The extensive research on phenols in tobacco smoke eventually led to the resolution of the question whether selective filtration of a particular component or class of components in cigarette MSS was possible. Despite listing effective filtration as an important means to reduce cigarette MSS particulate matter, Wynder and Hoffmann in 1961 (4311) categorized "selective filtration" of a particular component or class of components in cigarette MSS as an impossibility. However, the next year, because of their findings with low-molecular-weight phenols in the MSS of filter-tipped cigarettes, Wynder and Hoffmann (4314) reversed their previously expressed assertion on the impossibility of "selective filtration." They reported that the levels of MSS low-molecular-weight phenols were significantly reduced (75%–90%) by the plasticized cellulose acetate filter tip.

It was determined by numerous investigators within and outside the tobacco industry that highly volatile, low-molecular-weight phenols such as phenol and the isomeric methylphenols (the cresols) were selectively filtered from cigarette MSS. That the filter-tip plasticizer (usually triacetin) played a significant role in the selective filtration was demonstrated in the early 1960s by Lorillard (2399), Laurene (2295, 2295a, 2298), Laurene et al. (2311, 2312), Spears (3765), and Hoffmann and Wynder (1791). Brown and Williamson patented the use of Carbowax® as an alternative filter-tip additive for selective filtration of low-molecular-weight phenols. Low-molecular-weight phenol levels in MSS were reduced 75%–90% by the selective filtration of triacetin- or Carbowax-treated cellulose acetate. Because of the volatility of the low-molecular-weight phenols, an equilibrium exists between these components of the tobacco smoke aerosol vapor phase and of the tobacco smoke aerosol particulate phase. Thus, these components are substantially partitioned between the particulate phase and vapor phase of cigarette MSS aerosol. The selective filtration (75%–90%) occurs by removal from the smoke stream of significant amounts of low-molecular-weight phenols in the aerosol vapor phase. During the brief time of the MSS transit through the plasticized filter tip, removal of the phenols from the vapor phase results in vaporization of the phenols from the particles in an attempt to reestablish the original particulate-phase and vapor-phase equilibrium.

Subsequently, it was determined by Fredrickson (1236) in the mid-1960s and by Morie and Sloan (2635) and Brunnemann et al. (514) in the 1970s that similar selective filtration occurred with volatile *N*-nitrosamines such as *N*-dimethylnitrosamine and *N*-diethylnitrosamine with 70%–80% of the volatile *N*-nitrosamines being removed from MSS by a plasticized cellulose acetate filter tip.

The discovery in the early 1960s of the selective filtration of the low-molecular-weight phenols from cigarette MSS was subsequently confirmed by numerous investigators throughout the world. As shown by the citations in Table 9.17, the selective filtration of phenols from cigarette MSS was extensively studied from the early 1960s to the mid-1970s. A few additional studies have been described from the mid-1970s to date.

From these studies, it was also reported by Laurene et al. (2311, 2312) that the effectiveness of the selective filtration of plasticized filter-tip cigarettes decreased during the shelf life of the cigarette.

Discovery of the extensive partitioning of low-molecular-weight phenols between the particulate and vapor phase of cigarette MSS necessitated modifications in their determination. While several low-molecular-weight PAHs such as naphthalene (mol. wt. 128) and its alkyl derivatives also show some partitioning between the particulate and vapor phases, the high-molecular-weight PAHs [anthracene and phenanthrene (mol. wt. 178),

B[*a*]A (mol. wt. 228), DB[*a,h*]A (mol. wt. 278), B[*a*]P (mol. wt. 252)] exist almost exclusively in the particulate phase. Before the extent of this partitioning and the selective filtration of low-molecular-weight phenols had been determined, most early studies dealt with analysis for the per cigarette yield of the low-molecular-weight phenols in the particulate phase. Thus, the relationships between the per cigarette levels of the tumorigenic PAHs and these phenols in mainstream CSC and the proposed promotion of the specific tumorigenicity of the PAHs by the phenols required reassessment.

This research observation-based comment raises the question about the repeated assertion of the importance of the promoting activity of phenol and other low-molecular-weight phenols, particularly in their supposed enhancement of the specific tumorigenicity of PAHs: What kind of tobacco smoke promoter is it that exerts so little effect that, in its absence, the specific tumorigenicity in the mouse-skin-painting bioassay of the CSC remains essentially unaltered?

Table 9.18 illustrates the effect of several tobacco expansion procedures and inclusion of the expanded tobacco in the cigarette blend on the MSS phenol yield.

Brunnemann et al. (496, 497) confirmed the previous finding of Waltz et al. (4123) that that 1,2-benzenediol (catechol) was the phenol usually present at the highest yield in cigarette MSS. Brunnemann et al. determined that the level of 1,2-benzenediol (catechol) in the MSS of a nonfiltered cigarette varied from 160 to 500 µg/cig. The level of 1,2-benzenediol (catechol) in the MSS from a filter-tipped cigarette varied from 60 to 200 µg/cig. They also reported that 1,2-benzenediol (catechol) and its derivatives were not selectively reduced by commercial cigarette filter tips as were many low-molecular-weight monohydric (one hydroxyl group) phenols.

In 1953, when RTS was introduced into its cigarette products by R.J. Reynolds Tobacco Company as a cigarette design technology, little was known about either the nature or yields of phenols in cigarette MSS (see Table 9.4). Also, the promoting activity of low-molecular-weight phenols to the specific tumorigenicity of PAHs had not been reported

by Boutwell et al. (414). Until the early to mid-1960s, the contribution of RTS to MSS composition dealt primarily with the decrease in the yields of the MSS PAHs, particularly B[*a*]P, and the decrease in the specific tumorigenicity (mouse skin) of the CSC as the % inclusion of the RTS in the blend was increased [see pp. 531–532 in (4332)].

Reports presented during the "less hazardous" cigarette workshop held at the *1967 World Conference on Smoking and Health* were published the next year as an NCI monograph edited by Wynder and Hoffmann (4343). Moshy and Halter presented data on the effect of inclusion of experimental RTS in a blend. They wrote (2647a):

> It is apparent from the data [presented] that selective reductions of up to 45% for benzo[*a*]pyrene and up to 87% for phenol were achieved with some of the experimental tobacco leaves [sic].

At the same conference, Hoffmann and Wynder (1798) also discussed the % reduction of the PAH content, specifically the B[*a*]P content, of the cigarette CSC by inclusion of RTS in the cigarette tobacco blend. Although analytical data on the decrease in TPM, B[*a*]P, and phenol yields were presented graphically, they had no comment on the significant % reduction in the phenol content of the MSS, a % reduction that exceeded that of the B[*a*]P content.

In the NCI Smoking and Health Program on the "less hazardous" cigarette, the substantially lowering of the yields of phenol and the 2-, 3-, and 4-methylphenols (*o*-, *m*-, and *p*-cresols) in the MSS from RTS (paper process) cigarettes *vs*. the tobacco blend (SEBI) was recorded (1329).

At RJRT R&D, Newell et al. (2765) reported the results of a detailed study of the effect of increasing the level of RTS (G7) on the composition of cigarette MSS. Decreased MSS yields of the PAHs, nicotine, and phenols plus increased yields in carbon monoxide, aldehydes, ketones, and low-molecular-weight acids were observed.

In 1979, the U.S. Surgeon General (4005) reported the beneficial effects of inclusion of RTS on the MSS composition (B[*a*]P, phenols, specific tumorigenicity):

> Cigarette fillers low in wax layer components, either by use of tobacco stems, reconstituted tobacco sheet, or tobacco extracted with a hexane-ethanol mixture, delivered smoke significantly reduced in catechols … Although it has not been directly established that a selective reduction in catechol leads to a significant reduction of the tumorigenic potential of cigarette smoke, it is of interest that all those tars or whole smokes of cigarettes which are low in catechol also have a significant lower tumorigenic activity [Gori (1329, 1330, 1332)].

These comments on the relationship between RTS and the 1,2-benzenediol (catechol) yield in MSS are of interest because examination of the MSS data from the four sets of experimental cigarettes [Gori (1329, 1330, 1332, 1333), NCI (2683)] reveals that no analysis for 1,2-benzenediol (catechol) was conducted on any of the cigarette samples in the study, i.e., the 100 or so experimental cigarettes or the standard SEBI, SEBII, SEBIII, or SEBIV cigarettes and the Kentucky 1R1 reference cigarette.

In the late 1950s and the 1960s, one of the methods studied to control the pyrosynthesis of PAHs from tobacco during the smoking process was the addition of various materials (inorganic or organic) to the tobacco in attempts to control its combustion and lower the per cigarette PAHs yields, particularly the B[*a*]P yield, in the tobacco smoke [Alvord and Cardon (56, 57), Lindsey et al. (2370), Rodgman (3246, 3254), Bentley and Burgan (286), Candeli et al. (589), Wynder and Hoffmann (4311, 4317, 4319, 4332), Cuzin et al. (885), deSouza and Scherbak (953), Pyriki et al. (3046), Hoffmann and Wynder (1797, 1798)].

The most effective additives in PAHs reduction were the nitrates. The following explanation of their effectiveness was offered: When heated, the nitrates generate nitric oxide (NO), an odd-electron compound, capable of "scavenging" free radicals thermally generated from tobacco components during the smoking process, thus interrupting the free radical reactions postulated as contributing to one of the mechanisms important in the generation of PAHs in tobacco smoke [see Badger and Spotswood (152), Badger (139a, 140), Badger et al. (141, 142, 147)].

However, in addition to lowering the levels of PAHs in tobacco smoke, addition of nitrates or the use of high-nitrate tobacco affected MSS yield and composition in other ways. In the 1950s and early 1960s, the reductions in the MSS yields of "tar," nicotine, and PAHs in general and B[*a*]P in particular were viewed as desirable achievements. When concern was expressed about the supposed promoting action of the low-molecular-weight phenols, the reduction of their levels in MSS by nitrate addition to the tobacco was also viewed positively. These decreases were, however, accompanied by an increase in the level of NO in the smoke. Subsequently, two reported observations did much to dampen the enthusiasm for nitrate addition to the tobacco and/or the use of high-nitrate tobaccos in the blend:

- The identification of various volatile and tobacco-specific *N*-nitrosamines in tobacco and its smoke and the positive dependence of their levels in both tobacco and smoke on the nitrate level of the tobacco [Morie and Sloan (2635), Tso et al. (3985), Brunnemann et al. (499)].
- The identification of a series of nitrophenols, many of which are known to be highly toxic, in the MSS from cigarettes fabricated with nitrate-treated tobacco and/or with high-nitrate tobaccos in the blend [Kallianos et al. (2016), Klus and Kuhn (2137)].

Table 9.19 summarizes some of the studies on the use of nitrate addition to tobacco and/or use of high-nitrate tobacco to reduce the yields of PAHs in cigarette MSS. Also noted in Table 9.19 are some of the other compositional changes observed in MSS yield and composition. In most instances, the yields of MSS PAHs in general and B[*a*]P were reduced, although an

occasional exception was observed, e.g., in the NCI Smoking and Health Program on "less hazardous" cigarettes the MSS B[*a*]P yield increased with nitrate addition but the B[*a*]A yield decreased (1329). Benner et al. (274) reported that a comparison of the low-molecular-weight phenols in the MSS from high- and low-nitrate tobaccos showed little difference in the yields of phenol/mg TPM but significant decreases in the yields of the methylphenols (the cresols)/mg TPM. Benner et al. (276, 277) also reported that treatment of tobacco with an alternative combustion modifier (3:7 boric acid–sodium tetraborate decahydrate) increased the levels of low-molecular-weight phenols in cigarette MSS, an increase that was paralleled by the increase in low-molecular-weight phenols in the pyrolysates from cellulose or lignin treated with the same boric acid–tetraborate modifier.

In the mid-1970s, Brunnemann et al. (497) described an improved method for the quantitation of 1,2-benzenediol (catechol) in tobacco smoke and a possible way to reduce its MSS level. The procedure they described involved extraction of tobacco with a hexane–ethanol azeotrope which removed from the tobacco what Brunnemann et al. defined as "waxes." They noted:

> Compared to the corresponding control cigarette, the dry TPM [from a cigarette filled with reconstituted tobacco from which the "wax" layer had been removed by hexane-ethanol azeotrope extraction] had been reduced by 44%, the nicotine by 47% and catechol by 85%. This demonstrates a strong, selective reduction of catechols in the smoke by the removal of the "wax" layer.

Additional impetus to study the level and source of 1,2-benzenediol (catechol) in tobacco smoke was provided by Hecht et al. (1562) who asserted that 1,2-benzenediol (catechol) was an important tobacco smoke cocarcinogen. They also noted that the levels of 1,2-benzenediol (catechol) in cigarette MSS were reduced by prior extraction of the tobacco with a hexane–ethanol azeotrope or by inclusion of RTS in the tobacco blend.

From the results of their study of cellulose *vs.* carboxymethylcellulose as a precursor of 1,2-benzenediol (catechol) in tobacco smoke, Carmella et al. (599, 601) reported that the carboxymethylation of tobacco cellulose significantly reduced the level of 1,2-benzenediol (catechol) in tobacco smoke.

Wynder and Hoffmann asserted that cigarette MSS yield and composition were controllable in a beneficial way by increasing the number of cuts/in for the tobacco blend filler. Results obtained in the NCI program on the "less hazardous" cigarette and reported in 1976 by Gori (1329) and 1980 by NCI (2683) were contradictory to the unpublished results obtained in 1963 by Hoffmann and Wynder and later reported by Wynder and Hoffmann [see p. 318 in (4319), pp. 529–531 in (4332), (4330)]. In the NCI study, important analytes such as B[*a*]P, B[*a*]A, phenol, and the three methylphenols (cresols) showed no consistent relationship between their MSS yields and width of cut of the cigarette tobacco filler. The mouse-skin-painting bioassay also showed no consistency between % TBA and the CSCs generated from cigarettes with fillers of different cut widths.

In their report of the results of an unpublished study by Hoffmann and Wynder of the effect of width of cut of the cigarette filler, Wynder and Hoffmann reported that increasing the number of cuts/in (decreasing the cut width) decreased the per cigarette MSS yield of TPM and B[*a*]P. They did not report on the effect of cut width on phenols delivery. However, they did report that the specific tumorigenicity of the CSCs from cigarette fabricated with tobacco at 20, 30, and 50 cuts/in decreased as the number of cuts/in increased [see p. 318 in (4319), pp. 529–531 in (4332), (4330)]. Subsequently, Wynder and Hecht (4306d) tabulated the effect on chemical and biological properties of change in cut width as follows: "insignificant" for the change in per cigarette MSS yields of carbon monoxide, "tar," nicotine, and B[*a*]P, as "insignificant" for the change in MSS ciliatoxicity, as "insignificant" for the change in specific tumorigenicity (mouse skin) of the CSC, and "unknown" for the changes in tumor-promoting effect. Their table was used essentially unchanged by the Surgeon General in his 1979 report on smoking and health (4009).

In the NCI Smoking and Health Program on "less hazardous" cigarettes [Gori (1329), NCI (2683)], the effects of cut width on cigarette smoke properties (chemical composition, biological properties) were not as pronounced as the effects reported by Hoffmann and Wynder in Wynder and Hoffmann [see p. 318 in (4319), pp. 529–531 in (4332), (4330)]. Examination of the summary of these studies in Table 9.20 reveals the lack of confirmation of the Hoffmann–Wynder results. In fact, the proposal that cut width would be a significant technology in the design of a "less hazardous" cigarette was similar to many of the proposals from the so-called cigarette design experts not associated with the tobacco industry. Of the numerous technologies proposed during the decade-long NCI study, only those eight technologies proposed by U.S. tobacco company and/or tobacco supplier R&D personnel were eventually classified as significant by the NCI (2683), Gori (1332, 1333), the U.S. Surgeon General (4005, 4009), and other anti-tobacco smoking investigators such as Hoffmann and Hoffmann (1740).

The effectiveness of the various methods proposed to control the yield of the supposed promoting low-molecular phenols may be summarized as follows:

Tobacco extraction with wax-dissolving nonpolar organic solvents (hexane, pentane) to remove PAH precursors does indeed result in reduced levels of PAHs, including B[*a*]P, in cigarette MSS. However, the solution of what was considered by some as a possible PAH problem is accompanied by the creation of two alternative problems, both of which might be criticized from a scientific point of view. For example, extractive removal of the nonpolar organic solvent-soluble material results in an increase in the percentage of the organic solvent-insoluble biopolymers (the major phenol precursors cellulose, pectins, starch, lignin) in the extracted tobacco residue. Smoking of the extracted residue in cigarette form yields higher levels of low-molecular-weight phenols in the MSS (3277, 3305). In addition, nitrates in the tobacco are not removed by solution in nonpolar organic solvents, so their percentages in the extracted tobacco residue increase. Experimental results reported by Morie and Sloan (2635), Tso et al. (3985), and Brunnemann et al. (499) indicated that smoking of this increased nitrate level extracted residue in cigarette form would yield higher levels of *N*-nitrosamines in the MSS.

[d] Painting dose = 25 mg of cigarette smoke condensate/day.

Tobacco extraction with a hexane–ethanol azeotrope selectively reduced the levels of 1,2-benzenediols (catechols) in the cigarette MSS. Tobacco extraction with a polar organic solvent system (aqueous ethanol or aqueous methanol) removes chlorogenic acid, a known major precursor of 1,2-benzenediol (catechol), a phenol categorized as a cocarcinogen.

Because nitrate addition to tobacco resulted in reduction of the cigarette MSS deliveries of "tar," nicotine, PAHs including B[*a*]P, and the low-molecular-weight phenols, nitrate addition and/or use of high-nitrate tobacco was considered to be the way to introduce the most effective combustion modifier. However, while apparently solving several problems concerning MSS yield and composition, nitrate addition caused several alternate problems: Once the levels of *N*-nitrosamines and nitrogen oxides (NO) in tobacco smoke were shown to be positively correlated to the nitrate content of the tobacco filler, nitrate addition and/or the use of high-nitrate tobaccos was eventually viewed as undesirable technologies. In addition, higher nitrate tobacco fillers, whether a result of nitrate addition or inclusion of high-nitrate tobaccos, generated a series of nitrophenols, many of which are known to be highly toxic.

From a comparison of the pyrogenesis of 1,2-benzenediol (catechol) from cellulose *vs.* carboxymethylcellulose, it was reported that the carboxymethylation of tobacco cellulose significantly reduced the level of 1,2-benzenediol (catechol) in tobacco smoke (599, 601).

Of the various technologies proposed to control the levels of phenols in cigarette MSS, selective filtration appears to be the most effective and most efficient. A significant portion (65%–75%) of the low-molecular-weight monohydric phenols in cigarette MSS are removed from the smoke stream by a cellulose acetate filter tip plasticized with triacetin. As the cigarette ages, the plasticizer is slowly absorbed by the cellulose acetate fiber and the effectiveness of the selective filtration gradually decreases with time. The one drawback with selective filtration is that it does not occur with dihydric phenols such as 1,2-benzenediol (catechol) in the MSS, i.e., 1,2-benzenediol and its homologs are not selectively removed from MSS by a plasticized filter tip.

Many of the complex tobacco-only phenolic components have interesting structures in that they contain a cyclohexanecarboxylic acid moiety linked to one of the following: (1) a 4-hydroxyphenyl group, e.g., *p*-coumaroylquinic acid; (2) a 3,4-dihydroxyphenyl group, e.g., chlorogenic acid; or (3) a 3-methoxy-4-hydroxyphenyl group, e.g., 3-*O*-feruloylquinic acid. In each case, one can theorize that during the tobacco smoking process, the complex tobacco phenol could sequentially yield a substituted 2-propenoic acid, a substituted benzaldehyde, a substituted benzoic acid, and a simple phenol. Table 9.21 summarizes the possible sequence of the pyrogenesis of such components. Each of the compounds listed as tobacco smoke components in Table 9.21 has been identified in cigarette MSS.

A similar situation exists with a series of components in which a variously substituted 4*H*-1-benzopyranone is linked to a 4-hydroxyphenyl group, e.g., kaempferol, or a 3,4-dihydroxyphenyl group, e.g., quercetin, quercetrin, and rutin.

In Table 9.22, the various phenolic components of tobacco and tobacco smoke are listed, with appropriate references to the identifications for each. Many of the references cited

contain additional references pertinent to the phenolic component in question. The many references cited in Table 9.22 include a variety of topics pertinent to the particular phenol. They cover the following topics:

1. The isolation and/or identification of the phenol from tobacco and/or smoke
2. Methods to quantitate the phenolic component in tobacco and/or smoke
3. Determination of the precursors in tobacco of the phenolic compound in smoke
4. Cigarette design technologies to decrease the per cigarette MSS yield of the phenolic compound
5. The biological properties of the phenolic compound
6. Discussions by personnel from governmental agencies, medical institutions, etc., on the biological problems pertinent to a given phenolic compound

While 607 phenolic components have been completely or partially identified in tobacco and tobacco smoke, 305 were identified in tobacco only, 468 in tobacco smoke only, and 166 were identified in both tobacco and tobacco smoke. For the tobacco smoke components partially identified, the nature and/or position of an alkyl substitute was not defined by the investigator.

9.2 QUINONES

Even in the mid-1950s when knowledge of the composition of tobacco smoke was extremely limited and only a few phenols were known to be present in tobacco smoke, it was suggested that several of the phenols might be converted to the corresponding quinone during the smoking process.

This suggestion, coupled with the mouse-skin-painting bioassay results reported by Takizawa (3865a) that several simple quinones such as 2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone), 1,2-naphthalenedione (1,2-naphthoquinone), and 1,4-naphthalenedione (1,4-naphthoquinone) were tumorigenic to mouse skin, raised serious questions about the desirability of adding phenols to the tobacco blend to enhance the odor and flavor of its smoke. Despite the many studies in which benzene was used as the solvent for testing of the tumorigenicity of PAHs, benzene seldom induced tumors in the skin-painted solvent-control group of laboratory animals [Hartwell (1543, 1544), Shubik and Hartwell (3664, 3665), Thompson et al. (3908)]. Similarly, naphthalene was found to be nontumorigenic in skin-painting studies.

The mouse-skin-painting bioassay results with 2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone) were subsequently confirmed by Tiedemann (3916a). Neither of the higher molecular weight tricyclic quinones 9,10-anthracenedione (9,10-anthraquinone) (3865a) nor 9,10-phenanthrenedione (9,10-phenanthrenequinone) (3865a) was reported to be tumorigenic to mouse skin.

In the early days of the studies on the specific tumorigenicity of various classes of compounds to mouse skin, investigators were intrigued by the activities exhibited by aromatic hydrocarbons, their dihydric phenols, and the quinones corresponding to the dihydric phenols. The results of mouse-skin-painting bioassays with various aromatic hydrocarbons ranging in complexity from monocyclic to hexacyclic, their dihydric phenols, and the corresponding quinones are summarized in Table 9.23.

From the studies on the chemical relationship between aromatic hydrocarbons and their quinones, the theory of the oxidation–reduction potential of quinones was proposed. A prime proponent of this theory was Fieser (1180b) who reported the reduction potentials of the following quinones:

- Several anthracenediones other than 9,10-anthracenedione [Conant and Fieser (790b); Fieser (1180a-1)]
- 9,10-Phenanthrenedione (9,10-phenanthraquinone) [Fieser (1180a-2)]
- 2,5-Cyclohexadiene-1,4-dione (*p*-benzoquinone) [Fieser (1180a-3)]
- Several naphthalenediones other than the 1,2- and 1,4-naphthalenediones[Fieser (1180a-4)]
- 7,12-Benz[*a*]anthracenedione (7,12-benz[*a*]anthraquinone), 7,14-dibenz[*a,h*]anthracenedione (7,14-benz[*a,h*]anthraquinone), 5,6-chrysenedione (5,6-chrysenequinone), 6,12-chrysenedione (6,12-chrysenequinone) [Fieser and Dietz (1180a-5)]
- 3,5-Cyclohexadiene-1,2-dione (*o*-benzoquinone) and 1,2-naphthalenedione (1,2-naphthoquinone [Fieser and Peters (1180a-6)]
- 9,10-Anthracenedione (9,10-anthraquinone) [Fieser and Peters (1180a-7)]
- 1,4-Naphthalenedione (1,4-naphthoquinone) [Fieser and Fieser (1180a-8)]

After the first demonstrations by Kennaway and Hieger (2078) of the tumorigenicity to mouse skin of DB[*a,h*]A, a PAH synthesized by Fieser and Dietz (1184), and of B[*a*]P by Barry et al. (194), the coal tar component isolated from coal tar and subsequently synthesized by Cook et al. (796a, 797), the tumorigenicity of a great number of PAHs and their derivatives was studied.

TABLE 9.23
Comparison of the Tumorigenicities of Aromatic Hydrocarbons, Their Diols (Phenols), and Their Diones (Quinones)

Hydrocarbon		Diol		Dione	
Benzene	–	1,4-Benzenediol (hydroquinone)	–	2,5-Cyclohexadiene-1,4-dione (*p*-benzoquinone)	+
		1,2-Benzenediol (catechol)	–	3,5-Cyclohexadiene-1,2-dione (*o*-benzoquinone)	?
Naphthalene	–	1,2-Naphthalenediol	–	1,2-Naphthalenedione (1,2-naphthoquinone)	+
		1,4-Naphthalenediol	–	1,4-Naphthalenedione (1,4-naphthoquinone)	+
Anthracene	–	9,10-Anthracenediol	–	9,10-Anthracenedione (9,10-anthraquinone)	–
Phenanthrene	–	9,10-Phenanthrenediol	–	9,10-Phenanthrenedione (9,10-phenanthraquinone)	–
Chrysene	±	5,6-Chrysenediol	–	5,6-Chrysenedione (5,6-chrysenequinone)	–
		6,12-Chrysenediol	–	6,12-Chrysenedione (6,12-chrysenequinone)	–
Benz[*a*]anthracene	±	7,12-Benz[*a*]anthracenediol	–	7,12-Benz[*a*]anthracenedione (7,12-benz[*a*]anthraquinone)	–
Dibenz[*a,h*]anthracene	+	7,14-Dibenz[*a,h*]anthracenediol	–	7,14-Dibenz[*a,h*]anthracenedione (7,14-Dibenz[*a,h*]anthraquinone)	–
Benzo[*a*]pyrene	+			Benzo[*a*]pyroquinone	–
Dibenzo[*b,def*]chrysene	+			7,14-Dibenzo[*b,def*]chrysenedione	–

–, negative response in mouse-skin-painting bioassay; +, positive response in mouse-skin-painting bioassay; ±, equivocal response in mouse-skin-painting bioassay.

Soon observed was the pronounced contrast between the gradation in specific tumorigenicities in the mouse-skin-painting bioassay from the nontumorigenicity of the mono- and bicyclic aromatic hydrocarbons benzene and naphthalene, respectively, to the potent tumorigenicities of the pentacyclic aromatic hydrocarbons DB[*a,h*]A and B[*a*]P *vs.* the tumorigenicities of the quinones 2,5-cyclohexadien-1,4-dione (*p*-benzoquinone), 1,2-naphthalenedione (1,2-naphthoquinone), and 1,4-naphthalenedione (1,4-naphthoquinone) and the nontumorigenicities of dibenzanthraquinone and benzopyroquinone. Neither the tricyclic aromatic hydrocarbons anthracene and phenanthrene nor their corresponding quinones have elicited tumors in the mouse-skin-painting bioassay. The tumorigenicities of the tetracyclic hydrocarbons benz[*a*]anthracene and chrysene have been classified as extremely weak or equivocal. None of their quinones has shown tumorigenicity in the mouse-skin-painting bioassay (see Table 9.23). Initially, it was found that the higher the tumorigenic potency of the quinones, particularly the benzoquinones and the naphthoquinones, the higher was the reduction potential of the quinone. In essence, the oxidation–reduction potential theory was eventually used in an attempt to relate the oxidation–reduction potential of the hydrocarbon–quinone system to the specific tumorigenicity observed in the mouse-skin-painting bioassays for PAHs and their quinones.

Although none of the diols (phenols) listed in Table 9.23 was found to be tumorigenic, in subsequent research dealing with the metabolism of tumorigenic PAHs, it was found that some of the dihydrodiols and dihydrodiol epoxides were tumorigenic to mouse skin [see review by Dipple et al. (983)]. However, it is obvious from examination of the structures of the dihydrodiols and dihydrodiol epoxides that none of these metabolites is a phenol.

As the laboratory data and understanding of chemical carcinogenesis increased dramatically pre- and post-World War II, exceptions to the theory of oxidation–reduction potential resulted in its being supplanted by other more meaningful theories, e.g., the relationship between electronic configuration, the activity of the so-called K region, and the inactivity of the so-called L region in aromatic compounds, particularly PAHs, and their tumorigenicity [see reviews by Coulson (829), Pullman and Pullman (3003)]. The interest in the theory of the electronic configuration–tumorigenesis relationship of PAHs was such that the 1953 review by Coulson was selected as the introductory chapter in Volume 1 of the newly instituted publication *Advances in Cancer Research.*

It is interesting to note that even in the early 1950s, the idea of the involvement of a hydroxylated PAH metabolite in tumorigenesis was already being discussed. For example, Pullman and Pullman (3003) wrote:

> It is nevertheless generally admitted that [dihydro]diols are probably intermediates in the metabolism of aromatic hydrocarbons.

Although their speculation as to the precise nature of its involvement was somewhat in error, the Pullmans (3003) did propose that a dihydroepoxide might also be involved in the metabolism of PAHs, the metabolite–cellular component interaction, and the tumorigenicity attributed to some of the PAHs.

The oxidation–reduction potential of the aromatic hydrocarbon–quinone system was revisited some years later and its possible involvement in cigarette smoke. Schmeltz et al. (3510) reported that cigarette smoke condensate (CSC) possessed reducing properties sufficient to reduce 2,5-cyclohexadiene-1,4-dione (1,4-benzoquinone; *p*-benzoquinone) to 1,4-benzenediol (hydroquinone). This CSC-induced reduction apparently did not occur with 9,10-anthracenedione (9,10-anthraquinone).

Compared to the number of polycyclic aromatic hydrocarbons (PAHs) and phenols identified in tobacco smoke, the number of identified quinones is low despite the fact that many of the phenols after their pyrogenesis during the smoking process could realistically yield quinones. Table 9.24 lists the 49 quinones identified to date in tobacco and tobacco smoke. Of the 50 listed, 38 were identified in tobacco smoke, 19 in tobacco, and 7 in both. In his 1954 review of tobacco smoke components identified to that date, Kosak (2170) listed no quinone.

In view of tobacco smoke composition findings after the mid-1950s, the suggestion in the late 1950s by Rodgman that phenols were inappropriate additives for cigarette smoke flavor enhancement might have been an example of excessive caution. His suggestion was based on two factors: The promoting effect of phenols reported in 1955, 1956, and 1959 by Boutwell and his colleagues (414) plus the possible conversion during the smoking process of substituted phenols to corresponding quinones, several of which had been reported to be tumorigenic by Takizawa (3865a) and Tiedemann (3916a). Obviously, the latter situation occurred infrequently. The great discrepancy between the great number of phenols *vs.* the small number of quinones identified in tobacco smoke suggests that the phenol–quinone conversion does not occur in many instances or, if it does occur, the conversion results in the generation of extremely low levels of the quinone. As noted elsewhere, it has been estimated from examination of the many peaks and shoulders in the detailed glass capillary gas chromatograms from tobacco smoke and/or its fractions that the number of tobacco smoke components exceeds the number of identified tobacco smoke components by factors ranging from 10 to 25 [e.g., see Wakeham (4103)]. It is possible that quinones contribute to some of the extremely minor chromatographic peaks representing components as yet unidentified.

Table 9.25 lists the chronology of some of the major events pertinent to the identification of quinones in tobacco smoke. It is obvious that the number of significant events for these quinones is substantially less than those cataloged for the PAHs, the aza-arenes, the phenols, and the *N*-nitrosamines. More than likely, the difference is a direct reflection of the concern expressed relative to the tumorigenicity in laboratory animals of the various classes of compounds.

TABLE 9.25
Chronology of Identification of Quinones in Tobacco and/or Smoke

Year	Event
1924–1934	Fieser and his colleagues investigated the reduction of quinones and generated the theory of the oxidation–reduction potential of quinones. The reduction of the following quinones was studied: several anthracenediones other than 9,10-anthracenedione [Conant and Fieser (790b), Fieser (1180a)]; 9,10-phenanthrenedione (9,10-phenanthraquinone) (1180a); 2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone) [Fieser (1180a)]; several naphthalenediones other than the 1,2- and 1,4-naphthalenediones [Fieser (1180a)]; 3,5-cyclohexadiene-1,2-dione (*o*-benzoquinone) and 1,2-naphthalenedione (1,2-naphthoquinone) [Fieser and Peters (1180a)]; 9,10-anthracenedione (9,10-anthraquinone) [Fieser and Peters (1180a)]; 1,4-naphthalenedione (1,4-naphthoquinone) [Fieser and Fieser (1180a)]; 7,12-benz[*a*]anthracenedione (7,12-benz[*a*]anthraquinone), 7,14-dibenz[*a,h*]anthracenedione (7,14-benz[*a,h*] anthraquinone), 5,6-chrysenedione (5,6-chrysenequinone), 6,12-chrysenedione (6,12-chrysenequinone) [Fieser and Dietz (1180a)]. Later, the theory of the oxidation–reduction potential of quinones was advanced to explain the differences in tumorigenicity of the various quinones and their aromatic hydrocarbons sources
1940–1941	Takizawa (3865a) reported that several simple quinones [2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone), 1,2-naphthalenedione (1,2-naphthoquinone), 1,4-naphthalenedione (1,4-naphthoquinone)] were tumorigenic in mouse-skin-painting experiments
1942	Fieser (1180b) reviewed the theory of the oxidation–reduction potential of quinones. Because some nontumorigenic aromatic hydrocarbons (benzene, naphthalene) yielded tumorigenic quinones, some nontumorigenic aromatic hydrocarbons yielded nontumorigenic quinones, and some tumorigenic aromatic hydrocarbons (dibenz[*a,h*]anthracene) yielded nontumorigenic quinones, attempts were made to correlate the relationship between aromatic hydrocarbons, their quinones, the reduction potential of quinones, and the tumorigenicities (mouse skin) of the aromatic hydrocarbons *vs*. the tumorigenicities of their quinones
1953	Tiedemann (3916a) confirmed the finding of Takizawa on the tumorigenicity of 2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone) to mouse skin
1953–1955	The theory of oxidation–reduction potential of quinones was supplanted by other more meaningful theories, e.g., the relationship between electronic configuration, the activity of the so-called K region, and the inactivity of the so-called L region in aromatic compounds, particularly PAHs, and their tumorigenicity [see reviews by Coulson (829) and Pullman and Pullman (3003)]
1954	Kosak (2170) in his compilation of tobacco smoke components reported in the literature did not list a quinone
1957	Bonnet and Neukomm (396) suspected the presence of 2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone) in cigarette mainstream smoke because of the identification of 1,4-benzenediol (hydroquinone) when the smoke was collected under reducing conditions. Under similar reducing conditions, they were unable to identify 1,4-napthalenediol, concluding that 1,4-napthalenedione (1,4-naphthoquinone) was not present in the smoke
1959	Bentley and Berry (282) in their compilation of identified tobacco smoke components listed the report of 2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone) by Bonnet and Neukomm (396)
1959	In their review of tobacco and tobacco smoke composition, Johnstone and Plimmer (1971) listed no quinone in tobacco or tobacco smoke
1961	Onishi et al. (2860) reported the presence of 9,10-anthracenedione (9,10-anthraquinone) in tobacco smoke
1965	Kröller (2195) reported the presence of 9,10-anthracenedione (9,10-anthraquinone) and 9,10-phenanthrenedione (9,10-phenanthraquinone) in tobacco smoke
1965	To estimate the 1,4-benzenediol (hydroquinone) in tobacco smoke, Testa et al. (3891) used air oxidation to convert the 1,4-benzenediol (hydroquinone) to 2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone) which was subsequently derivatized and estimated. No effort was made to determine whether any 2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone) was already present in the smoke prior to the air oxidation
1968	In his review of tobacco and tobacco smoke composition, Stedman (3797) listed only two quinones, 9,10-anthracenedione (9,10-anthraquinone) in tobacco and 2,3,6-trimethyl-1,3-naphthalenedione (2,3,6-trimethyl-1,4-naphthoquinone) in tobacco smoke. He discussed the Bonnet and Neukomm (396) report. Because of the uncertainty of the Bonnet and Neukomm data and additional data from Testa et al. (3891), Stedman did not include 2,5-cyclohexadiene-1,4-dione (*p*-benzoquinone) as a tobacco smoke component. He also did not include the reports of the presence of 9,10-anthracenedione (9,10-anthraquinone) [Onishi et al. (2960), Kröller (2195)] or 9,10-phenanthrenedione (9,10-phenanthraquinone) (2195) in tobacco smoke
1968–1969	Bell et al. (246, 247) reported the presence of several alkylated 9,10-anthracenediones in tobacco smoke
1969–1978	RJRT R&D personnel identified numerous previously unidentified alkylated 2,5-cyclohexadiene-1,4-diones and 9,10-anthracenediones in tobacco smoke [Green et al. (1360, 1378), Schumacher et al. (3553), Heckman (1586), Newell et al. (2769)]
1976–1977	Schmeltz et al. (3510) identified several previously unidentified alkylated 2,5-cyclohexadiene-1,4-diones and 9,10-anthracenediones in tobacco smoke
1978–1980	Snook et al. (3747, 3748) identified a series of alkyl-, dialkyl-, trialkyl-, and tetraalkyl-1,4-naphthalenediones in tobacco smoke

10 Ethers

Assessment of the chronology of the number of ethers identified in tobacco and tobacco smoke provides another excellent example of the effect of the advancements in analytical technology on our ability to identify components in a complex mixture. In his 1954 review of the components identified to that date in tobacco smoke, Kosak (2170) lists only two ethers, 2-furancarboxaldehyde (furfural) and 1,6-anhydro-β-*D*-glucopyranose (levoglucosan). Johnstone and Plimmer (1971) did not list ethers as a specific class of components in tobacco and/or tobacco smoke but did mention the identification of several under different headings in their 1959 review, e.g., furan, 2-methylfuran, 2-furancarboxaldehyde (furfural) and two of its derivatives (3,4-dihydro-2,5,7,8-tetramethyl-2-(4,8,12-trimethyltridecyl)-2*H*-1-benzopyran-6-ol (α-tocopherol) and 3,4-dihydro-2,7,8-trimethyl-2-(4,8,12,16,20,24,28,32-octamethyl-3,7,11,15,19,23,27,31-tritriacontaoctaenyl)-2*H*-1-benzopyran-6-ol (solanachromene)), the monosaccharides (glucose and fructose), the disaccharide (sucrose), the trisaccharides (raffinose and planteose), and the tetrasaccharide (stachyose). Overall, fewer than 30 ethers are listed by Johnstone and Plimmer (1971).

From 1959 to date, the number of ethers identified in tobacco and/or tobacco smoke has increased over 40-fold to 1243, 654 of which have been identified in tobacco smoke, 847 identified in tobacco, and 258 identified in both tobacco and tobacco smoke. In his 1968 review, Stedman (3797) tabulated the presence of five cyclic ethers in tobacco smoke, i.e., furan, methylfuran, 2,5-dimethylfuran, tetrahydrofuran, and tetrahydropyran. Currently, the number of identified ethers with a furan nucleus is almost 400, and the number with a pyran nucleus exceeds 275. The methoxy and ethoxy ethers number almost 300, phenoxy ethers number 22.

One type of ether that received considerable attention included the ethers derived from the cyclotetradecanols (see Figure 10.1). Because of their unusual structure, none of them were counted in the furan or pyran nucleus group. Over 25 of these ethers have been identified in tobacco and/or tobacco smoke (9, 12, 3351, 3352, 3360, 3361, 4089–4091).

As noted by Rodgman (3266), many components, including a number of ethers, used by the tobacco industry in its flavor formulations [see listing by Doull et al. (1053)] are known components of additive-free tobacco and/or its smoke. Thus, such additives are not strangers to tobacco and/or its smoke, but their addition increases the consumer acceptable flavor. Table 10.1 lists some of the tobacco and/or tobacco smoke ether components that have been or are used in flavor formulations.

In Table 10.2 are listed the various ethers identified to date in tobacco, tobacco smoke, and tobacco substitute smoke. Of the 1243 ethers identified to date, 654 have been reported in tobacco smoke, 847 in tobacco, and 258 in both tobacco and tobacco smoke.

OVERALL SUMMARY OF OXYGEN-CONTAINING COMPONENTS OF TOBACCO AND/OR TOBACCO SMOKE: CHAPTERS 2 THROUGH 10

Table 10.3 summarizes the distribution in our catalogs in Chapters 2 through 10 of the *O*-containing components identified in tobacco and/or tobacco smoke. As we have noted in the introductions to each of the nine chapters, the numbers for the various classes of *O*-containing components have escalated tremendously since the last published review by Stedman (3797) in 1968 on tobacco and tobacco smoke components identified to that date.

104-45-0	Benzene, 1-methoxy-4-propyl-	Dihydroanethole	H	–
623-15-4	3-Buten-2-one, 4-(2-furanyl)-	4-(2-Furyl)-3-buten-2-one	+	+
100-06-1	Ethanone, 1-(4-methoxyphenyl)-	Acetanisole	+	+
1193-79-9	Ethanone, 1-(2-furanyl 5-methyl)-	2-Acetyl-5-methylfuran	+	+
611-13-2	2-Furancarboxylic acid, methyl ester	Methyl 2-furoate	+	+
93-18-5	Naphthalene, 2-ethoxy-	β-Naphthyl ethyl ether	–	+
470-82-6	2-Oxabicyclo[2.2.2]octane, 1,3,3-trimethyl-	Eucalyptol	+	+
91-10-1	Phenol, 2,6-dimethoxy-	2,6-Dimethoxyphenol	+	+
7786-61-0	Phenol, 4-ethenyl-2-methoxy-	2-Methoxy-4-vinylphenol	+	+
123-07-9	Phenol, 4-ethyl-	*p*-Ethylphenol	+	+
90-05-1	Phenol, 2-methoxy-	Guaiacol	+	+
93-51-6	Phenol, 2-methoxy-4-methyl-	2-Methoxy-4-methylphenol	+	+
122-84-9	2-Propanone, 1-(4-methoxyphenyl)-	1-(*p*-Methoxyphenyl)-2-propanone	I	–

I, compound is an isomer of an identified component; H, compound is a homolog of an identified component.

Note: The symbol (0) indicates the component identified in tobacco substitute smoke was not detected in tobacco smoke.

[a] The Tergitol ethers possessed the following structures: 
Tergitol ether I: R=CH_3, x = 1
Tergitol ether II: R=CH_3, x = 2
Tergitol ether III: R=CH_3, x = 3
Tergitol ether IV: R=H, x = 1

[a] Polyfunctional *O*-containing compounds are counted in each functional group; e.g., propanoic acid, 2-hydroxy- (lactic acid) appears in the alcohol catalog and the acid catalog; benzoic acid, 4-hydroxy-3-methoxy- (vanillic acid) appears in the acid catalog, the phenol catalog, and the ether catalog.

11 Nitriles

The nitriles in tobacco and/or tobacco smoke provide another excellent example of the escalation of the number of identified components. From the listing in 1954 by Kosak (2170) who recorded only HCN, in tobacco smoke to those cataloged in Table 11.2 which includes the simplest "nitrile," hydrocyanic acid (HCN) plus 155 nitriles identified to date in tobacco and/or tobacco smoke. HCN was first identified in tobacco smoke in 1828 by Vogler (4062). Examination of Table 11.2 indicates the listing of seven partially identified nitrile isomers plus 13 cyano group-containing pesticides used in tobacco agronomy. In the latter case, many were identified in tobacco only, but several identified in tobacco were also found to transfer intact to smoke, e.g., Cypermethrin® (52315-07-8).

In their 1959 review of tobacco and tobacco smoke components, Johnstone and Plimmer (1971) listed the following four components containing a -C≡N group: hydrogen cyanide, cyanogen, thiocyanic acid, and thiocyanogen. No alkyl nitriles were listed.

With the advent of gas chromatography, Grob used his gas chromatographic knowledge and skill to identify a series of nitriles in tobacco smoke in 1962 (1413) and 1965 (1416, 1417). His 1965 findings were accompanied by similar findings reported in 1965 by Newsome et al. (2782). Many of the nitriles identified in the Grob and Newsome et al. studies were discussed by Wynder and Hoffmann in their 1967 book [see pp. 450–451 in (4332)]. They also discussed the reports by Campbell et al. (582) and McKee et al. (2519b) on the indication that acetonitrile in the body fluids was indicative of exposure to tobacco smoke because no other respiratory exposure was known. Table 11.1 lists some of the nitriles identified in the early 1960s.

In his 1968 review on tobacco and tobacco smoke composition, Stedman (3797) listed 15 nitriles, including HCN, as chemical components of tobacco smoke. Many of the listed nitriles were those identified by Grob (1412, 1413, 1416, 1416a, 1419) in his gas chromatographic studies of tobacco smoke. Stedman also listed 2-pyridinecarbonitrile and 3-pyridinecarbonitrile (nicotinonitrile) as pyrolysis products of various alkaloids.

In addition to HCN, cyanogen, thiocyanic acid, and thiocyanogen, Schmeltz and Hoffmann in their 1977 review of *N*-containing components of tobacco and tobacco smoke listed 31 nitriles [see Table IX in (3491)]. Ishiguro and Sugawara in their 1980 catalog (1884) of the chemical components of tobacco smoke listed 30 nitriles in addition to HCN, cyanogen, thiocyanogen, and thiocyanic acid.

In its 1986 monograph on tobacco smoking, the International Agency for Research on Cancer (IARC) wrote very little about nitriles in tobacco smoke. IARC categorized HCN as one of the most toxic agents in the vapor phase of tobacco smoke and noted its presence in smoke was dependent on the level of nitrate, proteins, and amino acids in tobacco [see p. 96 in (1870)]. IARC also listed cyanogen as a tobacco smoke component. In its summary of its evaluation for carcinogenicity of chemical components identified in tobacco smoke, IARC did classify 2-propenenitrile (acrylonitrile) with sufficient evidence for carcinogenicity in animals but limited evidence in humans [see p. 392 in (1870)]. The per cigarette MSS yield of 2-propenenitrile (acrylonitrile) was listed at 3.2–15 µg, based on data provided by Wynder and Hoffmann from their 1982 publication (4348a). In a publication issued shortly after the IARC 1986 monograph on tobacco smoking, Hoffmann and Wynder estimated the number of tobacco smoke components to be approximately 3900, of which the number of nitriles was listed at 105 [see Table 1 in (1808)]. They listed HCN as a major toxic agent in nonfiltered cigarette smoke [see Table 2 in (1808)] and 2-propenenitrile (acrylonitrile) as a biologically active agent in MSS [see Table 13 in (1808)]. It is interesting to note that, despite the considerable contribution of Wynder and Hoffmann to the subject of smoke components and their biological properties in the IARC 1986 monograph on tobacco smoking, only HCN, cyanogen, and 2-propenenitrile (acrylonitrile) of the 105 nitriles noted by Hoffmann and Wynder (1808) appeared in the IARC monograph (1870).

In many of the publications issued between 1990 and 2001 in which various tumorigens in tobacco smoke, particularly cigarette smoke, were listed, 2-propenenitrile (acrylonitrile) was included [Hoffmann et al. (1727, 1740, 1741, 1743, 1744, 1783), Fowles and Bates (1217), OSHA (2825)]. In 2003, these lists were discussed in detail by Rodgman (3265).

HCN and cyanogen, while not listed as tumorigens, were listed in many instances as biologically active toxicants. In many cases, acetonitrile was listed as a vapor-phase component of tobacco smoke. For example, in their 1997 and 2001 articles, Hoffmann and Hoffmann (1740, 1743) and Hoffmann et al. (1744) listed HCN, acetonitrile,

TABLE 11.1
Nitriles Identified and/or Discussed in Tobacco Smoke by the Mid-1960s

CAS No.	Nitrile	References by Mid-1960s
75-05-8	Acetonitrile	Grob (1413, 1416), Newsome et al. (2782), Wynder and Hoffmann (4319, 4332)
140-29-4	Benzeneacetonitrile {α-tolunitrile}	Grob (1427)
100-47-0	Benzonitrile	Grob (1426)
109-74-0	Butanenitrile	Grob (1416, 1417, 1422), Wynder and Hoffmann (4332)
625-28-5	Butanenitrile, 3-methyl- {isovaleronitrile}	Grob (1416, 1417), Wynder and Hoffmann (4332)
4786-20-3	2-Butenenitrile {crotononitrile}	Newsome et al. (2782), Wynder and Hoffmann (4332)
628-73-9	Hexanenitrile {capronitrile}	Grob (1416, 1417, 1422), Wynder and Hoffmann (4332)
107-12-0	Propanenitrile	Grob (1413, 1416, 1422), Newsome et al. (2782), Wynder and Hoffmann (4319, 4332)
78-82-0	Propanenitrile, 2-methyl- {isobutyronitrile}	Grob (1413, 1416, 1422), Newsome et al. (2782), Wynder and Hoffmann (4319, 4332)
107-13-1	2-Propenenitrile {acrylonitrile}	Grob (1413, 1416, 1422), Newsome et al. (2782), Wynder and Hoffmann (4319, 4332)
126-98-7	2-Propenenitrile, 2-methyl- {methacrylonitrile}	Grob (1413, 1416, 1422), Newsome et al. (2782), Wynder and Hoffmann 4319, 4332
110-59-8	Pentanenitrile {valeronitrile}	Grob (1416, 1417, 1422), Wynder and Hoffmann (4332)
542-54-1	Pentanenitrile, 4-methyl- {isocapronitrile}	Grob(1416, 1417), Wynder and Hoffmann (4332)
100-54-9	3-Pyridinecarbonitrile {nicotinonitrile}	Grob (1426)

2-propenenitrile (acrylonitrile), and 10 unnamed nitriles as cigarette MSS vapor-phase components, but they listed only 2-propenenitrile (acrylonitrile) as a carcinogen. HCN was listed as a major toxic agent in cigarette smoke in their 2001 article (1743).

Because of its inclusion in so many of the Hoffmann et al. lists, 2-propenenitrile (acrylonitrile) was among the 40 or so smoke components that subsequently became classified as a "Hoffmann analyte." While it did not use the term "Hoffmann analyte" in its 2000 report, the Department of Health (Canada) proposed that analytical data on over 40 components from tobacco smoke should be a requirement (11A01). In its list, the Department of Health (Canada) included 2-propenenitrile (acrylonitrile) and HCN. Examination of the Department of Health (Canada) list reveals that most of its components appear in the biologically active component lists in the publications coauthored by Hoffmann (1727, 1773, 1808, 1740, 1741, 1743, 1744).

Table 11.2 lists the 156 nitriles identified to date in tobacco products. Of the 156, 145 have been identified in tobacco smoke, 30 in tobacco, and 19 in both tobacco and tobacco smoke.

12 Acyclic Amines

The great diversity and number of the *N*-containing components in tobacco and tobacco smoke make it difficult to categorize them and catalog the members in each category. Examination of past reviews indicates that their authors had the same problems even when the numbers of components in the various categories were much fewer than they are now. The categorization used herein is an attempt to present a simplified but complete system for the reader. Because of its nature, tobacco and its smoke contain a multitude of *N*-containing components distributed among various categories. The simplest categories, of course, are the nitriles and the acyclic or aliphatic amines. The latter category also includes individual amino acids and their complexes (proteins, polypeptides), many of which possess a nonsubstituted amino group. More complex are the pentacyclic and hexacyclic *N*-containing components plus those that are combinations of more than one of each type, i.e., linked pentacyclic structures (porphyrin), linked hexacyclic structures (2,3′-bipyridine), or a linked pentacyclic and hexacyclic structure [3-(1-methyl-2-pyrrolidinyl)-pyridine (nicotine)]. Even more complex are those structures in which two or more cyclic units are fused with at least one containing *N* in its cycle, i.e., the aza-arenes. Also pertinent to tobacco smoke chemistry are the components possessing a combination of an amino group with an aza-arene structure such as occurs in the *N*-heterocyclic amines.

All categories mentioned, except the amino acids, include components comprising carbon, hydrogen, and nitrogen. However, several other categories, like the amino acids and the *N*-nitrosamines, include oxygen in the molecule, e.g., the amides {I}, imides {II}, and lactams {III} (Figure 12.1). Herein, the amines will be discussed and cataloged. Subsequently, the other categories mentioned will be discussed and cataloged, i.e., amides, imides, and lactams, components with five-member *N*-containing rings, six-member *N*-containing rings, and combinations of them, the aza-arenes, and the *N*-heterocyclic amines. The amino acids were discussed and cataloged previously. Other components, similar to the *N*-heterocyclic amines in which an amino group is attached to a fused *N*-containing system, have been identified in tobacco and/or smoke, e.g., 1*H*-purin-6-amine (adenine).

Because of the multitude of nicotine-related alkaloids, amino acids, and proteins in tobacco, diligent research eventually led to the identification of a host of alkyl amines in tobacco and smoke. In addition to ammonia, the only alkylamine listed as a tobacco smoke component in 1954 by Kosak (2170) was methylamine, but he questioned its identification even though he cited the 1904 report by Thoms (3912) and the 1930 report by Koperina (2161) on its identification. A similar Koperina report (2162) appeared in a 1931 monograph edited by Shmuk on tobacco research (3655c).

In their 1959 review, Johnstone and Plimmer (1971) listed ammonia and trimethylamine as identified tobacco and smoke components and methylamine, dimethylamine, and ethylamine as identified tobacco smoke components. Nearly a decade later, in addition to the amino acids, Stedman listed over 40 components with either a free or substituted amino group [see Table XI in (3797)]. In their 1977 tabulations of aliphatic and aromatic amines, Schmeltz and Hoffmann listed nearly 80 components almost equally divided between aliphatic and aromatic amines [see Tables I and II in (3491)]. Many of those they listed were identified in tobacco in the late 1960s by Irvine and Saxby (1877) and in tobacco smoke by Pailer et al. (2882, 2883, 2889).

Ishiguro and Sugawara (1884) had a few more amines than those listed in the Schmeltz–Hoffmann compilation because they included as aliphatic amines several cyclic amines and their alkyl derivatives, e.g., pyrrolidine and piperidine. However, this need not be considered a discrepancy. Examination of the structures of *N*-ethylethanamine (diethylamine) {IV} *vs.* pyrrolidine {V} or *N*-(1-methylethyl)-2-propanamine {VI} *vs.* 2,5-dimethylpyrrolidine {VII} reveals the structural similarities (Figure 12.2).

While Tso (3973) in his 1990 book listed numerous nicotine alkaloid-related amines as identified tobacco components, his list also included ammonia but very few alkylamines and no aromatic aniline-related amines in tobacco [see Table 27-1, Part IV in (3973)].

In addition to the simplest amine of all, ammonia, included in Table 12.1 for the sake of completeness are hydroxylamine and hydrazine and several alkylhydrazine derivatives.

The source of many of the amines, including the alkylamines in tobacco and/or its smoke, is the disintegration of various proteins, individual amino acids, and nicotine-related alkaloids (2001, 3477, 4275a) during tobacco growth or the smoking process (3972). Obviously, a portion of those amines identified in both tobacco and tobacco smoke occur in the smoke because of their transfer from the tobacco during the smoking process. The various benzenamine (aniline)-related components in tobacco are considered to arise from

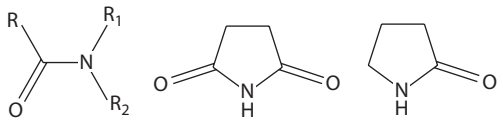

FIGURE 12.1 Oxygenated *N*-containing components of tobacco and tobacco smoke.

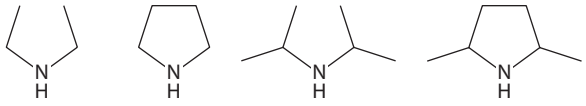

FIGURE 12.2 Structural similarities of alkylamines and pyrrolidines.

enzymatic or microbial disintegration of the amino acids phenylalanine or tyrosine (3491). Schmeltz et al. (3499) reported that the benzenamine-related amines were not generated from nicotine during the tobacco smoking process.

In its 1986 monograph on tobacco smoking, the International Agency for Research on Cancer (IARC) [see pp. 107–109 in (1870)] noted that about 200 amines had been identified in tobacco smoke, based on its citation of the 1977 review by Schmeltz and Hoffmann (3491) and the 1982 review by Dube and Green (1067) and the report by Heckman and Best (1587). IARC described the per cigarette smoke yield of several alkylamines, noting that the most plentiful was methylamine. Citing the data presented by Patrianakos and Hoffmann (2900), IARC also discussed the per cigarette

TABLE 12.1
IARC Evaluation of Carcinogenicity of Various Aromatic Amines in Tobacco Smoke (1870)

CAS No.	Amine	Yield, ng/cig	Degree of Evidence in	
			Animals	Humans
62-53-3	Benzenamine {aniline}	102, 364[a]	Limited evidence	—

104-94-9	Benzenamine, 4-methoxy- {*p*-anisidine}	Present	Sufficient evidence	—
92-67-1	[1,1′-Biphenyl]-4-amine {4-aminobiphenyl}	2–5.6[c] 2.4, 4.6[a]	Sufficient evidence	Sufficient evidence
302-01-2	Hydrazine	24–43[b]	Sufficient evidence	Inadequate evidence
57-14-7	Hydrazine, 1,1-dimethyl-	Present[b]	Sufficient evidence	—
134-32-7	1-Naphthalenamine	4.3, 2.5[a]	Inadequate evidence	Inadequate evidence
91-59-8	2-Naphthalenamine	1–334[b] 1.0, 1.7[a]	Sufficient evidence	Inadequate evidence
135-88-6	2-Naphthalenamine, *N*-phenyl-	Present	Inadequate evidence	Inadequate evidence

[a] Data cited by IARC (1870) from Patrianakos and Hoffmann (2900): first value is for a U.S. 85-mm nonfiltered cigarette; second value is for a French 70-mm nonfiltered cigarette.

[b] Data cited by Hoffmann and Hoffmann (1741, 1743, 1744).

[c] Data cited by Hoffmann and Hoffmann (1743, 1744).

mainstream and sidestream smoke yields of several aromatic amines including 11 benzenamines, the 1- and 2-naphthalenamines, and the [1,1′-biphenyl]-2-, 3-, and 4-amines (the aminobiphenyls). IARC noted that it had previously evaluated the carcinogenicity of several tobacco smoke aromatic amines, namely, 1- and 2-naphthalenamine, [1,1′-biphenyl]-4-amine, benzenamine (aniline), 2-methylbenzenamine (*o*-toluidine), *N*-phenyl-2-naphthalenamine, and 2-methoxybenzeneamine (*o*-anisidine). Table 12.1 summarizes the IARC categorization of several amines, including hydrazine and 1,1-dimethylhydrazine, identified in tobacco smoke [see Appendix 2 in (1870)].

The IARC monograph (1870) is based on the findings of its 1985 working group. Despite its review of the literature to 1985, the IARC had no comment about the numerous reports (1835a, 2491a, 2492, 2849, 2849a, 2949b, 3829a, 3862b, 3862c, 3862d, 3865b, 4365a, 4388) issued from 1975 to 1985 on the isolation initially from cooked food and subsequently from tobacco smoke of the tumorigenic and highly mutagenic *N*-heterocyclic amines.

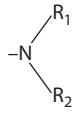
There are several interesting aspects to the Searle-edited American Chemical Society 1984 monograph on chemical carcinogens (3568):

- Despite a voluminous review by Dipple et al. (983) on PAHs and the tumorigenicity of many of them, no mention was made of a tumorigenic or carcinogenic PAH in tobacco smoke.
- The only significantly tumorigenic, carcinogenic, or biologically active tobacco and tobacco smoke components discussed in the 1400-page monograph were the *N*-nitrosamines [see pp. 839–844 in Preussmann and Eisenbrand (2990)]. Much of the data cited by Dipple et al. were those previously presented by Hoffmann et al. (514, 1680, 1685).
- In two chapters on the tumorigenicity of aromatic amines, neither Garner et al. (1275a) nor Parkes and Evans (12A02) mention the presence in tobacco smoke of the aromatic amines categorized as significant tumorigens or carcinogens, namely, 2-naphthalenamine, [1,1′-biphenyl]-4-amine, and 2-methylbenzenamine (*o*-toluene). Garner et al. [see Table I in (1275a)] tabulated the tumorigenicity results of studies on many substituted benzenamines (anilines). The data indicated that several appeared to be as tumorigenic as or even more tumorigenic than 2-methylbenzenamine (*o*-toluidine), a tobacco smoke component listed as a significant tumorigen (1217, 1727, 1740, 1741, 1743, 1744, 1773, 1808, 2825). Each of them has been identified as a tobacco smoke component, e.g., 3-methylbenzeneamine (*m*-toluidine), 4-methylbenzeneamine (*p*-toluidine), and 2,4,6-trimethylbenzenamine (mesitylamine), but none was listed as a significant tumorigen.
- Despite the number of reports issued after 1975 on *N*-heterocyclic amines, Garner et al. (1275a) did not mention their presence in tobacco smoke. They commented as follows:

A multitude of new aromatic amine or heterocyclic amino compounds will most likely be discovered in the foreseeable future, such as those found in cooked foods [Yamazoe et al. (4370a), Takeda et al. (12A03)].

Several of the components listed in Table 12.1 have been included in many of the lists of carcinogens, tumorigens, or biologically active components in cigarette smoke presented by Fowles and Bates (1217), Hoffmann et al. (1727, 1740, 1741, 1743, 1744, 1773, 1808), and OSHA (the Occupational Safety and Health Administration) (2825). Based on these lists, the per cigarette yields proposed by some authorities, e.g., the Department of Health (Canada) (12A01), to be determined of the "Hoffmann analytes" among the amines include 1-naphthalenamine, 2-naphthalenamine, [1,1′-biphenyl]-3-amine, [1,1′-biphenyl]-4-amine, 2-methylbenzenamine (*o*-toluidine), and ammonia.

The primary goal in Table 12.2 is the listing of those tobacco and/or smoke components that are acyclic amines. In some cases, an amino group, either unsubstituted (-NH_2) or substituted {VIII}, may be linked to a cyclic *N*-containing structure, e.g., 2-pyridinamine, 2-amino-1,7-dihydro-6*H*-purin-6-one (guanine), but the reason for inclusion of the component in Table 12.2 is that part of the molecule is an acyclic amine.



VIII

For the sake of completeness, several components have been included in Table 12.2 because they possess the amine function (-NH_2) but are not linked to a carbon atom, e.g., ammonia, hydrazine, hydroxylamine. None of these fits the definition of an amide, imide, or lactam. Other components included in Table 12.2 for the sake of completeness are the amino acids with acyclic unsubstituted or substituted amine group, the acyclic *N*-nitrosamines, and the *N*-heterocyclic amines. With the inclusion in Table 12.2 of the various items just mentioned, the number of acyclic amines and their derivatives totals 510, with 295 identified in tobacco smoke, 354 in tobacco, and 139 in both tobacco and tobacco smoke.

Note: The symbol (0) indicates the component identified in tobacco substitute smoke was not detected in tobacco smoke.

13 Amides

In his 1954 compilation of smoke components, Kosak (2170) listed no amide identified to that date. In their 1959 review of tobacco and tobacco smoke components, Johnstone and Plimmer (1971) described the identification of asparagine and glutamine in tobacco and glutamine and nicotinamide in tobacco smoke. The latter two were identified in smoke by Buyske et al. (562). In its 1963 monograph on tobacco and smoke components, Philip Morris (2939) listed the amides, asparagine, glutamine, citrulline, and nicotinamide as tobacco components but only glutamine and nicotinamide as smoke components.

Stedman (3797) in his 1968 review of tobacco and smoke components listed asparagine, citrulline, and glutamine as amino-acid-related components not as amides [see Table XIV in (3797)]. Nicotinamide and *N*-methylnicotinamide were not listed specifically as amides but as alkaloid derivatives [see Table XI in (3797)]. Cotinine was also listed in the same table.

Ishiguro and Sugawara (1884) in their 1980 monograph on tobacco smoke components listed a total of 72 amides, imides, and lactams (49 amides, 7 imides, 16 lactams) [see Table I-15 in (1884)]. The reference for all but two of the listed compounds (formamide and urethane) was that of Schumacher et al. (3553). Several amides, imides, and lactams were listed by Ishiguro and Sugawara in other tables, e.g., asparagine and glutamine under amino acids [Table I-19 in (1884)], cotinine and norcotinine under alkaloids, and caffeine under *N*-polycyclics (excluding alkaloids).

Citing publications by Schmeltz and Hoffmann (3491), Schumacher et al. (3553), and Heckman and Best (1587), the International Agency for Research on Cancer (IARC) in its 1986 monograph on tobacco smoking stated [see p. 109 in (1870)] that there was a large spectrum of amides, imides, and lactams in tobacco smoke (including some 50 aliphatic amides). While the IARC commented on the Johnston et al. 1973 report on the per cigarette yields of formamide, acetamide, and propanamide, it did not mention that Johnston et al. in their 1973 report (1965) had noted that only three amides, glutamine, asparagine, and nicotinamide, had been identified in tobacco smoke at that time. The IARC expressed concern about the 24 secondary amides identified in smoke, particularly *N*-methylformamide, *N*-methylacetamide, *N*-methylpropanamide, and *N*-methylnicotinamide, because of their propensity to generate tumorigenic nitrosamides. Despite the fact that these secondary amides have been identified in tobacco smoke and are known to readily form *N*-nitrosamides, no such *N*-nitroso compound has been identified to date in tobacco smoke [Rodgman and Green (3300)].

IARC also mentioned the two lactams *N*-methyl-2-pyrrolidone and *N*-methyl-2-piperidone and the urethanes but made no textual comment about their biological effect. Of the 53 amides identified in tobacco smoke by Schumacher et al. (3553), 32 were new to tobacco smoke composition. Their contribution in this regard was the result of the use of an analytical technology that permitted the fractionation and identification of many components in the water-soluble portion of cigarette smoke condensate.

In his study of the composition of smoke from an all-burley tobacco cigarette, Heckman (1586) identified 16 amides, ranging in complexity from acetamide to *N′*-formylnornicotine.

Although 227 amides are cataloged in Table 13.1, it should be realized that the number of amides in tobacco far exceeds the number of amides listed in Table 13.1 for tobacco and tobacco smoke. Each of the many thousands of enzymes, proteins, and proteinaceous components in tobacco possesses many amido linkages. Nearly 500 of the well-characterized enzymes and proteins are cataloged in Table 22.2, but that number is only a small fraction of the great number of such components in tobacco.

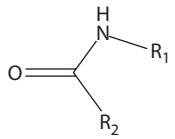
IARC had little to say about the possible ill effects of any of the amides in tobacco smoke. However, it did note in an appendix to its monograph [Appendix 2, pp. 389–394 in (1870)] that sufficient evidence existed for the initiating and cocarcinogenic activity in animals of urethane (ethyl carbamate) and the evidence was limited for acetamide. IARC listed the per cigarette yields of acetamide and urethane. In the first listing of tumorigens, carcinogens, and toxicants in tobacco smoke, by Hoffmann and Wynder in 1986 (1808), only urethane was included. Urethane was included in several subsequent lists, those by Hoffmann and Hecht (1727), Hoffmann et al. (1773), and Hoffmann and Hoffmann (1740). In their 1997 list (1740), Hoffmann and Hoffmann added acrylamide (2-propenamide) as present in cigarette smoke, but no per cigarette yield was included. In their next three lists of tumorigens, carcinogens, and toxicants in tobacco smoke issued between 1998 and 2001, Hoffmann and Hoffmann (1741, 1743, 1744) listed per cigarette yields of acetamide and urethane and the presence of acrylamide. Other listings of tumorigens, carcinogens, and toxicants in

tobacco and tobacco smoke by the Occupational Safety and Health Administration (OSHA) (2825) in 1994 and Fowles and Bates (1217) in 2001 included urethane but not acetamide or acrylamide. The various degrees of inclusion in the many lists issued between 1986 and 2001 were summarized by Rodgman (3265).

Acetamide, acrylamide, and urethane were not included in most of the requirements for "Hoffmann analyte" data as an indication of cigarette smoke hazard, e.g., the Department of Health (Canada) proposal in 2000 (25A06).

One other aspect of interest concerning amides is that several (asparagine, glutamine, urea) appear on the Doull et al. list of individual compounds used in cigarette manufacture by U.S. companies (1053). The Doull et al. list also includes the imide 3,7-dihydro-1,3,7-trimethyl-1*H*-purine-2,6-dione (caffeine).

Although they are on the borderline of the definition of an amide, urethane plus urea and several of its derivatives have been included in Table 13.1. Because each possesses structure I, each was included as an amide for the sake of completeness; e.g., urea is $H_2N\text{-}CO\text{-}NH_2$, and ethyl urethane is $H_2N\text{-}COO\text{-}C_2H_5$. Several of the urea derivatives are compounds used in tobacco agronomy.



The number of compounds in Table 13.1 totals 227 of which 191 are amides. The remaining components include urethane plus urea and several of its derivatives. Of the 227 compounds, 134 were identified in tobacco, 137 in tobacco smoke, and 44 were identified in both tobacco and smoke.

14 Imides

In his 1954 compilation of tobacco smoke components, Kosak (2170) listed no imide identified in tobacco smoke to that date.

Ishiguro and Sugawara in their 1980 monograph on tobacco smoke components listed a total of 72 amides, imides, and lactams, including 7 imides [see Table I-15 in (1884)]. Their reference for all the imides listed was that of Schumacher et al. (3553). Ishiguro and Sugawara did not list caffeine as an imide but listed it under *N*-polycyclics (excluding alkaloids) [see Table I-14 in (1884)].

In its 1986 monograph on tobacco smoking, the International Agency for Research on Cancer (IARC) stated that there was a large spectrum of amides, imides, and lactams in tobacco smoke (including some 50 aliphatic amides) [see p. 109 in (1870)]. The basis for the IARC comments was the 1977 review of *N*-containing components in tobacco and tobacco smoke by Schmeltz and Hoffmann (3491) and the smoke composition publication in 1977 of Schumacher et al. (3553) and in 1981 by Heckman and Best (1587).

Of the 24 imides identified in tobacco smoke by Schumacher et al. (3553), 6 were new to tobacco smoke composition. Many of the previously identified imides were derivatives of 1*H*-pyrrole-2,5-dione (maleimide), 2,5-pyrrolidinedione (succinimide), and 1*H*-isoindole-1,3(2*H*)-dione (phthalimide). The use of a recently developed analytical technology that permitted the fractionation and identification of components in the water-soluble portion of cigarette smoke condensate (CSC) was a key factor in their mid-1977 study. In a detailed study of the ether-soluble portion from the same CSC studied by Schumacher et al., Newell et al. (2769) identified five imides. In his earlier study of the composition of smoke from an all-burley tobacco cigarette, Heckman (1586) identified 15 imides.

Examination of the structures of several of the CSC components indicates that the decision of their categorization is somewhat difficult. In Figure 14.1, representative structures for an amide, an imide, and a lactam are presented. To which of these categories—amide, imide, or lactam—should the smoke component 1-acetyl-3-ethyl-1,5-dihydro-4-methyl-2*H*-pyrrol-2-one {I} be assigned? Its structure is depicted in Figure 14.2. In Structure {II} of Figure 14.2, the amide configuration is shown. Structures {III} and {IV} show the imide and lactam configurations, respectively. This same situation is present with several other smoke components. While there may be some disagreement of the preciseness of our selection, for completeness sake, such components are listed in each chapter in its major catalog table. As a result, the total number of components in each of the major catalog tables may be slightly inflated.

In addition to several amides (asparagine, glutamine, urea) on the Doull et al. list of individual compounds used in cigarette manufacture by U.S. companies (1053) is the imide 3,7-dihydro-1,3,7-trimethyl-1*H*-purine-2,6-dione (caffeine).

Over 100 imides identified in tobacco and tobacco smoke are cataloged in Table 14.1. Of the reported 103 imides, 45 have been identified in tobacco, 82 in tobacco smoke, and 24 in both tobacco and tobacco smoke.

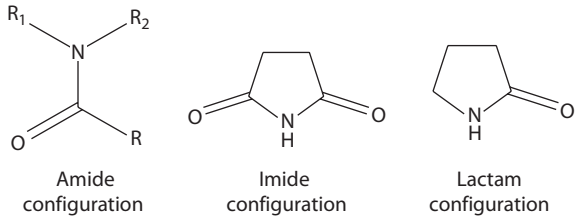

FIGURE 14.1 The amide, imide, and lactam configurations.

15 *N*-Nitrosamines

The introduction to this chapter on *N*-nitrosamines (NNAs) in tobacco and/or tobacco smoke is a considerably abbreviated but updated version of the lengthy unpublished 1993 memorandum by Rodgman (3256). Omitted from this outline are several sections covered in detail in (3256). These include much of the discussion on the early studies of the biological properties of NNAs [see pp. 117–178 in (3256)] and studies on alternate sources of exposure to NNAs [see pp. 107–116 in (3257)].

The numerous publications during the past two decades on the identification, quantitation, and bioassay of NNAs, particularly those found in tobacco-related entities (tobacco, mainstream smoke [MSS], sidestream cigarette smoke [SSS], and environmental tobacco smoke [ETS]), raise the question as to why this class of tobacco/tobacco smoke components has received such emphasis. Since the early 1950s, several classes of compounds in tobacco smoke have been proposed as prime contributors to cancer of the respiratory tract in smokers. The events that triggered detailed examination of the composition of cigarette MSS included:

1. The results of retrospective studies which were interpreted as indicating an association between cigarette smoking and carcinoma of the lung in smokers [Levin et al. (2355), Mills and Porter (2556), Schrek et al. (3529), Wynder and Graham (4306b), Doll and Hill (1027), McConnell et al. (2525), Sadowky et al. (3375a)]. Subsequently, the results from additional retrospective studies and several prospective studies on smoking and respiratory tract cancer bolstered the evidence for this association.
2. Bioassay results from studies (4306a, 4306c) in which carcinomas were produced in susceptible mouse strains at the site of repeated skin painting with massive doses of cigarette smoke condensate (CSC) prepared in a manner supposedly simulating the human smoking process (the puff frequency used was a 2 s puff each 20 s *vs*. the usually accepted routine was a 2 s puff each 60 s). Between 1953 and late 1966, the major skin-painting studies involving CSC administered to various laboratory animal species numbered about 60 (4332).

Despite numerous statements to the contrary—that the data from mouse-skin-painting experiments with CSC were not extrapolable from mouse skin to the human lung—some authorities continued to imply that such data were meaningful in terms of respiratory tract cancer in smokers. For example, Wynder (4292) wrote:

> The mouse skin test cannot give definitive proof for a human carcinogen, although it has long been used as a reliable tool for testing of carcinogenic materials…The animal data must be considered, not as a proof for the human experience, but as a tool with which to work toward the isolation and identification of carcinogenic agent(s). At this time we can only assume, on the basis of the combined human and animal data, that these carcinogens are the same for man and for mice.

In 1956, Wynder (4295) stated:

> We believe that no animal data can be used to establish a causative role in cancer in man. Such proof can come only from human epidemiologic data… animal evidence by itself can never establish a human carcinogen nor can it ever disprove it… For example, if we suspect tobacco as a carcinogen to man, animal experimentation can determine the specific parts of tobacco which are carcinogenic to animals. Once identified, we can only assume that the specific carcinogens are the same to which man also responds and introduce preventive measures accordingly.

Despite comments such as these and additional ones in later publications, animal experimentation, particularly mouse-skin-painting studies, constituted a substantial part of the bioassays on tobacco smoke. Such bioassays are not only expensive but also extremely time consuming (18–24 months). Because of the absence of a positive response in studies of tobacco smoke inhalation by laboratory animals, mouse-skin painting with CSC was selected as the bioassay of choice in the massive decade-long (1970–1980) study conducted by the National Cancer Institute (NCI) on "less hazardous" cigarettes, a study that involved nearly 100 test cigarettes and 30 standard or reference cigarettes (1329, 1330, 1332, 1333, 2683).

Successively after the late 1950s, various classes of smoke components were proposed as either the cause of (as tumor initiators) or contributors to (as promoters, cocarcinogens, ciliastats) the lung cancer in smokers:

1. Polycyclic aromatic hydrocarbons (PAHs).
2. Their polycyclic nitrogen analogs, the aza-arenes, reported to be carcinogenic to mouse skin.
3. Low-molecular-weight phenols reported to be promoters of tumorigenic PAHs.
4. Aldehydes and ketones reported to be ciliastatic in *in vitro* ciliated systems.
5. Aromatic amines.
6. Metallic items (^{210}Po, Ni).
7. Other miscellaneous compounds, e.g., ethyl urethan.

One by one, the claims for involvement of each of these classes of compounds were either discounted or seriously questioned [Rodgman (3255, 3257), Rodgman et al. (3307)].

PAHs were described as the only major tumor initiators in mouse-skin carcinogenesis [Wynder and Hoffmann (4332)]:

> The many detailed data obtained in studies of tobacco carcinogenesis on mouse skin exclude with some certainty the major tumor initiators other than the PAH type play a role in this assay system.

Benzo[*a*]pyrene (B[*a*]P), because of its potency in skin-tumor carcinogenesis and per cigarette MSS yield, was considered the major PAH of concern in tobacco smoke. In 1981, the Surgeon General commented as follows on PAHs [see p. 36 in (4009)]:

> BaP appears to be the most important single member of this class of compounds, taking into consideration both its concentration and its relative carcinogenic potency.

It was obvious that additional mechanisms were needed to explain the observed biological effect since (1) B[*a*]P in CSC acting alone accounted for less than 2% of the observed biological response in mouse-skin-painting studies, (2) the total PAH fraction accounted for less than 3% of the observed biological response in mouse-skin-painting studies, (3) no "supercarcinogenic" PAH was found in CSC (3756–3758, 4282), and (4) inclusion of tumorigenic aza-arenes in CSC explained very little more of the unexplained tumorigenicity.

The first additional explanation of the observed effect in skin-painting studies with CSC involved the mechanisms of promotion and cocarcinogenesis of tobacco smoke components. The smoke components first classified as promoters were the low-molecular-weight phenols because of their known promotion of such potent tumorigenic PAHs as B[*a*]P and dibenz[*a,h*]anthracene (DB[*a,h*]A) (414).

However, the significance of the promoting/cocarcinogenic effect of tobacco smoke phenols on PAH tumorigenicity [Wynder and Hoffmann (4309, 4317, 4344)] was offset by the following observations:

1. Removal of a substantial amount (70%–85%) of the low-molecular-weight phenols from CSC by selective filtration of the MSS did "not change significantly the biological activity of the resulting condensate" [Wynder and Hoffmann [see p. 626 in (4332)], Hecht et al. [see p. 2 in presentation manuscript (1582, 1583)]].
2. Low-molecular-weight phenols inhibited the tumorigenicity of B[*a*]P [Van Duuren et al. (4029, 4035)].
3. Inclusion of known initiators, promoters, and cocarcinogens in tobacco smoke in the calculation of its tumorigenicity explained less than 5% of the observed biological effect in skin-painting studies.

The failure of several groups of investigators [Candeli et al. (587), Kaburaki et al. (2006), Schmeltz et al. (3499, 3512), Snook (3733), Snook et al. (3750), Grimmer et al. (1409), Kamati et al. (2021), Sasaki and Moldoveanu (3414), Rustemeier et al. (3370)] to reproduce the findings of Van Duuren et al. (4027) on the presence and/or levels of the aza-arenes dibenz[a,h] acridine, dibenz[a,j]acridine, and 7*H*-dibenzo[c,g]carbazole in tobacco smoke was discussed by Rodgman [3255, 3260; see Table 4 in (3265)] and Baker (172).

