 mg/L [Fiddler et al. (26A35), Fine et al. (26A37, 26A38), Gough et al. (26A44), Cohen and Bachman (26A14), Kimoto et al. (26A72), Mitch et al. (26A112a)].

On the subject of industrial and occupational exposures to NNAs, Preussmann and Eisenbrand (2990) wrote:

> Data on occupational exposure to different nitrosamines are recent and not yet representative or complete. Nevertheless, the data indicate that certain industries have a serious nitrosamine problem and that the highest known concentrations of preformed *N*-nitrosamines occur in the workplace, especially in the rubber and leather industries … Exposures have been shown to vary considerably in regard to amount and type of nitrosamine found in different working places in several industries and occupations.

Preussmann and Eisenbrand (2990) summarized the following situations: In the rubber industry, workers were exposed to NDMA, NDEA, NMOR, and NPIP. In their study of the atmospheres in 132 sites in 12 rubber-processing plants in France, Ducos and Gaudin (26A24) reported the detection of NDMA, NDEA, and NMOR in 93%, 27%, and 13% of the sites surveyed, respectively. In the leather-tanning industry, exposures to NDMA occur [Bailey et al. (26A04), Skrabs (26A159), Wolf et al. (26A194)] and to NDEA [Skrabs, (26A159), Wolf (26A193)], and NMOR [Wolf (26A193)]. Exposures to NDELA [Erickson et al. (1159)] in the cutting oils used in machine shops and to NDMA and NDEA [Wolf et al. (26A194), Wolf (26A193)] in foundries have been reported. In a plant-producing rocket fuels, including 1,1-dimethylhydrazine by reduction of NDMA, workers were exposed to extremely high levels of NDMA. Shortly after this high exposure was recorded, the factory ceased manufacture of 1,1-dimethylhydrazine. In chemical and pharmaceutical factories where amines are used in production, exposures to NDMA and NDEA have been reported.

In Table 26.21 is presented a simplified summary of the possible exposures to non-TSNAs that are known components of tobacco smoke. All 10 NNAs listed are found not only in tobacco smoke but also in a great variety of commonly consumed foodstuffs and beverages.

26.2.1.4 Alternate Exposures to *N*-Heterocyclic Amines

Because of their concerns about the mutagenicity of commonly consumed heated foods, many of the studies of the isolation, identification, and estimation of *N*-heterocyclic amine in heated foodstuffs or heated food components, particularly amine-containing components such as amino acids, proteins, and peptides, were conducted by Japanese investigators. This becomes obvious from examination of the authors and coauthors of the references listed in Table 26.22.

With the advent of the Ames mutagenicity test with *S. typhimurium* in the mid-1970s and the demonstration of its utility, the number of studies on potential mutagenic systems and the mutagenicity–tumorigenicity relationship virtually exploded. By highly competent application of up-to-date isolation and characterization techniques plus utilization of the Ames test, Sugimura and his staff at the Japanese National Cancer Research Institute contributed significantly to our knowledge of the structures, properties, and precursors in foods of the mutagenic *N*-heterocyclic amines. While the methodologies differed, the 1977 isolation/identification of the mutagenic *N*-heterocyclic amines (Trp-P-1, Trp-P-2) from a tryptophan pyrolysate paralleled the historic 1932 isolation and identification of PAHs (B[*a*]P, B[*e*]P, B[*a*]A, perylene) from coal tar. In the 1930s, the Kennaway group in the United Kingdom used ultraviolet spectrophotometry [Hieger (1631)] to monitor coal-tar PAHs during their concentration and purification by repeated precipitations and recrystallizations of PAH–picric acid complexes [Cook et al. (796a, 797)]. In the mid-1970s, Sugimura et al. (3829) used the Ames test (*S. typhimurium*, TA 98 strain/S-9) to monitor tryptophan pyrolysate mutagens (Trp-P-1, Trp-P-2) during their concentration and purification by sequential chromatography on silicic acid, alumina, and CM-Sephadex® columns.

References to several early studies on the identification of biologically active compounds in heated foodstuffs are included in Table 26.22, e.g., the 1956 study of PAHs such

[a] This was a PAH study, with emphasis on the generation of B[*a*]P.
[b] No mutagens detected in glycylglycine pyrolysate.
[c] The pyrolysates from the various amino acids studied showed mutagenicities (Ames test) in the following sequence (revertant/mg of pyrolysate), the amino acid yielding the highest mutagenic pyrolysate listed first: tryptophan, serine, glutamic acid, ornithine, lysine, arginine, citrulline, threonine, alanine, cystine, glutamine, methionine, cysteine, tyrosine, phenylalanine, histidine, asparagine, valine.

as B[*a*]P in roasted coffee [Kuratsune (2237)] and the similar mid-1960s studies of PAHs in broiled meat [Lijinsky and Shubik (2364a, 2364b)]. PAHs such as B[*a*]P were identified in both studies. The major concern of the early investigators was the possible presence of tumorigenic PAHs, particularly B[*a*]P, in the heated foodstuff. Another PAH of concern was the potent tumorigen 3-methylcholanthrene because of its possible pyrosynthesis during cooking from cholesterol, a component of many meats. Of course, it was subsequently demonstrated that B[*a*]P, in addition to its tumorigenicity to mouse skin, is also mutagenic in the Ames test. However, its specific mutagenicity is insignificant compared to that of many *N*-heterocyclic amines.

From their studies of heated foods or food pyrolysates (30 different foods, including rice, flour, soy beans, fish, meat, eggs), Sugimura and Nagao (3828b) reported

- Mutagenicity was proportional to the protein content.
- Mutagenicity was proportional to the levels of specific amino acids (tryptophan, glutamic acid, etc.) in the constituent protein.
- Mutagenicity was dependent on water content and heating temperature, e.g., for foods with low water content, the mutagens appear at 300°C; for those with high water content, the mutagens appear at 400°C.

As noted in the sections on PAHs and NNAs in foods, estimates of daily exposures to these classes of compounds in foods, beverages, and other factors have been made by numerous investigators. Estimates of exposures to mutagenic *N*-heterocyclic amines are limited. Part of the reason is the difference in time span since the particular class of compounds was found to be tumorigenic and/or mutagenic. Exposures to PAHs tumorigenic in laboratory animal bioassays have been studied for more than seven decades since the early 1930s and the identification of B[*a*]P in coal tar by Cook et al. (796a, 797), and exposures to NNAs tumorigenic in laboratory animal bioassays were studied [Magee and Barnes (2441a)] since the mid-1950s. In contrast, exposures to mutagenic *N*-heterocyclic amines reported to be tumorigenic in laboratory animal bioassays have only been studied for about 30 years (since the mid-1970s and the availability of the Ames test).

In his mid-1980s review, Sugimura (3828c) attempted to estimate the exposure of humans to mutagenic *N*-heterocyclic amines with the limited data at his disposal. He wrote:

> Taking various factors into consideration, it is probably impractical and not realistic to make risk estimations from the carcinogenicity data on rodents given a single carcinogen. However, for a simple extrapolation of animal data for risk estimation, TD_{50} values, which are the doses needed to develop cancers in 50% of animals fed on carcinogens [IQ, Trp-P-1, Trp-P-2, Glu-P-1, Glu-P-2, A*a*C, and MeA*a*C] for

Mackerel	60 (2.1)	68,200	5683
Beefsteak	190 (6.7)	85,500	7125

[a] Calculation based on assumption of MSS yield of 12 ng/cig of B[*a*]P.
[b] Number in parentheses is weight in ounces.

> their life time, have been calculated based on mouse experiments … If we assume the average TD_{50} value of heterocyclic amines should be about 8mg/kg/day, we can roughly estimate the risk of these carcinogenic heterocyclic amines for human beings. The intake of heterocyclic amines was calculated from available data on their quantities in foods. Apparently the human intake is about 0.0002% times the TD_{50} obtained from animal data. This means that heterocyclic amines may not be so serious for human cancer development.

Sugimura added:

> On the other hand, it is also true that human beings are being exposed to many heterocyclic amines and many other carcinogens with tumor promoters and/or suppressing factors for carcinogenesis. At this moment, it is honest to state that no solid information on the estimation of risk of heterocyclic amines has been obtained in any direction, either positive or negative.

Sugimura (3828d) reported comparisons of the mutagenicities (Ames test) of various beverages (coffee, brandy, tea) and CSC. His data are summarized in Table 26.23.

In another comparison of mutagenicities toward *S. typhimurium* TA 98, Nagao et al. (2667c) calculated the B[*a*]P equivalency of extracts of charred fish and meat. Their data, with additions (charred food weight in ounces, cigarette equivalents based on B[*a*]P), are shown in Table 26.24.

26.3 SUMMARY

It is obvious from the numerous Hoffmann et al. lists (1727, 1740, 1741, 1743, 1744, 1773, 1808, 1870) summarized in Table 26.1 plus many other listings (1217, 2825) and articles that some 70 tobacco smoke components are defined as significant toxicants with most of the 70 being defined as significant tumorigens. Of the 70, 40 or so have recently been defined as "Hoffmann analytes," and their cigarette MSS yield reductions are used to define a "potentially reduced exposure product" (PREP). It should be noted that the various bioassays that generated the data used to define the tumorigenicity of the various cigarette smoke components are similar to and/or identical with the various bioassays that generated the data to define the antitumorigenicity of various compounds to several known potent tumorigens such as B[*a*]P or DB[*a,h*]A. Many of the compounds with demonstrated antitumorigenicity have been identified in CSC and are present in it at much higher levels than such potent tumorigens as B[*a*]P, DB[*a,h*]A, and DMB[*a*]A.

Why do so many of the proponents of the hazards of cigarette MSS seldom discuss in detail the many anticarcinogens, antitumorigens, or antimutagens present in MSS or the many alternate exposures to the various compound classes, the PAHs, aza-arenes, NNAs, and *N*-heterocyclic amines, defined as significant cigarette MSS problems?

At the 1962 American Association for Cancer Research conference (4314), in their 1964 review [see pp. 330–331 in (4319)], and in their 1967 book, Wynder and Hoffmann [see pp. 370–371 in (4332)] also described the results of their experiments on the antitumorigenicity of two tobacco smoke paraffinic hydrocarbons, *n*-hentriacontane ($C_{31}H_{64}$) and *n*-pentatriacontane ($C_{35}H_{72}$), coadministered separately at two different levels with B[*a*]P. Subsequently, they noted [see pp. 628–629 in (4332)]:

> An explanation of the tumorigenic activity of tobacco smoke condensate in terms of single constituents is made more difficult by the presence of substances that may act as anticarcinogens and/or absorption retarders, especially for tumorigenic agents. It is known that noncarcinogenic hydrocarbons can inhibit the effect of carcinogenic* hydrocarbons … The presence of substances such as long-chain paraffinic hydrocarbons may interfere with absorption of tumorigenic* components.

In their book, Wynder and Hoffmann described not only the 1951 results reported by Steiner and Falk (3814) on the antitumorigenicity of B[*a*]A to B[*a*]P when coadministered subcutaneously but also their own 1963 results of the antitumorigenicity of B[*a*]A to B[*a*]P when administered in a skin-painting bioassay [see pp. 246–247 in (4332)]. They noted:

> The existence of anticarcinogens, however, must be considered in evaluating any complex mixture such as tobacco smoke condensate.

Despite such a statement, neither Wynder and Hoffmann nor any of the proponents of the hazards of cigarette smoking

* It is interesting to note the authors' interchange of the two terms carcinogenic and tumorigenic.

discussed in any detail the presence of antitumorigens in cigarette MSS.

The same proponents usually disregard alternate exposures to various tumorigens despite the many pre-mid-1950s articles by Kennaway and Hueper on respiratory effect of air pollutants. Because of the chronology of the discovery of the tumorigenicity of NNAs in the mid-1950s and *N*-heterocyclic amines in the late 1970s, it is obvious that neither Kennaway nor Hueper could discuss alternate exposures to them. Examples of more recent research are the many publications by Grimmer et al. on exposure to PAHs (1397–1402, 1405, 1406a, 1406b, 1407b) and aza-arenes (1407a) as air pollutants.

In the Searle-edited monograph, comprising over 1400 pages on chemical carcinogens (3568), all but one of the major classes (PAHs, aza-arenes, *N*-heterocyclic amines) of tumorigenic components in MSS are not mentioned. The exception, the presence of NNAs in tobacco and smoke, was described briefly by Preussmann and Eisenbrand [see pp. 839–842 in (2990)]. The bulk of the material they cited on NNAs in tobacco and/or smoke included tabulated results by Hoffmann et al. on NNAs and TSNAs in tobacco smoke (514, 1680) and tobacco [including snuff (1675, 1677, 1685)]. However, Preussmann and Eisenbrand cited many pre-1984 publications in which much data were presented on exposure to NNAs from many alternate sources such as food [see pp. 832–834 in (2990)] beverages [see pp. 834–839 in (2990)], cosmetics [see pp. 842–844 in (2990)], prescriptions [see pp. 844–845 in (2990)], pesticides [see pp. 845–846 in (2990)], rubber products [see pp. 846–848 in (2990)], water [see pp. 848–849 in (2990)], and occupations [see pp. 851–857 in (2990)]. In his chapter in Searle (3568), Grasso (1345) described the results of much research on PAHs and NNAs in foods but none on *N*-heterocyclic amines in food. Many references to alternate exposures to NNAs are presented herein, but a great many more may be obtained by a search of the Internet.

27 Free Radicals

27.1 INTRODUCTION

Free radicals and reactive oxygen species (ROS) are common to all living animals and plants, including tobacco. ROS in plants include hydrogen peroxide (H_2O_2) and singlet oxygen ($^1O_2$), as well as several free radicals and radical anions such as nitric oxide (NO), superoxide anion radical ($O_2^{-\bullet}$), hydroxyl radical ($HO^\bullet$), and perhydroxyl radical ($HO_2^\bullet$) [Bartosz (27A06), Dat et al. (27A23), Halliwell (27A40)]. These highly reactive oxidation byproducts are created by normal cell metabolism and environmental factors such as pollution and are continuously produced by living organism.

Free radicals play an important role in the life processes of plants. Free radicals and ROS are produced predominantly in plant cells during photosynthesis and photorespiration and, to a lesser extent, in respiration processes. Free radicals and ROS play crucial roles as signaling molecules in various physiological processes. For example, during periods of environmental stress, intra- and intercellular levels of H_2O_2 and NO tend to increase. Additionally, specific types of free radicals and ROS interact with thiol-containing proteins and activate different signaling pathways as well as transcription factors, which in turn regulate gene expression and cell-cycle processes. Therefore, free radicals and ROS control numerous types of cellular redox reactions (homeostasis), signaling processes (photosynthetic and respiratory metabolism), and processes that regulate plant growth, development, acclimatory and defense responses [Ślesak et al. (27A105)].

The role of free radicals and ROS in plant biochemistry and physiology has been described in many review papers [Kuźniak and Urbanek (27A63), Neill et al. (27A80, 27A81), Apel and Hirt (27A02), Hung et al. (27A47)]. There are no free radicals or ROS that are unique to tobacco. As a result, there will not be an in-depth discussion of free radicals or ROS specifically found in tobacco. In most cases, the free radicals in biological systems are highly reactive and have half-lives of 10^{-6}–10^{-3} s. Nonetheless, free-radical activity has been observed in tobacco. Analytical methodologies rapid and specific enough to monitor and identify these free radicals are just emerging.

It is believed that the presence of oxygen (O_2) in the Earth's atmosphere originated from photosynthetic activity. However, oxygen is involved in two very different roles in biological systems. It is a prerequisite for aerobic metabolism and consequent normal growth and development, but at the same time, a reduction or an increase of molecular oxygen in biological systems very often results in the formation of ROS that can cause deregulation of normal cellular processes and eventually cause cell death. Therefore, in plants and in other aerobic organisms, antioxidant systems have evolved.

The balance of oxidants and antioxidants in plants and animals is critical for survival. The production of ROS is normally carefully controlled by living organisms. A dynamic equilibrium exists between the formation of ROS and the activity of the antioxidant scavenging systems [Hancock et al. (27A45), Irshad and Chaudhuri (27A49), Mittler et al. (27A74), Mittler (27A73), Vranova et al. (27A119)]. To protect themselves from ROS, plants possess a number of free-radical scavenging enzymes, such as ascorbate peroxidase, catalase, and superoxide dismutase (SOD), and low-molecular-weight antioxidants, like ascorbate and tocopherols [Hancock et al. (27A45), Vranova et al. (27A119)]. Antioxidants in tobacco and tobacco smoke are discussed in Chapter 26.

At the senescence stage in tobacco growth, enzyme activities (especially hydrolytic and other degradative enzyme systems) are intensified. These systems are responsible for breakdown of functional and structural components of the cell, such as proteins, nucleic acids, carbohydrates, and lipids. The latter stage of senescence resembles the early stage of leaf curing [Tso (27A114)]. During each of these processes, free-radical reactions are occurring in tobacco leaf. In 1955, Frankenburg et al. reported that free-radical reactions were occurring in cured tobacco leaves to form a nicotine dimer (1224, 1226).