The failure to explain the observed tumorigenicity of CSC in the mouse-skin bioassay by consideration of the following tobacco smoke systems led to the inclusion of ciliastasis by various water-soluble vapor-phase (VP) tobacco smoke components in an attempt to explain the causation of respiratory tract cancer in smokers:

1. The levels in CSC of mouse-skin tumorigenic PAHs, acting individually or in concert, could not account for the response in CSC-painted animals.
2. The CSC levels of mouse-skin tumorigenic PAHs plus the promoting/cocarcinogenic phenols, acting individually or in concert, could not account for the observed response in CSC-painted animals.
3. The CSC levels of mouse-skin tumorigenic PAHs plus promoting/cocarcinogenic phenols and non-tumorigenic PAHs, acting individually or in concert, could not account for the observed response in CSC-painted animals.
4. Inclusion of tumorigenic aza-arenes in the calculation could not account for the observed biological response.

In fact, when the levels of the known tumorigenic, promoting, and cocarcinogenic components of tobacco smoke and their activity toward mouse skin are included in the assessment, less than 5% of the observed biological response in the CSC-painted animals can be explained!

To circumvent this failure to explain the observations with CSC-treated laboratory animals and attempt to explain the epidemiological findings in human smokers, ciliastasis was introduced as an additional mechanism involved in the causation of smokers' lung cancer. In a variety of *in vitro* systems, ciliastasis was produced by cigarette MSS VP and by individual MSS VP components (hydrogen cyanide, formaldehyde, acetaldehyde, acetone, phenol). It was proposed that ciliastasis occurred in the smokers' respiratory tract and significantly diminished the lung clearance mechanism of the cilia, thus permitting tobacco smoke particulate-phase particles (and their included "tumorigens") to remain on the lung surface and initiate the cellular changes required for tumor development. However, this proposal was seriously compromised by the demonstration in intact animals as well as in human smokers that a large proportion (60%–75%) of the *in vitro* ciliastats (all water-soluble) in the inhaled smoke failed to reach the ciliated tissue in the respiratory tract because of solution in the aqueous secretions coating the oral cavity tissues [Rodgman et al. (3306), Dalhamn et al. (892, 893)].

Prior to the emphasis on NNAs, the class of tobacco smoke components subjected to the most study was the PAHs, with

particular emphasis on the CSC compound considered the most potent, B[*a*]P. Although the NNAs identified in tobacco and/or tobacco smoke number fewer than 60, the number of PAHs either identified or partially identified* exceeds 500 [Severson et al. (3619), Snook et al. (3756–3758), Rodgman and Perfetti (3306a)].

The role played by the PAHs, particularly B[*a*]P, in induction of skin carcinoma in skin-painted laboratory animals was seriously questioned because of the demonstrations by Roe (3310, 3311) that a 10-fold increase and by Lazar et al. (2320) that a 30-fold increase in the B[*a*]P level of CSC failed to produce an increase in its tumorigenicity to mouse skin. This lack of correlation between levels of PAHs [B[*a*]P, benz[*a*]anthracene (B[*a*]A)] in CSC and % tumor-bearing animals (TBAs) was demonstrated in the NCI "less hazardous" cigarette study [Gori (3329, 3230, 3232, 3233), NCI (2683)]. The results were acknowledged in the U.S. Surgeon General's 1981 report [see p. 36 in (4009)]:

> The contribution of BaP or PAH in general to mouse skin carcinogenesis by cigarette smoke condensate cannot be fully measured at this time. Wynder and Hoffmann (4332) found a correlation between BaP levels and carcinogenic activity of smoke condensates from several types of cigarettes. A much larger series of experimental cigarettes was studied in the smoking and health program of the National Cancer Institute. No significant dependence of carcinogenic potency on BaP was observed. [Gori (3329, 3230, 3232, 3233), NCI (2683)]

It should be noted that in the NCI "less hazardous" cigarette study, neither the tobaccos used in the nearly 100 experimental cigarettes and 30 standard and reference cigarettes nor the MSSs generated from them were analyzed for NNAs.

Despite observations that NNAs in CSC or NNAs individually induce few, if any, tumors at the application site in mouse-skin-painting studies with CSC, they are one of the two classes of tobacco product components to which the pro-health forces continue to devote their major efforts. In 1990, Hoffmann and Hecht (1727) noted:

> Mouse skin is particularly responsive to PAH tumorigenesis. It is not equally responsive to other important classes of carcinogens such as *N*-nitrosamines…

As noted in 1984 by Hoffmann et al. (1696), three types of NNAs are formed in tobacco processing and during the tobacco smoking process: volatile *N*-nitrosamines (VNAs), tobacco-specific *N*-nitrosamines (TSNAs), and nonvolatile NNAs. The latter include *N*-nitrosodiethanolamine (NDELA) and *N*-nitrosoproline (NPRO). Recently, several *N*-nitrosamino acids were identified in tobacco. The major NNAs identified in tobacco and/or tobacco smoke are listed in Table 15.1.

In the mid-1960s, Fredrickson (1236), using a laboratory procedure which precluded artifactual formation of NNAs, identified several volatile NNAs in cigarette MSS. He also reported that volatile NNAs, like the low-molecular-weight phenols, are selectively removed from MSS by plasticized (triacetin) cellulose acetate filters. Per cigarette MSS, volatile NNA yields are reduced by 75%–80% in this manner, a value similar to that observed with the selective filtration of low-molecular-weight phenols. This diminution of volatile NNA yields was confirmed several years later by Morie and Sloan (2635) and Brunnemann et al. (514).

TSNAs, because of their low volatility, occur predominantly in the MSS particulate phase and behave similarly to other particulate-phase components such as the PAHs; i.e., they are not selectively reduced by filtration with plasticized cellulose acetate. However, Hoffmann et al. (1685) noted that MSS TSNA yields are reduced by any technology designed to reduce the MSS particulate phase such as increased filtration efficiency, increased air dilution (filter-tip perforation, paper porosity), and tobacco expansion.

The precursors in tobacco of the NNAs in tobacco smoke have been studied extensively. Tobacco protein is reported by Brunnemann et al. (511) to be the major precursor of the volatile NNAs and NPRO. Based on these findings, Hoffmann et al. (1696) wrote:

> The protein fraction of tobacco appears to represent the major precursor group of the carcinogenic volatile nitrosamines in smoke. In addition, Tso et al. (3985) had previously reported that the volatile NNAs in smoke are proportional to the nitrate content of the tobacco filler, an observation also made by Morie and Sloan (2635).

Precursors of TSNAs in tobacco and smoke are nicotine, nornicotine, anabasine, and anatabine [Hecht et al. (1564), Adams et al. (29)]. Both nicotine and nornicotine are considered precursors of *N′*-nitrosonornicotine (NNN). Direct transfer of TSNAs from tobacco to the smoke accounts for about 40% of NNN and 30% of 4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK) in MSS. The remainder of these two TSNAs in the MSS is formed during the smoking process [Hoffmann et al. (1734), Hecht et al. (1564)]. Like the levels of the volatile NNAs in MSS, the yields of the TSNAs in MSS are proportional to the nitrate content of the tobacco filler (3985).

PAHs are ubiquitous: They are present in the atmosphere as components of a variety of dusts, soots, tars, oils, engine exhaust gases; in water; in many commonly consumed foodstuffs, particularly those that are heated, roasted, or broiled [Rodgman (15A48), Grasso (1345), Maga (2438)]; and in ETS. Similarly, exposure to NNAs is widespread. Volatile NNAs are not only components of MSS, SSS, and ETS, but they are also present in a variety of foodstuffs and beverages. Sen et al. (15A52) noted:

> Nitrosopyrrolidine,† which is a potent liver carcinogen [in laboratory animals], has been shown to be formed during the frying of bacon, and to be present in sausage, corned beef, luncheon meat, fried pig liver, cooked and uncooked cod fish and finned herring.

* The partial identification of a PAH refers to the instances where the positions of alkyl substituents and/or their precise identity are uncertain, e.g., a trimethyl *vs.* an ethylmethyl derivative.

† As noted previously, NPYR is a tobacco smoke component.

TABLE 15.1
Major NNAs in Tobacco and/or Tobacco Smoke

Chemical Name	Abbreviation	Common Name
VNAs		
1-Butanamine, *N*-butyl-*N*-nitroso-	NDBA	*N*-nitrosodibutylamine
1-Butanamine, *N*-methyl-*N*-nitroso-	NBMA	*N*-nitrosobutylmethylamine
Ethanamine, *N*,1-dimethyl-*N*-nitroso-		*N*-nitrosoisopropylmethylamine
Ethanamine, *N*-ethyl-*N*-nitroso-	NDEA	*N*-nitrosodiethylamine
Ethanamine, *N*-methyl-*N*-nitroso-	NEMA	*N*-nitrosoethylmethylamine
Methanamine, *N*-methyl-*N*-nitroso-	NDMA	*N*-nitrosodimethylamine
Morpholine, 4-nitroso-	NMOR	*N*-nitrosomorpholine
Piperidine, 1-nitroso-	NPIP	*N*-nitrosopiperidine
Propanal, 3-(methylnitrosamino)-		3-(methylnitrosamino)propionaldehyde
1-Propanamine, *N*,2-dimethyl-*N*-nitroso-		*N*-nitrosoisobutylmethylamine; *N*-nitrosomethyl(2-methylpropyl)amine
1-Propanamine, *N*-ethyl-2-methyl-*N*-nitroso-		*N*-nitrosoethylisobutylamine; *N*-nitrosoethyl(2-methylpropyl)amine
1-Propanamine, *N*-ethyl-*N*-nitroso-		*N*-nitrosoethylpropylamine
1-Propanamine, *N*-methyl-*N*-nitroso		*N*-nitrosomethylpropylamine
1-Propanamine, *N*-nitroso-*N*-propyl-	NDPA	*N*-nitrosodipropylamine
Propionitrile, 3-(methylnitrosamino)-		3-(methylnitrosamino)propionitrile
Pyrrolidine, 1-nitroso-	NPYR	*N*-nitrosopyrrolidine
Nonvolatile NNAs		
Diethanolamine, *N*-nitroso-	NDELA	*N*-nitrosodiethanolamine
2-Pyrrolidinecarboxylic acid, 1-nitroso-	NPRO	*N*-nitrosoproline; 2-pyrrolidinecarboxylic acid, 1-nitroso-
TSNAs		
2,3′-Bipyridine, 1-nitroso-1,2,3,6-tetrahydro-	NAT	*N*′-nitrosoanatabine
Butanal, 4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-		4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-butanal
Butanoic acid, 4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-	*iso*-NNAC	4-(*N*-methylnitrosamino)-4-(3-pyridinyl)- butanoic acid
1-Butanol, 4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-	NNAL	4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-butanol
1-Butanol, 4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-	*iso*-NNAL	4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-butanol
1-Butanone, 4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-	NNK	4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-butanone
1		2
Pyridine, 3-(1-nitroso-2-piperidinyl)-	NAB	*N*′-nitrosoanabasine
Pyridine, 3-(1-nitroso-2-pyrrolidinyl)-	NNN	*N*′-nitrosonornicotine
N-Nitrosamino acids, esters, nitriles		
Acetic acid, 2-(methylnitrosamino)-	NSAR	*N*-nitrosarcosine; *N*-methyl-*N*-nitrosoglycine
Acetic acid, 2-(methylnitrosamino)-, methyl ester		
Butanoic acid, 4-(methylnitrosamino)-	NMBA	4-(methylnitrosamino)butanoic acid
Butanoic acid, 4-(methylnitrosamino)-, methyl ester		4-(methylnitrosamino)butanoic acid, methyl ester
Hexanoic acid, 2,6-di-(methylnitrosamino)-		2,6-di-(methylnitrosamino)hexanoic acid
Pentanoic acid, 2,5-di-(methylnitrosamino)-		2,5-di-(methylnitrosamino)pentanoic acid
2-Piperidinecarboxylic acid, 1-nitroso-		1-nitroso-2-piperidinecarboxylic acid
Propanoic acid, 3-(methylnitrosamino)-	NMPA	3-(methylnitrosamino)propanoic acid; *N*-methyl-*N*-nitroso-β-alanine
Propanoic acid, 3-(methylnitrosamino)-, methyl ester		3-(methylnitrosamino)propanoic acid, methyl ester
Propanoic acid, 2-(methylnitrosamino)-3-phenyl-		2-(methylnitrosamino)-3-phenylpropanoic acid
2-Pyrrolidinecarboxylic acid, 1-nitroso-, methyl ester		1-nitroso-2-pyrrolidinecarboxylic acid, methyl ester; *N*-nitrosoproline, methyl ester

The magnitude of the occurrence of NDMA in beer was studied by Spiegelhalder (15A54) in a survey of many German beers: 70% of the sample showed NDMA at a mean concentration of 2.7 ppb with a maximum of 68 ppb. Barley malt was considered the NNA source. In 1988, Maga (2438) reviewed some 40 publications on NNAs in common foodstuffs, beverages, and spices.

The generation of NNAs by the reaction of ingested nitrates with body chemical components was discussed in a survey by the Office of Technology Assessment (15A38):

> Nitrate and nitrate salts naturally occur in vegetable, fish and meats, are in food for their preservative properties and are present in pesticide and drug residues in food. They react with other chemicals in the body to produce NNAs and *N*-nitrosamides.

In their 1990 list of 43 "tumorigenic agents in tobacco and tobacco smoke," a list cited frequently in reports issued by various governmental agencies (EPA, USPHS), Hoffmann and Hecht (1727) included five volatile NNAs (NDMA, NDEA, NEMA, NPYR, and NMOR), one nonvolatile NNA (NDELA), and three TSNAs (NNN, NNK, and NAB). Repetitively since the mid-1980s, Hoffmann et al. have published detailed reviews on NNAs, particularly TSNAs, their levels in tobacco, MSS, SSS, and ETS, and their supposed involvement in cancer induction in tobacco users plus many reports on other aspects of NNAs [Hecht et al. (15A18), Hoffmann et al. (1688, 1698, 1731, 1745, 1746, 1750, 1770–1772, 1774–1776), Hecht and Hoffmann (1571, 1571a, 15A19, 15A20), Hoffmann and Hecht (1725, 1727), Brunnemann et al. (459, 477), Brunnemann and Hoffmann (483, 484, 486, 487), Djordjevic et al. (977, 1013, 1015–1017), Andersen et al. (76), Rivenson et al. (3182), Prokopczyk et al. (2994, 2997)].

In addition to the studies by Hoffmann et al., a great number of conference presentations and journal publications on NNAs, particularly TSNAs, have been provided by other investigators. A representative sample includes the contributions by Brown et al. (437), Bush et al. (557), d'Andres et al. (895), de Roton et al. (951), Katsuya et al. (2050–2052), Moldoveanu et al. (2599), Nestor et al. (2700), Peele et al. (2917), Risner et al. (3176a), Risner and Wendelboe (3177), Tricker (3953), and Tricker et al. (3944–3948).

Finally, with regard to NNAs, it should be noted that CSCs from tobaccos grown under high-nitrate-fertilization regimes produce fewer TBAs than do the CSCs from tobaccos grown under low-nitrate-fertilization regimes even though high-nitrate tobaccos usually show higher levels of both volatile NNAs and TSNAs, and their smokes contain higher levels of these compounds than do low-nitrate tobaccos. The responses observed in mutagenicity testing (Ames test with *Salmonella typhimurium*) are opposite from those observed in mouse-skin-painting studies. Nitrate addition, use of high-nitrate tobacco, and/or use of tobacco stems which are generally much higher in nitrate than laminae result in reduced levels of MSS total particulate matter (and "tar") and in mainstream CSCs with reduced levels of phenols and PAHs, including B[*a*]P, plus increased levels of NNAs [Wynder and Hoffmann (4312, 4317), Hoffmann and Wynder (1797, 1798, 1801, 1802), Rathkamp and Hoffmann (3081, 3082), Hoffmann et al. (1783), Brunnemann and Hoffmann (480), Adams et al. (28)].

15.1 VOLATILE NNAs

The volatile NNAs in tobacco smoke usually reported as tobacco smoke components that contribute to the smoking health problem, particularly the cigarette smoke respiratory tract cancer problem, are the first seven listed in Table 15.2.

Table 15.3 summarizes much of the early research on the VNAs.

Almost a decade after the proposal by Boyland et al. (422, 423, 15A00) that the TSNAs, NNN, and NAB might be present in tobacco and tobacco smoke, NNN was identified in cigarette MSS by Klus and Kuhn (2136). This and subsequent identification of other TSNAs in tobacco and smoke resulted in a gradual decrease in the research effort on volatile NNAs and a significant increase in the research effort on TSNAs.

15.2 NONVOLATILE NNAs

As noted in Table 15.1, NDELA and NPRO are classified as nonvolatile NNAs in tobacco and tobacco smoke. In bioassays in laboratory animals, NPRO is the only tobacco/tobacco smoke NNA to give negative responses.

The one considered the more controversial of the two is NDELA. Prior to its identification in tobacco in 1977 and smoke in 1981, its biological properties in laboratory animals and other test systems had been studied for over a decade. Druckrey et al. (1058) reported that NDELA was a hepatic carcinogen in rats. In its review of biological data generated in NNA studies, the IARC (1866) reported that this compound induced tracheal carcinomas in the hamster. Lijinsky et al. (15A35) reported that NDELA induced carcinoma of the liver and kidney in rats. McMahon et al. (2521) reported that NDELA was mutagenic when tested in modifications of the Ames test with *S. typhimurium*.

In 1977, Schmeltz et al. (3480) isolated NDELA from tobacco and identified it. In 1981, Brunnemann and Hoffmann (479) reported that cigarettes fabricated from tobaccos treated with the diethanolamine salt of maleic hydrazide delivered 10–40 ng/cig of NDELA in the MSS. These two studies were conducted when it was permissible to treat tobacco with the diethanolamine salt of maleic hydrazide, a sucker growth inhibitor. Previously reported findings on the tumorigenicity in laboratory animals of NDELA and its level in cigarette MSS eventually led to the banning by the Environmental Protection Agency (EPA) (1147) of the use on tobacco of maleic hydrazide diethanolamine salt in the United States and acceptance of the maleic hydrazide potassium salt as replacement for the maleic hydrazide diethanolamine salt.

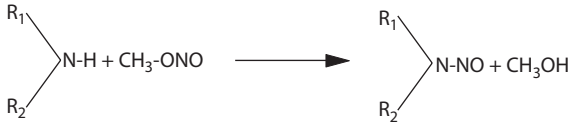
ND, not detected; P, present; NYL, no yield level listed for cigarette MSS; NL, not listed as a tumorigenic or carcinogenic component of cigarette MSS.

[a] A component listed in bold is no longer relevant (3300).

[b] A range listed in bold type contains a numerical error and/or a unit error (ng *vs*. μg).

TABLE 15.3
A Brief Chronology of the Research on VNAs from 1937 to 1990

Year	Investigation
1937	Freund (15A13) reported the acute toxicity of NDMA in humans accidentally exposed to the reagent
1954	Barnes and Magee (192) reported the hepatotoxicity of *N*-nitrosodialkylamines in several laboratory animal species
1956	Magee and Barnes (2441a) reported that almost all rats fed a diet containing 50 ppm of NDMA developed malignant liver tumors within less than a year
1960	Zak et al. (15A59) reported that feeding and daily oral dosing of rats with NDMA resulted in induction of lung tumors which adenomas, not the lung tumor type—squamous cell carcinoma—reported in various epidemiological studies to be associated with cigarette smoking
1960	Rodgman (15A49) proposed that NNAs were likely cigarette MSS components
1960	Tindall (15A55) patented the preparation of NNAs from methyl nitrite and secondary amines



The demonstration of the presence of methyl nitrite in tobacco smoke [Laurene (2293), Philippe and Hackney (2841), Laurene et al. (2310)] led to the suggestion by Rodgman (15A49) that this was their mode of formation in tobacco smoke. This mechanism of formation of volatile NNAs was also proposed by Wynder and Hoffmann [see p. 437 in (4332)]: "An opportunity for the formation of nitrosamines is the interaction of methyl nitrite and secondary amines. It could be demonstrated in these laboratories, that at least in the presence of water, methyl nitrite and diethylamine form DENA."

This proposal was subsequently negated when Vilcins and Lephardt (4058) demonstrated that methyl nitrite does not exist in the smoke within the cigarette or in the smoke at the instant it issues from the mouth end of the cigarette but begins to form artifactually immediately after the smoke exits the mouth end of the cigarette. As the level of the methyl nitrite in the aging smoke increases, its methanol level decreases. This artifactual formation of methyl nitrite was recognized by Brunnemann and Hoffmann (480): "Being aware of the artifactual formation of nitrogen dioxide and methyl nitrite by aging of smoke we prefer to report nitrogen oxides in cigarette smoke as NO [nitric oxide]."

1961	Druckrey et al. (1059) reported the results of their study on the formation, chemical structure, and tumorigenicity of NNAs. This publication did not deal with the possible presence in tobacco smoke of the NNAs, but their findings probably led to the1962 publication by Druckrey and Preussmann (1057)
1962	Druckrey and Preussmann (1057) theorized that the conditions in a burning cigarette were appropriate for the generation of NNAs; i.e., present in the reaction mixture were secondary amines, water, and nitrogen oxides
1962	Data reported by Dontenwill and Mohr (15A09) indicated that NDEA had an organ-specific effect in the tracheobronchial tree of hamsters
1962	Pasternak (15A40) and Rapoport (15A45) reported the mutagenicity of NNAs in pre-Ames (*S. typhimurium*) test systems. Numerous reports describing the mutagenicity of NNAs were issued over the next few years. The test systems used included *Drosophila melanogaster*, *Escherichia coli*, *Neurospora crassa*, *Saccharomyces cerevisiae*, among others [see review by Magee and Barnes (2442)]
1963–1964	Herrold (15A24) studied the tumorigenicity of NDEA. Herrold and Dunham (15A25) studied the tumorigenicity of subcutaneously injected NDMA and reported that intratracheal or intragastric administration of NDEA to laboratory animals resulted in a large number of respiratory tract tumors
1963	Boyland et al. (15A01) discussed the possibility of the presence of NNAs in tobacco smoke, particularly "in the acidic environment of the cigarette smoke" ($pH \leq 6.7$) as opposed to the alkaline environment ($pH \geq 7.0$) of cigar and pipe smoke
1964	Boyland et al. (422, 423) suggested that it was possible, because of the formation of NNAs by the reaction of NO_x with secondary amines, that cigarette MSS could contain NAB and NNN because of the presence in tobacco MSS of nornicotine and anabasine. They reported that NAB, when administered orally to rats, produced numerous esophageal tumors in the treated animals
1964	Neurath et al. (2751) reported the isolation and identification of *N*-nitroso-*n*-butylmethylamine and the isolation of two unidentified NNAs in cigarette MSS
1964	Boyland et al. (422, 423) suggested that it was possible, because of the formation of NNAs by the reaction of NO_x with secondary amines, that cigarette MSS could contain NAB and NNN because of the presence in tobacco MSS of nornicotine and anabasine. They reported that NAB, when administered orally to rats, produced numerous esophageal tumors in the treated animals
1964	Serfontein and Hurter (3595) reported the identification of NNAs in the MSS from South African cigarettes. Serfontein (15A53) reported the identification of NPIP. Robertson (15A47), president of the National Cancer Association of South Africa, commented on Serfontein and Hurter's report of the identification of NNAs in cigarette MSS: "The significance of this discovery lies in the fact that although the nitrosamine compound is known as a carcinogen, this is the first time that it has been established beyond doubt that various nitrosamines occur in cigarette smoke."
1964–1966	Serfontein and Hurter (3596–3598) developed a thin-layer chromatographic method for separation and analysis of extremely small amounts of NNAs and noted that "the method has been successfully applied to the analysis of nitrosamines in cigarette smoke." In a detailed account of the identification of NNAs in CSC, they reported: "In the course of initial scanning experiments, strong evidence was obtained by means of gas chromatographic analysis of the neutral fraction of cigarette smoke condensate…that various nitrosamines [*N*-nitrosodimethylamine (NDMA), *N*-nitrosodiethylamine (NDEA), and *N*-nitrosopiperidine (NPIP)] were present in cigarette smoke in measurable quantities."

They estimated the level of NPIP to range from 1 to 5 μg/cig

TABLE 15.3 (continued)
A Brief Chronology of the Research on VNAs from 1937 to 1990

Year	Investigation
1965	Neurath et al. (2750) discounted their reported 1964 findings (2751) on the identification of MSS NNAs because of their artifactual formation during their collection and analytical procedure. However, with a modified analytical and collection procedure, NDMA (4 ng/cig) and NPYR (4 ng/cig) were identified in MSS. The previously reported *N*-nitroso-*n*-butylmethylamine (NBMA) was found in the part of the collection system where artifactual formation was possible. Artifactual formation of NNAs during smoke generation, separation, and analysis was a recognized problem since the first NNA identification in MSS (573, 2750, 2751, 15A10, 15A33) and resulted in much debate. Krull et al. (15A33) discussed the artifactual generation of NNAs during their determination. Subsequent research eventually resolved the question concerning the presence or absence of NNAs in tobacco and/or tobacco smoke. However, some artifactual formation did occur, resulting in inflated values for NNAs in MSS and SSS [Caldwell and Conner (572–574)]
1965	Eisenstark et al. (15A11), nearly a decade before Ames' 1973 presentation on the use of *S. typhimurium* to test for mutagenicity, described the high mutagenicity obtained with NNAs in tests with *S. typhimurium*. Several potent NNAs became positive standards, e.g., *N*-methyl-*N′*-nitro-*N*-nitrosoguanidine in the Ames test with *S. typhimurium*
1965–1967	Besides identifying several volatile NNAs in burley tobacco MSS with a procedure that precluded artifactual formation, Fredrickson (1236) demonstrated that MSS volatile NNA yields were significantly reduced (60%–85%) by a plasticized cellulose acetate filter, a finding later confirmed (514, 1761, 2635). This reduction of volatile NNA yields by selective filtration paralleled that observed for phenols (2312, 4312). Concern over phenols and their promotion effect diminished after reports of removal of significant amounts of them from MSS by selective filtration. While concern about volatile NNAs did diminish, a new NNA concern arose: one involving TSNAs, a class of NNAs newly identified in tobacco and tobacco smoke, namely, NNN, and NAB
1967	In their NNA review, Magee and Barnes (2442) [cf. Barnes and Magee (192)] noted: "It is too early to be able to suggest with any confidence the part nitrosamines might play in the etiology of human cancer. In a whole range of experimental animals tumors can be produced in a number of different sites which bear in some cases a striking pathological resemblance to cancers seen in man. However, the species, the nature of the nitroso compound, and the dose and route by which it is administered can all play a part in determining the nature of the malignant lesion produced."
1967	Brune and Henning (15A02) reported the induction of eyelid carcinoma in mice treated with methylbutyl-*N*-nitrosamine
1967	Wynder and Hoffmann noted [see p. 436 and p. 628 in (4332)]: "To date, we lack a method of quantitative determination of nitrosamines in tobacco smoke although a few good quantitative techniques have emerged. Since the presence of nitrosamines in cigarette smoke bears considerable implications in tobacco carcinogenesis, it is hoped that further and more detailed studies will also be initiated by other groups to clarify fully this important factor… A most important question, however, is whether nitrosamines are indeed formed during smoking of tobacco and whether the induction of papillary tumors in the respiratory tree of hamsters bears any relation to the induction of human bronchiogenic cancer." They concluded [p. 639 in (4332)]: "At this time one cannot deny the potential of tobacco smoke to form nitrosamines; however, we are not convinced that these agents actually exist in the cigarette smoke inhaled by man."
1967	Hoffmann and Wynder (1797) and Rathkamp and Hoffmann (3081, 3082) demonstrated that addition of nitrates to tobacco decreased the per cigarette yields of TPM, promoting/cocarcinogenic phenols, and tumorigenic PAHs (including B[*a*]P) in MSS and the tumorigenicity of the mainstream CSC to mouse skin. Later, Brunnemann et al. (471, 499) reported that increased levels of tobacco nitrate increased MSS yields of both volatile NNAs and TSNAs, resulting in recommendations to reduce the nitrate levels in tobacco stems and ribs
1968	Montesano and Saffiotti (15A37) studied the carcinogenic response of the respiratory tract of Syrian golden hamsters to different doses of NDEA. They also summarized over two dozen previous studies with NDEA
1968	In their review of the identification and quantitation of NNAs in MSS, Johnson et al. (1952) wrote: "It is possible…that little or no nitrosamines are present in cigarette smoke under normal conditions of smoking. Because of the importance of these compounds and the known high incidence of lung cancer, the establishment of their presence in smoke is of importance in the health of man… Even if the nitrosamines are identified and unequivocally established as being present in cigarette smoke at a certain level then it must be investigated whether they contribute to the total toxic activity of tobacco smoke."
1970	Volatile NNA tumorigenicity in laboratory animals was repeatedly cited with the implication that this property was extrapolable to man because of cigarette smoke NNAs. In laboratory animals, NNAs are organ-specific tumorigens and seldom have been shown to induce carcinoma at the painting site in mouse-skin-painting experiments. Hoffmann and Wynder (15A29) noted: "We…need to consider that nitrosamines have so far not been reported to be carcinogenic to man."
1971	Hoffmann and Vais (1784) reported NDMA and NEMA in unaged MSS from an 85 mm nonfiltered U.S. blend cigarette: NDMA and NEMA yields were 80 and 30 ng/cig, respectively. NDEA and NDBA were not detected. The properties of an NNA thought to be NPIP did not match those of an authentic sample
1972	The chapter in the 1972 Surgeon General's report (4003) dealing with the harmful components of tobacco smoke noted that the reports describing the presence of various NNAs in cigarette smoke were published after the June 1970 conference on which the chapter was based
1973	Morie and Sloan (2636) reported the substantial reduction of the volatile NNA (NDMA) by plasticized cellulose acetate filters *vs*. the negligible reduction obtained with paper filters. Substantial selective filtration of NDMA was demonstrated by the 85% reduction in its delivery *vs*. the 36% reduction observed in the delivery of total particulate matter with the plasticized cellulose acetate filter. Minimal selective filtration was obtained with the paper filter: 66% reduction in NDMA *vs*. 55% reduction in total particulate matter, cf. Fredrickson (1236)

TABLE 15.3 (continued)
A Brief Chronology of the Research on VNAs from 1937 to 1990

Year	Investigation
1974	Hoffmann et al. (1761) confirmed the findings of Hoffmann and Vais (1784) on NNAs in cigarette MSS. They reported 84 ng/cig of NDMA, 30 ng/cig of NEMA, and less than 5 ng/cig of NDEA in the MSS of a nonfiltered U.S. blend cigarette. They also reported that selective filtration produced a 60%–85% reduction of volatile NNAs by use of a plasticized cellulose acetate filter, cf. Fredrickson (1236), Morie and Sloan (2636)
1974	Barnes (191) [the codiscoverer with Magee of the tumorigenicity of NNAs (Magee and Barnes (2441a)] stated: "Preoccupation with the occurrence and behavior of minute amounts of nitrosamines in the human environment will probably divert skills from more profitable studies of the behavior of nitrosamines in experimental systems… If [this essay] leaves the reader with the impression that nitrosamines have a much greater potential as research tools than they have as health hazards, it will have served its purpose."
1976	Magee et al. (2443) wrote: "That a wide range of species is susceptible to the carcinogenic action of nitrosamines suggests that man is probably not resistant…Many *N*-nitroso compounds are powerfully carcinogenic in experimental animals, and, although there is no proof, it is highly probable that they are also carcinogenic in man."
1977	Brunnemann et al. (514) reported that the volatile NNA levels in MSS and SSS were lower than previously reported, attributing the lower levels to the avoidance of artifactual formation of NNAs during smoke collection and analysis. They wrote: "In fact, several of the cigarettes which were machine smoked earlier and analyzed without precautions, when smoked by us under the same conditions but with precautions, yielded 25 to 100% lower values for DMN [*N*-nitrosodimethylamine] and NPY [*N*-nitrosopyrrolidine] for the mainstream smoke…The nitrate content of the tobacco appears to be a determining factor for the concentration of volatile nitrosamines in the smoke. Selective removal of these nitrosamines does occur with cellulose acetate filter tips but not with charcoal filter tips."
	They determined the levels of volatile NNA for unaged MSS and SSS from 17 commercial and experimental cigarettes (Table 15.3)

	Level Found, ng/cig	
Volatile NNA	**MSS**	**SSS**
NDMA	1.7–97	680–1770
NEMA	0.1–9.1	9–75
NDEA	0–4.8	8–73
NPYR	0–4.8	8–73

1977	The Royal College of Physicians (3364) reported that *N*-nitroso compounds were, along with the PAHs, the chief initiators of cancer in tobacco smoke. The College noted: "The NNAs in food and drink are regarded as a potential health hazards at concentrations as low as one part per billion. *N*′-Nitrosonornicotine has been identified in both tobacco smoke and unburnt tobacco, the concentration in the latter being 2,000 to 9,000 parts per billion…concentrations much higher than those of other nitroso compounds found in meat, fish, or beverages. Its presence may be of great biological importance and could explain the correlation between tobacco chewing and the development of cancer of the mouth."
1978	The problem of the artifactual formation of volatile NNAs during smoke collection and analysis was discussed previously by Neurath (2750, 2751) and by Fredrickson (1236). It was once again revisited. Krull et al. (15A33) described the problem of artifactual formation of NNAs during the collection, fractionation, and analysis of cigarette smoke and proposed methodology to reduce the problem. This problem resurfaced several times in the next decade in the determination of both volatile NNAs [Eisenbrand et al. (15A10); Caldwell and Conner (572, 573)] and TSNAs in tobacco smoke (572, 573); preventative measures were described
1978	Brunnemann and Hoffmann (477) described the results of their measurements of volatile NNAs in indoor air containing ETS
1979	In the 1979 U.S. Surgeon General report [see p. 107 in (4005)], it was noted: "The *N*-nitrosamine formation in tobacco smoke is determined by the nitrate content of the tobacco… More importantly…selective removal (70 to 80 percent) of volatile nitrosamines from the smoke can be achieved by cellulose filters [sic][a]… At present, it has not been demonstrated that a significant reduction of volatile *N*-nitrosamines will lead to a significant reduction of the tumorigenic potential of cigarette smoke."
	It was also stated that NNAs are animal carcinogens with the ability to induce pulmonary tumors (adenomas)
1979	Rinkus and Legator (3157) listed numerous tobacco and cigarette smoke components as mutagenic in the *S. typhimurium* system. Among these were the following volatile NNAs [excluding (NMOR)] known to occur in tobacco smoke: NDMA, NDEA, NPYR, NDBA, NDPA, NMOR, NPIP
1980	In discussing "The Less Harmful Cigarette," Hoffmann et al. (1783) included a table which showed that nitrate fertilization of tobacco (which leads to increased NNAs formation) has led to significant reductions in MSS levels of "tar," nicotine, and B[*a*]P, as well as in the specific tumorigenicity of the "tar" administered via skin painting to laboratory animals. They wrote that "the reduction of the tar content of cigarettes [*sic*] was an important step in reducing the hazards of cigarette smoking."
1980	Hoffmann et al. (1711) noted: "In the mainstream smoke of a cigarette, these carcinogens [the volatile *N*-nitrosamines] can be reduced significantly by utilization of tobacco low in nitrate content and acetate filter tips that selectively retain volatile *N*-nitrosamines."
	They also stated that "most present-day commercial filter cigarettes are effectively reducing volatile NNAs." This effective reduction in volatile NNAs in cigarette MSS has not lessened during the intervening years from 1980 to date
1980	Brunnemann et al. (467) presented additional data on the levels of NNAs in MSS and SSS, cf. Brunnemann et al. (457). The SSS levels exceeded those in the MSS. Much of the MSS and sidestream data for NNAs were summarized by Hoffmann et al. (1685)

(*continued*)

TABLE 15.3 (continued)
A Brief Chronology of the Research on VNAs from 1937 to 1990

Year	Investigation
1980	Bartsch et al. (203) listed numerous NNAs as mutagenic in the Ames *S. typhimurium* test system. The following volatile NNAs reported as tobacco and/or smoke components were included: NDMA, NDEA, NMPA, NDPA, NDBA, NPYR, NMOR, and NPIP. NNN was also tested
1980	Rühl et al. (3366) reported the levels of volatile NNAs and TSNAs in the MSSs and SSSs from American, German, and French cigarettes
1981	In the 1981 Surgeon General's report (4009) on smoking *vs*. health, volatile NNAs were discussed as "organ-specific carcinogens." The Surgeon General, citing Brunnemann et al. (514), noted that "The volatile nitrosamines…can be selectively reduced by filtration…" [cf. Fredrickson (1236), Morie and Sloan (2636)]
1982	In the Third Annual Report on Carcinogens by the National Technical Information Service (2686), it was noted that "there is sufficient evidence for the carcinogenicity of *N*-nitrosodimethylamine (NDMA) in experimental animals." Similar comments were made about NPYR (MSS yield estimated as being as much as 113 ng/cig) and NDEA (MSS, 8 ng/cig; SSS yield, about 10 times that in MSS)
1982	Hoffmann and Wynder (1807a) included a table which indicated that nitrate fertilization (known to increase the levels of NNAs in the tobacco and the smoke from it) significantly reduced the biological activity (carcinogenicity) of CSC to mouse skin. The PAH levels in the CSC were also reported to be reduced
1982	In contrast to suggestions made in the late 1950s/early 1960s to control the pyrogenesis of PAHs by reduction of the tobacco wax components, e.g., long-chained saturated hydrocarbons such as *n*-hentriacontane, and/or the use of high-nitrate tobacco, Brunnemann and Hoffmann (480) recommended the following approaches—the direct opposite of the earlier suggestions from the Wynder and Hoffmann laboratory—to control both the PAHs and the NNAs in tobacco smoke: "Selective filtration is highly effective in removing volatile *N*-nitrosamines from the smoke stream, but is ineffective for the selective reduction of tobacco-specific nitrosamines. Selective reduction of nitrate in tobacco stems offers one possible approach, but additional means of reducing nitrogen oxides and *N*-nitrosamines without diminishing PAH reduction need to be found. Selection of tobacco with high levels of long chain hydrocarbons (e.g. hentriacontane $C_{31}H_{64}$) may be helpful." These 1982 suggestions for the design of a "less hazardous" cigarette were in direct contradiction to those offered two decades previously when the main emphasis was not on NNAs (their presence in tobacco smoke was, at best, theoretical in the early 1960s) but on the tetracyclic and higher PAHs, particularly B[*a*]P, because of the known effect of it and other PAHs on the skin of laboratory animals
1982	The 1982 report of the Surgeon General (4010), citing the studies of Magee et al. (2443) and the IARC (1866), concluded: "More than 50 of the approximately 100 NNAs which have been tested have various degrees of carcinogenic potency in laboratory animals… There is a lack of direct evidence that these compounds are also human carcinogens. Nonetheless, many scientists concur with the [IARC] that, for practical purposes, these nitrosamines should be regarded as carcinogenic in humans." It was noted that NDMA and NPYR were the most plentiful NNAs in cigarette smoke. NDMA is listed in this report as a "toxic and tumorigenic agent" in the vapor phase of cigarette smoke. Both NEMA (MSS delivery, 1–40 ng/cig) and NDEA (MSS delivery, 0.1–28 ng/cig) were reported as "among the most potent environmental carcinogens" of the NNAs
1982	Stehlik et al. (3812) determined the levels of NDMA in the air of cigarette smoke-filled rooms
1983	In his concluding remarks at the 1983 NNA conference (published in 1984), Magee (2441) stated: "A major component of this evidence [that N-nitroso compounds probably can cause human cancer] is the large number of species known to be susceptible to cancer induction by nitrosamines… The question of whether any human cancer has been caused by nitrosamines remains open, but several relevant and interesting presentations were given during the meeting… Following up the well-established relationship between cigarette smoking and the incidence of human lung cancer, these workers [Hoffmann, Hecht, Castonguay, and their colleagues] presented persuasive evidence for a relationship between the use of chewing tobacco and snuff and human cancer…A role for nitrosamines in the causation of human cancer has not been established, but it should not be excluded and merits further study."
1984	Although their data showed that an increase in the nitrate content of cigarette tobacco reduced the levels of FTC "tar," nicotine, carbon monoxide, catechol, and B[*a*]P, Adams et al. (28) emphasized that significantly higher yields of volatile NNAs and TSNAs were found in the MSS of an 85 mm nonfiltered cigarette. They concluded: "The findings of this study support the recommendation that the nitrate content of tobacco products should be reduced." [Cf. 1967/1970 studies and comments by Hoffmann and Wynder (1797, 1798) and Rathkamp and Hoffmann (3081, 3082) that use of high-nitrate tobacco was beneficial in that it reduced the levels of CSC, PAHs, and CSC tumorigenicity to mouse skin. Also, the findings of Brunnemann et al. (481, 482) that addition of stems, high in nitrate, did not reduce "tar," nicotine, or carbon monoxide yields]
1984	Despite three decades of a variety of claims against the PAHs and their role in carcinoma induction in laboratory animals skin painted with CSC and their alleged role in carcinoma induction in cigarette smokers, it is interesting to note that in the *American Chemical Society Monograph* (2nd edn.) edited by Searle (3568), the only class of compounds in tobacco or cigarette smoke discussed with regard to their tumorigenicity in laboratory animals was the NNAs. Even though several chapters were written by experts in the fields of PAH, their nitrogen analogs, and aromatic amines; no mention was made throughout this two-volume 1400-page monograph of the numerous PAHs in tobacco or cigarette smoke, their levels, or their role in respiratory tract cancer attributed by some to the PAHs in cigarette smoke. The only class of tumorigens discussed was the NNAs and TSNAs. Most of the data cited were those of Hoffmann et al.
1984	The Preussmann and Eisenbrand summary (2990) of research on NNAs in tobacco and tobacco smoke was, according to their article, taken largely from a 1982 review by Hoffmann et al. Preussmann and Eisenbrand commented: "Although Hoffmann et al. have clearly demonstrated the effectiveness of cellulose acetate filters in model experiments, the values for U.S. commercial cigarettes are about the same for filter as for nonfilter cigarettes; the reductive effect of filters in practice may be counteracted by variations in tobacco composition between the two types of cigarettes… In conclusion, tobacco and tobacco smoke represent the largest nonoccupational source of exposure for preformed nitrosamines."

TABLE 15.3 (continued)
A Brief Chronology of the Research on VNAs from 1937 to 1990

Year	Investigation
1984	Matsushita and Mori (2495) determined the levels of nitrogen dioxide and volatile NNAs in indoor air and cigarette SSS
1984	Preussmann (15A43) tabulated the ranges of the reported levels of a variety of NNAs in tobacco and in cigarette MSS and SSS
1986	The IARC (170) concluded that NDMA, NDEA, NPYR, and NEMA were tumorigenic to laboratory animals and that NDMA was one of the two most abundant volatile NNAs in cigarette MSS
1987	Klus et al. (15A32) reported the levels of several volatile NNAs in ETS in several real-life situations
1987	The RTECS (Registry of Toxic Effects of Chemical Substances) (3095) reviewed the studies in which lung tumors were observed in laboratory animals treated with an NNA by a variety of administration routes. The RTECS categorized the positive inhalation findings involving NNAs as "equivocal." For example, the dose level used (200,000 ng/m^3) for NDMA in the inhalation experiments was significantly greater than the NDMA level observed (10–240 ng/m^3) in ETS exposure
1989–1990	Caldwell and Conner (573) reported: "The methodology previously reported [by others] leads to significant overestimation of *N*-nitrosamine concentrations in cigarette smoke."
	The overestimations were true for both volatile and tobacco-specific NNAs in MSS and SSS for the Kentucky Reference Cigarette 1R4F: MSS data indicated that the levels were 380% high for NPYR and 83%, 38%, 27%, and 19% for NAB, NAT, NNK, and NNN, respectively. Thus, it is probable that many of the previously reported levels of NNAs in MSS and SSS, tabulated in various articles [cf. Adams et al. (31), Hoffmann and Hecht (1727)] and cited by EPA (1148) and the U.S. Surgeon General (4005, 4009, 4010, 15A57) are incorrect.
	Hoffmann and Hecht (1727) did not acknowledge that the MSS levels listed for volatile NNAs and the TSNAs were likely to be incorrect (and high) because of the artifactual formation of both types during MSS (and SSS) collection for analysis as reported by Caldwell and Conner (572–574). EPA (1148) accepted without question the MSS volatile NNA and TSNA yields listed by Hoffmann and Hecht (1727) whose data were cited by the U.S. Surgeon General (4012). The levels of various NNAs reported in foodstuffs and beverages are also possibly in error because of artifactual formation of NNAs during the isolation procedure and subsequent quantitation
1990	In their list of 43 "tumorigenic agents" in tobacco and/or smoke, Hoffmann and Hecht (1727) included the following volatile NNAs: NDMA, NDEA, NEMA, and NPYR. Little comment was made about these four volatile NNAs and their supposed tumorigenicity to smokers. However, they did note that IARC (1870) had evaluated the bioassay data from laboratory animals exposed to these NNAs and considered the data sufficient to classify all four as tumorigenic to animals. IARC did not express an opinion as to whether these four were tumorigenic to humans
	Brunnemann et al. (1459, 460, 462) summarized data from several publications on the levels of various volatile NNAs (NDMA and NPYR) in indoor air at various sites (trains, offices, coffee shops, dance halls)

[a] This should read "cellulose acetate."

In his response to the Environmental Protection Agency's draft document (1148) on ETS, Rodgman (3255) criticized the inclusion by EPA of NDELA as a tumorigenic agent in tobacco and/or smoke. EPA had based its assessment of this compound on the Hoffmann–Hecht list of 43 "tumorigenic agents in tobacco and tobacco smoke" (1727). Rodgman's reasoning was as follows: since the diethanolamine salt had not been used in the United States for nearly a decade, the level of this nitrosamine should now be substantially reduced in tobacco as well as in MSS and SSS from cigarettes containing such tobacco.

The chronological pattern of decrease in levels of NDELA might parallel those reported for the decrease in levels of arsenic and DDT in tobacco (and its smoke) when arsenicals and DDT were no longer used on tobacco in the United States. For example, in 1952, arsenicals were removed from the list of recommended and permissible insecticides for tobacco. By 1968, the arsenic content of U.S.-grown tobacco had decreased to 0.5–1.0 μg/g from the 1951 level of about 50 μg/g of tobacco (1870, 4005); arsenic levels reported in 1975 by GRIFFIN et al. (1391) were 0.5–0.9 μg/g of tobacco. Similarly, discontinuance of the use of chlorinated insecticides such as DDT in U.S. tobacco culture in the late 1960s resulted in a gradual and substantial reduction of DDT residues in leaf tobacco. Between 1968 and 1974, the residual DDT level in American flue-cured tobacco decreased rapidly and substantially (1870, 4005) from 52 μg/g in 1968 to 6 μg/g in 1970, and to 0.23 μg/g in 1974.

Hoffmann et al. (1696) had predicted that the NDELA level in tobacco would decrease:

> At present, NDELA [*N*-nitrosodiethanolamine] levels are relatively high in US brands (290–300 mg/kg) but they are expected to decrease, since the herbicide was banned from use on tobacco as of October 1981 (1147).

In 1982, the U.S. Surgeon General concluded (4010) that NDELA was a carcinogen, noting not only did NDELA induce carcinomas in treated laboratory animals (carcinoma of the liver and kidneys in rats, carcinoma of the trachea in hamsters), but also it was present in tobaccos treated with the diethanolamine salt of maleic hydrazide.

In the National Technical Information Service Third Annual Report on Carcinogens (2686), it was concluded that there was sufficient evidence to classify NDELA as a carcinogen in laboratory animals.

In its review of tumorigenic components of tobacco and tobacco smoke, the IARC (1870) noted for NDELA:

> Its presence in tobacco products has been related to the use of the sucker growth inhibitor, maleic hydrazide when formulated with the diethanolamine salt ('MH-30' or 'MH-40')…; in the USA, that formulation has been replaced by the potassium salt… Tobaccos grown in a pesticide-free environment and smoke generated from such tobaccos are devoid of N-nitroso-diethanolamine. [(NDELA)]

Hoffmann and Hecht (1727) included five volatile NNAs [NDMA, NDEA, NEMA, NPYR, and NMOR] and the nonvolatile NDELA in their list of 43 "tumorigenic agents in tobacco and tobacco smoke." They noted that NMOR had not been reported as a tobacco smoke component. Possible relationships between diethanolamine {I}, NDELA {II}, morpholine {III}, and NMOR {IV} are illustrated in Figure 15.1. It is possible that as the NDELA level in tobacco has declined, the levels of morpholine and NMOR also have declined. More recent major efforts in the NNA-tobacco area have been devoted to the study of TSNAs and *N*-nitrosamino acids rather than to the NDELA/NMOR question.

Tobacco products and smoke, however, are not the only source of exposure to NDELA. As noted previously, it is highly likely that the current levels of NDELA in tobacco products are approaching zero because of the discontinued use of the diethanolamine salt of maleic hydrazide in U.S. tobacco agronomy. However, consumer exposure to NDELA from nontobacco sources is possible. Studies of NDELA-contaminated cosmetics indicated substantial levels of NDELA have been identified in cosmetics; e.g., Fan et al. (15A12) detected NDELA in 27 of 29 products tested at levels ranging from 1 to 48,000 ppb; Klein et al. (15A31) detected it in 5 of 10 cosmetic products (range from 20 to 4113 ppb). Hecht (15A15) found no NDELA in the products but did find *N*-nitrosomethyldodecylamine in six of seven cosmetics containing laurylamine (dodecylamine). NDELA is readily absorbed through the skin after application of NDELA-contaminated cosmetics and is detected in cosmetic users' urine, cf. Preussmann and Eisenbrand (2990).

The other nonvolatile NNA is NPRO (see Table 15.1). It was not included by Hoffmann and Hecht (1727) in their list of 43 "tumorigenic agents in tobacco and tobacco smoke" or any of the subsequent lists tabulated in Table 15.2.

Scott et al. (3566) and Brunnemann et al. (511) reported that cigarette and chewing tobaccos differed in their NPRO levels: Cigarette tobacco contained ≈2 ppm (less than 1% of free proline was nitrosated); chewing tobacco contained about 35 ppm (up to 40% of free proline was nitrosated). They reported that the NPRO level is dependent on proline level, nitrate level, and curing method.

Brunnemann et al. (509) reported the measurement of the endogenous formation of NPRO in smokers and nonsmokers on a controlled diet, relatively low in proline and ascorbic acid. The NPRO in urine was determined in 24-h urine samples on days 3, 6, 9, and 12. Different groups in the study were administered proline and/or ascorbic acid at appropriate times during the experiment. Ascorbic acid intake reduced urinary levels of NPRO. Differences in NPRO excretion by smokers and nonsmokers on the controlled diet, ascorbic acid supplement, no proline supplement were not statistically significant.

The results of numerous studies on the *in vivo* formation of NNAs were presented at the 1983 IARC conference [O'Neill et al. (15A39)]. Many dealt with the *in vivo* generation of NPRO in nitrite- and proline-treated mammalian species, including humans. Numerous investigations have been conducted on NPRO because of its presence not only in tobacco and tobacco smoke but also in a variety of consumer products (meat, bacon, ham, chicken, fish, toast, biscuits, cornflakes, beer) [Brunnemann et al. (509), Hansen et al. (15A14), Pensabene et al. (15A41), Pollock (15A42), Sen and Seaman (15A50), Sen et al. (15A51)].

In the IARC monograph (1870), it was noted that NPRO was detected in cigarette smoke at extremely low levels (<1 ng/cig) by Brunnemann et al. (511) despite the fact it is readily detected in tobaccos. Hoffmann et al. (1696) listed the levels of NPRO in various tobacco products (cigarette tobaccos, little cigars, cigars, chewing tobaccos, snuff). The reported values ranged from a low of 450 to a high of 22,000 ng/g of tobacco (dry weight).

15.3 TOBACCO-SPECIFIC NNAs

A year after the proposal by Druckrey and Preussmann (1057) that the conditions in a smoked cigarette were appropriate for the generation of NNAs, Boyland et al. (422, 423, 15A01) speculated that it was possible, because of the formation of NNAs by the reaction of nitrogen oxides with secondary

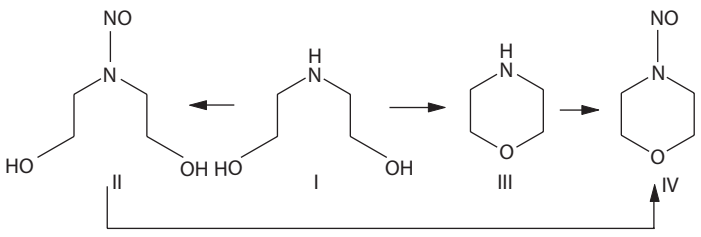

FIGURE 15.1 NDELA and *N*-nitrosomorpholine (NMOR).

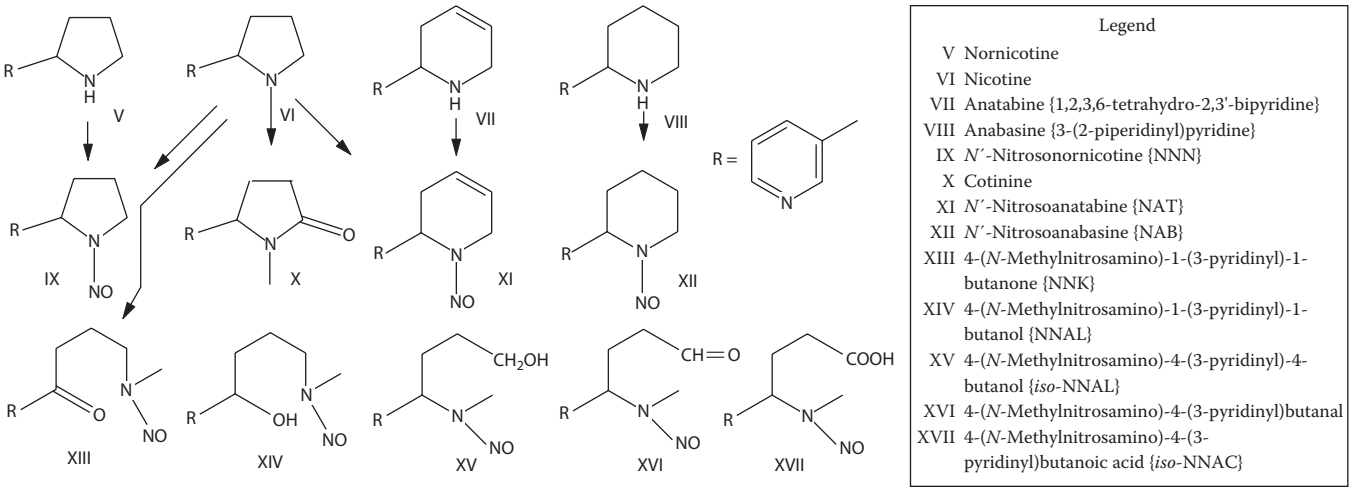

FIGURE 15.2 Tobacco-specific *N*-nitrosamines.

amines, that cigarette MSS could contain NNN and NAB because of the presence of the secondary amines nornicotine and anabasine in tobacco and smoke. They also reported that oral administration of NAB to rats induced esophageal tumors. After nearly a decade of investigation on the volatile NNAs in tobacco smoke, attention was turned to the higher molecular weight NNAs.

In Figure 15.2 are shown the relationships among the nicotine-related alkaloids—nornicotine {V}, nicotine {VI}, anatabine {VII}, anabasine {VIII}—and the NNAs {IX, XI–XVII} and cotinine {X}. Table 15.4 summarizes some of the early research on the TSNAs.

Between the early 1980s and 2004, a substantial number of studies were devoted to some aspect of the TSNAs in tobacco and/or its smoke. Included were conference presentations and journal publications in which analytical technology, artifactual TSNA generation during collection and analysis, quantitation, adverse biological effects and their inhibition, effect on various biological systems, and tobacco users. Figure 15.3 is a plot of the chronology from 1983 through 2004 of TSNA-related references listed in our Bibliography section. It is obvious from the graphical depiction that the decade from the late 1980s to the late 1990s was a highly productive period for such studies. It is also obvious from the references in bold print that the American Health Foundation was a major contributor to our knowledge on TSNAs.

15.4 *N*-NITROSAMINO ACIDS

The results of several epidemiological studies suggested an association between the use of chewing tobacco or snuff and oral cancer. These products differ from smoking products (cigarettes, cigars, pipe tobaccos) in that they are not subjected to the high temperatures encountered in the smoking process. Thus, smokeless products contain little, if any, of the combustion products alleged to be significant tumorigens, e.g., the PAHs and their *N*-containing analogs, in tobacco smoke. As a result, snuff and chewing tobacco NNAs became suspect because they were the only components known to be laboratory animal tumorigens. Preformed NNAs in these tobacco products and NNAs endogenously formed in the product users were considered by many to be the causal factor for oral cancer in snuff dippers [Hoffmann and Adams (1677), Brunnemann et al. (507a, 510, 15A04), Hoffmann et al. (1684, 1697, 1707, 1713, 1722), Hecht et al. (15A23), Adams et al. (33), Prokopczyk et al. (15A44), Carmella et al. (15A06), Tsuda and Kurashima (15A56), Djordjevic et al. (1008)] and in tobacco chewers [Brunnemann et al. (468, 498), Wenke et al. (15A58), Hoffmann et al. (1730, 1731), IARC (1869), Prokopczyk et al. (2995), Tsuda and Kurashima (15A56)].

In studies to elucidate the possible tumorigens in chewing tobacco and snuff, the only known components tumorigenic in laboratory animals identified were various NNAs, particularly the TSNAs, NNN, and NNK plus a group of *N*-nitrosamino acids, including NPRO. Whereas discussions and investigations on volatile NNAs [Druckrey and Preussmann (1057), Serfontein and Hurter (3595–3599)] and several TSNAs, NNN, and NAB [Boyland et al. (422, 423)] have appeared in the literature for over four decades, reports on identifications of *N*-nitrosamino acids are much more recent.

Ohshima et al. (2852) identified several *N*-nitrosamino acids, 3-(methylnitrosamino)propanoic acid (also known as *N*-methyl-*N*-nitroso-β-alanine) (NMPA), 4-(methylnitrosamino)butanoic acid (NMBA), and 1-nitroso-2-piperidinecarboxylic acid (also known as *N*-nitrosopipecolic acid), in various types of tobacco (cigarette, chewing, pipe, cigar, and snuff tobaccos). Decarboxylation of these *N*-nitrosamino acids would yield NEMA, *N*-nitrosomethylpropylamine, and NPIP. IARC (1986) did note the 1985 Ohshima et al. findings on these *N*-nitrosamino acids in tobacco.

Following their identification of several *N*-nitrosamino acids in snuff, Djordjevic et al. (992) investigated these acids in 1R1 and 1R4F reference tobaccos from the University of Kentucky. In addition to detecting 4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-1-butanol (*iso*-NNAL), 4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-1-butanal,

TABLE 15.4
A Brief Chronology of the Research on TSNAs

Year	Investigation
1964	Boyland et al. (422, 423) suggested that, because of the possibility of the formation of NNAs by the reaction of NO_x with secondary amines, cigarette MSS could contain NAB and NNN generated from nornicotine and anabasine in tobacco MSS. NAB, when administered orally to rats, induced esophageal tumors in the treated animals
1973	At the Austria Tabakwerke A.G., Klus and Kuhn (2136) detected 40 ng/cig of NNN in the MSS from cigarettes made with nornicotine-rich tobacco (1.95% nornicotine). However, they failed to detect NNN in the MSS from a blended commercial cigarette. They concluded: "From the biological and toxicological points of view, the expected quantity of nornicotine nitrosamine developed from a commercial cigarette containing an average of 0.04% nornicotine is almost meaningless."
1973	Rathkamp et al. (3080) reported that MSS from an 85 mm U.S. blend nonfiltered cigarette contained NAT at less than 20 ng/cig
1974	Hoffmann et al. (1761) confirmed the report by Klus and Kuhn (2136) of the presence of NNN in cigarette MSS. They suggested that nicotine and nornicotine were NNN precursors with nicotine actually being the more important precursor because of its preponderance in tobacco. Their results differed, however, from those of Klus and Kuhn on the level of NNN in MSS from a commercial blended cigarette; Hoffmann et al. (1761) reported that the MSS from a nonfiltered U.S. blended cigarette contained 137 ng of NNN
1974	Hecht et al. (1576) reported the level of NNN in tobacco paralleled the nitrate level. They also suggested the TSNA levels in tobacco may be controllable by appropriate selection of the curing process. Flue-cured tobaccos usually show the lowest NNN level *vs*. the levels in tobaccos cured by other methods, e.g., air curing
1974	Hoffmann et al. (1733) reported that various types of commercial tobacco contained substantial levels of NNN at levels ranging from 2 to 90 mg/g (2–90 ppm). Two commercial cigarette samples showed NNN levels of 2.2 and 6.6 mg/g. They noted: "This is to our knowledge the highest concentration of a positively identified NNA yet reported in an environmental source. NNAs in meat, fish, beverages, and related materials rarely exceed 0.1 ppm."
1976–1977	Hecht et al. (1563, 1565) suggested that nicotine was the precursor of NNK and 4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-1-butanal in tobacco via opening of the pyrrolidine ring of nicotine
1977	The Royal College of Physicians (3364) noted: "*N*′-Nitrosonornicotine has been identified in both tobacco smoke and unburnt tobacco, the concentration in the latter being 2,000 to 9,000 parts per billion—concentrations much higher than those of other nitroso compounds found in meat, fish, or beverages. Its presence may be of great biological importance and could explain the correlation between tobacco chewing and the development of cancer of the mouth."
1979	For tobaccos, Hoffmann et al. (1679) reported levels of 0.2–45 ppm of NNN and 0.1–35 ppm of NNK. For cigarettes, they reported MSS levels of 0.2–3.7 µg/cig for NNN and 0.12–0.44 µg/cig for NNK
1979	After reviewing earlier data that indicated NNN was moderately carcinogenic in the Syrian golden hamster, Hoffmann et al. (15A28) concluded: "Since NNN is present in ppm levels in tobacco and in microgram amounts in the smoke of a cigarette, it may contribute to the carcinogenicity of tobacco smoke."
1979	The U.S. Surgeon General (4005) reported the identification of NNN and NAT in MSS. MSS levels listed for NNN were those reported by Hoffmann et al. (1679) (0.2–3.7 µg/cig). No quantitative data were listed for NAT
1980	Hecht et al. (15A18) reported high rates of benign and malignant tumors in two groups of F344 rats treated with TSNAs. One group of rats was treated with NNN; the other group was treated with NNK. For each group, the TSNA (3.4 mmol total dosage) was administered in 60 subdoses over a period of 20 weeks
1981	Adams et al. (23) reported the results of their study on the transfer of 4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK) from tobacco to MSS and its formation from tobacco components during the tobacco smoking process
1981	McCoy et al. (15A36) studied the influence of ethanol in the diet on the tumorigenicity of NNN administered to Syrian golden hamsters at two dose levels. In the group of test animals whose caloric intake was equal to that of the control group, no accelerating effect of ethanol on NNN tumorigenicity was observed
1981	Hoffmann et al. (1710) reported that, in a study involving subcutaneous injections into Syrian golden hamsters, the tumor production data indicated NNK was a more potent carcinogen than NNN. The authors stressed the importance of this finding because of the relatively high exposure (approximately 1 µg/cig for an 85 mm filtered cigarette) of smokers to NNK [see also Table 9 in (1710)] which they described: "As a carcinogen more potent than the strongly carcinogenic *N*′-nitrosonornicotine… Exposure to NNK in tobacco and tobacco smoke should certainly be minimized."
1981	In the U.S. Surgeon General's 1981 report (4009), the relative tumorigenicities of NNN, NNK, and NAT were discussed: "NNN is a moderately active carcinogen in mice, rats, and Syrian golden hamsters, whereas NNK is a strong carcinogen to the respiratory tract of all three species; NAT has so far not been bioassayed." After it was noted that conclusive epidemiologic data were not available to define the precise effect of NNN in humans, the following statement was cited from a 1978 IARC report: "NNN should be regarded for practical purposes as if it were carcinogenic to humans."
1982	Brunnemann et al. (471) described the environmental occurrence of NNAs derived from foods and other consumer items, including tobacco products. They also discussed the possibility of the *in vivo* formation of NNAs in blood serum, gastric secretions, and urine
1982	The IARC (1867) concluded that there was sufficient laboratory evidence to categorize NNN as carcinogenic in laboratory animals

TABLE 15.4 (continued)
A Brief Chronology of the Research on TSNAs

Year	Investigation
1982	In the Third Annual Report on Carcinogens by the National Technical Information Service (2686), the National Toxicology Program officials noted: "Cigarette smokers, tobacco chewers, cancer researchers, and organic chemists are at greatest risk of exposure to *N*-nitrosonornicotine… Smokers and persons breathing tobacco smoke may inhale a significant amount of *N*-nitrosonornicotine. The amount of this substance in commercial U.S. tobacco products varies from 1.9 to 88.5 ppm; this is one of the highest values of an experimental nitroso compound reported in the literature
1982	In the U.S. Surgeon General's 1982 report (4011), it was stated: "At this time, there is no experimental evidence on the formation of TSN (tobacco-specific nitrosamines) in the lung upon inhalation of tobacco smoke. However, a smoker of one or two packs of cigarettes daily retains…1 to 4 milligrams of nornicotine…thus, *in vivo* formation of tobacco-specific NNAs is a real possibility. The report also concluded that NNK is "…by far the most potent carcinogens of the TSNAs." In this 1982 report, NNK was included in a list of "toxic and tumorigenic agents of cigarette smoke." It was noted that the level of NAT in MSS of U.S. cigarettes ranged from 0.15 to 4.6 ng/cig. It was also pointed out that no carcinogenicity bioassay data were currently available for NAT in 1982
1982	In their review on MSS and SSS composition and SSS/MSS ratios, Klus and Kuhn (2142) summarized the published data [Hoffmann et al. (1679)] on MSS and SSS yields of several tobacco-specific NNAs (NNN, NNK, NAT)
1983	Using radiolabeled compounds, Adams et al. (29) conducted a detailed study on the formation and transfer of NNK: It was reported that 6.9%–11.0% of the tobacco component transferred to MSS; this amount represented 26%–37% of the NNK in MSS, the remainder (63%–74%) was considered to be formed from nicotine during the smoking process. However, conflicting data were later presented by Fischer et al. (1193, 1199) who reported that NNN and NNK in cigarette MSS arose only by transfer from the tobacco rod and were not formed pyrogenetically during the smoking process
1983	Hecht et al. (15A16) reported the induction of lung tumors in Syrian golden hamsters treated with a single dose of 1 mg of 4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK)
1983	Castonguay et al. (15A08) reported: "As a result of tobacco smoking, NNN [*N′*-nitrosonornicotine] and NNK [4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-1-butanone] are among the most ubiquitous procarcinogens detected in the human environment." In their carcinogenicity study, Castonguay et al. found that a total dose of 0.1 mmol of NNK induced 3.76 lung tumor/mouse or a total of 86.5 lung tumors. This value was 29 times higher than that found in the similarly treated NNN group. The number of lung carcinomas in the NNK group was 41 times higher than that in the NNN group
1983	Brunnemann et al. (499) studied the influence of stem (and their nitrate content) on the volatile and tobacco-specific NNAs in MSS and SSS. They reported that the MSS yields of "tar," nicotine, carbon monoxide, and carbon dioxide were *not* greatly influenced by filler nitrate content. This should be contrasted with previous reports from the same laboratory—at a time when nitrate addition or high-nitrate tobacco use was touted as beneficial—on the reduction in smoke yields of "tar," nicotine, PAHs, phenols, and carbon monoxide as a result of nitrate addition [Wynder and Hoffmann (4332), Hoffmann and Wynder (1797, 1798)]. The SSS yield of NDMA was extremely high (>1000 ng/cig). SSS yields of NDMA and NNN were dependent on filler nitrate content
1983–1984	Hecht et al. (15A17, 15A22) and Hecht and Lin (15A21) demonstrated the genotoxicity (Ames test with *S. typhimurium*) of NNK and NNN [Hecht et al. (1984)]
1984	As noted previously, since the early 1980s, Hoffmann et al. at the American Health Foundation have presented or published numerous reviews, many repetitious in content, of their views on NNAs. In particular, they have emphasized the TSNAs, their levels in tobacco, in MSS and SSSs, and in ETS, their tumorigenicity in laboratory animals, and their supposed involvement in tumor induction in tobacco users, e.g., Hecht et al. (15A17), Hoffmann et al. (1688, 1730, 1731, 1746, 1770, 1772, 15A26, 15A27), Djordjevic et al. (1014), Hecht and Hoffmann (1571, 1571a, 15A20), Hoffmann and Hecht (1727), and Brunnemann and Hoffmann (15A03)
1984	Although their data showed that an increase in the nitrate content of cigarette tobacco reduced the MSS levels of FTC "tar," nicotine, carbon monoxide, catechol, and B[*a*]P, Adams et al. (28) emphasized that significantly higher yields of volatile NNAs and TSNAs were found in the MSS of an 85 mm nonfiltered cigarettes whose nitrate contents were increased by sodium nitrate addition. Despite reductions in MSS levels of "tar," nicotine, B[*a*]P, and catechol, Adams et al. considered that the "carcinogenic potential" of the whole MSS from the enhanced nitrate cigarettes was increased primarily due to elevated yields of nitrogen oxides (NO_x), volatile NNAs, and TSNAs. They stressed the importance of the NO_x as a precursor in the endogenous formation of NNAs during tobacco smoke inhalation. However, they ignored the fact that (1) only traces of nitrogen dioxide NO_2 exist in cigarette MSS, (2) over 95% of its NO_x content is nitric oxide, NO, and (3) other components in tobacco smoke reduce the nitric-oxide-to-nitrogen-dioxide conversion ($NO \rightarrow NO_2$) [Cooper (815), Cooper and Hege (816)]. On the basis of their findings, Adams et al. concluded: "The findings of this study support the recommendation that the nitrate content of tobacco products should be reduced."
1984	Hoffmann et al. (1769) reported the following results from the MSS and SSS analyses of U.S. commercial cigarettes:

	Ng/cig	
TSNA	**MSS**	**SSS**
NNN	120–1000	150–1700
NNK	80–770	170–410
NAT	140–1000	150–270

(*continued*)

TABLE 15.4 (continued)
A Brief Chronology of the Research on TSNAs

Year	Investigation
	In this study, subcutaneous injection of NNN (three levels: 9.0, 3.0, and 1.0 mmol/kg, thrice weekly for 20 weeks) into F344 rats showed a dose response with respect to nasal tumors (60% and 100% at the higher two levels) and carcinoma of the nasal cavity. Lung adenomas were observed at all three dose levels. In a parallel experiment with NNK, relatively high carcinogenicity in the rats was observed. They wrote: "Perhaps the most important finding was that even the lowest dose of NNK induced a high percentage of lung tumors in males (85%) and a significant yield of lung tumors in females (30%). These lung tumors included squamous cell carcinomas."
	In an NAT experiment, similar to those for NNN and NNK, NAT was not carcinogenic at any of the three dose levels
1986	IARC (1870) concluded that the TSNAs are the most abundant suspected carcinogens in tobacco smoke. It considered NNN and NNK to be proven carcinogens for laboratory animals. It considered the evidence limited for defining the carcinogenicity of NAB in laboratory animals and inadequate to label NAT as a carcinogen for laboratory animals
1987	Adams et al. (31) presented data on the levels of TSNAs in MSSs and SSSs from different types of cigarette. TSNAs comprised NNN, NNK, NAB, and NAT. For the latter three, the per cigarette SSS levels substantially exceeded the MSS levels
1987	Brunnemann et al. (469) identified a new TSNA 4-(*N*-methyl-nitrosamino)-4-(3-pyridinyl)-1-butanol (*iso*-NNAL) in snuff and cigarette tobaccos. It was not detected in either cigarette MSS or SSS. In a study involving iso-NNAL, NNN, and NNK, LaVoie et al. (15A34) determined the tumorigenicity of the three in mice
1987	Klus et al. (15A32) measured several ETS-related TSNAs in indoor air of an 83 m^3 office under various smoking conditions. NNN varied from 0.7 to 6 pg/L, NNK varied from 0.2 to 10.7 pg/L. They found no correlation with the carbon monoxide levels
1988	Tricker et al. (3945) reported that nicotine was not *N*-nitrosated to NNN under simulated gastric conditions. However, nornicotine, anabasine, and anatabine were *N*-nitrosated to NNN, NAB, and NAT, respectively, under such conditions. They also reported that NNK decomposed slightly under these conditions
1989	Hecht and Hoffmann (15A19) considered both NNN and NNK as powerful carcinogens because they induced benign and malignant tumors of the lung, nasal cavity, esophagus, pancreas, and/or liver in mice, rats, and hamsters
1989–1990	Caldwell and Conner (573) reported: "The methodology previously reported [by others] leads to significant overestimation of NNA concentrations in cigarette smoke."
	The overestimations were true for both volatile NNAs and TSNAs in MSS and SSS for the Kentucky Reference Cigarette K1R4F used in their study: MSS data indicate the levels found were 380% high for NPYR and 83%, 38%, 27%, and 19% for NAB, NAT, NNK, and NNN, respectively. Thus, it is highly probable that the levels of NNAs in smoke tabulated in articles such as those by Hoffmann and Hecht (1727) and frequently cited by the EPA and the Surgeon General are incorrect
1990	Hoffmann and Hecht (1727) reviewed the evidence supporting the roles of various classes of tobacco smoke components in cancer induction by tobacco smoke. They concluded that PAHs and NNK are the major carcinogens involved in lung cancer induction by cigarette smoke. In their 1990 publication, they stated: "These exposure estimates [for benzo[*a*]pyrene] and the determinations of the tumorigenic potential of [polycyclic aromatic hydrocarbons] in bioassays strongly suggest that [polycyclic aromatic hydrocarbons] play a significant role in the induction of respiratory tract cancer in smokers… Human exposure to [4-(N-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK)] is consistent with its potential role as a causative agent for lung cancer… These calculations [relating smoker exposure to 4-(N-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK) to dose level needed to induce respiratory tract tumors in hamsters], which ignore the probable endogenous formation of [4-(N-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK)…], point to a significant risk for the smoker and strongly support the role of [4-(N-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK)] as an important etiological factor in lung cancer."
	However, they also noted: "The organospecificity of [4-(N-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK)] for the lung is consistent with its role in tobacco smoke-induced respiratory carcinogenesis. The lung is the main target organ for [4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK)] administered [per os] or [subcutaneously] to rats and hamsters… Lung tumors[a] have also been induced in mice after topical applications of high doses of [4-(N-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK)]… It has not been tested by inhalation."
1990	In their list of 43 "tumorigenic agents in tobacco and tobacco smoke," a list cited frequently in reports issued by various governmental agencies (EPA, USPHS), Hoffmann and Hecht (1727) listed three TSNAs: NNN, NNK, and NAB, the same three listed previously in 1986 by Hoffmann and Wynder (1808) and IARC (1870) and subsequently by Hoffmann et al. (1740, 1741, 1743, 1744, 1773)
1991	In the introduction to their publication on lung and pancreatic cancer, Hecht and Hoffmann (1571a) reiterated their previous conclusion on the role of PAHs and NNK in cancer causation in tobacco smokers: "Polynuclear aromatic hydrocarbons and NNK [4-(N-methyl-nitrosamino)-1-(3-pyridinyl)-1-butanone] are the major carcinogens involved in lung cancer induction by cigarette smoke and that NNK [4-(N-methylnitrosamino)-1-(3-pyridinyl)-1-butanone] is a likely candidate for induction of pancreatic cancer in smokers."
1992	Mimicking intragastric conditions, Caldwell et al. (575, 576) studied nicotine *N*-nitrosation and found it to be extremely slow. They concluded: "It is unlikely that nicotine itself contributes to exposure to nitroso compounds [*N′*-nitrosonornicotine (NNN), 4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-1-butanal, and 4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-1-butanone (NNK)] due to chemically mediated intragastric nitrosation."
	Caldwell et al. confirmed, in part, the 1988 findings of Tricker et al. (3945) who had previously studied the potential endogenous formation of TSNAs under conditions simulating normal human gastric conditions

TABLE 15.4 (continued)
A Brief Chronology of the Research on TSNAs

Year	Investigation
1991–1992	Brunnemann et al. (459, 460) sampled indoor air in bars, restaurants, and trains; the levels found for NNN ranged from 0 to 23 pg/L; for NNK, 1–29 pg/L; for NAT, 0–9 pg/L
1992	In 1992, Chung et al. (793a) demonstrated that components, e.g., phenethyl isothiocyanate, indole-3-carbinol, in green tea and cruciferous vegetables inhibited lung tumorigenesis induced by NNK
1992	Klus et al. (4711) described the level s of TSNAs in ETS
1993	Carmella et al. (15A05) identified 4-(*N*-methylnitrosamino)-1-(3-pyridinyl)-1-butanol (NNAL) and its glucuronide in the urine of cigarette smokers, thus providing the first evidence for metabolites of TSNAs in human urine. No NNK was detected. Results with smokers' urine were consistent with those found previously with monkeys' urine
1993	Hoffmann et al. (1773) again cited the list of 43 tumorigens in tobacco and smoke from Hoffmann and Hecht (1727). Despite the fact that in 1991, Hecht and Hoffmann (1571a) concluded that "polynuclear aromatic hydrocarbons and NNK [4-(*N*-methyl-nitrosamino)-1-(3-pyridinyl)-1-butanone] are the major carcinogens involved in lung cancer induction by cigarette smoke and that NNK is a likely candidate for induction of pancreatic cancer in smokers," they listed NNK, NNN, and NNAL in this publication only as "likely causative agents for tobacco-related cancers."
1993	Castonguay (15A07) described the inhibition in A/J mice of NNK-induced lung tumorigenesis by ellagic acid, a polyphenolic dilactone
2006	Stepanov et al. (5566) listed the levels of TSNAs in smokeless tobacco products
2007	Chwoidak et al. (4547) described an improved LC/MS/MS method for the determination of TSNAs in tobacco and tobacco-related products
2007	The influence of curing on TSNA production in dark fire-cured tobacco was outlined by Bailey (4991)
2008	Moldoveanu and Borgerding (5008) outlined the formation of TSNAs in cigarette MSS
2009	Wang et al. (5091) described the control of TSNAs in cigarette MSS by a filter-tip additive
2010	Zhu et al. (5589) reported the control of TSNAs in cigarette MSS by a filter-tip additive
2010	The effect of agronomy and curing of burley tobacco on its TSNA content was described by Peek et al. (5550)
2010	Suzuki et al. (5569) reported the control of TSNAs and NO_x in tobacco smoke by nitrate control
2010	Yoshida et al. (5584) outlined an improved analytical method for the determination of TSNAs in cigarette MSS, cf. their report with that of the 2009 presentation by Mathis and Yeung (5063)

[a] The tumor type was the adenoma, not the squamous cell carcinoma supposedly associated with cigarette smoking in smokers.

and the common TSNAs, the following *N*-nitrosamino acids were identified: 4-(*N*-methylnitrosamino)-4-(3-pyridinyl) butanoic acid (*iso*-NNAC), NMBA, NMPA [*N*-methyl-*N*-nitroso-β-alanine], 2-(methylnitrosamino)acetic acid [*N*-methyl-*N*-nitrosoglycine, *N*-nitrosarcosine] (NSAR), 1-nitroso-2-piperidinecarboxylic acid, and NPRO. Djordjevic et al. considered these NNA compounds important in cancer causation, particularly in snuff and chewing tobacco users. Djordjevic et al. (992) confirmed the findings of Ohshima et al. (2852) on the presence of *N*-nitrosamino acids in tobacco. In addition to the *N*-nitrosamino acids identified by Ohshima et al., Djordjevic et al. identified 4-(*N*-methylnitrosamino)-4-(3-pyridinyl)-1-butanoic acid (*iso*-NNAC). The highest concentrations of these *N*-nitrosamino acids were found in snuffs and black tobacco. They also identified NMPA in tobacco and MSS and estimated its transfer from tobacco to MSS to be 0.85%.

In studies with *N*-nitrosamino-acid-spiked cigarettes, Brunnemann et al. (466) reported that added NMPA did not completely decarboxylate. Some was esterified to the methyl ester. Some of the intact acid, its methyl ester, and its decarboxylation product, NEMA, appeared in the MSS. Similarly with NMBA, some NMBA transferred intact from the tobacco to the MSS, some formed the methyl ester which appeared in the MSS, and some decarboxylated to yield *N*-nitrosomethylpropylamine which also appeared in the MSS. NPRO primarily decarboxylated to NPYR. NSAR primarily decarboxylated to NDMA.

Djordjevic et al. (1012) identified *iso*-NNAC in tobacco and in MSS. This acid was found only in the MSS from cigarettes containing tobacco spiked (2 mg/cig) with cotinine. From the results of *in vitro* nitrosation studies with radiolabeled cotinine and nicotine, Djordjevic et al. (995) proposed that the formation of *iso*-NNAC in tobacco proceeds *via* cotinine and its hydrolysis product 4-methyl-4-(3-pyridinyl)-1-butanoic acid rather than via nicotine.

Brunnemann et al. (464) presented a more detailed exposition of their 1989 findings on the fate in "spiked" cigarettes of several *N*-nitrosamino acids [NSAR, NMPA, NMBA, NPRO]. These acids are delivered intact to MSS, undergo esterification to the methyl ester and are delivered as such to MSS, and/or decarboxylate and are delivered to MSS as the NNAs NDMA, NEMA, NMPA, and NPYR, respectively.

Djordjevic et al. (1013) described in greater detail their identification of *iso*-NNAC in tobacco and in MSS. They reported that *iso*-NNAC was found only in the smoke from cigarettes containing cotinine-spiked tobacco (2 mg/cig) (*cf.* Djordjevic et al., 1989b). Djordjevic et al. (1005, 1008) identified three new *N*-nitrosamino acids

in snuff tobacco: 2-(methylnitrosamino)-3-phenylpropanoic acid, 2,5-di(methylnitrosamino)pentanoic acid, and 2,6-di(methylnitrosamino)hexanoic acid. They discussed not only the identification of the three new *N*-nitrosamino acids but also the carcinogenic potential of these and other *N*-nitrosamino acids, particularly in the context of tobacco chewing or snuff dipping.

Djordjevic et al. (993) reported that the levels of *N*-nitrosamino acids in snuff tobaccos were often 150 times those found in cigarette tobaccos (usually about 1 ppm).

Examination of the results of the studies on *N*-nitrosamino acids in tobacco smoke reveals the importance of amino acids (and their precursors, the tobacco proteins) in *N*-nitrosamino acid formation before and during the smoking process. Figure 15.4 illustrates some of the relationships among the amino acids, *N*-nitrosamino acids, their methyl esters, and NNAs.

15.5 TOBACCO-SPECIFIC NNAs: AN EXCEPTION AMONG THE MAJOR MSS TOXICANTS

Since the mid-1950s, various MSS toxicants, either as an individual component or a class of components, have had their moment of publicity, but one by one, their importance

gradually faded. Chronologically, the first toxicants to become infamous were the tumorigenic PAHs with B[*a*]P at the pinnacle because of its potent tumorigenicity to mouse skin and its per cigarette MSS yield. The chronology of the rise to notoriety of the various individual and/or class of toxicants has been previously depicted [see Figure 1 in Rodgman et al. (3307)] but not shown is when the prominence of most of them declined.

In the mouse-skin-painting bioassay, neither B[*a*]P nor the total tumorigenic PAHs accounted for the observed specific tumorigenicity (4354). The B[*a*]P content of CSC accounted for less than 2.5%, and the total tumorigenic PAH content of CSC accounted for less than 3.5% of the CSC specific tumorigenicity [1056, 4312, see p. 626 in (4332)]. Inclusion of tumorigenic aza-arenes reported by Van Duuren et al. (4027) did not improve the situation. Hoffmann and Wynder (1798) reported that doubling or tripling the level of 17 tumorigenic PAHs in CSC significantly increased the % TBAs, whereas others reported that a 10-fold (3311) or 30-fold (2320) increase in the B[*a*]P level in CSC produced no change in the % TBA. In the early 1960s, the promoting effect of MSS phenols on tumorigenic PAHs was advanced to explain the tumorigenic response observed in CSC-painted mice. Inclusion of this effect in the assessment accounted for about 5% of the % TBA. In addition, reports of no change in the tumorigenicity of CSC when significant amounts (75%–90%) of the phenols were removed from MSS (and the CSC) by selective filtration [see p. 626 in (55), 4344] and the inhibition of the specific tumorigenicity of B[*a*]P by phenol (149) diminished the alleged importance of the promoting effect of phenols.

To offset the decrease in importance of the PAHs, aza-arenes, and phenols, ciliastatic components in MSS then became the in-vogue toxicants. It was asserted, based on studies with clam cilia and mammalian ciliated tissue, that certain MSS toxicants impair lung ciliary activity thus preventing removal of tumorigen-containing smoke particles from the lung. MSS components proposed as significant ciliastats included formaldehyde, acetaldehyde, acrolein, HCN, formic and acetic acids, and phenol. However, after the reported findings of Dalhamn et al. in 1968, the ciliary assertion faded because of the demonstration that less than a third of the ciliastats reach the lung cilia in human smokers (892, 893).

In the mid-1960s, several other MSS toxicants had their brief moment of infamy, e.g., ^{210}Po, NO_2, CO, Ni. In their comparison of lung cancer incidence in uranium miners exposed to ^{210}Po *vs*. cigarette smokers exposed to MSS ^{210}Po, Harley et al. (75) questioned the significance of ^{210}Po in tobacco-induced lung cancer. Concern over NO_2 diminished with the demonstration that over 95% of the NO_x in MSS was NO, not NO_2, and the conversion of NO to NO_2 was impeded by other MSS components (94).

In the early 1960s, the formation of NNAs during tobacco smoking was suggested (423) as well as the possible presence of NNN and NAB in MSS (423, 3313). Between 1964 and the early 1970s, several volatile NNAs were identified in MSS. It was also reported that 60%–85% of the volatile NNAs, like the phenols, are selectively filtered from MSS (514, 1236, 1761, 2635). The identification of several TSNAs, including NNN and NAB, then followed.

Why have TSNAs maintained their status as important MSS toxicants while the importance of other individual and/or classes of toxicants has faded?

Alternate exposures are possible with other toxicant classes including NNAs other than the TSNAs, but the TSNAs, as defined, are "tobacco-specific." In other words, no alternate exposure exists for TSNAs. In the detailed 1984 outline of chemical carcinogenesis edited by Searle (3568), the only class of MSS tumorigens discussed in 22 chapters comprising nearly 1400 pages was the NNAs [see pp. 839–844 in Preusmann and Eisenbrand (2990)]. Most of the data cited [see Tables VII through IX, pp. 841, 843, 844 in (2990)] are those from publications by Hoffmann et al. (514, 1677, 1680, 1685).

Since the early 1960s, a "less hazardous" cigarette has been defined on the basis of three criteria: (1) the per cigarette delivery of a specific toxicant has been lowered, (2) the ratio of the specific toxicant to MSS "tar" has been lowered, and (3) the specific tumorigenicity of the MSS "tar" as measured in the mouse-skin-painting bioassay has been lowered.

From bioassay results of more than 330 NNAs plus knowledge of fewer than 60 specific NNAs in MSS, it is obvious that the MSS NNAs cannot meet criterion 3. Over 330 *N*-nitroso compounds variously administered to 40 different species have been reported as tumorigenic. No laboratory species is resistant to NNAs. In their summary of the results from 323 *N*-nitroso compounds bioassayed from 1956 to 1984, Preussmann and Stewart (2991) reported that 87% of the *N*-nitroso compounds are tumorigenic. Over 70% of the *N*-nitroso compounds studied were NNAs; the remainder was *N*-nitrosamides.

Administration of most NNAs to laboratory animals via skin painting seldom results in carcinoma induction at the application site. Generally, tumors develop at site(s) remote from the painting site, and various organs may be involved. This major difference between PAH and NNA tumorigenicity led to defining NNAs as organ-specific tumorigens. Failure to produce tumors with NNAs at the painting site subsequently led to studies of NNAs administered by alternate routes (injection [subcutaneous, intravenous, intraperitoneal], per os, intratracheal instillation, etc.). Administration of NNAs by inhalation was studied infrequently.

Skin-painting studies with six NNAs (*N*-nitrosobutylmethylamine, NDEA, NDELA, *iso*-NNAL, NNK, NNN) present in tobacco and/or tobacco smoke were reported by Brune and Henning (15A02), F. Hoffmann and Graffi (15A30), Herrold (15A24), Herrold and Dunham (15A25), IARC (1870), Hoffmann et al. (1786a), and LaVoie et al. (15A34). Tumors developed elsewhere in the test animals but none at the painting site. In a painting study by Deutsch-WenzeL et al. (956a), NNN induced a few skin tumors, but

no dose–response relationship was observed over a 12.5–200 µg range. In the same study, the tumorigenic potency to skin of *N*-nitroso-*N*-methylurea was estimated to be about 4% of that of B[*a*]P. In painting studies with *N*-nitroso-*N*-alkylureas, tumors did develop at the skin-painting site, but to date, no *N*-nitroso-*N*-alkylurea has been identified in tobacco or MSS.

15.6 DIRECT TRANSFER OF TSNAs FROM TOBACCO *VS.* THEIR FORMATION DURING THE SMOKING PROCESS

Nicotine, nornicotine, anabasine, and anatabine are precursors of TSNAs in tobacco and tobacco smoke (29, 1564). Both nicotine and nornicotine are considered to be NNN precursors. Since NNAs (both volatile and tobacco-specific) occur in tobacco, part of the NNAs in cigarette MSS was reported to be due to direct transfer of NNAs from tobacco to MSS, the remainder due to formation and transport during the smoking process (201). For NNK, the transfer from tobacco to MSS ranges from 6.9% to 11.0% of the amount in the tobacco; this represents about 30% of the NNK in MSS. Similarly, about 40% of the NNN in MSS is transferred from the tobacco. Hoffmann et al. maintain that the remainder of NNN and NNK in MSS is formed during the smoking process (1558, 1734). Both the levels of volatile NNAs and TSNAs in MSS are proportional to the nitrate content of the tobacco filler (3985). However, the premise of the pyrogenesis of NNN and NNK has been challenged by Fischer et al. (1193, 1199) who reported that these compounds occur in cigarette MSS only by transfer from the tobacco rod. Castonguay (15A07) stated that NNK is transferred from tobacco to smoke during the smoking process. In agreement with Fischer et al., Renaud et al. (15A46) concluded that direct tobacco-to-smoke transfer was the dominant factor explaining the presence of TSNAs in MSS. From their study of the contribution of ^{13}C-nicotine to ^{13}C-NNN and ^{13}C-NNK levels in MSS CSC, Moldoveanu et al. concluded that NNN and NNK are generated during the smoking process (2599), thus contradicting the views of Fischer et al. (1193, 1199), Castonguay (15A07), and Renaud et al. (15A46). Moreover, the pyrogenesis situation was further clouded by data on the effect of tobacco nitrate on the MSS TSNA yields (1552). Analysis of MSS TSNAs indicated that NNN and NAT yields increased when nitrate was added to the tobacco but the NNK yield did not.

15.7 INFREQUENTLY STUDIED TOBACCO AND/OR TOBACCO SMOKE SECONDARY AMINES AND THEIR *N*-NITROAMINES

During extensive investigations of the composition of tobacco smoke in general and cigarette MSS in particular, much effort was expended in the early 1960s to define the nature of *N*-nitrosation during curing and the smoking process. As more and more NNAs were identified in tobacco and/or tobacco smoke, they were categorized as follows: volatile NNAs, nonvolatile NNAs, TSNAs, and *N*-nitrosamino acids. Within these four categories, only about 60 NNAs have been identified to date as tobacco and/or tobacco smoke components. Except for an excursion into the identification of *N*-nitrosamino acids, identification of NNAs in MSS almost ceased when NNK and to some extent NNN became the toxicants of choice. This situation raises the question: If a detailed study similar to those conducted on the PAHs and aza-arenes were conducted, how many additional NNAs could be identified in tobacco and/or tobacco smoke?

Table 15.5 lists several NNAs reported as tobacco components that are seldom discussed. To date, none of them have been identified in tobacco smoke.

While Table 15.6 is not necessarily complete, it suffices for the following discussion: In Table 15.6 are listed 22

TABLE 15.5
NNAs in Tobacco and/or Tobacco Smoke

		Identified in Smoke (S) and/or Tobacco (T)		
NNAs	CAS No.	S	T	Activity

[a] Compound listed as a toxicant in one or more lists published since 1986 (1217, 1727, 1740, 1741, 1743, 1744, 1773, 1808, 1870, 2825).

[b] Bioassay results in laboratory animals are summarized in Preussmann and Stewart (2991); yes, tumor induction; no, negative response. Number in [] is catalog number in Preussmann and Stewart (2991).

dialkylamines, identified in tobacco and/or smoke as the amine or the NNA. For four NNAs (*N*-nitrosoisobutylmethylamine, *N*-nitrosoethylpropylamine, *N*-nitrosoethylisobutylamine, and *N*-nitroso-*n*-butylethylamine), the corresponding amines have not been identified in tobacco smoke. It is highly probable that the four amines are present as MSS components. Alternatively, NNAs corresponding to the other 10 dialkylamines identified in tobacco and/or tobacco smoke have not yet been identified in smoke; e.g., no NNA corresponding to *sec*-butylmethylamine, isopentylmethylamine, or isopropylidenemethylamine identified as MSS components has been identified in MSS. Synthetically, the corresponding NNAs are as easily prepared as *N*-nitrosodimethylamine or *N*-nitrosodiethylamine, so their pyrogenesis during the smoking process should not be hindered. Thus, it is highly probable that the 10 NNAs are present in tobacco smoke.

Many other secondary amines have been identified in tobacco smoke, but for most of them, no corresponding NNA has been identified in smoke. These include a series of *N*-substituted anilines, all amenable to *N*-nitrosation {XXXV}. Others include the alkyl derivatives of pyrrolidine {XXXVI}, piperazine {XXXVII}, and piperidine {XXXVIII}. The amines pyrrolidine {XXXVI}, piperazine {XXXVII}, and 1,2,3,6-tetrahydropyridine {XXXIX} have been identified in cigarette MSS but not piperazine {XXXVII} (see structures in Table 15.7). For each piperazine, mono- and di-*N*-nitroso derivatives are possible. Morpholine {XL} and an alkyl derivative have also been identified in tobacco. For completeness, azetidine {XLI} is included in Table 15.7. In many instances, the NNAs listed in Table 15.7 are readily synthesized and have been tested for tumorigenicity in laboratory animals [see Preussmann and Stewart (2991)].

Table 15.7 lists 46 secondary amines, most of which have been identified as components of tobacco and/or its smoke. In only a few cases have the corresponding NNAs been identified as tobacco and/or smoke components.

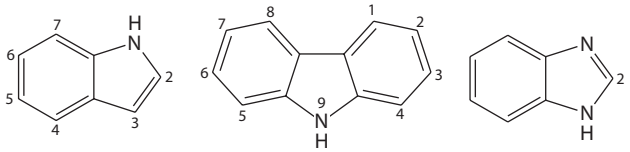
[a] Bioassay results in laboratory animals are summarized in Preussmann and Stewart (2991); yes, tumor induction; no, negative response. Number in [] is catalog number in Preussmann and Stewart (2991).

[b] *N,N′*-Dinitroso derivative, i.e., R = R_1 = NO.

[c] The *cis*- and *trans*-isomers were tested individually as well as mixture of them.



XLII XLIII XLIV

FIGURE 15.5 Indole {XLII}, carbazole {XLIII}, and 1*H*-benzimidazole {XLIV}.

It is highly probable that the NNAs corresponding to the remaining secondary amines may also be tobacco smoke components.

Among the numerous classes of smoke components are several other types of secondary amines, e.g., the pyrroles, indoles, carbazoles, and imidazoles. However, their highly aromatic nature and the acidity of the imino hydrogen probably preclude any significant *N*-nitrosation either in the tobacco or during the smoking process. Despite the fact that a dozen or so theoretically *N*-nitrosatable substituted pyrroles; nearly 50 alkyl derivatives of indole {XLII}; carbazole {XLIII} and several of its alkyl derivatives, benzocarbazoles, and dibenzocarbazoles; and several alkyl derivatives of imidazole and benzimidazole {XLIV} have been identified in

tobacco smoke, no NNA corresponding to any of them has been identified to date in tobacco smoke (Figure 15.5).

It is obvious that the number of NNAs in tobacco and/or tobacco smoke might be substantially greater than the 60 or so NNAs now known to be present. Since the per cigarette yields of the yet unidentified NNAs may be at the picogram or femtogram levels, their contribution to MSS toxicological properties may not be particularly meaningful or important. However, they may be just as important from a biological point of view as those MSS components repeatedly listed as toxicants for which no or questionable quantitative data are available, e.g., the much discussed dibenzo[*def*,*p*]chrysene (dibenzo[*a,l*]pyrene) (1557, 1727, 1740, 1741, 1743).

To put the NNAs in perspective and to determine how many more are actually present in MSS, what may be needed is an extensive study corresponding to the excellent studies on PAHs (3756–3758) and aza-arenes (3750) conducted and reported by U.S. Department of Agriculture (USDA) personnel in the late 1970s and early 1980s.

It is also interesting to note that 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL), the major metabolite of NNK (1557), is usually not listed as a cigarette MSS toxicant even though NNAL has been reported to be both tumorigenic to several rodent species (15A08) and mutagenic in the Ames *S. typhimurium* test.

15.8 FLUE CURING AND TSNAs

As described by Williams (4247), there is general agreement among tobacco scientists that TSNAs are not present in either freshly harvested, i.e., green flue-cured and burley tobaccos. As the tobaccos are cured either by air curing in the case of burley or in heated barns for flue-cured varieties, the amounts of TSNAs rise to their final levels. In the case of air curing, the process has changed little over the past 50 years. However, for flue curing, the process changed drastically in the United States during the 1960s and 1970s due to the introduction of energy-efficient bulk-curing barns heated by exhaust gases of liquid propane gas or similar burners. It is at this point that a breakdown must have occurred between tobacco agriculturists and chemists. The emission of NO_2 during the combustion of liquid propane or natural gas is well known. In fact, the North Carolina Department of Environment and Natural Resources (NCDENR) has electronic spreadsheets available for download from its website that North Carolina industries may use in estimating their NO_2 emissions during natural gas or liquid propane combustion. In retrospect, any competent chemist would predict the potential nitrosation of tobacco alkaloids during flue curing in the presence of combustion exhaust gases. However, without the knowledge of TSNA formation during direct heating of green tobaccos, the agricultural community adopted the new energy-efficient technique. It appears that prior to this "technological advance," the formation of TSNAs during flue curing by traditional methods was not a problem.

Earlier, at least two research groups discovered the problem with direct heating flue curing of tobacco. Peele et al. (2917) demonstrated that modification of the curing process for flue-cured tobacco permitted significant control of its TSNA levels. The curing process was altered from one involving direct fired burners to one involving a heat exchange system. During approximately the same period, Williams (258) applied for and was granted a U.S. patent on essentially the same modification of the flue-curing barns to achieve the same significant reduction in TSNAs. An example of the TSNA reductions in flue-cured tobacco and its smoke was shown by Rodgman and Green [see Figure 3, p. 522 in (3300)]. The tobacco data were from Williams (4247), and the smoke data were from Doolittle et al. (1051).

During the past few years, advances have been made to reduce NNAs, specifically TSNAs in tobacco and tobacco smoke. The agronomic community with the help of the tobacco industry has made significant headway in discontinuing direct heating for flue curing as a means to reduce TSNAs in tobacco and tobacco smoke. This advancement is desirable from a product stewardship perspective and has little if any effect on tobacco quality. Biological response data on individual TSNAs indicate that TSNAs play a minor role in MSS carcinogenesis [see Tables 1 and 5 in Rodgman and Green (3300)]. Comparisons of the biological effects (neutral red cytotoxicity, mutagenicity in the Ames test with several *S. typhimurium* strains) of mainstream CSCs from flue-cured tobacco cigarettes with normal and reduced levels of TSNAs indicated no significant difference between the biological activity of the two CSCs [Doolittle et al. (1051)]. Although the Doolittle et al. data appear to support the hypothesis on a whole-smoke basis that mainstream TSNAs are of relatively minor toxicological importance, the sensitivity of the Ames assay is not sufficient to differentiate between the cigarettes tested. For example, consider the following points published by Doolittle et al. (1051):

- The minimum amount of NNK needed for a mutagenic response in the Ames assay is 200 µg.
- The maximum amount of CSC that can be tested is 250 µg.
- In 250 µg of CSC, there is 1.33 and 0.13 ng of NNK from direct fired and heat exchanged flue-cured tobacco, respectively.
- The amount of NNK in the CSC from either flue-cured tobacco smoke is too low for a response.

Every practical effort should be made to reduce the amounts of alleged human carcinogens from tobacco products. However, whether the reduction or elimination of TSNAs from MSS will result in a "less hazardous" cigarette is unknown.

Table 15.8 lists the 66 NNAs identified to date in tobacco and/or tobacco smoke. Of the 66, 53 NNAs have been identified in tobacco smoke, 53 in tobacco, and 41 in both tobacco and tobacco smoke.

Note: The symbol (0) indicates the component identified in tobacco substitute smoke was not detected in tobacco smoke or vice versa.

16 Nitroalkanes, Nitroarenes, and Nitrophenols

In his 1954 catalog of tobacco smoke components, Kosak (2170) listed no organic nitro-containing component. In 1959, Johnstone and Plimmer (1971) in their compilation of tobacco and tobacco smoke components also listed no organic nitro-containing component.

In their 1964 review (4319) and 1967 book (4332) on tobacco smoke carcinogenicity, Wynder and Hoffmann did not mention a nitroalkane or a nitroarene. In his 1968 review, Stedman (3797) listed no organic nitro-containing component identified in tobacco and tobacco smoke composition. His list of the agricultural chemicals used in tobacco agronomy [see Table XVI in (3797)] also contained no nitro-containing compound.

In their review of the *N*-containing components in tobacco and smoke, Schmeltz and Hoffmann listed 30 nitro components [see Table X in (3491)] separated into 6 nitroalkanes identified by Hoffmann and Rathkamp (1755) and Rathkamp et al. (3086) in the late 1960s, 8 monocyclic nitroarenes identified by Hoffmann and Rathkamp in 1970 (1758), and 16 nitrophenols, including a methylnitro-1-naphthol, reported by Klus and Kuhn in 1975 (2137).

In their 1980 catalog (1884), Ishiguro and Sugawara also listed 30 nitro components in tobacco smoke. All the nitro components they listed were those tabulated in the 1977 article by Schmeltz and Hoffmann (3491).

With the limiting analytical technology available in 1982, Lee et al. (2329) at the American Health Foundation reported that they were unable to measure significant quantities of 4-nitro-1,2-benzenediol (4-nitrocatechol) in cigarette MSS. El-Bayoumy et al. in a conference presentation (1122) and a journal publication (1124) reported that 1-nitronaphthalene, 1-nitropyrene, and 6-nitrochrysene, if present in cigarette smoke, were at yields lower than their analytical capability.

In its 1986 monograph on tobacco smoking, the International Agency for Research on Cancer (IARC) discussed many of the details of *N*-nitrosamines and tobacco-specific *N*-nitrosamines in tobacco smoke. Despite the reports prior to 1985 on the identification in tobacco smoke of many nitro components (1755, 1758, 2137, 3086), the IARC listed only one nitro compound, 2-nitropropane, as a biologically active smoke component [see Table 19, pp. 86–87 in (1870)]. In its listing of the evaluation of tobacco smoke components for carcinogenicity, IARC defined the evidence in 1986 of the carcinogenicity in animals and humans of 2-nitropropane as sufficient [see Appendix 2, p. 393 in (1870)]. Hoffmann and Wynder (1808) included 2-nitropropane in their list of major toxic and tumorigenic agents in nonfiltered cigarette MSS. Although not dealing with cigarette smoke in this particular 1987 study, Grimmer et al. (1406a) identified 1-nitropyrene in diesel exhaust.

Of the many nitro components in tobacco smoke, only nitrobenzene, nitromethane, and 2-nitropropane have been discussed repetitively since 1986. In reports primarily dealing with commercial cigarettes, these three nitro compounds were listed periodically in various publications as toxic smoke components, biologically active smoke components, tumorigenic smoke components, or carcinogenic smoke components: nitrobenzene (1741, 1743, 1744, 5512), nitromethane (1743, 1744, 5512), 2-nitropropane (1217, 1727, 1740, 1741, 1743, 1744, 1773, 1808, 2825, 5512). 2-Nitropropane was also described as a known carcinogen in the MSS from all-flue-cured or all-burley cigarettes (1716).

In 2003, Cheng et al. (692, 693) reported the identification in CSC of five nitro-polycyclic aromatic hydrocarbons. They included 1- and 4-nitropyrene, 1,6- and 1,8-dinitropyrene, and 6-nitrochrysene. In 2004, Cheely et al. (683) described an analytical procedure which enabled the identification of 1-nitronaphthalene, 1-nitropyrene, and 6-nitrochrysene in cigarette MSS.

Although 2-nitropropane was much discussed as a tumorigen or carcinogen in cigarette smoke and its categorization by IARC as having yielded sufficient evidence to rate it as both an animal and a human carcinogen, it seldom was designated as a "Hoffmann analyte." While it did not use the term "Hoffmann analyte" in its report, the Department of Health (Canada) proposed that analytical data on the per cigarette yields of over 40 components in tobacco smoke should be a requirement to indicate the hazardous nature of cigarette smoke (16A01). No nitroalkane was included in its list. Neither nitrobenzene nor nitromethane appeared in any "Hoffmann analyte" list.

Table 16.1 lists the nitroalkanes, nitroarenes, and nitrophenols identified in tobacco, tobacco smoke, and tobacco substitute smoke. The list also contains over a dozen complex nitro components such as Butralin® and Imidacloprid® that are used in tobacco agronomy.

17 Nitrogen Heterocyclic Components

17.1 MONOCYCLIC FOUR- AND FIVE-MEMBERED *N*-CONTAINING RING COMPOUNDS

17.1.1 Background

Tobacco (*Nicotiana tabacum*) is a unique agricultural crop used to prepare a variety of commercial products (cigarettes, pipe tobacco, cigars, chewing tobacco, snuff, etc.). Consumers enjoy tobacco by placing it into their mouth or nasal cavity (in the case of oral and snuff products) or by lighting the tobacco article (cigarette, cigarillo, cigar, etc.) and inhaling the tobacco smoke produced. As a result, the chemical composition of both leaf and the tobacco smoke is important to consumers (for its flavor and appeal) and to scientists attempting to understand the chemical organoleptic, pharmacological, and toxicological properties of this extremely complex consumer product.

Tobacco is a natural product that contains numerous classes of chemical compounds. As a living entity, tobacco contains all of the complex biological machinery necessary to sustain life. Chemical constituents in the tobacco leaf are influenced by numerous factors as the tobacco plant develops from seed to cured leaf. These factors include genetic potential, environmental conditions, cultural practices, and curing methods. Interactions among the factors also influence the chemical composition of the cured leaf. The genetic makeup of the plant provides the potential to produce or not to produce certain compounds, and the realization of these potentials depends on environmental variations that the plant endures during growth and processing conditions employed to manufacture the finished tobacco product (677a).

Although the chemical composition of the tobacco leaf is important, tobacco smoke also contains an extensive variety of chemical compounds. The presence and relative concentrations of these tobacco smoke components depend upon (1) the composition of the tobacco leaf, (2) tobacco additives, (3) manufacturing processes, (4) the physical form and materials used to construct the different smoking articles, and (5) the smoking procedure.

An elemental analysis for carbon, hydrogen, and nitrogen in foods (2439) and tobacco indicates that there is only about 5% nitrogen in dry tobacco. The percent carbon, hydrogen, and oxygen (by difference) of dry tobacco leaf are about 43%, 6%, and 43%, respectively (2798), with the remainder being trace levels of metals and nonmetals. The majority of the nitrogen in tobacco leaf resides in the proteins, alkaloids, nitrates, and amino acids. The *N*-containing compounds in tobacco leaf have often been associated with the quality of the leaf. This is especially true with burley tobacco (3973). Nitrogenous compounds in tobacco and smoke have an enormous range of taste and odor quality and intensity. Many are odorless and tasteless (proteins, nitrates), some have extremely pleasant tastes and odors, e.g., some pyrazines (2439) and imidazoles, while others are very strong, pungent, and offensive, e.g., some pyridines (1803).

In this section, we present information on four- and five-membered *N*-containing ring compounds identified in tobacco, tobacco smoke, and tobacco substitute smoke. The classes of compounds include azetidines, pyrrolidines, 2- and 3-pyrrolines, pyrroles, pyrazoles, imidazolidines, imidazolines, imidazoles, and 1,2,4-triazoles (Figure 17.1).

17.1.2 Four-Membered *N*-Containing Rings

Few four-membered *N*-containing ring compounds have been identified in tobacco or tobacco smoke. These compounds are classified as azetidines. Nicotianamine, first isolated from tobacco by Noma et al. in 1971 (2796a), has also been identified in numerous other plant species (3528a). Nicotianamine is a derivative of 2-azetidinecarboxylic acid, an amino acid identified in numerous plant species, including *N. tabacum* (2330b). The precursor for the biosynthesis of azetidine in tobacco and azetidine-2-carboxylic acid, in particular, is considered to be methionine (2330b). The bacterial plant pathogen tabtoxin (*L*-threonine, *N*-[2-amino-4-(3-hydroxy-2-oxo-3-azetidinyl)-1-oxobutyl]-) was isolated from wildfire tobacco (a wild species of *N. tabacum*) in 1971 (3819a).

The scant information on azetidine compounds can be found in several review articles on the chemistry of compounds identified in tobacco and tobacco smoke. In their 1977 review, Schmeltz and Hoffmann (3491) reported the presence of 2-azetidinecarboxylic acid and nicotianamine in tobacco. Hecht et al. (1580) reported the identification of azetidine in both tobacco and smoke in 1977. Brunnemann and Hoffmann (486) reported the presence of the nitrosamine and 1-nitroso-2-azetidinecarboxylic acid in tobacco in 1991.

Table 17.1 lists the four-membered *N*-containing ring compounds identified in tobacco, tobacco smoke, and tobacco substitute smoke. Only five compounds are known to exist in tobacco and tobacco smoke that contain an

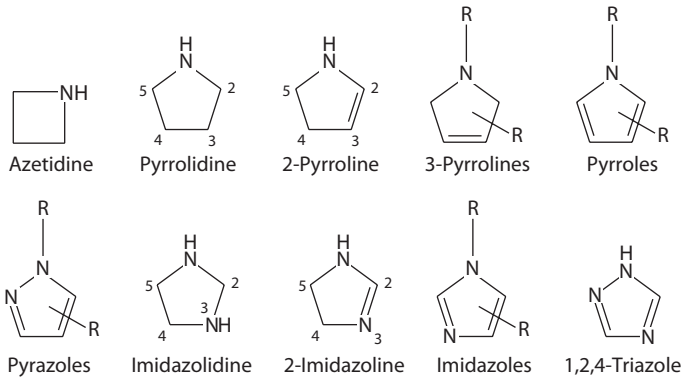

FIGURE 17.1 Representative structures of the four- and five-membered *N*-containing ring compounds in tobacco, tobacco smoke, and tobacco substitute smoke.

azetidine ring. All five have been identified in tobacco. Azetidine has been identified in tobacco and tobacco smoke.

17.1.3 Five-Membered *N*-Containing Rings

Tobacco and smoke chemists have shown an intense interest in the chemistry and biochemistry of this diverse class of compounds. Numerous studies on the presence of nitrogenous compounds in tobacco and tobacco smoke have appeared over the past 45 years, and various aspects of the origin of these compounds in tobacco and their presence in tobacco smoke by direct transfer, pyrosynthesis, and combustion processes have been examined. Books, reviews, and articles by Wynder and Hoffmann (4332), Stedman (3797), Neurath (2724), Tso (3972, 3973), Chaplin (677a), Leffingwell (2337), Schmeltz and Hoffmann (3491), Hecht et al. (1580), Leete (2330c), Bush and Saunders (557a), Green (1351), Newell et al. (2769), Ishiguru and Sugawara (1884), Heckman and Best (1587), Gorrod and Wahren (1334d), Davis and Nielsen (910a), and Gorrod and Jacob (1334c) contain synopses of much of the information we know today on *N*-containing ring compounds in tobacco and tobacco smoke.

During the 1970s and 1980s, an exceptional amount of research on tobacco and smoke component isolation and identification was conducted and published. This was largely due to many scientific advancements that occurred in chromatographic methods during this period. The results of several excellent studies on tobacco leaf composition by Lloyd et al. (2389), Dickerson et al. (965), Roberts and Rohde (3219), Takahara et al. (3858), Demole et al. (937–939, 941, 943, 943a), Fujimori et al. (1247, 1249, 1250), Chuman et al.

(731–739), Schumacher (3550), and Schumacher and Vestal (3561) are included here for reference. Swedish Tobacco Company published nearly 100 articles on the composition of tobacco, primarily Oriental tobacco. Many Swedish Tobacco Company investigators included Aasen, Almqvist, Behr, Enzell, Hlubucek, Kimland, Nishida, and Wahlberg, all of whom coauthored many tobacco composition articles (1–13, 52, 53, 84, 91–94, 227, 229–236, 1149–1157a, 1205a, 1660–1662, 2092–2095, 3315, 4083–4102). Excellent detailed summaries of their identification of hundreds of tobacco components and the generation of them from various terpenoid structures were presented and published in the late 1970s and the early 1980s by Enzell (1149, 1150), Enzell and Wahlberg (1156), and Wahlberg and Enzell (4089, 4090).

The basic five-membered *N*-containing ring compounds found in tobacco, whether they contain one or more nitrogens, arise from several metabolic and catabolic pathways. Additionally, many *N*-containing ring compounds are formed via nonenzymatic browning reactions.

Amino acids and proteins are produced in living species and are essential compounds of tobacco plants. One of the most important metabolic pathways in plants is the Krebs tricarboxylic acid cycle (2337, 3973). The Krebs cycle controls the metabolic carbon–nitrogen balance in living plants by converting carbon dioxide via photosynthesis to such intermediates as oxaloacetic, α-ketoglutaric, and pyruvic acids. Concurrently, inorganic nitrogen as nitrates is assimilated through the plant roots and is subsequently reduced to ammonia by hydrogen originating from reactions occurring in the Krebs cycle. Ammonia then reacts with oxaloacetic, α-ketoglutaric, and pyruvic acids to form aspartic and glutamic acids and alanine which provide the nitrogen for further synthesis of other amino acids (1351). These amino acids are then used as the nitrogen pool from which many of the other nitrogenous compounds of the tobacco plant are formed. For example, the pyrrolidine ring can be formed from arginine or ornithine via a series of metabolic reactions involving arginine decarboxylase or ornithine decarboxylase to form putrescine (1,4-diaminobutane) which is then converted to 4-methylaminobutanal via putrescine *N*-methyltransferase, *S*-adenosine-methionine, and methylputrescine oxidase. Via cyclization and demethylation, pyrrolidine is produced (3973). Numerous other metabolic reactions occur that produce five-membered *N*-containing ring compounds such as the pyrrolines, pyrroles, pyrazolines, pyrazole, imidazolidines, imidazolines, and imidazoles.

From the time of harvest through curing and aging, many changes take place in the concentrations of tobacco leaf amino acids and proteins (3972). According to Gaines and Miles (1270a), one of the extremely important aims of this process is to accomplish a degradation of tobacco proteins. This degradation produces numerous types of short-chained amino acid oligomers, free amino acids, and many functionalized *N*-containing compounds such as alcohols, aldehydes, acids, aldehydes, and esters. Among these catabolic breakdown products are the simple four-membered, five-membered, and six-membered *N*-containing ring compounds and a variety of alkaloids and alkaloid-type compounds that are oxidized, reduced, or otherwise functionalized.

The origins of the five-membered *N*-containing ring compounds in leaf are also attributed at least partially to nonenzymatic browning or Maillard reactions between sugars and amino acids (965). Many compounds formed by nonenzymatic browning reactions have desirable flavor and aroma characteristics that taken together form the characteristic bouquet and taste associated with tobacco (2337).

A wide variety of five-membered *N*-containing ring compounds have been isolated and identified in tobacco smoke. Two general mechanisms are involved: direct transfer of tobacco components to tobacco smoke and the generation of smoke components by combustion and pyrolysis of tobacco. In 1977, it was estimated that the direct transfer of components from leaf to smoke accounted for about one-third of the smoke constituents identified in tobacco smoke at that time (1351). This process is relatively simple, and many of its factors are understood. This process has been discussed in some length by Wakeham (4103). The second mechanism involves the pyrolysis, combustion, and subsequent pyrogenesis of smoke components. This process is complex and involves the tobacco, the means and materials used in constructing the smoking article, and the actual smoking process (puff volume, duration, puff interval, etc.). The relationships between various leaf constituents and their pyrolysis products are the ones most difficult to trace yet they are the most necessary to understand (1351).

In contrast to the number of leaf components that generally transfer directly to smoke (~33%), only about 16% of the 313 tobacco and tobacco smoke compounds that contain a five-membered *N*-containing ring were found in both tobacco and tobacco smoke. A considerable portion of the smoke yields from these compounds was no doubt due to transfer of the compounds directly from tobacco, although some of the yield of these compounds is produced by pyrolysis, combustion, and pyrogenesis of a variety of compounds in tobacco.

As mentioned previously, the largest contributors of organic leaf nitrogen are the leaf proteins, alkaloids, and amino acids. A majority of the protein in the tobacco consists of the enzymes associated with photosynthesis. The single most abundant protein in tobacco is called Fraction I and is designated functionally as ribulose-l,5-diphosphate carboxylase. Our knowledge of the genomic makeup of tobacco has advanced tremendously in the last 20 years. Once the Tobacco Genome Initiative is completed, over 90% of the genetic map of tobacco will be known (429b, 429c). Numerous databases of genes, enzymes, and reactions occurring in *Nicotiana* species are already available.

The identities of the free amino acids of cured leaf are well known (1351). Of the 44 amino acids reported in leaf,

a majority have also been found in tobacco smoke. Proline and asparagine are the major amino acids in flue-cured tobacco, whereas asparagine and aspartic acid are the major amino acids in burley tobacco. These plus glutamine and histidine are the principal amino acid precursors of the five-membered *N*-containing ring compounds in tobacco.

High-temperature pyrolysis studies of protein and amino acids have been described in a series of papers by Smith et al. (3724, 3727a, 3728a, 3729), Patterson et al. (2902–2905), Higman et al. (1647), Schmeltz (3477–3479), Sugimura et al. (3829), and Yamamoto et al. (4365a). Under these pyrolytic conditions, pyrodegradation and pyrosynthesis were extensive. In general, pyrolysis gave complex mixtures which were qualitatively similar regardless of the specific amino acid being pyrolyzed. Compounds identified included aromatic hydrocarbons such as benzene and naphthalene, their *N*-containing analogs such as pyridine and quinoline, pyrrole, aromatic nitriles such as benzonitrile and 1-naphthonitrile, aniline, and phenols. As suggested by Patterson et al. (2904), this similarity of results indicates that the amino acids and proteins undergo degradation into common intermediates of 2-, 3-, and 4-carbon types which subsequently recombine to form more thermally stable aromatic systems. To be discussed in a subsequent chapter is the pyrogenesis of the potent mutagens 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) and 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) from tryptophan (3829) and 2-aminodipyrido[1,2-*a*:3′,2′-d]imidazole (Glu-P-2) and 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1) from glutamic acid (3828a, 4365a), all four of which were subsequently identified in tobacco smoke (3828c). Table 17.2 catalogs many of the pyrolysis studies conducted on amino acids.

Pyrolysis and smoke studies of amino acids indicate that they are potential precursors of several nitrogen heterocyclic ring systems found in tobacco smoke. Proline has been shown to be efficiently converted to pyrrole upon pyrolysis (3219, 3724) and in addition has been proposed as a possible precursor of pyrocoll (2593, 4336). γ-Amino acids and dicarboxylic amino acids are capable, under pyrolytic conditions, of forming 2-pyrrolidones (1967, 3079), and by a similar mechanism, δ-amino acids can form 2-piperidones (1967, 3079). A side effect of the pyrolysis of amino acids is the formation of hydrogen cyanide.

Johnson, Kang, and Wakeham (1967) studied the hydrogen cyanide yields from pyrolysis of compounds containing ring nitrogen and found that these heterocycles, particularly those with five-membered rings, produced the highest yields of hydrogen cyanide. These results are in accord with those of Smith et al. (3724) in which proline was found to give high yields of hydrogen cyanide. The pathway seems to be through pyrrole which is formed in excellent yield (67%) on pyrolysis of proline. Patterson et al. (2908) had previously found that pyrrole on pyrolysis at 850°C is converted in 49% yield to hydrogen cyanide. This may not be the only pathway for the formation of hydrogen cyanide from proline because Johnson and Kang (1967) found that proline can generate hydrogen cyanide more readily than pyrrole.

Protein and free amino acids found in tobacco leaf contribute significantly through pyrodegradation and pyrosynthesis to the formation of many nitrogenous compounds found in tobacco smoke. The nonvolatility of these compounds either as free acids, proteins, or as members of

tobacco pigment, e.g., porphyrins, makes them particularly liable to pyrolytic destruction because they, unlike nicotine and the other plant alkaloids, are not readily volatilized and swept away as the more intense heat of the cigarette coal approaches (3724).

There are also interactions that occur among amino acids, proteins, and carbohydrates during plant growth and during smoke formation. These interactions form complex mixtures of leaf constituents and complex mixtures resulting from the pyrodegradation and pyrosynthesis of reaction products of amino acids, proteins, and carbohydrates.

In freshly harvested leaf, both reducing sugars and amino acids are present, and these are known to react to form nonvolatile sugar–amino acid compounds, known as Amadori compounds (1671b). A number of these Amadori compounds have been isolated from flue-cured tobacco leaf by Cousins (841a), Tomita et al. (3923), Yamamoto et al. (4362), and Wahl (4081a). Noguchi et al. (2794a) have shown how the free amino acid concentration of leaf decreases during aging and the Amadori compound levels initially increase and then slowly decrease. These changes, especially the decrease in Amadori compounds, indicated the possible progress of Maillard-type reactions during natural aging of leaf tobaccos.

Dickerson et al. (965) found evidence for progress of the Maillard reaction in their studies on aged flue-cured leaf where a number of formylpyrroles were isolated. Dickerson et al. (965) followed the formation of several formylpyrroles from a specific Amadori compound. The Amadori compound was converted via the Maillard reaction to a 3-deoxyosulose which further reacted with either an amino acid or an amine to form the isolated formylpyrroles. In addition to the formylpyrroles, a number of pyrazines and furans, characteristic of nonenzymatic browning reactions, were also isolated from flue-cured tobacco. Thus, there is evidence for the Maillard reaction occurring even before smoking.

Sometimes in sugar–amine browning systems where pyrazines are isolated, there is also found another class of nitrogen heterocyclic compounds, the imidazoles (1835b, 1947a). These compounds have been reported in tobacco smoke by Schumacher and coworkers (3553). In contrast to the pyrazines, only a few imidazoles have been isolated from nonenzymatic browning reactions of foods. This might be due to the unusually high boiling points and polarity of these compounds. Grimmett (1410b) has reviewed the formation of imidazoles from the interaction of carbohydrates and amine sources, and many of the same compounds found to be pyrazine precursors can also form imidazoles. Simple sugars, starches, and cellulose—all known tobacco leaf constituents—are reported to react with amines, including ammonia, to form imidazoles (1351).

Many of the reactions producing imidazoles in tobacco and tobacco smoke involve the interaction of carbohydrates with ammonia which has several precursors in tobacco. Amino acids and proteins can contribute to the formation of smoke amines and the formation of ammonia. Johnson et al. (1964) conclusively demonstrated through experiments with ^{15}N-glycine that it is an ammonia source. In addition to amino acids, nitrates have been shown to be efficiently converted during the smoking of a cigarette to ammonia (1964). This ammonia from nitrates was shown to participate in the formation of many nitrogenous compounds in smoke. Thus, leaf nitrates as well as amino acids and proteins are considered the major sources of ammonia in tobacco smoke.

As to the mode by which certain leaf constituents may form imidazoles, it is commonly recognized that α-dicarbonyl compounds may react with aldehydes in the presence of ammonia to form nitrogen heterocyclic compounds such as imidazoles. The required α-dicarbonyl compounds and aldehydes are well known pyrolysis products of carbohydrates either through thermal (1170a) or Maillard-type (1671a) degradations, and many of these compounds have been isolated from tobacco smoke (3797). It is possible that α-aminoketones, such as those proposed as intermediates in the formation of pyrazines, may also be involved with the formation of imidazoles because reactions producing imidazoles from these compounds have been reported (1410b). Although the formation of imidazoles through carbohydrate and amino acid or protein interaction is especially appealing due to the analogies which can be made with pyrazines, a second origin is also possible. Tobacco leaf contains an appreciable amount of the amino acid, histidine, either in its free form or as part of tobacco protein. Pyrodegradation of this compound in a manner similar to that of tryptophan (2047) could also be a source of some imidazoles in tobacco smoke.

The contribution of the five-membered *N*-containing ring compounds in tobacco and tobacco smoke to smoke flavor is not as well known. The flavor evaluations of some tobacco-derived imidazoles have been described by Schumacher et al. (3553a). The flavors of these compounds are an example of how relatively nonvolatile, flavorless compounds in tobacco leaf can be transformed during the smoking process into a part of the characteristic aroma of tobacco smoke. Leffingwell et al. (2341) and Roberts (3215) in his review of natural tobacco flavor reported that several acetylpyrroles provided a nutty, woody, and sweet taste to tobacco smoke but that formylpyrroles often added harshness to the tobacco smoke aroma. Imidazoles have been reported to provide a sweet chocolate or nutty character to tobacco smoke at low levels but can be bitter at high levels (3215).

The principal precursor for the biosynthesis of ring structures of pyrrolidine, pyrroline, and pyrrole is glutamine (2056b, 2659a, 2848a). Pyrrole structures can also be produced in plants from arginine or ornithine (2056b). The biosynthetic pathway for the production of the imidazole ring structure involves the biosynthesis of histidine through

a series of 10 enzymatic reactions (57a). The first intermediate of the pathway (phosphoribosyl pyrophosphate) is also the starting point for purine and pyrimidine biosynthesis. The amino acid glutamine provides much of the backbone for imidazole which is an intermediate in histidine biosynthesis (429d). From imidazole glycerol phosphate, five additional enzymatic steps are needed to the plant to produce histidine. The imidazoline and imidazolidine rings can be produced by enzymatic hydrogenation of the imidazole ring. The imidazolidine ring is also believed to be produced biosynthetically when glutamate condenses with carbamoyl phosphate to form hydantoin or imidazolidine-2,4-dione. The hydantoin can be enzymatically reduced to imidazolidines (225a). Additionally, hydantoin can be produced in plants by hydrogenation of allantoin (2,5-dioxo-4-imidazolidinyl urea), a cyclic amide naturally occurring in many plants (4068a). Pyrazolidine, pyrazoline, and pyrazoles are produced in plants from 1,3-diaminopropane via pyrazole synthase (C_3) (437a).

The five-membered *N*-containing ring compounds with three nitrogens are the 1,2,3-triazoles and the 1,2,4-triazoles. Triazoles are not produced in plants naturally but are found as structural components of many pesticides and herbicides. Seven herbicides containing a five-membered *N*-containing ring have been identified in tobacco as residues. The pesticides containing a 1,2,4-triazole ring include three fungicides (Triadimefon®, Penconazole®, and Triadimenol®), one herbicide (Sulfentrazone®), and one insecticide (Triazophos®). Two 1,2,3-triazoles (as benzotriazoles) have been identified in tobacco and tobacco smoke to date, Azinphos-Methyl-Oxon® and Azinphos-Methyl®. Both of these pesticides are insecticides. Azinphos-Methyl-Oxon has also been identified as a degradation product of Azinphos-Methyl. All of these triazoles were reported as tobacco pesticide residues (928a, 2913a, 3663, 2650a). The remaining fungicide in this series of five-membered *N*-containing ring compounds with three nitrogens is Iprodione®. Iprodione is an imidazolidinecarboxamide and has been reported as a fungicide residue on tobacco (3585, 3633, 3661a).

Table 17.3 lists the distribution of five-membered *N*-containing ring compounds identified in tobacco, tobacco smoke, and tobacco substitute smoke.

Table 17.4 contains 358 compounds. One hundred and sixteen are pyrroles, 79 are pyrrolidines, and 28 are pyrrolines. There are 16 pyrazoles in Table 17.4. Sixty-two imidazoles, 10 imidazolidines, and 3 imidazolines have been identified in tobacco and tobacco smoke. Five compounds with a 1,2,4-triazole ring have been identified in tobacco. Two compounds with a 1,2,3-triazole ring (as benzotriazoles) have been identified in tobacco and tobacco smoke. The compounds in Table 17.4 exhibit a great deal of functionality. Although each contains a five-membered *N*-containing ring, some are alcohols, ketones, sugar–amines, acids, esters, and imides. Of the 358 compounds listed in Table 17.4, 289 were identified in tobacco smoke, 151 identified in tobacco, and 82 identified in both tobacco and tobacco smoke.

17.1.4 Compounds in Tobacco, Tobacco Smoke, and Tobacco Substitute Smoke with Multiple Five-Membered *N*-Containing Rings

Porphyrins are a class of biologically important heterocyclic compounds with a characteristic chemical structure that includes four pyrrole groups (five-membered organic rings each containing a nitrogen atom) linked on opposite sides (α position) through four methine bridges (=CH–) to form a large flat ring structure (see Figure 17.2). A porphyrin in which no metal is inserted in its cavity is called a free base.

Many organic analogs that contain a porphyrin ring are biological pigments and are closely related molecules responsible for many of the vivid colors in living organisms. They often occur combined with metal ions and various substituents as coordination complexes. Chlorophylls are magnesium complexes of porphyrin derivatives (also called phorbines). In plants, these pigments are responsible for photosynthesis and play important roles as respiratory pigments, electron transport carriers, and oxidative enzymes. Several chlorophylls have been identified in tobacco, the most common being chlorophyll *a* and chlorophyll *b*. Chlorophyll a is a waxy blue-black microcrystalline green-plant pigment, $C_{55}H_{72}MgN_4O_5$, with a characteristic blue-green alcohol solution. Chlorophyll *b* is a similar green-plant pigment, $C_{55}H_{70}MgN_4O_6$, having a brilliant green alcohol solution. Several other chlorophyll derivatives have also been isolated from tobacco (3770a).

The biosynthesis of porphyrin involves glycine and succinyl-CoA (from the citric acid cycle) to form *d*-aminolevulinic acid (dALA). Two dALA molecules are combined into porphobilinogen (PBG), which contains the pyrrole ring. Four PBGs are then combined through deamination into hydroxymethylbilane (HMB), which is hydrolyzed to

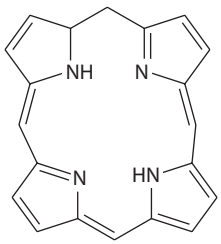

FIGURE 17.2 Porphyrin.

form the circular tetrapyrrole, uroporphyrinogen III. This molecule undergoes a number of further modifications. The biosynthesis is complicated and requires anywhere from 7 to 30 enzymatic reactions involving a variety of catalytic activities including decarboxylation, methylation, metal ion chelation, and porphyrin ring oxidation. Intermediates are used in different species to form particular substances, but, in plants and tobacco in particular, the main end product is protoporphyrin IX, which is combined with magnesium to form chlorophyll (3770a).

Table 17.5 lists the compounds in tobacco, tobacco smoke, and tobacco substitute smoke with multiple five-membered *N*-containing rings. While 14 porphyrin-containing compounds have been identified in tobacco, only porphyrin itself has been identified in tobacco smoke (1899, 3491).

17.2 MONOCYCLIC SIX-MEMBERED *N*-CONTAINING RING COMPOUNDS

17.2.1 Introduction

Over the years, several detailed composition studies on the volatile components in flue-cured [Lloyd et al. (2389) and Dickerson et al. (965)], burley [Roberts and Rohde (3219), Demole et al. (937, 938, 940–942), and Fujimori et al. (1249–1252, 1256)], Maryland [Schumacher (3550)], and Oriental tobaccos [Kimland et al. (2092–2095), Almqvist et al. (52), Aasen et al. (5, 11b), Hlubucek et al. (1660, 1660a, 1661, 1662), Schumacher (3561), Fukuzumi et al. (1257, 1258), and Chuman et al. (731–739)] have been published (2337, 3797). Similarly, the composition of tobacco smoke (3797) has advanced tremendously over the years (1373), notably by the works of Schumacher et al. (3553), Heckman and Best (1587), Grob (1412–1427), Bartle et al. (199, 200), Neurath (2719–2753), Elmenhorst (1129–1140), Newell et al. (2769), Hoffmann and his colleagues (480, 486, 735, 1580), the tobacco research personnel at the U.S. Department of Agriculture, Atlanta, GA, and many others [see additional listing in (2337)].

Tobacco chemists have shown considerable interest in the chemistry and biochemistry of the diverse set of *N*-containing compounds in tobacco and tobacco smoke. Numerous studies on the presence of nitrogenous compounds in tobacco and tobacco smoke have been published. These studies have reported on various aspects of the origins of nitrogenous compounds in tobacco, their synthesis, pyrolysis, and transfer to smoke. Several books and reviews [Tso (3972–3974b), Neurath (2724), Stedman (3797); Wynder and Hoffmann (4332), Schmeltz and Hoffmann (3491), Leffingwell (2337), Hecht et al. (1580)] have been written on *N*-containing compounds in tobacco and tobacco smoke.

The levels of chemical compounds in tobacco are affected by genetics, environmental conditions, and agronomic practices. Considering the six-membered *N*-containing ring compounds and especially the alkaloid-type components (five- and six-membered and multiple six-membered nitrogen heterocycles) of tobacco, this is especially true. There have been numerous reviews on factors affecting plant growth and nicotine/alkaloid accumulation in tobacco [Bush and Saunders (557a), Chaplin and Miner (677a), Bush and Crowe (17B04), Leete (2331a, 2331–2334), Bush (555a), Strunz and Findley (17B56), Bush et al. (17B05)].

Section 17.2.4 provides information on compounds in tobacco and tobacco smoke that contain a six-membered *N*-containing ring (piperidines, tetrahydropyridines, pyridines, piperazines, dihydropyrazines, pyrazines, pyrimidines, pyridazines, and triazines), compounds with a five-membered (pyrrolidine, pyrrole, imidazole) plus a six-membered *N*-containing ring (pyridine), and compounds containing two or more six-membered *N*-containing rings (piperidines, pyridines). The formation of these compounds in tobacco from biosynthetic pathways and from nonenzymatic processes will be presented as well as means of their generation and delivery to tobacco smoke.

17.2.2 Biosynthesis of Six-Membered *N*-Containing Ring Compounds and the Five- and Six-Membered and Multiple Six-Membered Nitrogen Heterocycles of Tobacco

The next few paragraphs will discuss the biosynthesis of the six-membered *N*-containing ring compounds and especially the alkaloid-type components (five- and six-membered and multiple six-membered nitrogen heterocycles) of tobacco. Following the biosynthesis section, information will be provided on the formation of some of the six-membered *N*-containing ring compounds that occurs during tobacco aging and processing. Finally, a discussion of how these six-membered *N*-containing ring compounds and especially the alkaloid-type components arise in tobacco smoke will be presented.

Over 60 species of *Nicotiana* exist that produce nicotine alkaloids (nicotine, nornicotine, anatabine, anabasine). Nicotine is the predominant alkaloid in over 50% of the *Nicotiana* species. Nornicotine is the major alkaloid in about 30%–40% of *Nicotiana* species. Anabasine and anatabine are not usually the principal alkaloids in *Nicotiana* (17B05). Tobaccos that accumulate and have high levels of alkaloids tend to also have accumulations of minor alkaloids, e.g., cotinine, myosmine, nicotyrine, 2,3′-bipyridine, and numerous derivatives of the major alkaloids, e.g., alkyl, acyl, and nitroso derivatives of nicotine and the other major alkaloids. The starting materials for the biosynthesis of the alkaloids are all present in tobacco. The precursors for pyridine, pyrrolidine, piperidine, and the most abundant nicotine alkaloids (nicotine, anabasine, anatabine, cotinine, myosmine) are well known and have been reviewed by Bush et al. (17B05). Although great advances in our understanding of alkaloid biosynthetic processes have occurred over the last 50 years, the metabolic and degradative processes occurring in *Nicotiana* species are still being researched. The biosynthesis of some of the six-membered *N*-containing ring compounds (pyrazines, pyridazines, triazoles) is still not completely understood. As mentioned earlier, the biosynthesis of pyridine, pyrrolidine, and piperidine will be presented. The subsequent biosynthesis of the major alkaloids will then follow. It should be noted that although biosynthesis is the most important means of producing the six-membered *N*-containing ring compounds and the alkaloids found in tobacco, other processes for their production in leaf are also operative. Several tobacco processing operations such as aging, fermentation, thermal treatments of tobacco prior to use in products, tobacco expansion, blending operations, and additive applications can vary (both increase or decrease) the concentration of various six-membered *N*-containing ring compounds and alkaloids.

Pyridine and the pyridine ring of nicotine, nornicotine, anabasine, and anatabine are formed from nicotinic acid.

Yang et al. (17B62) reported that quinolinic acid was the precursor to nicotinic acid via quinolinic acid phosphoribosyltransferase. Glyceraldehyde-3-phosphate (from glycerol) and aspartic acid via a series of enzymes are converted to quinolinic acid. Jackanioz and Byerrum (17B17) showed that ^{14}C-labeled aspartate and malate incorporated into the C-2 and C-3 positions of the pyridine ring when these amino acids were fed to tobacco plants. The total biosynthetic pathway and intermediates involved have not yet been completely elucidated.

The most accepted biosynthetic pathways for piperidine is lysine via Δ′-piperidine (3973, 17B05). Piperidine can also be formed through decarboxylation and dehydrogenation of nicotinic acid (17B37).

The pyrrolidine ring and particularly the *N*-methylpyrrolidine ring of nicotine is biosynthesized through putrescine (1,4-butanediamine), *N*-methylputrescine, and 4-methylaminobutanal to the *N*-methyl-Δ′-pyrrolinium salt (17B41). Dewey et al. (17B11) and Leete (17B29) fed ^{14}C-ornithine to tobacco and found incorporation of activity in the C-2′ and C-5′carbons of the *N*-methylpyrrolidine ring. Arginine via arginine decarboxylase forms agmatine that is converted to putrescine as a second source of this intermediate for the production of the pyrrolidine ring. Again, some of the intermediates and enzymes involved in the biosynthetic production of pyrrolidine are still not completely known (2334, 17B02, 17B63, 17B64).

Dawson et al. (17B07, 17B08) showed that nicotinic acid formed the pyridine ring in nicotine. Yang et al. (17B62) showed that the pyrrolidine ring of nicotine was attached at the C-3 position of the pyridine ring of nicotine. Dawson et al. (17B07) in another publication showed that the hydrogen at the C-6 position of nicotinic acid was lost during nicotine formation. Dawson and Osdene (17B09) and Leete (2330c) showed that nicotine formation proceeds through the reduction of nicotinic acid to 3,6-dihydronicotinic acid. Friesen and Leete (1241a) proposed that dihydronicotinic acid forms a zwitterion by proton transfer that readily decarboxylates to yield 1,2-dihydropyridine. 1,2-Dihydropyridine in turn reacts with *N*-methyl-Δ′-pyrrolinium salt to yield 3,6-dihydronicotine. The 3,6-dihydronicotine is oxidized with the loss of the hydrogen originally present at the C-6 position of nicotinic acid and retention of the hydrogen added in the reduction step to 3,6-dihydronicotinic acid. This pathway adequately explains the majority of the intermediates formed during nicotine biosynthesis and the fact that all nicotine in tobacco plants is (-)-2′S-nicotine (Figure 17.3).

Although nicotine is formed and is present in large quantities in tobacco, it is important to understand that the vast majority of all nicotine in tobacco is present in the form of organic salts. Very little exists in the free base form due to the acidic nature of tobacco. The exact identities of the nicotine salts that exist in tobacco are not known, but there have been several reports by Perfetti (2918a, 2924, 2926, 3156), Seeman et al. (17B48), and Dixon et al. (989) who have speculated on the various salt forms of nicotine.

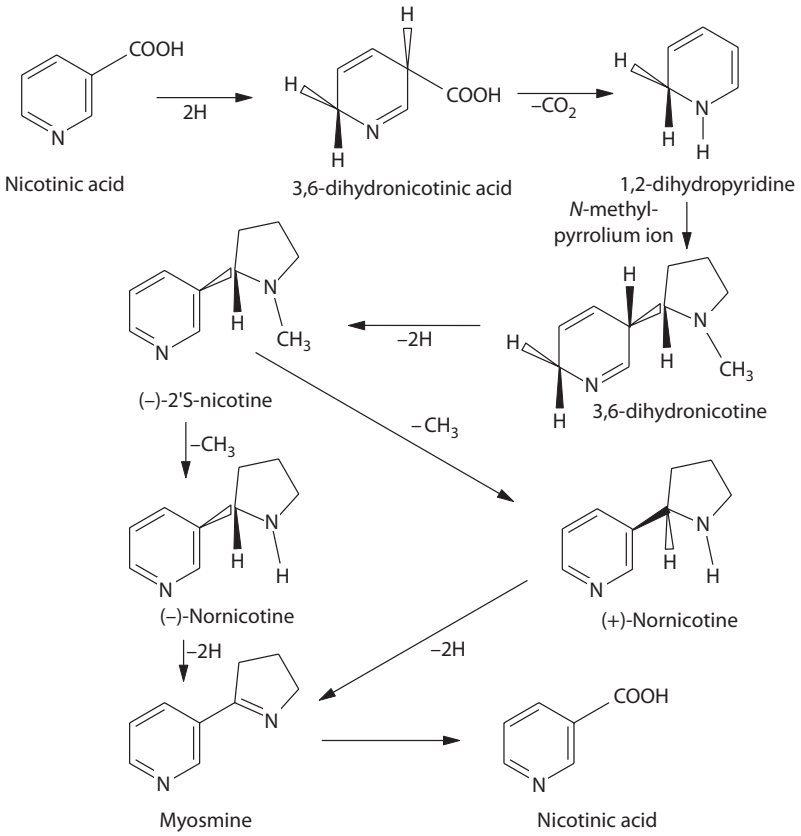

FIGURE 17.3 Proposed biosynthetic pathways for production of several pyridine alkaloids (17B05).

Both of the six-membered *N*-containing rings of anatabine (pyridine and piperidine) can be formed from the two methylene carbons and nitrogen of aspartate and two carbons from a glycerol derivative via nicotinic acid (2330c, 17B32, 17B33, 17B37). Nicotinic acid is reduced to 3,6-dihydronicotinic acid and decarboxylated to 1,2-dihydropyridine and 2,5-dihydropyridine. 1,2-Dihydropyridine reacts with 2,5-dihydropyridine via an electrophilic attack to form 3,6-dihydroanatabine which aromatizes to (-)-2′S-anatabine (17B36).

Although one might expect that anatabine and anabasine could be interconverted enzymatically in the plant, as these compounds differ by only two hydrogens, this does not appear to be true. The pyridine ring of anabasine has been shown to originate from nicotinic acid via decarboxylation (17B54). The precursor for the piperidine ring is lysine via Δ′-piperidine with the nitrogen derived from the ε-nitrogen of lysine (17B35). This was shown to occur via ^{14}C-lysine feeding studies by LEETE (17B30, 17B34). ^{14}C was incorporated into the C-2′ position of the piperidine ring of anabasine.

Nornicotine is formed from nicotine during the growth period of the tobacco plant and during senescence (17B06). Enzymatic demethylation of nicotine yields nearly equal quantities of the (+) and (−) isomers of nornicotine (17B05).

Myosmine can be formed from nornicotine by enzymatic dehydrogenation (2332, 17B24).

Cotinine and 2,3′-bipyridyl and their derivatives represent the major oxidized alkaloids in tobacco. Cotinine is synthesized from nicotine via enzymatic oxidation or auto-oxidation (1157, 17B03). 2,3′-Bipyridyl is formed by oxidation of anatabine. Frankenburg et al. (1221a, 1222–1224) were the first to identify 2,3′-bipyridyl as a fermentation product along with 3-acylpyridine. Other oxidized alkaloids identified in green and cured tobacco are nicotyrine, nicotinic acid, nicotinamide, and nicotine-*N*-oxides. Enzell et al. (1149a) found that these oxidation products of tobacco alkaloids tend to increase in yield during curing and storage of tobacco.

Pyrimidines play a central role in cellular regulation and metabolism. They are substrates for DNA/RNA biosynthesis, regulators of biosynthesis of some amino acids, and cofactors in the biosynthesis of phospholipids, glycolipids, sugars, and polysaccharides (17B45). Pyrimidine biosynthesis is very complicated and involves formic acid, glutamate, and aspartate as starting materials in a series of enzymatic reactions to eventually form orotic acid. Orotic acid, or uracil-6-carboxylic acid, is an intermediate in the metabolism of pyrimidine nucleotides. The naturally occurring derivatives of pyrimidine are components of the nucleic acids cytosine, thymidine, and uracil. Free pyrimidine and functionalized pyrimidine compounds in tobacco are believed to be formed from the catabolism of various nucleosides (17B21).

Although pyrazines, e.g., pyrazine-2-carboxylate and pyrazine-2,3-dicarboxylate, are formed biosynthetically, the vast majority of the varied pyrazine derivatives in tobacco are formed during curing via nonenzymatic reactions. Pyrazines can arise in tobaccos by a number of chemical pathways ranging from the heating or aging of proteins and amino acids to the interaction of amino acids and/or ammonia with sugars or carbonyl constituents. No single pathway is involved in the formation of pyrazine. The formation of pyrazine compounds is complex and depends on a variety of factors and chemical mechanisms (2339b). Adachi et al. (17B01) postulated that tetramethylpyrazine is derived enzymatically from 2 mol of acetoin (acetylmethylcarbinol) and 2 mol of ammonia. This finding was supported by the findings of Demain et al. (17B10) that a block in the isoleucine–valine pathway leads to the accumulation and excretion of a large amount of tetramethylpyrazine. Shu (17B51) treated acetoin with amino acids to determine whether ammonia is released, leading to the formation of tetramethylpyrazine. His results showed that all reactions between amino acids and acetoin generate not only alkylated pyrazines, e.g., tetramethylpyrazine, but also the corresponding Strecker aldehydes.

Pyridazines and triazines are not usually biosynthesized in plants. The exception is azathymine (6-methyl-1,2,4-triazine-3,5(2*H*,4*H*)-dione) which has been identified in modified bases from DNA of tobacco mosaic virus (3973). The majority of the identified pyridazines and triazines in tobacco are believed to originate from residues of agronomic chemicals. The pyridazine structure is found in herbicides containing maleic hydrazide. The triazine structure is found in the tobacco herbicide Metribuzin® and the fungicide Anilizine®.

A variety of alkyl-, acyl-, and hydroxyacyl-substituted alkaloids exist in tobacco. These have been identified and studied by a number of research groups [Bolt (389), Warfield et al. (4133), Matsushima et al. (17B39), Severson et al. (17B49), Zador and Jones (17B65)]. The mechanisms proposed for the biosynthesis of these alkaloids are oxidation or formylation. For example, *N*′-formylnornicotine [2-(3-pyridinyl)-1-pyrrolidinecarboxaldehyde] can be formed by formylation of nornicotine or by oxidation of the *N*-methyl group of nicotine (2330c, 17B03). Additionally, Burton et al. (17B03) have proposed that many acylated alkaloids are formed via acylation of secondary amine alkaloids (994). The concentrations of these alkylated and acylated alkaloids are small in comparison to the total alkaloid concentration in tobacco. Their occurrence is mainly influenced by plant genetics and agricultural practices (17B05). It is believed that their accumulation in leaf may be significant to flavor perception (17B05).

A number of tobacco *N*-nitrosamines are listed in this chapter. Chapter 15 is devoted to *N*-nitrosamines, but a few comments must be included here. Interest in tobacco-specific *N*-nitrosamines (TSNAs) has been a result of reports that some of them have induced malignant tumors in mice, rats, and hamsters [Boyland et al. (421a, 422, 423), Hecht et al. (1557–1559, 1563–1571a, 1574–1585)]. The TSNAs of greatest interest are *N*′-nitrosonornicotine (NNN), *N*′-nitrosoanatabine (NAT), *N*′-nitrosoanabasine (NAB), and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK). The formation of TSNAs can be biosynthetic (via mechanisms within the plant itself), produced by

bacteria on the surface of the plant, and by organic reactions of flue gas during curing practices [Peele et al. (2917); see also Figure 5 in Rodgman and Green (3300)].

17.2.3 Other Means for the Formation of the Six-Membered *N*-Containing Ring Compounds Found in Tobacco

Nitrogenous compounds in tobacco account for approximately 12%–25% of the dry weight of freshly harvested tobacco leaves (841a, 2337) (2%–6% expressed as nitrogen). As previously mentioned, the large variation in types and yields of nitrogenous compounds in tobacco is due to the great number of *Nicotiana* species, the variety of different agricultural practices, and soil types worldwide for the cultivation of different tobaccos. The major organic nitrogen constituents of tobacco leaf are nicotine and related alkaloids, proteins, and amino acids (2337). The alkaloids as discussed earlier are biosynthesized along with a portion of most of the six-membered *N*-containing ring compounds found in tobacco. But there are also other ways that these six-membered *N*-containing ring compounds can be produced.

The varied methods of curing and aging tobacco cause only a small decrease in the total nitrogen content, but significant changes occur as a result of organic transformations from one type of nitrogenous compound to another, e.g., the enzymatic hydrolysis of leaf protein produces free amino acids (1493). After curing, dynamic changes continue to occur during aging of tobacco leaf. Weybrew et al. (4226) and Tomita et al. (3923) recognized in 1965 that chemical reactions of amino acids in tobacco play an important role in the formation of tobacco flavor. Employing model systems, reactions of amino compounds with sugars or carbonyl compounds were shown to produce flavor compounds present in tobacco (2047, 2048, 2337, 3649).

During tobacco aging, tobacco undergoes a natural "sweating" process several times. This "sweating" is a mild, natural fermentation that produces some heating of the tobacco. This mild, natural fermentation releases reducing sugars, amino acids, phenolics, and flavonoids through nonenzymatic browning reactions to produce the flavor characteristic of aged tobacco. Much of the flavor that is produced is due to Maillard and Strecker reactions of amino acids with reducing sugars (or other carbonyls). The role of nonenzymatic browning reactions of amino acids and sugars is generally accepted as being one of the most important processes in which natural flavors are produced (2337).

There are at least three other ways (other than through biosynthesis) that the six-membered *N*-containing ring compounds can be formed in tobacco leaf (2337):

- Oxidative transformations
- Ambient temperature nonenzymatic transformations
- Heat-induced nonenzymatic transformations

It must be remembered that compounds formed by enzymatic processes can react subsequently in a nonenzymatic transformation. Additionally, by examining the chemical transformations involved in the production of compounds via nonenzymatic browning reactions, several routes can be involved in the production of the same compounds from different precursors (2337).

A type of Maillard reaction that occurs naturally in tobacco which requires the presence of active α-dicarbonyl components is the Strecker degradation of α-amino acids to aldehydes and ketones of one less carbon atom. Schonberg and Moubacher (17B46, 17B47) studied the mechanism of the Strecker degradation involving pyruvaldehyde and α-alanine, leading to the formation of 2,5-dimethylpyrazine and 2,5-dimethyl-3-ethylpyrazine. The fact that different amino acids can produce the same flavor compounds has been shown by a number of workers in studies on the relative formation of pyrazines under controlled reaction conditions between amino acids and glucose (2048, 2337). Similar studies have shown that thermal decompositions of various amino acids and other aminohydroxy compounds such as glucosylamine can directly form pyrazine mixtures (17B60). Because of the complexity of the chemical interactions and transformations involved, the types and ratios of active flavor products, e.g., pyrazines, formed by nonenzymatic browning are dependent on the reaction conditions which may occur during aging or during the smoking process itself.

Examples of how processing tobacco affects the production of flavorful pyrazine were provided by Mays et al. (17B40) and Green et al. (1369) of R.J. Reynolds Tobacco (RJRT) Company. Ammonia/carbon dioxide expansion was conducted on flue-cured, burley, and processed tobacco sheet. Test and control cigarettes were fabricated. The tobacco aroma of the ammonia/carbon dioxide–processed tobaccos increased in all cases after processing *vs*. the control materials. Comparison of the per cigarette mainstream smoke (MSS) yields of eight pyrazines indicated their yields in the MSS from ammonia/carbon dioxide–expanded tobacco were significantly greater than those in the control tobacco MSS [see Tables 3, 4, and 5 in (3261)].

Additionally, browning reactions can occur during the smoking process (2337). Some of the reaction products occurring during the smoking process involve six-membered *N*-containing ring compounds that can significantly contribute to tobacco smoke flavor and aroma, e.g., some pyrazine and pyridine derivatives (2339b).

17.2.4 Six-Membered *N*-Containing Ring Compounds in Tobacco and Tobacco Smoke

Knowledge of tobacco smoke composition grew rapidly each year by the application of new analytical methods. Prior to 1959, only 16 nitrogen compounds had been reported in tobacco and tobacco smoke. In 1959, Johnstone and Plimmer (1971) summarized the identification of about 50 nitrogen compounds. Ten years later, Neurath (2724) reported on the presence in tobacco and tobacco smoke of 181 nitrogen compounds, among which were 2 piperidines, 24 pyridines, 10 pyridines, and 11 alkaloids. In this report,

TABLE 17.6
Distribution of Six-Membered *N*-Containing Ring Compounds between Tobacco and Tobacco Smoke

	Number of Identified Six-Membered *N*-Containing Ring Compounds in Tobacco and Tobacco Smoke			
Component	**Total**	**Smoke**	**Tobacco**	**Smoke and Tobacco**
Piperidines	44	40	13	9
Tetrahydropyridines	7	3	5	1
Dihydropyridines	6	4	2	0
Pyridines	365	324	125	84
Piperazines	12	12	0	0
Dihydropyridazines	5	3	3	1
Pyrazines	106	90	57	41
Pyrimidines	33	14	20	1
1,2,4-Triazines	1	0	1	0
1,3,5-Triazines	2	0	2	0
Totals	581	490	228	137

we have cataloged 37 piperidines, 312 pyridines, 78 pyrazines, and over 160 alkaloids.

Table 17.6 provides the distribution of six-membered *N*-containing ring compounds in tobacco and tobacco smoke. Of the 581 identified compounds, about 84% (or 490 compounds) are found in tobacco smoke and about 39% (or 228 compounds) are found in tobacco. Of the 581 compounds, 23% (137 compounds) are found in both tobacco and smoke.

Figure 17.4 illustrates the general structures for the 10 types of six-membered *N*-containing ring compounds found in tobacco and tobacco smoke. The four major compound classes are the piperidines, pyridines, pyrazines, and the pyrimidines. A brief discussion of general information on each of these four classes of six-membered *N*-containing ring compounds follows.

17.2.4.1 Piperidine and the Tetra- and Dihydropyridines

Piperidine and Δ^3-piperideine were first identified by Neurath et al. in 1965 (2749) and 1966 (2734), respectively [see Table 3 in Neurath (2724)]. The piperidines in tobacco and tobacco smoke are found as substituted ketones, acids, and alkyl derivatives. None of the 48 nonaromatic six-membered *N*-heterocycles found in tobacco and tobacco smoke has been shown to provide positive contributions to the flavor of tobacco smoke, although piperidine is on the GRAS list as a food flavor (3215).

Pyrolysis and smoke studies of amino acids indicate that they are potential precursors of several nitrogen heterocyclic ring systems found in tobacco smoke (1351). For example, indole can be formed from tryptophan, proline has been shown to be efficiently converted to pyrrole upon pyrolysis (3219, 3726), and γ-amino acids can be pyrolyzed to form 2-pyrrolidones (1967, 3079). By a similar mechanism, γ-amino acids form 2-piperidones (1967, 3079).

17.2.4.2 Pyridines

A great variety of pyridines (currently 365) have been identified in tobacco and tobacco smoke. As a class, there are more pyridines in smoke than any other heterocycle. Vohl and Eulenberg (4064) were the first to isolate and identify pyridine in tobacco smoke in 1871. Since that time, a wide variety of substituted [methyl- (picolines), dimethyl- (lutidines), ethyl-, allyl-, butyl-, vinyl-, cyano-, formyl-, alkylamino-] pyridines have been identified. Most of the substituted groups in these pyridines occur at the 3-position, although there are some substituted pyridines with functionalities at the 2- and 4-positions (2724).

The presence of pyridine compounds in smoke is naturally associated with the tobacco alkaloids. The formation of substituted pyridines that occur during the pyrolysis of nicotine has long been known [Woodward et al. (4275a), Kaburaki et al. (2006), Jarboe and Rosene (1923a), Schmeltz et al. (3499)]. Pyridine, 3-methyl- and/or 4-methylpyridine, 3-vinylpyridine, and 3-cyanopyridine have all been identified as major pyrolysis products of nicotine. Minor pyridine pyrolysis products included 2-methylpyridine, dimethylpyridines, 3-ethylpyridine, and 2- and/or 4-cyanopyridine. All have been identified in tobacco smoke. While the formation of pyridines from nicotine might be expected to involve simple rupture of the pyridine–pyrrolidine bond, a more complex pathway is taking place. When either nicotine-*N*-methyl-^{14}C or nicotine-2′-^{14}C was pyrolyzed, several alkylated ^{14}C-labeled pyridines were among the products.

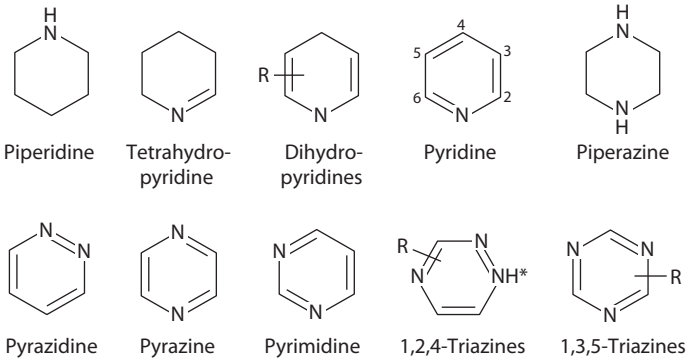

FIGURE 17.4 Structures of the six-membered *N*-containing compounds found in tobacco and tobacco smoke.