After tobacco is grown, cured, and aged, there are free radicals still found in the lamina. It is believed that free radicals are present on the polyphenols, carbohydrates, and lignin present in tobacco. This is supported by evidence for the generation of free radicals in cellulose by irradiation with ultraviolet light [Kleinert (27A61)]. The existence of stable free radicals in lignin has also been demonstrated [Rex (27A98), Steelink (27A107), Steelink et al. (27A108)]. The formation of free radicals in wood by ionizing radiation has been shown as well as the generation of free radicals in wood resulting from exposure to light [Kalnins et al. (27A57)].

Free radicals are ubiquitous. They are found in living plants and for practical purposes are essential to all life. They also exist in plant material that is dried. These types of free radicals are called persistent free radicals and are normally associated with free radicals present in the structural biomass of the plant (polyphenols, carbohydrates, and lignin). The tobacco precursors of free radicals found in the particulate phase of cigarette mainstream smoke (MSS) are also long-lived, persistent free radicals but arise from the thermolysis of the tobacco biomass to form numerous types of phenolic and quinoidal free radicals [Wooten et al. (27A120)]. Short-lived free radicals are also present in the vapor phase of MSS. Although the types of free radical in tobacco may be similar in form to those in tobacco smoke, in some cases, e.g., NO, they are formed/generated in very different manners.

Free radicals can participate in a wide variety of reactions such as additions, substitutions, eliminations, rearrangements, reductions, electron transfers, and oxidations (27A01). From the beginning of the twentieth century, free-radical chemistry has spread its influence over a wide range of research areas that impinge on our progress and well-being. Apart from polymer chemistry, synthetic organic chemistry, and environmental chemistry, much effort in recent times is expended on research in health and nutrition [Nagendrappa (27A78)].

There are some general features of a free-radical reaction. Free-radical reactions take three distinct, identifiable steps. The first is formation of the free radical that can happen by enzyme catalysis, homolysis, thermolysis, radiation, light induction, combustion, and pyrolysis, or other means. The second step, called propagation, is the heart of a free-radical reaction. In this step, free radicals are repeatedly regenerated and can react with neutral molecules to produce new free radicals. If there is no intervention, two free radicals can react to form a neutral molecule, and the reaction is terminated, which represents the third step in the general reaction scheme. Because of this repetitive nature of the reaction, free-radical reactions are called "chain reactions" and are often represented as a cyclic process [Nagendrappa (27A78)].

27.2 ANALYTICAL METHODS FOR DETERMINATION OF FREE RADICALS

The instrumental method historically used for the detection of free radicals is electron spin resonance (ESR) (sometimes called electron paramagnetic resonance [ERP]). ESR is a spectroscopic technique which detects species that have unpaired electrons. Free radicals can be organic compounds that have a free electron on carbon, oxygen or nitrogen, or inorganic compounds or complexes that have a free electron usually residing on a metal [EPR (27A31)]. ESR spectroscopy is the preferred and major analytical technique for the detection and quantification of free radicals [Demopoulos (27A28)]. ESR has been used in many fields of science to explore the presence and effects of free radicals in chemistry, physics, and biology.

Free radicals can be gases, liquids, or solids and generally exist in very low, and in some cases, steady-state concentrations. ESR can be used to make direct measurements of free radicals that exist in steady-state concentrations [Demopoulos et al. (27A29)]. For short-lived, highly reactive free radicals, regardless of their physical and chemical form, numerous methodologies are now available to convert these free radicals into longer-lived species for analysis. Short-lived free radicals are first treated with another reagent called a spin trap. The resultant product, the spin adduct, is a more stable free-radical species that can then be measured by ESR. Concentrations of free radicals are determined by measuring the spin-trap adducts. A wide variety of spin-trapping reagents have been used. Figure 27.1 shows the chemical structures for a selection of these spin traps.

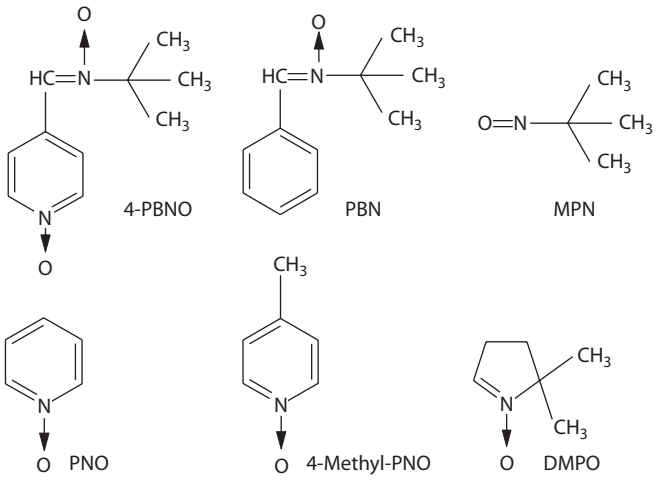

FIGURE 27.1 Chemical structures of 4-POBN, PBN, MNP, PNO, 4-methyl-PNO, and DMPO spin traps [McCormick et al. (27A71)].

Techniques that use ESR alone or ESR with spin-trapping methodologies have advanced tremendously over the last 40 years [Janzen and Gerlock (27A54), Janzen (27A52, 27A53), Janzen et al. (27A55)].

Unlike other typical analytical techniques, e.g., infrared spectroscopy, ESR measurements require a high level of technical skill and expertise. ESR sample measurements are highly dependent on sample collection, sample preparation, types of solvents, temperature, choice of spin trap, and instrument calibration of electrical and magnetic fields, among other things.

ESR, by itself, is considered a very specific, yet semiquantifiable, technique for the measurement of free radicals. It can be used in conjunction with other analytical techniques, such as gas chromatography (GC), mass spectroscopy (MS), and high-performance liquid chromatography (HPLC), for the study of free radicals [Cranton and Frackelton (27A20)]. ESR used in conjunction with other analytical techniques is an emerging field.

Free radicals can also be measured in biological samples. In a recent review by Sanchez-Moreno (27A103), several ESR techniques were described for the collection and determination of free radicals (superoxide, hydroxyl, and peroxyl) that occur in biological systems. These techniques include the total radical-trapping antioxidant parameter method (TRAP), the oxygen radical absorbance capacity method (ORAC), and the Trolox equivalent antioxidant capacity method (TEAC). McAnalley et al. (27A70) have provided descriptions and applications of these (and other) methodologies for the determination of free radicals in biological media. Sanchez-Moreno (27A103) concludes that "in spite of the diversity of biological methods, there is a great need to standardize measurements of antioxidant activity."

Sophisticated ESR instrumentation is now becoming available that allows for the direct study of free radicals and free radical damage in living systems. In 2006, Hirata and Fujii (27A46) reviewed newly developed technologies in ESR spectroscopy and imaging equipment that are useful for

the analysis of free radicals in living (biological) systems. Automatic control techniques used for a continuous-wave ESR spectrometer were discussed. Recent developments in time-domain ESR spectroscopy were also reported. Time-domain ESR spectroscopy is a technically challenging method but can be very useful for the detection of free radicals with very short relaxation times in biological tissues. ESR imaging techniques were also reviewed which are able to visualize free radicals in animal subjects noninvasively. Applications of in vivo ESR spectroscopy and imaging for the detection of free radicals generated in biological specimens is another emerging field especially designed for the noninvasive direct detection of free radicals in biomedical applications. Shulaev and Oliver (27A104) and Tarpey et al. (27A113) have also recently written reviews on ESR methods for the detection of reactive oxygen- and nitrogen-centered free-radical metabolites in in vitro and in vivo systems employing metabolic and proteomic markers for oxidative stress.

Additional articles, reviews, and books on ESR and methodologies to detect and measure reactive free radicals in vitro and in vivo in plants and animals have been written by Khan and Swartz (27A58), Khan et al. (27A59), Bacic and Mojovic (27A03), Muckenschnabel et al. (27A75), Halliwell and Whiteman (27A43), Utsumi and Yamada (27A116), Utsumi et al. (27A117), and Halliwell and Poulsen (27A42).

The newest methodologies for the detection, quantification, and identification of free radicals in cigarette smoke employ HPLC and high-resolution MS analysis of stable radical adducts [Bartalis et al. (27A05)], hyphenated LC-MS/MS techniques with a C18 reverse-phase column fitted to a triple quadrupole instrument for analysis of stable radical adducts [Rolando et al. (27A99, 27A100)], and electrospray ionization (ESI)–HPLC/MS analysis of stable radical adducts [Masselot et al. (27A68, 27A69)].

27.3 FREE RADICALS IN TOBACCO SMOKE

Tobacco smoke contains free radicals. As presented in previous chapters, tobacco smoke is a highly complex aerosol composed of more than 5000 components distributed between the vapor and the particulate phases. The enormous complexity of cigarette smoke is the result of multiple thermolytic processes that occur in heated tobacco within the confines of the burning cigarette rod. These processes involve distillation, pyrolysis, and combustion and are influenced by several factors including the design of the cigarette [Norman (27A82)] and the composition of the tobacco blend [Bokelman and Ryan (385), Leffingwell (2338)]. As indicated in the preceding Chapters 1 through 21, numerous classes of organic compounds are represented in cigarette smoke including saturated, unsaturated, and polycyclic aromatic hydrocarbons (PAHs), alcohols, aldehydes, ketones, carboxylic acids, esters, phenols, nitriles, *N*-nitrosamines, terpenoids, and alkaloids [see also Baker (172), Dube and Green (1067), Hoffmann et al. (1744)]. Invariably, the combustion of tobacco, like that of any organic matter, also produces free radicals via oxidative processes involving homolytic reactions. The high temperatures produced during the smoking process are easily capable of causing bond scissions that lead to free-radical production [Badger et al. (141), Brown (27A14)].

An elaborate description of the fluctuating thermal gradients and vapor environment inside a cigarette during smoking has been given by Baker (172). The chemical complexity of cigarette smoke is strongly dependent on the heating conditions inside the lit cigarette. To summarize briefly, when a smoker lights and draws on a cigarette, the temperature of the ignited tobacco rises rapidly, and a hot coal forms at the lit end of the cigarette (the combustion zone and pyrolysis zone). Peak temperatures inside the coal can exceed 900°C. The high temperature inside the coal during a puff causes an increase in the viscosity of the air flowing through the coal and a concomitant increase in the resistance to the draw of air through the cigarette. This effect forces air to be drawn primarily into the periphery of the coal at the paper burn line rather than through the center of the coal. The depletion of oxygen due to combustion inside the coal and the flux of air around the coal results in the formation of a region immediately behind the coal that is depleted of oxygen, but where the temperatures remain high enough to promote the thermal decomposition of the unburned tobacco. This area behind the coal is known as the pyrolysis/distillation zone. Large amounts of volatile and semivolatile smoke constituents evolve from this zone. These constituents result, in part, from the pyrolysis of tobacco and, in part, from the distillation of volatile constituents native to tobacco because of the heat of the encroaching coal. Numerous types of MSS free radicals are formed in this pyrolysis/distillation zone [Wooten et al. (27A120)].

Cigarette smoke can be divided into two phases, particulate- and vapor-phase smoke, by the use of Cambridge filter [Dube and Green (1067)]. The radicals in these two fractions differ greatly. The MSS particulate phase contains more than 10^{17} stable, long-lived radicals per gram of TPM. The vapor phase of smoke contains more than 10^{15} short-lived radicals per puff [Baker (27A04), Wooten et al. (27A120)]. Free radicals in tobacco smoke were initially detected in whole smoke by Lyons et al. (2429). After some years, scientists became interested in examining the population of free radicals in the particulate and vapor phase of MSS. This trend has continued for nearly 45 years. It has not been until recently that it was proposed that artifacts may be forming during the separation of the whole smoke [Culcasi et al. (27A22), Bartalis et al. (27A05)].

27.4 HISTORICAL REVIEW OF FREE-RADICAL RESEARCH ON CIGARETTE SMOKE

The following paragraphs chronologically summarize research reported on free radicals in MSS [Prier (27A84)] and important discoveries that shaped the mechanisms proposed to explain the generation of free radicals in MSS and their possible biological impact. This historical review of

free radicals in cigarette smoke is not exhaustive but attempts to capture much of the fundamental research that has shaped this field of science and gives the researcher ready sources for further examination.

In 1958, Lyons et al. (2429) first observed free radicals by ESR in whole cigarette smoke that was condensed at liquid oxygen temperature. These workers reported that whole cigarette smoke contains two populations of free radicals, an unstable population that can only be observed at −183°C and that vanishes when the condensate is warmed to 60°C, and a persistent, stable population that exists for "several days" at room temperature. They reported that the unstable population accounts for about one-sixth of the total free-radical population determined at −183°C and consists of about 10^{15} free electrons per gram of tar. This work was repeated by Forbes et al. (1211) in 1967 with very similar results.

In a second set of experiments, Lyons and Spence in 1958, studied the effect of extracting benzene solutions of the stable free radicals with water, 2*N* sodium hydroxide, and 2*N* sulfuric acid. They reported that the ESR signal of the stable free radicals was reduced in intensity following each extraction by 20%, 50%, and 57%, respectively. They concluded that whole cigarette smoke contains several different types of free radicals, some of which are very stable while others exist only fleetingly. They also suggested for the first time that free radicals might be involved in the carcinogenicity of cigarette smoke (2432).

In a follow-up study, Lyons and Spence in 1960 reported the detection of free radicals in sidestream smoke (SSS) as well as in MSS. They reported that dried SSS condensate contains 5×10^{14} spins per gram of tar, while MSS condensate contains 6×10^{15} spins per gram of tar. These results were compared to chimney soot and to the condensed exhaust material from diesel-powered automobiles that contain 5×10^{18} and 2×10^{19} spins per gram of material, respectively (2435).

Ingram and Allen in 1959 (1862) and Ingram in 1961 (1861) published two further extensions of earlier work in which the pyrolysis of organic material was related to the production of free radicals detected by ESR. They demonstrated that free-radical production by pyrolysis is a general phenomenon that occurs with various types of hydrocarbons and that the concentration of free radicals produced is proportional to the percent of carbon in the pyrolyzed material. A maximum free-radical concentration was detected at about 90% carbon. They concluded that such a high percentage of carbon is consistent with a PAH and that free electrons must reside within such a structure. Ingram (1861) postulated that the stable free radicals generated from the pyrolysis of tobacco could be benzosemiquinone radicals. He also postulated that PAH free radicals would be present in tobacco smoke condensate.

In 1963, Marsden and Collins (2466) reported on their results from measurements of α-activity in leaf tobacco used for cigarettes marketed in the United Kingdom and in specially made standard size unblended cigarettes made from tobaccos originating from widely separated geographical locations. The origin of free radicals in tobacco smoke was discussed. They speculated on contributions of α-radiation and free radicals in cigarette smoke in the induction of lung cancer.

In that same year, Westermark (4220a) suggested that free radicals generated during smoking could lead to a free-radical chain reaction, which could possibly generate enough free radicals to be carcinogenic.

Wynder and Hoffmann in their lengthy 1964 review of tobacco carcinogenesis (4319) discussed tobacco smoke as a "complete carcinogen" and in their evaluation of the role of tobacco smoke components in experimental carcinogenesis listed radicals with the comment that radicals are "suggested as possible carcinogens in disagreement with the experiments" [see p. 391, Table XXII in (4319)].

Takeshita and Ohe in 1964 published a paper on the effects of aging of cigarette smoke and its relation to radical concentration (3864). In their study, they used the radical scavenger α,α′-diphenyl-β-picrylhydrazyl (DPPH) and were able to detect free radicals in condensed whole smoke from flue-cured tobacco after 300 h, employing a colorimetric method. DPPH is a fluorescent stable free radical and will react with other radicals to form a neutral non-fluorescent hydrazine species. DPPH is not considered a spin trap which generally involves free radical addition to a nitroso function. The reaction produces stable nitroxides which build up to readily detectable concentrations in the presence of a free-radical source. The usefulness of radical addition reactions with nitrones has been found to exceed that of the nitroso compound because of their greater stability in a variety of reaction conditions. Much work has been done with phenyl α-*N*-*tert*-butylnitrone (PBN) in solution, although many new spin adducts are now available. The free-radical addition reaction is called a spin-trapping reaction. The nitrone or nitroso compound is called a spin trap, and the radical addition product is called a spin adduct [Janzen and Gerlock (27A54)].

In 1965, Boenig (369) reported on the pyrolytic products of cigarettes irradiated with ^{60}Co γ-radiation. ESR experiments were not conducted on the tobacco to determine the presence or extent of free radicals, although a reduction in concentration of free radicals in smoke condensate (as measured by ESR) was noted along with reductions in MSS tars and tar-like components. Later in 1975, Severson et al. (3610) conducted studies on γ irradiation of cigarettes and concluded that γ irradiation had no major effects on smoke composition. Their study negated the possibility of decreased formation of PAHs as a result of fewer free radicals and other suggested changes in smoke chemistry.