This indicated that fragments of the pyrrolidine ring can recombine and aromatize to give pyridines (1580).

The pyrolytic formation of pyridines has been observed in studies on a number of nitrogenous substances. Pyrolysis of tobacco pigment and of tobacco leaf gave a spectrum of pyridines similar to those observed in smoke [Schmeltz et al. (3499), Schlotzhauer and Schmeltz (3463)]. Pyridines were observed in the pyrolysis of proline [Higman et al. (1647)] and pyridine was a product of pyrolysis of poly-*L*-proline [Johnson et al. (1968)]. Pyrolysis of nicotinamide at 1050°C gave pyridines and 3-cyanopyridine, among other products [Bruzel and Schmeltz (515)]. Pyridines were also observed in pyrolysates of pyrrole, maleic hydrazide, and *N*,*N*-dimethyldodecylamine [Patterson et al. (2907, 2908)]. In view of the previously mentioned results on pyrolysis of nicotine-^{14}C and previous mechanistic studies [Hurd et al. (1851)], it is not surprising that pyridines should arise on pyrolysis of such diverse *N*-containing compounds. Studies on cigarettes enriched in nicotine or nornicotine indicated that nornicotine was an important precursor for pyridines [Glock and Wright (1316), Hecht et al. (1580)].

Pyridines can be formed by mechanisms other than pyrolysis. The reaction of aldehydes with amino acids has been shown to generate pyridines (50). When a glycine–propanal mixture was heated to 180°C, 3,5-dimethyl-2-ethylpyridine, 3,5-dimethyl-4-ethylpyridine, and 3,5-dimethylpyridine formed. Glycine–propanal mixtures, also heated to 180°C, gave 2,5-dimethylpyridine and 3,4-dimethylpyridine. This is an example of a nonpyrolytic method of forming pyridines. As small-chain aldehydes required for this reaction are abundant in smoke, this is a feasible route to pyridines.

Pyridines contribute to the characteristic tobacco flavor of smoke. Fujimori (1248) identified 26 pyridines as components of tobacco aroma. Leffingwell et al. have tabulated the flavor and aroma characteristics of many pyridines (2341). Pyridines as a class of compounds enhance tobacco flavor, add burley flavor, or can add flue-cured flavor. Pyridines are responsible for that characteristic note in smoke which identified the smoke as that from tobacco (1587a). Hoffmann and Wynder (1803) have made the comment that pyridines are responsible for the off-taste and irritancy of the smoke from large cigars and that pyridines reduce the inhalability of cigar smoke.

Roberts commented that two particular pyridine compounds were noteworthy, 2-acetylpyridine [1-(2-pyridinyl)-ethanone] and 2-methyl-5-isopropylpyridine [2-methyl-5-(1-methylethyl)-pyridine] (3215). The former adds some sweet, roasted, and musty notes, and the latter adds body and burley character to the tobacco blend. Additionally some pyridines may react with other smoke compounds synergistically. For example, it is believed that some pyridines reduce the sweet, burnt-sugar taste of cyclopentenones and furanones (3215).

17.2.4.3 Pyrazines

Pyrazines constitute a very small percentage by weight of smoke condensate (5–50 µg/cig), but pyrazines as a class of tobacco and tobacco smoke compounds are very important because of their positive flavoring properties. Pyrazine, methylpyrazine, and 2,6-dimethylpyrazine were first recognized in tobacco smoke in 1965 by Testa and Testa (3888). To date, 106 pyrazines have been identified in tobacco and tobacco smoke. Nearly 40% of the identified pyrazines are found in both tobacco and tobacco smoke.

In the 1968 review by Stedman (3797), he listed only three pyrazines as components of tobacco smoke: pyrazine, 2-methylpyrazine, and 2,6-dimethylpyrazine. In that same year, Neurath and Dünger (2732) identified eight additional pyrazines, including 2-methyl-5-(2′-furyl) pyrazine. Leffingwell in 1976 (3237) mentioned six new pyrazines, including three acetyl-substituted pyrazines. Green (1351), in 1977, disclosed another eight novel pyrazines including 2-methyl-5-phenylpyrazine, 3-methylpyrazinol, and pyrrolo[1,2-*a*]pyrazine. Heckman and Best (1587) have also identified a number of pyrazines including five cyclopentapyrazines. There is a great diversity of pyrazines that have been identified in tobacco smoke.

Pyrazines have also been isolated from tobacco (938). Their presence in leaf arises from biosynthesis and from browning reaction chemistry that can occur during curing and tobacco processing. At present, 58 pyrazines have been identified in tobacco. Bright et al. (431) have demonstrated that the necessary precursors for the formation of pyrazines are present in tobacco leaf. In their experiments, the levels of dimethylpyrazine in untreated tobaccos were measured, and then the same tobaccos were heated at 120°C for 4 h and the levels measured again. In each case, the level of dimethylpyrazine was found to be very low in the untreated tobacco and appreciably increased following the roasting. Their results also showed a decrease in amino acid levels during the heat treatment of the tobaccos, indicating the possible involvement of amino acids in the formation of the pyrazines. Some pyrazines have been isolated from flue-cured (965) and burley tobaccos (937). The presence of pyrazines in tobaccos may be due to reactions of leaf precursors at the temperature used in curing of these tobacco types (1351).

Amadori compounds are β-ketoamino acids that are structurally similar to β-hydroxyamino acids. Amadori compounds can yield pyrazines. Leffingwell (2337) and Green (1351) have both mentioned the presence of Amadori compounds in leaf as has Tomita (3923) who stated that Amadori compounds account for as much as 2% of the dry weight of flue-cured leaf. Thermal treatment of Amadori compounds does, in fact, give pyrazines as decomposition products [Shigematsu et al. (17B50)]. The formation of 2,5-bis-(tetrahydroxybutyl)pyrazine (fructosazine) from the reaction of fructose or glucose with alcoholic ammonia and from self-condensation of glucosamine or isoglucosamine has been known for a long time (17B57); in fact, the earliest reports date back to the beginning of the twentieth century. Deoxyfructosazine and its 2,6-isomer have been isolated from mixtures obtained by reaction of glucose and fructose with ammonia under weakly acidic conditions (1153, 1156, 17B13). The fructosazine and deoxyfructosazine isomers

can be obtained synthetically by use of such sugar–ammonia reactions. The yields and isomer ratios are somewhat contingent on the choice of sugar (glucose or fructose) and the mole ratio of sugar to ammonium formate (1153). For example, xylose and aqueous ammonium formate yielded 2,5-bis (*D*-threo trihydroxypropyl)pyrazine (xylulosazine) and the related 2,5- and 2,6-deoxyxylulosazines (1248). Several deoxyfructosazine isomers have been isolated from tobacco (1352). The tobacco-derived deoxyfructosazines were shown to improve the aroma and taste of tobacco (1351). Lynm (2420, 2421, 2423, 2424) at RJRT conducted several studies on the presence, formation, and analysis of deoxyfructosazines in tobacco and tobacco products.

Two mechanisms have been suggested for pyrazine formation during smoking: pyrolytic decomposition of leaf constituents and nonenzymatic sugar–amine reactions. Kato et al. (2048) showed that direct pyrolysis of serine yielded pyrazine, methylpyrazine, ethylpyrazine, 2-ethyl-6-methylpyrazine, 2,6-diethylpyrazine, and 2,6-diethyl-6-methylpyrazine. Pyrolysis of threonine gave 2,5-dimethylpyrazine, trimethylpyrazine, and 2,5-dimethyl-3-ethylpyrazine. Sugars condense with amino acids to form sugar–amino acid adducts which then undergo Amadori rearrangement to give Amadori compounds.

Although pyrolysis of selected leaf constituents generates pyrazines, the diversity and abundance of pyrazines in smoke cannot be adequately accounted for by this mechanism alone. Maga and Sizer (2439) and Enomoto et al. (17B12) have reviewed the occurrence of pyrazines in roasted foods and proposed pathways for pyrazine formation. Their summaries present a large array of pyrazines found in the flavor fractions of a number of roasted foods. It is striking that nearly all pyrazines commonly found in tobacco smoke have been identified in at least one roasted food. For example, 2,3-dimethylpyrazine has been found in peanuts, barley, coffee, baked potatoes, mushrooms, lamb fat, and tobacco smoke (1587a).

Of particular interest in relating leaf to smoke composition are the studies of Koehler and coworkers (17B26, 17B27) on the formation of pyrazine compounds in sugar–amino acid systems. Using model systems, Koehler and Odell (17B27) showed that pyrazines are formed when sugars and amino acids are heated between 100°C and 150°C. Glucose reacts with either an amino acid or ammonia to form a glycosylamine. The amino acid complex then undergoes a Strecker-type degradation to yield an eneaminol which can also be formed by the loss of water from glucosylamine. The eneaminol then isomerizes and undergoes reverse aldol condensation to form 1-aminoacetone which is known to self-condense to yield pyrazines (116). As shown by Schonberg and Moubacher (17B46), during the condensation of the aminoacetone, further reaction with aldehydes can take place. Similar pathways can be postulated for the generation of 1-aminoacetaldehyde, 1-aminopropionaldehyde, and 1-amino-2-butanone from sugar–amine reactions. Hypothetical reaction of these aminocarbonyl compounds either individually or in pairs can account for most of the alkylpyrazines reported in smoke (1351). Additionally, Koehler and Odell (17B27) showed that a number of smaller compounds, acetaldehyde, glycerol, glyoxal, 2,3-butanedione, and acetol, also yielded pyrazines when heated with nitrogen sources. Koehler et al. (17B26) had previously shown, using radiotracer techniques, that the sugar moiety served as the principal source of carbon atoms and that the amine furnished only nitrogen to the pyrazine molecule. These data imply that sugar decomposes to small intermediary carbonyl compounds which in turn react with the nitrogen source, e.g., amine and amino acid, to form pyrazines.

Other possible mechanisms for the formation of pyrazines during smoking are possible. For instance, leaf carbohydrates could be degraded either through pyrolysis or Maillard reactions to form α-dicarbonyl compounds, which could, in turn, react with amino acids to undergo a Strecker degradation forming the α-aminocarbonyl compounds [1671a, 2439, Velisek et al. (17B59)] which can condense to form pyrazines (1351).

Pyrazines are the most important *N*-heterocycles in characterizing the aroma and flavor of tobacco and tobacco smoke (2341, 3215, 3491, 3553). The alkylpyrazines, for example, provide the cocoa and nutty-type notes associated with tobacco smoke. 2-Acetylpyrazine [1-pyrazinylethanone], isolated and identified in burley tobacco by Roberts (3202, 3204) in 1963, contributes a nutty, popcorn-type flavor unique to tobacco smoke. Pyrazines, in general, contribute the "brown notes" associated with tobacco smoke taste (3215). It is obvious that cigarette MSS flavor and aroma may be enhanced by addition of appropriate pyrazine compounds to the tobacco blend, e.g., among the 460 pure compounds listed by Doull et al. (1053) as possible cigarette tobacco ingredients used by U.S. cigarette manufacturers are 23 (5%) pyrazine derivatives. In 1977, RJRT conducted an immense study on the Philip Morris' Merit cigarette that advertised the use of a "flavor package." One of the interesting results of that study was that the MSS from Merit contained numerous alkylpyrazines, particularly higher levels of tetramethylpyrazine and several trimethylpyrazines compared to other commercial cigarette brands of similar FTC "tar." Much of the Merit research conducted at RJRT was summarized by Lloyd (2385a).

17.2.4.4 Pyrimidines

Thirty-three pyrimidine derivatives identified in tobacco and tobacco smoke are listed in Table 17.7. The vast majority of these compounds (61%) have been identified in tobacco. Only 14 are known to exist in tobacco smoke. As previously mentioned, the naturally occurring derivatives of pyrimidine are components of nucleic acids: cytosine, thymidine, and uracil. Free pyrimidine and functionalized pyrimidine compounds in tobacco are believed to be formed from the catabolism of various nucleosides (17B21). Several of the pyrimidine-containing compounds in tobacco are agronomic chemical residues, while other compounds identified in tobacco smoke are formed from those agronomic residues.

Pyrimidine derivatives do not generally have positive flavor notes and are considered neutral to poor.

252.		Pyridine, (C_3-alkylphenyl)- {Two isomers detected}	568b, 1587, 4249		
253.	31388-09-7	Pyridine, butyl	5811b		
254.	65375-18-0	Pyridine, butenyl {three isomers}	4570a, 5811b		
255.	27175-64-0	Pyridine, dimethyl- {lutidine}	167, 480, 512, 1644, 1645, 1649, 1803, 2079, 2170, 2342, 2342a, 2524, 3255, 3397, 3733, 3750, 3752, 3976, 4064, 4249, 5034, 5079, 5811b	2727, 3491, 3973, 4064, 4249, 5079, 5382, 5811b	
256.	29011-62-9	Pyridine, dimethylethenyl-	3733, 3750, 3752, 4249		
257.		Pyridine, dimethylethyl- {Two isomers detected}		2339a, 4249	
258.		Pyridine, dimethyl-2-(1-methylethyl)-	4570a		
259.		Pyridine, dimethylphenyl-	3733, 3750, 3752, 4249		
260.	56842-43-4	Pyridine, diphenyl-	2141, 4249, 5811b		
261.	1337-81-1	Pyridine, ethenyl-	167, 480, 512, 1075, 1215, 1427, 1649, 1842, 2951, 4249, 5034, 5811b		
262.	25638-00-0	Pyridine, ethenylmethyl-	1644, 1645, 3398, 4249, 5034, 5811b		
263.		Pyridine, ethenyltrimethyl-	3733, 3750, 3752, 4249		
264.	28631-77-8	Pyridine, ethyl-	2777, 2858, 2939, 3190, 3992, 4249, 5034		
265.	27987-10-6	Pyridine, ethylmethyl- {four isomers}	1360, 1375a, 1587, 2727, 2761, 2762, 2765, 2766, 2773, 2777, 3491, 3559, 4249, 5034, 5811, 5811a, 5811b	2339a, 3430, 4249, 5811, 5811a, 5811b	1360, 1375a
266.	64849-96-3	Pyridine, ethylphenyl-	2141, 4249, 5811b		
267.	1333-41-1	Pyridine, methyl- {picoline}	167, 480, 512, 1263, 1316, 1445, 1644, 1645, 1647, 1649, 1744, 1842, 2079, 2170, 2270, 2342, 2342a, 2506, 2507, 2570, 2710, 2777, 2799a, 3190, 3308, 3976, 3992, 4064, 4065, 5034, 5079, 5140, 5512, 5811b	120, 395, 1263, 1852, 4064, 5079, 5382	2506 (0), 2507 (0)

TABLE 17.7 (continued)
Compounds in Tobacco, Tobacco Smoke, and Tobacco Substitute Smoke with a Six-Membered *N*-Containing Ring

			References		
	CAS No.	Name (per CA Collective Index)	Tobacco Smoke	Tobacco	Tobacco Substitute Smoke
268.	64828-54-2	Pyridine, methylphenyl-	3733, 3750, 3752, 4249, 5811b		
269.	65307-85-9	Pyridine, pentyl-	5811, 5811a, 5811b		
270.	64828-55-3	Pyridine, phenylpropyl-	2141, 4249, 5811b		
271.		Pyridine, phenyltrimethyl-	3733, 3750, 3752, 4249		
272.	65375-17-9	Pyridine, propenyl-	1075, 1360, 1375a, 2761, 2762, 2765, 2766, 4249, 5811b		1360, 1375a
273.	65307-84-8	Pyridine, propyl-	2777, 4249, 5811, 5811a, 5811b		
274.		Pyridine, tetramethyl-	3733, 3750, 3752, 4249		
275.	29611-84-5	Pyridine, trimethyl- {collidine}	1075, 1587a, 1971, 2079, 2142, 2170, 2326, 2342, 2342a, 2543, 2545, 2773, 2939, 3308, 3398, 3410, 3499, 3733, 3750, 3752, 4064, 4065, 4249, 5079, 5263, 5811b	4064, 5079, 5382, 5811b	
276.	6972-40-3	Pyridine, 1-ethyl-1,2,3,6-tetrahydro-	568b, 4249		
277.	694-05-3	Pyridine, 1,2,3,6-tetrahydro-	568b, 1140, 2724, 2734, 2883, 2889, 3308, 3410, 3491, 3797, 4249	568b, 1877, 2722, 2746, 3491, 3974a, 4249, 5811b	
278.		Pyridine, 2-(C_3-alkylphenyl)- {Two isomers detected}	1587, 4249		
279.	5058-19-5	Pyridine, 2-butyl-	568b, 1587, 4249, 4570a, 5811b		
280.	1929-82-4	Pyridine, 2-chloro-6-(trichloromethyl)- {Nitrapyrin®} 		3973, 4249	
281.	100-69-6	Pyridine, 2-ethenyl-	568b, 1099, 1100, 1371, 1427, 2233, 2234, 2727, 2775, 3190, 3255, 3491, 3733, 3750, 3752, 3992, 4249, 4407, 4570a, 5811b	5720	
282.	22382-94-1	Pyridine, 2-ethenyl-3-methyl-	568b, 1587, 4249, 5811b		
283.	3883-39-4	Pyridine, 2-ethenyl-5-methyl-	568b, 4249		
284.	1122-70-9	Pyridine, 2-ethenyl-6-methyl-	1371, 4249		
285.	14529-53-4	Pyridine, 2-ethoxy-	568b, 4249		
286.	100-71-0	Pyridine, 2-ethyl-	107, 299, 568b, 775, 1063–1066, 1068–1074, 1140, 1348, 1349, 1360, 1369, 1375a, 1587a, 2233, 2234, 2470, 2543, 2545, 2570, 2761, 2762, 2765, 2766, 2773, 2775, 3261, 3302, 3386, 3410, 4249, 4407, 4570a, 4921, 5811b	568b, 1157, 2339a, 3430, 3491, 3973, 3974a, 4249, 5720	1360, 1375a
287.	1123-96-2	Pyridine, 2-ethyl-3,5-dimethyl- = pyridine, 2,4-dimethyl-6-ethyl-	2545, 2761, 2762, 4249

Some pyrimidine-derived flavors (although not found in tobacco or tobacco smoke) have meaty notes. There are also some pyrimidine flavorants that do possess good flavor potential for tobacco products, e.g., 2-methyl-5,7-dihydrothieno[3,4-*d*]pyrimidine. This compound contains a bicyclic ring structure and has been identified in tobacco. 2-Methyl-5,7-dihydrothieno[3,4-*d*]pyrimidine is said to have a fresh roasted, sweet nut flavor with a popcorn character (17B22). It is a compound listed by Doull et al. as an ingredient in flavor formulations used by one or more members of the U.S. tobacco industry (1053).

17.2.5 Compounds in Tobacco and Tobacco Smoke Containing a Five- and Six-Membered *N*-Containing Ring

The origin of all the work that has been done on the isolation and identification of the tobacco and tobacco smoke began with this relatively small group of compounds. The initial tobacco and tobacco smoke compound that was of so much interest was nicotine. Literally thousands of scientific articles, reviews, and books have been published on various aspects of nicotine, e.g., pharmacological and metabolic properties, chemical and

structural properties, occurrence, biogenesis, and pyrolysis. The scope of all the work on nicotine alkaloids is so broad that a comprehensive review is beyond the scope of this chapter. The several hundred references listed in Table 17.7 testify to the enormous amount of research that has been conducted on the nicotine alkaloids. Instead, a brief history of the initial work on the isolation and identification of nicotine follows.

17.2.5.1 Nicotine and Tobacco Alkaloids with a Six-Membered *N*-Containing Ring and a Second Five-Membered *N*-Containing Ring

Nicotine is the unique component of tobacco. The history associated with the discovery of nicotine and use of the "oil" derived from tobacco dates to about 1571 (17B16). This "oil" prepared by the French chemist Gohory undoubtedly contained some level of nicotine and was used as a remedy for diseases of the skin. In 1660, another French chemist, Lefevre, described means to steam distill tobacco to obtain oil that had medicinal uses (3477). In 1807, Cerioli discovered what he called the *olio essenziale* of tobacco (17B15). In 1809, Vauquelin apparently made the same discovery. Both researchers described the oil as a volatile and colorless substance. Vauquelin recognized the basic nature of the material but failed to recognize its alkaloidal properties. He attributed the basicity of the material to the presence of ammonia (410).

In 1822, Hermbstädt confirmed Vauquelin's results of the presence of the oil described in 16 different species of what is now known as *Nicotiana* (17B15). It was not until 1828 that Posselt and Reimann (2981) succeeded in isolating a pure sample of the oil and recognized it as an alkaloid. They characterized it as a water-clear liquid, boiling at 246°C under atmospheric pressure, and miscible with water, alcohol, and ether. They named the pure compound nicotine after Jean Nicot who introduced tobacco into the French court in about 1560 (17B42). In 1826, Unverdorben isolated a water-soluble base from a dry distillate of tobacco (282). The base contained nicotine. Melsens (2528), in 1843, succeeded in isolating nicotine from the smoke of pipe tobacco and assigned the empirical formula, $C_{12}H_{14}N_2$ (2724). In 1893, Pinner (17B44) reported on the final clarification of the constitution of nicotine, determined via degradation studies. Pinner's structural formula for nicotine was confirmed by the classical synthesis of nicotine by Pictet and Rotschy (17B43) in 1895. For many years, nicotine was believed to be the only alkaloid in tobacco (17B18). It was not until 1928 that Ehrenstein reported the identification of nornicotine in tobacco [see Markwood (17B38)]. Anabasine was isolated in tobacco by Smith (17B53) in 1935. Späth and Kesztler (17B55) isolated anatabine in tobacco in 1934 (Markwood 1942). Gautier and LeBon in 1892 were the first chemists to clearly recognize that additional alkaloids accompanied nicotine in tobacco smoke. These additional alkaloids were the secondary alkaloids and decomposition products of alkaloids. Unfortunately, Gautier and LeBon did not report further on their observations (2223, 2224). Wenusch and Schöller (4210, 4211) in the early 1930s worked diligently to separate the secondary alkaloids in tobacco smoke. Though they were not wholly successful, they did discover and determine the formula for myosmine in cigar smoke in 1936 with the collaboration of Späth (2224). By 1936, Wenusch and Schöller (4213) had distinguished a large number of tobacco smoke bases in cigar and cigarette smoke by their behavior during steam distillation and extraction. Several of the alkaloid-related components (α-, β-, and γ-socratine, obelin, lohitam, anodmin, lathraein, poikiline, and gudham) first reported by Wenusch and Schöller (4210, 4211) were subsequently demonstrated to be mixtures or mislabeled components of previously known alkaloids. Until the study by Kuffner, Schick, and Bühn in 1959, there was much confusion concerning the correct identity of the secondary alkaloids of tobacco smoke. Kuffner et al. (2224) demonstrated that obelin was a salt of ammonia, α- and β-socratine were mixtures of nicotyrine and 2,3′-bipyridine, and γ-socratine was l-nornicotine. Poikiline was characterized as 4-amino-1-(3-pyridyl)-butanone. Many of these characterization corrections are described in Johnstone and Plimmer (1971) and Borgerding et al. (410).

To date, 111 components with both five- and six-membered *N*-containing rings have been identified in tobacco and tobacco smoke. In all cases, the six-membered ring is pyridine; the attached five-membered ring may be a pyrrolidine, pyrroline, pyrrole, or an imidazole ring. The vast majority of these tobacco alkaloids contain a pyrrolidine ring that is substituted at the 3-position of the pyridine ring. Table 17.8 shows the distribution of the tobacco alkaloids that occur in tobacco, tobacco smoke, and in both.

Over 60 nicotine-related alkaloids have been identified in tobacco. Many of them have been identified in tobacco smoke, and 22 of the nicotine alkaloids are found in both tobacco and tobacco smoke. The vast majority of the nicotine alkaloids contain a pyrrolidine ring connected to a pyridine ring. The most common functionalities associated with the pyrrolidine-containing nicotine alkaloids are alkyl, nitroso, carboxyl, amino, and acyl groups.

Totals	111	70	72	31

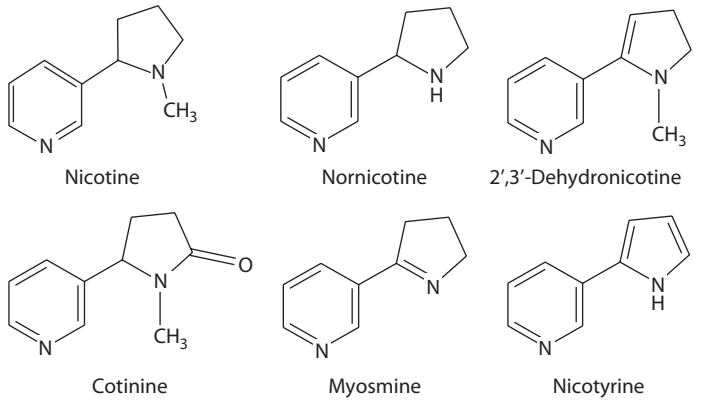

FIGURE 17.5 Common tobacco alkaloids found in tobacco and tobacco smoke.

The structures of some of the most common tobacco alkaloids found in smoke are shown in Figure 17.5. The transfer rate for nicotine is generally about 10%–12%, but a number of factors including the cutting width of the tobacco, the shape of the cigarette, the moisture content of the tobacco, and various tobacco additives can significantly affect nicotine delivery to MSS [Kuhn and Klus (2231), Hecht et al. (1580)]. Many of the alkaloids of tobacco smoke consist of components originally in the tobacco, which transfer unchanged, and various pyrolysis products of the nicotine alkaloids.

Nicotine is a major precursor of a large number of volatile bases in tobacco smoke. On heating nicotine at temperatures greater than 400°C, various patterns of fragmentation occur depending on the gaseous atmosphere and other experimental conditions. Myosmine (4275a) and 3-cyanopyridine [Woodward et al. (17B61)] are two of many pyrolysis products of nicotine at 500°C–730°C. The yields and type of pyrolysis products depend on the substrate used to hold the alkaloid, the particular alkaloid tested, e.g., nicotine or nornicotine, the temperature ramping regime, the final temperature attained, the holding time at maximum temperature, and reactor type employed for the pyrolysis experiment. The major identified pyrolytic products of nicotine at temperatures 400°C and 900°C (in a nitrogen or helium atmosphere) include all of the compounds shown in Figure 17.5. In addition to these compounds, ammonia, methylamine, and a number of smaller fragments are formed from heterolytic cleavage of nicotine. Nicotine is not fragmented significantly at temperatures below 600°C in reactors without packing. At reactor temperatures of 600°C (with samples in an inert atmosphere), about two-thirds of the nicotine is split mainly into myosmine (1′,2′-dehydronornicotine) and 3-vinylpyridine. At 700°C, nicotine is completely decomposed, with the major products being 3-vinylpyridine, 3-methylpyridine, and pyridine. At 800°C and 900°C, extensive cleavage and recombination of fragments occur to yield such products as quinoline, naphthalene, and benzonitrile. From examination of the pyrolysis products produced, dehydrogenation, demethylation, and scission of the pyrrolidine ring are initial steps in the pyrolysis of nicotine. In a C_1–C_2 fragmentation of this ring, dehydrogenation of the resulting *N*-methylaminoalkyl chain would give metanicotine which, on further elimination, produces the observed 3-(1,3-butadienyl)pyridine and subsequently 3-vinylpyridine by appropriate cleavage. Fragmentation of the pyrrolidine ring in the 2,3- or 1,5-positions might ultimately give 3-cyanopyridine after dealkylation of the side chain (3797).

The mechanism of thermal degradation of nornicotine is generally similar to nicotine, although differences in thermostability exist (175, 17B25). Nornicotine is less stable than nicotine and the pyrrolidine ring fragments at temperatures below 400°C. At 400°C (in an inert atmosphere), myosmine and 3-methylpyridine are major pyrolytic products, but at 500°C, only a small amount of myosmine is formed. Since myosmine is relatively stable (44% unchanged) on pyrolysis at 500°C, this compound may not be an intermediate of nornicotine pyrolysis at higher temperatures (175). An alternative explanation is that myosmine formed from nornicotine may react with other pyrolytic products which are not produced when myosmine is pyrolyzed alone. Although the available evidence is sparse, it appears that the pyrolytic mechanism of myosmine is different from that of nicotine and nornicotine (175). At 500°C (in an inert atmosphere), myosmine gives lower yields of 3-methylpyridine and 3-ethylpyridine and higher yields of 3-cyanopyridine than nornicotine. This pattern may indicate that a C_3–C_4 split is favored in the five-membered ring; scission of this bond might be preferred over a C_2–C_3 fragmentation adjacent to the relatively stable C═N bond (3797).

Studies with cigarettes treated with ^{14}C-nicotine have been valuable in determining the delivery of nicotine and its pyrolysis products to MSS and sidestream smoke (SSS). These experiments were reviewed in 1975 by Jenkins et al. (1933a). In a typical study with nicotine-2′-^{14}C, the total ^{14}C-activity in mainstream total particulate matter (TPM) was 15.4% of the original activity in the tobacco burned, while the contribution of the alkaloids to mainstream TPM was 14.9% (1836). Thus, 96.8% of the ^{14}C-activity of the mainstream TPM was due to transfer of alkaloids, and 3.2% was due to products formed from nicotine during smoking; mainstream gas phase (4.1%) contained only pyrolysis products. In the sidestream TPM, 41.1% of the original ^{14}C was detected, i.e., 10% of this material was decomposition products. Sidestream gas phase (16.3%) exclusively comprised pyrolysis products. Most of the remaining ^{14}C-activity (20.2%) was found in

the butt. Thus, approximately 30% of nicotine in a cigarette is converted to products which appear in the SSS and MSS. Pyrolysis studies on nicotine, discussed in the previous section, indicate that pyridines would comprise a significant portion of the particulate-phase products. However, nicotine can undergo other transformations during smoking, including reactions with nitrogen oxides (1580). These will be discussed in the chapter on nitrosamines.

Several studies have been conducted on the fate of nicotine during smoking. Jenkins and Comes (17B20) and Perfetti (2920–2922, 2924) have examined the fate of exogenous *vs*. endogenous transfer of nicotine during smoking. These authors concluded that the transfer into smoke of exogenous nicotine (regardless of its form [free base or salt, *d*- or *l*-conformation]) was similar to that of endogenous material, in contrast to observations with tobacco sterols. Thus, use of ^{14}C-nicotine in tracer studies on cigarette smoke is justified. A comparison of the fate of ^{14}C-nicotine in a pyrolysis study *vs*. its fate during the smoking of a cigarette resolved a long-standing disagreement between those investigators who maintained that the fate of compound on pyrolysis at a temperature similar to that in a burning cigarette was the same as the fate of that compound in a smoked cigarette and those who maintained that the fates would definitely be different. Schmeltz et al. (3512) with ^{14}C-nicotine in a pyrolysis *vs*. a cigarette smoking study reported that the fates were quite different. On the basis of their findings, they stated that these results suggest to us that pyrolysis experiments may be of limited value for establishing the fate of nicotine and possibly other tobacco components in a burning cigarette.

The transfer rate of nornicotine during smoking is significantly lower than that of nicotine, with typical values ranging from 5% to 8% [Glock and Wright (1316), Haag and Larson (17B14)]. When high nornicotine tobaccos were smoked, significant increases in the levels of myosmine were observed compared to conventional burley cigarettes. Similar results were obtained when cigarettes were enriched with nornicotine (1316). Thus, nornicotine is not only an efficient precursor for pyridines but also for myosmine as previously mentioned. This is thought to contribute to the unfavorable taste of smoke from nornicotine-rich (so-called cherry-red) tobacco. The ease of formation of myosmine from nornicotine is likely to be an important factor in its relatively low transfer rate.

The nicotine alkaloids contribute substantially to the unique flavor of tobacco smoke, mainly due to their rather large concentration in tobacco and their rather substantial transfer to tobacco smoke. The nicotine alkaloids as a class are not considered positive flavorants as they contribute a harsh, irritating flavor to the smoke. Nicotine and its contribution to smoking satisfaction are a subject unto itself that is fraught with numerous social and scientific controversies and will not be discussed here. It is well known that tobacco products that contain no or very low levels of nicotine (for numerous reasons) have never found consumer acceptance or commercial success.

17.2.5.2 Compounds in Tobacco and Tobacco Smoke with Two or More Six-Membered *N*-Containing Rings

In tobacco and tobacco smoke, the 76 identified compounds with two or more six-membered *N*-containing rings (Table 17.10) include 2,2′-bipiperidine, several bipyridines, anatabine-type compounds, anabasine-type compounds, anatalline, and nicotelline-type compounds. They are distributed as follows:

1. Over 50 bipyridines, the majority of which are derivatives of 2,3′-bipyridine plus several 2,2′-, 2,4′-, 3,3′-, and 4,4′-bipyridine derivatives.
2. Anatabine and anabasine derivatives which number 16 and 15, respectively.
3. Three compounds with two pyridine rings and a piperidine ring [anatalline [2,4-di(3-pyridinyl) piperidine] and anabasamine [5-(2-piperidinyl)-2,3′-bipyridine] plus its methyl derivative].
4. Two compounds with three pyridines, the so-called terpyridines, one of which is nicotelline (3,2′:4′,3″-terpyridine).
5. One bipiperidine compound has been identified in both tobacco and tobacco smoke (2,2′-bipiperidine).

Of the 76 compounds in this class, 66 have been identified in tobacco smoke, 33 in tobacco, and 23 in tobacco and tobacco smoke.

Figure 17.6 illustrates the structures of some of the common tobacco alkaloids found in tobacco and tobacco smoke with two or more six-membered *N*-containing rings.

Although nicotine is the principal alkaloid in commercial tobaccos (*Nicotiana tabacum* and *Nicotiana rustica*), nornicotine is the main alkaloid in most other species of *Nicotiana*. Anabasine is the third most abundant tobacco alkaloid. Anabasine is found in the stem of the (*Nicotiana glauca*) plant. Anatabine has been reported as a minor alkaloid in the roots of these plants, although it is present also in the leaf and stem (3491). All of the alkaloids in Figure 17.6, including bipiperidine, the bipyridines, anatabine, anabasine, anatalline, and nicotelline, can be biosynthesized from lysine and nicotinic acid in *Nicotiana* species to some extent depending on the species (429b, see KEGG, Alkaloid biosynthesis II - Reference pathway, EC-Number 1.1.1.206, Pathway 00960, see http://www.genome.jp/kegg/pathway/map/map00960.html).

Nicotelline (3,2′:4′,3″-terpyridine) is another minor alkaloid of tobacco initially isolated from tobacco by Kuffner and Kaiser (17B28). It was originally believed to be formed by the condensation of two molecules of nicotinoylacetic acid (17B31), although this compound could also result from the degradation of nicotine. However, feeding experiments of [2′-^{14}C]-nicotine or ethyl [carbonyl-^{14}C]-nicotinoyl acetate to tobacco (17B58) failed to yield labeled nicotelline. Currently, nicotelline and anatalline [2,4-di(3-pyridinyl)-piperidine] are considered to be formed by the trimerization of dihydropyridines from nicotinic acid (17B23). A similar reaction is proposed for the formation of the terpyridines.

Compounds in Tobacco, Tobacco Smoke, and Tobacco Substitute Smoke with a Six- and Five-Membered *N*-Containing Ring

			References		
	CAS No.	Name (per CA Collective Index)	Tobacco Smoke	Tobacco	Tobacco Substitute Smoke
31.	65-30-5	Pyridine, 3-(1-methyl-2-pyrrolidinyl)-, (S)-, sulfate (2:1) {Black Leaf 40}		3633, 3634, 3874c, 4249	
32.	6505-86-8	Pyridine, 3-(1-methyl-2-pyrrolidinyl)-, (S)-, sulfate {Black Leaf 40}		3633, 3634, 3874c, 4249	
33.	2820-55-5	Pyridine, 3-(1-methyl-2-pyrrolidinyl)-, 1-oxide, (S)- {nicotine-*N*-oxide}	353, 830a, 1702, 1890, 1891, 2128, 2224, 2228, 2349, 2482, 2724, 2939, 3031, 3302, 3308, 3386, 3444, 3491, 3505, 4249, 5079, 5348	120, 1114, 1223–1225, 1702, 1712, 2270, 2339a, 2349, 2724, 2914, 2917a, 2939, 3444, 3491, 3797, 3973, 3974, 3974a, 3983a, 4098a, 4249, 5079, 5390a, 5334, 5348, 5685, 5703, 5727, 5735, 5804, 5811b, 5828	
34.	2820-51-1	Pyridine, 3-(1-methyl-2-pyrrolidinyl)-, hydrochloride, (S)-		4249, 4849	
35.	16586-18-8	Pyridine, 3-(1-methyl-2-pyrrolidinyl)-, labeled with ^{14}C, (S)-		167, 1836, 1933a, 4249	
36.	25429-24-7	Pyridine, 3-(1-methyl-2-pyrrolidinyl)-, monohydroxy derivative, (S)-	568b, 3553, 3559, 4249	554, 568b, 3444, 4249	
37.	2055-29-0	Pyridine, 3-(1-methyl-2-pyrrolidinyl)-, *N*,1-dioxide, (S)-		568b, 4249, 4453, 5811b	
38.	491-26-9	Pyridine, 3-(1-methyl-2-pyrrolidinyl)-, *N*-oxide, (2S)-	568b, 1846b, 4249, 5811b	5811b	
39.	6912-85-2	Pyridine, 3-(1-methyl-2-pyrrolinyl)- {2,3-dehydronicotine} 	1195, 1316, 1567a, 1580, 1971, 2228, 2724, 3302, 3308, 3491, 3797, 3967, 4249	1221, 1567a, 4249	
40.	101540-79-8	Pyridine, 3-(1-methyl-2-pyrrolinyl)-6-methyl-		3547, 4249	
41.	487-19-4	Pyridine, 3-(1-methyl-1*H*-pyrrol-2-yl)- {nicotyrine} 	43, 172, 395, 438, 441, 442, 568b, 761, 922, 1225, 1375, 1375b, 1427, 1567a, 1580, 1586, 1702, 1890, 1891, 2079, 2170, 2224, 2228, 2327c, 2470, 2493, 2543, 2570, 2601a, 2724, 2761, 2762, 2765–2767, 2773, 2775, 2777, 2939, 3056, 3059, 3255, 3302, 3308, 3386, 3397, 3398, 3410, 3444, 3491, 3553, 3557, 3559, 3739–3742, 3797, 3967, 3972, 4202, 4210, 4249, 4407, 5079, 5811b	120, 404, 504, 543a, 568b, 689, 937, 984, 1063–1066, 1068–1074, 1113, 1114, 1221, 1567a, 1580, 1590a, 1702, 1854, 2079, 2224, 2270, 2338, 2339a, 2349, 2359, 2386, 2724, 2917a, 2939, 3056, 3059, 3444, 3491, 3511, 3549, 3550, 3797, 3905, 3972, 3974, 4098a, 4249, 5079, 5390a, 5330, 5407, 5454, 5464, 5465, 5582. 5685, 5735, 5811b, 5905

TABLE 17.10
Distribution of Components with Two or More Six-Membered *N*-Containing Rings between Tobacco and Tobacco Smoke

Component	Number of Identified Compounds in Tobacco and Tobacco Smoke with Two Six-Membered *N*-Containing Rings			
	Total	Smoke	Tobacco	Smoke and Tobacco
Compounds with two or more six-membered *N*-containing rings (type)				
Piperidine + piperidine	1	0	1	0
Pyridine + piperidine (anabasine type)	15	11	8	4
Pyridine + pyridine (bipyridines)	39	38	8	7
Pyridine + di- or tetrahydropyridine (anatabine type)	16	12	9	5
Two pyridines + piperidine	3	1	3	1
Three pyridines	2	2	2	2
Totals	76	64	31	19

These alkaloids are possibly artifacts produced by nonenzymatic reactions which could occur during the harvesting and curing of tobacco. The lack of optical activity in the isolated anatalline supports this hypothesis (17B31).

Various bipyridines are also formed during tobacco fermentation [Frankenburg and Gottscho (1223)]. As much as 3% of the nicotine originally present in cigar tobacco was converted to 2,3′-bipyidine and other oxidative compounds (3973).

One study by Dubinin and Chelintsev (1075a) reported on the pyrolytic products of anabasine heated at 580°C–650°C in a charcoal-filled reactor. Exclusive of gases, the major products were reported to be pyridine, 2-methylpyridine, 2-ethylpyridine, 5-methylisoquinoline, and 2,3′-bipyridine. The preponderance of the 2-alkylpyridines might indicate preferential cleavage of the pyridine ring which would be unexpected; evaluation of these findings is difficult since the use of charcoal in the reactor may have produced a catalytic effect and altered the pyrolytic reactions markedly (3797).

In terms of the flavor potential of this class of compounds, very little is known. A minor tobacco alkaloid, 2,3′-bipyridine, has been reported (17B19) to exhibit a sensitizing effect on tobacco flavor and to suppress astringency (3215, 17B52).

Table 17.11 lists the compounds containing two or more six-membered *N*-containing rings identified in tobacco and tobacco smoke.

Detailed examination of the lists presented in this chapter on monocyclic nitrogen heterocycles indicates many such compounds have been identified to date in tobacco and tobacco smoke. Some of the data are summarized in Table 17.12.

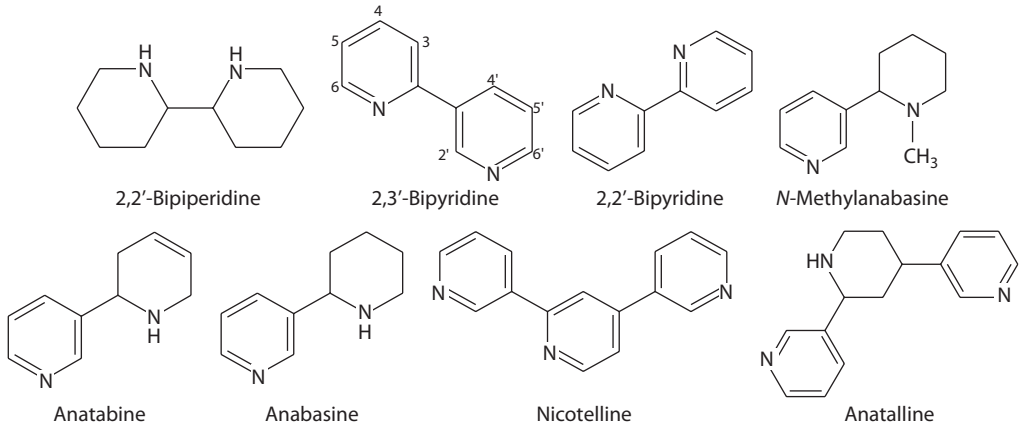

FIGURE 17.6 Common tobacco alkaloids found in tobacco and tobacco smoke with two or more six-membered *N*-containing rings.

It is obvious from the tabulation that the six-membered *N*-containing ring compounds with one or more nitrogens represent nearly 75% of the compounds identified to date.

17.3 LACTAMS

Kosak (2170) listed no lactam identified in tobacco smoke prior to 1954. In 1959, Johnstone and Plimmer (1971) listed cotinine as an alkaloid in tobacco and smoke. They did not categorize it or any other tobacco or smoke component as a lactam.

In its 1963 monograph on tobacco and smoke components, Philip Morris (2939) listed cotinine as a tobacco and smoke component. Ishiguro and Sugawara (1884) in their 1980 monograph on tobacco smoke components listed a total of 72 amides, imides, and lactams; a total of 16 lactams was listed [see Table I-15 in (1884)]. The reference for all of the 16 lactams listed was that of Schumacher et al. (3553).

The International Agency for Research on Cancer (IARC) working group met in 1985 to assess the carcinogenic risk from tobacco smoking. Its monograph summarizing the IARC findings was published in 1986. In it, the IARC stated that there was a large spectrum of amides, imides, and lactams in tobacco smoke (including some 50 aliphatic amides) [see p. 109 in (1870)]. The IARC view on these three compound classes was based on the 1977 review by Schmeltz and Hoffmann (3491) and publications in 1977 and 1981 by Schumacher et al. (3553) and Heckman and Best (1587), respectively.

Of the 35 lactams reported in tobacco smoke by Schumacher et al. (3553) at the 1975 *Tobacco Chemists' Research Conference (TCRC)* and published in 1977, 21 were new to the tobacco smoke literature. As noted in Chapters 13 and 14, used in this study was a recently developed analytical technology that permitted fractionation and identification of the water-soluble components of cigarette smoke condensate (CSC). Similarly in their 1978 TCRC presentation and 1981 publication, Heckman and Best (1587) reported the identification of two additional new lactams in tobacco smoke, 3-ethyl-5-methylene-3-pyrrolid-2-one and *N*-methyl-5-(1-methylethylidene)-3-pyrrolid-2-one. They also confirmed the presence in tobacco smoke of many of the lactams previously reported (3553). In his earlier study of the mainstream smoke from an all-burley tobacco cigarette, Heckman (1986) identified eight lactams.

Lactams frequently reported in both tobacco and its smoke but seldom classified as lactams are 1-methyl-5-(3-pyridinyl)-2-pyrrolidinone (cotinine) and several of its derivatives such as norcotinine. Ishiguro and Sugawara (1884) listed them as alkaloids [see Table I-12 in (1884)] not lactams.

Examination of the structures of several of the CSC components indicates that the decision of their categorization is somewhat difficult. In Figure 17.7, representative structures for an imide and a lactam are presented. To which of these categories—imide or lactam—should the smoke component 1,7-dihydro-6*H*-purine-2,6-dione (xanthene) {I} be assigned? Its structure {I} is depicted in Figure 17.8. In structure {II} in Figure 17.8, its imide configuration is accentuated. Structure {III} illustrates that two lactam configurations exist in the xanthene molecule. This same situation is present with the other purine-derived smoke components. While there may be some disagreement of the preciseness of our selection, for completeness sake, such components are listed in each chapter in its major catalog table. As a result, the total number of components in each of the major catalog tables may be slightly inflated.

Table 17.13 lists a total of 138 lactams identified in tobacco and/or tobacco smoke. Of the 138, 58 were identified in tobacco, 116 were identified in tobacco smoke, and 36 were identified in both tobacco and tobacco smoke.

17.4 OXAZOLES AND OXAZINES

Several oxazoles and oxazines have been identified in tobacco and tobacco smoke. Oxazoles are generally known as 1,3-azoles or five-membered-ring aromatic heterocyclic compounds with an oxygen and a nitrogen separated by one carbon. Oxazole is the parent compound. Isoxazoles are in this same family of compounds and are generally known as 1,2-azoles. These five-membered-ring aromatic heterocyclic compounds contain adjacent oxygen and nitrogen atoms. Oxazole is an analog of imidazole where the nitrogen atom in position 1 is replaced by oxygen. Isoxazole is an analog

of pyrazole, i.e., the nitrogen atom at position 1 is replaced by oxygen [Gilchrist (17D01)]. Oxazolidine and isoxazolidine are the reduced forms of oxazole and isoxazole, respectively. Several oxazolidine and isoxazolidine derivatives, e.g., oxazolidinediones and isoxazolidinones, have also been identified in tobacco and tobacco smoke. One other component identified in tobacco is related to the oxazoles and isoxazole. It is an oxadiazole derivative, *N*-(4-bromophenyl)-5-(1-naphthalenylmethyl)-1,3,4-oxadiazol-2-amine.

Benzoxazole is a heterocyclic aromatic organic compound with a fused benzene–oxazole ring structure. Benzoxazole (1-oxa-3-azaindene) and several alkylated benzoxazoles have been identified in tobacco smoke. Benzoxazoles found in tobacco smoke are believed to arise by the mutual condensation of the oxazole and benzene rings during the combustion/pyrolysis of tobacco (1884). The only substituted benzoxazole known in tobacco is residue from the organophosphate insecticide Phosalone®.

Oxazines are six-membered-ring analogs of piperazine where the nitrogen atom in position 4 is replaced by an oxygen atom. The oxazines in tobacco and tobacco smoke are morpholine and several morpholine derivatives. The most discussed morpholine recently is *N*-nitrosomorpholine (NMOR). This volatile *N*-nitrosamine (NMOR) has been identified in both tobacco and in tobacco smoke. Morpholine is an organic heterocycle that features both amine and ether functional groups. Morpholine is also called tetrahydro-1,4-oxazine. Figure 17.9 illustrates the parent structures of the oxazoles and oxazines identified in tobacco and tobacco smoke.

Numerous reviews have been written on the compounds identified in tobacco and/or tobacco smoke over the last five

decades (1884, 1900, 1971, 2170, 2270, 2939, 3224, 3797). Few have listed the oxazole- and oxazine-related compounds identified in tobacco and tobacco smoke. Latimer (2270) in 1955 listed 231 compounds identified from tobacco and tobacco smoke. In his review, he listed tetrahydro-2-methyl-6-(3-pyridyl)-1,2-oxazine, a tobacco alkaloid, as the first oxazine identified in tobacco smoke. Roberts et al. in 1975 (3224) listed 2783 compounds identified in tobacco and tobacco smoke. In their report, five oxazole-related compounds identified in tobacco smoke were listed (2,4-dimethylbenzoxazole, 2-methylbenzoxazole, oxazolidinedione, 5-ethyl-*N*-methyl-2,4-oxazolidinedione, and 5-methyl-2,4-oxazolidinedione). Roberts et al. did not report any oxazole- or oxazine-related compounds found in tobacco. In 1980, Ishiguro and Sugawara (1884) listed 1889 identified tobacco smoke components in their monograph; only six oxazole-related compounds were listed (dimethyloxazole, 5-methyl-2,4-oxazolidinedione, 2,4-oxazolidinedione, 3,4,5-trimethylisoxazole, 2-methylbenzoxazole, and 2,5-dimethylbenzoxazole). The citations by Ishiguro and Sugawara for all but the dimethyloxazole were to the Schumacher et al. (3553) and Newell et al. (2769) reports on tobacco smoke composition. Roberts in 1988

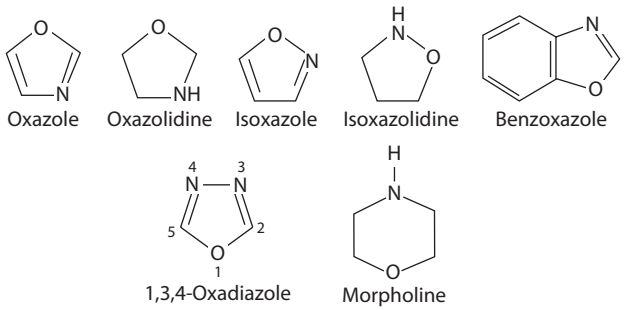

FIGURE 17.9 Parent structures of the oxazoles and oxazines identified in tobacco and tobacco smoke.

(3215) tabulated 5868 identified compounds in tobacco and tobacco smoke. By functional groups, 3044 compounds had been identified in tobacco, 3996 had been identified in smoke, and 1172 were identified in both tobacco and tobacco smoke. A large portion of the oxazole- and oxazine-related compounds in tobacco and tobacco smoke was originally identified by employees at the Research and Development Department of R.J. Reynolds Tobacco Company (RJRT) who were highly proficient in the isolation and identification of compounds in tobacco and tobacco smoke. From 1955 until 1988, they reported on 19 (of the 44) oxazole- and oxazine-related compounds in smoke and 6 (of the 14) oxazole- and oxazine-related compounds in burley, Maryland, flue-cured, Oriental, and Perique tobaccos (965, 1075, 1360, 1364, 1375a, 1586, 1587, 1590, 2270, 2337, 2339a 2761, 2762, 2765, 2766, 2767, 2769, 2775, 2777, 3547, 3549, 3550, 3553, 3557). Demole (4570a) at Firmenich [Geneva (Switzerland)], under contract to RJRT, identified 25 additional oxazoles in cigarette smoke condensate.

Oxazole- and oxazine-related compounds do not appear to be endogenous in green tobacco but are found in tobaccos that undergo heat treatments during curing and tobacco processing (965, 1590, 2337, 2339c, 2359). Additionally, it is known that in certain biomolecules, oxazoles can result from the cyclization and oxidation of serine or threonine nonribosomal peptides (17D02). Whether similar reactions occur in tobacco is not known. The Maillard or nonenzymatic browning reaction has generated much interest over the past 70 years [Nagodawithana (17D07)]. The Maillard reaction mainly involves the reaction of free amino groups of amino acids and reducing sugars (17D07). The principal chemistry of this reaction was reviewed by Hodge in 1953 (17D03). The aromas in most thermally processed foods, such as bread, cereal products, roasted peanuts, and roasted coffee, are generated during Maillard reactions [Maga (17D05, 17D06)]. Numerous heterocyclic compounds arising from the Maillard reaction have been identified in food and model systems. These heterocycles include furans, thiazoles, thiophenes, oxazoles, pyrroles, pyridines, and pyrazines (17D07). Several mechanisms have been proposed for the formation of oxazole- and oxazine-related compounds in food flavors, including the Strecker degradation (17D04). For example, hydroxy acid amides can react with acetone to produce oxazoles. Similar reaction products from the Maillard reaction and Strecker degradation are known in tobacco (965, 1590, 2337, 2339c, 2359).

Maga (17D06) has reviewed the occurrence of oxazoles and oxazolines in a variety of processed food systems. Most of them possess green, sweet, and nutty aroma qualities and have been identified in coffee, soy sauce, wheat, and cooked beef, and some of them have very low odor thresholds. In 1976, Leffingwell discussed how certain flavorants (reaction products) can be produced in tobacco and tobacco smoke (2337): "Because of the complexity of the chemical interactions and transformations involved, the types and ratios of active flavor products formed by nonenzymatic browning are dependent on the reaction conditions which may occur during aging or during the smoking process itself."

One of the flavorants discussed by Leffingwell (2337) that was identified in tobacco by Lloyd et al. (2389) was 3,4-dihydro-3-oxo-4-(phenylmethyl)-1*H*-pyrrolo[2,1-*c*][1,4]oxazine-6-carboxaldehyde. This particular tobacco flavor has a hot peppery characteristic (2337). Leffingwell and Alford (2339a) and Li et al. (2359) have reported that 2,4,5-trimethyloxazole has a boiled beef, nutty, sweet, and green flavor in Perique and burley tobacco, respectively. The application of oxazole- and oxazine-related flavor compounds to tobacco is not normally undertaken because the flavor and aroma characteristics of these compounds are rather weak. No oxazole- or oxazine-related compound was included in either the Doull et al. list (1053) of individual flavor compounds used by one or more of the U.S. cigarette manufacturers or individual flavor compounds used outside the United States [see Tables 1 and 7A in (3266)].

Agrochemical residues containing an oxazole-related functionality that have been found on tobacco include Clomazone®, a broad spectrum herbicide; Phosalone, an organophosphate commonly used as an insecticide; and Vinclozolin®, a common fungicide. Dimethomorph® or Acrobat® is a common fungicide used on tobacco that contains morpholine functionality.

Analytical measurements for the determination and quantification of oxazole- and oxazine-related compounds in tobacco and tobacco smoke include gas chromatography (GC) with packed or capillary columns, high-performance liquid chromatography (HPLC) usually with reverse phase (RP) columns, and mass spectrometry (MS) methods (GC-MS and LC-MS).

Table 17.14 lists the distribution of oxazole- and oxazine-related compounds identified in tobacco and tobacco smoke. A total of 63 compounds have been identified: 9 are benzoxazole derivatives, 4 are isoxazole derivatives, 30 are oxazole derivatives, 4 are oxazolidine derivatives, and 9 are morpholine derivatives. Fifteen of the compounds are found in tobacco, 51 are found in tobacco smoke, and only 3 have been reported in both tobacco and tobacco smoke. Table 17.15 lists the 63 oxazole- and oxazine-related compounds identified in tobacco and/or tobacco smoke.

Benzoxazole	9	8	1	0	1
Isoxazole	5	2	3	0	1
Oxazole	35	34	2	1	0
Oxazolidine	5	4	1	0	1
Morpholine	9	3	8	2	1
Total	63	51	15	3	4

17.5 AZA-ARENES

An aza-arene was defined as a fused-ring compound with two or more fused rings and consisting only of carbon, hydrogen, and nitrogen. Alkyl-substituted derivatives were also included in the aza-arene category. Overall, many of the aza-arenes are structurally comparable to the polycyclic aromatic hydrocarbons (PAHs) but include at least one nitrogen in the ring. In his early 1954 compilation of reported tobacco smoke components, Kosak (2170) listed no fused-ring polycyclic nitrogen compounds in tobacco smoke, the class of compounds subsequently termed the aza-arenes. Five years later, the only fused-ring *N*-heterocyclic compound listed by Johnstone and Plimmer (1971) as a tobacco smoke component was the bicyclic compound quinoline. Except for the replacement of a –CH═ linkage with a nitrogen (–N═) at the 1 position, quinoline is structurally similar to the PAH naphthalene (Figure 17.10). However, the reference cited by Johnstone and Plimmer was to the 1929 study by Gabelya and Kipriyanov (1263) who described the identification of quinoline in a "destructive distillate" of tobacco not in a sample of tobacco smoke prepared by a tobacco smoking procedure. A similar identification of benzo[*a*]pyrene (B[*a*]P) in the destructive distillate of tobacco by Roffo (3323, 3325) was criticized by Wynder and Hoffmann (4319, 4332) who asserted that a tobacco destructive distillate was not tobacco smoke.

In 1960, Van Duuren et al. (4027), in an extension of their studies on the tumorigenic PAHs in mainstream cigarette smoke condensate (CSC), described their findings on tumorigenic *N*-heterocyclic compounds in the CSC. They reported the identification of dibenz[*a,h*]acridine {I}, dibenz[*a,j*]acridine {II}, and 7*H*-dibenzo[*c,g*]carbazole {III} (Figure 17.11) in CSC at per cigarette levels of 0.1, 2.7, and 0.7 ng, respectively. These levels were substantially less than that of the reported per cigarette yield of B[*a*]P in the late 1950s or early 1960s. Similar to the situation noted earlier that quinoline is a nitrogen analog of naphthalene, dibenz[*a,h*]acridine {I} is a nitrogen analog of dibenz[*a,h*]anthracene (DB[*a,h*]A) {IV}. These two compounds are dimensionally similar. Over five decades ago, these three *N*-heterocyclics had been reported as tumorigenic to mouse skin [cf. summary by Hartwell (1544)]. Two of these compounds, dibenz[*a,h*]acridine and dibenz[*a,j*]acridine, were also reported by Van Duuren et al. to be present in the pyrolysates (750°C, nitrogen atmosphere) from both nicotine and pyridine.

Contradictory findings have been reported on the presence or absence of these three *N*-heterocyclic compounds; e.g., Wynder and Hoffmann (4319, 4332) reported that members of their research group—Candeli et al. (587)—were able to confirm the presence of dibenz[*a,j*]acridine but not dibenz[*a,h*]acridine in mainstream CSC. The per cigarette yield of dibenz[*a,j*]acridine reported by Candeli et al. was significantly greater than that reported by Van Duuren et al. (4027) [cf. 10.0 ng/cig *vs.* 2.7 ng/cig]. Other than brief mentions by Wynder and Hoffmann (4319, 4332) of the results obtained by Candeli et al. (587) on dibenz[*a,j*]acridine in CSC, the experimental procedures involved in its identification do not appear to have been published in the usual way in a peer-reviewed journal. At a mainstream smoke (MSS) yield for dibenz[*a,j*]acridine of 2.7 or 10.0 ng/cig as reported by Van Duuren et al. and Candeli et al., respectively, it is difficult to understand why no confirmation of the presence of this aza-arene has been reported by highly competent investigators from the early 1960s through the mid-1990s! Similarly, no confirmations of the presence of dibenz[*a,h*]acridine or 7*H*-dibenzo[*c,g*]carbazole have been presented to date. Studies on these and other aza-arenes in cigarette MSS or nicotine pyrolysates are described briefly in the following paragraphs. The question remains as follows: Was the preliminary isolation procedure (vacuum distillation of the smoke condensate at 100°C, 0.5 mm pressure) used by Van Duuren et al. (4027) responsible for the formation of the dibenzacridines and the dibenzocarbazole?

In 1970, Kaburaki et al. (2006) reported the results of their detailed study of the pyrolysis of nicotine at various temperatures in air and in an inert atmosphere (nitrogen). They did not report the identification of the two tumorigenic benzacridines reported previously by Van Duuren et al. (4027) as identified components in their nicotine pyrolysates.

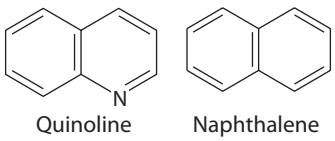

FIGURE 17.10 Quinoline and naphthalene.

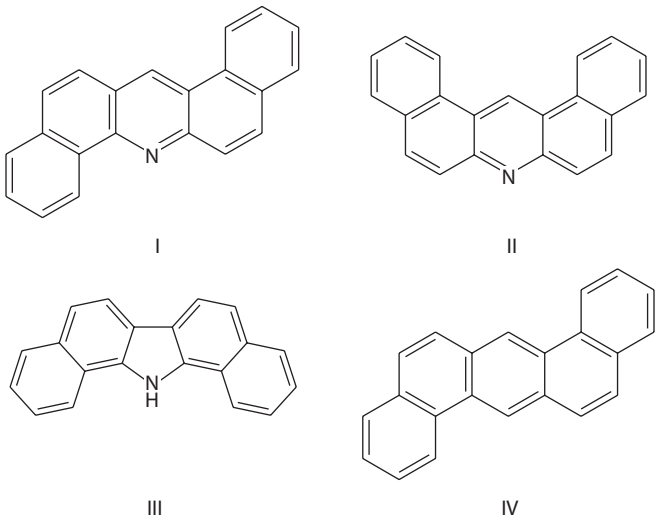

FIGURE 17.11 Some polycyclic components of tobacco smoke.

From their study of the pyrolysis of several nitrogenous components of tobacco, including nicotine, Schmeltz et al. (3499) reported:

> We could not detect benzo(a)pyrene in nicotine pyrolyzates, nor could we confirm the presence of the physiologically active dibenzacridines and dibenzcarbazole [sic] reported in tobacco smoke and in nicotine and pyridine pyrolyzates by Van Duuren [4027].

In their review of the pyrogenesis of tobacco smoke components, Chortyk and Schlotzhauer (722) emphasized these reported findings, i.e., the failures of several groups of investigators to confirm the presence of the two dibenzacridines and the 7*H*-dibenzo[*c*,*g*]carbazole in nicotine pyrolysates. They wrote:

> Since nicotine is the most abundant and best known tobacco alkaloid, its pyrolysis has been thoroughly studied [Woodward et al. (4275a), Jarboe and Rosene (1923a)]. More recent work [Kaburaki et al. (2006)] on the pyrolysis of nicotine and various alkyl-pyridines has resulted in a proposed mechanism for the thermal degradation of nicotine…Schmeltz [Schmeltz et al. (3499)] also studied nicotine and identified a number of previously unreported compounds in the nicotine pyrolysates… These included pyrrole, acenaphthene, indole, skatole, and anthracene and/or phenanthrene. However, the presence of dibenzacridines and dibenzcarbazole, previously reported in nicotine and pyridine pyrolysates, could not be confirmed [Van Duuren et al. (4027)].

Schmeltz and Hoffmann (3491) in their review of the *N*-containing components of tobacco and tobacco smoke discussed the generation of various pyridines from nicotine during both the actual smoking process and pyrolysis. Schmeltz and Hoffmann did report the identification by Van Duuren et al. (4027) of the two dibenzacridines in cigarette smoke and nicotine pyrolysate. They did not, however, comment on the reports issued between 1960 and 1977 of the inability of several other groups of investigators [Candeli et al. (587), Kaburaki et al. (2006), Schmeltz et al. (3499)] to confirm the 1960 findings of Van Duuren et al. (4027).

In 1979, Schmeltz et al. (3512) reported their results from an elaborate study on the fate of radiolabeled nicotine during pyrolysis and during the actual smoking of a radiolabeled nicotine-treated cigarette. Their major findings included the following: (1) Under combustion–tube pyrolysis conditions, nicotine in either silica gel matrix (pyrolysis temperatures at 600°C, 750°C, or 900°C) or tobacco matrix (pyrolysis temperature at 600°C) underwent extensive degradation to a mixture of pyridines, quinolines, arylnitriles, and aromatic hydrocarbons. (2) In a burning cigarette during actual smoking, a substantial portion of the nicotine (about 41%) remains intact, 12.5% is oxidized to carbon dioxide, as much as 11% is degraded to volatile alkylpyridines, and negligible amounts are converted to neutral or acidic components of the particulate phase. (3) Dibenz[*a,h*]acridine and dibenz[*a,j*]acridine reported nearly two decades earlier by Van Duuren et al. (4027) were not identified in this study by Schmeltz et al. (3512). They noted:

> In ongoing studies* we are now identifying those compounds that are formed from nicotine only as minor compounds (<0.1%) which nevertheless can contribute to the toxicity of the smoke. To this group of minor smoke constituents having nicotine as a precursor belong the dibenzacridines [Van Duuren et al. (4027)]…

(4) From the experimental results, the authors reached the following conclusion: "Pyrolysis experiments may be of limited value for establishing the fate of nicotine and possibly other tobacco components in a burning cigarette." (5) The pyrolysis system used in this study [cf. Higman et al. (1648)] was designed, according to Higman et al., to be the optimum simulation of the smoking process. Obviously, nicotine did not behave in this pyrolysis system as it did in the burning cigarette during actual smoking.

Critical examination of the text and the conclusions expressed in the 1979 Schmeltz et al. publication on the fate of nicotine during pyrolysis and during actual smoking reveals that at least two of the authors (Hoffmann, Schmeltz) have definitely changed their opinion with regard to their long-held view on the supposed equivalence of compound behavior during pyrolysis and actual smoking; e.g., Wynder and Hoffmann (4332) earlier wrote in support of this equivalence:

> Most pyrolysis studies with tobacco, tobacco extracts, extract fractions, individual components, and tobacco additives are performed in a nitrogen atmosphere. This procedure has often been criticized on the grounds that many of the toxic constituents formed during smoking of tobacco products occur as a result of combustion in air rather than in a nitrogen atmosphere. This criticism, however, cannot be maintained in view of studies by Newsome and Keith [2780] which demonstrated that a reducing rather than an oxidizing atmosphere exists at the cone region of a burning cigarette.

With regard to the dibenzacridines and the dibenzocarbazole from nicotine during pyrolysis and the smoking process, Table 17.16 summarizes the current state of knowledge.

For example, authors of numerous articles in the 1980s [Hoffmann and Wynder (1808)], in the 1990s [Hoffmann and Hecht (1727), Hoffmann et al. (1773), Occupational Safety and Health Administration (OSHA) (2825), Hoffmann and Hoffmann (1740, 1741)], and in the 2000s [Hoffmann and Hoffmann (1743), Hoffmann et al. (1744), and Fowles and Bates (1217)] on the toxicants in tobacco and tobacco smoke repeatedly listed dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole as tumorigenic or adversely biologically active MSS components despite the following: (1) The presence of these three aza-arenes in MSS had not been confirmed in several investigations conducted between 1963 and 1990 (3260). (2) Between 1990 and 2000, additional studies failed to confirm their presence in MSS (2021, 3414). (3) Several summaries of the attempts to confirm the findings of Van Duuren et al. have been published (172, 3260, 3265). In 2002, Rustemeier et al. (3370) did report the presence of dibenz[*a,j*]acridine in the MSSs from several ingredient-treated cigarettes. All yields were reported as less than 2.72 ng/cig. It might have been appropriate in view of the Rustemeier et al. to have provided more meaningful information on its presence.

Other tumorigens in cigarette MSS, including several the presence of which was and is suspect, have been listed since the early 1960s.

In 1960, Mold et al. (2592) reported the isolation and identification of the tricyclic *N*-heterocyclic 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) {V} (Figure 17.12) from CSC and demonstrated its relationship to its precursor in tobacco, the amino acid proline. Obviously, pyrocoll is not an aza-arene but an amide. Rodgman and Cook (3279) reported the identification of indole, carbazole, and several alkylated indoles and carbazoles in CSC and confirmed the presence of 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) {V} described previously by Mold et al. (2592). Rodgman and Cook also assessed previously reported biological studies on indole, 3-methylindole (skatole), and carbazole: none was reported to be tumorigenic in laboratory animals [Hartwell (1544), Shubik and Hartwell (3664)].

Poindexter and Carpenter (2972) identified 9*H*-pyrido [3,4-*b*]indole (norharman) {VI} and 1-methyl-9*H*-pyrido [3,4-*b*] indole (harman) {VII} (Figure 17.12) isolated from CSC.

* No report of the confirmation of the presence of the dibenzacridines (or the dibenzocarbazole) as a result of these ongoing studies has been found to date.

TABLE 17.16
Dibenz[*a,h*]acridine {I}, Dibenz[*a,j*]acridine {II}, and 7*H*-Dibenzo[*c,g*]carbazole {III} in Nicotine Pyrolysates (Pyr) and Mainstream CSC

	Dibenz[*a,h*]acridine		Dibenz[*a,j*]acridine		7*H*-Dibenzo[*c,g*]carbazole	
Investigators	**Pyr**	**CSC**	**Pyr**	**CSC**	**Pyr**	**CSC**
Van Duuren et al. (4027)	Yes	Yes	Yes	Yes	No	Yes
Candeli et al. (587); Wynder and Hoffmann (4319, 4332)	NE	No	NE	Yes	NE	NE
Kaburaki et al. (2006)	No	NE	No	NE	NE	NE
Schmeltz et al. (3499)	No	NE	No	NE	No	NE
Schmeltz et al. (3512)	No	No	No	No	No	No
Snook (3733)	NE	No	NE	No	NE	No
Snook et al. (3750)	NE	No	NE	No	NE	No
Grimmer et al. (1409)	NE	No	NE	No	NE	No
Kamata et al. (2021)	NE	No	NE	No	NE	NE
Sasaki and Moldoveanu (3414)	NE	No	NE	No	NE	NE
Rustemeier et al. (3370)	NE	No	NE	Yes	NE	NE

Yes, compound identified; No, compound not found or identified; NE, substrate not examined for compound in question.

Examination of these results indicates that Van Duuren et al. (4027) reported the identification of the three *N*-heterocyclic compounds {I, II, and III} in MS CSC and two of them {I and II} in a nicotine pyrolysate, whereas Candeli et al. (587) failed to identify {I} but did identify {II} in MS CSC. The 1963 Candeli et al. findings on {II} in MS CSC were not confirmed in 1979 by investigators (3512) from the same laboratory: Hoffmann participated in both the 1963 and 1979 studies. Two studies (3499, 3512) confirmed the 1960 report by Van Duuren et al. that 7*H*-dibenzo[*c,g*]carbazole {III} was not present in a nicotine pyrolysate.

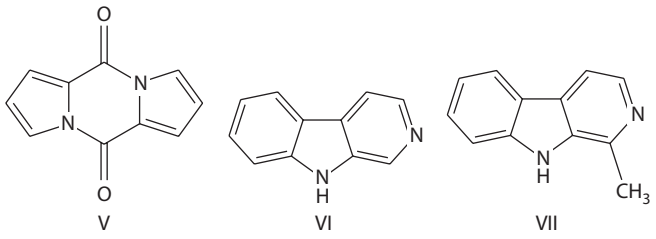

FIGURE 17.12 Some amino-acid-derived *N*-heterocyclics identified in tobacco smoke.

They reported the yield of the total harmans in burley and flue-cured smokes to be between 15 and 20 µg/g of tobacco smoked, values 40–50 times that of the total harmans in the unsmoked tobaccos. Since the weight of tobacco in cigarettes sold at that time approximated 1 g, the delivery of these two compounds was about 15–20 µg/cig. They concluded from experiments with radiolabeled tryptophan that the harmans (found to be radiolabeled in the smoke) were generated pyrogenetically from a reaction between aldehydes (formaldehyde for norharman, acetaldehyde for harman) and the tryptophan in tobacco. Schmeltz et al. (3505) reported 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) {V}, 9*H*-pyrido[3,4-*b*]indole (norharman) {VI}, and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) {VII} in tobacco smoke. Testa and Testa (3886, 3887) also confirmed the presence of 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) in CSC.

In 1964, the Advisory Committee to the U.S. Surgeon General (3999) briefly discussed only four fused-ring *N*-heterocyclic compounds in tobacco smoke: quinoline plus the two dibenzacridines (dibenz[*a,h*]acridine, dibenz[*a,j*]acridine) and the dibenzocarbazole (7*H*-dibenzo[*c,g*]carbazole) reported by Van Duuren et al. (4027).

In his 1968 review of tobacco and tobacco smoke composition, Stedman (3797) discussed the identification of tumorigenic *N*-heterocyclic compounds [dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, 7*H*-dibenzo[*c,g*]carbazole] reported by Van Duuren et al. (4027) as well as the identification of the following *N*-heterocyclic compounds: 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), 9*H*-pyrido[3,4-*b*]indole (norharman), 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman), and 9*H*-pyrido[2,3-*b*]indole.

In his early 1970s outline of recent research on tobacco and tobacco smoke composition, Wakeham (4103) noted the reported presence of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) in cigarette smoke and discussed their possible formation by reaction of tryptophan and an aldehyde. As noted by Rodgman (3253a), the structure of the aldehyde reacting with tryptophan ultimately dictates the structure of alkylated norharmans found in CSC (see Table 17.17).

In addition to 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), Izard et al. (1899) reported the identification of its homolog methyl-5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (methylpyrocoll) in CSC.

During a presentation at the 1975 TCRC and in a 1977 publication on their study of the water-soluble portion of CSC, Schumacher et al. (3553) reported the identifications of 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman), 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), octahydro-5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (octahydropyrocoll), and 2-ethyl-9*H*-pyrido[2,3-*b*]indole.