Boenig reviewed the literature on free radicals and health in 1966 (370, 371). In his reports, he considered the fundamental processes involved in the pyrolysis of tobacco during smoking, i.e., distillation, steam distillation, thermal oxidation, decomposition, and thermal cracking (thermal cracking apparently playing a major role in this combustion). He emphasized that thermal cracking probably is the most important step, during which free radicals are formed.

Interaction of a considerable proportion of these free radicals then leads to the formation of various types of molecules including the PAHs. He proposed a mechanism that would explain the formation of PAHs from various tobacco constituents and a variety of small reactive free radicals, e.g., NO, hydroxyl, alkyl. Later that year, he authored a paper in which he proposed a unifying concept that free-radical exposure and health are intimately linked (372).

Browning and Patton presented a paper at the *20th Tobacco Chemists' Research Conference (TCRC)* in 1966 on a quantitative analytical procedure to determine stable free radicals in tobacco smoke condensate by ESR (448). Their analytical method for the determination of stable free radicals in tobacco smoke condensate was generally applicable to all types of tobacco tars. Accuracy for the method was based upon standard coal reference samples that yielded 7.52×10^{16} spins/g of tar. The experimental precision was 10%. They discussed the limitations (heating effects, sample isolation and concentration, solvent effects) and utility of the method.

In 1966, Forbes reported on the role of free radicals in tobacco smoke carcinogenesis (1210). In that publication, he concluded that tobacco smoke condensates contained a variety of free-radical species that had a broad range of stability. Some of the free radicals had lifetimes of only a few seconds, while others are stable over long periods of time. The chemical nature of the radicals formed in tobacco smoke was not fully identified. Forbes postulated that some of the free radicals formed resembled radicals obtained from benzo[*a*]pyrene.

In 1967, Forbes et al. further examined free radicals present in tobacco smoke condensates by ESR (1211). They prepared and examined sulfuric acid solutions of smoke condensates. They reported that the free-radical species present in sulfuric acid solutions of smoke condensates corresponded to a modified benzopyrene-type cation radical and to the spectrum of a modified anthracene cation radical, with the latter decaying fairly rapidly. No definitive proof was given for these two cation radicals.

Rowlands et al. (27A101) studied the effect of MSS free radicals on the tissue of perfused rabbit lungs in 1967. The lungs were removed from the animals and attached to bell jars that were used to simulate the breathing operation. The animal blood was circulated through the veins and arteries attached to the lung while smoke were periodically drawn into the lung. The blood was then sampled and studied by ESR. They found a three-line ESR spectrum superimposed on a second broad singlet. They theorized that a covalent, hexa-coordinated ferric hemoglobin complex explained the ESR spectra.

In 1968, Rowlands et al. (27A102) published an extension of their previous work in which the reaction of cigarette smoke condensate (CSC) with hemoglobin was studied in more detail. In addition, the electron transfer properties of the smoke condensate were studied. The involvement of the oxides of nitrogen in the free-radical properties of the smoke was suggested by a selective condensation experiment in which the smoke was fractionated at various temperatures and the various condensates reacted with hemoglobin.

Cooper et al. published a paper (814) in the 1968 National Cancer Institute monograph "Toward a less harmful cigarette" (4343) in which they suggested that free radicals in MSS were possible contributors to tobacco smoke carcinogenesis. They summarized research from the previous decade on free radicals in tobacco smoke and discussed the possible role of free radicals as a cause of cancer (814). It should be noted that as early as 1954, Dorn reviewed the published experimental evidence that indicated that the products formed by the combustion of tobacco may cause skin cancer in mice. He stated that compared to other known carcinogens, the combustion products of tobacco smoke are relatively weak (27A30).

In their 1967 book, Wynder and Hoffmann [see pp. 461–463 in (4332)] briefly described the studies on cigarette smoke free radicals conducted up to that time. Summing up the available evidence, they wrote:

> Several facts seem to exclude an importance of radicals in tobacco smoke condensate carcinogenesis. Even though sidestream smoke condensate contains only about one tenth the amount of free radicals found in the mainstream smoke condensate, the tumor response of both sidestream and mainstream "tar" on mouse skin is not different statistically … Since both types of radicals are present mainly in the particulate matter, it remains questionable whether in freshly generated tobacco smoke organic radicals participate in the carcinogenic effect.

During 1968, Stedman wrote his review on the chemical composition of tobacco and smoke (3797). In his review, he summarized much of the prior work on free radicals in MSS. At that time, no free radicals in tobacco or tobacco smoke had been identified. As free radicals were considered to be playing some role in the induction of cancer, efforts were concentrated on determining the quantity of free radicals in smoke and their stability.

In 1961, Larson et al. (2264) published their book on experimental and clinical studies on tobacco. Free radicals in smoke were not mentioned. However, in Supplements I, II, and III, issued successively in 1968, 1971, and 1975, respectively, Larson and Silvette (2266) summarized reported research on free radicals in tobacco smoke. In the nearly 800-page 1968 Supplement I, they reviewed the free-radical findings of Lyons and Spence (2432), Ingram (1861), Ingram and Allen (1862), and Westermark (4220a) in a few paragraphs. In the over 500-page 1971 Supplement II, Larson and Silvette summarized the findings on free radicals in tobacco smoke by Boenig (370, 371), Peacock and Spence (27A82b), and Cooper et al. (814) in less than a page. In the nearly 800-page 1975 Supplement III, their only reference to radicals in tobacco smoke was in two separate paragraphs on a study by Dontenwill et al. (1046a) in which the specific tumorigenicities of the CSCs from control and tobacco treated with *n*-propyl gallate were compared. The *n*-propyl gallate was a known scavenger of free radicals. No tumorigenic difference was observed.

During 1969, Rathkamp and Hoffmann (3086) reported on the inhibition of the pyrosynthesis of several selective

smoke components. They suggested from the results of their pyrolysis studies on tobacco containing KNO_3 or I_2 that PAHs are at least partially formed via C and H free radicals.

In 1969, Tully et al. (27A115) were the first authors to publish a study of the free radicals in the vapor phase of MSS cigarette smoke that was condensed at liquid oxygen temperature. The condensed vapor phase of MSS produced no ESR signal until the temperature of the ESR cavity holding the sample was raised to −100°C. At this temperature, a three-line ESR spectrum was obtained that had nitrogen splitting [a(N)] of 1.26 mT. For cigarettes made with tobacco that contained 3.4% copper nitrate by weight, a complex ESR spectrum consisting of at least 17 lines was observed. The three-line spectrum from the untreated tobacco increased to a maximum intensity after 1.5 h at −100°C. When warmed to room temperature, the ESR signals observed at −100°C vanished irreversibly. These authors concluded that the observed free radicals may have formed as a result of some unspecified participation by nitrogen oxides (NO_x) in free-radical reactions within the smoke. Interestingly, nitrogen dioxide (NO_2), itself a free radical, adds to olefinic double bonds to produce carbon-centered free radicals [Estefan et al. (27A35)]. ESR spectra taken on solutions of NO_2 mixed with different olefins show three-line spectra that are very much like those observed by Tully et al. (27A115). In each case, a three-line spectrum with a(N) = 1.22–1.33 mT is obtained [Estefan et al. (27A35), Bielski and Gebicki (27A09), Pryor et al. (27A91)].

Short-lived particulate- and vapor-phase free radicals that cannot be measured directly by ESR can be measured with the aid of spin traps. The first application of spin trapping to the study of free radicals in tobacco smoke was reported in 1971 by Bluhm et a1. (349). MSS from commercial cigarettes, pipes, and cigars was bubbled through solutions of PBN in benzene (a spin trap). In each case, a doublet of triplets with a(N) = 1.376 and a(H) = 0.199 mT was obtained along with a triplet with a(N) = 0.801 mT. The former splittings were assigned to an alkoxyl free-radical adduct of PBN, while the latter signal was assigned to benzoyl *tert*-butyl nitroxide ($PBNO_x$). The intensity of the spin-adduct signal from cigarette smoke was the weakest, while that from cigars was the strongest. The identity of the specific alkoxyl radical was not determined.

Bilimoria et al. investigated the inhibition of radical-initiated polymerization of vinyl acetate by tobacco smoke and some PAHs in 1973 (329). Their results indicated that vapor phase of smoke is an efficient inhibitor of vinyl acetate polymerization and that conjugated dienes like isoprene are responsible for the inhibition. There were no free radicals from tobacco smoke specifically identified in this research. Nisbet and Schmeller presented the results of this research at the *27th TCRC* in 1973 (2789a).

At that same TCRC in 1973, Johnson (1956) presented a paper on the antioxidant activity of tobacco smoke. The investigation was undertaken to determine whether or not smoke initiates or promotes the formation of radical peroxides which would in turn lead to lipid peroxidation. He found that both the vapor phase and particulate phase of smoke behaved as an antioxidant. Fractionation of the total smoke condensate showed antioxidant activity in the neutral and water-insoluble acidic fractions, with virtually no activity in the basic fractions. The mode of antioxidant action of tobacco smoke was discussed in terms of free-radical mechanisms involving atom transfer, addition, substitution, and coupling.

De Hys et al. in 1973 (27A25) studied the spin trapping of free radicals in the filtered MSS of 1R1 research cigarettes. They obtained spin-adduct spectra that did not exhibit hydrogen splitting, although the three-line spectra were very broad (the hydrogen splitting was not resolved). They reported that smoke held in the syringe for 15 s before being bubbled through the PBN solution showed no change in spectral features, while smoke held in the syringe for 30 s resulted in a 50% decrease in the spin-adduct spectral intensity. These authors also found that spin-trapping unfiltered smoke resulted in no spin-adduct spectrum. Experiments were also performed using 2-nitrosotoluene and 5-nitroso-8-quinolinol as spin traps. In the first case, a three-line spectrum was obtained with a(N) = 1.56 mT, while the second spin trap gave no spin adduct. No attempt was made to identify the free radical trapped with 2-nitrosotoluene. These results indicate that time and smoke filtration impact free-radical collection and measurement.

NO_2 was bubbled through a solution of PBN in benzene and the resulting solution studied by ESR. A strong three-line ESR spectrum with a(N) = 1.0 mT was observed. Smoke bubbled through cyclohexene produced no ESR signal, although NO_2 can react with olefins to give the three-line spectrum described previously (27A35, 27A09, 27A91). These authors concluded that the free radicals in the vapor phase of cigarette MSS have half-lives of about 30 s and that NO_2 is not the dominant free-radical species responsible for production of spin adducts from cigarette smoke.

In 1974, Morie evaluated the effectiveness of free-radical traps in cellulose acetate filters for the removal of nitrogen oxides from cigarette smoke (2625). Four free-radical spin traps were tested as cigarette filter additives for the removal of nitrogen oxides from tobacco smoke. A filter consisting of cellulose acetate fibers containing 20 mg of 4-(3,5-di-*tert*-butyl-4-hydroxybenzylidene)-*tert*-butylamine *N*-oxide removed 42% of the nitrogen oxides from cigarette smoke. Three other free-radical traps when placed on cellulose acetate fibers or activated carbon within cigarette filters reduced the concentration of nitrogen oxides in the smoke to a lesser extent. The mechanism proposed by Morie for the removal of nitrogen oxides was that the free-radical spin trap reacted with a free radical in the tobacco smoke to yield a long-lived nitroxide radical, which in turn reacts with nitrogen oxides in the smoke.

A spin-trapping study of the free radicals in the MSS from 1R1 research cigarettes was performed by Menzel et al. in 1976 (27A72). These authors used spin-adduct spectral line broadening to determine that the MSS vapor-phase results in 1×10^{18} spin-trapped free radicals per cigarette puff (about 10^{19} spins/g of tar produced). Using spin-trap solutions in series, they estimated the efficiency of spin trapping of the

tobacco smoke free radicals with PBN to be about 47%. They obtained extremely broad spectral lines (by ESR) showing no hydrogen splitting. Their results were somewhat suspect as the spin-adduct concentration that they obtained (2×10^{19} spins/g) was much larger than any other free-radical concentration reported before or since (2429, 2435, 27A95).

During 1976, Pryor edited and contributed to a book on free radicals in biology (2998a). In that book, he authored a paper on the role of free radicals in biological systems where he discussed free radicals in cigarette smoke and the possible action of free radicals in smokers.

A comprehensive study of free radicals in the vapor phase of MSS produced by 1R1 research cigarettes was reported in 1976 by Pryor et al. (27A95). Using three different spin traps, PBN, 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO), and 3,5-(di-*tert*-butyl-4-hydroxyphenyl)-*N*-*tert*-butylnitrone (OHPBN), they found that MSS produces three types of spin adducts: an alkoxyl or aroyloxyl spin adduct, $PBNO_x$, and an unknown adduct with $a(N) = 1.00$ mT. They reported that the intensity of the alkoxyl adduct increases with the distance that the smoke must travel from the cigarette to the spin-trap solution and then decreased thereafter. They called this phenomenon the path length effect. The concentration of spin-trapped free radicals was found to be about 1×10^{15} spins/g of tar. In addition, the effect of aging on the absolute and relative concentrations of the spin adducts was studied. The conditions of collection also had an impact on free-radical measurement. Their data did not allow them to specify the identity of either the aromatic group in the aroyloxy ($ArCO2^{\bullet}$) radical or the alkyl group in the alkoxy ($RO^{\bullet}$) radicals.

Ishiguro and Sugawara published their review on chemistry of tobacco smoke in 1980 (1884). This was the last major review of compounds identified in tobacco smoke. In their massive report, they reviewed the literature on free radicals in tobacco smoke. There were no identified free radicals specifically mentioned in their review. They stated that:

> The study of radicals in smoke has not advanced very far because of the difficulty of identifying the radicals. It is hoped that further progress will be made in this field so that the formation routes of many components can be understood and the composition of smoke components can be better controlled.

In a paper written in 1982 entitled "Free radical biology: Xenobiotics, cancer, and aging," Pryor suggested that free radicals in cigarette MSS could pose a significant health risk to smokers (2998b). In that paper, he proposed several complicated interactions between MSS components, e.g., NO, dienes, phenols, and free radicals that he believed were operative means leading to carcinogenesis.

In 1983, Slaga et al. suggested that free radicals may be involved not only in initiation but also in the promotion of carcinogenesis (3687).

In 1983, using ESR spin-trapping techniques with PBN as the spin trap, Pryor et al. (2999a) observed free radicals in the vapor phase of both cigarette MSS and SSS. The principal vapor-phase free radicals appeared to be alkoxyl radicals ($RO^{\bullet}$). Pryor et al. determined that each of the vapor phases of cigarette MSS and SSS has about the same concentration of radicals, about 1×10^{16} radicals/cig (or 5×10^{14} per puff) (2999a).

In that same year, Pryor et al. (2999) examined and found that the particulate matter from both MSS and SSS contained persistent free radicals. The ESR signal was obtained when the particulate matter collected on Cambridge pads was measured directly and when the particulate matter was extracted from the Cambridge pad with various solvents. Pryor et al. listed the occurrence of four paramagnetic radical species in CSC. Three of these radicals, an inorganic phosphorus radical, a graphitic carbon associated radical, and a radical that appeared associated with an odd electron delocalized over an aromatic ring system, appeared to have relatively short half-lives. However, the fourth type of free radical had an unusually long half-life of several days. It was speculated that the dominant ESR signal from this fourth type was from free radicals generated from catechol and hydroquinone (HQ). Neither of these free radicals was unequivocally identified (2999). Treatment of alcoholic solutions of particulate matter with base generated a new group of radicals that appeared to be semiquinone radicals derived from the oxidation of phenolic and polyphenolic species in the particulate matter. Pryor et al. suggested this latter radical was associated with a quinone (QH)/HQ acceptor/donor chain (2999). Again, the identification of the specific free radicals was not obtained.

In these two papers and again in 1984 (3001), Pryor et al. suggested the possible involvement of particulate-phase MSS free radicals in smoking-related diseases (2999, 2999a). In vitro assays were performed that suggested that cigarette smoke may cause oxidative stress or oxidative damage to essential biological molecules (3000, 27A120). Specifically in 1984, ESR evidence of the binding of the particulate-phase MSS free radicals to DNA and polynucleotides was shown (3001).

In the 1984 American Chemical Society monograph on chemical carcinogenesis, edited by Searle (3568) and with contributions from experts in carcinogenesis, there was no mention on the carcinogenicity of free radicals, nor any tumorigenic PAH or aza-arene in tobacco smoke despite the reports by Snook et al. (3756–3759, 3750, 3752, 1544, 3664, 3665, 3908).

In 1985, Nakayama et al. published a report that described the generation and identification of H_2O_2 and superoxide anion radical from cigarette smoke (2677). H_2O_2 and superoxide anion radical were generated in a neutral buffer solution through which cigarette smoke was bubbled. They speculated that the H_2O_2 may have been formed by the autoxidation of polyphenols such as catechol and HQ in the cigarette smoke.

During 1985, Halpern and Knieper isolated and tentatively identified the *tert*-butoxy radical by the spin trapping of radicals in the vapor phase of cigarette smoke (27A44).

Cosgrove et al. in 1985 (828a) showed that it was possible to detect hydroxyl radicals in an aqueous extract of the particulate phase of cigarette MSS under metal-mediated conditions. An unidentified alkyl radical and the carbon dioxide

anion radical were also observed under their experimental conditions. They concluded that the results of their experiment indicated that the major particulate-phase free radical was a QH/HQ redox system in a polymeric matrix and that the radical signal could become associated with DNA. Unequivocal proof was not provided for these claims.

Church and Pryor in a 1985 publication (746) summarized their work (to that point) on the free-radical chemistry of cigarette smoke and its toxicological implications. They stated that cigarette smoke contains two very different populations of free radicals, one in the particulate phase and one in the vapor phase. The particulate phase contains several relatively stable free radicals. Church and Pryor stated that they had "identified" the principal radical as a Q/QH_2 complex held in the tarry matrix. However, no unequivocal identification was ever made. They suggested that this Q/QH_2 complex was an active redox system that is capable of reducing molecular oxygen to produce superoxide, eventually leading to H_2O_2 and hydroxyl radicals.

In that same publication, Church and Pryor (746) stated that the vapor phase of cigarette smoke contains small oxygen- and carbon-centered radicals that are much more reactive than the particulate-phase radicals. Although no vapor-phase radicals were specifically identified. They stated that the vapor-phase radicals do not arise from the initial combustion of the tobacco but are rather produced in a steady state by the oxidation of NO to NO_2, which then reacts with reactive species already present in smoke, such as isoprene. They suggested that these reactive vapor-phase free radicals and the metastable products derived from these radical reactions may be responsible for the inactivation of α1-proteinase inhibitor by fresh smoke.

Church and Pryor (746) proposed that the excess superoxide that is expected to form in lung tissue exposed to cigarette smoke is one possible means of inactivating α1-protease inhibitor, a protein associated with the onset of emphysema in deficient individuals. In the same report, the authors noted that after particulate-phase MSS was incubated with deoxyribonucleic acid (DNA), an ESR signal was observed in the recovered DNA. Later, it was suggested that hydroxyl free radicals generated from the particulate-phase MSS free radicals may cause DNA damage [Kiyosawa et al. (27A60), Pryor (27A85), Pryor et al. (27A93)]. Later in 1992, Pryor (27A85) noted that such molecular damage is not unique to tobacco smoke but also occurs with smoke from other sources such as diesel fuel and wood.

In 1986, Pryor wrote a paper on the formation, lifetimes, and reactions of oxy-radicals and related species (2998c). In his overview, he discussed some of the ways in which free radicals and other highly reactive species are produced in biological systems. He discussed the reactivity and lifetimes of these species and listed some pathological conditions and chronic diseases in which these species may be involved. He discussed that cigarette smoking is a rich source of free radicals and that much of the toxicity associated with cigarette smoking may be due to the presence of free radicals in MSS.

In 1986, the International Agency for Research on Cancer (IARC) issued its monograph on tobacco smoking (1870). Free radicals in tobacco smoke were discussed as follow:

> Smoke can be a major indirect or direct source of chemical oxidants and radicals, and also causes a rapid influx of pulmonary alveolar macrophages and polymorphonuclear neutraphils in the lung. These actively phagocytic cells release a variety of oxidative intermediates when exposed to particulates such as those in cigarette smoke. The intermediates found in cigarette smoke and/or released by activated macrophages include superoxide anion, hydrogen peroxide and hydroxyl radical …

Other than referring to the article on free radicals in cigarette smoke by Church and Pryor (746), IARC cited none of the many other pre-1986 references to free radicals in tobacco, e.g., Bilimoria et al. (329), Bluhm et al. (349), Boenig (370–372), Browning and Patton (448), Cooper et al. (814), Cosgrove et al. (828a), Forbes (1210), Forbes et al. (1211), Ingram (1861), Ingram and Allen (1862), Lyons et al. (2429), Lyons and Spence (2432, 2435), Marsden and Collins (2466), Morie (2625), Nakayama et al. (2677), Nisbet and Schmeller (2789a), Pryor (2998a, 2998b), Pryor et al. (2999, 2999a, 3001), Slaga et al. (3687), and Takeshita and Ohe (3864).

During the 1980s, R.J. Reynolds Tobacco (RJRT) Company developed a new cigarette product called Premier that heated rather than burned tobacco. A tremendous amount of research was conducted on that product prior to introduction. The research on Premier was summarized in a monograph by RJRT (3190). Free-radical analyses comparing the Premier product and University of Kentucky 1R4F reference cigarette were conducted by Rice and Hayes in 1989 (1555c, 3129). In two studies, Rice and Hayes reported that Premier had a 99% reduction in vapor- and particulate-phase free radicals compared to the 1R4F reference cigarette. Similar ESR spectra were obtained, but the yields of radicals in both phases were decreased. In the 1R4F cigarette, the particulate-matter free radicals appeared to be from species with an odd electron delocalized over an aromatic ring system, e.g., a PAH. The second source of particulate-matter free radicals appeared to come from what Church and Pryor (746) suggested was a donor/acceptor chain involving HQ as the donor and QH as the acceptor. ESR analysis of 1R4F vapor phase indicated the presence of radical species similar to those previously reported for tobacco-burning cigarettes. No identification of specific free radicals was conducted in these studies.

In 1988, O'Brien (27A82a) discussed the fate of free radicals and their effect on chemical carcinogenesis. Only one comment was included on cigarette smoke, and it involved the PAH B[*a*]P in MSS and the assertion of its involvement in lung cancer induction. O'Brien stated that PAHs like B[*a*]P donate a single electron to an enzyme which may be involved in the generation of tumorigenic diol epoxides of the PAH.

In 1989, Nakayama et al. (27A79) reported on a reliable method for the detection and quantitation of H_2O_2 generated

in aqueous extracts of cigarette smoke tar. Aqueous tar extracts (ACT) were passed through a short reverse-phase column, and the H_2O_2 concentration was determined by differential pulse polarography using an automatic reference subtraction system. The H_2O_2 concentration in the ACT increased with aging, pH, and temperature; the presence of SOD led to lower H_2O_2 concentrations. Their method was applied to several types of research and commercial cigarettes. They reported that, with few exceptions, the amount of H_2O_2 formed after a fixed time from each cigarette smoke was proportional to its tar yield.

Brunmark and Cadenas (27A15) reviewed the major mechanisms that are involved in QH-induced cytotoxicity in 1989. The redox chemistry of quinoid compounds was surveyed in terms of (1) reactions involving only electron transfers, as those accomplished during the enzymatic reduction of QHs and nonenzymatic interaction with redox couples generating semiquinones, and (2) nucleophilic addition reactions. In their explanation of the mechanisms involved, QH is reduced to the HQ or semiquinone radical by cellular reductase. The semiquinone radical then undergoes rapid autoxidation with the generation of the parent QH and concomitant formation of superoxide. The HQ reacts rapidly with superoxide to form H_2O_2 and the semiquinone.

In 1992, Pryor (27A85) reviewed, compared, and contrasted the chemistry of cigarette smoke, wood smoke, and the smoke from plastics and building materials that was inhaled by persons trapped in fires. He contended that cigarette smoke produced cancer, emphysema, and other diseases after a delay of years. He discussed that acute exposure to smoke from a fire could produce a loss of lung function and lead to death after a delay of days or weeks. Tobacco smoke and the smoke inhaled in a burning building have some similarities from a chemical viewpoint, e.g., both contain high concentrations of CO and other combustion products. In addition, both contain varied concentrations of free radicals, which if inhaled could lead to biological harm (27A65). At this time, personnel in Pryor's laboratory had studied these free radicals, largely by ESR methods, for about 15 years. The article reviewed what was known about the radicals present in these different types of smokes, soots, and tars. His article summarized the evidence that suggested that free radicals could be involved in cigarette-induced pathology and smoke-inhalation deaths.

In 1993, Diana and Pryor edited a book entitled *Tobacco Smoking and Nutrition: Influence of Nutrition on Tobacco-Associated Health Risks* (960c). In that book, Pryor and Stone wrote a chapter on oxidants (free radicals, H_2O_2, peroxynitrate, and peroxynitrite) in cigarette smoke (3000). They reported that methyl nitrite (CH_3ONO), NO, and NO_2 were primary oxidants in the vapor phase of MSS and that the proposed QH/semiquinone/HQ equilibrium complex was the primary oxidant in particulate-phase MSS. They postulated that peroxynitrite (HOO-N=O) and/or peroxynitrate (HOO-NO_2) or their esters (RO-ONO and RO-ONO_2) were present in the vapor phase of MSS. They argued that hydroxyl radicals were generated from H_2O_2 via the Fenton reaction (27A36), that carbon-centered radicals were generated from dienes in MSS and that peroxyl radicals ($ROO^{\bullet}$), alkoxyl radicals ($RO^{\bullet}$), and superoxide radicals ($O^{\bullet -}$) were present in the vapor phase of MSS. In that same book, Niki et al. in 1993 reviewed information on membrane damage from lipid oxidation by free radicals in cigarette smoke (2786a).

Cigarette smoke contains metals and metal ions (see Chapter 20). Certain metal ions are important in free-radical reactions, e.g., Fenton-type metal-catalyzed free-radical reactions. In 1993, Li and Trush (27A67) reported on the oxidation of HQ by copper and provided chemical mechanisms for the generation of QH species and their biological effects. Since the interaction of several xenobiotics with copper had been shown to result in their metabolism, Li and Trush investigated the role of copper in the oxidation of HQ and HQ-induced toxicity to mice bone marrow stromal cells, target cells of HQ in the bone marrow. In phosphate-buffered saline, HQ underwent autoxidation slowly to benzoquinone (BQ), while the presence of Cu^{+2} ions (1–50 μM) strongly accelerated the oxidation of HQ to BQ in a concentration-dependent manner. Reaction of HQ with Cu^{+2} was also accompanied by the reduction of Cu^{+2} to Cu^{+1}, the utilization of O_2, and the concomitant generation of H_2O_2. Their results indicate that Cu^{+2} strongly induced the oxidation of HQ and as such may be a factor involved in the oxidative activation and toxicity of HQ in target cells. As copper, HQ and BQ are known components of MSS, the relevance of the work of Li and Trush became important in light of the postulated mechanism of Pryor and Stone (3000).

Cueto and Pryor in 1994 (27A21), following up on the report by Pryor and Stone in 1993 (3000), reported their work on the conversion of NO to NO_2 by Fourier Transform IR. They also reported their results on the reactions of olefins with nitrogen oxides. In order to explain the apparent longevity of the presumably short-lived free radicals in aging filtered smoke, a steady-state production mechanism was proposed involving oxygen, nitrogen oxides, and vapor-phase olefins. No specific reaction products were discussed.

Tanigawa et al. (27A112) published a paper on the spin trapping of superoxide in aqueous solutions of fresh and aged cigarette smoke in 1994. Superoxide generation was determined as a function of the age of the smoke using spin trapping. DMPO was used as the spin trap. The superoxide adduct of DMPO was detected in a solution of fresh MSS for over 1 h. The superoxide-generating potential of smoke was rapidly lost as the smoke was kept in a plastic syringe. Smoke aged for 3 min did not generate superoxide. Additional evidence of superoxide generation in aqueous solutions of cigarette smoke was obtained by the chemiluminescence method.

Church in 1994 (27A19) published an article on the spin trapping of organic radicals. In that article, he postulated a steady-state mechanism that he believed explained the formation of longer-lived vapor-phase free radicals in cigarette MSS.

The proposed mechanism was based on the observation that NO_2 concentration in MSS followed the concentration of the free radicals in the vapor phase of MSS.

In 1995, Stone et al. (27A111) reviewed the previous work conducted in the laboratories of Pryor which showed that extracts from MSS or SSS nicked DNA. These solutions were believed to contain the semiquinone free radical. Aged solutions of catechol containing a semiquinone species that had ESR properties similar to those of the radical in cigarette tar extracts were used as a model for the MSS particulate-phase radical. Both the radical in aged catechol solutions and the cigarette tar radical become associated with the DNA in mammalian cells and nicked DNA. The nicking of DNA caused by both the MSS particulate-phase radical and aged catechol solutions followed saturation kinetics. The authors believed that aged catechol solutions could be used as a model for the MSS particulate-phase radical. Unfortunately, their model did not take into account the fact that MSS is a complex mixture and that other constituents in MSS could have altered their finding.

Stohs and Bagchi (27A109) reviewed the role of ROS, with the subsequent oxidative deterioration of biological macromolecules in the toxicities associated with transition metal ions in 1995. Studies have shown that metals, including iron, copper, chromium, and vanadium, undergo redox cycling and that this cycling can result in the production of ROS such as superoxide ion, H_2O_2, and hydroxyl radical. As a consequence, lipid peroxidation can be enhanced, DNA can be damaged, and calcium and sulfhydryl homeostasis can be altered. Various studies have suggested that the ability to generate ROS by redox cycling QHs and related compounds may require metal ions. Cigarette MSS contains metal ions. Some mechanisms associated with the toxicities of metal ions are very similar to the effects produced by many organic xenobiotics. Specific differences in the toxicities of metal ions may be related to differences in solubility, the complex mixture containing the metal, absorbability, transport, chemical reactivity, and the complexes that are formed within the body. Their review summarized studies (through 1995) that had been conducted with transition metal ions, regarding the production of ROS and oxidative tissue damage.

In 1995, Li et al. (27A66) reported on ESR evidence for the generation of ROS from the copper-mediated oxidation of the benzene metabolite, HQ, and its possible role in DNA damage. Prior to this study, Li and Trush (27A67) had observed that Cu^{+2} strongly induces the oxidation of HQ, producing BQ and H_2O_2 through a Cu^{+2}/Cu^{+1} redox cycle mechanism. The oxidation of HQ by Cu^{+2} also resulted in plasmid DNA cleavage. In this study, using ESR spectroscopy, they investigated whether this chemical-metal redox system could generate ROS which induce DNA damage. Studies were not performed with cigarette MSS but were conducted on solutions of HQ. Results indicated that both H_2O_2 and Cu^{+1} are critical for the formation of reactive oxygen from the HQ/Cu^{+2} systems. Aerobic conditions were necessary for the redox system to function. Reactive oxygen scavengers significantly inhibited the redox mechanism. Overall, the results indicated that it is possible, through a copper-redox cycling mechanism, to generate a ROS of HQ that may participate in DNA damage. The conditions of the experiments were not those that a smoker would experience.

Zang et al. investigated the presence of free radicals in ACT by ESR (27A122) in 1995. They demonstrated that ACT autoxidized to produce semiquinone, hydroxyl, and superoxide radicals in air-saturated, buffered aqueous solutions. Semiquinone species were detected by direct ESR measurements and were tentatively identified as *o*- and *p*-benzosemiquinone radicals by comparison with the ESR signals of catechol and HQ radicals under similar conditions. The rate of formation of these radicals was dependent on pH. Hydroxyl and superoxide radicals were detected as DMPO spin adducts by ESR spin trapping. SOD (20 units/mL) inhibited the formation of the superoxide spin adduct of DMPO completely. Addition of Fe^{2+} to this system increased the ESR signal intensity of hydroxyl radical spin adduct of DMPO. Their results indicated that superoxide and hydroxyl radicals are produced during the autoxidation of HQ- and catechol-related species in ACT under the specific conditions of their experiments.

Borgerding et al. (27A13) presented a paper at the 1995 TCRC on a method for the quantitative determination of free radicals in the vapor phase of cigarette MSS. The method was based on trapping free radicals in a PBN/benzene solution to form a stable radical species, i.e., spin trapping, followed by detection with an ESR spectrometer. Two smoke collection techniques were discussed which differed in the extent of smoke aging prior to spin trapping. Both techniques were found to be acceptable for the comparison of cigarette smoke yields. Free-radical analysis of the vapor phase of MSS from cigarettes which contained a novel carbon filter and experimental low *N*-containing tobacco blend demonstrated that vapor-phase free-radical reductions on the order of 80% were possible when compared to other equivalent "tar" cigarettes.

At the same conference in 1995, Blakley et al. (27A10) reported the results of their studies on MSS vapor-phase radical formation and possible formation mechanisms. Church and Pryor (746) had previously suggested a mechanism for formation of mainstream vapor-phase radicals that involved a reaction between NO_2 and reactive dienes, such as isoprene. Experiments were conducted to systematically explore the Church–Pryor proposed mechanism. Included in the experiments were cigarettes from different "tar" categories, cigarettes comprising a new type of carbon filter [Blakley et al. (27A12)] and blends, and cigarettes that primarily heated, rather than burn tobacco. Some results indicated that the suggested NO_2/diene mechanism was viable, while other results did not support the Church–Pryor mechanism. For many of the cigarettes studied, vapor-phase radical yields increased as either isoprene or NO_x smoke yields increased. (It should be noted that in 1978, Cooper and Hege (816) reported that there is very little NO_2 in cigarette smoke, most of the NO_x is NO.) However, in a series of experimental cigarettes where isoprene yield was held constant and NO_x levels substantially increased, vapor-phase free radicals were dramatically reduced.