TABLE 17.17
Chronology of Selected Aza-Arenes: Dibenz[*a,h*]acridine, Dibenz[*a,j*]acridine, 7*H*-Dibenzo[*c,g*]carbazole, Quinoline

Year	Event
1929	Gabelya and Kipriyanov (1263) reported the identification of quinoline in a destructive distillate from tobacco. Destructive distillation of tobacco is not considered to be equivalent to the tobacco smoking process [see comments by Wynder and Hoffmann (4319, 4332)]
1935	Barry et al. (194) (members of the Kennaway group in the United Kingdom) compared the tumorigenicity of dibenz[*a,h*]anthracene (DB[*a,h*]A) with that of heterocyclic compounds in which one or both of the *meso*-carbons were replaced by nitrogen. The aza-arene dibenz[*a,h*]acridine was found to be less tumorigenic (mouse skin) than its PAH counterpart DB[*a,h*]A. They also reported that the tumorigenicity of dibenz[*a,j*]acridine was less than that of dibenz[*c,h*]acridine
1937	In the first reported investigation of the tumorigenicity of 7*H*-dibenzo[*c,g*]carbazole, Boyland and Brues (421a) reported that mice skin painted with it developed carcinomas at the painting site
1937	Bachmann et al. (137a) reported that dibenz[*a,j*]acridine injected subcutaneously induced sarcomas in mice; i.e., dibenz[*a,j*]acridine was sarcogenic. Its sarcogenicity was relatively weak compared to that noted for similarly injected PAHs
1940	Badger et al. (140) reported that oral administration to 10 mice of 5 mg/week/mouse of dibenz[a,h]acridine resulted in one mouse with an epithelioma and papilloma of the forestomach; another mouse showed stomach papillomas. Duration of the experiment was 627 days Similar administration of dibenz[a,j]acridine (10 mice, 5 mg/week/mouse) gave no tumors in 572 days. In their introduction, the authors stated: "There is now little doubt that cigarette smoking is the major factor concerned with the ever-increasing incidence of bronchogenic carcinoma in men. Both cigarette-tobacco tars and particulates from air pollution contain various carcinogenic polynuclear compounds"
1940	In their study of the response of the lungs of strain A[a] mice to various compounds, Andervont and Shimkin (79) demonstrated that 20 of 20 strain A mice given a single injection of 0.5 mg of dibenz[*a,h*]acridine in 0.1 mL of tricaprylin developed multiple adenomas in 14 weeks but no sarcomas at the injection site. All 14 mice administered a single injection of 1 mg of dibenz[*a,h*]acridine in 0.3 mL of sesame oil developed multiple adenomas in 40 weeks but no sarcomas at injection site. Andervont and Shimkin also compared the response of the lungs of strain A mice to a single intravenous injection of 0.25 mg of each of nine compounds dispersed in 0.25 mL of water. Among the nine compounds were DB[*a,h*]A, B[*a*]P, benz[*a*]anthracene (B[*a*]A), dibenz[*a,h*]acridine, and 7*H*-dibenzo[*c,g*]carbazole. A calculated "carcinogenic index" [% tumor-bearing animals *x* mean number of adenomas in animals showing a positive response for each of these compounds at 8, 14, and 20 weeks] gave the following sequence: DB[*a,h*]A > 7*H*-dibenzo[*c,g*]carbazole > B[*a*]P > dibenz[*a,h*]acridine > B[*a*]A
1946	Dubinin and Chelintsev (1075a) reported quinoline, isoquinoline, and several substituted pyridines in a pyrolysate of anabasine, a tobacco alkaloid structurally related to nicotine
1951	Hartwell (1544) listed several studies in which dibenz[*a,j*]acridine and 7*H*-dibenzo[*c,g*]carbazole were reported to be tumorigenic in skin-painting (epitheliomas) and subcutaneous-injection (sarcomas) experiments
1954	At the International Cancer Congress, São Paolo, a new short-term test was reported by Smith (3722a). By this test, the "tumorigenicity" of a test compound could be estimated in less than a week *vs*. the 18–20 months required in skin-painting studies. The extent and rapidity of the disappearance of the sebaceous glands after 4 daily applications of the test compound (PAHs, aza-arenes, etc.) were considered to be related to the tumorigenicity of the test compound. Because of the absence of the ultimate end point—a tumor—this test did not receive the endorsement originally anticipated
1954	Kosak (2170) did not list quinoline as a tobacco smoke component, perhaps because it was reported as a component of a destructive distillate of tobacco rather than a component of tobacco smoke. However, he did list B[*a*]P as a questionable tobacco smoke component even though it too was identified in a destructive distillate of tobacco by Roffo (3323, 3325)
1956	Lacassagne et al. (2247a) reported the tumorigenicity of dibenz[*a,h*]acridine and dibenz[*a,j*]acridine to the skin and subcutaneous tissue of mice. The tumorigenicity of 76 other unsubstituted and substituted benzacridines was also cataloged. The authors noted: "All [angular benzacridines] have a characteristic odor which is reminiscent of cigar smoke" Since 1967, two unsubstituted angular benzacridines (benz[*a*]acridine, benz[*c*]acridine) and over a dozen of their alkyl-substituted derivatives have been identified in tobacco smoke (1409, 2021, 2120, 2132, 2596a, 3300, 3337, 3339, 3499, 3750, 3752)
1957	In the first supplement to Hartwell's 1951 compilation of compounds tested for tumorigenicity, Shubik and Hartwell (3664) summarized the results of additional published studies on the tumorigenicity of 7*H*-dibenzo[*c,g*]carbazole in mice and rats
1959	Johnstone and Plimmer (1971) listed quinoline as a tobacco smoke component, but the reference cited was the report of Gabelya and Kipriyanov (1263) who identified quinoline in a destructive distillate of tobacco
1960	Van Duuren et al. (4027) vacuum distilled a solution of the basic portion of 250 g of cigarette "tar" at 100°C/0.5 mm pressure. The residue (10 g) was successively chromatographed on alumina and several Whatman papers. Bands corresponding to the aza-arenes dibenz[*a,h*]acridine and dibenz[*a,j*]acridine were rechromatographed until their ultraviolet absorption and fluorescence spectra were identical with those of authentic samples. Chromatography of the neutral fraction of the CSC gave an isolate whose properties were identical with an authentic sample of 7*H*-dibenzo[*c,g*]carbazole. No 7*H*-dibenzo[*a,g*]carbazole was detected. The estimated amounts of dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole isolated from the "tar" were 0. 1, 2.7, and 0.7 ng/cig, respectively. They estimated the levels of B[*a*]P and DB[*a,h*]A in the same CSC to be 5.0 and 0.5 ng/cig[b], respectively. Van Duuren et al. noted: "It is clear that the heterocyclics here described make a significant contribution to the reported carcinogenicity of tobacco tars"

TABLE 17.17 (continued)
Chronology of Selected Aza-Arenes: Dibenz[*a,h*]acridine, Dibenz[*a,j*]acridine, 7*H*-Dibenzo[*c,g*]carbazole, Quinoline

Year	Event
1960	Van Duuren et al. (4027) also investigated the possibility that pyridine and nicotine were precursors of these nitrogen heterocyclics. Pyrolysis of pyridine or nicotine (750°C, nitrogen atmosphere) yielded pyrolysates in which dibenz[*a,h*]acridine and dibenz[*a,j*]acridine were identified by the same procedures used with CSC. As in the CSC case, dibenz[*a,j*]acridine was more plentiful than dibenz[*a,h*]acridine in the pyridine and nicotine pyrolysates. No 7*H*-dibenzo[*c,g*]carbazole was found in either pyrolysate
1960	Van Duuren et al., citing unpublished data by Nelson et al. (2689d) on mouse-skin painting with the basic fraction of CSC, noted that the skin-painting experiments gave negative results and attributed this finding to the fact that: "The basic fraction used in those experiments would not have been sufficient to yield skin tumors even if the benzacridines had been as potent for the skin as benzo[a]pyrene, which is not the case. They also noted that Wynder and Wright (4354) reported weak tumorigenicity with more concentrated fractions from the basic fraction"
1961/1962	Balasubrahmanyam and Quin (175) identified quinoline, isoquinoline, and various substituted pyridines in the pyrolysates from the tobacco alkaloids nornicotine and myosmine
1962	Van Duuren (4022a) described methods for the separation and identification of 7*H*-dibenzo[*c,g*]carbazole in cigarette MSS
1962	Rodgman and Cook (3279) reported the isolation in crystalline form and the identification of a series of homologous indoles (indole, skatole, etc.) as well as several carbazoles from cigarette MSS
1963	Candeli et al. (587) investigated the aza-arenes in CSC with the method described by Van Duuren et al. in 1960. It was noted: "With some modifications, this method …by Candeli et al…enabled us to isolate from 100 cigarettes 1.0 µg. [dibenz[a,j]acridine]. The presence of [dibenz[a,h]acridine] could not be confirmed"
1963	Wynder and Hoffmann (4317) described the results of mouse-skin-painting tests with dibenz[*a,j*]acridine applied in 0.5% and 0.1% acetone solutions three times weekly to the backs of 20 Swiss female mice. After 12–14 months, tumors were induced in 16 (80%) and 15 (75%) mice, respectively, with 60% of the animals in each test developing carcinomas. Wynder and Hoffmann (4332) offered the following explanation for the difference between these extremely high results and the much lower one reported by Lacassagne et al. (2247a): "This relatively high tumor response in mouse skin (compared to the findings of Lacassagne et al.) might be partially explained by the high purity of the compounds, due mainly to the absence of the 'Morgan's base' [a dihydro-dibenz[*a,j*]acridine]. Only by repeated column chromatography on alumina can a [dibenz[*a,j*]acridine] be isolated that is free of the dihydro product (absence of N-H band in infrared absorption spectrum)" In another study reported by Wynder and Hoffmann (4317), mouse skin was initiated with a single application of 300 µg of 7,12-dimethylbenz[a]anthracene and then painted with a 0.5% solution of dibenz[a,j]acridine, three times weekly. The same tumor response was observed as with dibenz[a,j]acridine alone except that the tumors appeared 2–3 months earlier. The investigators interpreted this finding as indicating: "There is no significant tumor-promoting activity of [dibenz[a,j]acridine], despite its strong hyperplastic effect"
1964	The report of the 1964 Advisory Committee to the U.S. Surgeon General (3999) identified dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole as carcinogenic polycyclic compounds isolated from cigarette smoke, classified them as weakly carcinogenic, and listed their amounts in cigarette MSS as 0.1, 2.7, and 0.7 ng/cig. The report also listed quinoline as a tobacco smoke component
1964	In addition to discussing the dibenzacridines and dibenzocarbazole in tobacco smoke and the two dibenzacridines in a nicotine pyrolysate reported by Van Duuren et al. (4027), Wynder and Hoffmann (4319) discussed the identification by Jarboe and Rosene (1923a) of quinoline in a nicotine pyrolysate produced at 600°C–900°C in an inert atmosphere
1964	Kuhn (2228) reviewed the pyrogenesis of aza-arenes from tobacco and nicotine. The dibenzacridines were tabulated with reference to the 1960 paper of Van Duuren et al. (4027). He listed quinoline as a pyrolysis product of nicotine and nornicotine but not as a tobacco smoke component
1964	Testa and Testa (3886) report quinoline as a tobacco smoke component. Its presence was subsequently confirmed by Grob and Völlmin (1427) and Kaburaki et al. (1992a)
1965	Sawicki et al. (3419a) identified dibenz[*a,h*]acridine and dibenz[*a,j*]acridine in polluted air in the amounts of 80 and 40 ng/1000 m^3 of air, respectively
1968	Stedman (3767) wrote: "The presence of the dibenzacridines and 7*H*-dibenzo[*c,g*]carbazole in cigarette smoke…is of special interest since these compounds are carcinogenic and may contribute to the weak tumorigenic activity of the basic fraction in laboratory animals [Wynder and Wright (4354); Wynder and Hoffmann (4319)]" *Note*: Stedman apparently missed the point that 7H-dibenzo[c,g]carbazole, because of its structure, was not present in the basic fraction but was found in the neutral fraction of CSC [see Van Duuren et al. (4027)]
1969	Rothwell and Whitehead (3339) improved the method of isolation of 7*H*-dibenzo[*c,g*]-carbazole from complex mixtures such as CSC by formation of complexes of the aza-arenes and PAHs with purines
1970	In a study of the composition of nicotine pyrolysates (400°C, 500°C, 550°C, 600°C, 650°C, 700°C, 800°C; nitrogen and air atmospheres), Kaburaki et al. (2006) were unable to confirm the presence of the aza-arenes (dibenz[*a,h*]acridine, dibenz[*a,j*]acridine) reported by Van Duuren et al. in 1960 for nicotine pyrolysis (750°C, nitrogen atmosphere). Because there is sufficient overlap between the pyrolysis conditions used by Kaburaki et al. and by Van Duuren et al., the profound difference in composition results (presence vs. absence of the aza-arenes in question) cannot be explained by minor differences in pyrolysis conditions

(*continued*)

TABLE 17.17 (continued)
Chronology of Selected Aza-Arenes: Dibenz[*a,h*]acridine, Dibenz[*a,j*]acridine, 7*H*-Dibenzo[*c,g*]carbazole, Quinoline

Year	Event
	In addition, the tumorigenicity of 7*H*-dibenzo[c,g]carbazole was compared with that of B[α]P: "Weekly administration of 3 mg of 7*H*-dibenzo[c,g]carbazole for 15 weeks resulted in 13% more animals dying with respiratory tract cancer than died with same dose level of B[α]P. With lower total dose levels (15 mg) of B[α]P only, 30% of the animals developed respiratory tract tumors vs. 89% of the animals treated with the same dose of 7*H*-dibenzo[c,g]carbazole. The tumors in the 7*H*-dibenzo[c,g]carbazole group appeared earlier than those in the B[α]P-treated group"
1972	Schmeltz et al. (3499) studied the pyrolysis (800°C–860°C, nitrogen atmosphere) of nitrogen-containing materials (tobacco, tobacco pigment, nicotine) and reported: "We could not detect benzo(a)pyrene in nicotine pyrolyzates, nor could we confirm the presence of the physiologically active dibenzacridines and dibenzcarbazole reported in tobacco smoke and in nicotine and pyridine pyrolyzates by Van Duuren…"
	Here again, the slight difference in the temperature (750°C *vs*. 800°C–860°C) of the inert atmosphere (nitrogen) pyrolysis cannot explain the profound difference in the compositional findings (presence *vs*. absence of the aza-arenes in question)
1973	The IARC working group reported that skin painting with dibenz[*a,h*]acridine induced skin tumors in mice (1864a). Subcutaneous injection into mice produced sarcoma at the injection site plus an increased incidence of pulmonary adenomas. In 1973, dibenz[*a,h*]acridine had not been tested by other administration routes or in other species. The IARC noted that no human data were available, but it did note: "Coal tar and other materials which are known to be carcinogenic to man may contain [dibenz[*a,h*]acridine]"
	The IARC concluded that dibenz[*a,j*]acridine induced skin tumors in mice following topical application. At the highest dose tested by subcutaneous injection, it induced sarcomas at the injection site and an increased incidence of pulmonary adenomas. Negative results were obtained by the oral route in the mouse, but the test was considered inadequate because of the small number of animals tested. Dibenz[*a,j*] acridine had not been tested in other species at that time. No human data were available, but the IARC considered that some materials known to be carcinogenic to man may contain dibenz[*a,j*]acridine
1973	The IARC working group considered 7*H*-dibenzo[*c,g*]carbazole to be: "Carcinogenic in the mouse, rat, hamster, and possibly in the dog. It has both a local and a systemic carcinogenic effect. Following oral administration in the mouse, forestomach tumors and hepatomas occurred; intratracheal administration to hamsters produced tumors of the respiratory tract. In comparison with benzo[*a*]pyrene, [7*H*-dibenzo[*c,g*] carbazole] appears to be a stronger respiratory tract carcinogen for the hamster"
	Though 7*H*-dibenzo[c,g]carbazole had been reported as a component of CSC, no case reports or epidemiological data concerning human exposure were available
1976	In his review on polycyclic tumorigens, Dipple (983) labeled dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole as "carcinogenic heterocyclic compounds" with "slight" activity. However, in a later review in 1984, Dipple et al. (984) revised the assessment of 7*H*-dibenzo[*c,g*]carbazole, listing it as a highly potent tumorigen
1976	Wynder and Hoffmann (4347) listed dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole as: "Tumorigenic agents identified in the particulate phase of tobacco smoke, each possessing low biological activity and only traces detected in the smoke of 100 cigarettes. Dibenz[*a,j*]acridine was detected in amounts of 1.0 µg/100 cigarettes [10 ng/cig]"
	They categorized dibenz[*a,j*]acridine and dibenz[*a,h*]acridine as "known animal carcinogens" but noted that these aza-heterocyclic compounds are "minor carcinogens" in tobacco smoke
1976	Hoffmann et al. (1780) reported that the basic fraction of CSC which contains dibenz[*a,h*]acridine and dibenz[*a,j*]acridine was not tumorigenic to mouse skin [cf. Wynder and Wright (1957) Wynder and Hoffmann (4319, 4332)]
1977	Schmeltz and Hoffmann (3491), in their review of *N*-containing compounds in tobacco and tobacco smoke discussed the benzacridines: "Nicotine has…been shown to produce on pyrolysis the animal carcinogens, dibenz[*a,h*]acridine…and dibenz[*a,j*]-acridine…both of which are present in tobacco smoke…Acridans have been reported in smoke… Subsequent dehydrogenation of the acridans could lead to acridines. The only examples of the latter reported in smoke are two benzacridines [dibenz[*a,h*]acridine, dibenz[*a,j*]acridine]; these have been shown to form during pyrolysis from nicotine… A dibenzocarbazole [7*H*-dibenzo[*c,g*]carbazole]…has also been reported in tobacco smoke… The last three fused ring compounds cited are tumorigenic in the experimental animal"
	Schmeltz and Hoffmann listed quinoline as both a tobacco and a tobacco smoke component as well as an "animal carcinogen (rat liver)"
1979	In a brief section of the chapter on cigarette smoke composition, the aza-arenes (including dibenz[a,h]acridine, dibenz[a,j]acridine, and 7*H*-dibenzo[c,g]carbazole), their tumorigenicity, and their mutagenicity were discussed in the 1979 Surgeon General's report (4005). The report noted: "Mutagens thus far identified in cigarette smoke are: Quinoline (MS 1.7 µg/cigarette; SS 18 µg/cigarette), all seven isomeric methylquinolines (MS 0.7 µg/cigarette; SS 8 µg/cigarette)… Quinoline induces hepatomas when fed in high doses to rats…"
1979	Rinkus and Legator (3157) reported dibenz[*a,h*]acridine and dibenz[*a,j*]acridine to be mutagenic substances in the Ames *S. typhimurium* test
1979	Schmeltz et al. (3512) studied the fate of radiolabeled nicotine during pyrolysis and during actual smoking in a burning cigarette spiked with radiolabeled nicotine. The radiolabeled nicotine was pyrolyzed (nitrogen atmosphere) from a silica gel matrix at several temperatures (600°C, 750°C, and 900°C) and from a tobacco matrix at 600°C. None of the three aza-arenes—dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, 7*H*-dibenzo[*c,g*] carbazole—identified by Van Duuren et al. (4027) in CSC were found in the smoke study by Schmeltz et al. Neither of the two dibenzacridines reported by Van Duuren et al. in a nicotine pyrolysate was found in the several nicotine pyrolysates generated by Schmeltz et al. (3512)
	The differences concerning the presence or absence of these aza-arenes in several such studies involving CSCs and/or nicotine pyrolysates were summarized by Rodgman (3255, 3257)

TABLE 17.17 (continued)
Chronology of Selected Aza-Arenes: Dibenz[*a,h*]acridine, Dibenz[*a,j*]acridine, 7*H*-Dibenzo[*c,g*]carbazole, Quinoline

Year	Event
1982	In the 1982 Surgeon General's report (4010), the aza-arenes dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole were described as "tumor-initiating agents in the particulate phase of tobacco smoke" and their MSS levels as 0.1, 3–10, and 0.7 ng/cig respectively. It was noted, from data provided by Hoffmann et al. (1781, 1782), that dibenz[*a,j*]acridine possessed much higher tumorigenic activity than dibenz[*a,h*]acridine and 7*H*-dibenzo[*c,g*]carbazole [cf. Dipple et al. (983)]
1982	Adams et al. (35) reported the identification and quantitation of quinoline (0.2–1.3 µg/cig), isoquinoline (0.1–0.9 µg/cig), and the seven isomeric methylquinolines (0.5–2.5 µg/cig) in the MSS of several commercial cigarettes. They noted: "Quinoline is the most abundant aza-arene in [mainstream] cigarette smoke"
1984	In their review of polycyclic aromatic tumorigens, Dipple et al. (983) classified dibenz-[*a,h*]acridine and dibenz[*a,j*]acridine as possessing only *slight* tumorigenicity. They classified 7*H*-dibenzo[*c,g*]carbazole as possessing *high* tumorigenicity (same category as 1,2-dihydro-benz[*j*]aceanthrylene (cholanthrene), 3-methyl-1,2-dihydro-benz[*j*]aceanthrylene (3-methylcholanthrene), 7,12-dimethylbenz[*a*]anthracene, and B[*a*]P)
1984	In their review of tumorigenic aromatic amines in which fused-ring polycyclic amines are discussed, Garner et al. (1275a) neither mention nor list quinoline as a tumorigenic compound
1985/86	The IARC (1870) in its 1986 report on its 1985 deliberations found sufficient evidence to classify dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole as carcinogenic in laboratory animals. The IARC noted that "nicotine is a specific precursor for the two acridines," totaling ignoring contradictory evidence from several groups of investigators who were unable to confirm the presence of these dibenzacridines in nicotine pyrolysates. The IARC listed quinoline as a smoke component but did not include it in its tabulation of compounds *vs*. "the degree of evidence [for carcinogenicity] in animals (and humans)"
1986	Hoffmann and Wynder (1808) published a list of components classified as toxicants and/or tumorigens in tobacco and smoke. Much of the information in their report on quinoline, dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole had been provided to the IARC for inclusion in its 1986 article (1870)
1990	Hoffmann and Hecht (1727), in their compilation of 43 "tumorigenic components of tobacco and tobacco smoke," listed dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, 7*H*-dibenzo[*c,g*]-carbazole, and quinoline as tumorigenic aza-arenes in CSC. This list was subsequently used by the EPA (1990) in its attempt to have environmental tobacco smoke classified as a Group A (human) carcinogen. Hoffmann and Hecht paid little attention to the discrepancies between the 1960 report of Van Duuren et al. on the presence of these aza-arenes in CSC and nicotine pyrolysates and later reports from other investigators who failed to confirm the Van Duuren findings on these compounds either in CSC or nicotine pyrolysates [see Table 17.16]
	In their tabulation, Hoffmann and Hecht listed quinoline with no comment as to its carcinogenicity as reported in the "IARC evaluation of evidence of carcinogenicity in laboratory animals [and] in humans." In their text, they noted: "Quinoline, a liver carcinogen in rats…and in newborn mice…, is present in cigarette smoke at a concentration of 1-2 µg/cigarette [Dong et al. (1042)]"
1991	In a memorandum to the EPA, Rodgman (3255) summarized the inconsistencies between the 1960 findings reported by Van Duuren et al. on dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole in nicotine pyrolysates and/or mainstream CSC *vs*. the findings in the comparable 1963 study of Candeli et al. [reported by Wynder and Hoffmann (4319, 4332)], the 1970 study of Kaburaki et al. (2006), the 1972 and 1979 studies of Schmeltz et al. (3499, 3512), and the 1986 and 1987 reports by Grimmer et al. (1409). The expanded summary is shown in Table 17.16. Summaries of the studies of benzacridines in cigarette smoke by Kamata et al. (2021) and Sasaki and Moldoveanu (3414) were added
	A possible explanation of the differences in the results concerning the presence or absence of these three aza-arenes in mainstream CSC may be the differences between cigarettes fabricated in 1960 and those fabricated more recently after the 1970s. The pre-1960 cigarettes were substantially higher in nicotine. However, there does not appear to be a logical explanation for the difference in the results (presence *vs*. absence) of these three compounds in nicotine pyrolysates prepared in 1960, 1963, 1970, 1972, and 1979. Post-1960 advances in analytical technology should have improved the ability to isolate/identify low levels of these three aza-arenes
1994	OSHA (2825), in its goals for clean air legislation, presented its own list of 43 tobacco smoke components tumorigenic in animals or man. Its list differed slightly from that of Hoffmann and Hecht (1727). OSHA included the three aza-arenes reported by Van Duuren et al. (4027) but omitted quinoline
1994	In a response to the OSHA (2825) publication, Rodgman (3257) presented the information in Table 17.16 as reasons why the benzacridines and the benzocarbazole should be removed from the list. Valid scientific reasons for deleting other listed components were also presented
1997	Hoffmann and Hoffmann (1740) revised the 1990 Hoffmann–Hecht list of "43 tumorigenic components" of tobacco smoke (1727), expanding the list to 60 components by deleting chrysene and crotonaldehyde in agreement with the OSHA (2825) list and by adding 19 other components, including the 8 *N*-heterocyclic amines known as the "cooked food" mutagens. Still retained in the Hoffmann–Hoffmann 1997 list were the aza-arenes quinoline, dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole
1998	In a letter to the editors of Beiträge Tabakforschung zur International, Hoffmann and Hoffmann (1741) submitted a list of biologically active components of cigarette MSS, including the four aza-arenes quinoline, dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole

(*continued*)

TABLE 17.17 (continued)
Chronology of Selected Aza-Arenes: Dibenz[*a,h*]acridine, Dibenz[*a,j*]acridine, 7*H*-Dibenzo[*c,g*]carbazole, Quinoline

Year	Event
2000	Fowles and Bates (1217) included dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole in their list of tobacco and tobacco smoke toxicants
2001	Hoffmann and Hoffmann (1743) in their list of tobacco and tobacco smoke toxicants again included dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole despite the numerous reports of research that failed to confirm the 1960 Van Duuren et al. reported finding.
	Hoffmann et al. (1744) again included dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole in their list of tobacco and tobacco smoke toxicants
2003	Rodgman (3265) assessed the various published reports in which numerous tobacco and tobacco smoke components were classified as toxicants (1217, 1727, 1740, 1741, 1743, 1744, 1773, 1808, 2825). The numerous deficiencies and errors in the reports were cataloged

[a] The strain A mouse was developed for lung tumor research in laboratory animals. Without treatment of any kind, 70%–90% of strain A mice develop adenomas, a type of lung tumor, between 12 and 18 months of age [Shimkin (3652)].

[b] It is interesting to note the deliveries recorded by Van Duuren et al. for B[*a*]P (5 ng/cig) and DB[*a,h*]A (0.5 ng/cig) and compare them to values subsequently listed by Hoffmann and Hecht (1727) and Hoffmann and Hoffmann (1740) who listed a range for B[*a*]P of 20–40 ng/cig and a single value for DB[*a,h*]A of 4 ng/cig! Why did these authors not acknowledge the values reported by Van Duuren et al?

The results of research in Japan in the late 1970s brought attention not to any aza-arenes themselves but to a group of their amine derivatives, many of which showed inordinately high mutagenicity in the Ames test with several strains of *Salmonella typhimurium*. The originally studied source was cooked foodstuffs and pyrolysis products from several amino acids which resulted in their being described as "cooked food" mutagens. Later, they became known as the *N*-heterocyclic amines. When the *N*-heterocyclic amines were shown to be tumorigenic in addition to being highly mutagenic and subsequently identified in tobacco smoke, they were included by Hoffmann and his colleagues in their numerous lists of tobacco smoke tumorigens published in 1997 and later (1740, 1741, 1743, 1744). The *N*-heterocyclic amines had not been included in their numerous lists published between 1986 and 1997 (1727, 1773, 1806) nor in similar lists by IARC (1870) and OSHA (2825). Even though their number in tobacco smoke is low, we decided to discuss them in a separate chapter that follows this one on aza-arenes.

In the 1979 Surgeon General's report (4005), the aza-arenes dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, 7*H*-dibenzo[*c,g*]carbazole, quinoline, and alkylated quinolines in CSC were discussed but not the presence or biological properties of any of the "cooked food" mutagens identified in tobacco smoke. In the 1982 report of the Surgeon General [see Table 10, p. 214 in (4010)], 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) were classified as "toxic and tumorigenic agents of cigarette smoke" in amounts of 3.2–8.1 and 1.1–3.1 µg/cig, respectively, in mainstream CSC. None of the other highly mutagenic *N*-heterocyclic amine mutagens present in tobacco smoke were discussed.

Table 17.17 lists, with appropriate citations, the chronology of the studies pertinent to the aza-arenes and other polycyclic nitrogen compounds in tobacco smoke. A similar chronology of studies pertinent to the *N*-heterocyclic amines, the "cooked food" mutagens, is presented in a subsequent chapter.

17.5.1 Alternate Exposures to Aza-Arenes

In the several lists of tumorigenic components in tobacco and/or tobacco smoke, three *N*-heterocyclic compounds (dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*]carbazole) appear on the list of 43 by Hoffmann and Hecht (1727) and OSHA (2825) and the list of 60 by Hoffmann and Hoffmann (1740). Quinoline was on several lists but was omitted from the OSHA list (Table 17.18).

In Table 17.19 are listed the many tobacco smoke components similar in structure to those listed in Table 17.18.

Even though, as indicated in Table 17.16 and the text accompanying it, the presence of the three pentacyclic *N*-heterocyclic compounds in tobacco smoke is equivocal, the alternate exposure to them and similar components is discussed in the following.

In their 1956 review of angular benzacridines and dibenzacridines and their tumorigenicity, Lacassagne et al. (2247a) made the following interesting observation, pertinent to the alleged "carcinogenicity" of benzene, frequently used as a solvent in tumorigenicity studies in the 1930s, 1940s, and 1950s:

> These molecules [the angular benzacridines] are very soluble in benzene and acetone (two solvents currently used for the investigations of carcinogenic activity)…

In addition to the exposure to acridines and benzacridines in tobacco smoke, other exposures to various acridines and benzacridines have been cataloged in the scientific literature. Many of the sources (Table 17.20) comprise environmental pollutants.

Unlike the PAHs and the *N*-nitrosamines, nontobacco smoke exposure to the acridines/benzacridines does not include foods. However, exposures other than tobacco smoke to polycyclic nitrogen compounds include exposures to the

TABLE 17.19
Tobacco Smoke Components Related to Aza-Arenes in Tumorigen Lists[a]

Quinolines [35][b]	Acridines [28][b]	Carbazoles [20][b]
Quinoline	Acridine	9*H*-Carbazole
Quinoline, 5-amino-	Acridine, 9,10-dihydro-	9*H*-Carbazole, 2-amino-
Quinoline, butyl-	Acridine, 9,10-dihydro- (four homologs)	9*H*-Carbazole, dimethyl- (four isomers)
Quinoline, dihydro-	Acridine, ethyl-	9*H*-Carbazole, 9-ethyl-
Quinoline, dihydroethyl- (three isomers)	Acridine, methyl-	9*H*-Carbazole, methyl- (five isomers)
Quinoline, dihydromethyl- (three isomers)	Acridine, propyl-	9*H*-Carbazole, tetramethyl-
Quinoline, dimethyl- (five isomers)		9*H*-Carbazole, trimethyl-
Quinoline, ethyl- (two isomers)	Benz[*a*]acridine	
Quinoline, methyl- (six isomers)	Benz[*a*]acridine, dimethyl-	11*H*-Benzo[*a*]carbazole
Quinoline, (1-methylethyl)-		
Quinoline, methyltetrahydro- (two isomers)	Benz[*c*]acridine	5*H*-Benzo[*b*]carbazole
Quinoline, propyl-	Benz[*c*]acridine, dimethyl- (five isomers)	
Quinoline, tetrahydro- (two isomers)	Benz[*c*]acridine, methyl- (five isomers)	7*H*-Benzo[*c*]carbazole
Quinoline, tetramethyl-	Benz[*c*]acridine, trimethyl- (two isomers)	
Quinoline, trimethyl-		1*H*-Dibenzo[*a,c*]carbazole
	Dibenz[*a,h*]acridine	
Quinolinecarbonitrile (two isomers)		13*H*-Dibenzo[*a,i*]carbazole
	Dibenz[*a,i*]acridine	
8-Quinolinol		7*H*-Dibenzo[*c,g*]carbazole
8-Quinolinol, 7-methyl-	Dibenz[*a,j*]acridine	
	Dibenz[*c,h*]acridine	

[a] Omitted from the list are the *N*-heterocyclic amines discussed in a subsequent chapter.
[b] Number in square bracket = number of reported components.

N-heterocyclic amines, the so-called cooked food mutagens, in a variety of foods.

In Table 17.21 are listed, with appropriate citations, the 343 aza-arenes and other polycyclic nitrogen compounds reported in tobacco and tobacco smoke.

Table 17.22 summarizes the variation in the structures of the aza-arene compounds identified in tobacco and/or tobacco smoke. Of particular interest with regard to the 343 aza-arenes cataloged in Table 17.21 is that only 25 of the 343 have been identified as tobacco components. Of 25, just 18 have been identified in both tobacco and smoke. The number of aza-arenes identified in smoke is 336. Those isolated from and/or identified in tobacco in greater than trace amounts include 1*H*-indole, 2,3-dihydro-1*H*-indole, 9*H*-pyrido[3,4-*b*] indole (norharman), 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman), 1*H*-purine, and quinoline.

Because of their classification as significant tumorigens in tobacco smoke (1740, 1741, 1743, 1744) and their inordinately high mutagenicity in the Ames test with *S. typhimurium* (2327c, 3828c), the amino derivatives of several aza-arenes

TABLE 17.20
Aza-Arene Sources Other than Tobacco Smoke

Acridine/Benzacridine Source	Reference
Automobile exhaust	3419b, 4247a
Coal-fired residential furnace emission	1407b
Coal distillate	1334c, 2210a
Coal tar	2261a, 2534a
Crude oil	1407a, 3519c
High boiling petroleum distillate	2519a
Industrial stack effluent	3419a
Urban suspended particulate matter	35, 636a, 1040a, 3419c
CSC	1884, 3491

are discussed in detail in a subsequent chapter (Section 17.6) devoted to the *N*-heterocylic amines identified in tobacco smoke. However, in addition to the *N*-heterocylic amines, several aza-arene-related fused *N*-containing-ring compounds with two or more ring nitrogens plus various functional groups have been identified in tobacco and/or tobacco smoke. Classic examples of such compounds in tobacco include adenosine, 5′-adenylic acid, and many purines. Table 17.23 lists many such components identified in tobacco and/or tobacco smoke. Examination of the structures of the various derivatives indicates the inclusion of a variety of functional groups, e.g., amino, carboxylic acid, carboxamide, hydroxyl, and various carbohydrates. It should be noted that Table 17.23 does not include the nine *N*-heterocylic amines because they are described and discussed in detail in Section 17.6. In contrast to the aza-arenes which occur predominately in tobacco smoke, 65 of the 88 components with functional groups listed in Table 17.23 were identified in tobacco, and only 29 have been identified to date in tobacco smoke.

17.6 *N*-HETEROCYCLIC AMINES

Although not originally classified at the time as "cooked food" mutagens, several amino-acid-derived *N*-heterocylic compounds were identified in cigarette smoke condensate (CSC) in the early 1960s: 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) {I} by Mold et al. (2592) and 9*H*-pyrido[3,4-*b*]indole (norharman) {II} and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) {III} by Poindexter and Carpenter (2972) (Figure 17.13).

Proline is the precursor in tobacco of 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) {I} in tobacco smoke. Tryptophan is the major precursor in tobacco of 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) {II} and 9*H*-pyrido[3,4-*b*]indole (norharman) {III}, as well as indole and its alkylated homologs, in tobacco smoke.

In the late 1970s, Japanese investigators—in their detailed studies of components of various "cooked foods"—isolated and identified the first of a series of *N*-heterocylic amines as pyrolysis products of several amino acids. Sugimura et al. (3829) reported the isolation and identification of 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (designated as Trp-P-1) {IV} and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) {V} (Figure 17.14) from tryptophan pyrolysates.

Yamamoto et al. (4365a) reported the isolation and identification of the mutagenic *N*-heterocylic amines 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1) {VI} and 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2) {VII} from glutamic acid pyrolysates. Yoshida and Matsumoto (4388) and Matsumoto et al. (2492) reported the identification of 2-amino-9*H*-pyrido[2,3-*b*]indole (AαC) {VIII} and 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (MeAαC) {XIII–IX} in CSC (Figure 17.14).

A unique feature of several of compounds {IV–VII} was their inordinately high mutagenicity in the Ames system (*Salmonella typhimurium*). Mutagenic activities on a revertant/μg basis as determined in the Ames test with *S. typhimurium* strains TA 98 and TA 100 for several of these compounds are shown in Table 17.24 [Sugimura (3828c), Lee et al. (2327c)]. To put in perspective the extremely high values for the mutagenic activities listed in Table 17.24, it should be noted that the mutagenic activity of benzo[*a*]pyrene (B[*a*]P) (strain TA 98) when tested under the same conditions is about 200 revertant/μg of B[*a*]P. In separate studies, Levitt et al. (2355a) and Nagao et al. (2667b) demonstrated the mutagenicity of the previously identified tobacco smoke components 9*H*-pyrido[3,4-*b*]indole (norharman) {II} and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) {III}.

Heckman and Best (1587) reported the identification of nearly 270 previously unidentified and confirmation of over 150 previously identified *N*-containing components in CSC. These included several components structurally similar to some of the *N*-heterocylic amines 9*H*-pyrido[2,3-*b*]indole, 2-methyl-9*H*-pyrido[2,3-*b*]indole, 2-(2-methylpropyl)-9*H*-pyrido[2,3-*b*]indole, 2-pentyl-9*H*-pyrido[2,3-*b*]indole, 1-butyl-9*H*-pyrido[3,4-*b*]indole, 1-propenyl-9*H*-pyrido[3,4-*b*]indole, and a partially characterized norharman.

In addition to their mutagenicity in the Ames test (*S. typhimurium*), several of the mutagenic *N*-heterocylic amines were subsequently reported to be tumorigenic to laboratory animals. They were reported to be tumorigenic, particularly in feeding experiments, to several laboratory animal species. The tumorigenicity in mice of 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) was reported by Matsukura et al. (2491a) and in rats by Hosaka et al. (1835a). Takayama et al. (3862d) demonstrated the tumorigenicity in rats of 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2).

Ohgaki et al. (2849b) described the tumorigenicity in mice, and Takayama et al. (3862b) described the tumorigenicity in rats of 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1) and 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2). 2-Amino-3-methylimidazo[4,5-*f*]quinoline (IQ) {X} was reported to be tumorigenic in rats by Takayama et al. (3862c) and Tanaka et al. (3865c) and in mice by Ohgaki et al. (2849, 2849a). Ohgaki et al. (2849, 2849a) also reported the tumorigenicity in mice of 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ)

TABLE 17.21
Aza-Arenes and Other Polycyclic Nitrogen Compounds in Tobacco, Tobacco Smoke, and Tobacco Substitute Smoke

and 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ), both compounds being components in broiled fish, fried beef, and beef extract. As indicated in Table 17.24, both 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ) (4367, 4368) and 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ) (2039) have been reported in tobacco smoke.

Rodgman (3253a) discussed the theoretical relationships (Figures 17.15 and 17.16) among glutamic acid {XII}, its possible degradation products, 4-aminobutanoic {XIII} and 2-aminobutanoic acid {XIV}, 2-amino-3-methylpyridine {XV} and 2-amino-6-methylpyridine {XVI}, 2-aminopyridine {XVII}, and the possible reactions between these substituted aminopyridines to form 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1) {VI}, 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2) {VII}, and two similar products, 2-amino-9-methyldipyrido[1,2-*a*: 3′,2′-*d*]imidazole {XVII} and 2-amino-3,6-dimethyldipyrido[1,2-*a*:3′,2′-*d*]imidazole {XIX}, not yet identified in tobacco smoke or cooked foods. The aminobutanoic acids {XIII and XIV} and the aminopyridines {XV–XVII} noted in Figures 17.15 and 17.16 have been reported as tobacco smoke components.

Rodgman also discussed the already identified and other possible theoretical relationships (Figure 17.17) between tryptophan {XX} and 9*H*-pyrido[3,4-*b*]indole (norharman) {II}; its methyl homolog 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) {III} and other substituted norharmans {VI, R = C_2H_5, $CH_3CH{=}CH$, and *n*-C_4H_9}; the tryptophan pyrolysis products 3-amino-1,4-dimethyl-5*H*-pyrido-[4,3-*b*]indole

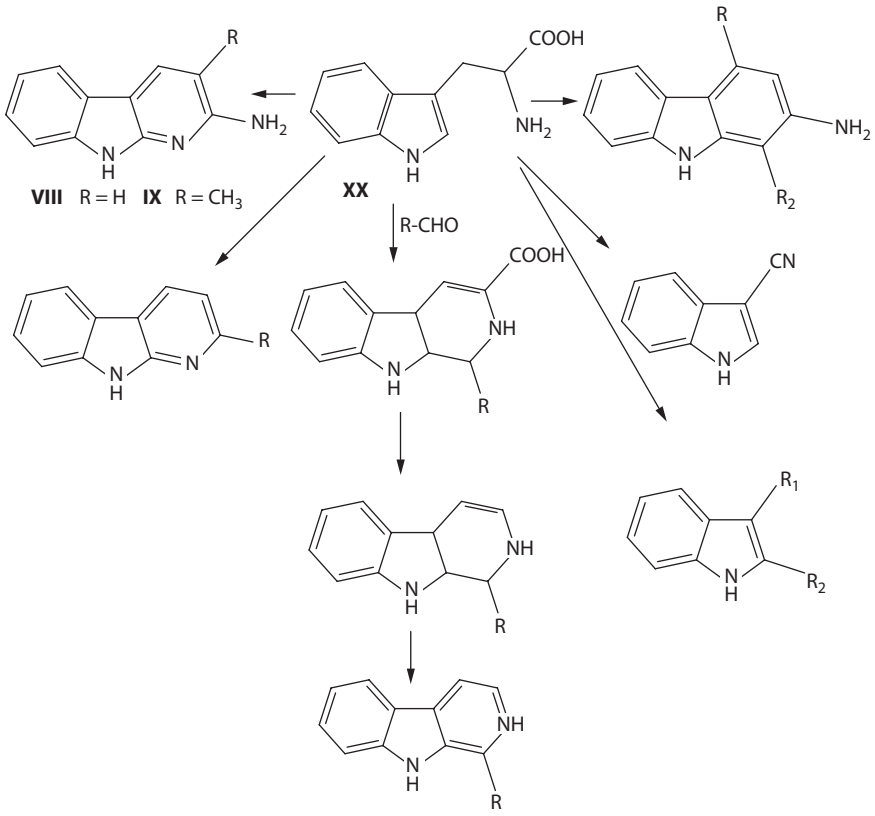

FIGURE 17.17 Possible tryptophan-derived compounds in tobacco smoke.

(Trp-P-1) {IV} and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*] indole (Trp-P-2) {V}; the alkyl- and dialkylindoles; indole-3-acetonitrile; the 2-amino-9*H*-pyrido[2,3-*b*]indoles [AαC {VIII} and MeAαC {IX}] plus other pyrido[2,3-*a*]indoles {R = H, CH_3, C_2H_5, $(CH_3)_2CHCH_2$, or n-C_5H_{11}} (see Table 17.29). All of the compounds noted in (Figure 17.16) have been reported as tobacco smoke components.

In the 1979 report of the U.S. Surgeon General (4005), the azaarenes dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, 7*H*-dibenzo[*c,g*] carbazole, quinoline, and alkylated quinolines in CSC were discussed but not the presence or biological properties of the *N*-heterocyclic amines identified in tobacco smoke. However, in the 1982 report of the Surgeon General (4010), 9*H*-pyrido[3,4-*b*] indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) were classified as "toxic and tumorigenic agents of cigarette smoke" in amounts of 3.2–8.1 and 1.1–3.1 µg/cig, respectively, in mainstream CSC. None of the *N*-heterocyclic amines present in tobacco smoke were discussed.

Snook and Chortyk (3739, 3740) reported the cigarette mainstream smoke (MSS) yield of 9*H*-pyrido[3,4-*b*]indole (norharman) to be 1.2–13.4 µg/cig and that for 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) to be 0.3–3.8 µg/cig. They found a linear relationship between the yield of MSS "tar" and the yields of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman). In contrast to the 1962 findings of Poindexter and Carpenter (2972), Snook and Chortyk reported yields of these two compounds were not influenced by the tobacco type.

In his review of the studies of the mutagenicity of CSC, Demarini (933) discussed the significance of the findings of Yoshida and Matsumoto (4388) and Matsumoto et al. (2492) on the mutagenicity of 2-amino-9*H*-pyrido[2,3-*b*]indole (AαC) (80 ng/cig) and 2-amino-3-methyl-9*H*-pyrido[2,3-*b*] indole (MeAαC) (7 ng/cig).

None of the authors contributing to the American Chemical Society's 1984 monograph [Searle (3568)] on chemical carcinogens mentioned the *N*-heterocyclic amines as mutagens and/or tumorigens.

Yamashita et al. (4367, 4368) identified and quantitated the following *N*-heterocyclic amines in mainstream CSC: 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ) (0.3 ng/cig), 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) (0.3 ng/cig), 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) (0.2 ng/cig), 2-amino-9*H*-pyrido[2,3-*b*]indole (AαC) (16.9 ng/cig), and 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (MeAαC) (1.6 ng/cig).

In his 1986 review of the isolation and identification of the *N*-heterocyclic amines, the high mutagenicity in the Ames test (*S. typhimurium*) of several of them, their tumorigenicity in laboratory animals, and their various sources, including

CSC, Sugimura (3828c) wrote the following about their importance as human carcinogens:

> Taking various factors into consideration, it is probably impractical and not realistic to make risk estimations from the carcinogenicity data on rodents given a single carcinogen. However, for a simple extrapolation of animal data for risk estimation, TD_{50} values, which are the doses needed to develop cancers in 50% of animals fed on carcinogens [IQ, Trp-P-1, Trp-P-2, Glu-P-1, Glu-P-2, AαC, and MeAαC] for their life time, have been calculated based on mouse experiments… If we assume the average TD_{50} value of heterocyclic amines should be about 8mg/kg/day, we can roughly estimate the risk of these carcinogenic heterocyclic amines for human beings. The intake of heterocyclic amines was calculated from available data on their quantities in foods. Apparently the human intake is about 0.0002% times the TD_{50} obtained from animal data. This means that heterocyclic amines may not be so serious for human cancer development.

Sugimura added:

> On the other hand, it is also true that human beings are being exposed to many heterocyclic amines and many other carcinogens with tumor promoters and/or suppressing factors for carcinogenesis. At this moment, it is honest to state that no solid information on the estimation of risk of heterocyclic amines has been obtained in any direction, either positive or negative.

As in the case of the carcinogens whose activity can be substantially reduced by anticarcinogens [see review by Rodgman (3255)], Lee et al. (2327c) reported that mainstream CSC significantly inhibited the mutagenicity of several of these *N*-heterocyclic amines when tested in the Ames assay with *S. typhimurium*, strain TA 98 in the presence of the S-9 mix. The *N*-heterocyclic amines tested included 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ), 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ), 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1), 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2), 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1), and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2). The mutagenic activities of these mutagens were suppressed as much as 80% by addition of 50–100 µg of CSC per plate. Enzymatic studies indicate that CSC is a potent inhibitor of cytochrome-P-450-dependent monooxygenase. Therefore, it appears that CSC exerts its antimutagenicity by inhibiting the P-450 system. Lee et al. (2327c) also reported that fractionation of CSC yields fractions that show low mutagenicity themselves but are significantly antimutagenic.

Although many of the *N*-heterocyclic amines are indeed present in cigarette MSS, it should be remembered that the major part of the research on this class of compounds was initiated and extended because of their presence in a great number of cooked foodstuffs consumed by a great number of people. When the *N*-heterocyclic amines were shown to be tumorigenic in addition to being highly mutagenic and subsequently identified in tobacco smoke, they were included by Hoffmann and his colleagues in their numerous lists of tobacco smoke tumorigens published in 1997 and later (1740, 1741, 1743, 1744). The *N*-heterocyclic amines had not been included in their numerous lists published between 1986 and 1997 (1727, 1773, 1806) nor in similar lists published by IARC (1870) and OSHA (2825). Table 17.25 summarizes some details of these *N*-heterocyclic amines in tobacco smoke.

Because of their concerns about the mutagenicity of numerous commonly consumed heated foods, many of the studies of the isolation, identification, and estimation of *N*-heterocyclic amines in heated foodstuffs or heated food components, particularly amine-containing components such as amino acids, proteins, and peptides, were conducted by Japanese investigators. This becomes obvious from examination of the authors and coauthors of the references listed in Table 17.26.

With the reporting of the Ames mutagenicity test with *S. typhimurium* in the mid-1970s and the demonstration of its utility, the number of studies on potential mutagenic systems and the mutagenicity–tumorigenicity relationship virtually exploded. By highly competent application of up-to-date isolation and characterization techniques plus utilization of the Ames test, Sugimura and his staff at the Japanese National Cancer Research Institute contributed significantly to our knowledge of the structures, properties, and precursors in foods of the *N*-heterocyclic amines. While the methodologies differed, the 1977 isolation/identification of the *N*-heterocyclic amines (Trp-P-1, Trp-P-2) from a tryptophan pyrolysate paralleled the historic 1932 isolation and identification of polycyclic aromatic hydrocarbons (PAHs) [B[*a*]P, benzo[e]pyrene (B[*e*]P), benz[*a*]anthracene (B[*a*]A), perylene] from coal tar. In the 1930s, the Kennaway group in the United Kingdom used ultraviolet spectrophotometry [Hieger (1631)] to monitor coal tar PAHs during their concentration and purification by repeated precipitations and recrystallizations of PAH–picric acid complexes [Cook et al. (796a, 797)]. In the mid-1970s, Sugimura et al. (3829a) in Japan used the Ames test (*S. typhimurium*, TA98 strain/S-9) to monitor tryptophan pyrolysate mutagens (Trp-P-1, Trp-P-2) during their concentration and purification by sequential chromatography on silicic acid, alumina, and CM-Sephadex® columns.

References to several early studies on the identification of biologically active compounds in heated foodstuffs are included in Table 17.26, e.g., the 1956 study by Kuratsune (2237) of PAHs such as B[*a*]P in roasted coffee and the similar mid-1960s studies of PAHs in broiled meat [Lijinsky and Shubik (2364a, 2364b)]. PAHs such as B[*a*]P were identified in both studies. The major concern of the early investigators was the possible presence of tumorigenic PAHs, particularly B[*a*]P, in the heated foodstuff. Of course, it

[a] AαC, 2-amino-9*H*-pyrido[2,3-*b*]indole; MeAαC, 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole; Glu-P-1, 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole; Glu-P-2, 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole; PhIP, 2-amino-1-methyl-6-phenyl-1*H*-imidazo[4,5-*b*]pyridine; IQ, 2-amino-3-methyl-3*H*-imidazo[4,5-*f*]quinoline; MeIQ, 2-amino-3,4-dimethyl-3*H*-imidazo[4,5-*f*]quinoline; Trp-P-1, 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole; Trp-P-2, 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole.

was subsequently demonstrated that B[*a*]P, in addition to its tumorigenicity to mouse skin, is also mutagenic in the Ames test. However, its specific mutagenicity is insignificant compared to that of several of the *N*-heterocyclic amines (see Table 17.24). The presence of PAHs in numerous foods was discussed previously.

From their studies of heated foods or food pyrolysates (30 different foods, including rice, flour, soy beans, fish, meat, eggs), Sugimura (3828b) reported the following:

- Mutagenicity was proportional to the protein content.
- Mutagenicity was proportional to the levels of specific amino acids (tryptophan, glutamic acid, etc.) in the constituent protein.
- Mutagenicity was dependent on water content and heating temperature, e.g., for foods with low water content, the mutagens appear at 300°C; for those with high water content, the mutagens appear at 400°C.

Estimates of daily exposures to PAHs and *N*-nitrosamines in foods, beverages, and other factors have been made by numerous investigators. Estimates of exposures to *N*-heterocyclic amines are limited. Part of the reason is the difference in time span since the particular class of compounds was found to be tumorigenic and/or mutagenic: Exposures to PAHs tumorigenic in laboratory animal bioassays have been studied for more than seven decades (since the early 1930s and the identification of B[*a*]P in coal tar by Cook et al. (796a, 797)) and exposures to *N*-nitrosamines tumorigenic in laboratory animal bioassays have been studied [Magee and Barnes (2441a)] since the mid-1950s. In contrast, exposures to *N*-heterocyclic amines tumorigenic in laboratory animal bioassays have only been studied for about 30 years (since the mid-1970s and the availability of the Ames test).

Sugimura (3828b) reported comparisons of the mutagenicities (Ames test) of various beverages (coffee, brandy, tea) and CSC. The data are summarized in Table 17.27.

As noted previously, Sugimura (3828c) reported in his 1986 review his estimate of the exposure of humans to *N*-heterocyclic amines with the limited data at his disposal. From his estimate, Sugimura concluded that at that time, *N*-heterocyclic amines might not be serious in human cancer development and no solid information on the estimation of risk of *N*-heterocyclic amines had been obtained in any direction, either positive or negative.

In another comparison of mutagenicities toward *S. typhimurium* TA98, Nagao et al. (2667c) calculated the B[*a*]P equivalency of extracts of charred fish and meat. Their data, with additions (charred food weight in ounces, cigarette equivalents based on B[*a*]P), are shown in Table 17.28.

Table 17.29 lists identified tobacco smoke components actually or possibly derived from the amino acids glutamic acid, tryptophan, or proline. In the mid-1980s, Rodgman (3253a) discussed both the known relationships as well as several theoretically possible relationships between the

three amino acids and many of the compounds listed in Table 17.29. It also lists, with appropriate citations, the amino-acid-derived compounds reported in tobacco smoke and citations to the studies demonstrating their mutagenicity and tumorigenicity. Additional references to the tobacco smoke components may be found in the chapters on the aza-arenes (Section 17.5) and the three amino acids (Section 4.2).

Table 17.30 summarizes the chronology of the studies pertinent to the *N*-heterocyclic amines in tobacco smoke and in commonly consumed cooked foodstuffs. Included in Table 17.30 are events pertinent to the studies of 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), 9*H*-pyrido[3,4-*b*]indole (norharman), and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman). Although none is an *N*-heterocyclic amine, their pyrogenesis from specific amino acids was the background for the subsequent studies on *N*-heterocyclic amines, each of which is derived from an amino acid.

Table 17.31 lists, with appropriate citations, the *N*-heterocyclic amines reported in tobacco and tobacco smoke. While Table 17.31 lists the citations pertinent to the nine highly mutagenic *N*-heterocyclic amines, as noted previously, citations pertinent to tobacco smoke components related to them are available in several other chapters (Section 4.2; Section 17.5).

TABLE 17.29
Components Related to *N*-Heterocyclic Amines in Tobacco Smoke: Identification and Biological Properties

Compound	References to		
	Identification in Smoke	Mutagenicity[a]	Tumorigenicity[b]
Glutamic acid derived			
Glutamic acid	Buyske et al. (526), Izawa et al. (1910), Izawa and Taki (1914)		
Butanoic acid, 2-amino-	Hecht et al. (1580)		
Butanoic acid, 4-amino-	Izawa et al. (910), Izawa and Taki (1914)		
2-Pyridinamine	Heckman and Best (1587), Saint-Jalm and Morée-Testa (3386)		
2-Pyridinamine, 3-methyl-	Lippiello et al. (2378a)		
2-Pyridinamine, 6-methyl-	Lippiello et al. (2378a), Sanders et al. (3410)		
Dipyrido[1,2-*a*:3′,2′-*d*]imidazole, 2-amino- {Glu-P-2}	Clapp (751), Clapp et al. (755, 756), Massey (2484a)	Yamamoto et al. (4365a), Sugimura (3828c), Lee et al. (2327c)	Ohgaki et al. (2849a, 2849b), Takayama et al. (3862c), Sugimura (3828c)
Dipyrido[1,2-*a*:3′,2′-*d*]imidazole, 2-amino-6-methyl- {Glu-P-1}	Clapp (751), Clapp et al. (755, 756), Massey (2484a)	Yamamoto et al. (4365a), Sugimura (3828c), Lee et al. (2327c)	Ohgaki et al. (2849a, 2849b), Takayama et al. (3862c), Sugimura (3828c)
Tryptophan-derived			
Tryptophan		+	
9*H*-Pyrido[3,4-*b*]indole {norharman}	Poindexter and Carpenter (2972)	Levitt et al. (2355a), Nagao et al. (2667g)	USPHS (4010)
9*H*-Pyrido[3,4-*b*]indole, 1-butyl-	Heckman and Best (1587)		
9*H*-Pyrido[3,4-*b*]indole, 1-ethyl-	Schumacher et al. (3553)		
9*H*-Pyrido[3,4-*b*]indole, 1-methyl- {harman}	Poindexter and Carpenter (2972)	Levitt et al. (2355a), Nagao et al. (2667g)	USPHS (4010)
9*H*-Pyrido[3,4-*b*]indole, 1-methyl-1,2,3,4-tetrahydro-	Schumacher et al. (3553)		
9*H*-Pyrido[3,4-*b*]indole, 1-propenyl-	Heckman and Best (1587)		
5*H*-Pyrido[4,3-*b*]indole, 3-amino-1,4-dimethyl- {Trp-P-1}	Yamashita et al. (4367, 4368)	Sugimura et al. (3828c, 3829, 3829a), Lee et al. (2327c)	Matsukura et al. (2491a), Hosaka et al. (1835a), Takayama et al. (3862d), Sugimura (3828c)
5*H*-Pyrido[4,3-*b*]indole, 3-amino-1-methyl- {Trp-P-2}	Yamashita et al. (4367, 4368)	Sugimura et al. (3829, 3829a), Sugimura (3828c), Lee et al. (2327c)	Matsukura et al. (2491a), Hosaka et al. (1835a), Takayama et al. (3862d), Sugimura (3828c)
1*H*-Pyrido[2,3-*b*]indole	Heckman and Best (1587)		
9*H*-Pyrido[2,3-*b*]indole, 2-ethyl-	Schumacher et al. (3553)		
9*H*-Pyrido[2,3-*b*]indole, 2-methyl-	Heckman and Best (1587)		
9*H*-Pyrido[2,3-*b*]indole, 2-(2-methylpropyl)-	Heckman and Best (1587)		
9*H*-Pyrido[2,3-*b*]indole, 2-pentyl-	Heckman and Best (1587)		
9*H*-Pyrido[2,3-*b*]indole, 2-amino-{AαC}	Yoshida and Matsumoto (4388), Matsumoto et al. (2492), Yamashita et al. (4367, 4368)	Yoshida and Matsumoto (4388), Matsumoto et al. (2492), DeMarini (933), Sugimura (3828c)	Ohgaki et al. (2849b), Sugimura (3828c)
9*H*-Pyrido[2,3-*b*]indole, 2-amino-3-methyl- {MeAαC}	Yoshida and Matsumoto (4388), Matsumoto et al. (2492), Yamashita et al. (4367, 4368)	Yoshida and Matsumoto (4388), Matsumoto et al. (2492), DeMarini (933), Sugimura (3828c)	Ohgaki et al. (2849b), Sugimura (3828c)

Components Related to *N*-Heterocyclic Amines in Tobacco Smoke: Identification and Biological Properties

Compound	References to		
	Identification in Smoke	Mutagenicity[a]	Tumorigenicity[b]
Imidazo[4,5-*f*]quinoline, 2-amino-3,4-dimethyl- {MeIQ}	Bao et al. (179a), Levasseur et al. (2354a), Massey (2484a), Rodgman (3255, 3257, 3265), Rodgman and Green (3300), Smith et al. (3714)	Ohgaki et al. (2849), Lee et al. (2327c)	Ohgaki et al. (2849)
Imidazo[4,5-*f*]quinoline, 2-amino-3-methyl- {IQ}	Yamashita et al. (4367, 4368)	Yoshita et al. (4389a), Ohgaki et al. (2849a), Lee et al. (2327c)	Ohgaki et al. (2849a), Takayama et al. (3862b, 3862c), Tanaka et al. (3865c)
Indole, 2,3-dimethyl-	Rodgman and Cook (3279), Izard et al. (1898), Schmeltz et al. (3506)		
Indole-3-acetonitrile	Izard et al. (1898)		
Proline derived			
Proline	Izawa et al. (1910), Izawa and Taki (1914)		
5*H*,10*H*-Dipyrrolo[1,2-*a*:1′,2′-*d*] pyrazine-5,10-dione {pyrocoll}	Mold et al. (2592), Rodgman and Cook (3279), Schmeltz et al. (3505), Testa and Testa (3886)		
5*H*,10*H*-Dipyrrolo[1,2-*a*:1′,2′-*d*] pyrazine-5,10-dione, methyl- {methylpyrocoll}	Izard et al. (1898)		
5*H*,10*H*-Dipyrrolo[1,2-*a*:1′,2′-*d*] pyrazine-5,10-dione, 1,2a,3,5a,8,10a-hexahydro-	Schumacher et al. (3553)		
5*H*,10*H*-Dipyrrolo[1,2-*a*:1′,2′-*d*] pyrazine-5,10-dione, 1,2a,3,5a,8,10a-hexahydro-3-methyl-	Schumacher et al. (3553)		
5*H*,10*H*-Dipyrrolo[1,2-*a*: 1′,2′-*d*] pyrazine-5,10-dione, octahydro-	Schumacher et al. (3553)		

[a] Mutagenic (*S. typhimurium*).
[b] Tumorigenic to mammalian skin.

TABLE 17.30
Chronology of *N*-Heterocyclic Amine Studies

Year	Event
1959	The only fused-ring *N*-heterocyclic compound listed by Johnstone and Plimmer (1971) as a component of tobacco smoke was the bicyclic compound quinoline
1960	Mold et al. (2592) reported the isolation and identification of the tricyclic *N*-heterocyclic 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) from CSC and its relationship to its precursor in tobacco, the amino acid proline
1961/1962	Poindexter and Carpenter (2972) reported the isolation and identification of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) from CSC. They reported that the yield of the total harmans in burley and flue-cured MSSs was between 15 and 20 µg/g of tobacco smoked, values which were 40–50 times that of the harmans in the unsmoked tobacco. Since the weight of tobacco in cigarettes sold at that time approximated 1 g, the yield of these two compounds was about 15–20 µg/cig. Poindexter and Carpenter concluded from experiments with radiolabeled tryptophan that the harmans (found to be radiolabeled in the smoke) were generated pyrogenetically from a reaction between aldehydes (formaldehyde for norharman, acetaldehyde for harman) and the tryptophan in tobacco
1962	Rodgman and Cook (3279) confirmed the presence in CSC of 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) and also reported the identification of indole, carbazole, and several alkylated indoles and carbazoles. Rodgman and Cook (3279) also reviewed the previously reported biological studies on indole, 3-methylindole (skatole), and carbazole: none of the three were reported to be tumorigenic
1964	Schmeltz et al. (3505) reported 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), 9*H*-pyrido[3,4-*b*]indole (norharman), and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) as tobacco smoke components. Testa and Testa (3886) also identified 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) as components of CSC
1964	The Advisory Committee to the U.S. Surgeon General (3999) briefly discussed only four fused-ring *N*-heterocyclic compounds in tobacco smoke, quinoline and the two dibenzacridines (dibenz[*a,h*]acridine, dibenz[*a,j*]acridine) and the dibenzocarbazole (7*H*-dibenzo[*c,g*]carbazole) reported by Van Duuren et al. (4027)
1968	In his review of tobacco smoke composition, Stedman (3797) discussed the identification of tumorigenic *N*-heterocyclic compounds (dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, 7*H*-dibenzo[*c,g*]carbazole) reported by Van Duuren et al. (4027) as well as the following *N*-heterocyclic compounds: 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll) reported by Mold et al. (2592) and 9*H*-pyrido[3,4-*b*]indole (norharman), 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman), and 9*H*-pyrido[2,3-*b*]indole reported by Poindexter and Carpenter (2972)
1971/1972	Wakeham (4103) noted the reported presence of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) in cigarette smoke and discussed their formation from a reaction product of tryptophan and an aldehyde. As noted by Rodgman (3253a), the structure of the aldehyde reacting with tryptophan ultimately dictates the structure of alkylated norharmans found (see Table 17.29) in CSC
1974	In addition to 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), Izard et al. (1899) reported the identification of methyl-5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (methylpyrocoll) in CSC
1974/1975/1977	In a 1974 in-house report, a 1975 TCRC presentation, and a 1977 publication on their study of the water-soluble portion of CSC, Schumacher et al. (3553) reported the identifications of 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman), 5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (pyrocoll), octahydro-5*H*,10*H*-dipyrrolo[1,2-*a*:1′,2′-*d*]pyrazine-5,10-dione (octahydropyrocoll), and 2-ethyl-9*H*-pyrido[2,3-*b*]indole
1977	Sugimura et al. (3829a) reported the isolation and identification of the *N*-heterocyclic amines 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) from tryptophan pyrolysates
1977	In separate studies, Levitt et al. (2355a) and Nagao et al. (2667b) demonstrated the mutagenicity of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) in the Ames test
1978	Yamamoto et al. (4365a) reported the isolation and identification of 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1) and 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2) from glutamic acid pyrolysates
1978/1981	Heckman and Best (1587) reported the identification of nearly 270 previously unidentified and over 150 previously identified *N*-containing components in CSC. These included several components structurally similar to the *N*-heterocyclic amines: 9*H*-pyrido[2,3-*b*]indole, 2-methyl-9*H*-pyrido[2,3-*b*]indole, 2-(2-methylpropyl)-9*H*-pyrido[2,3-*b*]indole, 2-pentyl-9*H*-pyrido[2,3-*b*]indole, 1-butyl-9*H*-pyrido[3,4-*b*]indole, 9*H*-1-propenyl-pyrido[3,4-*b*]indole, and a partially characterized norharman isomer
1979	In the 1979 Surgeon General's report (4005), the aza-arenes dibenz[*a,h*]acridine, dibenz[*a,j*]acridine, 7*H*-dibenzo[*c,g*]carbazole, quinoline, and alkylated quinolines in CSC were discussed but not the presence or properties of the *N*-heterocyclic amines identified in tobacco smoke
1980/1981	Yoshida and Matsumoto (4388) and Matsumoto et al. (2492) reported the identification of 2-amino-9*H*-pyrido[2,3-*b*]indole (AαC) and 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (MeAαC) in CSC
1981	Matsukura et al. (2491a) demonstrated the tumorigenicity in mice of 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) Hosaka et al. (1835a) demonstrated the tumorigenicity in rats of 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2)

(*continued*)

TABLE 17.30 (continued)
Chronology of *N*-Heterocyclic Amine Studies

Year	Event
1982	In the 1982 report of the Surgeon General (4010), 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) were classified as "toxic and tumorigenic agents of cigarette smoke" in amounts of 3.2–8.1 and 1.1–3.1 μg/cig, respectively, in cigarette MSS. None of the other *N*-heterocyclic amines present in tobacco smoke were discussed
1982/1984	Snook and Chortyk (3739) reported the MSS yield of 9*H*-pyrido[3,4-*b*]indole (norharman) to be 1.2–13.4 μg/cig; that for 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman) to be 0.3–3.8 μg/cig. They found a linear relationship between the yield of cigarette MSS "tar" and the yields of 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman). In contrast to the 1962 findings of Poindexter and Carpenter, Snook and Chortyk reported that the MSS yields of these two compounds were not influenced by the tobacco type
1983	Demarini (933) reviewed the studies on the mutagenicity of CSC. He discussed the studies of Yoshida and Matsumoto (4388) and Matsumoto et al. (2492) on the mutagens 2-amino-9*H*-pyrido[2,3-*b*]indole (AαC) (80 ng/cig) and 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (MeAαC) (7 ng/cig)
1984	None of the authors contributing to the second edition of the *American Chemical Society's Monograph*, edited by Searle (3568), on chemical carcinogens mentioned the tumorigenic and mutagenic *N*-heterocyclic amines reported in cigarette smoke and/or numerous cooked foods. In fact, the only class of tumorigens in cigarette MSS discussed in the 1400-page treatise was the *N*-nitrosamines. No tumorigenic PAH was mentioned as a component of cigarette MSS
1984	Ohgaki et al. (2849) demonstrated the tumorigenicity in mice, and Takayama et al. (3862b) demonstrated the tumorigenicity in rats of 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1) and 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2) Takayama et al. (3862c) demonstrated the tumorigenicity in rats of the tobacco smoke component 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ)
1984/1985	Ohgaki et al. (2849a, 2849b) demonstrated the tumorigenicity in mice of 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ) and 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ), found in broiled fish, fried beef, beef extract, and CSC
1985	Takayama et al. (3862d) demonstrated the tumorigenicity in rats of 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) Tanaka et al. (3865b) demonstrated the tumorigenicity of 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ)
1985	In an in-house presentation, Rodgman (3253a) discussed the already identified and other possible theoretical relationships between tryptophan and the substituted norharmans, the tryptophan pyrolysis products 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2), the 2-amino-9*H*-pyrido[2,3-*b*]indoles (AαC and MeAαC), indole-3-acetonitrile, and the alkyl- and dialkylindoles He also discussed the theoretical relationships among glutamic acid, its possible degradation products, 2- and 4-aminobutanoic acid, 2-aminopyridine, 2-amino-3- and 6-methylpyridine, and the possible reactions between these substituted aminopyridines to form 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1), 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2), and two similar products not yet identified
1985/1986	In its 1985 review, published in 1986, of the various problems from exposure to numerous components in tobacco smoke, the IARC (1870) did not designate the *N*-heterocyclic amines as a problem. IARC did list several tryptophan-derived tobacco smoke isolates including 9*H*-pyrido[3,4-*b*]indole (norharman) and 1-methyl-9*H*-pyrido[3,4-*b*]indole (harman). The per cigarette MSS yields of these two components were listed as 9.5–14.1 and 2.5–5.8 μg/cig, respectively. No mention was made of the *N*-heterocyclic amines in CSC or the degree of evidence for their carcinogenicity in animals and humans The identification of several *N*-heterocyclic amines was reported in 1985 and 1986 by Yamashita et al. (4367, 4368)
1985/1986	Yamashita et al. (4367, 4368) identified and quantitated the per cigarette yields of the following *N*-heterocyclic amines in CSC: 2-Amino-3-methylimidazo[4,5-*f*]quinoline (IQ) 0.3 ng/cig 3-Amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) 0.3 ng/cig 3-Amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) 0.2 ng/cig 2-Amino-9*H*-pyrido[2,3-*b*]indole (AαC) 16.9 ng/cig 2-Amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (MeAαC) 1.6 ng/cig
1986	Hoffmann and Wynder (1808) in their list of tobacco and tobacco smoke tumorigens did not list any *N*-heterocyclic amine
1986	Sugimura (3828c) reviewed the isolation and identification of the *N*-heterocyclic amines, their high mutagenicity in the Ames test (*S. typhimurium*) of several of them, their tumorigenicity, and their various sources—including CSC for many. However, Sugimura did write the following about the importance of the "cooked food" mutagens as human carcinogens: "Taking various factors into consideration, it is probably impractical and not realistic to make risk estimations from the carcinogenicity data on rodents given a single carcinogen. However, for a simple extrapolation of animal data for risk estimation, TD_{50} values, which are the doses needed to develop cancers in 50% of animals fed on carcinogens [IQ, Trp-P-1, Trp-P-2, Glu-P-1, Glu-P-2, AαC, and MeAαC] for their life time, have been calculated based on mouse experiments… If we assume the average TD_{50} value of heterocyclic amines should be about 8mg/kg/day, we can roughly estimate the risk of these carcinogenic heterocyclic amines for human beings. The intake of heterocyclic amines was calculated from available data on their quantities in foods. Apparently the human intake is about 0.0002% times the TD_{50} obtained from animal data. This means that heterocyclic amines may not be so serious for human cancer development"

TABLE 17.30 (continued)
Chronology of *N*-Heterocyclic Amine Studies

Year	Event
	Sugimura added: "On the other hand, it is also true that human beings are being exposed to many heterocyclic amines and many other carcinogens with tumor promoters and/or suppressing factors for carcinogenesis. At this moment, it is honest to state that no solid information on the estimation of risk of heterocyclic amines has been obtained in any direction, either positive or negative"
1990	Felton and Knize (1177d) reviewed the results of numerous studies on the mutagenicity and tumorigenicity of the *N*-heterocyclic amines
1990	Manabe et al. (2448) identified the *N*-heterocyclic amine 1-methyl-6-phenyl-1*H*-imidazo[4,5-*b*]pyridin-2-amine (PhIP) in CSC
1991	By their addition to tobacco, Clapp (751) reported the contribution of various individual amino acids (asparagine, aspartic acid, arginine, glutamine, glutamic acid, histidine, proline, lysine, tryptophan, phenylalanine, creatine, creatinine) to the Ames test mutagenicity of cigarette MSS
1993	Lee et al. (2327c) reported that the CSC from cigarette MSS significantly inhibited the mutagenicity of several *N*-heterocyclic amines as measured in the Ames assay with *S. typhimurium* strain TA 98 in presence of the S-9 mix. The *N*-heterocyclic amines tested included the following: 2-Amino-3-methylimidazo[4,5-*f*]quinoline (IQ) 2-Amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ) 2-Amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1) 2-Aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2) 3-Amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) 3-Amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) The mutagenic activities of these mutagens were suppressed as much as 80% by addition of 50–100 µg of CSC per plate
1993	In their list of toxicants and tumorigens in tobacco and MSS, Hoffmann et al. (1773) did not include any *N*-heterocyclic amines
1994	In its list of toxicants and tumorigens in MSS, OSHA (2825) did not include any *N*-heterocyclic amines
1997	Hoffmann and Hoffmann (1740) issued a revised list of tumorigenic components in tobacco and tobacco smoke. Their revision of the Hoffmann–Hecht (1727) list included, in addition to several vapor-phase components, the following eight *N*-heterocyclic amines: 2-Amino-3-methylimidazo[4,5-*f*]quinoline (IQ) 2-Amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ) 2-Amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1) 2-Aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2) 3-Amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1) 3-Amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2) 2-Amino-9*H*-pyrido[2,3-*b*]indole (AαC) 2-Amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (MeAαC)
1998	In a letter to the editors of Beiträge zur Tabakforschung International, Hoffmann and Hoffmann (1741) listed eight *N*-heterocyclic amines as biologically active agents in the MSS of nonfiltered cigarettes. They also included the three aza-arenes reported as MSS components by Van Duuren et al. in 1960
1999/2000	Clapp et al. (755,756) reported that reduction of the level of protein in flue-cured tobaccos by 70% resulted in a reduction of 80% in the mutagenicity of the MSS "tar" (strain TA98 *S. typhimurium*) and 50% (strain TA100). Reduction of the protein level in burley tobacco by 50% resulted in reductions in mutagenicity of its MSS "tar" of 81% and 54%, with strain TA98 and TA100, respectively
2001	Hoffmann and Hoffmann (1743) and Hoffmann et al. (1744) listed eight *N*-heterocyclic amines as biologically active agents in the MSS of nonfiltered cigarettes. In both publications, the three aza-arenes reported as MSS components by Van Duuren et al. in 1960 were listed
2002/2003	In a presentation and publication, Rodgman and Green (3300) discussed the deficiencies of many of the lists of toxicants in cigarette MSS
2003	Rodgman (3265) outlined the major problems with the lists published by Hoffmann and colleagues (1740, 1741, 1743, 1744) and others
2005	Kinae et al. (2095a) reported that *N*-heterocyclic amines [2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ), 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ), 1-methyl-6-phenyl-1*H*-imidazo[4,5-*b*]pyridin-2-amine (PhIP)] were produced in an incubated solution of *D*-glucose and several amino acids at much lower temperatures and longer time periods than those encountered in the cooking of various foodstuffs (beef, poultry, fish). Several *N*-heterocyclic amines not found in CSC were also generated. The generation of the *N*-heterocyclic amines, as measured by the Ames test (*S. typhimurium* TA98), increased in proportion to the conditions imposed: 37°C (90 d), 50°C (30 d), 128°C (2 h)

18 Miscellaneous Components

18.1 SULFUR-CONTAINING COMPONENTS

Sulfur is a well-known constituent of tobacco and is essential for growth of the plant. In 1990, Tso (3973) reviewed the chemistry, biology, and physiological aspects of sulfur in tobacco. It is absorbed by the plant as sulfate, some of which undergoes reduction during assimilation and becomes incorporated into amino acid components of proteins (18A11). The sulfur content of tobacco varies by tobacco type and has been reported (3973) to range from 0.4% for flue-cured varieties to 1.1% for the Maryland tobacco (4246). Sulfur-containing (*S*-containing) compounds in or on tobacco can also come from added flavors and casings such as cocoa, as a contaminant of the leaf or of flavors and casings, or from agrochemicals (fertilizers, pesticides, herbicides insecticides, etc.) applied to the tobacco. Endogenous *S*-containing compounds of tobacco include numerous proteins, peptides, nucleotides, several amino acids (methionine, cysteine, cystine, taurine, homocysteine), and B vitamins (thiamine and biotin). Sulfur is also available as various inorganic sulfates or sulfides found in tobacco.

Sulfur is found in many casings and flavors used on tobacco. Solid flavorants or casing materials used on tobacco such as cocoa and licorice are natural products, and just like tobacco, they contain *S*-containing amino acids and proteinaceous substances. Some flavor additives used on tobacco products are *S*-containing compounds. In 1994, the tobacco rod of a cigarette produced by any of the six major manufacturers could have had any combination of 599 different ingredients (1053), 460 of which were individual compounds as described by Rodgman (3266). Of the 460, Rodgman listed 212 identified as untreated tobacco components, 245 identified in its smoke, and 168 in both tobacco and smoke. Those numbers have changed slightly since several of the 460 components have recently been identified in tobaccos by Leffingwell and Alford (2339a) and Peng et al. (2917a). Within the compounds listed by Doull et al. (1053) are nine *S*-containing compounds, e.g., methyl sulfide, *d,l*-methionine, 5-methyl-2-thiophenecarboxaldehyde, 3-methylthiopropionaldehyde, and methional.

Tobacco contains residual levels of the *S*-containing agrochemical compounds that are used to treat tobacco, e.g., Benfuracarb®, Oryzalin®, Thiofide®, Malathion®, Pebulate®, Cyolane®, Thiodicarb®, Trapex®, and Zineb®.

Cigarette mainstream smoke (MSS) contains a wide variety of *S*-containing compounds, e.g., *S*-containing amino acids, residues of herbicides, pesticides, insecticides, and growth promoters [Malathion, Captan®, Thiodan®; α- and β-Endosulfan®, Disulfoton®, Guthion®; and Chlorpyriphos®)], certain organic sulfates and sulfides, and decomposition products of *S*-containing agrochemicals. MSS components possess a wide variety of *S*-containing functionalities (thiol, alkylthio, mercapto, isothiocyanatoalkyl, thiazolyl, phosphinothioyl, alkyldithio, phosphoramidothio, phosphonodithio, thiacycloalkyl, thiadiazinyl, thienyl, thiocarbamato, sulfide, sulfonate, sulfonyl, sulfuroxides, and trisulfide). MSS also contains several polycyclic compounds that contain sulfur (18A14), e.g., benzothiophenes, dibenzothiophenes, and nonbenzenoid aromatic heterocycles, e.g., benzodioxathiepins.

The sulfur compounds in cigarette MSS reside in both the volatile and semivolatile fractions of MSS. Some *S*-containing compounds are also present in the particulate phase of MSS. The largest amount of research on *S*-containing compounds in MSS has been on those in the vapor phase of MSS. The low-molecular-weight *S*-containing compounds are volatile and highly odorous at ppm and ppb concentrations. Their odor characteristics have been reported by a GC–port sniffing technique [Alford and Houpt (18A01), Ayya (18A03)].

Because of the odiferous nature of many of the vapor-phase *S*-containing compounds in MSS, their presence has often been considered undesirable. However, it must be kept in mind that smoke is a complex mixture and the contribution of any single component depending on its concentration can actually add to the overall characteristic of tobacco smoke. Certain *S*-containing compounds are excellent tobacco flavors such as butyl sulfide (floral), furfuryl mercaptan (coffee), and allyl disulfide (garlic, nutty) and provide positive smoke taste characteristics, although their aroma is considered harsh or garlic (2341). *S*-containing compounds in tobacco are also possible precursors to Maillard reaction flavors. *S*-containing compounds can participate in Amadori rearrangement and Strecker degradation (18A03). The unpleasantness of a single odorant should never be a valid reason to ignore or to reduce their effects in a complex mixture like tobacco smoke.

Ayya (18A03) in 1994 posed the question of whether any of the *S*-containing compounds of tobacco smoke might be important pharmacologically if present in sufficiently high concentration. There are a number of *S*-containing compounds that are pharmacologically active [Rezanka et al. (18A12)], but none is found in tobacco smoke at concentrations that are of any concern. In terms of any of the *S*-containing compounds in tobacco or tobacco smoke being biologically active, the International Agency for Research on Cancer (IARC) has only tested sulfur dioxide and various sulfites, bisulfites, and metabisulfites. In their 1992 monograph (18A05), IARC stated:

> There is inadequate evidence for the carcinogenicity in humans of sulfur dioxide, sulfites, bisulfites and metabisulfites. There is limited evidence for the carcinogenicity in experimental animals of sulfur dioxide. There is inadequate evidence for the carcinogenicity in experimental animals

of sulfites, bisulfites and metabisulfites. Overall evaluation: sulfur dioxide, sulfites, bisulfites and metabisulfites are not classifiable as to their carcinogenicity to humans (Group 3).

IARC provides a classification for its overall evaluations of carcinogenicity to humans (18A04). It classifies individual compounds and mixtures into five categories based on scientific data on humans and animals. The classification is as follows:

- Group 1: Carcinogenic to humans
- Group 2A: Probably carcinogenic to humans
- Group 2B: Possibly carcinogenic to humans
- Group 3: Not classifiable as to carcinogenicity to humans
- Group 4: Probably not carcinogenic to humans

There are no known *S*-containing compounds in tobacco or tobacco smoke in groups 1, 2A, or 2B. There are only six compounds that are found in group 3 (Malathion, ethylenethiourea, Parathion®, Parathion-methyl®, sulfur dioxide, and ethylene sulfide). The evidence for the carcinogenicity in humans of all these compounds was classified as inadequate (18A04).

Periodically during the past five decades, various reviews and catalogs on the composition of tobacco and tobacco smoke have been published. Some have listed *S*-containing compounds in tobacco and tobacco smoke, while others have not. In 1936, Bruckner (451) listed 120 known components in tobacco and tobacco smoke. Of the identified compounds that Bruckner listed, only one contained sulfur (sulfate). In 1954, Kosak (2170) categorized about 50 components in tobacco smoke whose identities were certain. Under his heading of *Inorganic Components*, Kosak listed hydrogen sulfide and thiocyanic acid (?). The question mark indicated that Kosak did not consider the evidence in the literature to be definitive proof of the identity of the component. Latimer (2270) in 1955 listed 231 compounds identified from tobacco and tobacco smoke. Cystine, methionine, thiamine, and sulfur were present in tobacco, and thiocyanic acid, carbonyl sulfide, and methyl mercaptan were identified in tobacco smoke. Johnstone and Plimmer in 1959 (1971) listed 950 compounds in tobacco and tobacco smoke. In their review, they listed only two sulfur compounds as identified in tobacco, cystine and methionine. Obi and Nakano conducted studies on sulfur in tobacco and tobacco smoke, in 1962 (2822). They determined that the sulfur content in Japanese tobacco was 0.3%–3%, of which 30%–60% is organic sulfur. In a review of compounds identified in tobacco and tobacco smoke, Philip Morris, Inc., in 1963 (2939) listed 17 *S*-containing compounds. Stedman (3797) in 1968 listed 950 identified compounds in tobacco and tobacco smoke; of these, only 10 compounds were *S*-containing and all were from tobacco smoke. Izawa (1900) in 1961 reported on 440 identified tobacco and tobacco smoke components; of these, only two *S*-containing compounds in tobacco were mentioned (cystine, methionine). Roberts et al. in 1975 (3224) listed 2783 compounds identified in tobacco and tobacco smoke. In their report, they listed 41 *S*-containing compounds identified in tobacco smoke. There were no *S*-containing compounds reported in tobacco. In 1980, Ishiguro and Sugawara (1884) listed 1889 identified tobacco smoke components in their monograph; 46 *S*-containing compounds were listed. IARC, in 1986, (1871) listed only three *S*-containing agrochemicals in tobacco. Elmenhorst and Schultz in 1986 (1140) listed 13 *S*-containing compounds in their publication. Roberts in 1988 (3215) tabulated that there were 5868 identified compounds in tobacco and tobacco smoke. By functional groups, 3044 compounds had been identified in tobacco, 3996 had been identified in smoke, and 1172 were identified in both tobacco and tobacco smoke. Under the function group heading *Sulfur Compounds*, three compounds had been identified in tobacco, 37 were identified in tobacco smoke, and two compounds were found in both tobacco and tobacco smoke. In 1994, Ayya (18A03) summarized the previous work on *S*-containing compounds in tobacco smoke. He listed 32 sulfur compounds that had previously been identified in tobacco smoke. In his report, he cited work at Brown and Williams Tobacco Company on the odor characterization of low-molecular-weight *S*-containing compounds employing a gas chromatograph with a sniffing port.