In addition, preliminary research suggested that some processed tobaccos yielded diminished radicals as compared to unprocessed tobaccos, while NO_x smoke concentrations remained constant. Data were also presented on a cigarette constructed from wood shavings that produced a substantial free-radical response with virtually no isoprene or NO_x present in the smoke.

Rahman and MacNee (27A96, 27A97) reviewed the literature in 1996 on the imbalance between oxidants and antioxidants concerning the pathogenesis of smoking-induced lung diseases, such as chronic obstructive pulmonary disease (COPD), particularly emphysema. There was evidence that indicated that increased neutrophil sequestration and activation occurred in the pulmonary microvasculature in smokers and in patients with COPD, with the potential to release ROS. ROS generated by airspace phagocytes or inhaled directly from the environment can increase the oxidant burden and may contribute to the epithelial damage. Although much research has focused on the protease/antiprotease theory of the pathogenesis of emphysema, less attention had been paid to the role of ROS in this condition. The possible effects of the increased oxidant burden in smokers and in patients with COPD are opposed by the lung antioxidant defenses. In their article, they reviewed the evidence for the presence of an oxidant/antioxidant imbalance in smoking-induced lung disease and its relevance to therapy in these conditions. They noted that the involvement of MSS vapor-phase free radicals in oxidative damage was unclear because generally, the reactive vapor-phase free radicals in MSS are quenched immediately on contact with moist surfaces of the respiratory tract.

In 1997, Kodama et al. (27A62) analyzed multiple components in cigarette smoke for their ability to form active oxygen species using a spin-trapping agent, DMPO. The main source of O_2 and H_2O_2 was ascribed to polyphenols in a particulate phase of MSS. $OH^{\bullet}$ were identified in the vapor-phase of MSS. Carbonyl sulfide in the vapor phase was shown to be a source of DMPO-OH adduct. NO in the vapor phase of MSS did not show appreciable reactivity. They added that the quantification and identification of active oxygen species in cigarette smoke could provide important information for elucidating the mechanism of tobacco carcinogenesis, as certain types and concentrations of free radicals have shown genotoxic effects to induce DNA strand breaks, as well as epigenetic effects, to act as cell proliferation signals.

In 1997, Pryor summarized the free-radical mechanisms developed in his laboratory over the previous 21 years (27A86). He stated

> Cigarette smoke is a rich source of free radicals, as well as other oxidants and puts an oxidative burden on the entire organism. Smoke contains two phases, operationally defined as gas-phase smoke, which passes through a glass-fiber Cambridge filter and particulate matter, or tar, which is retained on the filter. Gas-phase smoke contains reactive, short-lived radicals that can be detected and quantified using electron spin resonance (ESR) spin trap methods. The radicals in gas-phase smoke do not result from the flame directly, but rather are continuously generated by the oxidation of NO to NO_x, which then adds to reactive species in the smoke (primarily isoprene) to give $R^{\bullet}$ radicals, which react with O_2, to give RO^- and $ROO^{\bullet}$ radicals. Gas-phase smoke, with up to 500 ppm NO as well as oxyradicals, also produces a variety of reactive nitrogen species (RNS), including HOONO, $NOONO^{\bullet}$, $ROONO^{\bullet}$, and $ROONO^{\bullet}$. Gas-phase smoke oxidizes α-I-antiproteinase by a process involving H_2O_2 and RNS. Cigarette tar contains a stable semiquinone radical $Q^{-\bullet}$, that can be observed by direct ESR; the tar radical reduces O, and thus aqueous cigarette tar (ACT) extracts contain $O_2^{-\bullet}$, H_2O_2 and $^{\bullet}OH$. The tar radical binds to and associates with DNA (both by ESR and by ^{14}C). ACT extracts nick DNA, and $^{\bullet}OH$ or a species like it are responsible for the damage. Fractionation of ACT shows that the fractions that contain the tar radical $O_2^{-\bullet}$ are responsible for >85% of the nicks.

In 1997, Stohs et al. (27A110) reviewed the potential of metal ions reacting in conjunction with other constituents of tobacco smoke to cause cellular damage by free-radical reactions. Various studies had demonstrated the role of ROS in the toxicity of transition metals. They concluded that the presence of several reactive metal ions in tobacco smoke indicates that there may be a role for metal ions in the subsequent toxicity and carcinogenicity of tobacco smoke. They described the metal-catalyzed mechanisms that might be involved.

By the early 1990s, free radicals generated from MSS were considered a significant health risk because of their potential involvement in oxidative stress. Müller et al. (27A77) reported that NO in cigarette smoke could react with superoxide derived from the reducing constituents in the particulate phase of cigarette smoke to form peroxynitrite ($ONOO^-$). NO may also be converted to a number of more reactive nitrogen derivatives, such as NO_2, dinitrogen trioxide (N_2O_3), and dinitrogen tetraoxide (N_2O_4). Their results were consistent with a rapid NO-consuming reaction coupled with superoxide-generating properties of the particulate phase of MSS.

The roles of superoxide ($O_2^{\bullet-}$), peroxynitrite, and carbon dioxide (CO_2) in the oxidative chemistry of NO was reviewed by Squadrito and Pryor (27A106) in 1998. Each of these ROS can cause biological damage at high concentrations. They contended that NO and superoxide are produced by several cell types and can rapidly combine to form peroxynitrite. Peroxynitrite is a potent and versatile oxidant that can attack a wide range of biological targets, if not held in check. In previous publications, Pryor implied that NO and superoxide (both known MSS components) could be linked to numerous diseases associated with smoking. Of course, CO_2 is also present in MSS. Peroxynitrite is normally scavenged by antioxidants, but CO_2 can also compete with certain antioxidants. Squadrito and Pryor proposed a mechanism for the reaction of CO_2 with $OONO^{\bullet}$ that produced metastable nitrating, nitrosating, and oxidizing species as intermediates. An analysis of the lifetimes of the possible intermediates and of the catalysis of peroxynitrite decomposition suggested that the reactive intermediates responsible for reactions with a

variety of substrates may be the free radicals NO_2 and $CO_3^{\bullet-}$. In closing, Squadrito and Pryor noted that increased formation of peroxynitrite has been linked to Alzheimer's disease, rheumatoid arthritis, atherosclerosis, lung injury, amyotrophic lateral sclerosis, and other diseases.

Flicker and Green (27A38) developed a new HPLC method for the detection of free radicals in cigarette smoke and diesel exhaust in 1998. Carbon-centered radicals were trapped from the vapor phase of cigarette smoke and diesel engine exhaust by reaction with a nitroxide, 3-amino-2,2,5,5-tetramethyl-1-pyrrolidinyloxy (3AP). The resulting mixture of stable, diamagnetic adducts was derivatized with naphthalenedicarboxaldehyde (NDA) to produce highly fluorescent products. Derivatives were separated by HPLC, which revealed distinctly different sets of radicals present in the two systems. Integration of HPLC peaks gave approximately 22 ± 7 nmol of radicals per cigarette and 3 ± 1 nmol of radicals per liter of diesel engine exhaust. An estimated 8–10 different carbon-centered radical species are present in each system. No identification of the free radicals was made.

In 1999, Halliwell and Gutteridge (27A41) published a second edition of their book *Free Radicals in Biology and Medicine*. It has become a classic text in the field of free-radical and antioxidant research. In their book, they reviewed the role of free radicals in the life and biomedical sciences and provided methods available to measure reactive species and oxidative damage (and their potential pitfalls), as well as the importance of antioxidants in the human diet. It is important to note that free radicals in cigarettes were not discussed. Although, their text has often been cited concerning oxidizing species/free radicals found in MSS that are known to cause oxidative damage in essential biomolecules.

In 1999, a World Patent was granted to Emami on a cigarette filter additive to capture and remove free radicals from cigarette MSS (27A34). The filter additives described in the patent were based on natural polyphenols which efficiently scavenge free radicals in cigarette smoke. Among the various polyphenols tested, oils of rosemary extracts from *Rosemarinus officinalis* L. proved to be the most active in reducing the yields of both vapor- and particulate-phase free radicals. The additive-containing filters were stable at high temperature, had a 12-month shelf life, were not air sensitive, and had normal pressure drop characteristics.

Emami et al. reported on the free-radical scavenging efficiency of the cigarette filters containing rosemary extract in 2000 (1143). Employing ESR, Emami et al. were only able to tentatively identify the presence of hydroxyl, methoxyl, and cyano free radicals in MSS. Unfortunately, ESR techniques alone give poor structural information on the nature of free radicals.

In 2000, Liu et al. (2380a) presented their research on the design of a unique low-"tar" cigarette designed to yield approximately 40% less particulate-phase free radicals. The cigarette employed a special filter, casing additives to reduce free radicals (vitamin E, vitamin A, cysteine, and selenic compounds of mannitol), a specially formulated casing with burn control agents, expanded tobacco, and tobacco filler rich in selenium. Although it was not possible to determine the interactive effects of all the changes in the uniquely designed cigarette, ESR results confirmed a reduction in particulate-phase free radicals.

Blakley et al. (27A11) published a paper in 2001 that questioned published reports postulating that the particulate-phase free radicals of cigarette MSS consisted of a HQ/semiquinone/QH shuttle. Their results showed that there was no positive correlation between the smoke yield of HQ and the presence of particulate-phase free radicals. When a 10-fold reduction in MSS HQ yield was obtained when KNO_3 was applied to the surface of tobacco of an American blended cigarette, there was no significant corresponding change in the yield of particulate-phase free radicals. In experiments testing MSS from low and high HQ-yielding tobaccos, there was no consistent corresponding relationship between HQ and particulate-phase radical yields. In one series of blends, there was at best an inverse relationship between HQ and particulate-phase radical yields. In contrast with the published literature, Blakley et al. concluded that the particular compound or compounds driving particulate-phase free-radical formation are currently unknown.

Flicker and Green (27A37) published an improved method for trapping carbon-centered free radicals ($R^{\bullet}$) from the vapor phase of the MSSs from cigarettes and cigars in 2001. They compared free-radical concentrations trapped from various cigarettes and model smoke systems. Using a nitroxide trap, 3-amino-2,2,5,5-tetramethyl-1-pyrrolidinyloxy (3AP), on solid support, they trapped radicals directly from the vapor phase, washed them off the support, and analyzed them with HPLC. Separation of the trapped radicals showed that the vapor phase of smoke from each cigarette type produced a unique set of free radicals (4–10 distinct peaks). Vapor mixtures used to model tobacco smoke consisted of NO, air, isoprene, and methanol. The model systems produced a set of free radicals that consisted of four major and several minor peaks, two of which matched peaks in tobacco smoke chromatograms. Quantities of free radicals trapped from cigarettes tested varied from 54 ± 2 to 66 ± 9 nmol. The cigar tested produced 185 ± 9 nmol of free radicals. In their experiments, oxygen competed with the nitroxide trap for MSS vapor-phase radicals. A kinetic analysis of the O_2 competition shows that actual radical concentrations in the smoke were approximately 100-fold higher than measured.

Valavanidis and Haralambous reported in 2001 (27A118) on the free-radical populations in the MSS and SSS of cigarettes with conventional acetate filters compared to biofilters (BF) that claimed reductions in yields of certain toxic substances and oxidants in the vapor phase of the MSS [Deliconstantinos et al. (27A26)]. They found that BF cigarette smoke had similar tar radical species with the same intensity ESR signals to those of the other cigarettes containing cellulose acetate filters. The ability of the ACT to produce hydroxyl radicals in the cigarettes with the BF filter was very similar to, or even higher than, the other three brands tested. The vapor phase of the MSS of the BF cigarette showed a 30%–35% reduction in the production of oxygen-centered radicals.

In the case of the SSS, BF cigarettes produced substantially higher concentrations of vapor-phase free radicals, compared to the other brands. Their results suggested that cigarettes with the BF were partially effective at removing some of the vapor-phase oxidants but not effective in the reduction of tar and its radical species in the MSS and SSS.

In their paper at the *55th TSRC* in 2001, Wooten et al. reviewed free radicals and proposed mechanisms for their generation in tobacco smoke (4277). Their review was mainly a synopsis of work published by Pryor et al. over the previous 20+ years. No specifically identified free radicals were presented.

The free-radical NO is both found in all living organisms and is required for many physiological functions. NO is also an important regulatory molecule for immune response and cytotoxicity. It is naturally produced from *l*-arginine by NO synthases (NOS). As a free radical, it produces many reactive intermediates that account for its bioactivity. NO is also a component of MSS. One mechanism for NO-induced cytotoxicity was through its interaction with superoxide to produce peroxynitrite, which can cause DNA damage. Müller et al. (27A76) and Squadrito and Pryor (27A106) previously suggested that this same mechanism may be operative for free radicals in MSS. In 2001, Lala and Chakraborty published a paper on the role of NO in carcinogenesis and tumor progression (27A64). However, they also suggested that selective inhibitors of NOS may have a therapeutic role in certain cancers associated with free radicals.

In 2002, Takanami et al. reviewed their research on the detection of free radicals in vapor phase of cigarette smoke by ESR at the *56th TSRC* (3862).

Usually, highly reactive free radicals are detected by ESR techniques once stable spin adducts are formed, but this may lead to many pitfalls. In 2002, Masselot et al. (27A68) reported a new methodology to study free radicals based on ESI and MS. The concentration of free radicals in MSS smoke is too low, compared to the total concentration of MSS, to allow for their identification by molecular ion identification alone. Stable spin adducts of free radicals from samples of MSS were analyzed by ESI–MS/MS, and the resulting fragmentation spectra were used to determine the nature of the free radicals trapped in MSS. With this methodology, Masselot et al. successfully identified two free radicals in the cigarette smoke, the $OH^{\bullet}$ and the $CH_3^{\bullet}$ radicals, and were able to tentatively identify the $O_2^{\bullet -}$ radical. When coupled to LC techniques, the ESI–MS/MS analyses allowed not only for radical identification but also for their quantification. Masselot et al. applied their new method to characterize and optimize a new filter, based on rosemary extracts which efficiently scavenged free radicals in cigarette smoke and had been patented by Emami in 1999. The relative efficiency in the removal of the various free radicals present in cigarette smoke (C centered, O centered) was discussed.

In 2002, Anderson et al. presented a review on the importance of previous work conducted on free radicals in cigarette smoke at the *56th TSRC* (74).

Ingebrethsen and Lyman (27A48) examined the mechanism proposed by Cueto and Pryor (27A21) and Pryor and Stone (27A93a) for the formation of reactive free-radical species from NO and NO_2 in the vapor phase of cigarette MSS in 2002. Inspection of the generic reaction scheme proposed by Cueto and Pryor (27A21) and Pryor and Stone (27A93a) suggested that some condensable materials were likely to result. The possibility of particle formation and growth due to this condensable material suggested only one route for phase transformation in filtered smoke. From a practical perspective, those working with cigarette smoke have long been aware that totally filtered smoke can yield condensable deposits in smoking machine plumbing even in the absence of temperature gradients. Ingebrethsen and Lyman reported that aerosol particle formation and growth were observed in aging, initially particle-free vapors obtained from filtered cigarette MSS. The timescale of particle formation and growth was on the order of minutes and was highly dependent on cigarette tobacco type. Measurements by both ensemble and single particle light-scattering methods were consistent with scattering from an aerosol with a fixed number of particles that grew into the 10th micron range. The rate of particle size increase agreed best with that predicted for growth controlled by condensable species formation by vapor-phase reaction slower than the diffusion rate of the reaction products. A simple reaction scheme involving NO oxidation and reaction with isoprene reproduced the observed form of the particle growth curves but did not yield a consistent reaction rate constant for the various cigarette tobacco types. Their results were inconsistent with the proposed mechanisms of Cueto and Pryor (27A21) and Pryor and Stone (3000) and suggested that additional reactants are involved in the particle formation.

Müeller and Intorp reported on the longer-lived particulate-phase free radicals (QH, HQ, and semiquinone species) they detected in MSS by ESR directly after extraction of Cambridge filter pads in 2003 (27A76). They also reported on their study of short-lived vapor-phase free radicals (alkoxy and alkyl species) in MSS. These radicals were spin trapped with PBN and detected by ESR. No specific identification of the free radicals was reported.

In 2003, Baum et al. (27A08) reported on a rigorous set of experimental protocols they believed were necessary to conduct ESR experiments on particulate- and vapor-phase free radicals in MSS. In their paper, they discuss experiments that were conducted in order to determine the optimal conditions for maximum signal intensities and reproducibility of results. Their results showed that radical concentrations in smoke vary among cigarettes in both the vapor phase and particulate phase of MSS. By use of a series of commercial cigarettes, where many parameters change from cigarette to cigarette, no statistically significant correlations were found between radical levels and total particulate matter in smoke. However, a weak correlation was found between the vapor-phase free-radical levels and total particulate-matter levels in smoke. They also reported that there may also be a complex effect of tobacco type on radical levels in smoke.

Emami et al. presented a paper at the 2003 CORESTA meeting in Freiburg, Germany, on an improved method for the detection, quantification, and identification of vapor-phase free radicals in MSS (27A32). They commented that the detection and quantification of vapor-phase free radicals by ESR have two main limitations: (1) Free-radical/spin-trap adducts are readily oxidized to give nonradical species, which cannot be detected by ESR; and (2) ESR techniques have a low capability to give structural information in the case of mixtures. Consequently, the unequivocal identification of many free radicals in cigarette smoke is still to be determined, and in addition, quantitative results for comparison studies are difficult to obtain (27A08). Masselot et al. (27A68, 27A69) had previously reported on use of 4,5,5-trimethylpyrroline-*N*-oxide for characterizing *O*-centered radicals and of 3-amino-2,2,5,5 tetramethyl-1-pyrrolidinyloxy for C-centered radicals. These two free-radical-trapping agents were used to identify the hydroxyl ($OH^{\bullet}$) and methoxyl ($CH_3O^{\bullet}$) radicals and cyano ($CN^{\bullet}$) radical, respectively. In this report, they described the quantitation of these radicals employing a hyphenated LC-MS/MS technique with a C18 reverse-phase column fitted to a triple quadrupole MS instrument. The addition of a stable free radical as internal standard (TEMPO, 2,2,6,6-tetramethyl-1-piperinodyloxy) allowed them to cleanly quantify the detected free radicals by the so-called multireaction monitoring (MRM) mode. The absolute quantification they obtained (ca. 10^{16} radicals/cig) was in good agreement with previous experiments based on ESR techniques. They applied their improved free-radical method to characterize a new filter containing rosemary extracts which scavenge free radicals in cigarette smoke patented by EMAMI in 1999 (27A34). The relative efficiency in the removal of the various free radicals present in cigarette smoke (C centered, O centered) was 50% for filters containing 50 mg of formulated rosemary extract.

Numerous presentations on free radicals were made in 2004 at the *58th TSRC* and at the *CORESTA Congress* in Kyoto, Japan.

In 2004, Zhou et al. (27A123) presented a systematic approach to the study of these free radicals in particulate-phase MSS at both the *CORESTA Congress* and at the *58th TSRC* (4415). They reviewed much of the prior research on detection methods for free radicals and discussed means to reduce free radical in MSS and the need for more biomedical evaluation.

In 2004, Rolando et al. (27A100) reported on the identification and quantitation of the hydroxyl ($OH^{\bullet}$), methoxyl ($CH_3O^{\bullet}$), cyano ($CN^{\bullet}$), formyl ($HC(O)O^{\bullet}$), peroxyl ($^{\bullet}OOH$), and nitrite ($NO2^{\bullet}$) free radicals employing their previously reported hyphenated LC–MS/MS technique that used a C18 reverse-phase column fitted to a triple quadrupole instrument at the *CORESTA Congress* in Kyoto.

Little et al. presented results of their investigation of phenolic particulate-phase free radicals (e.g., BQ–HQ radicals) in MSS measured by direct ESR measurements at low temperatures (2379) at the *58th TSRC*. Variable temperature ESR studies were performed on the particulate-phase free radicals in MSS. Different particulate-phase free radicals showed temperature dependence. Isolated particulate-phase free radicals began to form at about 450°C. It should be noted that stable BQ–HQ complexes (CAS No. 106-34-3) had been identified in tobacco smoke and Cytrel® smoke in 1969 by Green et al. (1378) and by Newell et al. (2767) in 1974. In neither study was any special procedure used to deal with free radicals.

At the *58th TSRC*, Rickert et al. reported on an ESR method used at LabStat for the determination of the yields of vapor-phase and particulate-phase free radicals generated in MSS (3134). No specific identified free radicals were discussed.

In 2004 at the *58th TSRC*, Johnson and Chapman presented a general review on the identification of free radicals in whole smoke (1957). Again, no specifically identified free radicals were discussed.

Johnson reported at the *59th TSRC*, in 2005, on the results of the identification of spin-trapped vapor-phase free radicals in MSS via an ESI triple quadrupole tandem MS analysis method. Four alkoxyl free radicals were unequivocally identified ($^{\bullet}OC_2H_5$, $^{\bullet}OC_3H_7$, $^{\bullet}OC_4H_9$, and $^{\bullet}OC_5H_{11}$). The superoxide free radical was also tentatively identified (27A56).

Employing an Amplex Red assay, Yan et al. (27A121) were able to detect, quantify, and positively identify H_2O_2 in whole cigarette smoke. Although not a free radical, H_2O_2 has been proposed as an intermediate in certain free-radical reactions. Church and Pryor (746) proposed that HQs present in the particulate phase of MSS can reduce dioxygen (O_2) to produce $O_2^{-\bullet}$ and semiquinone ($Q^{-\bullet}$) radical anions. The superoxide radical anion was thought to be the immediate precursor to H_2O_2, which could then be reduced to the hydroxyl radical by metals such as iron. Church and Pryor (746) suggested that the resulting $HO^{\bullet}$ radical can then damage DNA. Yan et al. found that there was a time dependency of H_2O_2 production in whole cigarette smoke in their experiments. The Amplex Red assay showed an increase in the production of H_2O_2 of up to 120 min and then reached a plateau thereafter, suggesting H_2O_2 was formed over this time period by some reaction(s) involving the highly complex mixture of chemical constituents present in whole cigarette smoke. In the work of Yan et al., concentrations of 3–8 μM H_2O_2 were found in aqueous solutions of whole smoke bubbled samples, while there was negligible H_2O_2 formation from vapor-phase bubbled samples. The data in this work suggest that the major constituents responsible for H_2O_2 formation are in the particulate phase. Aqueous solutions of HQ and catechol, both of which are particulate-phase constituents of cigarette smoke, generated no H_2O_2 even though they are free-radical precursors involved in the production of ROS in the smoke matrix.

In 2005, Chouchane et al. (27A18) studied cigarettes that had varied levels of polyphenols in the tobacco filler (flue-cured, burley, Oriental tobacco, and blends of these tobaccos).

Chouchane et al. found that the yield of particulate-phase free radicals generated in the MSS from these cigarettes was not directly related to the total amount of polyphenolic compounds in the tobacco leaf filler. For example, cigarettes prepared from flue-cured tobacco, which contains a significantly higher amount of polyphenols in comparison to burley tobacco, did not generate a higher yield of particulate-phase free radicals in MSS compared to cigarettes prepared with burley tobacco.

Halliwell and Poulson recently published a book on cigarette smoke and oxidative stress (27A42). The currently proposed mechanisms for free-radical production in cigarette smoke were discussed. They concluded that the proposed mechanisms by which cigarette smoke causes or contributes to inflammatory diseases like chronic obstructive pulmonary disease, cardiovascular disease, and cancer remain unclear. In several chapters in their book, they discussed recent developments in cellular signaling and suggested that cigarette smoke may cause oxidative stress in cellular systems. The assessment, consequences, and possible modulation of biological effects from oxidative stress were discussed. Analytical methods for the determination of isolated free radicals and biological assays for free radicals were also discussed.

In 2006, Rolando et al. (27A99) developed a new methodology based on LC, MS (LC-MS and LC-MS/MS) for the identification and quantification of free-radical spin-trap adducts. The improved method involved the use of a nano-LC fitted with a 75 µm column for separation that allowed for shorter analysis time and higher sensitivity. The main advantage of their improved method was its ability to detect and identify certain free-radical adducts (so-called ESR silent adducts) which had been oxidized or reduced after the trapping. By using spin traps which were specific for the trapping of C- or O-centered free radicals, they unambiguously identified the $OH^{\bullet}$ and $CH_3^{\bullet}$ radicals. Using this new methodology, they were able to ascertain the presence and identification of the cyanide radical ($CN^{\bullet}$) and nitrite ($ONO^{\bullet}$) radical. They stated that they were continuing their work on the structure of more complex free radicals at higher molecular mass by comparing spectra from chemically generated free radicals to those present in MSS.

Free radicals in cigarette smoke have attracted a great deal of attention because they are hypothesized to be responsible in part for several of the pathologies related to smoking. HQ, catechol, and their methyl-substituted derivatives are abundant in the particulate phase of cigarette smoke, and they are known precursors of semiquinone radicals. In the study by Chouchane et al. (27A17) in 2006, the in vitro cytotoxicity of these dihydroxybenzenes was determined with the neutral red uptake (NRU) assay, and their radical-forming capacity was determined by ESR. All of the dihydroxybenzenes studied were found to generate appreciable amounts of semiquinone radicals when dissolved in the cell culture medium employed in the NRU assay. HQ exhibited by far the highest capacity to form semiquinone radicals at physiological pH, even though it was not the most cytotoxic dihydroxybenzene. Methyl-substituted dihydroxybenzenes were found to be more cytotoxic than either HQ or catechol. The formation of semiquinone radicals via autoxidation of the dihydroxybenzenes was found to be dependent on the reduction potential of the corresponding QH/semiquinone radical redox couple. The capacity to generate semiquinone radicals was found to be insufficient to explain the variance in the cytotoxicity among the dihydroxybenzenes in their study; consequently, other possible mechanisms of toxicity must also be involved. The observed interactions between 2,6-dimethylhydroquinone and HQ in the cytotoxicity assay and ESR analysis suggested that care needs to be taken when studying the bioactivity of cigarette smoke constituents, i.e., the effect of the whole cigarette smoke complex matrix on the activity of the single constituent studied must be taken into consideration. Biological studies of the separated particulate and vapor phases of MSS may provide results that are different from those of studies of whole MSS.

In 2006, Culcasi et al. (27A22) also reported on the free-radical-related cytotoxicity of the vapor phase of MSS and the paradoxical temporary inhibition of cytotoxicity of vapor-phase free radicals by the MSS particulate phase. In their ESR studies, the spin-trap 5-(diethoxyphosphoryl)-5-methyl-1-pyrroline-*N*-oxide (DEPMPO) was employed. They experimented with cigarettes made with cellulose acetate filters, empty cavity filters, and cavity filters containing carbon (charcoal). In their study, filters containing carbon were effective in reducing vapor-phase free-radical formation, cytotoxicity, and lipid peroxidation in three cell lines. The results of their experiments also showed that NO and NO_2 are more important than hydroxide free radicals in generating the cytotoxicity of vapor-phase MSS free radicals generated from MSS constituents. Culcasi et al. also suggested that *something* in the MSS TPM reduced the cytotoxicity of vapor-phase free radicals in MSS as there was an unexpected protective effect of TPM on the cytotoxicity of whole smoke compared to that of vapor phase of MSS alone. They concluded that the conventional smoke collection method (separation of the smoke into vapor and particulate phases) distorts the true picture of free-radical activity. In other words, free-radical activity in cigarette smoke should only be evaluated on a "whole smoke" basis.

In 2007, Dellinger et al. (27A27) conducted and reported on the formation and stability of resonance stabilized free radicals of the type hypothesized by Pryor and his associates in the particulate phase of MSS. They concluded that the commonly observed free radicals in the particulate phase of MSS were not a surface associated semiquinone and were more likely an intrinsic, polymeric radical with a delocalized electron. The EPR signal observed by Pryor in the alcohol extract of the particulate phase of MSS may be from an extracted and autoxidized HQ, not a particulate-phase-associated semiquinone radical. The semiquinone radical was observed in the particulate phase of MSS collected below 400°C and has a five-line spectrum with $g \sim 2.006$.

Semiquinone radicals were formed in the particulate phase of MSS only after aging.

Ghosh et al. in 2007 (27A39) presented their research results on the ESR study of free radicals in the vapor phase of the MSS from 2R4F reference cigarettes. The vapor phase of MSS trapped with DMPO contained a mixture of three free-radical species correspond to two oxygen-centered radicals (90%) and an unidentified radical (10%) resulting from the decomposition of the spin adducts. They were able to identify the methoxy free radical in the vapor phase of MSS via computer simulation. The oxygen-centered free-radical concentration in the vapor phase of MSS was in the range of 10^{14}–10^{15} spins/cig smoked under ISO standard smoking conditions.

In 2007, Bartalis et al. (27A05) identified 7 acyl and 11 alkylaminocarbonyl radicals in whole MSS employing HPLC and high-resolution MS analysis of stable radical adducts. Their combined abundance of these free radicals measured in fresh whole smoke from a single 2R4F cigarette was approximately 225 nmol (1.4×10^{17} radicals). The fiberglass Cambridge filter pad conventionally employed to separate the vapor phase from the particulate phase of MSS was found to reduce the apparent yield of these radicals, introducing artifacts of measurement. They stated that the long-accepted steady-state mechanism for the formation of C-centered radicals in cigarette smoke involving NO_2 chemistry cannot account for these newly identified radicals and does not in general appear to be a major source of C-centered radicals in fresh cigarette MSS. Consequently, they suggested that the precise nature of radicals in cigarette smoke warrants reexamination.

27.5 PROPOSED MECHANISM FOR THE GENERATION OF FREE RADICALS IN MSS

Smoking has been implicated in numerous diseases (4012, 27A50, 27A51, 27A83, 27A87). Over the last 50–60 years, extensive research has been conducted to understand relationships between individual smoke constituents and smoking-related diseases. Because cigarette smoke is a complex mixture and a great number of complex biological processes are involved in each disease, no simple correlations have been found between smoking and disease. This is not to say that we have not progressed in our understanding of the biological effects of smoking and disease, but causal relationships are still largely unknown (27A17).

Numerous constituents of cigarette smoke have been identified as potential agents of biological damage, including tobacco-specific *N*-nitrosamines, PAHs, phenolic compounds, and free radicals (746, 1727, 2999, 3712).

Free radicals in tobacco smoke have attracted much attention during the last 30 years. Free radicals in biological systems can cause DNA damage, lipid peroxidation, and protein oxidation [Baskin and Salem (27A07), Halliwell and Gutteridge (27A41)] if not moderated by the body's oxidative stress defenses. Cigarette smoke and other environmental pollutants contain free radicals (2999, 2999a). Although free radicals in tobacco smoke have been implicated in human disease, no unequivocal proof of their harm has been established. Tobacco smoke is a complex mixture containing thousands of chemical constituents that can readily produce free radicals in aqueous media (828a, 2999). Tobacco smoke also contains an even greater concentration of antioxidants, antimutagens, and anticancer agents that have been shown to effectively inhibit several biological processes that could lead to disease. In Chapter 26 on carcinogens, cocarcinogens, anticarcinogens, and antimutagens, this subject is reviewed. Nevertheless, there are still many unanswered questions concerning the involvement of free radicals in the toxicology of tobacco smoke. In-depth studies are needed to delineate their precise effects (27A17).

In 1958, Lyons et al. (2429) first observed free radicals by ESR in whole cigarette smoke that was condensed at liquid oxygen temperature. These workers reported that whole cigarette smoke contains two populations of free radicals, an unstable population that can only be observed at −183°C and that vanishes when the condensate is warmed to 60°C and a persistent, stable population that exists for "several days" at room temperature. The unstable population of free radicals included those in the vapor phase of whole cigarette smoke, and the more stable population of free radicals included those found in the particulate phase of whole smoke. As a result, the early examination of the chemical and physical characteristics of free radicals in tobacco smoke was mainly conducted on free radicals in the particulate phase. In 1969, Tully et al. (27A115) were the first to publish a study of the free radicals in the vapor phase of cigarette MSS that was condensed at liquid oxygen temperature. By passing whole cigarette smoke through a fiberglass filter, called a Cambridge pad, the particulate phase of cigarette smoke can be efficiently separated from the vapor-phase constituents (172, 1067). The use of Cambridge pads allowed investigators to separate and independently investigate the free radicals in both phases of whole smoke. The chemical behaviors of the vapor- and particulate-phase free radicals of MSS smoke were found to be quite distinct. The vapor-phase radicals have been shown to be unstable and very reactive, whereas the radicals in the particulate phase are much longer lived (2999, 2999a, 27A95). Derivative methods or spin-trapping techniques were developed to stabilize the vapor-phase free radicals for quantitation. From about the mid-1960s, chemical and biological research on free radicals in tobacco smoke involved separation of the smoke stream into vapor and particulate phases.

From 1976 through 2006, Pryor and his associates studied both vapor- and particulate-phase free radicals in tobacco smoke (746, 828a, 2999, 2999a, 3000, 3001, 27A19, 27A21, 27A24, 27A84–27A95, 27A106, 27A111, 27A122). They generated experimental evidence that suggested possible mechanisms for the initiation, propagation, and termination of free radicals in tobacco smoke. They also alleged that free radicals in MSS were important to numerous smoking-related diseases. They hypothesized that vapor-phase free radicals in tobacco smoke were formed by a continuous mechanism, whereby NO reacted with molecular oxygen in air to form

NO_2, and subsequent reactions between NO_2 and unsaturated molecules in cigarette smoke, e.g., isoprene and butadiene, yielded alkyl, peroxyl, and alkoxy radicals. They contended that the reaction of peroxyl radicals with NO generated additional NO_2, creating a steady-state cycle (2999a, 27A94).