As mentioned previously, several reviews on tobacco and tobacco smoke have not included or have omitted the *S*-containing compounds in tobacco and tobacco smoke. These include the reports by Bentley and Berry in 1959 and 1960 (282, 283), Berry (296) in 1963, and the reports by Sakuma et al. (3394, 3397, 3398) in 1983 and 1984. Bentley and Berry reported in 1959 that "Sulphur compounds have been found in smoke [Izawa et al. (1905)] but these have not been identified."

Whether there was a lack of analytical instrumentation and/or methodology for the determination of *S*-containing compounds in tobacco and smoke or a lack of concern for these types of compounds cannot be said. But it is interesting that even by 1994 (18A03), only about 40 *S*-containing compounds were identified as components of tobacco and tobacco smoke.

From 1966 through 1974, several notable studies were conducted on *S*-containing compounds in tobacco smoke. In 1966, Philippe (2940) reported on the identification of thiocyanogen, thiocyanic acid, hydrogen sulfide, carbonyl sulfide, methylthionitrite, dimethyl sulfide, carbon disulfide, and thiophene in MSS. In that same year, ethyl mercaptan has been qualitatively detected by Grob (1419).

Williams and McRae (4246) examined the fate of *S*-containing compounds in tobacco during cigarette smoking in 1967. The nonfiltered cigarettes in their experiments contained approximately 0.5% sulfur. They determined that 61.4% of the total sulfur content of the cigarette was found in the cigarette ash and 33.2% was found in the cigarette butt. They reported that the sulfur content of the whole MSS was 39 μg per cigarette, which was equivalent to 0.5% of the total sulfur in the cigarette. In total, they could account for over 95% of the total sulfur content measured in the cigarettes used in their experiments.

Groenen and Van Gemert (1429) in 1971 and Horton and Guerin (1831) in 1974 reported on the identification of *S*-containing compounds in the vapor phase of MSS. Both investigator groups employed flame photometric detection (FPD) gas chromatography (GC) for the determination of sulfur compounds in smoke (1831). Groenen and Van Gemert identified 37 compounds, while Horton and Guerin identified 28 *S*-containing compounds. Typical cigarette yields reported by Horton and Guerin were approximately 85 µg of H_2S, 35 µg of COS, 2 µg of CS_2, and 3 µg of SO_2 per cigarette when smoked under standard conditions. Horton and Guerin reported that the vapor phase of MSS contained *at least* 28 sulfur components but that the quantitative distribution of these components was highly sensitive to sampling methodologies. Quantitation is an obvious issue as Williams and McRae (4246) only could account for 39 µg of sulfur per cigarette in whole MSS.

Generally, sulfur compounds in tobacco samples can be converted by wet oxidation to sulfate. The sulfate is then reduced to H_2S which is separated by distillation and determined as methylene blue by the method of Johnson and Nishita (18A06). Protein sulfur can also be determined by the oxidation of sulfur to sulfur dioxide and titration with 0.1 N I_2 with starch as an indicator (18A02). These classic methods serve as determinations of total sulfur in a sample. Similar wet methods for the analysis of sulfur compounds in tobacco now employ autoanalyzers and robotics [Mottershead (18A10)]. Total sulfur in the sample can also be analyzed by x-ray emission spectroscopy [Keen et al. (18A07)], atomic absorption spectrometry [SAH and Miller (18A13)], atomic emission spectroscopy (AES) and inductively coupled plasma ICP-AES [Littlefield et al. (18A08)], or a variety of other instrumental methods. For example, ESR has also been used for the analysis of the presence of sulfur in tobacco (18A09). Specific *S*-containing amino acids in tobacco, e.g., methionine, cysteine, and cystine, are generally analyzed by GC, GC-MS, or liquid chromatographic techniques such as HPLC and LC-MS. Sulfur in proteins, nucleotides, and peptides is normally analyzed by digestion of samples into free amino acids and then determination of the amino acids by GC or LC.

FPD-GC (1429, 1831) and flame ionization detection (FID) GC (1419) have been used for the determination of sulfur compounds in tobacco smoke. Although these methods are still used today, GC–mass spectrometry is normally the preferred method for the determination and quantification of *S*-containing components in MSS.

Table 18.1 lists the *S*-containing components in tobacco, tobacco smoke, and tobacco substitute smoke. A total of 289 *S*-containing components have been identified in tobacco and/or tobacco smoke. Of these compounds, 139 were identified in tobacco smoke, 194 were identified in tobacco, and 44 were identified in both tobacco and tobacco smoke. It is interesting to note that over 80 of the 289 *S*-containing components in tobacco and/or its smoke are compounds that are used or have been used in tobacco agronomy.

18.2 HALOGENATED COMPONENTS

All of the halogens [chlorine (Cl), bromine (Br), fluorine (F), and iodine (I)] are minor constituents of tobacco and are essential for growth of the plant. In 1990, Tso (3973) reviewed the chemistry, biology, and physiological aspects of each halogen in tobacco. Soil contains low levels of all of the halogens in the form of salts (halides). Low levels of these halogenated salts generally promote growth in the plants and improve quality and yield. At high levels of absorption, all halides can cause toxicity (3979). The various halides are absorbed by the plant roots and are important in certain oxidative, enzymatic, and plant regulatory processes (3973). The content of Cl, Br, F, and I in tobacco varies by tobacco type, soil, and climatic conditions. Typical ranges of Cl, Br, F, and I reported in tobacco are 0.07%–3%, 100–200 ppm, 4–40 ppm, and 0.55–1.75 ppm, respectively (3979). Other sources of halogens in tobacco come from trace amounts of halides in fertilizers and from agrochemical treatments of tobacco.

Over the last 70 years, several review articles on the constituents of tobacco and tobacco smoke have been published. In 1936, Bruckner (451) discussed the biochemistry of tobacco. In his book, he briefly mentioned that tobacco contained *chloride*. Kosak (2170) in 1954 categorized about 50 components in tobacco smoke whose identities were certain. Under his heading of *Inorganic Components*, Kosak listed "chlorides" (?). The question mark indicated that Kosak did not consider the evidence in the literature to be definitive proof of the identity of the component. Latimer (2270) in 1955 listed 231 compounds identified from tobacco and tobacco smoke. At that time, methyl chloride was the only halogenated compound identified in tobacco smoke. Johnstone and Plimmer in 1959 (1971) listed 950 compounds in tobacco and tobacco smoke. In their review, they listed only one halogenated compound as identified in tobacco, 1,1,-dichloro-2-2(4,4′-dichlorodiphenyl)ethane (TDE or DDD), and two in tobacco smoke, methyl chloride (specifically) and certain other unnamed volatile chlorides. Bentley and Berry in 1959 and 1960 (282, 283) and Berry (296) in 1963 failed to report any halogenated compounds in tobacco or tobacco smoke. Izawa (1900) in 1961 reported 440 identified compounds in tobacco and tobacco smoke. In his report, he listed only methyl chloride as being identified in tobacco smoke.

In a review of compounds identified in tobacco and tobacco smoke, Philip Morris, Inc., in 1963 (2939) listed seven halogenated compounds: Cl, bromomethane, chloromethane, chloroethane, bromoethane, Endrin®, and TDE. Stedman (3797) in 1968 listed 950 identified compounds in tobacco and tobacco smoke; of these, only 17 compounds were halogen containing. Cl, F, and I were identified in tobacco, along with tobacco residues of methylene bromide, 1,1,1-trichloro-2-(4,4′-dichlorodiphenyl)ethane (DDT), Dieldrin®, Dyrene®, Endrin, TDE, Telodrin®, Thiodan®, Toxaphene®, Trichlorfon®, and Diclone®. *o*-Chloroaniline, ethyl chloride, and agrochemical residues from TDE, Endrin, chloro-2,2-bis-(4′-chlorophenyl) ethylene (TDEE), Telodrin, Thoidan, and Dyrene were reported in tobacco smoke. Roberts et al. in 1975 (3224) listed 2783 components identified in tobacco and tobacco smoke.

TABLE 18.1

In their report, they listed 30 chloro compounds, two bromo-containing compounds, two fluoro-containing compounds, and one iodo-containing compound. Thirty-one halogenated compounds were identified in tobacco smoke, 12 were identified in tobacco, and several were found in both tobacco and tobacco smoke. In 1980, while noting that the number of confirmed components exceeded 2500, Ishiguro and Sugawara (1884) listed 1889 identified tobacco smoke components in their monograph; 17 were halogenated. In their review, Ishiguro and Sugawara stated:

> All of the halogenated compounds found in smoke are chlorinated compounds. These probably originate from the chloride ions [3797] in the tobacco or from residual chlorinated organic additives. The chlorine atom in methyl chloride originates [712] mainly from inorganic chlorides.

They listed Cl, Br, I, and F as identified components in tobacco smoke. In their review, Ishiguro and Sugawara also examined several agrochemicals and their decomposition products transferred to smoke. The distribution of the chlorinated organic chemicals was examined in detail. It was clear to them that chlorinated organic agricultural chemicals produced the chlorinated compounds mentioned in their review during smoking. They stated:

> At present, the use of chlorinated organic insecticides has been banned in many countries, and their residues in tobacco have been decreasing every year. Organophosphorus types and synthetic organic compounds which are less likely to persist have become the mainstay of agricultural chemicals for tobacco cultivation, displacing the chlorinated organic types.

Unfortunately, their prediction was not totally correct as a great variety of chlorinated organic agrochemicals are still being discovered and used today in parts of the world. However, since 1969, the use of chlorinated pesticides has been banned in the cultivation of tobacco in the United States. As a result, DDT and TDE in tobacco and in cigarette smoke have drastically decreased. In the tobacco of a cigarette made in 1965, 13.4 ppm DDT and 20.2 ppm TDE were measured, and in the tobacco of the leading cigarette brand made in 1993, only 0.02 ppm DDT and 0.013 ppm TDE were detected, a decrease of more than 98% (999). The small amounts of residual DDT and TDE in more recently produced cigarettes appear to originate from imported tobaccos used for blended cigarettes (1714). It is interesting to note the following: Despite the fact that DDT was banned from agronomic use on tobacco in the United States in 1969, Chopra and his colleagues between 1969 and 1973 conducted exceptionally detailed studies on the degradation products generated during the smoking process from the *p,p′*-DDT in *p,p′*-DDT-treated cigarettes (703, 707–709, 711–714). Examination of the citations in the catalog (Table 18.4) of chloro compounds identified in the smoke from DDT-containing tobacco indicates that Chopra and his colleagues identified 10 chloro compounds, including transferred DDT.

New types of chlorinated organic agrochemicals though are still being developed. Their popularity and efficiency have not been displaced by organophosphorus types of agrochemicals or other synthetic organic compounds. Sakuma et al. (3394, 3397, 3398) in 1983 and 1984 reported on the identification of numerous compounds in tobacco smoke. In their reports, no halogenated compounds were reported. IARC, in 1986 (1871), listed only four halogen-containing compounds in tobacco and tobacco smoke in their report on the evaluation of the carcinogenic risk of chemicals to humans: vinyl chloride and the agricultural chemicals, DDT, Captan®, and Endrin. Of these compounds, only vinyl chloride and DDT showed sufficient evidence of carcinogenicity in experimental animals according to the IARC criteria. Most recently in 2005, Eberhardt (21A19) prepared an extensive review of pesticides used on tobacco, the transfer rates of pesticides to MSS and sidestream smoke (SSS), and decomposition products of pesticide residues identified in MSS. In his review, much data previously presented by Ishiguro and Sugawara (1884) were presented and updated.

The vast majority of the halogenated compounds presented in this chapter are covered in other chapters of this book, e.g., Chapters 4, 9, 10, 19, 20, and 21. One particular group of halogenated compounds only reviewed in this chapter is the dioxins. Dioxins are polychlorinated heterocycles. The three forms found in tobacco and tobacco smoke are polychlorodibenzo-*p*-dioxins (PCDDs), polychlorodibenzofurans (PCDFs), and polychlorinated biphenyls (PCBs). Another group of compounds that is not reviewed elsewhere in the book is the Freon® compounds. Green et al. (1375b) recently reviewed the various chemicals used in the expansion of tobacco and their effect on cigarette MSS properties. In their review, Green et al. (1375b) discussed the use of various Freon compounds for tobacco expansion. Rix, in 1989, analyzed expanded tobacco for the expansion agent Freon 123 (4859). Additionally, sulfur hexafluoride and perfluoropropane have been investigated as alternate tobacco expanding agents (4860, 18B17). As a result, these classes of compounds will not be discussed further in this chapter, and the reader is directed to the review by Green et al. (1375b) and references from R.J. Reynolds Tobacco Company (4859, 4860, 18B05, 18B06 18B08, 18B16, 18B17).

In 2002, Rodgman and Green (3300) reviewed the literature on tobacco smoke toxicants. In their review, they discussed the PCDDs and PCDFs identified in tobacco and tobacco smoke. Rodgman and Green noted that among the smoke toxicants conspicuous in their absence from all toxicant lists except that of Fowles and Bates (1217) are the PCDDs and PCDFs. The presence of dioxins in cigarette smoke was first reported in 1980 by Crummett (854). There are at least five other publications in which the presence of dioxins (PCDDs and PCDFs) in cigarette tobacco or its MSS (3300) is reported. These include publications by Muto and Takizawa (2664), Ball et al. (177), Matsueda et al. (2490, 2491), and Löfroth and Zebühr (2391).

The smoke yield data of Muto and Takizawa (2664) were obtained from a single smoking puff that entirely consumed the cigarette and are clearly not appropriate for comparisons of MSS yields obtained by FTC or Coresta methods. The MSS and SSS data of Löfroth and Zebühr (2391) were obtained from only one Swedish cigarette brand. The PCDD and PCDF data reported by Matsueda et al. (2491) were for the amount of these compounds contained in the cigarette tobacco rather than the smoke. The smoke yield data for the Ball et al. (177) and Matsueda et al. (2490) experiments were similar. The Ball et al. data were collected and analyzed by a well-validated method, and the laboratory where the analyses were performed, i.e., ERGO Forschungsgesellschaft mbH, Hamburg, has been accredited by the World Health Organization (WHO) for dioxin analysis (177). The analytical data of Ball et al. (177) represent results from the 10 top selling brands in Germany during the fourth quarter of 1989. The ERGO scientists chose to present individual data on each of the tested cigarettes. It should be noted that the most toxic isomer, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), was not detected in any of the samples, and additionally, not every isomer present was quantifiable in each product tested. The total amount of total PCDDs and PCDFs was 7.50 and 2.98 pg/cig, respectively (see Table 2 of 3300). In 1998, Radovanović and Mišić (18B15) examined the MSS of Yugoslavian cigarettes for PCBs. They identified 10 PCBs. The level of PCBs identified ranged from less than 1 to 78.1 ng/g of smoke condensate (18B15). Generally, the levels of PCBs in MSS are considerably less than the PCDDs and PCDFs (3715).

Dioxins are not typical herbicides used on tobacco. So where do they come from and why are they so important?

2,4-Dichlorophenoxyacetic acid (2,4-D) was introduced in 1944 as the first of the phenoxy herbicides, phenoxyacetic acid derivatives, or hormone weed killers. The phenoxy herbicides have complex mechanisms of action resembling those of auxins (growth hormones). They affect cellular division, activate phosphate metabolism, and modify nucleic acid metabolism. These herbicides are highly selective for broadleaf weeds and are translocated throughout the plant. 2,4-D provided most of the impetus in the commercial search for other organic herbicides in the 1940s. Several compounds belonged to this group, of which 2,4-D and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) are the most familiar. Other important compounds in this group are 4-(2,4-dichlorophenoxy)butyric acid (2,4-DB), 2-methyl-4-chlorophenoxy-acetic acid (MCPA), and 2-(2,4,5-trichlorophenoxy)propionic acid (Silvex® or Fenoprop®) [Ware and Whitacre (18B18)].

2,4-D, MCPA, and 2,4,5-T have been used worldwide for years in very large volume. The latter product, 2,4,5-T, used mainly to control woody perennials, became the subject of extended investigation, particularly because of its use in Vietnam in combination with 2,4-D as Agent Orange. Certain samples were found to contain small amounts of a highly toxic impurity, TCDD, commonly referred to as tetrachlorodioxin, or dioxin. Although alterations in manufacturing procedures reduced the dioxin content to minimal levels, 2,4,5-T registrations were canceled, and the product was voluntarily removed by the manufacturers in 1985 (18B18).

2,4-D has been and continues to be one of the most useful herbicides ever developed. More than 33 million pounds manufactured in the United States are used each year in 35 ester and salt forms. In agriculture, it is used on cereal, grain crops, and sugarcane for the control of broadleaf weeds and on rights-of-way, turf and lawns, and in forest conservation programs. The manufacturing process for 2,4-D used in the United States does not result in any level of tetrachlorodioxin contamination. Other members of the phenoxys in wide use are 2-(2,4-dichlorophenoxy)propionic acid (Dichlorprop® or 2,4-DP), 4-(4-chloro-2-methylphenoxy)butanoic acid (MCPB), and 2-(4-chloro-2-methylphenoxy)propanoic acid (Mecoprop® or MCPP) (18B18). None of these compounds [2,4-DB, 2,4-DP, MCPB, MCPA, MCPP, 2-(2,4,5-trichlorophenoxy)propionic acid] have been found in tobacco or tobacco smoke.

Of the three forms of dioxins found in tobacco and tobacco smoke, the PCDDs, PCDFs, and PCBs are a group of chemical compounds which are among the most toxic and hazardous pollutants in the environment. The PCDDs, PCDFs, and PCBs compounds, collectively referred to as dioxins, are impurities associated with certain end products resulting from the treatment of chlorinated benzenes at elevated temperature and pressure under alkaline conditions. The most notable contaminant of the group is TCDD which can be formed along with other dioxin compounds during the manufacture of several commercially important products such as the herbicide 2,4,5-T, the fungicide pentachlorophenol, and the germicide Hexachlorophene® (18B19). Numerous investigators have found PCDDs, PCDFs, and PCBs in tobacco as well as tobacco smoke [1457, Gichner et al. (18B14), Djordjevic et al. (1000, 1006), Radovanović and Mišić (18B15)].

Suspicions of the possible long-term health hazards of dioxins arose after it was found that 2,4,5-T was teratogenic in rat and mouse [Courtney et al. (18B10)]. Shortly thereafter, it was discovered that the 2,4,5-T sample used in this study contained about 30 ppm TCDD (18B10). It was primarily the report by Courtney et al. (18B10) implicating TCDD as a contaminant of 2,4,5-T that led to its further evaluation for teratogenicity [Courtney and Moore (18B11)] and its eventual testing for mutagenicity. These and other similar reports published during the late 1960s and early 1970s also stimulated toxicological studies on other dioxin derivatives as well as studies dealing with issues such as environmental contamination and movement and analytical detection of these compounds. Numerous detailed reviews summarizing work in these areas have been published. The latest and perhaps the most comprehensive review was prepared by the World Health Organization in 2002 (18B07).

Additionally, IARC has prepared a monograph on dioxins (7A03), and Wassom et al. (18B19) reviewed the genetic toxicology of PCDDs.

Dioxins are produced inadvertently as a by-product of chemical production or during combustion and are widespread pollutants in the environment. They are ubiquitous. The biggest source of PCDDs, PCDFs, and PCBs is the large-scale burning of municipal and medical waste. Other sources include

- The production of iron and steel
- Backyard burning of household waste, especially plastics
- Fuel burning, including diesel fuel and fuel for agricultural purposes and home heating
- Wood burning, especially if the wood has been chemically treated
- Electrical power generation
- Tobacco smoke

Dioxins can also be produced from natural processes, such as forest fires, explosions, and volcanic eruptions. Most dioxins are introduced to the environment through the air. The airborne chemical can attach to small particles that can travel long distances in the atmosphere. PCDDs, PCDFs, and PCBs are found in very small amounts in the environment, including in the air, water, and soil. As a result, they are also present in some foods. They can also present a health risk at elevated dosages. As for tobacco smoke, the dosage of dioxins from cigarettes is extremely low. Exposure estimates suggest that the smoking of 20 cigarettes/day contributes approximately 2%–4% of the total daily exposure to dioxins for a 70 kg adult (177). The major source of exposure to PCDDs, PCDFs, and PCBS is the diet [Canady et al. (18B07)].

Rodgman and Green (3300) noted in their review of MSS toxicants that certain dioxins are antitumorigens. Slaga and DiGiovanni (3685) summarized the studies in which dioxins were shown to interfere with the enzyme pathways responsible for tumorigenesis of several of the most potent polycyclic aromatic hydrocarbons (PAHs). The dioxins were not listed as MSS toxicants in previous tabulations of MSS toxicants reviewed by Rodgman (3255, 3255a, 3257, 3265) and Rodgman and Green (3300). In fact, only one MSS toxicant list issued since 1990, that of Fowles and Bates (1217), has included the dioxins even though their presence in MSS was known in 1980 (854). Dioxins are antitumorigenic to DMB[*a*]A (7,12-dimethylbenz[*a*]anthracene), MC (3-methylcholanthrene, more recently named 1,2-dihydro-3-methylbenz[j]aceanthrylene), B[*a*]P (benzo[*a*]pyrene), 7-MB[*a*]A (7-methylbenz[*a*]anthracene), 12-MB[*a*]A (12-methylbenz[*a*]anthracene), 5-MeC (5-methylchrysene), and DB[*a,h*]A (dibenz[*a,h*]anthracene) [Berry et al. (18B04), Cohen et al. (18B09), DiGiovanni et al. (976), DiGiovanni et al. (18B12)].

The IARC classification of carcinogenicity (18A04) places 25 halogen-containing compounds in tobacco or tobacco smoke in groups 1, 2A, 2B, and 3. Table 18.2 lists the individual halogen-containing chemicals (agents) and families of chemicals (groups of agents) identified in tobacco and tobacco smoke. IARC lists TCDD and vinyl chloride as group 1 human carcinogens. Trichloroethylene, epichlorohydrin [(chloromethyl)oxirane], ethylene dibromide, and PCBs are listed by IARC as group 2A (probably carcinogenic to humans). Ten halogen-containing compounds are listed in group 2B (possibly carcinogenic to humans): Chlordane®, *p*-chloroaniline, chloroform, chlorophenoxy herbicides, chlorothalonil (2,4,5,6-tetrachloro-1,3-benzenedicarbonitrile), DDT (*p,p′*-DDT), dichloromethane (methylene chloride), 1,3-dichloropropene, Heptachlor®, and hexachlorobenzene. Nine halogen-containing compounds are listed in group 3 (not classifiable as to carcinogenicity to humans): chloroethane, *m*-dichlorobenzene, *o*-dichlorobenzene, 1,2-dichloropropane, Hexachlorophene®, Methoxychlor®, methyl iodide, polychlorinated dibenzofurans, and 1,1,1-trichloroethane.

There are numerous analytical methodologies to identify and quantify halogenated compounds in tobacco and smoke. The method of analysis will vary among the halogenated compounds and particularly the pesticide types. Sources of methods include the *FDA Pesticide Analytical Manuals* (PAMs) I and II (18B13), the *FDA Index of Residue Analytical Methods* (RAM) (18B13), the methods in the *Journal of the Association of Official Analytical Chemists* (18B02, 18B03), and methods found in journal articles. Generally, the preferred methods of analysis involve gas chromatography (GC), liquid chromatography (LC), or GC–mass spectrometry (MS) techniques. Flame ionization detectors (FIDs) are normally used for quantitative analysis of halogen-containing organics, while electron capture detectors (ECDs) are preferred for quantitative determination of PCDDs, PCDFs, PCBs, and other pesticides [Radovanović and Mišić (18B15)].

There are 266 identified halogenated compounds in tobacco and/or tobacco smoke. As seen in Table 18.3, the vast majority (215 compounds) contain chlorine only. Thirteen compounds contain bromine only, four containing iodine only, and 14 contain fluorine only. Twenty are multihalogen-containing components. Over 85% of all the halogenated compounds found in tobacco and tobacco smoke are either halogenated agrochemicals, impurities found in the agrochemicals (PCDDs, PCDFs, PCBs), or decomposition products from the agrochemicals. Table 18.4 lists the 266 halogenated compounds identified in tobacco and/or tobacco smoke. In a few cases, a halogenated component has been identified in tobacco substitute smoke. Table 18.4 is divided by halogen type (chloro, bromo, iodo, and fluoro compounds) and includes several halogenated compounds with two or more halogens (mixed halogenated compounds).

Agents, groups of agents, mixtures, and exposure circumstances (associated with tobacco) evaluated in IARC Monographs Volumes 1–95. This list contains all agents evaluated as of November–December 2006 that are considered: carcinogenic to humans (group 1), probably carcinogenic to humans (group 2A), and possibly carcinogenic to humans (group 2B). For details of the evaluation, the relevant monograph should be consulted; see http://monographs.iarc.fr/ENG/Classification/crthgr01.php. Those agents listed have been identified in tobacco or tobacco smoke.

19 Fixed and Variable Gases

This chapter deals with gases found in tobacco and tobacco smoke. The gases discussed will be mainly inorganic gases. Two types of gases will be discussed, fixed gases and variable gases.

In the atmosphere, gases, the volume percentages of which do not change, are called fixed gases. Table 19.1 gives the volume percentages of these fixed gases. At altitudes below 100 km, nitrogen (N_2) makes up about 78% of all atmospheric gas by volume, and oxygen (O_2) makes up about 21%. The volume percentages of these fixed gases are constant with increasing altitudes, and the partial pressures of N_2 and O_2 are constant fractions of air pressure. Together, N_2 and O_2 make up 99% of all gases in the atmosphere by volume. Argon (Ar) at 0.93% makes up the bulk of the remaining 0.97%, with neon (Ne), helium (He), krypton (Kr), and xenon (Xe) present in trace quantities (19A04). As a result, the concentrations of fixed gases are the same not only in the atmosphere but in every material present on the Earth's surface where atmospheric gases reside.

Variable gases are gases with volume percentages that change with time and location. For example, water vapor in different areas of the world varies with climatic conditions and geography. Radon is a variable gas as it occurs in only specific areas of the world. The major variable gases are water vapor (H_2O), carbon dioxide (CO_2), carbon monoxide (CO), ozone (O_3), sulfur dioxide (SO_2), nitric oxide (NO), nitrogen dioxide (NO_2), low-molecular-weight hydrocarbons, and simple aromatic chemicals. Much of the variability in the concentration of these gases in the atmosphere arises from the combustion of fossil fuels. Table 19.2 summarizes the volume percentages of some variable gases in a clean atmosphere and a polluted atmosphere, e.g., urban or industrial areas. Water vapor can vary tremendously and is primarily dependent on the environment. For example, water vapor in the atmosphere is always higher in areas near water and always lower in desert areas. As can be seen, some of the inorganic and organic gases change appreciably (CO, SO_2, NO, NO_2, organic gases) while others change minimally (CO_2, O_3), even in polluted atmospheres (19A04). For example, the concentration of CO_2 at point sources such as smoke stacks can be very elevated. O_3 concentrations during electrical storms can be elevated to the point that its characteristic odor is noticeable. As a result, they are termed variable gases.

Again, just as the fixed gases are present in nearly every material present on the Earth's surface, variable gases are also present in all materials that are porous and can be found on the surfaces of many other materials.

Tobacco contains all of the fixed gases that are present in the atmosphere. It also contains a variety of variable gases because it is grown in areas lacking a pristine atmosphere. Tobacco is often treated with agrochemicals (fertilizers, pesticides, herbicides, etc.). As such, these chemicals can decompose and create residues in/on the tobacco. Additionally, as tobacco is often cured in atmospheres that contain pollutants and/or combustion gases, e.g., NO, NO_2, SO_2, SO_3, the concentration of variable gases in the leaf can be elevated. Nitrogen and oxygen are the most plentiful fixed gases found in tobacco. Although the other fixed gases Ar, Ne, He, Kr, and Xe have not been identified in tobacco, there is no reason to believe that they are not present. The variable gases found in tobacco include ammonia (NH_3), bromine (Br_2), CO_2, CO, chlorine (Cl_2), fluorine (F_2), iodine (I_2), phosgene ($COCl_2$), hydrazine ($H_2N\text{-}NH_2$), hydrogen cyanide (HCN), isocyanic acid (H-N═C═O), nitrous oxide (N_2O), NO, NO_2, mixed nitrogen oxides (NO_x) [N_2O + NO + NO_2], phosphine (PH_3), radon (Rn and ^{222}Rn), and H_2O. Biochemically, some of these variable gases are produced by the plant to regulate growth processes, e.g., NO, NO_2, while others are formed, e.g., NH_3 via fertilization, or absorbed by the plant (H_2O) and used as energy sources. Some of the variable gases are found as plant residues from the atmosphere (Rn), while some are residues from water sources (halogens), agrochemicals ($COCl_2$, $H_2N\text{-}NH_2$, HCN, isocyanic acid, PH_3, etc.), or other environmental sources, e.g., SO_2.

The concentration of the fixed and variable gases in tobacco smoke is not directly related to the concentration of these gases in tobacco. As tobacco smoke is the result of combustion and pyrolysis of tobacco, the concentration and types of fixed and variable gases formed vary considerably.

Over the years, several scientific articles and reviews have been published that catalog the fixed and variable gases found in tobacco and tobacco smoke (172, 1140, 1067, 1140, 1971, 2068, 2170, 2799a, 3224, 3797, 4012, 4332, 19A05). One of the earliest articles that identified certain fixed and variable gases in tobacco smoke was published by Kosak (2170) in 1954. Kosak listed O_2, NH_3, CO, CO_2, HCN, other "cyanides" (?), hydrogen sulfide (H_2S), thiocyanic acid (?), "chlorides" (?), "nitrates" (?), and "unsaturated hydrocarbons." It should be noted

TABLE 19.1
Volume Percentages of Fixed Gases in the Earth's Atmosphere

Gas Name	Chemical Formula	Percent
Molecular nitrogen	N_2	78.08
Molecular oxygen	O_2	20.95
Argon	Ar	0.93
Helium	He	0.0015
Neon	Ne	0.0005
Krypton	Kr	0.0001
Xenon	Xe	0.000005

that the question marks associated with some of the compounds listed by Kosak indicate that Kosak did not consider the evidence in the literature to be definitive proof of the identity of the component. It is conceivable that the designation "chlorides" (?) and "nitrates" (?) could have indicated the presence of Cl_2, NO, NO_2, and other NO_x in tobacco smoke.

Johnstone and Plimmer (1971) reviewed the constituents of tobacco and tobacco smoke in 1959 and listed CO, CO_2, carbonyl sulfide (COS), NH_3, carbon disulfide (CS_2), cyanogen [$(CN)_2$], HCN, thiocyanogen [$(SCN)_2$], NO, and numerous small saturated and unsaturated hydrocarbons as components of the vapor phase of cigarette mainstream smoke (MSS).

Keith and Tesh reported in 1965 on the measurement of the total MSS issuing from a burning cigarette (2068). By utilizing a simple puffing mechanism which employed a cold trap packed with 5 Å molecular sieve pellets, they were able to quantitatively measure the total vapor mixture from a burning cigarette. This quantity when combined with the separately trapped particulate material provided a measure of the total effluent. It was found, contrary to previous thinking, that the vapor components of smoke comprised over 95% of the weight of material collected from a burning cigarette. By far, the greatest proportion of the collected weight of the total MSS vapor phase was contributed by the air entering the cigarette.

Wynder and Hoffmann in 1967 (4332) reviewed the known constituents of the particulate and vapor phase of MSS. Chapter VIII of their book provided historical information on our understanding of cigarette combustion processes and the composition of the vapor phase of tobacco smoke at that time. Wynder and Hoffmann cited the pioneering work of Jarrell and de la Burde (1924) and Keith and Tesh (2068) who reported in 1965 that the O_2 content in whole MSS is a function of air entering through the burning cone of the cigarette, part of which is consumed during combustion, and diluting air entering through the cigarette paper. The cigarette burning rate, dictated by the cigarette rod packing density, the tobacco type employed, and the cigarette paper air permeability affected O_2 consumption. Nitrogen and argon do not react with tobacco constituents during the burning as they are inert gases. Their concentrations were affected by the air entering through the burning cone, mainly the diluting air. Jarrell and de la Burde (1924) found that the burning zone of a cigarette represented a reducing atmosphere. The H_2 in the whole smoke was derived nearly exclusively from the

TABLE 19.2
Volume Percentages of Some Variable Gases (Inorganic and Organic) in the Atmosphere (19A04)

Gas Name	Chemical Formula	Clean Atmosphere (ppbv)	Polluted Atmosphere (ppbv)
Inorganic			
Water vapor	H_2O	$3{,}000–4.0 \times 10^7$	$5.0 \times 10^6–4.0 \times 10^7$[a]

R, hydrogen or alkyl functionality.

[a] 4.0×10^7 indicates that the volume percentage is negligible, on average.

burning of tobacco. During burning, certain tobacco components split off elementary hydrogen, which for the most part formed water with available oxygen. The presence of 8% H_2 (by volume) in the gas leaving the burning cone was indicative of the existence of a reducing atmosphere in the fire cone. The large concentrations of both CO and CO_2 relative to air indicated that several combustion and pyrolysis processes were occurring in the burning cigarette. The low ratio of CO_2 to CO indicated that incomplete combustion of tobacco was occurring. The ratio of CO_2 to CO is considered to be an index (3482) of the combustibility of tobacco. Generally, the ratio of CO_2 to CO is less than 3 in nonfiltered cigarettes.

In 1968, Stedman reviewed the chemical composition of tobacco and tobacco smoke (3797). The review noted that gaseous NH_3, I_2, and H_2O were identified constituents of tobacco. It also listed CO, CO_2, NH_3, CS_2, COS, Cl_2, F_2, H_2S, HSCN, and [$(SCN)_2$] as compounds present in the vapor phase of MSS.

In 1968, Elmenhorst and Schultz (1140) reported on the concentrations of various inorganic gaseous components in the vapor phase of MSS (Table 19.3).

In 1975, Roberts et al. (3224) reported on R.J. Reynolds Tobacco Company's (RJRT) literature study of tobacco and smoke components. RJRT had been collecting information from the literature and conducting extensive research on the identification of chemicals in tobacco and smoke since the early 1950s. As of 1975, RJRT had compiled a listing of 2783 components from tobacco, tobacco smoke, and other smoking products. Of these compounds, 1235 were tobacco isolates, 2266 were tobacco smoke components, and 356 have been identified from other smoking products. Approximately one-half of all the tobacco and smoke components were first isolated by RJRT research personnel. The lists were divided into functional group classes, including fixed and variable gases found in tobacco and smoke. Twenty-five gases had already been identified in tobacco and smoke by 1975. The number of fixed and variable gases identified in tobacco and tobacco smoke has not changed substantially since then.

Ishiguru and Sugawara in 1980 (1884) cataloged the components of tobacco smoke. In their review, they listed 1889 components of tobacco smoke [see Table 1 in (1884)]. They commented that the number could be about 2500, but they had omitted those components that were only partially identified. Among the components that they discussed were the fixed and variable gases in tobacco smoke.

In 1982, Dube and Green (1067) calculated the contribution of the fixed gases from 500 mg of unfiltered cigarette MSS. From 500 mg of whole smoke, 22.5 mg was the wet particulate matter, and 67.5 mg was vapor-phase compounds, of which ~10% (or 6.75 mg) was water vapor, ~80% (or 54 mg) was CO_2, and ~10% was organic compounds. The remaining 410 mg of whole smoke contained 310 mg of N_2, 65 mg of O_2, 20 mg of CO, an additional 5 mg of CO_2, 4 mg of Ar, and 1 mg H_2. Similar analyses were conducted by Keith and Tesh in 1965 (2068), Norman in 1977 (2799a), and Hoffmann and Hecht in 1990 [see Table 1 in (1727)]. Table 19.4 illustrates the data on fixed and variable gases in whole tobacco smoke that were provided by these investigators.

In 1999, Norman (19A05) and Baker (172) reviewed the literature on cigarette design and materials and smoke chemistry, respectively. Their works represent the most recent and comprehensive reviews on these subjects. Baker

[a] Percent of total tobacco smoke generated based on 500 mg of whole smoke (1067).
[b] Number in parentheses represents % of individual compound identified in fixed gases from whole smoke (1727).

discussed the present fundamental knowledge of cigarette combustion and smoke formation including how the concentrations of fixed gases, e.g., O_2 and H_2, fluctuate during cigarette combustion and how variable gases, e.g., CO, CO_2, are formed. Norman discussed the complicated field of cigarette design and how each design variable (tobacco type, cigarette shape, weight, and size, cigarette paper properties, filter designs, etc.) affects cigarette performance and ultimately cigarette smoke yields (including fixed and variable gases).

19.1 ANALYTICAL METHODS

In 1996, Green and Rodgman (1373) summarized all the historical and currently used analytical methods for the identification of chemicals isolated from tobacco and tobacco smoke. Their review is so complete and so well documented that the reader is directed to read their review article to determine the analytical method best suited for the analysis of a particular chemical constituent in tobacco and smoke. All of the past and current methods for the determination of fixed and variable gases in tobacco and tobacco smoke can be found in their article and will not be included in this chapter. Only a few specific examples of analytical methods for the most important variable gases will be provided (1884).

Although there is no standard ISO or FTC method for the analysis of fixed gases in cigarette smoke, fixed gases are normally analyzed by mass spectrometry (MS), gas chromatography (GC), or GC-MS. Generally, the fixed gases, e.g., N_2, O_2, Ar, He, H_2, have been determined chromatographically with separation based on molecular size. A molecular sieve packing is normally used in a stainless steel packed column. Samples are introduced with either a gas tight syringe or a sampling valve with a fixed volume loop. Upon injection, the sample is swept through a gas chromatograph with carrier gas. After separation in the column, components are quantified based on the difference in thermal conductivity between the carrier gas and the component. For the analysis of H_2 and He, Ar is used as the carrier. He is used for all the other gases, such as N_2 and O_2. Detection limits using a thermal conductivity detector are typically 0.01% by volume (19A08). Gas samples can be analyzed by MS via a gas inlet port on the mass spectrometer. Methods for the determination of fixed gases in cigarette smoke have been reported by Routh (19A06) and Reynolds and Wheeler (3120). There are several methods for the analysis of the major variable gases from tobacco smoke, e.g., CO, CO_2, NO, NO_2, HCN, and NH_3. The current standard methods approved by International Organization for Standardization (ISO), Federal Trade Commission (FTC), and Cooperation Centre for Scientific Research Relative to Tobacco (CORESTA) for the determination of the variable gases are described by Counts et al. along with analytical results from a recent worldwide market sample of cigarette brands (19A02, 19A03).

19.1.1 Carbon Dioxide and Carbon Monoxide

CO_2 is a major vapor-phase MSS component exceeded only by N_2. Its concentration is about 10% of the weight of the whole tobacco smoke (4145), similar to that of O_2. The concentration of CO is next highest, being about 4% (4145). The ratio of CO_2 to CO is considered to be an index (3482) of the combustibility of tobacco. The currently approved methods for the determination of CO are ISO Standard Methods 3308, 3402, 4387, 8454, 10315, and 10362-1. In these methods, CO is determined by nondispersion infrared (NDIR) spectroscopy (19A02).

Historically, GC (474, 2123, 2662, 4145) and NDIR spectroscopic analysis (781, 782, 4251, 4252) have generally been the preferred methods for analysis of CO_2 and CO in MSS, but an electrochemical transducer (ECT) method (447) has also been used for the analysis of CO, in which the electrochemical reaction during oxidation by catalysis is converted to electrical signals. Sample treatments before GC or NDIR analyses such as oxidation (474, 4145) of CO to CO_2 with iodine pentoxide, reduction (2123, 2124) of CO to CH_4 with a Ni catalyst, and separation (2634) by lowering the column temperature to –70°C have also been studied. GC (2662) with 5 Å molecular sieves as the packing materials has also been employed. The levels of both CO_2 and CO in smoke increase (4251) as the number of puffs increases. The amounts of these combustion gases produced in the early puffs of a cigarette are lower than those analyzed at the end of a cigarette during smoking (4251, 4252). The relationship to the length of the cigarette is such that the concentrations of these components in the vapor phase decrease (3881, 3883) with increasing length, and this can be explained by the reduction in the amount of tobacco burned and diffusion of CO from the wrapper during smoking (19A05). Tobacco quality is an important factor in terms of the amount of CO and CO_2 produced during cigarette combustion. The amount of CO produced (474, 3088) is greater for low- to medium-grade tobaccos, and the amount of CO_2 increases (474) as tobacco quality becomes higher. Experiments with ^{18}O as the source of atmospheric oxygen indicated that more than 50% of the oxygen atoms in the CO_2 and CO molecules come from the atmosphere (1884).

19.1.2 Nitrogen Oxides

NO_x in tobacco smoke has been quantified by calorimetric analyses (189, 3441, 3720) such as the Saltzman method (19A07) and by the chemical emission method (2122) which has been shown to be a rapid method for quantification (1884). Most of the NO_x present in fresh MSS is NO; only a small amount of NO_2 is present (189, 816, 2803). The concentration of NO_2 in MSS increases (189, 2803, 3691) with the age of the smoke and can reach levels of 200 ppm after 60 s (189). NO_2 formation is believed to result from the autoxidation of NO. It has also been suggested that some of the NO_2

produced by oxidation is converted (2941, 4058) to methyl nitrite through a reaction with methanol in the smoke (1884). Predominate precursors of NO are nitrates (189) and other *N*-containing compounds in the tobacco. N_2O (2941) and HNO_3 (4058) have also been reported as components of MSS in addition to the earlier compounds (1884). The currently preferred method for the determination of NO_x is chemiluminescence (1930, 19A02).

19.1.3 Hydrogen Cyanide

HCN in smoke has been analyzed by colorimetry (110, 779, 780, 3088), by the ion-selective electrode method (3482), and by GC (513). An analysis of HCN in tobacco smoke by Vickroy and Gaunt (4053) illustrated that HCN can vary from 144 to 351 µg/cig depending on different brands of cigarettes. The concentration of HCN in MSS increases (110) with puff number similar to other MSS components. HCN is present in both the vapor phase and the particulate phase of MSS (110). Considerable amounts of HCN have also been found in cigarette butts (110, 779, 780). Today, the preferred method for the determination of HCN in the vapor and particulate phase of MSS is colorimetry. HCN is converted to cyanogen chloride, treated with pyridine, and complexed with diethyl acetone dicarboxylate (779, 780, 3145). Schmeltz and Hoffmann (3491) found that tobacco smoke contains $(CN)_2$ and that up to about 5% of the HCN analyzed was produced by conversion of HCN to $(CN)_2$ during analysis (1884).

19.1.4 Ammonia

The preferred method for the determination of NH_3 in MSS is currently ion-exchange chromatography (IEC) (2681a, 19A02). In this method, NH_3 is collected from Cambridge pads and sulfuric acid traps and then analyzed by IEC (19A02). Previous methods for the analysis of NH_3 in MSS such as titration and colorimetry suffered from interferences (2724, 2787, 19A01.), principally low-boiling amines. Quantification of NH_3 by means of selective electrodes (3693) has been attempted, but the results were affected (475) by methylamine. GC (129, 475, 2541) has also been employed with good results since the effects of the presence of other substances can be substantially reduced. Early methods for the determination of NH_3 involved trapping MSS in an aqueous acidic solution. The trapped MSS solution was then steam distilled under alkaline condition to obtain the sample for analysis. It was discovered that this early method produced extra NH_3 (30%–80%) during the steam distillation procedure (475, 1884). NH_3 collected from MSS should be analyzed directly to achieve accurate quantification (1884). Cigarette blends with higher levels of nitrogen such as blends high in burley tobacco tend to have higher yields of MSS NH_3. The yield of NH_3 in MSS is known to vary with the permeability of the cigarette wrappers, when cigarettes were tested with comparable blends (475). The amount of NH_3 produced was greater for wrappers with higher air permeability. The rate of formation of NH_3 depended strongly on temperature. The yield of NH_3 increased with decreasing temperature (1884). Therefore, it was thought that variations in the burning temperature resulting from differences in wrapper quality or its air permeability determined the amount of NH_3 produced (1884).

Table 19.5 is a catalog of the fixed and variable gases in tobacco, tobacco smoke, and tobacco substitute smoke. The catalog contains only 36 entries. This number of entries represents a very small fraction of the total number of identified compounds in tobacco and tobacco smoke, but amazingly, the weight contributed by fixed and variable gases represents about 90% of the whole smoke from a cigarette.

Note: The symbol (0) indicates the component was not identified in tobacco smoke studies or was not identified in the smoke from specific tobacco substitutes.

20 Metallic and Nonmetallic Elements, Isotopes, Ions, and Salts

20.1 ELEMENTS, ISOTOPES, AND IONS IN PLANTS

Plants require numerous nutrients and compounds to sustain life. There are at least 20 elements that are used by plants that are considered essential for growth and reproduction (20A06, 20A10). For higher plants (such as tobacco), a significantly higher number of other elements are needed.

Justus von Liebig (1803–1873) in the mid-nineteenth century stated that nutrients are essential for plant life:

> We have determined that a number of elements are absolutely essential to plant life. They are essential because a plant deprived of any one of these elements would cease to exist (20A58).

Von Liebig (20A58) taught of the absolute need to provide plants with essential minerals necessary for successful agricultural production. If the soil is not replenished with these essential elements and associated ions, plant yields decrease and numerous plant diseases occur. Healthy plants require and thus contain a great variety of elements, isotopes, and ions.

In general, significant efforts are normally exerted to maintain a plant's requirement for nitrogen (N), phosphorus (P), and potassium (K) through fertilization while taking for granted its basic need for carbon (C), hydrogen (H), and oxygen (O). Knowing the nutrients required to grow plants is only one aspect of successful crop production. Optimum plant yield also requires knowing the rate to apply, the method and time of application, the source of nutrients to use, and how the elements are influenced by soil and climatic conditions. The primary nutrients—N, P, and K—are commonly found in blended fertilizers, e.g., 10-10-10, or equivalent grades. Primary nutrients are utilized in the largest amounts by crops and, therefore, are applied at higher rates than secondary nutrients and micronutrients. The secondary nutrients—calcium (Ca), magnesium (Mg), and sulfur (S)—are required in smaller amounts than the primary nutrients. The major source for supplementing the soil with Ca and Mg is dolomitic lime, although these nutrients are also available from a variety of fertilizer sources. Sulfur is available in fertilizers in the form of potassium and magnesium sulfate, gypsum (calcium sulfate), and elemental sulfur. Micronutrients—iron (Fe), manganese (Mn), zinc (Zn), copper (Cu), boron (B), and molybdenum (Mo)—are required in even smaller amounts than secondary nutrients. They are available in manganese, zinc and copper sulfates, oxides, oxysulfates, and chelates, as well as in boric acid and ammonium molybdate.

Table 20.1 gives the elemental composition of a typical plant. It is interesting to note that about 96% of the makeup of a plant is C, H, and O. These elements come from carbon dioxide and water. The carbon dioxide in the atmosphere contributes the C and O found in plants. It is taken up by plants through small pores located in the leaves. Water, on the other hand, is taken up by the roots of plants and is responsible for contributing only H to the makeup of a plant. However, the H used to produce water also comes from the atmosphere. Table 20.1 also shows the classification of the elements in plants. The elements are classified as structural elements, primary and secondary nutrients, and micronutrients. Therefore, the atmosphere and sun provide about 96% of the necessary ingredients for plant growth, and minerals provide about 4% of the necessary ingredients for plant growth (20A10). The elemental composition in Table 20.1 of a typical plant is nearly identical with the elemental composition of tobacco, with the exception that tobacco generally has a slightly higher N level. Elemental analyses for C, H, and N in tobacco indicate that there is about 5% N in dry tobacco (2798, 20A06, 20A10). The percent C, H, and O (by difference) of dry tobacco leaf are about 43%, 6%, and 43%, respectively (2798, 20A06, 20A10), with the remainder being trace levels of metals and nonmetals (3973).

20.1.1 Elements, Isotopes, and Ions in Tobacco

As of 2007, the periodic table contains 117 elements whose discoveries have been confirmed. Ninety are found naturally on Earth, and the rest are synthetic elements that have been produced artificially in particle accelerators. Of these 90 naturally occurring elements, nearly 80 have been identified in tobacco. Additionally, 44 isotopes and 24 ions have been identified in tobacco. Tobacco is undoubtedly one of the most thoroughly evaluated plant materials evaluated for metal content. It should be noted that the omission of information about other microelements does not necessarily imply the absence of these elements in tobacco, but rather a lack of information (3973). The discovery of elements, isotopes, and ions in tobacco (and for that matter tobacco smoke) has only been limited by the discovery and advancement of new analytical techniques.

Over the years, numerous scientific articles, reviews, and books have been published that catalog the elements, ions, and isotopes found in tobacco. One of the earliest articles on the identification of metals in tobacco was published by Grandeau in 1862 (20A25) on the identification of rubidium

TABLE 20.1
Elemental Composition of a Typical Plant (1127b, 20A10)

Element	Symbol	Percent of Wet Weight	Percent of Dry Weight	Descriptor
Oxygen	O	81.0	45.0	Essential structural elements available from air and water
Carbon	C	6.8	44.5	
Hydrogen	H	11.5	6.0	
Nitrogen	N	0.2	1.5	
Phosphorus	P	0.03	0.2	Primary nutrients
Potassium	K	0.15	1.0	
Calcium	Ca	0.05	0.35	
Magnesium	Mg	0.03	0.20	Secondary nutrients
Sulfur	S	0.02	0.15	
Chlorine	Cl	0.015	0.10	
Iron	Fe	0.015	0.10	
Molybdenum	Mo	0.008	0.05	Micronutrients

Copper	Cu	0.001	0.01	
Others		0.175	0.80	

(Rb) and cesium (Cs) in tobacco. Although it was well known in the 1860s that numerous metals and nonmetals existed in tobacco and higher plants (20A58), analytical techniques to isolate the small levels of metals were not established. A 1934 bibliography by Heffer and Sons (20A26) reviewed literature citations for 1921–1933 on antimony (Sb), bismuth (Bi), cadmium (Cd), chromium (Cr), cobalt (Co), Cu, lead (Pb), Mn, mercury (Hg), nickel (Ni), thallium (Tl), tin (Sn), and Zn. Johnstone and Plimmer (1971) published their review of chemical constituents of tobacco and tobacco smoke in 1959. In 1966, Tso (20A105) published an excellent historical review of elements identified in tobacco to that date. Stedman (3797), in his 1968 review, listed aluminum (Al), arsenic (As), Cu, Cr, Co, Fe, Pb, Mn, Mo, Ni, titanium (Ti), vanadium (V), and Zn as identified elements in tobacco and smoke. In 1974, Elliot (1127b) reviewed the nutritional requirements of tobacco including metals and metal ions, and Franzke et al. (1227) published their investigation of the heavy metals in tobacco. In 1977, Norman (2799a) reviewed the subject of metals in tobacco at the *Tobacco Chemists' Research Conference* (TCRC). The most recent review, in 1996, by Jones and Wilkinson (20A54), concerning historical agronomic achievements in tobacco science, provided current information on elements identified in tobacco. The most prolific writer on elements, isotopes, and ions in tobacco is Tso. From his 1966 review of the subject to his 1972 book on the physiology and biochemistry of tobacco plants (3972) and his 1990 book (3973) on the production, physiology, and biochemistry of the tobacco plant, Tso has continuously provided tobacco scientists with valuable information. His 1990 book (3973) devoted three chapters to metals, isotopes, and ions in tobacco. In Chapters 17 and 19 (3973), Tso discussed the presence, physiology, and biochemistry of the following elements in tobacco plants: Al, As, barium (Ba), beryllium (Be), Bi, B, bromine (Br), Cd, cerium (Ce), Cs, chlorine (Cl), Cr, Co, Cu, dysprosium (Dy), erbium (Er), fluorine (F), gadolinium (Gd), germanium (Ge), gold (Au), hafnium (Hf), holmium (Ho), indium (In), iodine (I), iridium (Ir), Fe, lanthanum (La), Pb, lithium (Li), Mg, Mn, Hg, Mo, neodymium (Nd), Ni, N, osmium (Os), palladium (Pd), P, platinum (Pt), polonium (Po), K, praseodymium (Pr), radium (Ra), rhenium (Re), rhodium (Rh), Rb, ruthenium (Ru), samarium (Sm), scandium (Sc), selenium (Se), silicon (Si), silver (Ag), sodium (Na), strontium (Sr), sulfur (S), tantalum (Ta), tellurium (Te), terbium (Tb), TI, thorium (Th), thulium (Tm), Sn, Ti, tungsten (W), uranium (U), V, ytterbium (Yb), Zn, and zirconium (Zr). As Tso stated (3973), "No attempt is made to include all publications about each element; in fact, some papers were eliminated intentionally to avoid duplication."

Tso (3973) estimated that tens of thousands of article have been written on the production, physiology, and biochemistry of the tobacco plant. In Chapter 18 (3973), Tso discussed radiochemical elements in tobacco and smoke, and in Chapter 19, he discussed the physiological disorders in tobacco plants associated with deficiencies in minerals and micronutrients.

Tobacco plants, like other higher plants, are autotrophs possessing the capacity to synthesize all of its complex organic materials, provided that carbon dioxide, water, minerals, and the proper physical environment are available. Their chemical composition is influenced by environmental factors such as light, temperature, moisture, soil type, and cultural practices, as well as inorganic nutrition.

The inorganic requirements of tobacco were considered in the 1962 book by Sutcliffe (20A101) and in reviews by Steinberg and Tso (20A98) and others, e.g., McMurtrey (20A66). The essential elements of tobacco may be grouped

into categories depending on their source and the relative amounts required. C, H, and O are considered structural elements and are grouped separately because they are derived from air or water. Obviously, C, H, and O are found in the vast number of the organic components identified in tobacco. Evans and Russell (20A20) described the requirements for these elements that were established when early investigators determined the basic chemical composition of tobacco matter and elucidated the essential nature of the respiratory and photosynthetic processes that occur in plants. Another group of elements referred to as primary nutrients include P, K, N, S, Ca, and Mg. These elements also make up a relatively large portion of the inorganic components of tobacco tissues and were established to be essential by plant physiologists such as Knop, Nobbe, and Sachs (20A101) prior to 1910. In this period, reagent chemicals were exceedingly crude and contained many of the essential trace elements that were being investigated. As a consequence, the proof of many trace elements in tobacco could not be established until chemists learned how to purify the analytical reagents for testing.

Another group of elements, including B, Cl, Co, Cu, Fe, Mn, Mo, and Zn, occur in exceedingly small concentrations in plant materials and are referred to as micronutrient elements. Fe was shown to be essential by Sachs (20A101) prior to 1910, but the other trace elements were demonstrated to be essential only after 1920 (20A20).

During the period 1923–1931, Sommer and Lipman (20A96) established that a variety of plants including tobacco required Zn and Cu. During the same period, Warrington (20A111) in England demonstrated that boron was a required in micronutrient in broad beans. Since then, it has become clear that these elements are needed for a variety of species, including tobacco. In 1939, Arnon and Stout (20A05) demonstrated that tomato plants required Mo and since then it has become apparent that all species need this element for metabolism (20A20).

The biochemical role of minerals in metabolic processes of various organisms has been covered in several reviews by Malstrom and Neilands (20A60), McElroy and Nason (20A65), Nason and McElroy (20A81), and Nicholas (20A84). The function of C, H, and O is obvious since they are constituents of fats, carbohydrates, and proteins. N and S are constituents of amino acids, proteins, coenzymes, and other compounds. Ca forms a complex with pectic acid and functions as a constituent of the middle lamella of cell walls. Dixon and Webb (20A13) showed that Ca also plays a role as a cofactor for certain adenosine triphosphate hydrolyzing enzymes, for phospholipases, and as a cofactor for the amylases from a variety of plants. Many elements, especially the cations, play essential roles as cofactors for the enzymes of various metabolic sequences.

Tso (3973) provided numerous examples in which mineral deficiency such as Fe or Mo resulted in metabolic lesions that have been satisfactorily interpreted on the basis of detailed knowledge of the biochemical role of metals in enzymes of important metabolic pathways. This biochemical approach to plant nutrition problems has proved exceedingly valuable to plant scientists and agricultural producers in terms of identifying diseases and finding solutions to improve crop yields. Today, an enormous amount of work is being undertaken to understand the total genome of tobacco (429b, 429c). Detailed analyses of the metabolic pathways, involved enzymes, and feedback control and gene repressor mechanisms, including the metal and nonmetal elements and ions, as essential catalysts in tobacco, are being thoroughly documented (429b, 429c).

Mineral ions participate in a wide variety of metabolic processes, electron transport mechanisms, and in nitrate reduction. By manipulation of the level of inorganic elements and ions in the nutrient medium, it is possible to influence the constituents in plants. For over 100 years, tobacco scientists have employed a fundamental research approach in attempts to understand the complex physiology and biochemistry of tobacco involved in the biosynthesis of compounds in tobacco (3973). Their efforts have greatly improved the economics of tobacco production and have led to advancements associated with health issues associated with tobacco and its various commercial uses (20A20).

Inorganic ions play a very important role in tobacco metabolism (20A20). There are various sites where inorganic ions, e.g., Ca^{+2}, Mn^{+2}, Mg^{+2}, PO_4^{-3}, Zn^{+2}, and K^{+1}, participate in glycolytic reactions. Phosphate participates in a majority of the reactions as a component of sugar-phosphate compounds. Phosphate also functions as an important component of coenzymes such as uridine diphosphate-glucose, di- and triphosphopyridine nucleotides, adenosine di- and triphosphate, etc. Practically every reaction in which phosphate is transferred requires Mg as a cofactor, but most of these enzymes are not highly specific for a divalent cation activator and will respond to other cations such as Mn (2489). Another interesting aspect of the glycolytic enzymes is that Zn is required for alcohol dehydrogenase, lactic acid dehydrogenase, aldolase, and triosephosphate dehydrogenase. The role of Zn as an important inorganic ion, as a bound component of dehydrogenases and other enzymes, has been discussed in detail by Vallee (20A110).

K ion is a cofactor for the aldolase reaction. Pyruvic kinase from all known sources also requires univalent cations, in addition to a divalent cation. This enzyme needs K, ammonium, or Rb ions as a cofactor. Mg ions serve an important function in photosynthetic processes in tobacco as it is an essential constituent of chlorophyll a and chlorophyll b. Some heavy metal and nonmetal ions are toxic to tobacco and can serve as metabolic inhibitors. The toxicity of fluoride, for example, is explained in part on the basis of the formation of a magnesium-fluorophosphate complex which inhibits the enolase reaction in glycolysis. Other enzymes are inhibited by substrate analogs, sulfhydryl complexing agents, and metal chelating agents.

Several cations function as essential cofactors for enzymes of the citric acid cycle. Magnesium is necessary for the pyruvic acid oxidase complex, and ferrous Fe is necessary for the activity of aconitase from certain sources (20A20). The isocitric dehydrogenase system which catalyzes a

dehydrogenation of isocitric acid and also the decarboxylation of oxalosuccinate to yield α-ketoglutarate requires Mn for the decarboxylation step (20A03). Mg is a necessary cofactor for the α-ketoglutarate dehydrogenase complex, and Fe is a cofactor for succinate dehydrogenase (20A19, 20A64, 20A65, 20A80, 20A84). There are numerous cofactors (Fe^{+2}, -SH compounds, Mn^{+2}, Mg^{+2}, PO_4^{-3}) and inhibitors (SCN^{-1}, Br^{-1}, I^{-1}, Cl^{-1}, Na^{+1}, Cu^{+2}, Hg^{+2}, CN^{-1}) of citric acid cycle enzymes in tobacco. It is apparent that the various enzymes not only require cations but are also inhibited by substrate analogs, substrate competitors, heavy metals, and sulfhydryl complexing agents (20A20).

Mineral ions play important roles in the electron transport portion of the terminal respiratory process in tobacco. In this process, nonheme Fe serves an important function in the electron transfer process. There is also convincing evidence that Cu ion is important in the process (20A20). Mineral ions also play an important role in the electron transport processes of the initial reactions of photosynthesis. In the photosynthetic processes of tobacco, Fe, Cu, Mn, and chloride ions are essential to the electron transfer processes (20A20).

Metal ions play an important role in nitrate reduction. The discovery and characterization of the pyridine nucleotide enzymes involved in nitrate reduction (20A18, 20A65, 20A81, 20A83) made it possible to understand the role of mineral ions in the nitrate reduction processes. Reduced pyridine nucleotides and flavin adenine dinucleotide function as cofactors in reduction of nitrate, nitrite, hyponitrate, and hydroxylamine. The first step of the reaction involves the reduction of nitrate to nitrite, and Mo is essential for this reaction. The reduction of nitrite to hyponitrite and hyponitrite to hydroxylamine requires Cu and Fe ions (20A20).

Many types of tobacco contain radioactive elements such as ^{226}Ra and ^{210}Po at concentrations ranging from 0.1 to 0.47 pCi/g (1742, 2815, 3982, 3983). Phosphate fertilizers are the major source of these radioelements (3982, 3983); minor contributions come from airborne particles carrying ^{210}Pb and ^{210}Po. These particles are trapped by the trichomes on the undersides of the tobacco leaves (2467) and were first reported by Nystrom and Bellin (2815) in 1964.

The 1999 Coresta monograph on tobacco (910a) pointed out that trace elements and metal ions can have a profound effect on tobacco quality. Fe, for example, has been implicated in the speckling effects which develop in "gray tobacco" deficiency of Virginia tobacco (2338). Aluminum is associated with development of the black color of cured tobacco or so-called black tobacco (20A57). Tso (3973) devoted an entire chapter in his 1990 book on the absolute need for trace elements in tobacco disease prevention (3973, 20A106). Although concentrations of most of these metals are not very high in tobacco (usually well below percent levels, typically in the low to middle ppm range), many of these elements are extremely important to the health of the plant. Trace levels of metals (Mn, Fe, etc.) in tobacco are important as quality factors as they can affect the combustibility and smolder rate of tobacco. Some of the metals in tobacco are desirable as quality factors while others are not (Cd, Pb, and Cr) as they have been associated with human health concerns (20A100). The type and amount of certain inorganic ions are also important factors in determining the burn and smolder properties of tobacco. Peterson and Tibbitts (20A86) found that the concentrations of K^{+1}, Cl^{-1}, SO_4^{+2}, S^{-2}, Mg^{+2}, and NO_3^{-1} in tobacco (descending order of importance) account for 80% of the variation in leaf combustibility and smolder (4332).

Tobacco is probably the most frequently examined plant in the study of microelements. Many microelements are important for normal tobacco growth and development (3973). However, the specific roles of some of these elements are still not well understood. Frequently, the presence of certain microelements is merely a result of the circumstances of site, season, or species and therefore may not bear any physiological or agronomic significance. Tobacco plants are widely distributed in various locations of the world under different climatic, soil, and culture conditions. Any report of a certain microelement regarding its level, distribution, and fertilizer and soil requirements may or may not be applicable to that particular element under different circumstances. In 1986, Isakander et al. (20A47) determined 28 elements were in American cigarette tobacco. Today, nearly 150 elements, ions, and isotopes have been identified in tobacco.

20.1.2 Elements, Isotopes, and Ions in Tobacco Smoke

In 1954, Kosak (2170) published a list of components reported to be present in tobacco smoke. His list included "inorganic components." The inorganic compounds included ammonia, carbon monoxide, carbon dioxide, hydrogen cyanide, hydrogen sulfide, thiocyanic acid (?), oxygen, arsenic (probably present as As_2O_3), "acetates" (?), "chlorides" (?), "cyanides" (?), and "nitrates" (?). The question marks in Kosak's publication indicated that he did not consider the evidence in the literature to be definitive proof of the identity of the component. Since then, a tremendous amount of research has been conducted and published on metals and ions in tobacco smoke. During the late 1950s, Cogbill and Hobbs (769) conducted pioneering work on elements found in tobacco smoke. Two reviews in 1959 by Johnstone and Plimmer (1971) and Bentley and Berry (282) documented elements found in tobacco smoke. During the late 1960s and throughout the 1970s, a tremendous amount of research was published by the Martin Brinkman Co. (2468), Celanese Fiber Marketing Co. (641), Nadkarni (2666, 20A70), Nadkarni et al. (2667, 20A71–20A79), Morie and Morrisett (2633), Jenkins (20A49), Franzke et al. (1227), John (2052), Allen and Vickroy (50), and Perinelli and Carugno (2929) on elements, isotopes, and ions in tobacco smoke. Concurrently, scientists within the tobacco industry were conducting research on metals in tobacco smoke. Much of this work was reviewed by Jenkins of Philip Morris in 1990 on the uses of nuclear radiation in tobacco and smoke research (1933).

At present, 80 metals and nonmetal elements, 24 isotopes, and 12 ions have been identified in tobacco smoke by

numerous classical and instrumental analytical techniques. It is an amazing achievement that nearly 90% of the naturally occurring elements have now been identified in tobacco and tobacco smoke. Although numerous ions in tobacco were known, research on their identity in tobacco smoke was not established until the advent of commercial application of ion chromatography (IC) in the late 1980s. Since then, many laboratories have gathered extensive experience in the application of IC for the analysis of inorganic and organic anions, in both tobacco and tobacco smoke (250, 1273, 2931, 3160, 20A59, 20A114, 20A16, 20A17, 20A85).

The presence of radioactivity, both α- and β-particles, in leaf and tobacco smoke has been reported in many publications. At earlier periods, the main concern was for β-activity found in cigars, cigarettes, and tobacco ash (113, 2657, 3367, 20A97). The α-emitting radioactive isotopes were suggested to be significant because of health concerns to smokers. The total α-activity in tobacco varies widely in green leaf, cured leaf tobacco, and tobacco smoke (2466, 3367, 3973). A very minor amount of ^{210}Po is transferred into the mainstream smoke (MSS). Twenty-three isotopes have been identified in tobacco smoke. The discovery of elements, isotopes, and ions in tobacco smoke has only been limited by the discovery and advancement of new analytical techniques.

20.2 METHODS FOR THE DETECTION AND IDENTIFICATION OF METALS, IONS, AND ISOTOPES IN TOBACCO AND TOBACCO SMOKE

Numerous analytical techniques with a variety of different methodologies have been employed for the analysis of metals, nonmetals, isotopes, and ions in tobacco and tobacco smoke and various other types of organic matter. The subject of the choice of analytical methodology best suited for the detection of elements, isotopes, and ions in different matter has been reviewed by Fassel (20A21), Bock (20A08), Jones and Case (20A53), Jenkins (1933), Ivanova et al. (20A48), Thompson et al. (20A103), Sigg et al. (20A94), and Jimoh (20A51). The analytical methods included classical microanalytical determination (wet methods), colorimetric determinations, various atomic absorption spectrophotometric techniques (such as classical atomic absorption spectroscopy [AAS]) (with single or multiple element capability), cold vapor atomic absorption (CVAA), argon-supported inductively coupled plasmas (ICP), ICP with atomization–excitation processing, graphite furnace (GF) atomic absorption spectroscopy (AAS) (with/without Zeeman background correction), GF-AAS with deuterium lamp, inductively coupled plasma atomic emission spectrometry (ICP-AES), and microwave digestion), x-ray emission, competitive ligand-exchange/stripping voltammetry (CLE-SV), diffusion gradients through thin films (DGT), instrumental neutron activation analysis (INAA), IC, and high-performance liquid chromatography (HPLC). Hyphenated techniques are also becoming popular such as inductively coupled plasma mass spectrometry (ICP-MS) and IC-ICP-MS (20A51). The selection of the appropriate method depends on several factors such as the kind of equipment available, the ease of digestion, the kind of sample, elements of interest, fume removal, contamination considerations, matrix effects, and necessary safety precautions (20A08, 0A53, 20A103).

The inorganic components of tobacco and tobacco smoke have been determined by microanalytical techniques, classical colorimetric determinations, and modern instrumental methods. For example, Cogbill and Hobbs (769) described several colorimetric methods for the determination of metals in tobacco smoke.

X-ray emission spectroscopy has been used to the determination of metals and metal isotopes in tobacco and tobacco smoke (20A62).

Atomic absorption spectroscopy is widely used and is one of the most established methods for the determination of metals in tobacco and tobacco smoke. Although quite reliable, AAS can require separate analyses and recalibrations at varying ranges for each element, with a separate lamp for each analyte (dependent on the type of AAS equipment). Concurrent determination of multiple metals is possible, while speciation is often lacking in this method. The determination of metals in tobacco smoke is often more complicated. One reason for this difficulty is the conversion of smoke samples to homogeneous solutions so that they can pass through the aspirator of the instrument. Another is that for the determination of the ultratrace quantities of metals in cigarette smoke, a preconcentration step is often required. Solvent extraction is the method of preconcentration preferred over most other methods. The choice of solvents that can provide a high degree of selectivity over a broad pH range is limited. Alternately, metal complexes that are relatively insensitive to pH changes have been used, e.g., ammonium pyrrolidinecarbodithioate, successfully for a wide variety of metals (2633) in tobacco and tobacco smoke. The work of Morie and Morrisett (2633) on the use of AAS in the determination of metals in tobacco smoke serves as an excellent example.

ICP-AES and ICP-MS techniques are modern, sophisticated, very sensitive, and generally quite expensive. These methods have been successfully used for the determination of metals in tobacco and tobacco smoke (20A90, 20A112). The success of these two methods can be affected by the metal-solvent matrix employed. In many cases, preseparation procedures and other special handling techniques are required. Each method for analysis of metals in tobacco and tobacco smoke has its own set of advantages and challenges.

INAA is an extremely sensitive method for the determination of metals and metal isotopes. INAA has been successfully used by Nadkarni et al. (20A73), Jenkins et al. (1934), and Kubota (2214) to determine numerous inorganic constituents (elements and several elemental isotopes) in both tobacco and tobacco smoke (1933). The use of INAA for tobacco and tobacco smoke analysis has been accepted worldwide (1933). Tobacco is ideally suited for INAA because of its large abundance and variety of inorganic components. Tobacco is a readily available, easy-to-handle solid, produces little gas during irradiation, and is rapidly

assayed by INAA. The literature on the use of INAA in tobacco is very large because tobacco is often used as a model in nontobacco-oriented reactor facilities system for INAA (1933). However, the applicability of neutron activation analyses (INAA) is limited by the availability and cost of the necessary equipment. INAA requires a neutron flux source and gamma-ray counting facilities. The most conventional laboratories are thus unlikely to pursue this approach. Further, some elements are normally not determinable by INAA (Pb and Ni), either because of low sensitivity or strong interferences from other metals [Perini (20A85)]. Jenkins (1933) noted that despite the widespread use INAA for tobacco and smoke analysis, meaningful intercomparison of the INAA results published in the literature is difficult as there is a lack of descriptive experimental information on the exact types of the tobaccos or tobacco smoke tested. Many laboratories studied only tobaccos and tobacco smoke native to their own country.

Many laboratories have gathered extensive experience in the application of IC for the analysis of inorganic and organic anions. Small carboxylate anions, groups IA and IIA cations, and heavy metal ions have been identified in tobacco and tobacco smoke by this method. Several of these applications have been presented as TSRC papers (250, 2931, 1273). At the 1999 TSRC, Perini (20A85) presented a method associated with IC called transition metal IC (TMIC). TMIC can be used for specific resolution and speciation of transition metal ions in tobacco and related matrices. Perini showed that TMIC could be used to detect and speciate at least 19 transition metal ions.

20.3 THE TRANSFERENCE OF ELEMENTS, ISOTOPES, AND IONS FROM TOBACCO TO TOBACCO SMOKE

Nearly all trace metals in tobacco transfer at some small level into tobacco smoke. The transfer of metals from tobacco into MSS and sidestream smoke (SSS) has been of interest for a number of years (2133, 3836–3838, 2530). Transfer of metals from filters containing metal catalysts has also been of interest as they were thought to be a source of metals entrained into the MSS (2633). For example, experimental filters with permanganate salts (20A104) and hopcalite (20A69) have been reported to remove nitrogen oxides from smoke. The percent transfer rate of metals in tobacco to tobacco smoke varies greatly but generally falls within a 0.002%–7.0% range (20A91), although percentages as high as 19% have been reported for Sb (2666).

Numerous researchers have addressed the question of metal transference employing a variety of different cigarette types, collection devices, and analytical techniques. Depending on the metal or metals of interest, the method used, and the cigarette type, the reported results cover a wide range of values. In some cases, the range covers several orders of magnitude. For one to draw any significant conclusions from this mass of data would be tenuous. Some of the inadequacies associated with diversity of transfer rate reported by Morgan and Akers (20A68) are as follows:

- Tobacco types or blends of tobaccos were often not identified, and in most cases, tobacco filler types were not processed in a standard fashion.
- Cigarette configurations were often varied, and in many cases, the cigarette configuration and materials used to construct the cigarette were not mentioned.
- Often only one or two metal species were studied for a particular tobacco.
- TPM collection procedures were not uniform among studies.
- Analytical methods varied widely and were often not calibrated against standard materials of known metal content.
- Large analytical errors were often tolerated to obtain a numerical value.

Stöber (20A99) in his review of the generation, size distribution, and composition of tobacco smoke aerosols made the observation that more than one mechanism for the transport of metals into MSS is operative. The predominant mechanism is entrainment of small particulate matter. For the more volatile elements, however, vaporization followed by condensation into the particulate phase appears dominant. The rate of metal transfer to the smoke is dependent on the volatility, the temperature profiles in the burning cigarette, and the filter type. In cigarette smoke, element concentrations vary among brands and even within the same brand. Numerous factors influence the metal concentration found in tobacco, including soil type and pH, the atmosphere, genotype, stalk position, application of metal-containing fertilizers, or agricultural chemicals, e.g., herbicides and pesticides (3973). These same factors affect the concentration of elements transferred to MSS and SSS. Table 20.2 lists the percent transfer of selected metallic and nonmetallic elements between tobacco and tobacco MSS.

20.3.1 Elements in Tobacco Smoke of Special Interest

Eighty elements, 23 isotopes, and 12 ions have been identified in tobacco smoke. Table 20.2 contains data on the percent transfer of selected elements into tobacco smoke. Based upon literature data, small portions, at most a few percent of the metals and nonmetals, transfer from the tobacco into the smoke. The predominant route of exposure of humans to metals in cigarette smoke is inhalation. The smoker will likely inhale both the mainstream vapor and particulate phase of the smoke plus some of the smoke that is generated while the cigarette is smoldering between puffs (20A50). Nonsmokers may also be exposed to metals in cigarette smoke, through passive inhalation of environmental tobacco smoke (ETS), but these concentrations are hundreds of times more dilute (3257).

TABLE 20.2
Percent Transfer of Selected Metallic and Nonmetallic Elements between Tobacco and Tobacco Smoke

CAS No.	Name (per CA Collective Index)	Transference to Smoke (%)	References
7429-90-5	Aluminum	0.009–0.0014	1934
7440-36-0	Antimony	0.003–19	769, 1934,2666, 20A21, 20A67, 20A68,
7440-38-2	Arsenic	[0.016][a]–7.0	769, 1934, 2666, 20A21, 20A68, 20A76

7440-23-5	Sodium	0.25–1.06	769, 1934
7440-66-6	Zinc	0.4–2.7	769, 2530, 2666, 20A21, 20A67, 20A68

[a] [] = limit of detection.
ND, not detected.

Among the metals that transfer into the smoke and are thus inhaled, the International Agency for Research on Cancer (IARC) (1870) considered As, Be, Cr, Ni, and Cd as human carcinogens (1742, 20A28, 20A29) in 1985. In 1989, the U.S. Department of Health and Human Services (4012) listed Cr and Pb as possible carcinogenic agents in humans. Additionally, Zn in tobacco smoke has also been a metal of concern (20A49, 20A50). Today, the list of metals classified as group 1 (human carcinogens) has grown to include As, Be, Cd, Cr^{+6}, Ni, ^{32}P, ^{239}Pu, ^{240}Pu, α- and β-particle-emitting radionuclides (in general), ^{222}Rn, ^{224}Ra, ^{226}Ra, ^{228}Ra, and ^{232}Th. Additionally, smokeless tobacco (classified as a group 1 mixture) and ETS and tobacco smoke and tobacco smoking (classified as group 1 exposure circumstances) have been classified by IARC as agents considered carcinogenic to humans (Table 20.3). IARC listed the following agents identified in tobacco smoke as group 2A (probably carcinogenic to humans) or group 2B (possibly carcinogenic to humans): Pb, Co, Ni, nitrates, and nitrites.

Nearly all of the metals and isotopes found in tobacco that transfer to tobacco smoke are a consequence of the use of metals found naturally in the soil (some radionuclides in the soil from nuclear reactions and reactors in the area), use of fertilizer containing metals, or agrochemicals applied to the tobacco. The radioactive compounds found in highest concentration in cigarette smoke are ^{210}Po and ^{40}K. Other radioactive compounds present include ^{226}Ra, ^{228}Ra, ^{232}Th, and ^{228}Th (1870). As and As compounds and chromium and some chromium compounds are causally associated with cancer in humans, while nickel and cadmium and their compounds are probably carcinogenic to humans. Arsenic levels in tobacco have been elevated in the past due to the use of arsenical pesticides. Cd levels may be related to the presence of Cd in phosphate fertilizers (1870). Today, the so-called Hoffmann

TABLE 20.3
IARC Classification and References to Agents, Groups of Agents, Mixtures, and Exposure Circumstances Evaluated by IARC That Are Metals, Metallic Compounds, Radioisotopes, or Tobacco or Tobacco Smoke-Related Materials

Name	CAS No.	IARC Reference
Group 1		
Agents and Groups of Agents[a]		
Arsenic	7440-38-2	20A42, 20A36
Beryllium and beryllium compounds	7440-41-7	20A27, 20A28
Cadmium and cadmium compounds	7440-43-9	20A27, 20A28
Chromium [VI]	1333-82-0	20A32
Gallium arsenide	1303-00-0	20A33
Nickel and nickel compounds	7440-02-0	20A32
Phosphorus-32, as phosphate	14596-37-3	20A41
Plutonium-239 and its decay products (may contain plutonium-240 and other isotopes), as aerosols	15117-48-3 and 14119-33-6	20A41
Radionuclides, α-particle-emitting, internally deposited	Numerous isotopes in tobacco smoke	20A41
Radionuclides, β-particle-emitting, internally deposited	Numerous isotopes in tobacco smoke	20A41
Radium-224 and its decay products	13233-32-4	20A41
Radium-226 and its decay products	13982-63-3	20A41
Radium-228 and its decay products	15262-20-1	20A41
Radon-222 and its decay products	10043-92-2 or 14859-67-7	20A37, 20A41
Silica, crystalline (inhaled in the form of quartz or cristobalite from occupational sources)	14808-60-7	20A39
Thorium-232 and its decay products	7440-29-1	20A41
Mixtures[a]		
Tobacco, smokeless		20A44, 20A36, 20A40
Exposure Circumstances[a]		
Involuntary smoking (exposure to secondhand or ETS)		20A45
Tobacco smoking and tobacco smoke		20A45
Group 2A		
Agents and Groups of Agents[a]		
Indium phosphide	22398-80-7	20A33
Lead compounds, inorganic	7439-92-1	20A35
Nitrate or nitrite (ingested) under conditions that result in endogenous nitrosation	14797-55-8 and 14797-65-0	20A34
Exposure Circumstances[a]		
Cobalt metal with tungsten carbide		20A33
Group 2B		
Agents and Groups of Agents[a]		
Antimony trioxide	1309-64-4	20A43
Carbon black	1333-86-4	20A38, 20A30
Cobalt and cobalt compounds	7440-48-4	20A31
Cobalt sulfate and other soluble cobalt(II) salts	10026-24-1	20A33
Lead	7439-92-1	20A42, 20A36
Nickel, metallic and alloys	7440-02-0	20A32
Titanium dioxide	13463-67-7	20A43, 20A30
Vanadium pentoxide	1314-62-1	20A33
Exposure Circumstances[a]		
Cobalt metal without tungsten carbide		20A33

[a] Agents, groups of agents, mixtures, and exposure circumstances (associated with metals and nonmetals, or tobacco) evaluated in IARC Monographs Volumes 1–95. This list contains all agents evaluated as of November–December 2006 that are considered carcinogenic to humans (group 1), probably carcinogenic to humans (group 2A), and possibly carcinogenic to humans (group 2B). For details of the evaluation, the relevant monograph should be consulted (see http://monographs.iarc.fr/ENG/Classification/crthgr01.php).

analytes include the following metals, isotopes, and ions: As, Be, Cd, Pb, Cr, Cr^{+6}, Co, Hg, Ni, ^{210}Po, and Se (3300).