Pryor and his associates also postulated a mechanism for the generation and reaction of free radicals in the particulate phase of tobacco smoke. In that mechanism, particulate-phase free radicals in MSS were postulated to be semiquinone radicals in a polymeric matrix (2999). They stated that the particulate phase of MSS contained numerous dihydroxybenzenes, which could generate semiquinone radicals (27A122). They supported their hypothesis by showing that HQ and catechol can undergo oxidation in air to form semiquinone radicals and ultimately QHs. They further showed under laboratory conditions that reactions between the semiquinone free radicals and molecular oxygen, either in ACT or in living cells, could lead to the creation of ROS such as superoxide radical, H_2O_2, and hydroxyl radical (27A122). It is important to note that the measurements of Pryor et al. (27A93) and others performing research on free radicals in tobacco smoke are not representative of free-radical formation under physiological conditions or in biological systems (27A17). The free-radical mechanisms proposed by Pryor and his associates were very convincing, but like all mechanisms as scientific curiosity is peaked, they were vigorously tested by others.

In 2001, Blakley et al. (27A11) showed that the yield of particulate-phase free radicals was not correlated with the yield of HQ in MSS. For a series of cigarettes containing different tobacco blends with variable yields of MSS HQ, the amount of free radicals in the particulate phase of MSS remained unchanged. In their experiments, methylene chloride was used to extract the particulate matter from Cambridge pads, the solvent evaporated, and the residue redissolved in benzene for EPR measurements. Under these experimental conditions, HQ would be less likely to undergo autoxidation, which is less favorable in organic solvents. Nevertheless, significant levels of particulate-phase free radicals were observed, which calls into question the exact nature of the radicals that could be involved in biological damage.

Ingebrethsen and Lyman in 2002 conducted experiments on particle formation and growth in vapors from totally filtered cigarette MSS (27A48). In their experiments, they tested a simple reaction scheme involving nitrogen oxide oxidation and its reaction with isoprene. Their experiments reproduced the expected and observed form of the particle growth curves and did not yield a consistent reaction rate constant for the various cigarette tobacco types. Their results were inconsistent with the proposed vapor-phase free-radical mechanisms of Cueto and Pryor (27A21) and Pryor and Stone (3000) and suggested that additional reactants are involved in the particle formation.

Cytotoxicity is regarded as a potential step in several chronic disease processes, including carcinogenesis and emphysema [Butterworth et al. (27A16)]. The cytotoxic constituents of cigarette smoke and their mechanisms of action are poorly understood [Chouchane et al. (27A17)]. Thus far, most research has focused either on the chemistry of cigarette smoke or on the in vitro and in vivo effects of cigarette smoke on biological systems. The lack of a bridge between these two approaches has made it difficult to assess the relationship between cigarette smoke constituents and their effects in biological systems. It is known, e.g., that cigarette smoke contains a substantial amount of dihydroxybenzenes in the particulate phase of MSS (2681, 3175, 3743). In vitro assays have demonstrated that ACT, which contains significant amounts of HQ, catechol, and other mono- and dihydroxybenzenes, can damage DNA [Pryor et al. (27A93)]. However, there is no direct evidence to suggest that pure HQ or catechol can induce the same level of free-radical formation and DNA damage as any isolated fraction of ACT [Chouchane et al. (27A17)]. Again, it must be repeated that the experimental conditions employed by Pryor and others for measurement of free-radical activity in tobacco smoke are not representative of free-radical formation under physiological conditions or in biological systems (27A17).

In 2006, Culcasi et al. (27A22) suggested that *something* in the MSS particulate phase reduced the cytotoxicity of MSS vapor-phase free radicals as there was an unexpected protective effect of particulate phase on the cytotoxicity of whole smoke compared to that of vapor phase of MSS alone. They concluded that the conventional smoke collection method, i.e., separation of the smoke into vapor and particulate phases, distorted the true picture of free-radical activity. In other words, free-radical activity in cigarette smoke should only be evaluated on a "whole smoke" basis, unlike much of the research that had been conducted previously. Therefore, a reexamination of some of the toxicological data on free radicals would be prudent.

Chouchane et al. (27A17) recently studied the involvement of semiquinone radicals in the in vitro cytotoxicity of cigarette MSS. Prior to their study, it was known that dihydroxybenzenes can generate semiquinone radicals, QHs, and ROS in oxygenated physiological media in vitro, e.g., in the growth media used in cytotoxicity assays. It was believed that certain dihydroxybenzenes could possibly generate similar semiquinone radicals, QHs, and ROS in vivo in the epithelial lining fluid of the lungs of smokers. Brunmark and Cadenas (27A15) suggested that the cytotoxicity of quinols and QHs may be due to the concerted action of several processes that include redox cycling, alteration of thiols balance through oxidation or arylation, inhibition of cellular functions, alteration of Ca^{+2} homeostasis, and covalent binding to nucleic acids, proteins, and lipids. It is difficult to extrapolate in vitro data analysis to an in vivo system, especially if the in vitro experiments were not conducted under conditions close to physiological conditions. Moreover, few data are available on the cytotoxicity of pure dihydroxybenzenes to compare with the toxicity of a complex mixture containing dihydroxybenzenes, such as cigarette smoke. The dihydroxybenzenes in their study were constituents of the particulate phase of MSS and were found to exhibit significant cytotoxicity. The methyl-substituted dihydroxybenzenes were shown to have higher cytotoxicity than the unsubstituted compounds. The dihydroxybenzenes

were shown to generate semiquinone radicals in the medium used in the NRU cytotoxicity assay. Nevertheless, a correlation between the abundance of semiquinone radicals formed and their cytotoxicity was not found. The observed interaction between 2,6-dimethylhydroquinone and HQ in the cytotoxicity assay and EPR analysis demonstrates that the EC_{50} values in binary mixtures of the dihydroxybenzenes cannot, in general, be assumed to be additive. Consequently, the interpretation of the bioactivity of cigarette smoke evaluated by similar methods should consider the possible effects of the complex mixture of MSS on the activities of the individual constituents.

The most recent study of free radicals in tobacco smoke, published by Bartalis et al. (27A05), indicated that the analysis of whole smoke *vs.* vapor-phase and/or particulate-phase samples is not only important but absolutely necessary in evaluating the true chemistry of free radicals in tobacco smoke. Bartalis et al. measured and identified 7 acyl and 11 alkylaminocarbonyl radicals in fresh whole smoke from a single 2R4F cigarette. These 18 free radicals had a spin concentration of 1.4×10^{17} radicals/cig and accounted for nearly the entire ESR signal. They showed that the long-accepted steady-state mechanism for the formation of carbon-centered radicals in cigarette smoke involving NO_2 chemistry cannot account for these newly identified radicals, and that it does not in general appear to be a major source of carbon-centered radicals in fresh cigarette MSS. The fiberglass Cambridge filter pad conventionally employed to separate the vapor phase from MSS was found to reduce the yield of these radicals, introduced artifacts of measurement. The introduction of a Cambridge pad reduced the yield of the 18 free radicals measured and identified by 96%. In their experimental procedure, that does not use Cambridge pads or any spin traps; no NO_2 was detected in the smoke. (This finding parallels that of Cooper and Hege (816) who reported that, even under unfavorable conditions, the nitrogen oxides in cigarette MSS are predominantly NO.) NO_2 formation was shown to be an artifact of the smoke separation procedure. Bartalis et al. found no evidence of any type of free radicals containing a NO_2 group as previously proposed by Pryor and his associates (746, 2999, 27A88, 27A89) and Flicker and Green (27A37, 27A38). The proposed mechanism of the addition of NO_2 to dienes in cigarette smoke, cigarette pyrolysates, or model gas mixtures of NO, air, and isoprene was found to have no merit. The long-accepted steady-state mechanism for the formation of carbon-centered radicals in cigarette smoke involving NO_2 chemistry cannot account for these newly identified radicals; consequently, they suggested that the precise nature of radicals in cigarette smoke warrants a total reexamination.

Bartalis et al. stated:

> The widely accepted mechanism for the formation of both alkyl and alkoxyl radicals in cigarette was proposed by Pryor and co-workers and supported by persuasive, but primarily indirect, evidence was based on comparisons of gas-phase cigarette smoke and model gas mixtures.

Based on the work of Blakley et al. (27A11), Ingebrethsen and Lyman (27A48), Chouchane et al. (27A17, 27A18), Culcasi et al. (27A22), and Bartalis et al. (27A05), the proposed mechanisms of Pryor and his associates certainly need to be reexamined. Additionally, the previously made biological assertions need to be reevaluated since the free radicals presumably present in MSS may not actually exist. The clear evidence of artifacts formed by the separation of whole smoke into particulate and vapor phases supports the total reexamination of the chemistry and biology of free radicals in tobacco smoke proposed by Bartalis et al. (27A05).

In summary, it would appear that we have come full circle over the last 50 years. Lyons et al. (2429) initially examined free radicals in whole smoke without the use of Cambridge pads, and today, this appears to be the collection method of choice. Tremendous analytical advancements have occurred over the last 50 years, and now, the identification and quantification of free radicals in whole tobacco smoke are finally possible. Artifact formation is always possible in research and is not a weakness of the experimenter. As additional research continues on free radicals in tobacco smoke, we express the same concerns and hopes of Ishiguru and Sugawara (1884) in 1980:

It is hoped that further progress will be made in this field so that the formation routes of many smoke components can be understood and the composition of smoke components can be better controlled.

Table 27.1 is a catalog of free radicals identified to date in tobacco and tobacco smoke. The catalog contains only 50 entries, plus a general entry labeled Radicals, free. The vast majority of the entries in the table are tobacco smoke components, except for NO and oxygen that are also found in tobacco. Hydrogen peroxide was added for completeness since it was discussed several times in the chapter. It is anticipated that with the new analytical methods recently demonstrated by Bartalis et al. (27A05), Masselot et al. (27A68), and Rolando et al. (27A99, 27A100), many additional free radicals in tobacco smoke will soon be identified. It should be kept in mind that, in light of the recent discovery by Bartalis et al. (27A05), some of the previously identified free radicals in tobacco smoke may be artifacts.

Since the first edition of this book was published in 2008 several new presentations on free radicals have been given and several new articles have been published. As a result, the list of free radical found in Table 27.1 has grown as well as the total number of references located within that table. The following paragraphs will give short synopses of the most significant work reported since the first edition.

Late in 2007, Park et al. (4830) published the results of their study on the effect of additives (antioxidants for free radicals reduction) in cigarette filter treated with various antioxidants (three types of proanthocyanidins and ascorbic acid) and various concentrations of ascorbic acid and loaded with activated carbon on the delivery of free radicals of MS by ESR. Their results showed that cigarette filters treated with ascorbic acid delivered less HQ, isoprene, and quinoline

to MSS than those treated with the other antioxidants. They concluded that the antioxidants tested were useful for reducing free radicals in MSS because of the fast reaction rate between the antioxidant and free radicals.

In 2008, Moldoveanu and Borgerding (5008) reexamined the mechanism for the formation of tobacco-specific nitrosamines in MSS via the formation of N_2O_3 from NO and NO_2. Both secondary and tertiary amines can react with N_2O_3. Tertiary amine alkaloids can undergo free-radical reactions involving the formation of organic monodentate radicals and bidentate radicals via N_2O_3 to generate nitrosamines. Their proposed mechanism can be used to explain the formation of *N′*-nitrosonornicotine (NNN) and 4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK) from nicotine by pyrosynthesis during smoking (and during different curing processes that expose tobacco to NO_x).

During 2009, several significant papers were published, and presentations given on free radicals. Adam and Mitschke (5034) conducted an investigation of tobacco pyrolysis gases and puff-by-puff resolved cigarette smoke by single-photon ionization (SPI)—time-of-flight MS. In their investigation, they found that the transit time of the smoke to the analyzer was greater in the presence of the Cambridge pad (*vs.* no pad) because of the tortuous path of the smoke through the filter pad. This allowed more time for various free-radical reactions of NO with assorted organics and resulted in the measurement of lower quantities of NO when the Cambridge filter pad is present. They stated that "it is experimentally convenient to

use a Cambridge pad in smoke analysis but it does not give an absolute separation of the two phases. The materials collected on the pad are affected by a host of factors, including moisture content, temperature, flow rate and specific chemical interaction between aerosol constituents and the fiber glass." They observed that different separation techniques, such as electrostatic precipitation and jet impaction traps, give different values for the vapor/aerosol composition.

At the *63rd TSRC*, no less than eight papers were presented that dealt with various aspects of free radicals:

- Bennett (5036) discussed the comparative quantification of oxygen and nitrogen free radicals induced by cigarette smoke in human lung cells in vitro.
- El-Mahdy et al. (5042) discussed the development of an in vivo mouse model for smoking-induced cardiovascular disease that was sensitive to various fixed and variable gases found in MSS including NO, NO_2, O_2, HCN, H_2S, NH_3, SO_2, and CO. White blood cells in smoke-exposed mice demonstrated significantly higher cell-specific ROS generation associated with free-radical reactions.
- Gerardi and Coleman, from RJRT Company, made two presentations at the 2009 TSRC. One was on new methodologies for quantitative and semiquantitative determination of carbon-centered free radicals in cigarette smoke using LC-MS and GC-MS (5043). Their method quantitated 14 different carbon-centered free radicals, both acyl and alkylaminocarbonyl type. Another was on qualitative and relative quantitative determination of carbon-centered free radicals in whole smoke from various cigarette types (5044). In the first presentation, several approaches were explored to develop a high-throughput procedure for relative determination of 14 different carbon-centered free radicals, both acyl and alkylaminocarbonyl type, in cigarette smoke. In the second presentation, a variety of commercial and reference cigarettes with "tar" yields from 5 to 14 mg/cigarette were smoked using two different smoking regimes to quantitate the level of multiple 3-CNP/radical adducts and several formyl and ethyl radical adducts. The range of carbon-centered free-radical concentration was related to "tar" delivery and was found to be 41–348 nmol/cigarette with the 35/60/2/0 regime and 349–647 nmol/cigarette with the 55/30/2/100 regime.
- Robinson and coworkers, from Lorillard, made three presentations at the 2009 TSRC (5074–5076). The first presentation examined the formation of radicals from cigarettes under different smoking conditions. The second concerned the identification of gas-phase radicals by tandem MS. The third gave results of modulating effects of Fe(II), Fe(III), and QH/HQ on tobacco smoke–mediated hydrogen peroxide formation.
- Takanami (5086) presented results from his study on the detection of ROS by DMPO spin-trapping method in aqueous extract of cigarette smoke and made a comparison of his results with other model reaction systems. These authors tried to detect superoxide anion radicals and hydroxyl radicals by ESR using a DMPO spin-trapping technique on aqueous extracts of cigarette smoke. Their results indicated that the signals of DMPO-OH originally found (but later eliminated by adding superoxide dismutase and not by adding catalase) were derived from degradation of DMPO-OOH, which is a reaction product of DMPO and superoxide anion radicals. Their data support the conclusion that aqueous extracts of cigarette smoke generate superoxide anion radicals and not hydroxyl radicals.

In 2009, McAdam et al. (5963a) delivered a presentation at the *42nd Annual International Meeting* of the Electron Spin Resonance Spectroscopy Group of the Royal Society of Chemistry that was a literature review of free radicals in cigarette smoke. It was a historical walk from 1958 to the present, containing much of the information in this chapter.

Continuing work on the effects of hydrogen peroxide in an aqueous extracts of cigarette smoke, Takanami et al. (5975) examined the effect of pH on the yield. An aqueous extract of the particulate phase of cigarette smoke was analyzed by HPLC with an electrochemical detector (ECD). The recovery of hydrogen peroxide by using an extract of the particulate phase of the cigarette smoke was more than 80%. An increase in the amount of hydrogen peroxide was observed during extraction with the phosphate buffer at higher pH values. In contrast, extraction with phosphoric acid did not increase the amount of hydrogen peroxide during extraction.

Gerardi and Coleman (5503) made presentations at the 2010 *CORESTA Congress* and the *64th TSRC*. The first presentation dealt with the use of high-resolution MS to confirm several previously proposed 3-CNP/radical adducts, the formyl and ethyl radical adducts that they had reported in 2009. The second talk which was made at the 2010 *CORESTA Congress* and subsequently published was on two methods for the detection and quantitation of free radicals. GC-MS was employed for the first time as an alternate means of detecting several relatively highly concentrated radical adducts. LC-MS/MS with either precursor ion monitoring (PIM), selected reaction monitoring (SRM), or selected ion monitoring (SIM) was used for detecting the large array of radicals, including several not previously reported: formyl, crotonyl, acrolein, aminocarbonyl, and anilinocarbonyl radicals. Relative quantitation was achieved using external calibration standards of 4-[1-pyrrolindino]benzaldehyde and nicotine. They determined that the yield of carbon-centered free radicals for reference cigarette 2R4F was approximately 265 nmol/cigarette at 35 cc puff/60 s interval/2 s duration smoking conditions.

In 2010, Takanami (5571) continued to present his work on aqueous extract of particulate-phase cigarette smoke. This presentation described the identification of hydrogen peroxide precursors by fractionation of the aqueous extract of particulate-phase cigarette smoke.

Zweier et al. (5590) made a presentation at the *64th TSRC* on the application of carbon fiber microelectrodes for measurement of kinetic constants of nitric oxide decay in blood.

In 2011, Takanami and Nakayama (5976) reported the generation of superoxide anion radicals generated from an aqueous extract of particulate-phase cigarette smoke by ESR using DMPO. The ESR signals of DMPO-OH were detected from the extract by using DMPO. These signals were eliminated by adding superoxide dismutase but hardly by catalase. These responses of the ESR signals to the scavengers were similar to those of a hypoxanthine–xanthine oxidase system. The results indicate that the signals of DMPO-OH from the extract were derived from a reaction product of DMPO with superoxide anion radicals and clarify the mechanism by which the extract generated superoxide anion radicals.

Finally, in 2011, a special edition of *Mini-Reviews in Organic Chemistry* was published that was dedicated to a better understanding of cigarette smoke free radicals and their relationship to smoking-related disease (5959). This special issue containing 11 review articles by experts in this area of research provides reader with an up-to-the-date overview of this evolving subject. Five review articles are particularly germane to this chapter of the book, namely, the reviews by Liu et al. (5960) on "Some recent topics in cigarette smoke science," by Menshov and Trofimov (5964) on hydrogen peroxide derived from cigarette smoke: "Pardon impossible, to be sent to Siberia"?, by Robinson and Johnson (5966) on "Methods for analysis of free radicals in cigarette smoke," by Wooten (5979) on "Gas-phase radicals in cigarette smoke: A re-evaluation of the steady-state model and the Cambridge filter pad," and by Dellinger et al. (5927) on "Free radicals in tobacco smoke."

28 Summary

In the Chapter 28 Summary of our 2008 cataloging of the chemical components of tobacco and tobacco smoke, Rodgman and Perfetti noted the following (5078):

> Since the mid-1950s, the combined referenced cataloging of the chemical components of tobacco and tobacco smoke may have been conducted in-house at various U.S. and foreign tobacco companies as well as by various governmental agencies but none has been published since the excellent 1968 review by R.L. Stedman of the U.S. Department of Agriculture (3797). Prior to that, there were only a few such publications, one in 1959 [Johnstone and Plimmer (1971)] and one in 1963 [Philip Morris, Inc. (2939)]. In subsequent years, several tobacco and tobacco smoke publications dealt with specific types of components, e.g., the 1977 review by Schmeltz and Hoffmann on the nitrogen-containing components in tobacco and tobacco smoke (3491). Several catalogs of the chemical components of only tobacco smoke have been published, but the most recent one was that of Ishiguro and Sugawara (1884) in 1980. Since the 1968 Stedman article, the number of identified tobacco and tobacco smoke components has increased sevenfold to more than 8600. No other commercial product has been so completely defined. This catalog is our attempt to categorize with references the identified and reported components in tobacco and tobacco smoke as of 2007.

Hundreds of scientific articles (many of them referenced in this text) have stated that tobacco and tobacco smoke are complex mixtures (5551). This is an accurate statement. But some have alluded to or emphasized that they are primarily complex, i.e., these mixtures of chemicals are just too multifarious, too difficult to completely understand, or so complicated and/or convoluted that the normal individual could not possibly comprehend the totality of the concept or composition of the mixture. This was never the intent of the definition of a complex mixture, but nevertheless, some have implied that this multifaceted conglomeration of chemical components in tobacco and tobacco smoke is too difficult to explain and understand. The tobacco industry has often stated that tobacco and tobacco smoke are complex mixtures, without providing a basis for the statement. This text illustrates the complexity of tobacco and tobacco smoke. It provides the reader with a historical perspective on the identification of thousands of chemical components in tobacco and tobacco smoke, it contains reviews of all known and identified classes of chemical components in tobacco and tobacco smoke, and it provides thousands of accessible references on identified chemical components in tobacco and tobacco smoke. Also provided in the preceding pages are references and discussions of one of the major problems with a complex mixture, i.e., the extrapolation of a biological property found in experimental studies with an individual compound in the mixture to the property of that component in a mixture which may contain components that either enhance or offset the experimentally observed biological property of the component. Even though tobacco and tobacco smoke are complex mixtures, they are not incomprehensible.

Tobacco and tobacco smoke are among the most extensively studied complex mixtures (5551). There are literally millions of protein fragments being cataloged as part of the tobacco genome projects. Over 30,000 enzymes are known to participate in plant growth and regulation. Oxidation, reduction, additions, hydrogenation, pyrolysis, decarboxylation, and dehydration are but a few of the many chemical reactions known to be involved in tobacco pyrolysis and combustion. These reactions are capable of producing hundreds of thousands of reaction products. The limiting factor in the discovery and identification of additional chemical components in tobacco and tobacco smoke was the early analytical technology, but this was changed significantly over the years by the development of new and ever-improved analytical technologies.

Since the 1954 listing of fewer than a hundred tobacco smoke components by Kosak (2170), various investigators have estimated from gas chromatographic scans that for each component identified in tobacco smoke, there are 5–20 components present at extremely low per cigarette yields that have not yet been identified. Thus, as noted by Wakeham (4103) in 1971 when the identified tobacco smoke components numbered about 1350:

> Gas chromatographic scans indicate there are many more, probably over ten thousand, possibly even a hundred thousand [tobacco smoke components].

Grob (1422), one of the pioneers of the use of glass capillary gas chromatography in tobacco smoke composition studies, as well as other tobacco smoke investigators, also noted that the number of peaks, each of which represented at least one component, in the chromatographic scans far exceeded the number of identified components.

If it were not for scientists' curiosity and the tremendous advances in analytical chemistry over the last 50–60 years, the need for this up-to-date catalog of compounds in tobacco and tobacco smoke would not be critical. As analytical technology advances, surely thousands of new chemical components in tobacco and tobacco smoke will be added to the listings found in this text.

In each chapter of this text, one or more tabulations were made that contained the distribution of the components (by chemical class) that were identified in tobacco, tobacco smoke or in both tobacco and tobacco smoke. Table 28.1 illustrates the total distribution of chemical components distributed between tobacco and tobacco smoke.

TABLE 28.1
Distribution of Chemical Components between Tobacco and Tobacco Smoke

Component	Table	Total[a]	Smoke	Tobacco	Smoke and Tobacco
Hydrocarbons					
Alkanes	1.10	136	116	100	80

Subtotals		2362	1077	2070	785
Summary of item entries		1422	1319	368	265
Hydrocarbons		8030	4161	6008	2139
Oxygen-containing components[b]		1139	769	639	269
Nitrogen-containing components[b]		1794	1458	674	338
Nitrogen hetrocyclic components		2362	1077	2070	785
Grand totals		14,747	8784	9759	3796

[a] This number includes the various isomers of alkyl-PAHs reported in which the position of the alkyl group or groups has not been precisely defined.
[b] Polyfunctional *O*-containing compounds are counted in each functional group, e.g., propanoic acid. 2-bydroxy- {lactic acid} appears in the alcohol catalog and the acid catalog; benzoic acid, 4-hydroxy-3-methoxy- {vanillic acid} appears in the acid catalog, the phenol catalog, and the ether catalog.
[c] The number of aza-arene derivatives does not include the nine *N*-heterocyclic amines.

There are 27 chapters in the book (excluding this Summary). Table 28.1 contains summary data on the distribution of chemicals discussed in all but one chapter (Chapter 25 on Pyrolysis). The tobacco and tobacco smoke components discussed in Chapter 25 are all previously covered in the remaining chapters of the book. Table 28.1 is divided into five sections: Hydrocarbons (Tables in Chapter 1), Oxygen-Containing Components (Tables in Chapters 2 through 10), Nitrogen-Containing Components (Tables in Chapters 11 through 16), Nitrogen Heterocyclic Components (Tables in Chapter 17), and Miscellaneous Components (Tables in Chapters 18 through 24, 26, and 27). Below each section in Table 28.1 is a subtotal of the total of identified chemical components found in tobacco, tobacco smoke, or both tobacco and tobacco smoke.

As previously mentioned throughout the text, a great number of the individual identified components found in tobacco and/or tobacco smoke are multifunctional. Many contain two or more functionalities, and for that reason, they are located in multiple chapters. The current Alphabetical Index to Components Identified in Tobacco, Tobacco Smoke, and Tobacco Substitute Smoke that follows the Reference section now contains 9390 components. The following is a summary of the overall change in the Index during the past 3 years:

Index Date	Tobacco Smoke	Tobacco	Tobacco and Tobacco Smoke	Subtotal	Smoke Isomers	Total
2012	6010	5595	2215	9390	192	9582
2008	5315	4994	1879	8430	192	8622

Between the 2008 assembly of the data on tobacco and tobacco smoke components and the current assembly of the revised edition, several meaningful procedures were utilized. A detailed review of the various major chapter tables and the Alphabetical Index in the 2008 Rodgman–Perfetti publication (5078) revealed the following:

- Several dozen components were duplicated in one or more of the major chapter tables and/or in the Alphabetical Index. The duplicates occurring in specific tables have been deleted. The following are several examples of such deletions from a chapter table and from the Index: In Table III-13 in (5078), cycloheptanone {suberone} was duplicated on pages 262 and 268. Because the page 268 item was out of sequence, it has been deleted. On page 1494 of the Index in (5078), the items 7-Azaindole and 7-Azaindole, *N*-methyl- were deleted because they were duplicated as 1*H*-Pyrrolo[2,3-*b*]pyridine and 1*H*-Pyrrolo[2,3-*b*]pyridine, 1-methyl- on pages 1761 and 1762, respectively. On page 1508 of the Index, the item 1,4-Benzenediol, monoacetate was duplicated several units apart; the second one has been deleted in the amended Index.
- Some components were inadvertently inserted in the wrong table. In Table III-12 (5078), three compounds were listed incorrectly as aldehydes. They are actually oxime derivatives of an aldehyde {propanal, 2-methyl-2-(methylsulfinyl)-, *O*-[(methylamino) carbonyl]oxime} {aldicarb sulfoxide}; propanal, 2-methyl-2-(methylsulfonyl)-, *O*-[(methylamino) carbonyl]oxime {Aldoxycarb®}; and propanal,

2-methyl-2-(methylthio)-, *O*-[(methylamino)carbonyl]oxime {Aldicarb®}. Such incorrect insertions have been deleted from Table 3.12. From Table III-13, 2*H*-1-benzopyran-3,5,7-triol, 3,4-dihydro-2-(3,4,5-trihydroxyphenyl)-, (2R-*Z*)- was deleted because it is not a ketone.

- Over 900 newly reported tobacco and/or tobacco smoke components, many with CAS Nos., have been appropriately inserted in one or more of the major chapter tables and in the updated Alphabetical Index.
- Because of the availability of significant analytical data on a component identified in tobacco, the same analytical data were eventually used during the past 3 years to certify the same component in tobacco smoke. The reverse situation was also applicable, i.e., significant analytical data available for a smoke component was used to identify a tobacco component. This situation resulted in modest changes in the number of tobacco smoke and tobacco components, and the number of components identified in both.

These deletions and additions resulted in an overall increase in the number of cataloged components from the 8622 previously reported [see p. 1764 in (5078)] to the current number, 9077. Inclusion of these newly reported components in the Alphabetical Index and various major chapter tables was also accompanied by a substantial increase, almost 1000, in the number of references listed in the updated Bibliography. The new references also contributed to expansion of many of the major chapter tables because of the insertion of the reference numbers in the reference lists for many components.

The updated Alphabetical Index contains 9390 individually identified components and numerous isomers. Each component is tabulated to indicate its identification in smoke, tobacco, or both. The total number of isomers noted in the Index is 292, but 100 of them are accounted for in the 9390 listed components. Thus, the number of identified/partially identified components in tobacco and tobacco smoke listed in our recent Index totals 9582 = (9390 + 292 − 100). The total number of chemical component entries in the chapters tables listed in Table 28.1 is 14,747. There are 9759 entries for tobacco, 8785 entries for tobacco smoke, and 3797 entries for both tobacco and tobacco smoke. The difference between 14,747 and 9583 indicates that indeed many of the chemical components of tobacco and smoke are multifunctional and as such are listed in several chapters.

The oxygen-containing components (tables in Chapters 2 through 10) account for the largest number of compounds found in tobacco and tobacco smoke, i.e., 8029. These components are distributed as follows: 6008 in tobacco and 4161 in tobacco smoke, with 2139 reported in both tobacco and tobacco smoke. The components in Chapters 18 through 24, 26, and 27 listed under Miscellaneous Components number 2362. There are 2070 components identified in tobacco, 1077 components identified in tobacco smoke, and 785 found in both tobacco and tobacco smoke. The nitrogen heterocyclic components (tables in Chapter 17) represent the next largest class of compounds with 1794 components identified in tobacco and tobacco smoke. In this section, there are 674 components identified in tobacco, 1458 components identified in tobacco smoke, and 338 found in both tobacco and tobacco smoke. The hydrocarbons (the five major tables in Chapter 1) represent the next class of compounds identified in tobacco and tobacco smoke. This section of Table 28.1 contains 1316 compounds. There are 368 hydrocarbons identified in tobacco, 1213 hydrocarbons identified in tobacco smoke, and 265 found in both tobacco and tobacco smoke. The nitrogen-containing components (tables in Chapters 11 through 16) are the smallest and last group of compounds identified in tobacco and tobacco smoke. This group of compounds numbers 1139. There are 639 nitrogen-containing components identified in tobacco, 769 nitrogen-containing components identified in tobacco smoke, and 269 reported in both tobacco and tobacco smoke.

Because of the great interest in the components in tobacco and tobacco smoke by academic and governmental agencies, we prepared a second index of the identified components. It is a listing of the components in the sequence of their CAS Nos. It follows the Alphabetical Index.

In closing, the authors hope that this amended version will serve a useful purpose. The content of the book represents over 60 years of effort by the researchers attempting to build a framework about our understanding of the complex mixtures of tobacco and tobacco smoke. Much progress has been made during the last 60 years in terms of understanding of tobacco and tobacco smoke. During that time, the number of identified components in tobacco and tobacco smoke has increased more than sevenfold. This progress has been due, in large part, to the great strides that have been made in analytical technology, but more than that, these scientists have shown great perseverance in the face of uncertainty and controversy surrounding the roles of tobacco and tobacco smoke and health.

> Great works are performed, not by strength, but by perseverance. (Samuel Johnson, ca. 1740)

We hope that present and future scientists will persevere and use the information contained herein to answer new questions by looking back to history.

> If you want to understand today, you have to search yesterday. (Pearl Buck, 1892–1973)

2809. Number of identified tobacco smoke components—A comment: Since the mid-1980s, few newly identified tobacco and tobacco smoke components have been reported. Reasonable explanations for why the number of identified smoke components may exceed 3,900 include: (a) At the 38th TCRC, Arrendale et al. reported the identification of a series of long-chained aliphatic esters [Arrendale, R.F., R.F. Severson, O.T. Chortyk, and M.G. Stevenson: Isolation and identification of the wax esters from the cuticular waxes of green tobacco leaf; Beitr. Tabakforsch. Int. 14 (1988) 67–84]. Although many matched those reported by Rodgman et al. [Rodgman, A., L.C. Cook, S.A. Bellin, S.S. Mims, and G.W. Young: The composition of cigarette smoke. IX. The composition of an aliphatic ester fraction from tobacco and tobacco smoke; Tob. Sci. 6 (1962) 42–49], other esters with higher molecular weight acid and alcohol moieties plus *iso* and *anteiso* structures were found by Arrendale et al. Since each ester reported by Rodgman *et al*. was found in tobacco *and* smoke, logic dictates that each new tobacco ester found by Arrendale et al. is also present in smoke. (b) In the PAH studies by Snook et al. [Snook, M.E., R.F. Severson, H.C. Higman, R.F. Arrendale, and O.T. Chortyk: Polynuclear aromatic hydrocarbons of tobacco smoke: Isolation and identification; Beitr. Tabakforsch. 8 (1976) 250–272; Snook, M.E., R.F. Severson, R.F. Arrendale, H.C. Higman, and O.T. Chortyk: The identification of high molecular weight polynuclear aromatic hydrocarbons in a biologically active fraction of cigarette smoke condensate; Beitr. Tabakforsch. Int. 9 (1977) 79–101; Multi-alkylated polynuclear aromatic hydrocarbons of tobacco smoke: Separation and identification; Beitr. Tabakforsch. Int. 9 (1978) 222–247], numerous peaks are listed as being mixtures of two or more isomers, a fact ignored by many cataloguers of smoke components. (c) In tobacco smoke, several dozen secondary amines exist for which no corresponding NNAs have been reported. Because these NNAs are known and stable, they probably exist in smoke. (d) Similarly, the parent amines for several volatile NNAs in smoke have not been identified in tobacco smoke.