Despite ample scientific evidence to the contrary, many in the scientific community continue to contend that many of the Hoffmann analyte represent a "clear and present danger" to smokers. The following excerpts provide information and comments to the contrary (3300).

20.3.1.1 Arsenic

Over time, substantial decreases have been reported for As residues on tobacco and dramatic reductions in tobacco smoke. As, usually considered as As_2O_3 in tobacco, was removed from tobacco agronomy in 1952. Between 1917 and 1951, the As level in tobacco rose from about 12 to 57 µg/g (1459). By 1968, the As level in tobacco had decreased from the 1951 value of more than 50 µg/g to a 1968 value of 0.5–1.0 µg/g, a value similar to that reported by Griffin et al. (1391). Some of these chronological data were summarized by the U.S. Surgeon General in 1979 (20A107) and IARC (1871). In 1957, Cogbill and Hobbs (769) reported the transfer of As from a cigarette containing 7.1 µg of As to MSS to be 3.5%. With the tobaccos analyzed for As by Griffin et al. (1391), the As content of the MSS would range from 0.018 to 0.035 µg/cig. In 1968, Guthrie (1457) reported the As transfer from cigarette tobacco to its MSS varied between 4% and 12%. In 1990, Tso (3973) noted that for most tobaccos at that time, the As level was around 0.1–0.5 µg/g (3300).

20.3.1.2 Beryllium

Studies on laboratory animals exposed to high Be dose and epidemiological data have indicated that Be may cause cancer, although Be has been classified as a group 1 substance by IARC. However, IARC noted a number of limitations in the epidemiological studies, namely, poor exposure characterization, relatively low excess cancer risk, and the lack of discussion of exposure to other lung carcinogens. The potential of Be to induce developmental effects has not been investigated adequately (20A02). No literature information was found on the toxicity of Be by ingestion (20A116). The level of Be reported in cigarette MSS ranges from 0 to 0.5 ng/cig (1742, 1744, 3711).

20.3.1.3 Chromium, Cadmium, and Lead

The possible roles of Cr, Cd, and Pb in tobacco carcinogenesis are difficult to evaluate given the present database. In 1990, Hoffmann and Hecht (1727) stated:

> Taken together, the evidence for a major role of these materials as etiologic factors in tobacco carcinogenesis is not compelling.

20.3.1.4 Chromium VI

Seventeen years have elapsed since the IARC originally evaluated the carcinogenicity of Cr and Cr compounds. In 2000, De Flora (20A12) reviewed the toxicology of Cr compounds. A wealth of results indicate that Cr metal, Cr (III), and Cr (VI) can induce a variety of genetic and related effects *in vitro* (20A12). But there is a lack of carcinogenicity of Cr metal and Cr (III) compounds in experimental animals, and only a minority of animal carcinogenicity data with Cr (VI) compounds were positive (30 out of 70, i.e., 42.9%). Moreover, most positive studies used administration routes which do not mimic any human exposure and bypass physiological defense mechanisms. Typically, positive results were only obtained at implantation sites and at the highest dose tested. Exposure to Cr (VI) has been known for more than a century to be associated with induction of cancer in humans (20A12).

De Flora stated:

> Carcinogenicity requires massive exposures, as is only encountered in well defined occupational settings, and is site specific, being specifically targeted to the lung and, in some cases, to the sinonasal cavity. Increased death rates for cancers at other sites, which were occasionally reported in some epidemiological studies, were almost invariably not statistically significant and inconsistent (being counterbalanced by other studies which apparently showed decreased rates for the same cancers) (20A12). Chromium (VI) can be reduced in body fluids and nontarget cells, which results in its detoxification, due to the poor ability of chromium (III) to cross cell membranes. In target cells, chromium (VI) tends to be metabolized by a network of mechanisms leading to generation of reduced chromium species and reactive oxygen species, which will result either in activation or in detoxification depending on the site of the intracellular reduction and its proximity to DNA. When introduced by the oral route, chromium (VI) is efficiently detoxified upon reduction by saliva and gastric juice, and sequestration by intestinal bacteria. If some chromium (VI) is absorbed by the intestine, it is massively reduced in the blood of the portal system and then in the liver. These mechanisms explain the lack of genotoxicity, carcinogenicity, and induction of other long-term health effects of chromium (VI) by the oral route. Within the respiratory tract, chromium (VI) is reduced in the epithelial-lining fluid, pulmonary alveolar macrophages, bronchial tree and peripheral lung parenchyma cells. Hence, lung cancer can only be induced when chromium (VI) doses overwhelm these defense mechanisms. The efficient uptake and reduction of chromium (VI) in red blood cells explains its lack of carcinogenicity at a distance from the portal of entry into the body. All experimental and epidemiological data, and the underlying mechanisms, point to the occurrence of thresholds in chromium (VI) carcinogenesis (20A12).

Although Cr (VI) has often been alleged to exist in MSS, it has never been unequivocally identified in tobacco smoke (20A95).

20.3.1.5 Nickel

The USPHS (20A109) made the following statement on the occurrence of Ni in tobacco smoke and stated that "It is not likely that nickel plays a significant role in the etiology of lung cancer in cigarette smokers."

During the 1960s, the Sundermans reported that they had found Ni in MSS (3837). They speculated that Ni could possible react with CO in MSS to form nickel carbonyl. The Sundermans did not successfully induce lung cancer in rats exposed to tobacco smoke, although much furor was raised as to their allegations (3837, 3838).

20.3.1.6 Cobalt

Co has been identified in both tobacco and tobacco smoke. Co and Co-containing compounds have been evaluated by IARC and are classified as group 2B (possibly carcinogenic agents) (20A31).

This category [2B] is used for agents for which there is *limited evidence of carcinogenicity* in humans and less than *sufficient evidence of carcinogenicity* in experimental animals. It may also be used when there is *inadequate evidence of carcinogenicity* in humans but there is *sufficient evidence of carcinogenicity* in experimental animals. In some instances, an agent for which there is *inadequate evidence of carcinogenicity* in humans and less than *sufficient evidence of carcinogenicity* in experimental animals together with supporting evidence from mechanistic and other relevant data may be placed in this group. An agent may be classified in this category solely on the basis of strong evidence from mechanistic and other relevant data (IARC Preamble, see http://monographs.iarc.fr/ENG/Preamble/CurrentPreamble.pdf).

20.3.1.7 Mercury

Hg has been identified in both tobacco and tobacco smoke. Hg and inorganic Hg compounds (20A27) are classified by IARC as group 3 agents (not classifiable as to carcinogenicity to humans).

This category [3] is used most commonly for agents for which the evidence of carcinogenicity is *inadequate* in humans and *inadequate* or *limited* in experimental animals. Exceptionally, agents for which the evidence of carcinogenicity is *inadequate* in humans but *sufficient* in experimental animals may be placed in this category when there is strong evidence that the mechanism of carcinogenicity in experimental animals does not operate in humans. Agents that do not fall into any other group are also placed in this category. An evaluation in group 3 is not a determination of noncarcinogenicity or overall safety. It often means that further research is needed, especially when exposures are widespread or the cancer data are consistent with differing interpretations (IARC Preamble, see http://monographs.iarc.fr/ENG/Preamble/CurrentPreamble.pdf).

20.3.1.8 Selenium

Se has been identified in both tobacco and tobacco smoke. The MSS yield of Se in the University of Kentucky reference cigarette 1R4F is 1.2 ng/cig (3300). Se and Se compounds (20A36) are classified by IARC as group 3 agents (not classifiable as to carcinogenicity to humans). Se is not an antioxidant nutrient unto itself but is a component of antioxidant enzymes. It possesses excellent antioxidant, antimutagenic, and anticarcinogenic properties (1177a, 3257, 3685, 20A92, 20A93, 20A113, 20A46, 20A102).

El-Bayoumy (20A15) described the protective role of Se on genetic damage and on cancer. Fiökin et al. (20A22) conducted research that demonstrated protective effect of vitamin E and Se against ETS exposure through reduction in the occurrence of lipid peroxidation. Clark et al. (20A09) reported that taking a Se supplement decreased the incidence of prostate cancer in men by more than 60% (20A09). The final analysis of the trial, published in 2002, by Duffield-Lillico et al. (20A14) showed a 52% reduction of prostate cancer in men taking Se daily.

Two large randomized were conducted on antioxidants, e.g., β-carotene and α-tocopherol, and Se to determine their effects on cancer risk (Chinese Cancer Prevention Study and the Selenium and Vitamin E Cancer Prevention Trial [SELECT]). The Chinese study showed that a combination of β-carotene, vitamin E, and Se significantly reduced total mortality (9%), cancer mortality (13%), gastric cancer mortality (20%), and mortality of the other cancers (19%) (20A07). The SELECT is currently taking place in the United States, Puerto Rico, and Canada to determine if taking Se and/or vitamin E supplements can prevent prostate cancer in men age 50 or older (20A82).

20.3.1.9 ^{210}Polonium

For the last quarter of a century, there has been a controversy over the presence and health effects of ^{210}Po in tobacco smoke. The quantities of ^{210}Po found in the lungs of smokers are generally about three times higher than those in nonsmokers. However, the significance of ^{210}Po in tobacco-induced lung cancer has been questioned upon comparison of these data with those obtained in miners (1509, 1727). In the case of ^{210}Po, a recent in-depth study raises doubts on the significance of ^{210}Po as a factor contributing to lung cancer in smokers (3300). ^{210}Po is present in tobacco and tobacco smoke (0.03–1.0 pCi/cig); however, it is unlikely that these traces represent a major risk for the smoker (20A109).

20.3.1.10 ^{235}Uranium and ^{238}Uranium

In addition to the 1985 Sharma et al. study (5559), Sharma had also coauthored another paper on the uraniums in tobacco products (5526). Lal and Sharma were obviously knowledgeable in uranium analyses because of their previously published numerous uranium studies on a variety of foodstuffs such as milk, coffee, and cereals (5526a) as well as the uranium contents of drinking water, river water, farm plants, and different soils.

In a 1992 book on smokeless tobacco issued in duplicate—a U.S. government department issue and a privately published issue—Brunnemann and Hoffmann (5485) and Hoffmann et al. (5513) listed the two uraniums ^{235}U and ^{238}U, as well as ^{210}Po as carcinogens in snuff.

In 1996, Rana et al. (5554a) published another study on uraniums in chewing tobacco. An abstract of their article follows:

> The sandwiched pellet technique using Makrofol-E plastic track detectors has been employed to determine trace quantities of uranium in nine brands of flavored chewing tobaccos consumed by the Indian population. In this technique the nuclear reaction, 235-U(n,f), is used for the quantitative estimation of uranium. The maximum value of uranium (1.88 ppm) has been found in raw tobacco leaves (Surti), while the minimum (0.13 ppm) in Tulsi (Double Zero brand). Other seven brands showed intermediate values of U-contents which are also reported in this paper. These values are compared with the U-contents reported in the literature for other forms of tobaccos.

More recently in 2010, British American Tobacco (BAT) described its procedures for analyzing a host of components in smokeless tobacco (5482a). The analysis for uraniums was described as follows:

> Uranium-235 & -238 are determined by alpha-spectrometry following addition of U-232 internal tracer, ashing, dissolution in acid, co-precipitation, ion-exchange chromatography, and electro-deposition onto stainless-steel discs.

Also in 2010, Schaller and Nair (5558a) listed ^{235}U, ^{238}U, ^{210}Po, TSNAs, VNAs, formaldehyde, B[*a*]P, and nicotine as health problems in snus.

In 2002, Rodgman and Green (3300) published a cancer risk assessment on toxicants in tobacco and tobacco smoke. Where there were sufficient data on carcinogenicity (animal and/or human), incremental lifetime cancer risks (ILCR) were calculated for those elements and isotopes. None of the elements (discussed previously) called "Hoffmann analytes" exhibited more than a low to very low ILCR (3300). For some of the elements, there was insufficient cancer risk information necessary to calculate an ILRC, e.g., Co, Hg, Se, and Cr. For these elements, either there were little health concerns anticipated by regulatory bodies (such as USEPA or WHO) or studies documenting cancer associated with these elements were not available. In view of these various uncertainties in published data and comments made by known authorities and regulatory bodies (as to either the level of these elements in smoke or their carcinogenic potency of the element), it is difficult at the present time to conclude that any of the metals and metal isotopes represents a significant hazard to the human smoker.

20.4 SUMMARY

To date, 85 elements (metals and nonmetals), 51 isotopes, and 24 ions have been identified in tobacco and tobacco smoke. As indicated in Table 20.4, 155 have been identified in tobacco, 122 have been identified in tobacco smoke, and 117 are found in both tobacco and tobacco smoke. Table 20.5 provides a tabulation of the metallic and nonmetallic elements, isotopes, and ions in tobacco, tobacco smoke, and tobacco substitute smoke.

There are numerous compounds in tobacco and tobacco smoke that contain metals and nonmetals. No review articles have been published on these types of compounds in tobacco and smoke. In most papers, when they are mentioned, they are collectively called *miscellaneous compounds*. The compounds listed in Table 20.6 consist mainly of acid salts of sodium, potassium, magnesium, and calcium, metal oxides, hydroxides, carbonates, and carbonyl-containing compounds, halide salts of organic compounds, a variety of organometallic compounds, e.g., triphenylarsine, aluminum and magnesium phosphide, triphenylstannium hydroxide, certain agrochemicals that contain metals, e.g., Alloxydim-sodium®, potassium salt of gibberellic acid, and Zineb®, and several metal-containing biomolecules, e.g., globulins, cytochrome c6, and chlorophyll a and b. For the sake of completeness, several ammonium compounds and the acid salts and various ions of nitric, sulfuric, and phosphoric acids are included in Table 20.6. Overall, Table 20.6 contains 195 chemical components.

TABLE 20.5 (continued)
Metallic and Nonmetallic Elements and Ions in Tobacco, Tobacco Smoke, and Tobacco Substitute Smoke

			References		
	CAS No.	Name (per CA Collective Index)	Tobacco Smoke	Tobacco	Tobacco Substitute Smoke
24.	14127-61-8	Calcium, ion (Ca^{+2})		20A20	
25.	15124-81-9	Calcium, isotope of mass 49		3973, 4357, 20A115	
26.	7440-44-0	Carbon	2939, 5811b	2939, 5079, 5189, 5192, 5193, 5811b	
27.	14762-75-5	Carbon, isotope of mass 14	4249, 4541		
28.	7440-45-1	Cerium	17, 50, 1933, 1934, 4249, 5811b	17, 1933, 1934, 3973, 4249, 5079, 5479, 5811b	50, 4249
29.	14762-78-8	Cerium, isotope of mass 144		20A23	
30.	7440-46-2	Cesium	641, 2799a, 4249, 5811b	2338, 2939, 3797, 3973, 3974a, 4249, 5079, 5422, 5811b, 20A25	641, 4249
31.	13967-70-9	Cesium, isotope of mass 134	20A73	3973, 5811b, 20A73	
32.	10045-97-3	Cesium, isotope of mass 137	20A01	1190a, 4249, 4901, 5811b	
33.	16887-00-6	Chloride	641, 1628, 1933, 1933b, 1934, 1939, 2170, 2524a, 2931, 3255, 4249, 5079, 5811b	193, 256, 385, 486, 677b, 963, 1063–1066, 1068–1074, 1189, 1333, 1373, 1895, 1933, 1934, 1939, 2079, 2154, 2283, 2313a, 2338, 2356, 2529, 2543, 2545, 2627, 2761, 2762, 2765, 2766, 2847, 3160, 3797, 3976, 4249, 4261, 4262, 4357, 5053, 5079, 5113, 5126, 5189, 5195, 5252, 5277, 5293, 5302, 5337, 5448, 5642, 5811b	641, 4249
34.	7782-50-5	Chlorine	50, 1240, 2779, 3797, 4249, 5811b	1127b, 1240, 2779, 3973, 3974a, 3974b, 4108, 4512, 5654, 5688, 5811b	50, 4249
35.	14158-34-0	Chlorine, isotope of mass 38		3973, 4381, 20A115	
36.	7440-47-3	Chromium	50, 126a, 174b, 174c, 273, 603, 688, 746b, 769, 966, 1148, 1217, 1273, 1329, 1373, 1386, 1445, 1557, 1673, 1727, 1740, 1741, 1743, 1744, 1773, 1842, 1870, 1871, 2214, 2270, 2667, 2799a, 2825, 2939, 3007, 3255, 3257, 3265, 3300, 3302, 3308, 3370, 3377, 3378, 3711, 3876, 4005–4007, 4230, 4242, 4249, 4331, 5512, 5541, 5811b, 5869a	174c, 769, 1219, 1219a, 1219b, 1329, 1330, 1445, 1951, 2079, 2270, 2313a, 2338, 2667, 2939, 3377, 3797, 3973, 3974a, 3974b, 4249, 4381, 4816, 5018, 5053, 5079, 5094, 5514, 5541, 5811b, 20A26	50, 641, 4249
37.	16055-83-1	Chromium ion (3+)	5811a		
38.	18540-29-9	Chromium ion (6+)	5811a

TABLE 20.5 (continued)
Metallic and Nonmetallic Elements and Ions in Tobacco, Tobacco Smoke, and Tobacco Substitute Smoke

			References		
	CAS No.	Name (per CA Collective Index)	Tobacco Smoke	Tobacco	Tobacco Substitute Smoke
131.	7440-24-6	Strontium	50, 160, 641, 769, 2079, 2799a, 2939, 3302, 4229, 4230, 4249, 5079, 5811b	769, 2079, 2338, 2939, 3005, 3797, 3973, 3974a, 4249, 5079, 5218, 5424, 5811b, 5883	50, 641, 4249
132.	14158-27-1	Strontium, isotope of mass 89		444, 3973, 4249	
133.	10098-97-2	Strontium, isotope of mass 90		444, 1190a, 3006, 4249	
134.	14808-79-8	Sulfate	1445, 2931, 4249, 5811b	385, 1545, 1895, 2154, 2338, 2356, 2543, 2545, 2627, 2761, 2762, 2765, 2766, 3160, 4249, 5053, 5079, 5189, 5195, 5670, 5715, 5811b	
135.	18496-25-8	Sulfide	2621, 2627, 4249, 5811b	4248, 20A89	
136.	14265-45-3	Sulfite	4249, 20A88	1243a, 4249	
137.	7704-34-9	Sulfur	50, 641, 1240, 1933b, 2270, 2524a, 3302, 4229, 4230, 4249, 5811b	116, 193, 1127b, 1240, 2079, 2270, 2283, 2338, 2393, 3476, 3633, 3797, 3973, 3974b, 4249, 5079, 5113, 5189, 5220, 5282, 5378, 5448, 5670, 5715, 5811b	50, 641, 4249
138.	7440-25-7	Tantalum	641, 4249, 5811b	3973, 5811b	641, 4249
139.	13494-80-9	Tellurium	50, 2799a, 3775, 4005–4007, 4230, 4249	3775, 3973, 4249	50, 4249
140.	7440-27-9	Terbium	17, 5811b	16, 3973, 4249, 5811b	
141.	7440-28-0	Thallium	50, 641, 2466, 3302, 3308, 4249, 5811b	1278, 3797, 3973, 3974a, 3974b, 4249, 5079, 5280, 5377, 5428, 5811b, 20A26	50, 641, 4249
142.	302-04-5	Thiocyanate	1445, 4249	20A56	
143.	14274-82-9	Thorium, isotope of mass 228	20A01, 20A87	16, 3873, 4249, 4836, 5066, 5811b, 20A55, 20A87	
144.	14269-63-7	Thorium, isotope of mass 230		5066	
145.	7440-29-1	Thorium, isotope of mass 232	50, 641, 2468, 4249, 5811b	16, 17, 2468, 3973, 4249, 5066, 5811b	50, 641, 4249
146.	7440-30-4	Thulium	641, 2799a, 4249	3973, 5811b	641, 4249
147.	7440-31-5 7740-31-5	Tin	50, 641, 4230, 4249, 5811b	3797, 3973, 3974a, 4249, 5079, 5448, 5811b, 20A26	50, 641, 4249
148.	7440-32-6	Titanium	50, 160, 273, 641, 769, 966, 1445, 2079, 2270, 2338, 2799a, 2939, 3302, 3876, 4230, 4242, 4249, 4319, 5079, 5811b	769, 2079, 2270, 2338, 2939, 3797, 3973, 3974a, 4249, 5079, 5218, 5422, 5448, 5811b, 5883	50, 641, 4249
149.	7440-33-7	Tungsten	641, 4249, 5811b	3973, 5811b	641, 4249
150.	13966-29-5	Uranium, isotope of mass 234		3973, 5066, 5811b	

TABLE 20.5 (continued)
Metallic and Nonmetallic Elements and Ions in Tobacco, Tobacco Smoke, and Tobacco Substitute Smoke

			References		
	CAS No.	Name (per CA Collective Index)	Tobacco Smoke	Tobacco	Tobacco Substitute Smoke
151.	15117-96-1	Uranium, isotope of mass 235		5066, 5482a, 5485, 5513, 5526, 5554a, 5558a, 5559	
152.	7440-61-1	Uranium, isotope of mass 238	50, 641, 4249, 5811b	3797, 3973, 3974a, 4249, 5066, 5079, 5167, 5168, 5482a, 5485, 5513, 5526, 5554a, 5558a, 5559, 5811b	50, 641, 4249
153.	7440-62-2	Vanadium	50, 273, 641, 1445, 4230, 4249, 5541, 5811b	3797, 3973, 3974a, 4249, 5079, 5448, 5541, 5811b, 5883	50, 641, 4249
154.	7440-64-4	Ytterbium	641, 4230, 4249, 5811b	16, 3973, 4249, 4804, 5811b	641, 4249
155.	7440-65-5	Yttrium	50, 641, 4230, 4249	3005, 3973, 4249, 5811b	50, 641, 4249
156.	10098-91-6	Yttrium, isotope of mass 90		3006	
157.	7440-66-6	Zinc	50, 126b, 172, 237, 273, 623, 641, 769, 1329, 1445, 1674, 2079, 2133, 2134a, 2142, 2214, 2460, 2633, 2667, 2799a, 2929, 2939, 3255, 3302, 3376, 3377, 4005–4007, 4229, 4230, 4249, 4319, 5811b	193, 250, 769, 1127b, 1219, 1445, 2079, 2338, 2460, 2667, 2929, 2939, 3377, 3797, 3973, 3974a, 3974b, 4074, 4249, 4357, 4381, 5079, 5094, 5189, 5285, 5308, 5402, 5448, 5514, 5654, 5811b, 5883, 20A26	50, 641, 4249
158.	23713-49-7	Zinc, ion (Zn^{2+})		20A20	
159.	13982-39-3	Zinc, isotope of mass 65	20A73	20A73	
160.	7440-67-7	Zirconium	50, 641, 4230, 4249, 5811b	1735, 3973, 4249, 5811b	50, 641, 4249

192.	1314-62-1	Vanadium pentoxide		3476	
193.	12122-67-7	Zinc, [[1,2-ethanediylbis[carbamodithioato]](2-)]- {Zineb®}		3481, 3491, 3513, 3633, 4249, 4271a, 4645, 4757, 5629, 5811b, 21A19	
194.	18920-65-5	Zinc, bis(thiocarbamato)-		3481, 3513, 4249	
195.	11126-30-0	Zirconium chloride		5811	

21 Pesticides and Growth Regulators

Since before 2500 BC, farmers have used pesticides to prevent damage to their crops. The first known pesticide was elemental sulfur, used to dust crops in Sumeria about 4500 years ago. By the fifteenth century, pesticides containing arsenic, mercury, and lead were being applied to crops. In the seventeenth century, nicotine was extracted from tobacco leaves as nicotine sulfate for use as an insecticide. In the nineteenth century, two more natural pesticides were introduced: pyrethrum (extracted from chrysanthemums) and rotenone (extracted from the roots and stems of several tropical and subtropical plant species of the genus *Lonchocarpus* or *Derris*) [Miller (21A46)].

From the 1860s until the advent in 1942 of DDT (1-chloro-2-[2,2,2-trichloro-1-(4-chlorophenyl)ethyl]benzene), there were numerous development and use of inorganic and naturally occurring compounds (inorganic and organic components extracted from plants and animals) for control of insects and plant diseases, particularly fungi. Little progress occurred in the discovery of natural or chemical means to control weeds. The chemistry of arsenicals was further exploited to control insects (Paris Green [copper(II) acetoarsenite]). Bordeaux mixture (copper sulfate and lime) was found to be extremely useful in the control of plant diseases, leading to its widespread usage. The invention of the pressure sprayer (both hand and power driven) made efficient large-scale application of pesticides feasible and economical. Aerial application was also invented (early 1920s), leading to expanded applications in agriculture. The availability of DDT, beginning in 1945 for civilian/agricultural usage, opened a new era of pest control, leading not only to its extensive usage but also to the development of numerous other synthetic organic insecticides, e.g., organophosphates (1946). About the same time (1944), selective synthetic organic herbicides were discovered, starting with 2,4-D (2,4-dichlorophenoxyacetic acid), which revolutionized weed control in agriculture and elsewhere. Also, synthetic organic fungicides (metal based) were developed as effective controls of plant diseases (and for other applications). During the 1950s and 1960s, granular pesticide formulations were developed, which led to large expansions of pesticide usage on major field crops [Aspelin (21A02)].

Prior to the advent of DDT (and other organic pesticides which rapidly followed), most pesticides used in agriculture were applied to protect high value/small acreage crops, principally fruits, vegetables, and cotton. This, however, changed dramatically in the 1950s, as major field crops, e.g., corn, sorghum, grains, tobacco, and soybeans, rapidly accounted for a majority of pesticide usage [Aspelin (21A02)].

By the 1960s, some very important new families of chemicals were discovered as herbicides, e.g., triazines, acetanilides, and dinitroanilines. In the 1970s, synthetic pyrethroids replaced much of the insecticide chemistry developed during the previous 20 years. During the 1980s, imidazolinone and sulfonylurea herbicides dramatically lowered application rates for weed control. During the 1990s and currently, agrochemical companies are employing new synthetic methods to produce safer pesticides (and growth regulators) for use on crops. The emphasis today in the development and use of pesticide and growth regulators is toward safer, more effective biological agents and pesticides applied at lower levels and enhanced stewardship in use of available pesticides [Aspelin (21A02)].

Tobacco is an agricultural product processed from the leaves of plants in genus *Nicotiana* of the nightshade family Solanaceae. *Nicotiana* is indigenous to North and South America, but numerous species of *Nicotiana* (over 60) are found throughout the world. The two main species cultivated and grown to produce tobacco and tobacco products worldwide are *Nicotiana tabacum* and *Nicotiana rustica*. *N. tabacum* is the most widely cultivated and used for production of tobacco leaf for cigarettes, cigars, chewing tobacco, snuff, snus, pipe tobacco, and other forms of tobacco products. *N. rustica* is the second most widely grown *N.* species. Its leaves are extracted for nicotine, pyridine products, and solanesol (3973).

Tobacco has evolved over the centuries to be resistant to many types of pests and infections. The plants produce numerous compounds that provide for its protection. For example, the plants contain high levels of nicotine. It constitutes 0.3%–5% in *N. tabacum* and up to 8%–10% in *N. rustica* based on the dry weight of the tobacco leaves. Its biosynthesis takes place in the roots, and it accumulates in the leaves. It is a potent neurotoxin for many pests with particular specificity to insects. Therefore, nicotine and salts of nicotine, e.g., Black Leaf 40 (nicotine sulfate), have been widely used as insecticides in the past (21A06, 21A07, 21A39–21A42), and currently, nicotine derivatives such as Imidacloprid [1-((6-chloro-3-pyridinyl)methyl)-*N*-nitroimidazolidinimine] continue to be widely used (3973).

Pesticides and plant growth regulators are important parts of modern agricultural and horticultural productivity. These pesticides can be naturally occurring in the plant or synthetically produced. Although naturally produced pesticides and growth regulators are effective, their concentrations in the plant are often lower than necessary to completely eradicate harmful pests and infections. Some naturally occurring pesticides are harvested from plants and sold commercially, e.g., *Bacillus thuringiensis*, *Derris* (rotenone), pyrethrum, Neem oil, and nicotine (nicotine salts) [EPA (21A21)]. Over the last 60–70 years, hundreds of synthetic pesticides and

growth regulators have been developed for application to tobacco at various stages in its development and during storage prior to use in commercial tobacco products to reduce or eradicate certain pests, e.g., insects, mice and other animals, unwanted plants (weeds), fungi, microorganisms such as bacteria and viruses, and infectious proteins. Some of the most effective pesticides and growth regulators are synthetic. Unfortunately, a number of highly effective synthetic pesticides are extremely harmful to both the environment and humans. One significant problem with synthetic insecticides is their longevity. This longevity is mostly due to the fact that many synthetic insecticides are not biodegradable.

Consequently, these pesticides remain in the ecosystem for long periods of time and can have disastrous consequences on organisms that subsequently absorb the insecticide. Arsenic salts (1459, 1460) and DDT (707–709) are good examples of synthetic pesticides that remained in the ecosystem for a long period of time and that have had considerable negative consequences. As a result of the possible harm to both humans and the environment, associated with synthetic pesticides, worldwide regulations are now in place. These regulations vary from country to country and apply to both synthetic agrochemicals and harvested natural pesticides [EPA (21A21)].

Based on a definition by the U.S. Environmental Protection Agency (EPA), a pesticide is any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest. The term pesticide also applies to herbicides, fungicides, and various other substances used to control pests. Under U.S. law, a pesticide is also any substance or mixture of substances intended for use as a plant regulator, defoliant, or desiccant. Pests are living organisms that are present where they are not wanted or that cause damage to crops or humans or other animals. In the United States, the EPA regulates both naturally occurring chemicals in harvested/extracted from plants as pesticides and growth regulators, as well as synthetic agrochemicals [EPA (21A21)].

There are five broad chemical classifications or categories of pesticides (four for synthetic pesticides and one for natural or plant-derived pesticides). Each of the following five chemical/biological categories of synthetic and harvested/extracted natural pesticides and growth regulators includes examples of commercial pesticides:

1. Organochloride pesticides: Aldrin, Chlordane, Dieldrin, DDT, Endosulfan, Endrin, Heptachlor, Lindane, Methoxychlor, Mirex, and TDE
2. Organophosphorus pesticides: Acephate, Azinphos-methyl, Chlorpyrifos, Chlorpyriphos-methyl, Diazinon, Dichlorvos (DDVP), Dicrotophos, Dimethoate, Disulfoton, Ethoprop, Fenamiphos, Fenitrothion, Fenthion, Fosthiazate, Malathion, Methamidophos, Methidathion, Methyl-parathion, Mevinphos, Naled, Oxydemeton methyl, Parathion, Phorate, Phosalone, Phosmet, Pirimiphos-methyl, Profenofos, Terbufos, Tetrachlorvinphos, and Trichlorfon
3. Carbamate pesticides: Aldicarb, Carbofuran, Carbaryl, and Methomyl
4. Pyrethroid pesticides: Allethrin, Bifenthrin, Deltamethrin, Permethrin, Resmethrin, Tetramethrin, and Tralomethrin
5. Plant-derived pesticides: Azadirachtin A and B (obtained from *Azadirachta indica*), *B. thuringiensis*, *Derris* (rotenone), Neem oil (obtained from *A. indica*), nicotine, Pyrethrum, Spinosad (a mixture of spinosyn A and spinosyn D) derived from soil bacterium *Saccharopolyspora spinosa*

Not every pesticide and growth regulator example listed earlier may be approved for use on tobacco.

This chapter provides information on pesticide and growth regulator residues (synthetic and natural occurring) identified on tobacco and identified in tobacco smoke. It also provides data of the transfer rates of these residues on tobacco to tobacco mainstream smoke (MSS) and certain examples of degradation/decomposition products from pesticide and growth regulator residues identified in MSS. Finally, a brief review of analytical methods for the analysis of pesticide and growth regulator residues on tobacco and in tobacco smoke is provided.

21.1 SYNTHETIC PESTICIDES AND PLANT GROWTH REGULATOR RESIDUES ON TOBACCO

Pesticide and growth regulator residues on tobacco and their transfer rates to MSS have been the subject of several reviews and multiple chapters in books. In the late 1960s, Guthrie and Bowery (21A25) and Guthrie (1457, 1458) reviewed the early literature dealing especially with residues of arsenic and the chlorinated hydrocarbon insecticides as well as those of carbamates and organophosphorus compounds used on tobacco. In another publication, Guthrie (21A24) summarized legislation on pesticide residues on tobacco and tobacco products in countries around the world as of 1973. In that paper, he also included an updated account of residues in U.S. tobacco and tobacco products. Ladisch in 1973 reviewed the known chlorinated pesticides in tobacco and tobacco smoke (21A31). Two reviews published in 1979 discuss the influence of growth regulators and herbicides [Steffens (3811a)] and insecticides and nematicides [Sheets and Leidy (3634)] on the chemistry of tobacco. These reviews contained updates on residues of pesticides. Ishiguro and Sugawara (1884) reviewed the known pesticides in tobacco and smoke and literature on decomposition products from pesticides in 1980. In 1986, Wittekindt (4271a) reviewed the pesticides recommended for use of tobacco in 22 countries, listed the maximum residues for 11 pesticides allowed on tobacco products in Germany, and presented a list of maximum amounts recommended by the German cigarette industry for 71 other pesticides. Davis et al. (21A17) and Meyer et al. (21A45) presented a detailed analysis of maleic

hydrazide (MH) residues in U.S. tobacco and discussed the toxicological implications of the residues. In 1989, the *43rd Tobacco Chemists' Research Conference* (TCRC) symposium was dedicated to the subject of regulation of insect and pathogen activity in tobacco and tobacco products. In that symposium, Benezet (21A05) reviewed chemical means to control pests in tobacco and tobacco products and their interaction. At that same symposium, Danehower (21A16) and Jackson et al. (21A29) reviewed the role of natural tobacco constituents that are effective pesticides (21A30). Cousins (21A14a) published a review on herbicides and suckering agents in 1989. In 1972 and again in 1990, Tso published books on the chemistry and biology of tobacco (3972, 3973). In both books, he devoted two chapters to pesticides and growth regulators (both compounds native to tobacco and applied agrochemicals). In 1991, Sheets (3633) presented a very thorough review of all known pesticides to that date. Davis and Nielsen edited a book in 1999 on tobacco production, chemistry, and technology (910a). Several chapters in that book reviewed various types of pesticides employed in the production of different types of tobacco (2483a, 2650b, 2892a, 3646a, 3661a). In 2002, Blanc et al. (21A06) reviewed the use of natural insecticides/pesticides for use on tobacco. Mueller (2650a) reviewed current approaches and tools for the management of pesticide residues on tobacco in 2005 at the *59th Tobacco Science Research Conference*. Most recently in 2005, Eberhardt (21A19) prepared an extensive review of pesticides used on tobacco, the transfer rates of pesticides to MSS and sidestream smoke (SSS), and decomposition products of pesticide residues identified in MSS.

The most commonly used commercial pesticides and growth regulators for tobacco, as of 1998, include the following:

Insecticides: Acephate, Aldicarb, *B. thuringiensis*, Carbaryl, Carbofuran, Chlorpyrifos, Diazinon, Disulfoton, Endosulfan, Ethoprop, Fenamiphos, Fonofos, Imidacloprid, Malathion, Methidathion, Methomyl, Spinosad, and Trichlorfon
Herbicides: Benefin, Clomazone, Diphenamid, Isopropalin, Napropamide, Pebulate, Pendimethalin, Sethoxydim, and Sulfentrazone
Fungicides: Dimethomorph, Mancozeb, Mefenoxam, and Metalaxyl
Plant growth regulator: Ethephon and Flumetralin
Plant growth regulators as herbicides: maleic hydrazide
Fumigants as insecticides: Chloropicrin
Fumigants as insecticides or herbicides: methyl bromide
Fungicides as insecticides or herbicides: 1,3-dichloropropene (1,3-D) (21A59)

Worldwide pesticide use has increased 50-fold since 1950, and 2.5 million tons of industrial pesticides is now used each year [Miller (21A46)]. More than 25 million pounds of pesticides is used in tobacco production in the United States, and tobacco ranks sixth among all agricultural commodities in the amount of pesticides applied per acre, according to the U.S. Government Accounting Office (GAO) (21A59).

Tobacco farmers use a considerable quantity of pesticides and growth regulators to increase leaf yield and quality and, hence, a greater profit for their crop. Even with the greatest caution used by farmers in applying the agrochemicals, a certain level of these pesticides and growth regulators remains on the leaf after harvesting and curing. Additional pesticides are often used on tobacco that is stored to control insect populations, and small but detectable levels of pesticides remain on tobacco prior to its use in manufacture of tobacco products. Therefore, certain residual pesticides are expected to be present on tobacco. Since about 1950, over 200 types of pesticides and growth regulators have been used on tobacco crops. Some are no longer used as many technological improvements have been made during that time and our knowledge of the effectiveness of different agrochemicals on pest has improved. All the newer pesticides are now regulated, and strenuous testing programs exist to assure that these agrochemicals meet safety (human and environmental [soil and air]) requirements (21A21). Additionally, agricultural breeding practices have generated new varieties of tobacco plants that are often more resistant to certain plant diseases and insects (21A21). Even with all the safety measures in place, residual levels of agrochemicals have been identified in both tobacco and tobacco smoke. Degradation products from the thermal degradation, pyrolysis, and combustion of these agrochemicals have also been identified on tobacco and in tobacco smoke. Generally, the level of residue tobacco pesticides and growth regulators is very small (ng/kg tobacco, ppm range). The transfer rate of these pesticides and growth regulators to MSS varies tremendously but is generally less than 30%, in many cases less than 10%, and in some cases less than 1% [Eberhardt (21A19)]. The existence of trace levels of pesticides and growth regulators in tobacco smoke was made possible by the advent of modern analytical methodologies, particularly gas capillary/gas chromatography (GC/GC), gas chromatography/mass spectrometry (GC/MS), and high-performance liquid chromatography (HPLC).

21.2 NATURALLY OCCURRING PLANT GROWTH REGULATORS AND PESTICIDES IN TOBACCO

Auxins are a class of plant growth substance (often called phytohormones or plant hormones). The most important member of the auxin family found in all plants is indole-3-acetic acid (IAA). It generates the majority of auxin effects in intact plants and is the most potent native auxin. Naturally occurring auxins include gibberellic acid, IAA, phenylacetic acid (PAA), and indole-3-butanoic acid (IBA) (3973). Gibberellic acid and several gibberellins are sold commercially as plant growth regulators. Auxins play an essential role in coordination of many growth and behavioral processes in the plant life cycle. When stimulated during normal plant growth or when applied to the plant at high concentrations, auxins produce ethylene.

Excess ethylene inhibits elongation growth, causes leaf abscission, and can even kill the plant (21A14). Synthetic auxins and commercially available auxins are effective herbicides by their effective promotion of ethylene in plants. Synthetic auxin analogs include 1-naphthaleneacetic acid (NAA), 2,4-D, IBA, and 2-methoxy-3,6-dichlorobenzoic acid [Hobbie and Estelle (21A27), Hobbie et al. (21A28), Lomax et al. (21A35)]. Additionally, compounds such as naturally occurring pyrethrins (21A15, 21A20, 21A23, 21A32–21A34), Neem oil (a mixture from *A. indica* of more than 135 compounds), Azadirachtin A and B from *A. indica* [Akol et al. (21A01), Biswas et al. (21A05a), Cousins (21A14a)], rotenone [Chamberlin and Madden (21A11)], and *B. thuringiensis* (B.t.) are effective naturally occurring pesticides (3973, 21A54). Of course, the most plentiful naturally occurring insecticide in tobacco is nicotine [Busbey and McIndoo (21A07, 21A08), McIndoo et al. (21A40–21A42), McIndoo (21A39), Steppuhn et al. (21A55)]. In 1989, Danehower (21A16) reviewed the field of naturally occurring tobacco growth regulators and pesticides at the 43rd TCRC. Numerous naturally occurring pesticides are found on the surface of tobacco leaves. Effective naturally occurring pesticides on the surface of tobacco leaves include *n*-, *iso*-, and *anteiso*-paraffinic hydrocarbons; aliphatic alcohols and acids; wax esters; α- and β-4,8,13-duvatrien-1-ols, the α- and β-duvatrienediols and monols; (12,*Z*)-labda-12,14-diene-8α-ol, *Z*-abienol; (13,*E*)-labda-12-ene-8α, 15-diol, labdenediol; numerous sucrose esters (C2–C8 acids); several labdane diterpenes (sclareol type); nicotine; nornicotine; formylnornicotine; acetylnornicotine; 3-hydroxy-acylnornicotines (C12–C16); acyl nornicotines (C12–C13) with *n*-, *iso*-, and *anteiso*-methyl branching; and numerous phenolic compounds derived from shikimic acid, e.g., caffeic acid, ferulic acid, gentisic acid, cichoriin, isoquercetin, rutin and their glucosides, and the mevalonic acid, e.g., capsidol, solavetivone, solanascone, occidol, and numerous other sequiterpenoids, biological pathways in tobacco.

21.3 TRANSFER RATES OF PESTICIDES AND PLANT GROWTH REGULATORS TO MSS

Tobacco, because it is subject to many types of pests, can be damaged both physically and chemically. Serious infections can result and have led to total crop failures. Efforts are continually being made to breed new varieties of tobacco resistant to disease and various pests (aphids, hornworms, various nematodes, etc.). Additionally, herbicides of various types are widely used to control unwanted vegetation in the fields. As a result, the use of pesticides and various plant growth regulators is widespread and at present is the primary means used by tobacco farmers to improve tobacco quality and yield. The level of pesticide (and plant growth regulator) residues on tobacco has always been a concern to tobacco growers, the tobacco industry, and governmental regulators in terms of the safety of the resulting tobacco products. Hundreds of tobacco pesticides and plant growth regulators have been developed and marketed in the past. Fewer than 25 are currently regulated and employed by farmers and the tobacco industry (3633). Regardless of the intended use of these pesticides and growth regulators, it seems inevitable that certain levels remain on the tobacco leaf. This is particularly true today, not necessarily because inordinate levels of pesticides are employed on tobacco but because tremendous advances in analytical chemistry have enabled scientists to detect extremely low levels (picogram to fentagram levels) of these residues (or their decomposition products). As certain agrochemicals used for pest control and growth regulation leave residues on cured tobacco leaves, some residual pesticides and growth regulators have been identified in tobacco smoke. An important question concerning consumer safety is whether the residual levels of pesticides (or growth regulators) represent a danger to the public.

At the completion in 1976 of the study of the second set of experimental cigarettes in the National Cancer Institute (NCI) decade-long study on the "less hazardous" cigarette, it was reported that the long-chained alcohols used as suckering agents on tobacco had no adverse chemical or biological effect on cigarette MSS. In the 1976 report, Gori (1330) summarized this aspect of the NCI second study as follows:

> The fatty alcohol, fatty alcohol x 100, and hand-suckered blends showed no significant difference among themselves or from the SEB II blend [see p. 2 in (1330)].
>
> No statistically significant differences were observed among Hand-suckered, Fatty Acid-Normal, and Fatty Acid x 100 Blends (variables 60, 61, and 62) [see p. 14 in (1330)]

In the fourth NCI study completed in 1980, the chemical and biological properties of the MSSs from cigarettes made from pesticide-treated tobacco and pesticide-free tobacco were compared. Gori wrote [see p. 7 in (1333)]:

> No significant differences were observed between cigarettes made from pesticide-treated tobacco leaves and pesticide-free tobacco leaves.

The pesticide-treated vs. pesticide-free tobaccos used in this phase of the NCI study were those grown in Prince Edward Island, Canada. The commercial pesticides used on the tobacco included Chlorpyriphos, Trichlorfon, diphenamide, Methomyl, DDT, Carbaryl, MH, and C10 alcohol. The pesticide-treated tobacco properties were described in 1980 by Tso et al. (3973, 3977):

> It appears that chemicals currently registered for use on tobacco, when applied as directed, are of no significance in increasing biological activity of cigarette smoke condensate [see p. 151 in (3973)].

In 2005, Eberhardt (21A19) reported on pesticide residues on tobacco, the transfer rates of selected pesticide residues, and pyrolysis products of some pesticide residues as part of the CORESTA subgroup study on pesticide residues. Information on 40 agrochemicals (used from the 1950s to the present) was obtained from 64 literature references. The agrochemicals evaluated were insecticides, fumigants, fungicides, herbicides, and growth regulators. These represented a diverse set of compounds including alcohols, acids, organophosphates, organohalides, carbamates, dithiocarbamates, pyrethrins, dinitro compounds, organonitrogen compounds, and heterocyclics. Prior to the work by Eberhardt (21A19), Rix (4857, 4858) evaluated the transfer of selected agrochemicals (Dicamba, Formothion, and Thiodan) from tobacco to smoke.

For the majority of the commercial pesticides (and plant growth regulators), reviewed by Eberhardt (21A19), only minimal information existed for their transfer into the smoke and for pyrolysis products. It must be noted that some of the agrochemicals listed, e.g., Leptophos and TDE, had only minor significance in tobacco cultivation and were added to tobacco for purely experimental reasons to study smoke transfer rates. Additionally, not all authors that provided information on transfer rates gave precise details on the pesticide concentrations in the original material used. There are only a few pesticides, such as DDT, MH, and several dithiocarbamates, where the transfer rates seemed to be adequately investigated, i.e., in sufficient number and by different research groups [Atallah et al. (1051d, 21A03, 21A04), Chopra et al. (707, 708, 712, 714, 716), Guthrie et al. (1457, 1458), Hoffmann and Rathkamp (1756), and Hoffmann et al. (1761, 1767)]. A number of publications by these authors used labeled agrochemicals (16 of the 64 studies), which provided information on the fate of the original substance in tobacco MSS and SSS as well as their presence in the vapor and particulate phases of the smoke streams. As most of the naturally occurring pesticides and plant growth regulators exist in tobacco, no information on the transfer rates to tobacco smoke is available. Table 21.3 lists the majority of known pesticides and plant growth regulators used on and identified in tobacco and tobacco smoke. Although Table 21.3 lists a great number of natural and synthetic pesticides and growth regulators found in tobacco and tobacco smoke, there are still other pesticides and plant growth regulators that could have been used on tobacco but where no information could be found in the literature. Additionally, individual pesticides and growth regulators often have multiple common names. Therefore, in reviewing Table 21.3, pesticides and growth regulators should be searched by Chemical Abstract number or chemical name. Table 21.3 contains only a selected number of naturally occurring pesticides and plant growth regulators found in tobacco and tobacco smoke. All of the compounds mentioned in this chapter as naturally occurring pesticides and plant growth regulators are covered in other chapters, e.g., the hydrocarbons are discussed in Section 1.1, the duvatrienediols are discussed in Chapter 2, and the nicotinoids are discussed in Section 17.2.

The evaluation by Eberhardt (21A19) of the available literature demonstrated that the transfer rate for all residues studied was much less than 100%. In most studies, the transfer rate of the pesticide to MSS is stated as being <30%. For a small number of agrochemicals, e.g., DDT, TDE, Lindane, and HCH-alpha, markedly higher transfer rates were found, although it should be kept in mind that very broad ranges in transfer rates exist for many of the pesticides examined. Only in a few studies were the transfer rates of residues in plain and filtered cigarettes presented and compared. The data suggested that the presence of a filter in cigarettes slightly reduces the transfer into MSS of some pesticides, e.g., DDT, Disulfoton, and TDE (1127). Several other factors also influenced the transfer rates, e.g., the type of tobacco tested, the form of the smoking article (e.g., cigarette, cigar, cigarillo, and pipe), the type of a filter employed, the method of adding the original substance and its amount, variation in smoking conditions (e.g., puff volume, and number of puffs), and the analytical methods employed to determine the agrochemical [Mussalo-Rauhamaa et al. (21A48), Mold and Walker (2596), Carugno (21A10), Schmid and Rastetter (21A52), Mestres et al. (21A43), Hengy and Thirion (1619), Hoffmann et al. (1761), Atallah and Dorough (21A03, 21A04), Thorstenson and Dorough (3915), Smith et al. (3724), Lorenz et al. (21A36–21A38), Guthrie (1457), Dickes et al. (21A18), Dorough and Atallah (1051d), Bowery et al. (415), Hawk et al. (1553), Ceschini and Chauchaix (644), Clark et al. (21A12), Moshy and Halter (21A47), Hengy and Thirion (1618), Meikle (2527), Sitaramaiah et al. (21A53), Thurm (21A57), Stone (21A56), Barkemeyer et al. (186), Chopra and Domanski (707), Chopra and Sherman (712), and Underwood (21A58)].

Table 21.1 shows the percentage transfer of selected pesticides applied to tobaccos that transfer to MSS. The percentage transfers were generally taken from the publication or were calculated based on data provided in the literature [Eberhardt (21A19)].

21.4 DECOMPOSITION PRODUCTS OF AGROCHEMICALS IN MSS

The decomposition products identified in MSS of various agrochemicals added to tobacco are shown in Table 21.2.

In some of the published studies reviewed by Eberhardt (21A19), the determination and quantification of the pyrolysis products were the primary objective of the study, e.g., Hoffmann et al. (1761), Mestres et al. (21A44), and Higman et al. (1645), and MSS transfer rates for the pesticide were not determined. In other studies, ^{14}C-labeled pesticides, e.g., Atallah and Dorough (21A03, 21A04), Frisch et al. (1243), and Clark et al. (21A12), were evaluated. In most

TABLE 21.1
Percent Transfer of Intact Agrochemicals to MSS (1884, 21A19)

Pesticide	Percent Transfer of Intact Compound
Anilazine	1
Azinphos-methyl	0.2–0.27
Benomyl	ND
Captan	ND–2.7
Carbaryl	1–11
Carbofuran	0.3–20
Chlorpyrifos	13.5–15
Cyhalothrin	5.2
Cypermethrin	1.51
DDT	1.2–83.3
Deltamethrin	2.64
Diamidofos	ND
Dieldrin	4–32
Diflubenzuron	6.9
Disulfoton	6–14.8
Dithiocarbamates	ND
Endosulfan	ND–15.3
Endosulfan sulfate	15.5–16.3
Endrin	18.18–31.58
Fenpropathrin	15.5
Fenvalerate	1.72
HCH-alpha	45
Heptachlor	4–5
3-Hydroxycarbofuran	0.1–3.26
Imidacloprid	5.3
Isobenzan	3.5–5.1
Leptophos	3–10
Lindane	3.1–40
Linuron	6.7
Malathion	ND–9.4
Maleic hydrazide	ND–23
Methoprene	38.2
Metobromuron	3.7–4
Mirex	9–23
Monolinuron	2.5–4.5
Naphthol	5.7–13.8
Parathion	ND–15.3
Phosphine	ND
TDE	0.007–63.75

ND, not determined.

cases, the agrochemicals tested were used as purchased, e.g., Comer et al. (21A13), Chopra et al. (716), and Chopra and Zuniga (717).

For the majority of the pesticides reviewed by Eberhardt (21A19), only minimal information existed for their transfer into smoke and for their pyrolysis products. There are only a few pesticides, such as DDT, MH, and several dithiocarbamates, where the transfer rates seem to be adequately investigated in a sufficient number of studies by different research groups [Atallah et al. (1051d, 21A03, 21A04), Chopra et al. (707, 708, 712, 714, 716), Guthrie et al. (1457, 1458), Hoffmann and Rathkamp (1756), and Hoffmann et al. (1761, 1767)].

21.5 METHODS FOR ANALYSES OF PESTICIDES AND PLANT GROWTH REGULATORS

Numerous analytical methods, e.g., GC/GC, GC/MS, and HPLC, have been published for the determination of various classes of pesticides [Haeberer and Chortyk (470, 21A26), Schmeltz et al. (3483), Sagredos and Eckert (3379–3381), Sagredos and Moser (3382), Nesemann and Seehofer (2699), Nesemann et al. (2697, 2698), Schmid and Rastetter (21A52), Schmid (3513), Dattilo et al. (904, 905), Guhlmann et al. (1451), Cai et al. (21A09), Carpenter and Frost (606), Nowell and Resek (21A50), Zaugg et al. (21A63), Werner et al. (21A60), Yamazaki and Tomara (21A62), and many others].

21.6 RESIDUES OF SYNTHETIC PESTICIDES AND PLANT GROWTH REGULATORS IDENTIFIED IN TOBACCO AND TOBACCO SMOKE

The number of pesticide, plant growth regulators, and their decomposition products identified in tobacco and tobacco smoke listed in Table 21.3 is 308. Of these, 114 have been identified in tobacco smoke, 302 in tobacco, and 108 in both tobacco and tobacco smoke. There are more natural pesticides and growth regulators known than are listed in Table 21.3 because only selected examples of these natural pesticides and growth regulators, described by Danehower (21A16), are given.

TABLE 21.2
Degradation Products of Pesticides in MSS (1884, 21A19)

Pesticide	Degradation Products of the Intact Compound	References
Anilazine	*o*-Chloroaniline	1457
Azinphos-methyl	Oxyguthion	419, 1457
Captan	CO_2	21A37
Carbaryl	Degradation products: 7 (not further characterized), CO_2	1051d, 21A03, 21A04
Carbofuran	Degradation products: 2 (not further characterized), CO_2	1051d, 1553, 21A03, 21A04
Chlorpyrifos	Decomposition into unknown fragments	717
DDT	1,1-Dichloro-2,2-bis(*p*-chlorophenyl)ethane (DDD = TDE), 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene (DDE), 1-chloro-2,2-bis(*p*-chlorophenyl)ethylene (DDM = TDEE), 4,4′-dichlorobenzophenone (DCBP), bis(*p*-chlorophenyl)methane (BCPM), CO_2, chloroform, methyl chloride, *trans*-4,4′-dichlorostilbene (DCS), DDD-olefins	644, 707, 712, 714, 708, 758, 1000, 1051d, 1457, 1756, 1767, 2697, 3915, 21A18, 21A37, 21A38, 21A43
Diamidafos	Phenol	2527
Dieldrin	Chlorinated and dechlorinated degradation products	21A57
Diflubenzuron	4-Chloroaniline, 4-chlorophenylurea	21A53
Dithiocarbamates	CO_2, carbon disulphide, COS, ethylene thiourea, hydrogen sulfide	124, 186, 21A10, 21A38, 21A44, 21A51
Endosulfan	Ether	1619
Imidacloprid	CO_2, CO (traces), urea compound	21A12
Leptophos	Degradation products: 4 (not further characterized), CO_2	1051d, 21A03, 21A04
Lindane	CO_2	21A36, 21A38
Linuron	3,4-Dichloroaniline	822
Malathion	CO_2	21A38
Maleic hydrazide	Acetonitrile, acrylonitrile, aminobutanoic acid, ammonia, aniline, butanoic acid, benzonitrile, CO_2, CO, cyanide, 1*H*-pyrrole-2,5-dione, hydrazine (traces), indole, succinimide	716, 1761, 2383–2385, 3724, 3725, 1553, 4274, 21A56
Methoprene	CO_2, CO	1243
Metobromuron	4-Bromoaniline	822
Mirex	Degradation products: 3 (not further characterized), CO_2	1051d, 21A03, 21A04
Monolinuron	CO_2, 4-chloroaniline	822, 21A37
Naphthol	Degradation products: 6 (not further characterized)	21A03, 21A04
TDE (DDD)	Dechlorinated TDE, 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene (DDE), 1-chloro-2,2-bis(*p*-chlorophenyl)ethylene (DDM = TDEE), 4,4′-dichlorobenzophenone (DCBP), bis(*p*-chlorophenyl)methane (BCPM), *trans*-4,4′-dichlorostilbene (DCS)	415, 416, 714, 758, 1457, 3915

Note: The symbol (0) indicates the component identified in tobacco substitute smoke was not detected in tobacco smoke or vice versa.

22 Genes, Nucleotides, and Enzymes

Prior to discussing genes, nucleotides (DNA/RNA strands), and enzymes identified in tobacco, a general discussion of genetics, genes, nucleotides, and enzymes is appropriate (3973). There are numerous excellent reference texts that the reader can access for more detailed information on genetics [910a, 3973, Acquaah (22A01), Bernardi (22A03), Griffiths et al. (22A12), Hartl and Jones (22A14)] and several sources of encyclopedic information (22A05, 22A17, 22A34). The general discussion will be followed by a review of work accomplished over many decades toward an understanding of the mysteries of tobacco genetics.

22.1 GENERAL DISCUSSION OF GENETICS

Genetics is the science of heredity and variation in living organisms (22A12, 22A14, 22A17). Knowledge that desired characteristics were inherited has been implicitly used since prehistoric times for improving crop plants and animals through selective breeding. The science originated from human experience to improve crop and animals through the use of varied methods, such as domestication. However, the modern science of genetics, which seeks to understand the mechanisms of inheritance, only began with the work of Gregor Mendel in the mid-1800s (3973, 22A32).

Inheritance is fundamentally a discrete process with specific traits that are passed on in an independent manner. These basic units of inheritance are now known as genes. In the cells of organisms, genes exist physically in the structure of the molecule DNA, and the information contained in the genes is used to create and control the components of cells. Although genetics plays a large role in determining the appearance and behavior of organisms, it is the interaction of genetics with the environment an organism experiences that determines the ultimate outcome. For example, *Nicotiana tabacum* seeds planted and cultivated in different soils and under different climatic and agronomic conditions can produce different types of tobacco that have vastly different appearances and chemical composition, e.g., Maryland vs. Virginia tobacco (3973).

A gene is a set of segments of nucleic acid. A nucleic acid is a complex, high-molecular-weight biochemical macromolecule composed of nucleotide chains that convey genetic information. The most common nucleic acids are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA).

Genes are arranged linearly in long chains of DNA sequences, called chromosomes. In eukaryotic organisms (which include plants and animals), each cell has its DNA arranged in multiple linear chromosomes. These DNA strands are often extremely long. The largest human chromosome, for example, is about 140 million base pairs in length (22A11).

Certain segments of nucleic acid contain the information necessary to produce a functional RNA product in a controlled manner. They contain regulatory regions dictating under what conditions this product is made, transcribed regions dictating the sequence of the RNA product, and/or other functional sequence regions (22A23, 22A24). The physical development and phenotype, i.e., a measurable characteristic, such as color or disease resistance, of organisms can be thought of as a product of genes interacting with each other and with the environment, and genes can be considered as units of inheritance.

In cells, genes consist of a long strand of DNA that contains a promoter, which controls the activity of a gene, and coding sequences, which determine what the gene produces. When a gene is active, the coding sequence is copied in a process called transcription, producing an RNA copy of the gene's information. This RNA can then direct the synthesis of proteins via the genetic code. The genetic code is the set of rules by which information encoded in genetic material (DNA or RNA sequences) is translated into proteins, i.e., amino acid sequences and enzymes, by living cells. However, RNAs can also be used directly, e.g., as part of the ribosome, which is a small, dense organelle in cells that assembles proteins. Molecules produced from gene expression, whether RNA or protein, are known as gene products.

Most genes contain noncoding regions that do not code for the gene products but can regulate gene expression. Additionally, there are large segments of the DNA that do not carry any genetic information. One single gene can lead to the synthesis of multiple proteins. The total complement of genes in an organism or cell is known as its genome. The estimated number of genes in the human genome has been repeatedly revised downward since the completion of the Human Genome Project, but current estimates place the human genome size at just under 3 billion base pairs and about 20,000–25,000 genes (22A15).

The vast majority of living organisms encode their genes in long strands of DNA. DNA consists of a chain made from four types of nucleotide subunits: adenosine (A), cytidine (C), guanosine (G), and thymidine (T). Each nucleotide subunit consists of three components: a phosphate group, a deoxyribose sugar ring, and a nucleobase. Thus, nucleotides in DNA or RNA are typically called bases; consequently, they are commonly referred to simply by their purine (adenine and guanine) or pyrimidine (cytosine and thymine) original base components. The most common form of DNA in a cell is a double helix structure in which two individual DNA strands twist around each other in a right-handed spiral. In this structure, the base pairing rules specify that guanine pairs with cytosine and adenine pairs with thymine (each pair contains

one purine and one pyrimidine). The base pairing between guanine and cytosine forms three hydrogen bonds, while the base pairing between adenine and thymine forms two hydrogen bonds. The two strands in a double helix must therefore be complementary, i.e., their bases must align such that the adenines of one strand are paired with the thymines of the other strand, and so on.

Due to the chemical composition of the pentose residues of the bases, DNA strands have directionality. One end of a DNA polymer contains an exposed hydroxyl group on the deoxyribose; this is known as the 3′ end of the molecule. The other end contains an exposed phosphate group; this is the 5′ end. The directionality of DNA is vitally important to many cellular processes, since double helices are necessarily directional (a strand running 5′-3′ pairs with a complementary strand running 3′-5′) and processes such as DNA replication occur in only one direction. All nucleic acid synthesis in a cell occurs in the 5′-3′ direction because new monomers are added via a dehydration reaction that uses the exposed 3′ hydroxyl as a nucleophile.

The expression of genes encoded in DNA begins by transcribing the gene into RNA, a second type of nucleic acid that is very similar to DNA, but monomers of which contain the sugar ribose rather than deoxyribose. RNA also contains the base uracil (U) in place of thymine. Genes that encode proteins are composed of a series of three-nucleotide sequences called codons. A codon is a set of any three adjacent bases in the DNA or RNA. There are 64 different codons of which 61 specify the incorporation of an amino acid into a polypeptide chain while the remaining 3 are stop codons that signal the end of a polypeptide. For example, the DNA codon ACG via its complementary RNA codon CGU specifies the amino acid arginine. For another example, the DNA codon TAC via its complementary RNA codon GUA specifies the amino acid valine. There are three stop codons: uracil–adenosine–adenosine (UAA), uracil–adenosine–guanosine (UAG), and uracil–guanosine–adenosine (UGA). They are also called termination codons or nonsense codons. The genetic code specifies the correspondence during protein translation between codons and amino acids. The genetic code is nearly the same for all known organisms.

Many molecular definitions of a gene relate to their role in directing the production of specific proteins. Production of protein itself is made possible via certain enzymes known as polymerases. Various DNAs and RNAs could not be produced without these polymerases, and therefore, they are of primary importance. Numerous other enzymes are produced that control metabolic and catabolic processes (enzymatically), provide structural components, and perform regulatory functions in cells.

A single gene can encode multiple enzymes, and an enzyme can have multiple genes. For example, ribulose bisphosphate carboxylase–oxygenase in *N. tabacum* is a multimeric protein of 16 peptides, 8 small subunits (nuclear encoded) and 8 large subunits (chloroplast encoded); thus, 2 genes are responsible for this enzyme (3974c, 22A27, 22A35).

Metabolic and catabolic enzymes are specialized proteins that catalyze chemical reactions. In enzymatic catalyzed reactions, the molecules at the beginning of the process are called substrates, and the enzyme converts them into different molecules or products. Almost all processes in a biological cell need enzymes in order to occur at significant rates. Since enzymes are extremely selective for their substrates and accelerate only a few reactions from among many possibilities, the set of enzymes made in a cell determines which metabolic pathways occur in that cell (3973).

Each type of enzyme is generally geared to interact chemically with only one particular substance or type of substance, termed a substrate. The two parts fit together, according to a widely accepted theory introduced in the 1890s by the German chemist Emil Fischer (1852–1919), as a key fits into a lock. Each type of enzyme has a specific 3D shape that enables it to fit with the substrate, which has a complementary shape.

The link between enzymes and substrates is so strong that enzymes often are named after the substrate involved, simply by adding *ase* to the name of the substrate. For example, lactase is the enzyme that catalyzes the breakdown of lactose, while urease catalyzes the chemical breakdown of urea. Enzymes bind their reactants or substrates at special folds and clefts, named active sites, in the structure of the substrate. Because numerous interactions are required in their work of catalysis, enzymes must have many active sites and therefore can have molecular weights as high as one million.

22.2 TOBACCO GENETICS

Tobacco has been used in one form or another in civilized society for nearly five centuries. Eventually in the late nineteenth century, investigations as to its composition began, but they were not particularly numerous. The major driving force in the escalation in the mid-twentieth century of studies on tobacco composition was the attempt to define (1) its components that contributed to the consumer acceptability of the taste and aroma of tobacco itself and its smoke and (2) the precursors in tobacco of the toxicants in its smoke (3973, 22A30).

In 1972, Tso (22A30) remarked

> The characteristics of cigarette smoke are functions of the physical and chemical properties of leaf tobacco which make the cigarette. Smoke constituents may be modified by changing leaf characteristics. The questions are: What kinds of changes are needed? and, how can these changes be achieved?

Tobacco genetics is a rather new field of study although research on tobacco to understand its physical and chemical makeup has been a goal of tobacco scientists for over a hundred years. The initial problem in undertaking the goal of trying to understand the origins of the chemical and physical essence of tobacco was that our understanding of life processes, in general, was inadequate prior to the discovery of the structure and function of DNA. Additionally,

the life processing functions of numerous DNAs and RNAs in tobacco were not understood. Although scientists had an empirical knowledge of how the genetics worked via the tobacco breeding program, basic fundamental knowledge was lacking until technology was developed to execute the search for information on the genetic code for tobacco (3973).

Regardless, research directed toward the ultimate goal of understanding of the fundamental life processes of tobacco began. The early genetic research was conducted in the areas of tobacco breeding (as a means to improve leaf characteristics, quality, and disease resistance) and the chemical composition of tobacco via identification of extractable material in tobacco, e.g., amino acids, various proteins, enzymes (424a, 2341a, 3972, 3973, 22A06, 22A29, 22A30). It was not until the 1970s and 1980s with the development of new analytical and genetic tools, e.g., HPLC, GC/MS, instrumental polymerase chain reaction (PCR), plant transformation, genetic mapping with molecular markers, gene tagging, and positional cloning, that significant progress was possible in the understanding of tobacco genetics directed toward improved pest resistance, yield, and quality (424a).

The chemical composition of tobacco smoke is highly dependent upon the physical and chemical properties of the leaf tobaccos used in cigarette manufacture. It is a basic tenet that the biological properties of cigarette mainstream smoke (MSS) and cigarette smoke condensate (CSC) can be improved through changes in the genetics of tobacco. Numerous types of chemical and physical modifications performed on tobacco, e.g., tobacco extraction, tobacco reconstitution, tobacco expansion, inclusion of tobacco substitutes, have indicated that this tenet is possible (1375a, 1375b). Thousands of genes, nucleotides, and enzymes have been identified in tobacco. Although they do not transfer intact to MSS, hundreds of decomposition products from their combustion and pyrolysis products have been identified. Many of the combustion and pyrolysis products found in MSS and CSC have been called "Hoffmann analytes" because of their alleged adverse biological effects, e.g., quinoline, HCN, and several other undesirable nitrogenous compounds, certain PAHs, aza-arenes, and phenolics (3974c). It is hoped that through genetic modifications, precursors in tobacco of the toxicants in its smoke can be altered significantly to improve the safety of tobacco products (3794b, 3974c, 3975, 3976, 3984, 22A30).

22.3 GENES, NUCLEOTIDES, AND ENZYMES IDENTIFIED IN TOBACCO

The 65 species related to *N. tabacum* represent sources of a divergent germplasm for biochemical and physical variations (3793, 22A19, 22A30). These species differ widely in growth habit and in chromosome numbers (3793). Tobacco breeding via interspecific hybridization has been the major tool for agricultural scientists to improving the health and quality of tobacco (22A30). Possible approaches that plant scientists can take to modify tobacco leaf have been reviewed by Tso (22A31). Modifications discussed by Tso (3973, 22A31) involved genetic and cultural modification, nitrogen fertilization technology, leaf and plant population, the physiological stage of topping, and pesticide treatments. Postharvest modifications were also discussed (22A31), as leaf composition is markedly affected by the curing process, aging, or other treatment of cured leaves (4005).

The U.S. *Nicotiana* Germplasm Collection was initiated by the U.S. Department of Agriculture (USDA) in 1934 as a resource for tobacco breeders. The collection currently consists of approximately 1244 tobacco introductions, 656 cultivars, and 224 accessions representing 59 *Nicotiana* species, 50 interspecific hybrids, and a newly introduced set of mutants (22A19). The gene pool of the *Nicotiana* Germplasm Collection represents enormous possibilities for researchers in plant pathology, plant molecular biology, and biotechnology to modify and improve the quality, yield, and safety of tobacco. It has been estimated that the genetic makeup of tobacco includes 25,000–50,000 genes (22A22). *N. tabacum* has a very large genome size compared with other cultivated solanaceous plants (22A13, 22A21, 22A22). At approximately 4.5 billion base pairs, it is 1.5 times the size of the human genome (22A13, 22A21, 22A22).

There are at least two major (and several minor) initiatives to sequence the tobacco genome: the Tobacco Genome Initiative (TGI) and the European Sequencing of Tobacco Project (ESTobacco). Both projects have an ultimate goal of sequencing the greater part of the tobacco genome. Although tobacco has been cultivated for more than 500 years and is a crop of great economic significance, relatively little information exists on its genome structure and organization.

The overall goal of the TGI is to sequence and annotate more than 90% of the open reading frames in the genome of cultivated tobacco, *N. tabacum*. *N. tabacum* is an amphiploid species ($2n = 48$) likely resulting from an interspecific cross between *Nicotiana sylvestris* ($2n = 24$) and *Nicotiana tomentosiformis* ($2n = 24$) and, at approximately 4.5 billion base pairs, has a very large genome size compared with other cultivated solanaceous plants. A complete gene catalog will provide the raw information to investigate physiological and genetic processes in the tobacco plant, a widely used model in plant biotechnology. Tobacco genomics may lead to the elucidation of genetic factors that impact constituents associated with tobacco consumption. Improving our understanding of these processes may potentially contribute to achieving the goal of reducing the harm associated with cigarette smoking. In addition, important agronomic traits such as disease and pest resistance genes could be identified and thus could be available for use in traditional and molecular breeding projects, the goal of which is to enhance the performance of tobacco as a crop in different environments. Finally, *N. tabacum* is a member of the agriculturally important *Solanaceae* family, which also includes tomato, potato, eggplant, and pepper crop plants. All of these plants may benefit from gene discovery in tobacco. The TGI is housed in the laboratories of the Plant Pathology Department of the North Carolina State University (NCSU) Centennial Campus, College of Agricultural and Life Sciences

(Raleigh, NC). NCSU will make the TGI data available to authorized academic researchers. The TGI is supported by Philip Morris USA, Inc. (22A13, 22A21, 22A22).

The TGI has identified a large percentage of genes in *N. tabacum* by utilizing a combination of strategies. Researchers at TGI have employed a methyl filtration approach to identify gene-rich regions in *N. tabacum* in order to expedite the gene discovery process. As of 2006, TGI had sequenced 1,700,000 lanes of methyl-filtered clones and observed a dramatic increase in gene discovery in filtered vs. nonfiltered libraries. TGI has also performed expressed sequence tag (EST) sequencing from various *Nicotiana* libraries and to date has sequenced over 80,000 ESTs. Genes tagged by these two strategies have been used as probes to identify bacterial artificial chromosome (BAC) clones for more targeted sequencing. Numerous BACs have been sequenced, revealing information about both gene structure and genome organization in *Nicotiana* species (22A13, 22A21). The TGI has a projected completion date in late 2007.

The second major tobacco genomic project is centered in Europe and was started in 2006. It is known as the European Sequencing of Tobacco Project or ESTobacco. This project is being conducted by Advanced Technologies (Cambridge) Ltd. (a wholly owned subsidiary of British American Tobacco) and Institut du Tabac de Bergerac (part of the Altadis Group). The aim of the ESTobacco project is to be complementary to other projects currently underway concerning the tobacco genome. The strategy of ESTobacco is to sequence only genes expressed in tobacco and not the whole genome. They believe that the size of the tobacco genome is too large to be totally sequenced. The tobacco genome is thought to be about 29 times larger than *Arabidopsis thaliana* (Table 22.1).

The plan of the ESTobacco project is to investigate three commercial varieties of tobacco used throughout the world: K326 for the flue-cured type, Burley 21 and TN86 for the burley types. To obtain the major genes, the organs of the plant (seeds, roots, stems, midribs, laminae, and flowers) prepared at different stages of development (germination, young seedlings, before and after topping, maturity) will be used as a basis for this work. A large tobacco EST data set was obtained from 11 normalized cDNA libraries comprising 56,000 clones. It is envisioned that a DNA array designed with these sequences will allow the large-scale study of the genes expressed in tobacco. This new tool should lead to the acceleration of programs already underway concerning the origins of risks associated with tobacco and provide strategies for harm reduction. To encourage a wide range of initiatives on tobacco plant genetic, as with other crops, the resulting sequences obtained during the ESTobacco project will be available to the worldwide scientific community through public access databases (22A08, 22A26).

TABLE 22.1
Relative Size of Genomes and Number of Genes by Species

Species	Genome Size (Mb)	Number of Genes
A. thaliana	125	25,500
Homo sapiens	3000	20,000–25,000
N. tabacum	3500–4500 (est.)	25,000–50,000 (est.)

As whole gene sequences and nucleotide sequences (DNA and RNA sequenced strands) become available, they are being entered into GenBank (22A10). GenBank is the National Institute of Health (NIH) genetic sequence database, an annotated collection of all publicly available DNA sequences (22A02). There were approximately 65,369,091,950 bases in 61,132,599 sequence records in the traditional GenBank divisions and 80,369,977,826 bases in 17,960,667 sequence records in the whole-genome shotgun (WGS) division as of August 2006. GenBank is part of the International Nucleotide Sequence Database Collaboration, which comprises the DNA DataBank of Japan (DDBJ), the European Molecular Biology Laboratory (EMBL), and GenBank at the National Center for Biotechnology Information (NCBI). Information located in GenBank can be accessed on the Internet (1282a).

Within the next few years, our understanding of the tobacco genome will be greatly improved. It is anticipated or predicted that advances in tobacco genomic will lead to the next major improvement in safety and health associated with cigarette smoking via genetic modifications of various *Nicotiana* species. The symposium at the *61st Tobacco Science Research Conference* featured presentations from representatives from the TGI and the ESTobacco projects. Updates on both projects were given as well as how new types of biotechnologies are being employed to provide both fundamental and practical information of genes that could be used to improve pest resistance, quality, yield of tobacco, and the safety of tobacco products (22A09, 22A20).

In the late 1950s and through the 1960s, enormous breakthroughs in DNA enzymology took place. For example, in 1955, Kornberg et al. (22A18) isolated DNA polymerase, Weiss and Richardson (22A33) isolated DNA ligase in 1967, and Smith and Wilcox (22A28), and Kelley and Smith (22A16) isolated and characterized the first sequence specific restriction nuclease in 1970. These enzymes, respectively, play roles in the synthesis of DNA molecules, the attachment of two or more DNA molecules to one another, and the breaking of DNA molecules into fragments. Importantly, these enzymes make it possible to create entirely new kinds of DNA molecules and, equally important, to manipulate the functioning of the genes located on these new molecules. The types of enzymes that Smith, Wilcox, and Kelley (22A16, 22A28) discovered are called restriction enzymes. Restriction enzymes recognize and cut specific short sequences of DNA. They are found in bacteria, which use the enzymes to digest invading DNA. The bacteria add methyl groups to their own DNA to protect them from digestion. Molecular biologists began using these enzymes, along with DNA polymerase and DNA ligase in the early 1970s to cut, manipulate, and analyze pieces of DNA in a predictable and reproducible way. The enzymes became an important, early tool for mapping genomes. There are over 900 types of restriction enzymes

that have been isolated from over 230 strains of bacteria; some of these enzymes provide specific sequence segments of DNA and some do not. About 180 restriction enzymes are commercially available.

There have been hundreds of thousands of nucleotide sequences (DNA and RNA sequenced strands) that have been produced via restriction enzymes from various forms of DNA and RNA in tobacco (22A13, 22A21). Not every DNA strand though holds or is encoded with genetic information. There are considerable lengths of DNA that contain no genetic information or the function of which has yet to be identified. These segments are called "junk" or "noncoding" DNA. For example, about 97% of the human genome has been designated as "noncoding" (22A24). So, of the hundreds of thousands of nucleotide sequences that have been produced from various forms of DNA and RNA in tobacco, only a small percentage contains the essential genetic information needed to direct its life processes. However, all of these DNA and RNA strands serve a very important purpose during the construction of genomes. By employing sophisticated computer programs that can identify patterns in the bases in the DNA fragments, DNA fragments can be sequenced. "Fingerprinting" of large insert genomic fragment libraries, also known as bacterial artificial chromosomes (BAC) clones, can lead to the construction of a physical map of a genome. These maps are critical to genome sequencing, positional cloning, and understanding the relative organization of genes and markers. When BAC libraries are arranged into maps that reflect the DNA sequence in a chromosome, they provide maximal information and utility. Generally, these BAC libraries are deposited in the GenBank. For example, BAC clone libraries for *N. tabacum*, currently being compiled as part of the TGI and ESTobacco projects, are being deposited in the GenBank.

There are vast arrays of enzymes that have been identified in tobacco (429b,c, 3973). Plant enzymes perform valuable functions almost as soon as seeds are planted and continue to be important even through the tobacco-curing process. Enzymes are in fact essential molecules that assimilate carbon dioxide from air (via photosynthesis) and nitrogen by roots from the soil and utilize hydrogen liberated by dehydrogenation from the components of the Krebs tricarboxylic acid (TCA) cycle to produce a variety of organic acids, e.g., oxaloacetic, α-ketoglutaric acids. The net result of nitrogen assimilation is the utilization of a portion of newly photosynthesized carbon chains into the nitrogenous pool. When the nitrogen supply is abundant, there will be more synthesis of amino acids, e.g., aspartic and glutamic acids, and nicotine and less sugars and starch. If the nitrogen supply is limited, there will be an excess accumulation of acetate in the TCA cycle which results in higher production of carbohydrates, fats, volatile oils, resins, and polyterpenes. Tobacco enzymes efficiently and effectively control and regulate the type and level of tobacco constituents available to the plant for growth. The variations in leaf characteristics, texture, color, porosity, and combustibility; quality, e.g., aroma and flavor based on chemical composition; and yield (poundage per acre/hectare) are a reflection of the genetic makeup of the plant, agronomic practices, soil types, and environmental conditions (3972, 3973, 22A29, 22A30).

Enzymes can either work individually or in teams. In a metabolic pathway (like the TCA cycle), several enzymes work together in a specific order; one enzyme takes the product of another enzyme as a substrate. Two sources of information on hundreds of enzymes that have been identified in tobacco are Brenda and Kegg (429b,c). Brenda is the comprehensive enzyme information system and is a database of enzymes and enzyme pathways. It was developed and is maintained at the Institute of Biochemistry at the University of Cologne and is available through the Internet at http://www.brenda.uni-koeln.de//. Kegg stands for the Kyoto Encyclopedia of Genes and Genomes. Kegg is a bioinformatics resource that was developed and is maintained as part of the research projects of the Kanehisa Laboratories in the Bioinformatics Center of Kyoto University and the Human Genome Center of the University of Tokyo.

The phase of plant growth that extends from maturity to actual death (called senescence) is characterized by an accumulation of metabolic products, increase in respiratory rate, and a loss of dry matter (3973). At the senescence stage, enzyme activities (especially hydrolytic and other degradative enzyme systems) are intensified. These systems are responsible for breakdown of functional and structural components of the cell, such as proteins, nucleic acids, carbohydrates, and lipids. The latter stage of senescence resembles the early stage of leaf curing. Curing is a vital process which falls into the category of starvation phenomena or inanition of excised plant parts (3972, 3973).

The most conspicuous chemical conversions during curing involve two phases. The first phase is dominated by hydrolytic enzymes and occurs in either flue curing or air curing. In this phase, disaccharides and polysaccharides are hydrolyzed to simple sugars; proteins are hydrolyzed to amino acids which undergo oxidative deamination; and the pectins and pentosans are hydrolyzed to pectic acid, uronic acid, and methyl alcohol. The second phase is dominated by oxidative reactions and takes place mostly in air-curing processes. Among the conversions are the following: oxidation of simple sugars to acids, oxygen, and water; the increased oxidative deamination of amino acids leads to the formation of ammonia and amides, particularly asparagine; changes in organic acids, including conversion of malic to citric acid and also decarboxylations; and the oxidative and polymerization of phenols to brown products. There is a small decrease in alkaloids and some loss of dry weight (3972, 3973).

Although not discussed specifically, the tobacco plant contains many thousands of different proteins that are produced by the plant to perform both structural and functional roles. The abundance and types of proteins differ according to the plant organ and cell type being considered. And at the cellular level, proteins with functional roles in chloroplasts and mitochondria may be encoded by the small DNA genomes of those organelles or may be specified by nuclear genes and imported into those organelles.

A significant percentage of proteins in the tobacco leaf are those involved in photosynthesis. This complex process is mediated by the action of hundreds of enzymes involved in the capture of energy from sunlight and the use of that energy to assimilate carbon dioxide from the atmosphere. A key enzyme responsible for this process is ribulose-1,5-bisphosphate carboxylase–oxygenase (sometimes referred to as RuBP carboxylase or simply "Rubisco") (22A35). It is an enzyme that has a dual function in that it catalyzes the carboxylation and oxygenation of ribulose-1,5 bisphosphate. Therefore, it catalyzes the crucial reactions of both photosynthesis and photorespiration; the ratio of these two processes determines plant productivity (3973, 3974c). This important enzyme is the most abundant individual leaf protein and has been proposed as the most important and abundant single protein in nature. On the other hand, the majority of nicotine biosynthesis occurs in root tissues, so the enzymes involved in that process are expressed most abundantly in roots.

Before the advent of modern plant biochemistry and molecular biology, tobacco leaves, as well as the leaves of other higher plants, were considered to possess two broad classes of proteins based on their solubility properties during extraction. Of the total tobacco leaf proteins, approximately half are "soluble" and half "insoluble." The most abundant soluble protein came to be known as "Fraction-1 protein" (F-1 protein, shown to be primarily RuBP carboxylase), a material that can constitute as much as 50% of the total soluble tobacco leaf protein. During the 1980s, this material was considered as a potential source of food protein and for a number of other food applications due to its abundance and a number of other favorable properties. The remaining leaf protein consisting of multitude of smaller soluble proteins and unfractionated protein in the cytoplasm and chloroplast was referred to as "Fraction-2 protein" (F-2 protein) (3973, 3974c). In addition to tobacco proteins having functional roles such as RuBP carboxylase, tobacco and other plants contain proteins, the primary role of which is structural. For example, extensins, a family of glycoproteins rich in hydroxyproline residues, may constitute as much as 15% of the primary cell wall. Extensins are incorporated into the carbohydrate structure of cell walls and are thought to help provide structural support as cell walls develop.

Contemporary research has tended to concentrate on the identification and function of individual proteins that play key roles in plant growth, development, and response to environmental cues. While much of this research has shifted from tobacco to the more easily manipulated model plant system *A. thaliana*, tobacco continues to be the subject of considerable research due to the historical database of tobacco-specific information, its ease of genetic manipulation, and its interesting biochemical pathways for alkaloid biosynthesis. This research has shown tobacco to possess an amazing diversity of proteins, the roles of which continue to be elucidated.

Tobacco "leaf protein" by itself contributes little to smoking quality, but it is a major precursor of hundreds of tobacco smoke components, e.g., numerous nitrogenous compounds and amino acids. Similarly, other major tobacco components such as the carbohydrates, carboxylic acids, pigments, polyphenols, fatty compounds, phytosterols, and many primary or secondary compounds play a significant role in producing a myriad of tobacco smoke compounds (3972–3974c).

> Plant material and smoke composition are closely interrelated. Properties of leaf material can be modified through genetic and biochemical manipulation from seed to curing (22A30).

In dealing with an organic material as complex as tobacco, there are limitations in the range of possible changes that can be made to improve the biological interaction and metabolic balance within a plant system and at the same time improve or alter the smoke composition and ultimately the biological activity of the smoke. The challenge that faces the tobacco industry today in light of the numerous possibilities that will come from the genetic mapping of *N. tabacum* is the development of new tobacco types that can satisfy farmers, manufacturers, regulators, and consumers in quality and tobacco safety.

Solutions to the questions posed by Tso in 1972 (22A30) as to: What kinds of changes are needed [to produce safer tobacco products]? and [H]ow can these changes be achieved? may be attainable in the future with the newfound knowledge from the genetic mapping of the tobacco genome.

Table 22.2 is a catalog of the genes, nucleotides (DNA/RNA strands), enzymes, and a few major proteins identified to date in tobacco. The format of this table differs from those in most other chapters since all listed are tobacco components. As a result, the Tobacco Smoke column was deleted from Table 22.2. The catalog contains 580 entries. The increase in this number from the 491 cited in our First Edition is primarily due to the inclusion in Table 22.2 of a number of bacteria recently described as tobacco components (5169, 5369, 5498). However, this number of entries represents only a very small fraction of the genes identified and nucleotides created recently during the tobacco genome projects. As more time passes, the totality of the genes and nucleotides identified in the tobacco genome will be published or made available in databases for researchers to access. The majority of the known enzymes identified in tobacco are contained in Table 22.2.

ACKNOWLEDGMENTS

The authors are grateful to Dr. Gary Hellmann and Dr. Lynwood Sawyer for a review of this chapter.

TABLE 22.2
Enzymes, Genes, Clones, Bacteria in Tobacco

	CAS No.	Name (per CA Collective Index)	Tobacco References
1.	9012-33-3	β-Acetylglucosaminidase	5811, 5811b
2.		Acetylserine sulfhydrylase	4249, 4896
3.	9040-07-7	Acetyltransferase, chloramphenicol	3912a, 4249
4.		*Acinetobacter*	5369, 5498
5.		*Actinobacteria, Actinobacteria*	5369
6.	141733-40-6	Acyltransferase, glycerol phosphate (*A. thaliana* clone BX3.6/BB2.6 reduced)	922d, 2663a, 4249
7.	9012-52-6	Adenosyltransferase, methionine	429b, 922d, 4249
	9012-39-9	Adenylyltransferase, sulfate	429b, 922d, 3973, 4249, 4853, 5811b
8.	9006-50-2	Albumin	2529, 4249, 4561

111.	9007-49-2	Deoxyribonucleic acid	5079, 5395
112.	159844-35-6	Deoxyribonucleic acid (*A. thaliana* clone TAY029 gene UbcAt3 ubiquitin-carrier enzyme E 2 messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 1282b, 4249
113.	141712-74-5	Deoxyribonucleic acid (*A. thaliana* strain Heynhold glycerol phosphate acyltransferase messenger RNA complementary)	950b, 2791a, 4249
114.	140812-74-4	Deoxyribonucleic acid (*Nicotiana plumbaginifolia* gene pma1 plus 5′- and 3′-flanking region fragment)	950b, 4249
115.	130061-32-4	Deoxyribonucleic acid (*N. sylvestris* clone NySS4 ribulose diphosphate carboxylase small subunit gene)	950b, 1919a, 4249, 5811, 5811b
116.	144997-82-0	Deoxyribonucleic acid (*N. sylvestris* clone yaDC12/yaDC17 gene psaDa protein D 2 messenger RNA complementary)	950b, 4249, 4366a
117.	155317-25-2	Deoxyribonucleic acid (*N. tabacum* clone NeIF-4A11 protein formation initiation factor eIF 4A messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2878c, 4249
118.	155317-10-5	Deoxyribonucleic acid (*N. tabacum* clone NeIF-4A13 protein formation initiation factor eIF 4A messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2878c, 4249
119.	155317-11-6	Deoxyribonucleic acid (*N. tabacum* clone NeIF-4A14 protein formation initiation factor eIF 4A messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2878c, 4249
120.	155317-12-7	Deoxyribonucleic acid (*N. tabacum* clone NeIF-4A15 protein formation initiation factor eIF 4A messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2878c, 4249
121.	155317-13-8	Deoxyribonucleic acid (*N. tabacum* clone NeIF-4A6 protein formation initiation factor eIF 4A messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2878c, 4249
122.	155317-14-9	Deoxyribonucleic acid (*N. tabacum* clone NeIF-4A7 protein formation initiation factor eIF 4A messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2878c, 4249
123.	155317-15-0	Deoxyribonucleic acid (*N. tabacum* clone NeIF-4A9 protein formation initiation factor eIF 4A messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2878c, 4249
124.	160074-66-8	Deoxyribonucleic acid (*N. tabacum* clone Ubi.U4 gene Ubi.U4 polyubiquitin plus 5′ and 3′ flanking region fragment)	950b, 2969a, 4249
125.	160075-53-6	Deoxyribonucleic acid (*N. tabacum* cv. SR1 leaf clone Ntfad3 ω-3 fatty acid desaturase mRNA complementary plus 5′ and 3′ flanking region fragment)	950b, 1492a, 4249
126.	131553-16-7	Deoxyribonucleic acid (*N. tabacum* samsun 16.5 kDa protein messenger RNA complementary)	950b, 2687a, 4249
127.	131553-15-6	Deoxyribonucleic acid (*N. tabacum* samsun chitinase isoenzyme messenger RNA complementary)	950b, 4039a, 4249
128.	143514-65-2	Deoxyribonucleic acid (*N. tabacum* samsun clone NeIF-5A3 protein formation initiation factor eIF 5A isoform gene)	950b, 4249
129.	141093-81-4	Deoxyribonucleic acid (*N. tabacum* samsun clone pMOG404 osmotin messenger RNA complementary)	950b, 4249, 4273a
130	143638-33-9	Deoxyribonucleic acid (*N. tabacum* samsun clone pTOL1 osmotin messenger RNA complementary)	950b, 3863b, 4249
131.	143341-52-0	Deoxyribonucleic acid (tobacco 1-109-extensin-like protein precursor specifying)	950b, 4249
132.	152619-15-3	Deoxyribonucleic acid (tobacco chitinase acidic isoenzyme III messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 3370d, 4249

(*continued*)

TABLE 22.2 (continued)
Enzymes, Genes, Clones, Bacteria in Tobacco

	CAS No.	Name (per CA Collective Index)	Tobacco References
133.	152619-16-4	Deoxyribonucleic acid (tobacco chitinase basic isoenzyme III messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 3370d, 4249
134.	142978-98-1	Deoxyribonucleic acid (tobacco chloroplast clone L27-1 ribosome protein L 27 messenger RNA complementary)	950b, 1124b, 4249
135.	139872-58-5	Deoxyribonucleic acid (tobacco clone lambda 5A gene RB7 plus 5′- and 3′-flanking region fragment)	790e, 950b, 4249
136.	139872-57-4	Deoxyribonucleic acid (tobacco clone lambda 5A gene RB7)	790e, 950b, 4249
137.	128284-58-2	Deoxyribonucleic acid (tobacco clone lambda CHN17 chitinase basic isoenzyme gene)	950b, 1256b, 4249
138.	156553-68-3	Deoxyribonucleic acid (tobacco clone 59 gene chi-V chitinase plus 5′- and 3′-flanking region fragment)	950b, 1848a, 4249
139.	156553-69-4	Deoxyribonucleic acid (tobacco clone cA-3 gene chi-V chitinase messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 1848a, 4249
140.	155663-09-5	Deoxyribonucleic acid (tobacco clone cpb20-52 antifungal protein CPB 20 messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2972a, 4249
141.	124757-79-5	Deoxyribonucleic acid (tobacco clone E22 protein PR 5 gene)	950b, 4038a, 4249
142.	148757-18-0	Deoxyribonucleic acid (tobacco clone G27.1/G27.2 gene Npg1 plus 5′- and 3′-flanking region fragment)	950b, 3874b, 4249
143.	158928-85-9	Deoxyribonucleic acid (tobacco clone lambda T-FLO 4 gene NFL2 exon 1 fragment)	950b, 2072a, 4249
144.	158928-86-0	Deoxyribonucleic acid (tobacco clone lambda T-FLO 4 gene NFL2 exon 2 fragment)	950b, 2072a, 4249
145.	158928-87-1	Deoxyribonucleic acid (tobacco clone lambda T-FLO 4 gene NFL2 exon 3 fragment)	950b, 2072a, 4249
146.	145137-42-4	Deoxyribonucleic acid (tobacco clone NtDAHPS-1 phospho-2-keto-3-deoxyheptonate aldolase messenger RNA complementary)	950b, 2380b, 4249
147.	151876-45-8	Deoxyribonucleic acid (tobacco clone OMT3.4 catechol methyltransferase isoenzyme II messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2481c, 4249
148.	128512-15-2	Deoxyribonucleic acid (tobacco clone pBSGlu39.1 endo-1,3-β-glucanase isoenzyme gene coding region)	950b, 3370c, 4249
149.	128512-16-3	Deoxyribonucleic acid (tobacco clone pBSGlu39.3 endo-1,3-β-glucanase isoenzyme gene coding region)	950b, 3370c, 4249
150.	147626-92-4	Deoxyribonucleic acid (tobacco clone pcGS2-17 glutamine synthetase isoenzyme 2 messenger RNA complementary)	225a, 950b, 4249
151.	128512-19-6	Deoxyribonucleic acid (tobacco clone pGL31 endo-1,3-β-glucanase isoenzyme messenger RNA complementary)	950b, 3370a, 4249
152.	128512-20-9	Deoxyribonucleic acid (tobacco clone pGL36 endo-1,3-β-glucanase isoenzyme messenger RNA complementary)	950b, 3370a, 4249
153.	128512-21-0	Deoxyribonucleic acid (tobacco clone pGL43 endo-1,3-β-glucanase isoenzyme messenger RNA complementary)	345c, 950b, 4249
154.	103469-25-6	Deoxyribonucleic acid (tobacco clone PROB12 protein TL messenger RNA complementary)	293a, 950b, 4249
155.	158928-82-6	Deoxyribonucleic acid (tobacco clone pTGF220 gene NFL1 exon 1 fragment)	950b, 4129a, 4249
156.	158928-83-7	Deoxyribonucleic acid (tobacco clone pTGF220 gene NFL1 exon 2 fragment)	950b, 4129a, 4249
157.	158928-84-8	Deoxyribonucleic acid (tobacco clone pTGF220 gene NFL1 exon 3 fragment)	950b, 4129a, 4249
158.	141002-75-7	Deoxyribonucleic acid (tobacco clone pVK5 osmotin messenger RNA complementary)	950b, 2235a, 4249
159.	150001-42-6	Deoxyribonucleic acid (tobacco clone TSC81 ribosome protein L 17 messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 1274a, 4249
160.	128512-25-4	Deoxyribonucleic acid (tobacco endo-1,3-β-glucanase isoenzyme messenger RNA complementary)	950b, 3772a, 4249
161.	143341-55-3	Deoxyribonucleic acid (tobacco extensin-like protein 107-amino acid fragment specifying)	950b, 1024a, 4249
162.	143341-56-4	Deoxyribonucleic acid (tobacco extensin-like protein 81-amino acid fragment specifying)	702a, 950b, 4249
163.	160936-44-7	Deoxyribonucleic acid (tobacco leaf curl virus coat protein gene)	950b, 2911a, 4249
164.	141004-11-7	Deoxyribonucleic acid (tobacco ribosome protein L 2 messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2481b, 4249

TABLE 22.2 (continued)
Enzymes, Genes, Clones, Bacteria in Tobacco

	CAS No.	Name (per CA Collective Index)	Tobacco References
165.	143513-68-2	Deoxyribonucleic acid (tobacco strain NK326 gene oee2-A plus 5′- and 3′-flanking region fragment)	950b, 3625, 4249a
166.	143513-69-3	Deoxyribonucleic acid (tobacco strain NK326 gene oee2-A)	950b, 3625a, 4249
167.	149309-58-0	Deoxyribonucleic acid (tobacco thioredoxin h2 gene plus 5′- and 3′-flanking region fragment)	452, 950b, 4249
168.	140114-22-3	Deoxyribonucleic acid (tobacco thioredoxin messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2934a, 4249
169.	141712-75-6	Deoxyribonucleic acid (*A. thaliana* strain Heynhold glycerol phosphate acyltransferase messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2791a, 4249
170.	148037-15-4	Deoxyribonucleic acid (*A. thaliana* thioredoxin h messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 2254a, 4249
171.	147533-09-3	Deoxyribonucleic acid (*Nicotiana alata* clone NaPRP3g12 proline-rich protein PRP 3 gene plus 5′- and 3′-flanking region fragment)	685a, 950b, 4249
172.	139860-37-0	Deoxyribonucleic acid (*N. plumbaginifolia* clone NeIF-4A2 protein formation initiation factor eIF 4A messenger RNA complementary plus 5′-and 3′-flanking region fragment)	950b, 2878b, 4249
173.	146150-24-5	Deoxyribonucleic acid (*N. plumbaginifolia* clone NeIF-4A2 protein formation initiation factor eIF 4A messenger RNA complementary)	950b, 2878b, 4249
174.	140095-89-2	Deoxyribonucleic acid (*N. plumbaginifolia* clone NeIF-4A3 protein formation initiation factor eIF 4A messenger RNA complementary plus 5′-and 3′-flanking region fragment)	950b, 2878b, 4249
175.	146150-26-7	Deoxyribonucleic acid (*N. plumbaginifolia* clone NeIF-4A3 protein formation initiation factor eIF 4A messenger RNA complementary)	950b, 2878b, 4249
176.	140360-04-9	Deoxyribonucleic acid (*N. plumbaginifolia* clone NeIF-5A2 protein formation initiation factor eIF 5A isoform messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 4249
177.	143514-64-1	Deoxyribonucleic acid (*N. plumbaginifolia* clone NeIF-5A2 protein formation initiation factor eIF 5A isoform messenger RNA complementary)	669a, 950b, 4249
178.	141374-52-9	Deoxyribonucleic acid (*N. plumbaginifolia* clone pSOD3 copper–zinc superoxide dismutase messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 1623b, 4249
179.	143348-77-0	Deoxyribonucleic acid (*N. plumbaginifolia* clone pSOD3 copper–zinc superoxide dismutase messenger RNA complementary)	950b, 1623b, 4249
180.	144997-81-9	Deoxyribonucleic acid (*N. sylvestris* clone yaDC12/yaDC17 gene psaDa protein D 2 messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 4249, 4366a
181.	140110-39-0	Deoxyribonucleic acid (*N. tabacum* samsun clone NeIF-5A3 protein formation initiation factor eIF 5A isoform gene plus 5′- and 3′-flanking region fragment)	950b, 2878b, 4249
182.	141093-82-5	Deoxyribonucleic acid (*N. tabacum* samsun clone pMOG404 osmotin messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 4249, 4273a
183.	141093-84-7	Deoxyribonucleic acid (*N. tabacum* samsun clone pMOG4041-226-osmotin specifying plus 5′- and 3′-flanking region fragment)	950b, 4249, 4273a
184.	142978-99-2	Deoxyribonucleic acid (tobacco chloroplast clone L27-1 ribosome protein L 27 messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 1124b, 4249
185.	145093-14-7	Deoxyribonucleic acid (tobacco clone EPSPS-1 5-enolpyruvoylshikimate 3-phosphate synthase messenger RNA complementary plus 5′- and 3′-flanking region fragment)	53a, 950b, 4249
186.	139837-73-3	Deoxyribonucleic acid (tobacco clone NtDAHPS-1 phospho-2-keto-3-deoxyheptonate aldolase messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 4249, 4398b
187.	128512-17-4	Deoxyribonucleic acid (tobacco clone pBSGlu39.1 endo-1,3-β-glucanase isoenzyme gene coding region plus 5′- and 3′-flanking region fragment)	950b, 3370c, 4249
188.	128512-18-5	Deoxyribonucleic acid (tobacco clone pBSGlu39.3endo-1,3-β-glucanase isoenzyme gene coding region plus 5′- and 3′-flanking region fragment)	950b, 3370c, 4249
189.	145735-56-4	Deoxyribonucleic acid (tobacco clone pcGS2-17 glutamine synthetase isoenzyme 2 messenger RNA complementary plus 5′- and 3′-flanking region fragment)	225a, 950b, 4249
190.	128512-22-1	Deoxyribonucleic acid (tobacco clone pGL31 endo-1,3-β- glucanase isoenzyme messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 4249

(*continued*)

TABLE 22.2 (continued)
Enzymes, Genes, Clones, Bacteria in Tobacco

	CAS No.	Name (per CA Collective Index)	Tobacco References
191.	128512-23-2	Deoxyribonucleic acid (tobacco clone pGL36 endo-1,3-β-glucanase isoenzyme messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 3370a, 4249
192.	128512-24-3	Deoxyribonucleic acid (tobacco clone pGL43 endo-1,3-β-glucanase isoenzyme messenger RNA complementary plus 5′- and 3′-flanking region fragment)	345c, 950b, 4249
193.	143341-58-6	Deoxyribonucleic acid (tobacco clone pMG15 extensin-like protein messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 1320a, 4249
194.	128512-26-5	Deoxyribonucleic acid (tobacco endo-1,3-β-glucanase isoenzyme messenger RNA complementary plus 5′- and 3′-flanking region fragment)	950b, 3772a, 4249
195.	143341-53-1	Deoxyribonucleic acid (tobacco extensin-like protein 171-amino acid C-terminal fragment specifying plus 3′-flanking region fragment)	848a, 950b, 4249
196.	143341-54-2	Deoxyribonucleic acid (tobacco extensin-like protein 264-amino acid C-terminal fragment specifying plus 3′-flanking region fragment)	950b, 2534b, 4249
197.	143341-57-5	Deoxyribonucleic acid (tobacco extensin-like protein 393-amino acid C-terminal fragment specifying plus 3′-flanking region fragment)	950b, 2113a, 4249
198.	139637-37-9	Deoxyribonucleic acid, d(A-T-G-T-T-C-T-C-T-C-T-T-T-T-T-A-A-T-G-G-T-G-G-T-T-C-T-T-T-A-G)	950b, 4249
199.	152789-83-8	Deoxyribonucleic acid, d(C-A-T-C-A-C-G-T-G-A-G-A-T-A-A-G-A-G-C-C-G-C-C-A), double-stranded complementary	950b, 4249
200.	152789-84-9	Deoxyribonucleic acid, d(T-A-A-A-G-T-C-A-A-A-G-A-A-T-T-T-C-A-A-T-G-T-C-A-C-A), double-stranded complementary	950b, 4249
201.	67880-95-9	Desaturase, fatty acid ω3-	1859a, 4249
202.	159965-67-0	Desaturase, fatty acid ω3- (tobacco clone Ntfad3)	1492a, 4249
203.	107544-21-8	Desaturase, phytoene	429b, 4249
204.		*Dialister*	5369
205.	37340-89-9	Diaphorase	429b, 4249
206.	9025-33-6	Dipeptidase, prolyl	429b, 4249
207.	9054-89-1	Dismutase, superoxide	429b, 4249, 4748, 5811b
208.	143352-40-3	Dismutase, superoxide (*N. plumbaginifolia* clone pSOD3 copper–zinc protein moiety reduced)	1623b, 4249
209.	9007-57-2	Edestin	429b, 2079
210.		*Enterococcus gallinarum*	5369

401.	9068-40-0	Oxygenase, *p*-coumarate 3-mono-	429b, 2878e, 4249, 4492
402.	9028-06-2	Oxygenase, protocollagen proline di-	429b, 2878e
403.	39335-11-0	Oxygenase, ribulose diphosphate	429b, 2236a, 2878e, 4249, 4641
404.		*Pantoea*	5369
405.	142193-29-1	Parasiticein	1855a, 3126b, 4249
406.	142193-19-9	Parasiticein (*Phytophthora parasitica* reduced)	1855a, 3126b, 4249
407.	9031-96-3	Peptidase	923, 4249
408.	9055-26-9	Permease, sulfate	4249, 4896
409.	9003-99-0	Peroxidase	543a, 1111, 1127b, 2550, 3103, 3434, 3434a, 3630, 3973, 4221, 4249, 4426, 5079, 5123, 5128, 5137, 5189, 5275, 5301, 5570, 5614, 5615, 5792
410.	72906-87-7	Peroxidase, ascorbate	3973, 4249
411.	9013-66-5 97089-70-8	Peroxidase, glutathione	2954, 4249
412.	9013-05-2	Phosphatase	429b, 1971, 2948a, 4249, 5079, 5188, 5189
413.	122319-88-4	Phosphatase, 2-carboxyarabinitol 1-	429b, 2948a, 4249
414.	9001-77-8	Phosphatase, acid	429b, 2948a, 3973, 4249, 4423, 5811b
415.	9000-83-3	Phosphatase, adenosine tri-	429b, 2948a, 4249
416.	134632-85-2	Phosphatase, adenosine tri- (*Petunia hybrida* strain 3704 mitochondria subunit 9)	429b, 349b, 2948a, 4249
417.	9001-78-9	Phosphatase, alkaline	429b, 2948a, 4249, 4821
418.	9001-52-9	Phosphatase, fructose di-	429b, 2948a, 4249
419.	9001-39-2	Phosphatase, glucose 6-	429b, 2948a, 4249
420.	69669-68-7	Phosphatase, glucose di-	429b, 2948a, 4249, 4827, 4834
421.	9027-69-4	Phosphatase, nucleoside di-	429b, 2948a, 4249, 4693
422.	9075-51-8	Phosphatase, nucleoside tri-	429b, 2948a, 4249, 4726
423.	9055-30-5	Phosphatase, phosphoglycerate	429b, 2948a, 4249, 4705
424.	9025-76-7	Phosphatase, phosphoglycolate	429b, 2948a, 4249, 4546
425.	52227-92-6	Phosphatase, phosphorylcholine	429b, 2948a, 4249, 4912
426.	37341-58-5	Phosphatase, phytate	429b, 2948a, 4249, 4825
427.	9059-33-0	Phosphatase, sucrose	4249, 4489
428.	9025-82-5	Phosphodiesterase	5811
429.	9036-21-9	Phosphodiesterase, adenosine cyclic 3′,5′-phosphate	429b, 4249, 4503, 4970
430.	39434-01-0	Phosphodiesterase, nucleotide	429b, 4249, 4435
431.	12712-31-1	Phosphodoxin	340
432.	9001-81-4	Phosphomutase, glucose	429b, 4249, 4489
433.	9030-26-6	Phosphoribosyltransferase, nicotinate	429b, 922d, 4249, 4764
434.	9035-74-9	Phosphorylase	3973, 4249, 4694
435.	9032-10-4	Phosphorylase a	429b, 4249, 4674
436.	9030-28-8	Phosphorylase, guanosine	429b, 4249

TABLE 22.2 (continued)
Enzymes, Genes, Clones, Bacteria in Tobacco

	CAS No.	Name (per CA Collective Index)	Tobacco References
437.	9014-12-4	Phosphorylase, polynucleotide {nucleotidyltransferase, polyribonucleotide}	429b, 4249, 4506
438.	37297-20-4	Phytoalexins	2614a
439.		*Planctomycetes, Planctomycetacia*	5369
440.	9032-75-1	Polygalacturonase	429b, 4249, 4446a, 4934
441.	152415-56-0	Polygalacturonase (tobacco clone G27.1/G27.2 gene Npg1 precursor reduced)	3874a, 4249
442.	9002-10-2	Polyphenoloxidase {oxygenase, monophenol mono; tyrosinase}	429b, 543a, 1102, 2550, 2878e, 3630, 3677, 4221, 4249, 4899, 5079, 5123, 5570, 5737, 5739, 5760, 5808, 5811b, 5856
443.		Poly(U)polymerase	4249, 4507
444.	9030-77-7	Polyprenyltransferase, 4-hydroxybenzoate	5085
445.	159965-71-6	Polyubiquitin (*N. tabacum* clone Ubi.U4 gene Ubi.U4)	2969a, 4249
446.	9055-40-7	Porphobilinogenase	429b, 4249
447.	37259-58-8	Protease	543a, 2914, 5079, 5189, 5323
448.		Protease, serine	4287
449.		Protease, sulfhydryl	4249, 4287
450.	144419-45-4	Protein (*A. thaliana* clone G9.1 gene A9 11.6 kDa reduced)	3566a, 4249
451.	132966-19-9	Protein (tobacco 27.4 kDa RNA-binding precursor reduced)	2400b, 4249
452.	132966-16-6	Protein (tobacco 27.4 kDa RNA-binding)	2400b, 4249
453.	137801-72-0	Protein (tobacco chloroplast clone pTB24 gene psbK)	2530b, 4249
454.	139874-83-2	Protein (tobacco clone .lambda.18C gene RB7 reduced)	790d, 4249
455.	139874-82-1	Protein (tobacco clone .lambda.5A gene RB7 reduced)	790c, 4249
456.	162572-20-5	Protein (tobacco clone lambda T-FLO 4 gene NFL2)	2072a, 4249
457.	147445-75-8	Protein (tobacco clone pMG15 extensin-like precursor reduced)	1320a, 4249
458.	146591-93-7	Protein (tobacco clone PRP3g12 gene PRP3 pistil-specific proline-rich precursor)	2169a, 4249
459.	162572-19-2	Protein (tobacco clone pTGF220 gene NFL1)	2072a, 4249
460.	145895-79-0	Protein (tobacco flower-associated reduced)	1841a, 4249
461.	155077-18-2	Protein (tobacco gene MST1 hydrogen ion–monosaccharide cotransporting reduced)	3417a, 4249
462.	160936-45-8	Protein (tobacco leaf curl virus coat)	2911a, 4249
463.	155663-14-2	Protein CPB 20 (tobacco clone cpb20–44 antifungal reduced)	2972a, 4249
464.	155663-12-0	Protein CPB 20 (tobacco clone cpb20–52 antifungal reduced)	2972a, 4249
465.	155663-10-8	Protein CPB 20, prepro-(tobacco clone cpb20–52 antifungal reduced)	2972a, 4249
466.	155663-13-1	Protein CPB 20, pro-(tobacco clone cpb20–44 antifungal reduced)	2972a, 4249
467.	155663-11-9	Protein CPB 20, pro-(tobacco clone cpb20–52 antifungal reduced)	2972a, 4249
468.	144997-83-1	Protein D 2 (*N. sylvestris* clone yaDC12/yaDC17 gene psaDa precursor)	4366a, 4249
469.	144997-84-2	Protein D 2 (*N. sylvestris* clone yaDC12/yaDC17 gene psaDa)	4366a, 4249
470.	146150-25-6	Protein formation initiation factor eIF 4A (*N. plumbaginifolia* clone NeIF-4A2 isoform reduced)	2878b, 4249
471.	146150-27-8	Protein formation initiation factor eIF 4A (*N. plumbaginifolia* clone NeIF-4A3 isoform reduced)	2878b, 4249
472.	162572-22-7	Protein formation initiation factor eIF 4A (*N. tabacum* clone NeIF-4A9)	2878c, 4249
473.	162572-23-8	Protein formation initiation factor eIF 4A (*N. tabacum* clone NeIF-4A11)	2878c, 4249
474.	162572-24-9	Protein formation initiation factor eIF 4A (*N. tabacum* clone NeIF-4A7)	2878c, 4249
475.	162572-25-0	Protein formation initiation factor eIF 4A (*N. tabacum* clone NeIF-4A15)	2878c, 4249
476.	162572-26-1	Protein formation initiation factor eIF 4A (*N. tabacum* clone NeIF-4A6)	2878c, 4249
477.	162572-27-2	Protein formation initiation factor eIF 4A (*N. tabacum* clone NeIF-4A13)	2878c, 4249
478.	162572-28-3	Protein formation initiation factor eIF 4A (*N. tabacum* clone NeIF-4A14)	2878c, 4249
479.	143514-66-3	Protein formation initiation factor eIF 5A (*N. plumbaginifolia* clone NeIF-5A1 isoform C-terminal fragment reduced)	669a, 4249
480.	143514-67-4	Protein formation initiation factor eIF 5A (*N. plumbaginifolia* clone NeIF-5A2 isoform reduced)	669a, 4249
481.	143514-68-5	Protein formation initiation factor eIF 5A (*N. tabacum* samsun clone NeIF-5A3 isoform reduced)	2997b, 4249
482.	152745-97-6	Protein L 17 (tobacco clone TSC81 ribosome reduced)	1274a, 4249

(*continued*)

TABLE 22.2 (continued)
Enzymes, Genes, Clones, Bacteria in Tobacco

23 Hoffmann Analytes

In essence, the terminology "Hoffmann analyte" or "Hoffmann-type analyte" or "Hoffmann list compound" had its beginning over two decades ago in 1985. Early that year, a working group of the International Agency for Research on Cancer (IARC) met to evaluate the carcinogenic risk of chemicals to humans with particular emphasis on tobacco smoking. The next year, the working group's assessment of tobacco smoking was published in an IARC monograph (1870). Among the 28 members of the working group were Ernst L. Wynder and Dietrich Hoffmann from the American Health Foundation whose participation in the discussions on the components of tobacco and particularly tobacco smoke was obviously quite extensive. The number of references cited in the various smoke component figures, tables, and appendixes in the IARC monograph (1870) reveals the extent of the Wynder–Hoffmann contribution to the working group study (see summary in Table 23.1). Nearly 44% of the citations on smoke components considered deleterious represented a Hoffmann-related publication. In all of the 44 references listed in Table 23.1, Hoffmann was a coauthor.

A few months after the *IARC 1985 Working Group Meeting*, Hoffmann and Wynder presented a paper on biologically active tobacco smoke components at a conference, and its contents were published in 1986 (1808). Deriving their assessment of various tobacco smoke components from the conclusions of the IARC 1985 working group, Hoffmann and Wynder listed 40 biologically active components in cigarette mainstream smoke (MSS) and sidestream smoke (SSS). Over the next decade and half, a series of articles were published with Hoffmann as a coauthor of each, and in each article was a listing of tobacco and/or smoke components that were classified as biologically active (1808, 1741), carcinogenic (1808, 1740, 1743, 1744), cocarcinogenic (1808), or tumorigenic (1717, 1773).

Table 23.2 summarizes the chronology of the list-containing articles and the varied classifications of the activity of the components listed. In those publications in which the classification "biologically active" was used, no mention was made of the fact that many biologically active components in tobacco smoke, e.g., α-tocopherol and α- and β-4,8,13-duvane-1,3-diol, have been demonstrated to exert anticarcinogenic or inhibitory effects on the activity of several tobacco smoke components considered potent tumorigens or mutagens [see Table 3 in (3255a), Table 6 in (3265), Table 11 in (3300)]. In contrast to the multiple listings of benz[*a*]anthracene (B[*a*]A) as a biologically active MSS component (1741, 1808) or as a tumorigen (1727, 1773) or as a carcinogen (1740, 1743, 1744), Hoffmann and Wynder (1786) reported in 1959 that, in their mouse-skin-painting study, B[*a*]A coadministered with benzo[a]pyrene (B[*a*]P) reduced the tumorigenicity of the B[*a*]P, i.e., B[*a*]A was anticarcinogenic to B[*a*]P.

Eventually, the number of biologically active smoke components, primarily the tumorigens, was expanded from the 43 listed in 1990 by Hoffmann and Hecht (1727) to 82 listed in 1998 by Hoffmann and Hoffmann (1740). Much of the increase was due to the inclusion of the *N*-heterocyclic amines and several vapor-phase components. Because of the change in its assessment concerning their tumorigenicity, chrysene and di(2-ethylhexyl) phthalate were no longer considered as tumorigens by the IARC. Several other similar lists, not coauthored by Hoffmann, were issued after 1986. They included the 1994 list by the U.S. Occupational Health and Safety Administration (OSHA) (2825) and the 2001 list by Fowles and Bates (1217). Neither of these lists differed significantly from those issued by Hoffmann and his colleagues between 1986 and 2001.

Table 23.3 is a tabulation of the toxicants in tobacco and tobacco smoke from the IARC 1986 publication (1870) plus the seven lengthy publications coauthored from 1986 to 2001 by Hoffmann with his American Health Foundation colleagues. Examination of the various lists reveals several anomalies, none of which detracts from the meaningfulness of the publications. The anomalies include

1. Several instances where the per cigarette yield range unit was listed as μg in one article and ng in another, e.g., the per cigarette yield range for quinoline listed as 1–2 ng in (1743) and 1–2 μg in (1744).
2. Several instances where the per cigarette yield range differs significantly in two different publications, e.g., the per cigarette yield range for *N*-nitrosopyrrolidine is listed as 1.5–110 ng in (1727) and 3–60 ng in (1740).
3. Several instances where the per cigarette yield range differs in different tables in the same article, e.g., the per cigarette yield range for catechol is listed as 25–360 μg in Table 5 in (1808), as 100–350 μg in Table 11 in (1808), and 140–500 μg in Table 13 in (1808).
4. The per cigarette yield range is listed for the wrong component, e.g., the range 1.7–3.2 ng is listed for dibenzo[*a,l*]pyrene in (1741, 1743, 1744), but in each case, that range should be listed for the omitted dibenzo[*a,i*]pyrene, cf. (1727, 1740, 1773).
5. In some instances, particularly with several PAHs, the per cigarette yield ranges include data generated from cigarettes manufactured in the 1950s and 1960s with "tar" and nicotine yields far in excess of more recently manufactured cigarettes.

TABLE 23.1
Hoffmann Contributions on Smoke Components to the 1985 IARC Working Group on Tobacco Smoking

Item	Topic	No. of Specific References Cited	No. of Hoffmann et al. References Cited	Hoffmann et al. References
Figure 5	Some chemical constituents of tobacco smoke	1	1	3491

[a] Three of the cited references were to IARC monographs.

TABLE 23.2
Hoffmann-Related Lists of Toxicants in Tobacco and Tobacco Smoke

Year	Authors	Ref. No.	Table No.	Table Title	No. of Component Listed
1986	International Agency for Research on Cancer (IARC)	1870	19	Concentrations of biologically-active agents in nonfilter cigarette mainstream smoke	60
1986	Hoffmann and Wynder	1808	5	Carcinogens and cocarcinogens in the smoke of a nonfilter cigarette	21
		1808	6	Organ-specific carcinogens in cigarette smoke	14
		1808	13	Biologically-active agents in mainstream smoke (of nonfilter cigarettes)	40
1990	Hoffmann and Hecht	1727	3	Tumorigenic agents in tobacco and tobacco smoke	43
1993	Hoffmann et al.	1773	1	Tumorigenic agents in tobacco and tobacco smoke	41
1997	Hoffmann and Hoffmann	1740	3	Carcinogens in tobacco and cigarette smoke	60
1998	Hoffmann and Hoffmann	1741	1	Biologically-active agents in the mainstream smoke of nonfilter cigarettes	82
2001	Hoffmann and Hoffmann	1743	5-4	Carcinogens in cigarette smoke	68
2001	Hoffmann et al.	1744	4	Carcinogens in cigarette smoke	68

6. The per cigarette yield range is incomplete, e.g., a single value of 4 ng/cig is listed for dibenz[*a,h*]anthracene (DB[*a,h*]A) in (1727, 1773, 1740, 1741, 1743, 1744, 1870), but an incorrect single value of 40 ng is listed in (1808); all DB[*a,h*]A listings in the references cited fail to take into account the reporting of a DB[*a,h*]A yield of 5 ng/cig by Van Duuren in 1958 (4020). The MSS yield of 4 ng/cig of DB[*a,h*]A was obtained by Hoffmann and Wynder in the late 1950s (1787, 1788) from a 1959 cigarette and reported as such in 1963 by Wynder and Hoffmann [see Table 1 in (4317)].
7. A component with no known per cigarette yield is treated the same as a component with literally hundreds of per cigarette yield values, e.g., dibenzo[*a,l*]pyrene *vs.* B[*a*]P.
8. For the identification of dibenzo[*a,l*]pyrene in MSS, IARC [see Footnote 33 in Table 20 in (1870)] cited the footnote in the 1958 publication by Van Duuren (4020). However, like many other investigators

[t] See Table 3 in (1744).
[u] See Table 2 in (1740).
[v] See Table 5-2 in (1743).

[Lyons and Johnston (2430), Rodgman and Cook (3273), Wynder and Wright (4354), Wynder et al. (4355)], Van Duuren had reported the identification of dibenzo[*a*,*l*]pyrene in MSS. However, in 1966, Lavit-Lamy and Buu-Hoï (2314) reported that the compound previously thought to be dibenzo[*a,l*] pyrene was actually its isomer dibenz[*a,e*]aceanthrylene (dibenz[*a,e*]fluoranthene) [see also Lacassagne et al. (2250)]. In 1983, IARC had commented that all pre-1966 studies involved with dibenzo[*a,l*]pyrene were actually dealing with dibenz[*a,e*]fluoranthene not dibenzo[*a,l*]pyrene (1868a). Dibenzo[*a,l*]pyrene was eventually identified in MSS by Snook et al. (3756), but no quantitative data were given.

9. The repetitious inclusion in the lists published by Hoffmann and his colleagues (1727, 1773, 1740, 1741, 1743, 1744, 1808) of the aza-arenes dibenz[*a,h*] acridine, dibenz[*a,j*]acridine, and 7*H*-dibenzo[*c,g*] carbazole reported by Van Duuren et al. despite the failure of numerous investigators in several countries between 1970 and 2000 to confirm their presence in MSS [(3260), also see Table 12-7 in Baker (172) and Table 4 in Rodgman (3265)].

These and other anomalies were described in detail by Rodgman (3265).

A more recent publication by Hoffmann and Hoffmann on the "changing cigarette" presents an interesting situation. In a chapter in a book published in 2010, Hoffmann and Hoffmann once again present their list of carcinogens in cigarette smoke [see Table 6.4 in (5512)]. Examination of the data presented for the amount of each listed carcinogen in the MSS of a non-filter cigarette reveals that the presented data are identical with the data presented for each carcinogen in the 2001 article by Hoffmann, Hoffmann, and El-Bayoumy (1744). Does the similarity between the two identical listings of cigarette smoke data indicate that, despite the title of their 2010 article "The changing cigarette" (5512), the authors consider that the MSS delivery of the cigarette has not changed between 2001 and 2010, particularly in regard to the listed carcinogens?

Although one or more of the earlier problems and/or anomalies were described in publications by Rodgman in 1998 and 2003 (3260, 3265), Baker in 1999 (1972), Rodgman and Green in 2002 and 2003 (3300), and Rodgman and Perfetti in 2008 (5078) in response to the numerous lists on tobacco and/or tobacco smoke toxicants (1217, 1727, 1773, 1740, 1741, 1743, 1744, 1808, 1870, 2825), no toxicant list author or agency—whether Wynder, Dietrich Hoffmann, Ilse Hoffmann, Hecht, El-Bayoumy, Fowles, Bates, IARC or OSHA—has ever published a single contradiction to any item in the previous list of problems and anomalies.

The many publications coauthored by Hoffmann (1727, 1773, 1740, 1741, 1743, 1744, 1808), each of which contained a list of biologically active components identified in tobacco smoke, led to two interesting episodes as a result of his efforts. Because of those numerous coauthored publications and the listing of toxicants in tobacco and tobacco smoke, Dr. Dietrich Hoffmann was dubbed "The Author of the List" in 2002 (23A05). This recognition was subsequently extrapolated in numerous scientific conference presentations and journal publications in which Dr. Hoffmann's list contributions were acknowledged by the authors in the title of many scientific conference presentations and journal publications by inclusion of the term "Hoffmann analytes" or "Hoffmann-type analytes" or "Hoffmann list compounds." In some published articles, the term "Hoffmann analytes" does not appear in the title but does appear in the headings of tables in the articles, e.g., in several publications by Baker and his colleagues at British American Tobacco (BAT), the term "Hoffmann analytes" appears in the title of several tables (174a, 174c). Table 23.4 catalogs some of the presentations and/or publications in which the term "Hoffmann analyte" or its equivalent was used in tobacco-related scientific literature from the year 2000 to 2006.

Table 23.5 catalogs the components in the various Hoffmann coauthored lists. In an attempt at simplification, the sequence of components in Table 23.5 approximates the sequence in many of the Hoffmann coauthored list articles. Also in Table 23.5, the various components listed by Hoffmann and his colleagues in their various articles (1727, 1740, 1741, 1743, 1744, 1773, 1808) are listed in the most recently accepted nomenclature, e.g., benzo[*b*]fluoranthene is listed as benz[*e*]acephenanthrylene, dibenzo[*a,l*]pyrene is listed as dibenzo[*def,p*] chrysene, catechol is listed as 1,2-benzenediol. In each case, the nomenclature used in the Hoffmann coauthored articles accompanies the most recent nomenclature listing.

Also included in Table 23.5 are several components which do not appear in any of the Hoffmann coauthored lists but recently have been included with analyses of Hoffmann-listed components, e.g., 1-naphthalenamine (1-aminonaphthalene; α-naphthylamine), 3-aminobiphenyl ([1,1′-biphenyl]-3-amine), propionaldehyde (propanal), butyraldehyde (butanal), and acetone (2-propanone). Table 23.5 includes several tobacco smoke components which the IARC has reclassified with regard to their tumorigenicity, e.g., chrysene and di(2-ethylhexyl) phthalate. Thus, chrysene no longer appears on the more recent Hoffmann lists (1740, 1741, 1743, 1744) and di(2-ethylhexyl) phthalate was omitted from other lists (1743, 1744).

One point of interest in the Table 23.5 catalog is the tremendous number of references which deal with some aspect of the various Hoffmann-listed components.

Over the years, numerous reports have been issued in which analytical data were presented on the per cigarette yields of numerous components in the MSS of the 1R4F Kentucky Reference Cigarette. Many of the analytes were defined as "Hoffmann analytes." Table 23.6 summarizes several such analyses on the 1R4F MSS reported by Baker et al. [see Table 11 in (174b)], Rustemeir et al. (3370), and R.J. Reynolds Tobacco (RJRT) (3190)]. Also included in Table 23.6 are the "Hoffmann analyte" yields reported by Chen and Moldoveanu (688) for the MSS of the 2R4F Kentucky Reference Cigarette. Similar examples of "Hoffmann analyte" data are available in Baker et al. [see Table 12 in (174b)] and Rodgman and Green (3300). Table 23.6 lists the MSS analytes proposed by the

TABLE 23.4
Abbreviated Chronology of the Use of the Term "Hoffmann Analyte" or Its Equivalent in Tobacco Smoke-Related Scientific Literature

Year	Author(s) and Title of Article
2000	While it did not use the term "Hoffmann analyte" in its report, the Department of Health (Canada) proposed that analytical data on the following smoke components from tobacco smoke should be a requirement (23A06): " 'tar,' nicotine, formaldehyde, acetaldehyde, propionaldehyde, butyraldehyde, acrolein, crotonaldehyde, acetone, benzo[*a*]pyrene, NNN, NNK, NAB, NAT, 1-aminonaphthalene, 2-aminonaphthalene, 3-aminobiphenyl, 4-aminobiphenyl, pyridine, quinoline, styrene, catechol, resorcinol, hydroquinone, phenol, *o*-cresol, *m*-cresol, *p*-cresol, eugenol, 1,3-butadiene, isoprene, benzene, toluene, acrylonitrile, NH_3, CO, HCN, NO, NO_x, As, Cd Cr, Pb, Hg, Ni, Se." Examination of the Department of Health (Canada) list reveals that most of its listed components appear in the biologically-active component lists in the publications coauthored by Hoffmann (1727, 1773, 1808, 1740, 1741, 1743, 1744)
2001	In a memorandum to the Department of Health (Canada), Levine (23A10) described the results of an interlaboratory comparison on "Hoffmann analytes" in the MSSs from three different cigarette brands
2001	At the *55th Tobacco Science Research Conference* (TSRC), Purkis et al. (3007) in their description of the reliability of measurements of smoke analytes discussed the measurement of 44 "Hoffmann analytes." Their TSRC presentation was published in 2003
2002	At the *56th TSRC*, Baker and Willoughby (later Bishop) (172a) described the compounds generated by the pyrolysis of relatively volatile tobacco ingredients. Subsequently, the presentation was published in 2004 and linked to the "Hoffmann analyte" concept
2002	At the *56th TSRC*, Cashmore (631) presented a paper entitled: Alternative smoking regimes: *Hoffmann analyte* formation and prediction as a consequence of changing smoking regimes and filter vent blocking
2003	At the *57th TSRC*, Chang et al. (23A04) presented a paper entitled: Influence of tip ventilation on *Hoffmann analyte* deliveries
2003	In their study of a new Kentucky Reference Cigarette 2R4F, Chen and Moldoveanu (688) described the quantitation of more than 44 analytes in smoke, including most compounds considered as biologically active and described elsewhere as "Hoffmann analytes." They referred to the biologically-active components listed in 1998 by Hoffmann and Hoffmann (1741)
2003	At the *57th TSRC*, Dimandia et al. (23A07) described the analysis of *Hoffmann list compounds* by comprehensive 2D gas chromatography/ time-of-flight mass spectrometry
2003	Also at the *57th TSRC*, Ellisor et al. (23A08) described the variation in the level of *Hoffmann analytes* for cigarette MSS when a large volume of air passes through the collection device and Volgger et al. (23A14) described the influence of different cigarette paper properties on the formation of *Hoffmann-type analytes* in smoke
2003	Warren presented two papers at the *57th TSRC*; both of which dealt with "Hoffmann analytes." They were entitled: The *Hoffmann analyte* to "tar" ratio paradox (4136) and Prediction of mainstream cigarette smoke *Hoffmann analyte* yields by statistical modeling (4137)
2004	Baker and Bishop (172a) in their report on the pyrolysis of tobacco ingredients noted the following: "Of the approximately 4800 substances in tobacco smoke (1373), 44 are believed … to be relevant to tobacco-related diseases (23A06). These include … some volatile carbonyl compounds, tobacco-specific *N*-nitrosamines, aromatic amines, phenols, volatile alkenes, benzo[*a*]pyrene and metals. These substances are sometimes called colloquially 'Hoffmann analytes' since similar lists of toxicological substances have been proposed by Dietrich Hoffmann et al. of the American Health Foundation in New York since the mid 1980s. The latest compilation by Hoffmann et al. lists 82 substances (1741, 1743, 1744)." From their experimental findings, Baker and Bishop concluded "Particular attention has been paid to assessing the generation of 'Hoffmann analytes,' i.e., biologically-active analytes in smoke, from the pyrolysis f the ingredients. In general, the number of 'Hoffmann analytes' detected among the pyrolytic products of the ingredients, and their levels, are low."
2004	In a series of three papers on the effect of tobacco ingredients on smoke chemistry, Baker et al. (174a, 174b, 174c) did not include the term "Hoffmann analyte" or its equivalent in the three titles. However, the term "Hoffmann analyte" was used throughout each of the publications, e.g., in the abstract of Baker et al. (174a), it is stated: "The studies are: pyrolysis of the ingredients; influence of the ingredients on smoke constituents believed by regulatory authorities to be relevant to smoking-related diseases ("Hoffmann analytes") … " The term "Hoffmann analytes" also appeared in the title of Table 3 in (174a). In the abstract of Baker et al. (174b), the following was stated: "The effects of 450 tobacco ingredients added to tobacco on the 44 'Hoffmann analytes' in mainstream cigarette smoke have been determined … They are based on lists published by D. Hoffmann and coworkers of the American Health Foundation …" In their summary of the effect of casing ingredients on smoke composition, Baker et al. (174c) stated "The effects of 29 casing flavour ingredients and three humectants on the yields of 44 'Hoffmann analytes' in cigarette smoke have been assessed." The term "Hoffmann analytes" also appeared in the title of Table 10 in (174c)
2004	Case and Warren (23A03) were issued a European patent on a multivariate regression system for predicting "Hoffmann analytes" in tobacco smoke. While the term "Hoffmann analyte" did not appear in the title of the patent, in its text, the term was used as follows: "The concentration of yields of a first set of components in a particular tobacco smoke, such as the *Hoffmann analytes*, are predicted on the basis of a statistical model"

(*continued*)

TABLE 23.4 (continued)
Abbreviated Chronology of the Use of the Term "Hoffmann Analyte" or Its Equivalent in Tobacco Smoke-Related Scientific Literature

Year	Author(s) and Title of Article
2004	Imperial Tobacco Co. (23A09) discussed "Hoffmann analytes" as follows: "Additional information may be requested by governmental agencies. This may include measurements of large numbers of smoke constituents of regulatory interest such as the 'Hoffmann analytes' (usually a list of 44 smoke constituents). We have participated in studies requested by Australian and U.K. agencies and have provided information to Health Canada. Our interpretation of these studies, other studies in the literature, and our own internally-produced data is that these smoke constituents are generally proportional to tar measurements for a given blend style"
2004	At the *58th TSRC*, Loureau et al. (2400d) described the influence of cigarette paper and filter ventilation on the yields of "Hoffmann analytes"
2004	At the *CORESTA Congress* in Japan, Röper et al. (23A11) presented a paper entitled: "Hoffmann" analytes and cigarette smoke *in vitro* toxicity revisited—How do the data compare?
2005	Baker and Bishop (172b) did not mention the term "Hoffmann analyte" in the title of their publication on the pyrolysis of nonvolatile tobacco ingredients but did note the following: "The study has concentrated on the biologically active substances produced by pyrolysis, in particular the 'Hoffmann analytes.' These analytes are believed by regulatory authorities in Canada and U.S.A. to be relevant to smoking-related diseases. They are based on lists published by Hoffmann and co-workers of the American Health Foundation in New York. For the pyrolysis of many of the non-volatile ingredients, no 'Hoffmann analytes' were detected amongst the products. When they were occasionally formed, they included phenols, benzene, toluene, styrene and furfural (furfural is biologically active but it does not appear on any of the Hoffmann or regulatory authority lists)"
2005	At the *CORESTA Joint Study Group Meeting* in Stratford-on-Avon, United Kingdom, in 2005, BAT personnel presented the following three papers under the general heading "The effect of cigarette design variables on assays of interest to the Tobacco Industry": Case et al. (23A01) presented the first paper subtitled: (1) Experimental design and some initial findings on Hoffmann analyte yields. Sheppard et al. (23A12) presented the second paper subtitled: (2) Prediction of smoke and *Hoffmann analytes* using two different modeling methods. Winter et al. (23A15) presented the third paper subtitled: (3) Tobacco blend types. Although the latter paper did not include the term "Hoffmann analytes" in its title, its abstract indicated it involved the examination of the potential relationships between various tobacco blend components and "Hoffmann analyte" yields across three distinct lamina tobacco blend styles, Virginia, burley, and Oriental plus a 1:1 Virginia–burley mixture
2005	At the *59th TSRC*, Zemann et al. (4406a) presented a paper entitled: On-line puff-by-puff analysis of gaseous and *Hoffmann analytes* in cigarette smoke
2006	At the *60th TSRC*, Case et al. (23A02) presented a paper entitled: The role of cigarette paper and other factors that influence *Hoffmann analyte* yields in sidestream smoke
2006	Also at the *60th TSRC*, Streibel et al. (23A13) presented a paper entitled: Real-time on-line characterization of selected *Hoffmann analytes* in inhaled and exhaled cigarette smoke (mouthspace) by photo ionisation time-of-flight mass spectrometry
2007	At presentations at the *61st TSRC*, much emphasis was placed on the determination of Hoffmann analytes. Gerardi et al. (4623) described an improved analytic procedure to determine Hoffmann analytes in cigarette smoke with particular emphasis on selected carbonyls and phenols. Guan et al. (4636) reported the relationship of cigarette tobacco composition and the MSS yield of various Hoffmann analytes such as PAHs, TSNAs, aza-arenes, NO, carbonyl compounds, and phenols. Lauterbach (4732) recommended the determination of several cytotoxic components in smoke other than a variety of Hoffmann analytes. He mentioned several compounds not on the Hoffmann analyte list. They included cyanohydrins and dicarbonyl compounds such as diacetyl and malondialdehyde.
2009	Intorp et al. (5049) described their findings on "Hoffmann analytes" in cigarette MSS in a study conducted on behalf of CORESTA
2010	At the *2010 CORESTRA Congress*, the results of several studies on "Hoffmann analytes" were presented. Le Moigne et al. (5529) described the effect of additive-treated filters and their fibers on the MSS deliveries of specific "Hoffmann analytes." Nie et al. (5546) reported the effect of cigarette paper and filters on "Hoffmann analytes."; *2010 CORESTA Congress Abstracts*, Paper SSPT 12, p. 112. Otte and Intorp (5547) described a GC–MS method for the determination of selected volatile "Hoffmann analytes" in cigarette MSS

Department of Health (Canada) (23A06). Assessment of all the lists in Table 23.6 reveals that the number of analytes in each case is in the mid-1940s, and most of them may be considered, based on the various listings by Hoffmann and his colleagues, as "Hoffmann analytes." The sequence of components in Table 23.6 parallels the component class sequence usually used in the tables in the various articles by Hoffmann and his colleagues (1727, 1740, 1741, 1743, 1744, 1773, 1808).

Table 23.6 also indicates the many components in the Hoffmann lists that are not usually analyzed or included in the "Hoffmann analyte" list of 44 or 45 biologically active components.

24 Tobacco and/or Tobacco Smoke Components Used as Tobacco Ingredients

For nearly four decades after the early 1950s, an exceptional amount of information has been generated on the composition of the various types of tobacco, the smoke from many of the types, and the relationship between the two. Although much of the information has been published, much has not. Exemplary in this regard were the research conducted by personnel not only at the R.J. Reynolds Tobacco Company but also at many other tobacco companies. Much information has been published in peer-reviewed journals, and the remainder is available on the Internet. In the early tobacco and tobacco smoke studies, the chemical nature of one or two components was defined by means of classical chemical procedures, e.g., the identification of the terpenoid alcohol solanesol in fluecured tobacco (3359), the phenols eugenol and isoeugenol in the mainstream smoke (MSS) from Oriental tobacco (3280), and maltol in the MSS from an ingredient-free German tobacco blend (1131). However, as analytical methodology became more sophisticated and precise, many more components—sometimes several hundred newly identified in tobacco or smoke—were reported in a single publication.

In 1986, each major U.S. cigarette manufacturer listed the ingredients used at that time in its cigarette products. A combined list was submitted to the U.S. Office on Smoking and Health. That list, comprising 599 additives, was subjected by a panel of eminent toxicologists not only to an extensive literature survey but also to an examination of unpublished data provided by the tobacco industry members on the chemistry and toxicology of the ingredients. The panel assessed the safety of each listed ingredient with regard to its pyrolysate components and its possible effect when added to cigarette tobacco on the chemical and biological properties of the cigarette MSS. The results were summarized in 1994 by Doull et al. (1053). Of the 599 ingredients, 460 (~77%) are individual compounds. The remaining items are mixtures such as natural oils, plant extracts, oleoresins, etc. Many investigators have noted in their publications that numerous compounds on the list of ingredients are tobacco and/or cigarette MSS components. The following pages chronicle such a relationship between individual added components and their presence in untreated tobacco and/or its smoke. While Paschke et al. (2896) attempted to catalog every material ever added to tobacco and its effect on MSS chemical and/or biological properties, the present article deals only with those materials in the list by Doull et al. While some of the additives cataloged by Paschke et al. did reduce the responses in specific bioassays and the levels of some MSS components considered toxic, they also rendered the MSS unacceptable to the consumer. Obviously, the ingredients listed by Doull et al. did not suffer from such a problem since their addition was specifically designed to enhance the consumer acceptability of the MSS from the product.

As a beginning, Doull et al. (1053) in their report noted

> Many of the ingredients added to cigarettes are identical or essentially similar in composition to natural leaf tobacco components.

In their 1998 report of the effect on rats of inhalation of MSS from ingredient-treated tobacco cigarettes, Gaworski et al. (24A04) expressed a similar view:

> The addition of flavoring ingredients to the cigarette prior to smoking did not significantly alter the type or extent of biologic changes normally seen in smoke-exposed rodents. Given the fact that many of the added flavoring ingredients are structurally similar or identical to [*sic*] natural constituents of tobacco leaf or of tobacco smoke itself [Lloyd et al. (2389)], these results are not totally unexpected.

Later, Rustemeier et al. (3370) in their description of the chemistry of MSS from ingredient-treated tobacco cigarettes noted

> Many of these compounds or mixtures are also natural constituents of the tobacco leaf.

Rodgman (3263) concurred with the preceding statements when he wrote

> Many flavorful tobacco additives listed by Doull et al. are structurally identical with or similar to highly polar, volatile components identified in the aqueous alcohol-soluble portion of cigarette MSS and tobacco.

More recently, Rodgman and Green (3300) wrote

> With the capability to isolate and identify highly polar and volatile components of tobacco and its MSS, it was obvious that many were identical with or similar to ingredients of flavor formulations added to specific tobacco blends to impart unique smoking characteristics…Many "top-dressing" components are structurally identical with or similar to identified tobacco components. With no evidence to the contrary, it is assumed that such an individual added flavorant would

behave during the smoking process (in terms of direct transfer to smoke or degradation, reaction, etc.) much in the same manner as the naturally occurring tobacco component.

While many investigators considered many individual compounds added to cigarette tobacco filler to be tobacco and/or tobacco smoke components, it seemed worthwhile to catalog the extent to which this was true. Obviously, if a specific flavorful compound is already a tobacco component, then its addition to tobacco is an attempt to enhance its flavorful effect. If it is a compound generated during the smoking process, then its addition to tobacco enhances the level in the smoke by tobacco-to-smoke transfer.

The compounds added as ingredients to cigarette tobacco may fall into one of the following categories:

- It is a component of one or more of the tobacco types (flue-cured, Oriental, burley, Maryland) commonly used in cigarette blends.
- It is a component of cigarette MSS.
- It is a component of both tobacco and tobacco smoke.
- It is not a component of either the tobaccos or their smoke.

An ingredient compositionally similar to but not identical with a tobacco leaf or smoke component may be categorized as an isomer or a homolog of a compound identified in natural tobacco leaf and/or its smoke. In the broad spectrum of chemistry, biochemistry, and biology, cases exist where the properties of one homolog vary significantly from those of another or where the properties of one isomer differ significantly from those of another.

For example, whether classified as a "Group 2A carcinogen" by the International Agency for Research on Cancer (IARC) (1868a), or a significant carcinogen in cigarette MSS by Hoffmann and Hecht (1727), or overall as a borderline carcinogen by others, e.g., Dipple et al. (983), the specific tumorigenicity of mice skin painted or subcutaneously injected with benz[*a*]anthracene (B[*a*]A) is insignificant compared to that of its homolog, 7,12-dimethylbenz[*a*]anthracene (DMB[*a*]A). The isomeric $C_{20}H_{12}$ polycyclic aromatic hydrocarbons (PAHs) benzo[*a*]pyrene (B[*a*]P) and benzo[*e*]pyrene (B[*e*]P) differ markedly in their specific tumorigenicities in studies involving mouse-skin painting or subcutaneous injection (983). B[*a*]P under appropriate laboratory conditions is one of the most potent tumorigens known, whereas the isomeric B[*e*]P under the same conditions is essentially nontumorigenic.

In the 1950s, the organic solvent extraction of tobacco was studied extensively with the purpose of removing PAH precursors from the tobacco. One process involved an aqueous ethanol–hexane partition to separate the polar, more flavorful tobacco components from the lipophilic PAH precursors. At that time, little was known about the nature of the polar tobacco components, although it was apparent they made a considerable positive contribution to the flavor and aroma of cigarette MSS. Despite the lack of knowledge about the precise nature of the polar components, it was demonstrated they were not significant PAH precursors (3262). The lack of knowledge about the polar tobacco components was due to our inability to separate highly polar compounds in a complex mixture. This situation continued during years of intensive effort on cigarette MSS composition but was finally resolved and utilized by Schumacher et al. (3553) in the 1970s. Among 1490 MSS components identified by Schumacher et al. (3553), Newell et al. (2769), and Heckman and Best (1587) were over 1125 components new to the tobacco smoke literature, many of which were highly polar. By glass capillary gas chromatography, Grob (1416) also identified many polar components in the MSS from cigarettes containing additive-free tobacco. Later, it was shown that some of the identified polar components reported in MSS by Grob are also in the Doull et al. list.

With regard to tobacco, Lloyd et al. (2389) identified 275 previously unidentified components of additive-free flue-cured tobacco, 132 new to all tobacco types. Many of these compounds were highly polar and considered significant contributors to MSS flavor and aroma. Similar studies were conducted on the composition of burley (3219), Oriental (3561), and Maryland (3550) tobaccos. Later, it became apparent that many of the highly polar components of tobacco and tobacco smoke were identical with or similar to many of the components used in the flavor additive formulations, i.e., the "top dressing," added to a specific tobacco blend to impart its unique smoking characteristics (1053).

As previously mentioned, in the mid-1980s, each major U.S. cigarette manufacturer listed the ingredients added to its cigarette products at that time. In 1986, a combined list, comprising 599 entities, was submitted to the U.S. Office on Smoking and Health. From an extensive literature survey and examination of much unpublished data from the cigarette manufacturers on the chemistry and toxicology of the ingredients, a panel of eminent toxicologists assessed the safety of each listed ingredient with regard to its pyrolysis products and its possible effect when added to cigarette tobacco on the chemical and biological properties of cigarette MSS. Subsequently, Doull et al. (1053) listed the ingredients assessed and summarized the conclusions of the panel on their effect on the chemical and biological properties of cigarette smoke.

In their assessment of available information on these ingredients variously used as cigarette tobacco ingredients, Doull et al. concluded that none of the materials used as flavorants on smoking tobacco products, particularly cigarettes marketed by U.S. manufacturers, imparted any significant adverse chemical or biological properties to the MSS from the ingredient-treated tobacco. However, Doull et al. did not publish an overview of the studies and reports they had examined or provide any details on their analysis. In their detailed assessment of reported chemical and biological properties of the MSS from cigarettes fabricated with tobacco with or without one or more additives, Paschke et al. (2895) reached a similar conclusion; namely, that in general, no significant

increase in the biological activity of tobacco was reported from cigarettes containing specifically described added ingredients. In his examination of extensive laboratory data generated from additives and additive-treated cigarettes between the mid-1950s and the late 1970s, Rodgman (3263, 3264) reached a conclusion similar to that of Doull et al. (1053) and Paschke et al. (2896).

Previously [see Table 1 in (3266)], the individual compounds listed by Doull et al. (1053) as possible U.S. cigarette ingredients were assigned a number somewhat indicative of the alphabetical order in which the 460 individual components were listed by Doull et al. That numerical listing is listed in Table 24.1. A similar number assignment [see Table 7A in (3266)] was made in the case of individual components used as tobacco ingredients by cigarette manufacturers outside of the United States. That numerical listing appears in Table 24.2. In each case, a few citations on the identification of the component in tobacco and/or smoke were included in the previous publication [see Tables 1 and 7A in (3266)] to indicate that the ingredient was indeed a tobacco and/or tobacco smoke component. A more complete listing of citations on the identification of the ingredient in tobacco and/or smoke is included in Table 24.3. Examination of Reference column in Table 24.3 indicates that the number of references for many of the tobacco and/or tobacco smoke components used as ingredients is substantial. They include not only reports on the identification of the component in additive-free tobacco and/or its tobacco smoke but also reports on the effect of the added ingredient on MSS composition, particularly references dealing with "Hoffmann analyte" yields. In several instances, ingredients not previously included as tobacco and/or smoke components in (3266) are cataloged in Table 24.3 because of their identification in tobacco after the publication of (3266), e.g., previously unidentified 2-hexenol and several naphthalene derivatives identified in tobacco by Peng et al. (2917a), several esters identified in tobacco by Leffingwell and Alford (2339a).

Examination of the data presented previously [see Tables 1 and 7A in (3266)] permits verification of the statements by numerous investigators that many of the ingredients in the Doull et al. list have been identified as components in untreated tobacco types and/or the MSS from cigarettes containing such tobaccos. Such an examination also permits an assessment of the effect of a number of the listed ingredients that have been reported in a variety of studies to not adversely affect the chemical or biological properties of the MSS from cigarettes containing such ingredients or the chemical properties of the pyrolysates from individual ingredients.

Table 24.3 catalogs those individual compounds that have been identified in untreated tobacco and/or its tobacco smoke and are listed by Doull et al. (1053) as tobacco additives used by U.S. cigarette manufacturers in and prior to 1994. The references cited are pertinent not only to their tobacco/tobacco smoke identification but also to their effect on the chemical and biological properties of the MSS from cigarettes containing ingredient-treated tobacco. The components are cross-referenced to the numbers assigned to their listing in the Doull et al. (1053) and Baker et al. (174b, 174c, 24A01) articles (see Tables 24.1 and 24.2). Over 260 of the 460 individual compounds (57%) listed by the Doull et al. and 19 of the 50 compounds (38%) in the Baker et al. list have been identified as components in additive-free tobacco and/or its smoke.

In 1957, Wynder (4296) proposed that reduction of the per cigarette "tar" yield by about 50% would have beneficial health-related results. By the late 1970s, early 1980s, the tobacco industry had exceeded the suggested reduction by generating the low-"tar" and ultralow-"tar" cigarette. This led to the criticisms and assertions that (1) some commercial low-"tar" brands might have additive levels much higher than those in previous high- and medium-"tar" cigarettes and (2) the fates during the cigarette smoking process of many individual added components were unknown.

The criticisms and assertions of the early 1980s about tobacco additives were not new but an extension of those made earlier, e.g., in 1967, Wynder and Hoffmann wrote about additives [see pp. 488 and 628 in (4332)]:

> The importance of flavor-enhancing agents as contributors to the tumorigenicity in the experimental animals varies for different tobacco products. For cigarettes it may be a minor factor compared to the overwhelming effects of other constituents and variables. Nevertheless, one should emphasize that further studies on the toxicity of flavorants and their combustion products could provide a scientific basis for the selection of less harmful additives… In evaluating the effect of tobacco additives, we need to consider whether such additions may contribute to the production of tumorigenic agents during the smoking of a tobacco product. If an additive increases the formation of carcinogenic substances during smoking to an analytically significant extent, it would, of course, be most undesirable. If, however, an additive should inhibit the production of tumorigenic agents during smoking and at the same time not yield other types of toxic substances, it may represent an effective and useful agent.

However, the proponents of problems with added tobacco ingredients became more vocal when the nearly 70% reduction in sales-weighted MSS "tar" yield achieved by 1985 not only answered the "tar" criticisms of the late 1950s, early 1960s, but exceeded the goal that halving the "tar" yield was a means to lower lung cancer incidence in cigarette smokers (4296).

In 1980, LaVoie et al. (24A06) wrote

> The development of the low-tar, low-nicotine cigarette required cigarette fillers with a potential for smoke flavor contribution to make these cigarettes acceptable to the consumer. Such products can be realized either by selecting tobaccos rich in flavor or by addition of tobacco extracts or certain plant extracts, addition of synthetic flavor compounds, or a combination of several of these factors…New cigarettes should be assayed for toxicity and tumorigenicity, so that the reduction of toxic and tumorigenic effects in the smoke of low-tar, low-nicotine cigarettes is not offset by the introduction of unknown factors.

TABLE 24.1
As Listed by Doull et al. (1053), Individual Ingredient Components Used in U.S. Smoking Products

Assigned No.	Name in Doull et al. (1053)	Assigned No.	Name in Doull et al. (1053)	Assigned No.	Name in Doull et al. (1053)

As Listed by Doull et al. (1053), Individual Ingredient Components Used in U.S. Smoking Products

Assigned No.	Name in Doull et al. (1053)	Assigned No.	Name in Doull et al. (1053)	Assigned No.	Name in Doull et al. (1053)
442	4-(2,6,6-Trimethylcyclohexa-1,3-dienyl)-but-2-en-4-one	**449**	2-Undecanone	**456**	Valine
		450	10-Undecenal	**457**	Vanillin
443	2,6,6-Trimethylcyclohexanone	**451**	Urea	**458**	Veratraldehyde
444	2,3,5-Trimethylpyrazine	**452**	Valencene	**459**	Water
445	*l*-Tyrosine	**453**	Valeraldehyde	**460**	3,4-Xylenol
446	δ-Undecalactone	**454**	Valeric acid		
447	γ-Undecalactone	**455**	γ-Valerolactone		
448	Undecanal				

Note: The assigned numbers are those assigned by Rodgman (3266) to the individual component ingredients listed alphabetically in their more or less common name by Doull et al. (1053).

[a] A number in bold print indicates the component has been identified as a tobacco and/or a tobacco smoke component (see Table 24.3).

[b] Sugars include glucose, fructose, sucrose, galactose, and mannose.

TABLE 24.2
As Listed by Baker et al. (174a), Individual Ingredient Components Not Used in U.S. Smoking Products but Used Outside of the United States

Assigned No.	Name in Baker et al. (174a)	Assigned No.	Name in Baker et al. (174a)	Assigned No.	Name in Baker et al. (174a)
1A	Ambroxide	18A	Ethyl isobutyrate	**35A**	Methylcyclopentenolone
2A	Ammonium glycyrrhizinate[a]	**19A**	Hexen-2-al	36A	6-Methyl-5-hepten-2-one
3A	Amyl hexanoate	**20A**	2-Hexenol	37A	Methyl 2-octynate
4A[b]	Anisole	**21A**	2-Hexenyl acetate	38A	4-Methyl-5-thiazole ethanol
5A	Anisyl propionate	**22A**	Ionone	39A	Neryl acetate
6A	Benzyl formate	23A	Isoamyl propionate	40A	δ-Nonalactone
7A	Benzyl isobutyrate	**24A**	Isoamyl salicylate	**41A**	Pectin
8A	Benzyl isovalerate	25A	Isobutyl butyrate	**42A**	Pent-4-en-4-olide
9A	Bornyl isovalerate	26A	*dl*-Isomenthone	43A	Potassium citrate
10A	Butyl valerate	27A	Isopropyl myristate	44A	Rose oxide
11A	*d*-Carvone	28A	Linalyl benzoate	45A	Sodium ethyl 4-hydroxybenzoate
12A	Cinnamyl isobutyrate	29A	Linalyl isobutyrate	46A	Sodium methyl 4-hydroxybenzoate
13A	Citronellal	**30A**	Methional	47A	Sodium propyl 4-hydroxybenzoate
14A	Citronellyl acetate	31A	5*H*-5-Methyl-6,7-dihydrocyclopenta-[*b*]pyrazine	**48A**	Sorbic acid
15A	Cyclamen aldehyde	32A	Menthyl isovalerate	**49A**	Sorbitol
16A	Dextrin	**33A**	Methyl anthranilate[c]	50A	Tetradecalactone
17A	3-Ethyl-4-hydroxy-5-methyl-3(2*H*)-furanone	34A	1-Methyl-2,3-cyclohexadione		

[a] The Doull et al. list does not include this item per se but does include glycyrrhizin, ammoniated (see Table 24.1, item No. 184).

[b] A number in bold print indicates the component has been identified as a tobacco and/or a tobacco smoke component (see Table 24.3).

[c] Methyl anthranilate, a component in the Doull et al. list, was inadvertently listed in Table 7A in (3266).

1.	64-19-7 [2]	Acetic acid CH_3-COOH	18, 126a, 126b, 167, 172, 237, 239, 424, 563, 565, 568b, 722, 916, 937, 938, 960, 966, 1023, 1063–1066, 1068–1074, 1099, 1132, 1140, 1232, 1263, 1348, 1350, 1354, 1360, 1364, 1365, 1375, 1375a, 1375b, 1377, 1388–1390, 1437, 1445, 1586, 1668, 1674, 1744, 1842, 1882, 1884, 1903, 1904, 1917, 2043, 2079, 2086, 2088, 2133, 2170, 2195, 2200, 2203, 2253, 2270, 2293, 2310, 2337, 2387, 2414, 2475, 2529, 2543, 2545, 2570, 2582, 2601a, 2619, 2623, 2628, 2702, 2765, 2767, 2777, 2799a, 2821, 2855, 2857, 2858, 2934, 2939, 3060, 3064, 3105, 3187, 3255, 3257, 3263, 3266, 3300, 3302, 3308, 3324, 3384, 3394, 3397, 3403, 3452, 3495, 3553, 3557, 3559, 3797, 3799, 3876, 3973, 3992, 4064, 4065, 4249, 4301, 4304, 4319, 4332, 4342, 4406, 4570a, 5079, 5189, 5359, 5512, 5811b, 5835	120, 212, 404, 565, 568b, 647, 937, 938, 1053, 1063, 1085, 1087, 1276, 1550, 1893b, 1705, 1982, 1999, 2014, 2079, 2154, 2270, 2283, 2293, 2337, 2338, 2339a, 2386, 2389, 2529, 2544, 2862a, 2917a, 2939, 3052, 3188, 3266, 3328, 3374, 3507, 3549, 3550, 3655b, 3787, 3797, 3905, 3973, 3974a, 3983a, 4064, 4249, 5079, 5114, 5165, 5189, 5381, 5419, 5478, 5695, 5708, 5709, 5712, 5735, 5811b, 5846, 5896	1228, 1354, 1360, 1375a, 1377, 2244, 2387, 3393, 3401, 3402, 3404, 3405
2.	123-86-4 [54]	Acetic acid, butyl ester {butyl acetate} CH_3-COO-C_4H_9	222–224, 568b, 1140, 1416, 1422, 1445, 3266, 3302, 3797, 4249, 5811b	172a, 174b, 568b, 1053, 1063, 2339a, 3186, 3188, 3266, 3905, 4249	

TABLE 24.3 (continued)
Tobacco and/or Tobacco Smoke Components Used as Tobacco Ingredients

	CAS No.	Name (per CA Collective Index)	Tobacco Smoke	Tobacco	Tobacco Substitute Smoke
3.	141-78-6 [125]	Acetic acid, ethyl ester {ethyl acetate} CH_3-COO-C_2H_5	565, 1140, 1375, 1375a, 1375b, 1377, 1378, 1413, 1414, 1416, 1418, 1445, 1449, 1590, 1903–1905, 1907, 2088, 2782, 2804, 2858, 2939, 3254, 3266, 3308, 3508, 3530, 3553, 3797, 4249, 4319, 5811b	120, 1053, 1063, 1590, 2339a, 2389, 2544, 2861a, 2939, 3266, 3797, 3973, 3974a, 4249, 5811b	1375a, 1377, 1378
4.	142-92-7 [207]	Acetic acid, hexyl ester {hexyl acetate} CH_3-COO-$(CH_2)_5$-CH_3	1157, 4249	172a, 174b, 1053, 1063, 1157, 3266, 3370, 4249	
5.	123-92-2 [223]	Acetic acid, 3-methylbutyl ester CH_3-COO-$(CH_2)_2$-CH═$(CH_3)_2$		404, 1053, 2339a, 3266
